Springer

Handbook of Marine Biotechnology

Kim

Editor

Springer

Springer Handbook of Marine Biotechnology

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Marine Biotechnology

Se-Kwon Kim (Ed.)

With 580 Figures and 181 Tables

Springer

Editor
Se-Kwon Kim
Pukyong National University
Department of Marine-Bio. Convergence Science
Specialized Graduate School Science & Technology Convergence
Marine Bioprocess Research Center
Busan, Korea

Contents

List of Abbreviations XXXIII

1 **Introduction to Marine Biotechnology**
Se-Kwon Kim, Jayachandran Venkatesan 1
1.1 Marine Biotechnology – Definition 1
1.2 Marine Biotechnology – Tools 2
1.3 Marine Sources and Research Areas 4
1.4 Applications of Marine Biotechnology 4
1.5 Research Scope 6
1.6 Organization of the Handbook 7
References 8

Part A Marine Flora and Fauna

2 **Marine Fungal Diversity and Bioprospecting**
Kalaiselvam Murugaiyan 13
2.1 Preamble 13
2.2 Diversity of Fungi 14
2.3 Habitats of Fungi in the Marine Ecosystem 16
2.4 Habitat Characteristics and Their Effect on Fungal Diversity 17
2.5 Collection, Isolation, and Identification of Fungi 19
2.6 Bioprospecting of Marine Fungi 22
2.7 Conclusions 22
References 23

3 **Diversity of Marine Phototrophs**
Hideaki Miyashita 27
3.1 Traditional Understanding of Primary Producers (≈1970s) 27
3.2 Recognition of Picocyanobacteria Dominance (1970s–2000s) 28
3.3 Discovery of Ubiquitous Photoheterotrophs (2000–Current Times) 29
3.4 Oxygenic Photosynthesis Using Far-Red Light (1990s–2011) 30
3.5 Discovery of Picoeukaryotic Phytoplankton (1990s–2011) 30
3.6 Strange Phototrophic(?) Microorganisms (1990–2011) 31
3.7 Diversity of Light Energy Transformation Systems and Reconsideration of *Photosynthesis* 31
3.8 Conclusion 33
References 33

4 **Marine Viruses**
Jeeva Subbiah 35
4.1 Viruses 35
4.2 General Characteristic Features of Viruses 36
4.3 Host Specificity 36

4.4 Viral Families in Marine Ecosystems 36
4.5 Marine Phages 37
4.6 Impact of Marine Viruses on Mollusks 40
4.7 Marine Viruses and Shrimp Aquaculture 40
4.8 Conclusion 46
References 47

5 **Marine Microalgae**
Tsuyoshi Tanaka, Masaki Muto, Yue Liang, Tomoko Yoshino, Tadashi Matsunaga 51
5.1 Overview 51
5.2 Marine Microalgae 52
5.3 Microalgal Genomes 53
5.4 Genetic Engineering of Microalgae 54
5.5 Photobioreactors for Marine Microalgae 57
References 58

6 **Seaweed Flora of the European North Atlantic and Mediterranean**
Leonel Pereira 65
6.1 Marine Macroalgae (Seaweeds) 65
6.2 The Marine Algae and Their Biotechnological Potential 67
6.3 Taxonomy and Description of Marine Algae with Biotechnological Potential 67
References 141

7 **Corals**
Mohammad Kazem Khalesi 179
7.1 Background 179
7.2 Potential Pharmaceuticals from Soft Corals 180
7.3 Potential Pharmaceuticals from Hard Corals 196
7.4 Mycosporine-Like Amino Acids (MAAs) 197
7.5 Conclusion 197
References 204

8 **Marine Sponges – Molecular Biology and Biotechnology**
Stephen A. Jackson, Jonathan Kennedy, Lekha Menon Margassery, Burkhardt Flemer, Niall O'Leary, John P. Morrissey, Fergal O'Gara, Alan D. W. Dobson 219
8.1 Marine Sponges 219
8.2 Sponge-Associated Microorganisms 222
8.3 Symbiotic Functions of Sponge-Associated Microorganisms 227
8.4 Biotechnological Potential of Marine Sponges – Pharmacological Potential 229
8.5 Exploiting the Pharmacological Potential of Marine Sponges 229
8.6 Metagenomic Strategies for Natural Product Discovery 230
8.7 Conclusions 243
References 243

Part B Tools and Methods in Marine Biotechnology

9 **Bioprocess Engineering of Phototrophic Marine Organisms**
Gregory L. Rorrer 257
9.1 Introduction to Marine Process Engineering 257
9.2 Growth Characteristics of Phototrophic Suspension Cultures 261
9.3 Basic Elements of Photobioreactor Design and Operation 267
9.4 Limiting Factors in Photobioreactor Design and Operation 277
9.5 Future Directions for Process Scale Enclosed Photobioreactors 290
9.6 Notation 291
References 293

10 **Bioinformatic Techniques on Marine Genomics**
A. Mir Bilal, H. Mir Sajjad, Inho Choi, Yoon-Bo Shim 295
10.1 Background 295
10.2 Marine and Bacterial Fluorescence Shining Light on Biological Questions 297
10.3 Recent Advances in Imaging Techniques for Marine Biotechnology 297
10.4 Chemical Analysis of Volatile Microbial Metabolites 297
10.5 Bioinformatics Resources 298
10.6 Large-Scale Sequence Analysis 299
10.7 Integrating Sequence and Contextual Data 300
10.8 Proteomics as Potential Tool for Survey in Marine Biotechnology ... 301
10.9 Proteomics and Seafood 301
10.10 Present Status and Future Trends of Proteomics in Marine Biotechnology 302
10.11 Pharmacophore Model Hypo1, Virtual Screening for Identification of Novel Tubulin Inhibitors with Potent Anticancer Activity 302
10.12 The Polymerase Chain Reaction: A Marine Perspective 303
10.13 Conclusions and New Frontiers 303
References 304

11 **Microbial Bioprospecting in Marine Environments**
Mariana Lozada, Hebe M. Dionisi 307
11.1 Bioprospecting 307
11.2 Marine Microbial Habitats and Their Biotechnologically-Relevant Microorganisms 308
11.3 Methods for Microbial Bioprospecting in Marine Environments 309
11.4 Conclusions 319
References 319

12 **Novel Bioreactors for Culturing Marine Organisms**
Debashis Roy 327
12.1 Biofilm Reactors (BFR) 327
12.2 Photobioreactors (PBR)-Tubular, Plate/Panel and Stirred Tank Configurations 331
12.3 Airlift Bioreactors (ALBR) and Bubble Column Bioreactors (BCBR) ... 337
12.4 Membrane Bioreactors (MBR) 349

12.5 Immobilized-Cell Bioreactors 353
12.6 Hollow Fiber Bioreactors (HFBR) 359
12.7 Fluidized Bed and Moving Bed Bioreactors (FBBR and MBBR) 363
12.8 High-Temperature and/or High-Pressure Bioreactors (HP-/HTBR) ... 368
References 382

13 **Transgenic Technology in Marine Organisms**
Thomas T. Chen, Chun-Mean Lin, Maria J. Chen, Jay H. Lo, Pinwen P. Chiou, Hong-Yi Gong, Jen-Leih Wu, Mark H.-C. Chen, Charles Yarish 387
13.1 Synopsis 387
13.2 Production of Transgenic Marine Organisms 388
13.3 Characterization of Transgenic Marine Organisms 396
13.4 Biotechnological Application of Transgenic Marine Organisms 398
13.5 Concerns and Future Perspectives 405
References 406

14 **Marine Enzymes – Production and Applications**
Kai Muffler, Barindra Sana, Joydeep Mukherjee, Roland Ulber 413
14.1 Overview 413
14.2 Cultivation Techniques of Marine Bacteria 414
14.3 Examples of Marine Enzymes 417
14.4 Molecular Biology 422
14.5 Downstream Processing of Marine Enzymes 422
14.6 Conclusion 424
References 425

15 **Biofouling Control by Quorum Quenching**
Vipin C. Kalia, Prasun Kumar, Shunmughiah K. T. Pandian, Prince Sharma 431
15.1 Overview 431
15.2 Bacterial Biosensors 432
15.3 Quorum Quenching (QQ) 432
15.4 Applications 436
References 438

16 **Detection of Invasive Species**
Nathan J. Bott 441
16.1 Background 441
16.2 Traditional Techniques 442
16.3 Sample Collection 442
16.4 Molecular Approach to the Identification of Marine Invasive Species 443
16.5 PCR-Based Methods Utilized for Routine Identification and/or Surveillance 445
16.6 Ecogenomic Techniques 447
16.7 Future Approaches 448
16.8 Concluding Remarks 449
References 450

Part C Marine Genomics

17 **Marine Sponge Metagenomics**
Valliappan Karuppiah, Zhiyong Li 457
17.1 Background and Problems of Sponge Research 457
17.2 The Principle of Metagenomics and Related Techniques 460
17.3 Application and Latest Progress in Sponge Metagenomics 465
17.4 Future Perspectives 469
References 470

18 **Proteomics: Applications and Advances**
Vernon E. Coyne 475
18.1 Omics 475
18.2 Overview of Proteomics Techniques 476
18.3 Proteomics and Marine Biotechnology 477
18.4 Aquaculture 478
18.5 Environment 482
18.6 Natural Products 486
18.7 Algal Toxins 488
18.8 Conclusion 490
References 491

19 **Marine Metagenome and Supporting Technology**
Tetsushi Mori, Haruko Takeyama 497
19.1 Bacteria and Marine Ecosystems 497
19.2 Technologies Supporting Metagenomic Research 502
19.3 Summary 505
References 505

20 **Microfluidic Systems for Marine Biotechnology**
Morgan Hamon, Jing Dai, Sachin Jambovane, Jong W. Hong 509
20.1 Basic Principal of Microfluidics 510
20.2 Microfluidic Devices for Marine Biology and Ecosystem Studies 511
20.3 Microfluidic Devices for Sea-Related Health and Safety 517
20.4 Microfluidic Systems for Other Marine Biotechnology Applications 521
20.5 Conclusion 524
References 524

21 **Genome Mining for Bioactive Compounds**
Soumya Haldar, Kalpana H. Mody 531
21.1 Overview 531
21.2 Temporary Halt in the Discovery of Bioactive Compounds 533
21.3 Future Directions 533
21.4 The Hurdles of Drug Discovery 536
21.5 Marine Pharmaceuticals Under Clinical Trials 536
References 538

Part D Marine Algal Biotechnology

22 **Cell Wall Polysaccharides of Marine Algae**
Andriy Synytsya, Jana Čopíková, Woo J. Kim, Yong Il Park 543
22.1 Overview 544
22.2 Structural Diversity of Algal Polysaccharides 545
22.3 Isolation from Algal Raw Material 555
22.4 Algal Polysaccharides such as Phycocolloids 558
22.5 Biological Activities and Medicinal Applications 562
References 571

23 **Iodine in Seaweed: Two Centuries of Research**
Frithjof C. Küpper 591
References 594

24 **Marine Macrophytes: Biosorbents**
Chiara Pennesi, Fabio Rindi, Cecilia Totti, Francesca Beolchini 597
24.1 Marine Macrophytes 597
24.2 Heavy Metals: Definition and Toxicity 601
24.3 Biosorption 601
24.4 Biosorption Experiments: Procedure 606
24.5 Conclusions 606
References 607

25 **Marine Algae Biomass for Removal of Heavy Metal Ions**
Laura Bulgariu, Dumitru Bulgariu, Constantin Rusu 611
25.1 General Remarks 611
25.2 Chemical Characteristics of Marine Algae Biomass 613
25.3 Experimental Methodology 615
25.4 Influence of Experimental Parameters 618
25.5 Modeling of Biosorption Process in Batch Conditions: Isotherm and Kinetic Models 628
25.6 Modeling of Biosorption Process in Dynamic Continuous-Flow Conditions 637
25.7 Mechanism of Biosorption 639
25.8 Final Remarks 642
References 642

Part E Marine Microbiology and Biotechnology

26 **Biotechnological Potential of Marine Microbes**
Gian M. Luna 651
26.1 Microbial Diversity in the World's Oceans and Biotechnological Applications of Marine Microbes 651
26.2 Why Do Marine Microbes Matter in Biotechnology? 652
26.3 Biotechnology of Marine Microbes, from Viruses to Microbial Eukaryotes 654
26.4 Conclusions and Future Perspectives 657
References 658

27 **Marine Actinomycetes in Biodiscovery**
D. İpek Kurtböke, Tanja Grkovic, Ronald J. Quinn 663
27.1 Overview 663
27.2 Advances in the Field of Biodiscovery: Genomics and Genome Mining for Discovery of New Antibiotics 665
27.3 Ecological and Physiological Perspectives 666
27.4 An Australian Example: Exploring the Biosynthetic Potential of a Marine-Derived Streptomycete 668
27.5 Future Prospects 671
References 672

28 **Biotransformation of Nitriles by Marine Fungi**
Julieta Rangel de Oliveira, Mirna H. Reagli Seleghim, André L. Meleiro Porto 677
28.1 Overview 678
28.2 Experimental Methods 691
28.3 Results and Discussion 696
28.4 Conclusion 705
References 706

Part F Marine Derived Metabolites

29 **Drugs and Leads from the Ocean Through Biotechnology**
José de Jesús Paniagua-Michel, Jorge Olmos-Soto, Eduardo Morales-Guerrero 711
29.1 Overview and Current Status 712
29.2 Approved Marine Drugs as Pharmaceuticals 713
29.3 Marine Natural Products – Overcoming Hurdles 718
29.4 *Quo Vadis*? Marine Natural Products and Clinical Trials 718
29.5 Marine Natural Products: New and Recurrent Challenges 720
References 724

30 **Biocatalysts from *Aplysia*: Sweet Spot in Enzymatic Carbohydrate Synthesis**
Antonio Trincone 731
30.1 Biocatalysis, Glycosylation and Marine Enzymes 731
30.2 Biocatalytic Methodologies to Access Glycosides and Oligosaccharides 732
30.3 The Marine Ecosystem as a Source for New Glycoside Hydrolases ... 734
30.4 Glycoside Hydrolases Present in the Genus *Aplysia* 735
30.5 Other Enzymatic Activities of Interest Present in *Aplysia* sp. 741
30.6 Conclusion 742
References 742

31 **Antimicrobial Peptides from Marine Organisms**
Venugopal Rajanbabu, Jyh-Yih Chen, Jen-Leih Wu 747
31.1 Marine Antimicrobial Peptides 747
31.2 Isolation of Antimicrobial Peptides 748

31.3 Characterization and Functions of AMP 748
31.4 Future Directions in Marine AMP Applications 753
References 755

32 **Marine-Derived Fungal Metabolites**
Sherif S. Ebada, Peter Proksch 759
32.1 Overview 759
32.2 Drug Screening from Marine Organisms 760
32.3 Marine Organic Compounds 765
32.4 Conclusions 782
References 782

33 **Marine Dinoflagellate-Associated Human Poisoning**
Samanta S. Khora 789
33.1 Preface 789
33.2 Historical Perspective 791
33.3 Marine Dinoflagellates 792
33.4 Algal Blooms and Red Tide Dinoflagellates 793
33.5 Toxigenic Dinoflagellate-Associated Human Poisoning 794
33.6 Biotechnological Significance of Toxic Marine Dinoflagellates 805
33.7 Control and Prevention 806
33.8 Discussion and Conclusion 807
References 808

34 **Carotenoids, Bioactive Metabolites Derived from Seaweeds**
Ratih Pangestuti, Se-Kwon Kim 815
34.1 Seaweeds 815
34.2 Biological Activities of Carotenoids and Health Benefit Effects 816
34.3 Concluding Remarks 819
References 819

35 **Marine Bioactive Compounds from Cnidarians**
Joana Rocha, Miguel Leal, Ricardo Calado 823
35.1 Cnidarians 823
35.2 The Most Promising Marine Natural Products from Cnidaria 828
35.3 Concluding Remarks and Future Challenges 838
References 840

36 **Fatty Acids of Marine Sponges**
Pravat Manjari Mishra, Ayinampudi Sree, Prasanna K. Panda 851
36.1 Fatty Acids – Pharmaceutical and Biomedical Importance 851
36.2 Sponge Fatty Acids 854
36.3 Bioactive Lipids/FAs from Marine Sponges 862
36.4 Summary 863
References 863

37 **Marine Biotoxins**
Aníbal Martínez, Alejandro Garrido-Maestu, Begoña Ben-Gigirey, María José Chapela, Virginia González, Juan M. Vieites, Ana G. Cabado ... 869
37.1 Marine Toxins 870

37.2 Lipophilic Toxins 871
37.3 Hydrophilic Toxins 872
37.4 Other Toxins 873
37.5 Biotechnological Techniques Used to Study Toxic Microalgae and Marine Biotoxins 875
37.6 Biotechnology Application for Phytoplankton Detection, Monitoring, and Toxins Production 879
37.7 Potential Pharmacological Uses of Phycotoxins 884
References 892

38 **Marine Microbial Enzymes: Current Status and Future Prospects**
Barindra Sana 905
38.1 Overview 905
38.2 Marine Extremozymes and Their Significance 906
38.3 Current Use of Marine Microbial Enzymes 909
38.4 Current Research Status of Marine Microbial Enzymes 909
38.5 Future Prospects 913
38.6 Conclusion 914
References 914

39 **Marine-Derived Exopolysaccharides**
Christine Delbarre-Ladrat, Vincent Boursicot, Sylvia Colliec-Jouault 919
39.1 In Search of New Polysaccharides 919
39.2 Marine Biodiversity 920
39.3 Bacterial Polysaccharides 925
39.4 Applications of EPSs 928
39.5 Marine EPSs as Glycosaminoglycans (GAGs) 930
39.6 Conclusion 933
References 933

40 **Sulfated Polysaccharides from Green Seaweeds**
MyoungLae Cho, SangGuan You 941
40.1 Overview 941
40.2 Extraction and Chemical Composition of Sulfated Polysaccharides 942
40.3 Structural Characteristics of Sulfated Polysaccharides 942
40.4 Biological Activities of Sulfated Polysaccharide from Green Seaweeds 945
40.5 Conclusion 949
References 949

Part G Application of Marine Biotechnology

41 **Marine-Derived Pharmaceuticals and Future Prospects**
Kalpa W. Samarakoon, Don A. S. Elvitigala, You-Jin Jeon 957
41.1 Marine Bioresources 957
41.2 Marine Secondary Metabolites 958
41.3 Marine Proteins 961

41.4 Marine Lipids 963
41.5 Molecular Biology Approaches 963
41.6 Future Trends in Marine Pharmaceuticals 964
References 965

42 **Marine Functional Foods**
Ana C. Freitas, Dina Rodrigues, Ana P. Carvalho, Leonel Pereira, Teresa Panteleitchouk, Ana M. Gomes, Armando C. Duarte 969
42.1 General Overview 969
42.2 Marine Sources as Healthy Foods or Reservoirs of Functional Ingredients 971
42.3 Food Marine-Derived Ingredients with Biological Properties 974
42.4 Functional Foods Incorporating Marine-Derived Ingredients 979
42.5 Current Understanding and Future Trends 987
References 988

43 **Marine Nutraceuticals**
S.W.A. Himaya and Se-Kwon Kim 995
43.1 Marine Bioactives as Potential Nutraceuticals 995
43.2 Functional Carbohydrates 996
43.3 Polyunsaturated Fatty Acids 1002
43.4 Carotenoids 1003
43.5 Soluble Calcium 1005
43.6 Fish Collagen and Gelatin 1006
43.7 Marine Probiotics 1007
43.8 Nutraceutical Market Trends and Quality Control 1008
43.9 R&D for Facing the Challenges and Supply for the Demand 1008
References 1009

44 **Cosmetics from Marine Sources**
Elena M. Balboa, Enma Conde, M. Luisa Soto, Lorena Pérez-Armada, Herminia Domínguez 1015
44.1 Scenario of Marine Sources in the Cosmetic Industry 1015
44.2 Cosmetics: Definition and Regulations 1016
44.3 Cosmeceuticals 1017
44.4 Target Organs and Cosmetics Delivery Systems 1018
44.5 Components of Cosmetics 1019
44.6 Major Functions of Some Marine Components in Cosmetics and Cosmeceuticals 1020
44.7 Treatments Based on Marine Resources 1029
44.8 Products Based on Marine Resources 1032
44.9 Conclusions 1033
References 1033

45 **Omega-3 Fatty Acids Produced from Microalgae**
Munish Puri, Tamilselvi Thyagarajan, Adarsha Gupta, Colin J. Barrow 1043
45.1 Importance of Unsaturated Fatty Acids 1043
45.2 Potential Alternative Sources for PUFA Production 1045

45.3 Marine Microalgae 1045
45.4 Biosynthesis of Omega-3 Fatty Acids in Marine Algae 1048
45.5 Microalgae Fermentation for the Production of PUFAs 1049
45.6 Thraustochytrid Fermentation 1051
45.7 Conclusions 1052
References 1053

46 **Selenoneine in Marine Organisms**
Michiaki Yamashita, Yumiko Yamashita 1059
46.1 Biochemistry of Selenium 1059
46.2 Selenium and Selenoneine Determination 1060
46.3 Biochemical Characterization of Selenoneine 1062
46.4 Nutritional and Functional Properties of Dietary Organic Selenium 1063
46.5 MeHg Detoxification 1065
46.6 Conclusion 1067
References 1068

47 **Biological Activities of Marine-Derived Oligosaccharides**
Tatsuya Oda 1071
47.1 Overview 1071
47.2 Preparation of Alginate Oligosaccharide Mixture 1072
47.3 Antioxidant Activities of Alginate Oligosaccharides 1073
47.4 Cytokine-Inducing Activities of Alginate Oligosaccharides 1076
47.5 Induction of Cytokines in Mice 1080
47.6 Growth-Promoting Effect of Alginate Oligosaccharides 1083
References 1085

48 **Vector and Agricultural Pest Control**
Venkateswara Rao Janapala 1089
48.1 Preamble 1090
48.2 Current Status of Research and Development in the Subject 1090
48.3 Research in India 1092
48.4 Preparation of Crude Extracts 1094
48.5 Active Extracts of Marine Origin 1094
48.6 Pesticidal Properties of Alkyl Xanthates 1099
48.7 Antifeedant and IGR Activities of Xanthates 1101
48.8 Conclusions 1108
References 1108

Part H Bioenergy and Biofuels

49 **Nanotechnology – from a Marine Discovery Perspective**
Ramachandran S. Santhosh, Visamsetti Amarendra 1113
49.1 Marine Nanotechnology 1113
49.2 The Ocean as Source for Nanomaterials and Nanodevices 1114
49.3 Ocean in Climate Control 1123
49.4 Detoxification of Nanomaterials 1123

49.5 Biomimetics 1124
49.6 Conclusions 1125
References 1125

50 **Algal Photosynthesis, Biosorption, Biotechnology, and Biofuels**
Ozcan Konur 1131
50.1 Overview 1131
50.2 Algal Photosynthesis 1132
50.3 Algal Biofuels 1136
50.4 Algal Biotechnology 1145
50.5 Algal Biosorption 1150
50.6 Conclusion 1157
References 1158

51 **Biofuel Innovation by Microbial Diversity**
Thiago Bruce, Astria D. Ferrão-Gonzales, Yutaka Nakashimada, Yuta Matsumura, Fabiano Thompson, Tomoo Sawabe 1163
51.1 Bioprospecting of Marine Microbial Diversity 1163
51.2 Marine Microbial Diversity Applied to Biofuel Innovation 1166
51.3 Conclusions 1176
References 1176

52 **Maraine Biomaterials as Antifouling Agent**
Parappurath Narayanan Sudha, Thandapani Gomathi, Jayachandran Venkatsan, Se-Kwon Kim 1181
52.1 Pollution 1181
52.2 Use of Marine Biomaterials for Water Treatment 1182
52.3 Modification of Marine Biomaterials 1183
52.4 Antifouling Marine Biomaterials for Water Treatment 1185
52.5 Conclusion 1189
References 1189

Part I Biomedical Applications

53 **Marine Biomaterials**
Jayachandran Venkatesan, Se-Kwon Kim 1195
53.1 Examples of Marine Biomaterials 1195
53.2 Marine Polysaccharides 1197
53.3 Marine Ceramics 1207
53.4 Current Understanding and Future Needs 1209
53.5 Conclusions 1209
References 1209

54 **Marine Materials: Gene Delivery**
Bijay Singh, Sushila Maharjan, Yun-Jaie Choi, Toshihiro Akaike, Chong-Su Cho 1217
54.1 Nonviral Vectors for Gene Delivery 1217
54.2 Chitosan 1218

54.3 Alginate 1221
References 1224

55 **Marine Organisms in Nanoparticle Synthesis**
Pallavi Mohite, Mugdha Apte, Ameeta R. Kumar, Smita Zinjarde 1229
55.1 Basic Concepts in Nanotechnology 1229
55.2 Marine Ecosystems 1231
55.3 Nanostructures Inherently Produced by Marine Organisms 1231
55.4 Metal Interactions in Marine Biological Forms 1231
55.5 Bacteria in Nanoparticle Synthesis 1232
55.6 Fungi in the Synthesis of Nanomaterials 1236
55.7 Algae in the Synthesis of Nanoparticles 1239
55.8 Marine Plants in Nanoparticle Synthesis 1240
55.9 Nanoparticle Synthesis by Sponges 1241
55.10 Mechanistic Aspects 1241
55.11 Current Understanding and Future Needs 1242
References 1242

56 **Marine Biomaterials in Therapeutics and Diagnostics**
Ashutosh Srivastava, Arti Srivastava, Ananya Srivastava, Pranjal Chandra 1247
56.1 Biomaterials 1247
56.2 Classification of Biomaterials 1248
56.3 Marine Biodiversity 1249
56.4 Biomaterials from Marine Origin 1249
56.5 Status of Marine Natural Product as Therapeutic Agents 1252
56.6 Marine Resources for Medical Diagnostic Devices 1255
References 1260

57 **Enzymatically Synthesized Biosilica**
Xiaohong Wang, Heinz C. Schröder, Werner E.G. Müller 1265
57.1 The Sponges: The Earliest Ancestor of the Metazoa 1265
57.2 Silicatein-Based Siliceous Spicule Formation 1266
57.3 Spiculogenesis 1268
57.4 Bio-Silica: The Enzymatically Formed Scaffold of Siliceous Sponge Spicules 1270
57.5 1271
57.6 Bio-Silica: The Osteogenic Bioinorganic Polymer 1272
57.7 Future Design of Novel Bioinspired, Silica-Based Materials 1273
References 1274

58 **Biomineralization in Marine Organisms**
Ille C. Gebeshuber 1279
58.1 Overview 1279
58.2 Materials – Biominerals 1281
58.3 Materials – Proteins Controlling Biomineralization 1290
58.4 Organisms and Structures That They Biomineralize 1290

58.5 Functions 1294
58.6 Applications 1294
References 1298

Part J Industrial Applications

59 **Functional Feeds in Aquaculture**
Jorge Olmos Soto, José de Jesús Paniagua-Michel, Lus Lopez, Leonel Ochoa 1303
59.1 Overview 1304
59.2 Food Formulation Ingredients 1304
59.3 Conventional Feeds Versus Functional Feeds 1309
59.4 Aquaculture Regulations 1310
59.5 Functional Feeds in Aquaculture 1311
59.6 Results Obtained in Crustaceans and Fish Using Functional Feeds 1312
59.7 Conclusions 1317
References 1317

60 **Mussel-Derived Bioadhesives**
Bong-Hyuk Choi, Bum J. Kim, Chang S. Kim, Seonghye Lim, Byeongseon Yang, Jeong H. Seo, Hogyun Cheong, Hyung J. Cha 1321
60.1 Marine Mussel Adhesion 1322
60.2 Application of MAPs to Tissue Engineering 1323
60.3 Application of MAP to Tissue Engineering Scaffolds 1326
60.4 Application of MAP Using Complex Coacervation 1328
60.5 MAP-Based Biosensors for Industrial Applications 1330
References 1332

61 **Marine Silicon Biotechnology**
Katsuhiko Shimizu 1337
61.1 Overview 1337
61.2 Silicateins: Structure and Molecular Mechanisms 1338
61.3 Silicatein-Mediated Synthesis of Inorganic Materials 1344
61.4 Genetically Engineered Silicateins 1350
61.5 Prospectives 1351
References 1351

62 **Microalgal Biotechnology: Biofuels and Bioproducts**
José de Jesús Paniagua-Michel, Jorge Olmos-Soto, Eduardo Morales-Guerrero 1355
62.1 Sustainable Biofuels from Marine Microalgae: Closer to Reality than Fiction 1356
62.2 Why Microalgae is Promissory for Biofuel Production 1356
62.3 Biodiesel Production by Microalgal Lipid Transesterification 1358
62.4 Bioethanol from Microalgae: A Simpler Procedure 1359
62.5 Microalgal Biohydrogen Production Through Sunlight and Seawater 1360

62.6 Genomics and Metabolic Engineering of Microalgae for Biofuels Production 1361
62.7 Microalgal Culture Systems: A Contribution to the Sustainability of Biofuels 1363
62.8 Products of Industrial Interest from Microalgae 1365
62.9 Future Needs: Making Sustainable the Unsustainable Lightness of Biofuels 1368
References 1368

63 **Marine Actinobacterial Metabolites and Their Pharmaceutical Potential**
Panchanathan Manivasagan, Jayachandran Venkatesan, Kannan Sivakumar, Se-Kwon Kim 1371
63.1 Marine Actinobacteria 1371
63.2 Research on Marine Actinobacteria 1372
63.3 Novel Metabolites from Marine Actinobacteria 1373
63.4 Conclusion 1381
References 1382

64 **Marine Microbial Biosurfactins**
Jen-Leih Wu, Jenn-Kan Lu 1387
64.1 Overview 1387
64.2 Methodology of Production of Marine Biosurfactants 1388
64.3 Applications of Marine Bioactive Biosurfactants 1392
64.4 Conclusions 1399
References 1400

65 **Nutraceuticals and Bioactive Compounds from Seafood Processing Waste**
V. Venugopal Menon, Smita S. Lele 1405
65.1 Seafood as a Source of Nutraceuticals 1406
65.2 Bio-Waste from Processing of Seafood 1406
65.3 Seafood Waste and Discards as Sources of Nutraceuticals 1407
65.4 Nitrogen-Derived Compounds 1407
65.5 Lipid-Based Nutraceuticals 1412
65.6 Polysaccharide-Derived Nutraceuticals 1415
65.7 Mineral-Based Nutraceuticals 1419
65.8 Novel Marine Organisms and Compounds 1419
65.9 Commercial Aspects 1420

Erratum to: Springer Handbook of Marine Biotechnology
Se-Kwon Kim E1

List of Abbreviations

Symbols

β-HB	β-hydroxy butyrate
γ-PGA	γ-polyglutamic acid
ω-3	Omega-3 fatty acid
^{1}H NMR	proton nuclear magnetic resonance
(HPLC–DAD)	high pressure liquid chromatography with diode array detection
L-DOPA	L-3,4-dihydroxyphenylalanine
1-D	one-dimensional
12-DS	12-doxylstearic acid
19HF	19′-hexanoyloxy-fucoxanthin
2-D	two-dimensional
2D-DIGE	two-dimensional difference in-gel electrophoresis
3-PGA	3-phosphoglyceric acid
4-DSC	four-disulfide core
8-HPETE	(8*R*)-hydroperoxyeicosa-5,9,11,14-tetraenoic acid

A

A549	human alveolar epithelial cells
A549	human lung adenocarcinoma
AA	arachidonic acid
aa	amino acid
AAPB	aerobic anoxygenic photosynthetic bacteria
AAPH	2,2′-azobis(2-amidino-propane) dihydrochloride
AAR	acyl–acyl carrier protein reductase
ABAP	2,2′-azo-bis-2-amidinopropane
ABC	ATP-binding cassette
ABTS	2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)
AC	alternating current
ACCase	acetyl-CoA carboxylase
ACE	angiotensin-I-converting enzyme
ACE	angiotensin-converting enzyme
AChE	acetylcholinesterase
ACP	acyl carrier protein
ACP	acyl–acyl carrier protein
ADBAC	alkyldimethylbenzylammonium chloride
ADHD	attention-deficit hyperactivity disorder
ADO	aldehyde-deformylating oxygenase
AF	antifouling
AfDD	acriflavine direct detection
AFLP	amplified fragment length polymorphism
AFM	atomic force microscope
AGC	arginine-graft-chitosan
AgNP	silver (argentum) nanoparticle
AGS	gastric adenocarcinoma
AGS	human gastric cancer cell
AHA	α-hydroxy acids
AHL	acyl-homoserine lactone
AHRE	aromatic hydrocarbon response element
AIDS	acquired immunodeficiency syndrome
AKG	α-ketoglutarate
Akt	nuclear phosphatidylinositol 3,4,5-triphosphate phosphotidyinositol 3-kinase
AL	airlift
ALA	α-linolenic acid
ALBR	airlift bioreactor
ALCL	anaplastic large cell lymphoma
AMD	acid mine drainage
AMIS	anaerobic methane incubation system
amoA	α-subunit
amoA	ammonia-oxidation
AmoB	ammonia mono-oxygenase membrane bound subunit β
AMOP	aquatic microbial oxygenic photoautotroph
AMP	antimicrobial peptide
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
AMS	air membrane surface
anammox	anaerobic ammonium-oxidizing
AnAPB	anaerobic anoxygenic photosynthetic bacteria
AnMBR	anaerobic membrane bioreactor
ANME	anaerobic methanotrophic archaea
anti-MRSA	anti-methicillin-resistant *Staphylococcus aureus*
AOA	ammonia-oxidizing archaea
AOB	ammonia oxidizing bioreactor
AOM	alginate oligosaccharide mixture
AOM	anaerobic oxidation of methane
APTT	activated partial thrombinplastin time
aPTT	activated partial thromboplastin time

ARA	arachidonic acid
Ara-A	arabinofuranosyl adenine or adenine arabinoside
Ara-A	vidarabine
Ara-C	cytarabine
Ara-C	arebinosyl cytosine
ARfD	acute reference doses
ARP	ankyrin repeat protein
ASAP	automated simultaneous analysis phylogenetics
ASC	acid-soluble collagen
ASP	amnesic shellfish poisoning
ASW	artificial seawater
AT	acyltransferase
ATCC	American Type Culture Collection
ATN	autotrophic nitrifier
ATP	adenosine triphosphate
ATSDR	Agency for Toxic Substances and Disease Registry
AttM	lactonase of *A. tumefaciens*
Au-CNT	gold-coated carbon nanotubes
AuNP	gold (aurum) nanoparticle
AZA	azaspiracid
AZP	azaspiracid shellfish poisoning

B

BAC	bacterial artificial chromosome
BALB/c	albino, laboratory-bred strain of the house mouse
BaP	benzo[*a*]pyrene
BAPD	bis(*p*-aminophenoxy)-dimethylsilane
BC	bubble column
BCBR	bubble column bioreactor
BChl	bacteriochlorophyll
BD	biofilm density
BDL	beyond detectable limit
BDS	bunodosine
BE	bioemulsifer
BF	biofouling
BFR	biofilm reactor
BHA	butylated hydroxyanisole
BHT	butylated hydroxytoluene
BLAST	basic local alignment search tool
BMNV	baculoviral midgut gland necrosis virus
BMP	bone morphogenetic protein
BMSC	bone marrow stomal cell
BNR	biological nitrate removal
BP	*Baculoviruspenaei*
BPA	bisphenol A
BPR	back pressure regulator
BPS	back-pressure-system
BS	biosurfactant
Bs	*Bacillus subtilis*
BSA	bovine serum albumin
BSD	blasticidin
BSP	sialoprotein
BTX	brevetoxin
BTX	square wave generator
bvPLA	bee venom, phospholipase AZ

C

C-CTX	Caribbean-CTX
C-g-PEI	chitosan-graft-PEI
C-PE	C-phycoerythrin
C12-TE	*Cinnamomum camphora*
C14-TE	*Umbellularia californica*
Ca-SP	calcium spirulan
CA4	combretastatin
Ca9-22	human gingival carcinoma
CAF	chlorophyll autofluorescence
CAMERA	community cyber infrastructure for advanced marine microbial ecology research and analysis
cAMP	cyclic adenosine monophosphate
Campto	camptothecin
CARD	catalyzed reporter deposition
CARMA	characterizing short read metagenome
CAS	CRISPR-associated
CAS	chemical abstracts service
CAS	chrome azurol S
CAT	chloramphenicol acetyltransferase
CC	column chromatography
CCCP	carbonylcyanide *m*-chlorophenylhydrazone
CCF	conico-cylindrical flask
CCI	chronic constriction injury
CCRF-CEM	human T-cell lymphoblast-like cell line
CCRF-CEM	human Caucasian acute lymphoblastic leukaemia
CD	compact disc
CD	circular dichroism
CD	cluster of differentiation
Cd	cadmium
cDNA	copy DNA
cDNA	complementary DNA
CdO	cadmium oxide
CdS	cadmium sulfide
CEB	cell entrapping bead

CEME	cecropin-medilitin hybrid peptide
CES	collagen and elastin sponge
CF	cystic fibrosis
CFE	cell-free extracts
CFP	ciguatera fish poisoning
Cg-Def	oyster defensin
CGC	cerebellar granule cell
CGN	cerebellar granule neuron
CGRP	calcitonin gene-related peptide
CGS	chitosan-graft-spermine
CH	carbohydrate
CHA	carbonated hydroxyapatite
CharProtDB	Characterized Protein Database
ChAT	choline acetyltransferase
CHD	coronary heart disease
CHL	chlorophyll
CHO	carbohydrate
CHO	Chinese hamster ovary
ChOx	cholesterol oxidase
CI	cyclic imines
CI	cyclic imine
CL	chemiluminescence
CLP	chitosan-linked-PEI
CMC	critical micelle concentration
CMFRI	Central Marine Fisheries Research Institute
CML	chronic myeloid leukemia
CMV	cytomegalovirus mosaic virus
CNN	cloud condensation nuclei
CNS	central nervous system (CNS)
CNS	central nervous system
CO_2-TR	CO_2 transfer rate
CoA	coenzyme A
COC	cyclic olefin co-polymer
COC1	human ovarian adenocarcinoma cisplatin-sensitive cell
COG	Clusters of Orthologous Group
COG0610	restriction enzymes, type I helicase
COG1715	restriction endonuclease
CoML	Census of Marine Life
ConA	concanvalin A
COS	chitooligosaccharide
COS	chitosan oligosaccharides
COS	chitosan chito-oligosaccharide
COSY	correlation spectroscopy
COX	cyclooxygenase
COX-2	cyclooxygenase-2
CPBR	column-type PBR
CPCD	chitosan-graft-PEI-β-cyclodextrin
CPG	consumer packaged good
CPP	cell-penetrating peptide
CPS	capsular polysaccharide
CPU	central processing unit
CR	complement receptor
Cr	chromium
CRISPR	clustered regularly interspersed short palindromic repeat
CRISPR	clustered regularly interspaced short palindromic repeat
CS	chondroitin sulfate
CS-F	Fucosylated CS
CSIR	Council of Scientific Industrial Research
CSMCRI	Central Salt and Marine Chemicals Research Institute
CSP	cell surface protein
CT	computer tomography
CT	collection tank
CTT	conventional thermal treatment
CTX	ciguatoxin
CTX	cholera toxin
CV	cardiovascular
CV	check valve
CyDyes	cyanine dyes
Cys	cysteine
Cytosar-U1	Cytarabine

D

DA	domoic acid
DAE	Diethylaminoethyl
DAG	diacylglycerol
DAN	diaminonaphthalene
DAP	dorsal arm plate
DB	digestion basin
DBMIB	2,5-dibromo-3-methyl-6-isopropyl-*p*-benzoquinone
DCMU	3-(3,4-dichlorophenyl)-1,1-dimethyl urea
DD	degree of deacetylation
DD	decadienal
DEAE	diethylaminoethyl cellulose
delta-DOPA	decarboxy (E)-alpha,beta-dehydro-3,4-dihydroxyphenylalanine
DENV	dengue virus
DF1	fraction 1
DGGE	denaturing gradient gel electrophoresis
DH	dehydratase
DHA	docosahexaenoic acid
DIG	digoxigenin 11-dUTP
DIN	dissolved inorganic nitrogen
DIPS	diffusion induced phase separation
DLD	dihydrolipoamide dehydrogenase

DLS	dynamic light scattering
DMAPP	dimethylallyl pyrophosphate
DMF	dimethylformamide
DMPO	5,5-dimethyl-1-pyrroline N-oxide
DMPO-OH	DMPO-hydroxyl
DMRB	dissimilatory metal reducing bacteria
DMSO	dimethyl sulfoxide
DMXBA	3-(2,4-dimethoxybenzylidene)-anabaseine
DN-BPR	denitrifying biological phosphorus removal
DNA	deoxyribonucleic acid
DNAML	DNA maximum likelihood
DNaseI	deoxyribonuclease
DO	dissolved oxygen
DOC	dissolved organic carbon
DON	dissolved organic nitrogen
DOPA	dihydroxy-L-phenylalanine
DOTUR	defining operational taxonomic units and estimating species richness
DOX	doxorubicin
DP	degree of polymerization
DPPH	1,1-diphenyl-2-picrylhydrazyl
DPPH	2,2-diphenyl-1-picrylhydrazyl
DS	dermatan sulfate
dsDNA	double-stranded DNA
DSLSS	disodium lauryl sulfosuccinate
DSP	diarrhetic shellfish poisoning
DspB	Dispersin B
dsRNA	double-stranded RNA
DTP	diethylenetriamine pentaacetic acid
DTX	dinophysis toxin
DVChl	divinyl-chlorophyll
DVD	digital video disc
DXP	1-deoxy-xylulose-5-phosphate

E

E7389	eribulin mesylate
EBPR	enhanced biological phosphorus removal
ECD	electronic circular dichroism
ECM	extracellular matrix
ECP	extracellular product
ED	electrodialysis
EDC	endocrine disrupting compound
eDNA	environmental DNA
EDP	Entner–Doudoroff pathway
EDS	energy dispersive spectra
EDS	energy dispersive spectroscopy
EDTA	ethylenediaminetetraacetic acid
EDX	energy dispersive X-ray spectroscopy
ee	enantiomeric excess
EF	Erlenmeyer flask
EFC	efficiency of feed conversion
EFSA	European Food Safety Authority
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
ELISA	enzyme-linked immunosorbent assay
EM	electron microscopy
EMEA	European Medicines Agency
EMEA	European Agency for the Evaluation of Medicinal Products
EMP	Embden–Meyerhof pathway
EMP	Earth Microbiome Project
EPA	environmental protection agency
EPA	eicosapentaenoic acid
epi-DA	epi-domoic acid
EPRE	electrophile response element
EPS	extracellular polysaccharide
EPS	exopolysaccharide
ER	enoyl reductase
ESCRT	endosomal sorting complexes required for transport
ESI	electrospray ionization
ESI-MS	electrospray ionization mass spectrometry
ESR	electron spin resonance
ESSV	extended surface shaken vessel
EST	express sequence tag
ET-743	ecteinascidins
EtOAc	ethyl acetate
ETS	external transcribed spacer
EU	European Union

F

FA	formaldehyde
FA	fatty acid
FACS	fluorescence activated cell sorting
FAEE	fatty acid-ethyl-ester
FAME	fatty acid methyl ester
FAO	Food and Agriculture Organization
FAP	flat alveolar panel
FAP-PBR	flat alveolar panel PBR
FBBR	fluidized bed bioreactor
FcεRI	Fc region of immunoglobulin E
FCA	ferrous ion chelating ability
FCB	free-cell photobioreactor
FCC	face centred cubic
FCF	food conversion factor

FCR	food conversion ratio
FDA	Food and Drug Administration
FD&C	Food, Drug, and Cosmetic Act
FETAX	frog embryo teratogenesis assay-xenopus
FF	functional feed
FISH	fluorescence in situ hybridization
FM	fish meal
FO	fiber optic probe
FOS	fucooligosaccharide
FOSHU	food for specified health uses
FOSMID	F1 origin-based cosmid vector
FPH	fish protein hydrolyzate
FPT	farnesyl protein transferase
FP&LA	Fair Packaging and Labeling Act
FR	fouling-release
FRAP	ferric reducing antioxidant power
FRAP	ferric ion reducing antioxidant power
FRET	fluorescent resonance energy
FRET	fluorescence resonance energy transfer
FTIR	Fourier transform infrared spectroscopy
FXR	farnesoid X-activated receptor

G

G	guluronate
G	guluronic acid
G-CSF	granulocyte colony-stimulating factor
g.b.f.	glass-ball filter
G3–G9	trimer to nonamer of G
GA	glutaraldehyde
GABA	γ-amino-butyric acid
GAG	glycosaminoglycan
GAO	glycogen accumulating organism
GAPDH	glyceraldehyde 3-phosphate dehydrogenase
GAV	gill-associated virus
GB	glove box
GC	galactosylated chitosan
GC-FID	gas chromatography-flame ionization detector
GC-MS	gas chromatography-mass spectrometry
GC-TOF-MS	chromatography-time-of-flight mass spectrometry
GCL	glutamate cysteine ligase
GCS	GC-g-spermine
Gd	gadolinium
gDNA	genomic DNA
GDSL	amino acid motif specific to the esterases
GDSLS	amino acid residues considered as an important motif in the EstHE1 esterase
GEBA	Genomic Encyclopedia of Bacteria and Archaea
GERD	gastroesophageal reflux disease
GFP	expression of signal molecule
GFP	green fluorescent protein
GG	homopolymeric blocks in alginates
GH	glycoside hydrolase
GH	growth hormone
GHF	glycoside hydrolase family
GHG	greenhouse gas
GI	gastrointestinal
GI_{50}	growth inhibition
GLA	γ-linolenic acid
GlcNAc	*N*-acetylglucosamine
GLDC	glutamate decarboxylase
Glu	glutamic acid
Glu-Plg	glutamic plasminogen
Glu-tag	octaglutamic acid-tag
GM	alternating blocks in alginates
GM	genetically modified
GM-CSF	granulocyte-macrophage colony-stimulating factor
GMO	genetically modified organism
GMP	good manufacturing practices
GNO	hydrated gallium nitrate
GOD	glucose oxidase
GOLD	Genomes OnLine Database
GoM	Gulf of Mannar
GoMBR	Gulf of Mannar Marine Biosphere Reserve
GORD	gastroesophageal reflux disease
GOS	Global Ocean Sampling
GPC	gel permeation chromatography
GPCS	galactosylated PEG-chitosan-graft-spermine
GPDH	glycerol-3-phosphate dehydrogenase
GPx	glutathione peroxidase
GRAS	generally recognized as safe
GRPSp	gastrin-releasing peptide, Scylla paramamosain
GSH	glutathione
GST	genome sequence tag
GT	glycosyltransferase
GTA	glycidyl trimethyl ammonium
GulA	α-D-guluronic acid
GWP	green wall panel
GWP-PBR	green wall panel PBR
GYM	gymnodimine
GYM	glucose yeast extract and malt

H

HA	hydroxyapatite
HA	hyaluronic acid
HAB	harmful algal bloom
hADSC	human adipose-derived stem cell
HAP	hydroxyapatite
HBME	human brain microvascular endothelial
HBV	hepatitis B virus
HCMV	human cytomegalovirus
HCN	hydrogen cyanide
HCT	human colorectal tumor
HCT116	human colorectal carcinoma cell line
HCV	hepatitis C virus
HDAC	histone deacetylase
HDL	high density lipoprotein
He	helium
HeLa	human cervix carcinoma cells
HeLa	Henrietta Lacks
Hep3B	human liver carcinoma
HepG2	hepatoma cell line
HepG2	Hepatoma Growth2
HF	hydrofluoric
HF	hollow fiber
HF-MBR	hollow-fiber membrane bioreactor
HF-MFBR	hollow-fiber microfiltration bioreactor
HF-sMBR	hollow-fiber submerged MBR
HFAR	hybrid flow-through anaerobic reactor
HFBR	hollow-fiber bioreactor
HGF	hepatocyte growth factor
hGH1	human growth hormone 1
His-tag	hexahistidine-tag
HIV	human immunodeficiency virus
HIV-1	human immunodeficiency virus
HJ	hydrogen supply
HLE	human leukocyte elastase
hli	high light inducible gene
HM	high methoxy
HMT	histone methyltransferases
HNE	human neutrophil elastase
HP-CI	high-pressure continuous incubation system
HP-MI	high-pressure manifold incubation system
HPAEC-PAD	high-performance anion-exchange chromatography with pulsed amperometric detection
HPBBR	high-pressure batch bioreactor
HPBR	high-pressure bioreactor
HPHT	high-pressure/high-temperature
HPHTBR	high-pressure/high-temperature bioreactor
HPLC	high-performance liquid chromatography
HPLC-DAD	high-performance liquid chromatography with diode-array detection
HPTGS	high-pressure thermal gradient system
HPU	high-pressure unit
HPV	hepatopancreatic parvovirus
HPX	hypoxanthine
HR-SEM	high-resolution scanning electron microscopy
HRM	high resolution melting
HRMS	High Resolution Mass Spectrometry
HRP	horseradish peroxidase
HRT	hydraulic retention time
HRTEM	high-resolution transmission electron microscope
HS	heparin sulfate
HS	high-solid
HS	heparan sulfate
HSC70	heat-shock cognate protein 70
HSDH4	17β-hydroxysteroid dehydrogenase type 4
HSV	herpes simplex virus
HT-29	human colon adenocarcinoma
HTHPBR	high-temperature, high-pressure bioreactor
HTLV	T-cell leukaemia virus
HTS	high throughput screening
HUVEC	human umbilical vein endothelial cells

I

I-CTX	Indian-CTX
i.p.	intraperitoneal
I/O	inlet/outlet
IAA	imidazole acetic acid
IAAC	IAA-coupled chitosan
IAC	internal amplification control
IAEA	International Atomic Energy Agency
IAST	ideal adsorbed solution
IBPCS	integrated biomass production conversion system
ICC	intrahepatic cholangiocarcinoma
Ichip	isolation chip
ICP	ion concentration polarization
ICP-MS	inductively coupled plasma mass spectrometry
ICR	imprinting control region
IDO	indoleamine 2,3-dioxygenase

IEMBR	ion exchange membrane bioreactor
IgE	immunoglobulin E
IGF-IR	insulin-like growth factor-I receptor
IgG	immunoglobulin G
IgM	immunoglobulin M
IGR	insect growth regulator
IGS	intergenic spacer
IHHNV	infectious hypodermal and hematopoietic necrosis virus
IHNV	infectious hematopoietic necrosis virus
IISA	integrated in situ analyzer
IISA-Mn	integrated in situ analyzer for Mn
IKK	inhibitor of nuclear factor κ-B kinase subunit beta
IL	ionic liquid
IL	interleukin
IL-6	interleukin-6
IMG	Integrated Microbial Genomes
IMG/M	Integrated Microbial Genomes and Metagenomes System
IMNV	infectious myonecrosis virus
IMO	International Maritime Organization
IMPDH	inosine 5′-monophosphate dehydrogenase
INCI	International Nomenclature of Cosmetic Ingredients
INF	interferon
INF-γ	interferon-γ
InHA	immune inhibitor A precursor
iNOS	inducible nitric oxide synthase
IPCP	integrated pest control programs
IPG	immobilized pH gradient
IPNV	infectious pancreatic necrosis virus
IPP	isopentyl pyrophosphate
IR	Infrared Spectroscopy
IR	infrared
iRFP	near-infrared fluorescent protein
ISH	in situ hybridization
iso-DA A–H	isodomoic acids A, B, C, D, E, F, G, and H
IT	information technology
iTRAQ	isobaric tags relative absolute quantification
ITS	internal transcribed spacer
IUB	International Union of Biochemistry and Molecular Biology
IUPAC	International Union of Pure and Applied Chemistry
IV	intravenous injection
IV1	injection vessel
IV2	injection vessel

J

JNK	c-Jun N-terminal kinase

K

K562	human chronic myeloid leukemia cells
KB	human epidermoid carcinoma
KC	keratinocyte-derived chemokine
KF	Kahalalide F
KGF	keratinocyte growth factor
KM	kinetic modeling
KR	ketoreductase
KS	ketosynthase
KS	ketoacyl synthase
KSa-KSb-ACP	ketosynthase alpha subunit-ketosyntahase beta subunit-acyl carrier protein
KSR1	kinase suppressor of Ras1

L

L/D	light/dark
LasR	transcriptional activator
LB	Luria-Bertani broth
LB	Luria Bertani
LC	liquid chromatography
LC_{50}	lethal concentration
LC-ESI-MS	liquid chromatography electrospray ionization mass spectrometry
LC-MS	liquid chromatography-mass spectrometry
LCA	life cycle
LCB	lactophenol cotton blue
LCFA	long-chain fatty acid
LD_{50}	lethal dose 50
LDL	low-density lipid
LDL	low-density lipoprotein
LDLR	low-density lipoprotein receptor
LDPE	low-density polyethylene
LFB	limited filamentous bulking
LHCII	light-harvesting chlorophyll protein complex apoproteins associated with photosystem II
LM	low methoxy
LMA	low methoxy amidated
LN	lymphocytes
LOC	lab-on-a-chip
LOD	limit of detection
LoVo	human colon adenocarcinoma
LOVV	lymphoid organ vacuolization virus

LPS	lipopolysaccharide
LPV	lymphoidalparvo-like virus
LRT	larval rearing tank
LS	low-solid
LS	light source
LSNV	Laem–Singh virus
LSU	long sub-unit
LT	lipophilic toxin
LTA	lipoteichoic acid
LTR	long terminal repeat
LuxR	transcriptional activator
Lys	lysine

M

M	mannuronate
M	mitosis
M	mannuronic acid
M-PBR	membrane photobioreactor
M/G	molar ratio between mannuronic and glucuronic acids in alginates
M3–M9	trimer to nonamer of M
MA	maslinic acid
MAA	mycosporine-like amino acid
mAb	monoclonal antibodies
MABV	marine birnavirus
MAE	microwave-assisted extractions
MALDI	mass spectrometry using assisted laser desorption ionization
ManA	β-D-mannuronic acid
MAP	mussel adhesive protein
MAP	mitogen-activated protein
MAPK	mitogen-activated protein kinase
MAR	microautorardiography
Mb	met-myoglobin
MBA	mouse bioassay
MBBR	moving bed bioreactor
MBC	minimum bactericidal concentration
Mbp	million base pairs
MBR	membrane bioreactor
MBT	magnetotactic bacteria
MBV	monodon baculovirus
MCF	Michigan Cancer Foundation-7
MCF7	breast carcinoma cell
MCF7	human breast cancer cell line
MCH	melanin-concentrating hormone
MCP	monocyte chemoattractant protein
MCP	marine collagen peptide
MCP	monocyte chemotactic protein
MCP-1	monocyte chemoattractant protein-1
MDA	multiple displacement amplification
MDA-MB-231	human breast carcinoma
MDD	major depressive disorder
MDR	multi-drug resistant
MEGAN	meta genome analyzer
MegDB	Microbial Ecological Genomics DataBase
MeHg	methylmercury
MeHgCy	MeHg-cysteine
MEL-28	human melanoma cell
MEMS	microelectromechanical system
MEMS/NEMS	micro- and nanoelectromechanical systems
MetaBioME	Metagenomic BioMining Engine
MF	microfiltration
MG	heteropolymers of mannuronate and guluronate
MG	alternating blocks in alginates
MG-RAST	meta genomics rapid annotation using subsystem technology
MG-RAST	meta genomics rapid annotation using subsystems technology
MGB	minor groove binder
MHDS	multihead deposition system
MIC	minimum inhibitory concentration
MicroScope	microbial genome annotation & analysis platform
MIP	molecularly imprinted polymer
MIP	macrophage inflammatory protein
MISS	microbially induced sedimentary structures
MLVSS	mixed liquor volatile suspended solids
MM	homopolymeric blocks in alginates
MMAE	monomethyl auristatin E
MMP-9	metalloproteinase-9
MMP2	matrix metalloproteinase 2
MNP	marine natural product
MO	morpholino antisense oligo
MO	morpholino phosphorodiamidate oligonucleotide
MOLT	molybdate uptake transporter
MoMLV	Moloney murine leukemia virus
Mon	manganese
MoV	Mourilyan virus
Mp-TX	*Millepora platyphylla*
MPA	mycophenolic acid
MPBR	membrane photobioreactor
MPL	maximum permitted level
MRBC	Modified roller bottle cultivation
MRE	metal response element
MRI	magnetic resonance imaging

mRNA	messenger RNA
MRSA	methicillin-resistant *Staphylococcus aureus*
MS	mass spectrometry
MS	mass spectroscopy
MS^n	de novo tandem MS
MS/MS	tandem mass spectrometry
MSA	multiple sequence alignment
MSC	mesenchymal stromal cell
MSC	mesenchymal stem cell
MSSA	methicillin-susceptible *Staphylococcus aureus*
MT	shrimp maturation tank
MT	metallothionein
MT	metric ton
mTOR	mammalian target of rapamycin
MTT	3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
MTT	microculture tetrazolium assay
MTX	maitotoxin
MTZ	mass transfer zone
MUF-diNAG	4-methylumbelliferyl β-D-*N*,*N*′-diacetylchitobioside
MUFA	monounsaturated fatty acid
MurNAc	*N*-acetylmuramic acid
MVL	mevalonate
MW	molecular weight
MW	microwave
MWT	microwave treatment

N

NADH	nicotiamide adenine dinucleotide
NADPH	nicotinamide adenine dinucleotide phosphate
nanoSIMS	nanometer-scale secondary-ion mass spectrometry
NaPDoS	natural product domain seeker
NASBA	nucleic acid sequence-based amplification
NB-L	nitrobenzene with linoleic acid
NBC	nitrifying bacterial consortia
NCBI	National Center for Biotechnology Information
NCE	new chemical entity
NCI	human tumor cell line
NCI	National Cancer Institute
NCI-H460	human lung cancer cell line
NCN-Pt	platinum-dimethylamino pincer complex
NDGA	nordihydroguaiaretic acid
NER	nucleotide excision repair
NF	nuclear factor
NF-κB	nuclear factor-κB
NFT	neurofibrillary tangles
NGS	next generation sequencing
NHase	Nitrile hydratase
NHE	normal hydrogen reference electrode
NHP	*N*-(2-hydroxyphenyl)-2-phenazinamine
Ni	nickel
Ni-NTA	nickel nitrilotriacetic acid
NICD	Notch intracellular domain
NIO	National Institute of Oceanography
nirS	nitrite reductase
nirS	nitrification gene
NK	natural killer
NLase	Nitrilase
NMC-g-PEI	*N*-maleated chitosan-graft-PEI
NMDA	*N*-metyl-D-aspartic acid
NMNP	new marine natural product
NMP	*N*-methylpyrrolidone
NMR	nuclear magnetic resonance
NO	nitric oxide
NOAA	National Oceanic and Atmospheric Administration
NOB	nitrite-oxidizing bioreactor
NOESY	nuclear Overhauser and exchange spectroscopy
NP	nanoparticle
NP	nonylphenol mixture
NPU	net protein utilization
NRPS	nonribosomal peptide synthase
NRPS	nonribosomal peptide synthetase
NS	neutral sugar
NS2	nonstructural protein-2
NSC-g-PEI	*N*-succinyl chitosan-graft-PEI
NSCLC	non-small cell lung cancer
NSOM	near field scanning optical microscopy
NSP	non-starch polysaccharide
NSP	neurotoxic shellfish poisoning
NTA	nitrilotriacetic acid
NTC	no template controls
NTG	*N*-methyl-*N*′-nitro-*N*-nitroso guanidine
NTS	nontranscribed spacer
NVSCC	N-type voltage-sensitive calcium channel

O

OA	okadaic acid
OA	ocean acidification

OECD	Organization for Economic Cooperation and Development
OHT	overhead tank
OLED	organic light emitting diode
OmpA	outer membrane protein A
OP	organophosphorus
OPCW	Organization for the Prohibition of Chemical Weapons
OPD	organic photodetector
OPF	orange fluorescent protein
OPG	osteoprotegerin
OPH	organophosphorus hydrolase
ORAC	oxygen radical absorbance capacity
ORF	open reading frame
OTAB	octyl-trimethyl ammonium bromide
OTC	over-the-counter

P

P-388	mouse lymphocytic leukemia
P-CTX	Pacific-CTX
PAA	peak antibiotic activity
PAAR	peak activity attainment rate
pAb	polyclonal antibodies
PAFP	photoactivatable fluorescent protein
PAGE	polyacrylamide gel electrophoresis
PAH	polycyclic aromatic hydrocarbon
PAMA	peak antimicrobial activity
PAMAM	poly(amido amine)
PAN	plane polyacrylonitrile
PAO	phosphorus accumulating organism
PAPS	3′-phosphoadenosine 5′-phosphosulfate
PAR	photosynthetically active radiation
PB-PBR	packed bed photobioreactor
PBBR	packed bed bioreactor
PBEL-ALBR	packed bed external loop airlift bioreactor
PBMC	peripheral blood mononuclear cells
PbNP	lead (plumbum) nanoparticle
PBR	photobioreactor
PBS	phosphate buffered saline
PbTx	brevetoxin
PC	phycocyanin
PCA	principal component analysis
PCD4	programmed cell death 4
PCL	polycaprolactone
PCNA	proliferative cell nuclear antigen
PCP	PEG-graft-chitosan-graft-PEI
PCP-Pd	paradium-diphenylphosphino pincer complex
PCPA	PEG-graft-chitosan-graft-polyarginine
PCR	polymerase chain reaction
PDMS	polydimetylsiloxane
PE	phycoerythrin
PEEK	poly-ether-ether-ketone
PEG	poly(ethylene glycol)
PEI	polyethylene imine
PEI-g-C	PEI-graft-chitosan
PEI-g-SAC	PEI-conjugated stearic acid-graft chitosan
PEP-C	phosphoenolpyruvate carboxylase
PER	protein efficiency ratio
PES	protein expression signature
PET	photoinduced electron transfer
Pfu DNA	thermostable DNA polymerase named after the thermophilic bacterium *Pyrococcus furiosus*
PG	homopolymer of guluronate
PG	propyl gallate
PG	pressure gauge
PGE2	prostaglandin E_2
PGM	personal genome machine
PHA	poly-β-hydoxyalkanoate
PHA	polyhydroxyalkanoate
PHPA	*p*-hydroxyphenyl acetic acid
pI	isoelectric point
PIA	polysaccharide intercellular adhesin
PIA	pyrrole-imidazole alkaloid
PK	polyketide synthase
PKC	protein kinase C
PKD	polycystic kidney domain-like
PKS	polyketide synthase
PLA	polylactide
PLGA/PCL	poly(D,L-lactide-co-glycolide)/polycaprolactone
PlTX	palytoxin
PM	homopolymer of mannuronate
PM	petrosaspongiolide M
PMMA	poly(methyl methacrylate)
PMSF	phenylmethylsulfonyl fluoride
PMT	photomultiplier
PMT	photomultiplier tube
PNAG	poly-*N*-acetyl glucosamine polysaccharide
PnTX	pinnatoxin
PNV	pneumatic valve
POC	particulate organic carbon
POM	poly-oxy-methylene
PON1	paraoxonase
PP	protein phosphatase
PP	piston pump

PP9	perfluoromethyldecalin
PPC	proparacaine
PPE	poly(*para*-phenylene ethynlyene)
ppm	parts per million
PPO	polyphenol oxidases
PPP	Pentose phosphate pathway
ppp-3	palmitoyl pentapeptide-3
PR	proteorhodopsin
Prialt1	ziconotide
ProLuCID	name of a tandem mass spectrabased protein identification program
PRRSV	porcine reproductive and respiratory syndrome virus
PS	polysaccharide
PSC	pepsin-solubilized collagen
PSF	polysulfone
PSI	photosystem I
PSII	photosystem II
PSP	paralytic shellfish poisoning
PST	paralytic shellfish poisoning toxin
PT	prothrombin time
PT	pressure transducer
PTFE	polytetrafluoroethylene
PtOEP	Pt(II)-octaethylporphin
PTP1B	protein tyrosine phosphatase 1B
PtTX	pteriatoxin
PTX	pectenotoxin
PTX	palytoxin
PTX2SA	PTX2 seco acid
PU	polyurethane
PU-g-SP	pullulan-graft-spermine
PUFA	polyunsaturated fatty acid
PV	polyvinyl
PVA	polyvinyl alcohol
PVC	polyvinylchloride
PVDF	polyvinylidene fluoride

Q

QCM-D	quartz crystal microbalance dissipation
qPCR	quantitative PCR
QQ	Quorum Quenching
QS	quorum sensing
QSI	quorum sensing inhibitor

R

r-silicatein	recombinant silicatein
RACE-PCR	rapid amplification of cDNA ends-PCR
RANK	receptor activator of NF-κB
RANKL	ligand of the receptor activator of NF-κB
RANTES	regulated upon activation, normal T-cell expressed and secreted
RAP	RNA III activating protein
RAPD	random amplified polymorphic DNA
RAS	recirculating aquaculture system
RAST	rapid annotation using subsystem technology
RAW	ATCC cell line
RB	Remazol Black B
RBA	Receptor Binding Assay
RBBR	Remazol Brilliant Blue R
RBC	human red blood cell
RBC	rotary biological contactor
RBE	rat brain endothelial
RDBR	rotating disk bioreactor
rDNA	ribosomal DNA
RDP	Ribosomal Database Project
RFLP	restriction fragment length polymorphism
RFP	red fluorescent protein
RGD	arginylglycylaspartic acid
RGY	Remazol Golden Yellow
RHR	resting heart rate
RIA	radioimmunoassay
RIP	RNA III-inhibiting peptide
RiPP	ribosomally synthesized and post-translationally modified peptide
RISC	RNA-induced silencing complex
RNA	ribonucleic acid
RNAi	RNA interference
RO	reverse osmosis
ROS	reactive oxygen species
RP	magnetically driven vapor recirculation pump
RP-HPLC	reversed phase high performance
RPS	relative percent survival
RPS	rhabdovirus of penaeid shrimp
RR	Remazol Red RR
rRNA	ribosomal RNA
RSM	response surface methodology
RT	reverse transcriptase
RT-PCR	reverse transcription-polymerase chain reaction
RuBisCo	ribulose-1,5-bisphosphate carboxylase-oxygenase
RuBP	ribulose-1,5-bisphosphate

S

S	synthesis
SAG	single amplified genome
SAHA	suberoylanilide hydroxamic acid
SAM	S-adenosyl-L-methionine
SAR	structure-activity relationship
SAV	surface area volume
SBM	soybean meal
SC	stratum corneum
SCA	Sabouraud chloromphenicol agar
SCG	single-cell genomics
SCIE	science citation index expanded
SCO	single-cell oil
SCUBA	self-contained under water breathing apparatus
SDS	sodium dodecyl sulfate
SDS-PAGE	polyacrylamide gel electrophoresis
Se	selenium
SEAP	secreted form of alkaline phosphatase
Sec-tRNA	Selenocysteine-transfer RNA
SELDI	surface enhanced laser desorption/ionization
SEM	scanning electron microscope
SEM	scanning electron microscopy
SeN	selenoneine
SEQUEST	tandem mass spectrometry data analysis program used for protein identification
SERS	surface enhanced Raman scattering
SF	surfactin
SF-268	human CNS cancer cell line
SFE	supercritical fluid extraction
SFF	solid freeform fabrication
SGC 7901	human gastric cancer cell line
SGNH	a motif representing amino acid residues
SGP	polysaccharide
SGR	specific growth rate
SHRV	snakehead rhabdovirus
SIGEX	substrate-induced gene expression
SIP	stable isotope probing
Sir	strontium
siRNA	small (short) interfering RNA
SIV	subintestinal vessel plexus
SL	level of significance
SLM	St. Lawrence Mesocosm
SLRP	small leucine-rich repeat proteoglycan
SLS	sodium laureth sulfate
SMase 1	sphingomyolinase 1
sMBR	submerged-membrane bioreactor
SMF	submerged fermentation
SMTH	serine hydroxymethyltransferase
SMV	spawner-isolated mortality virus
SNP	single nucleotide polymorphisms
SOC	store-operated Ca^{2+}
SOD	superoxide dismutase
SONAR	sound navigation and ranging
SP	splenocyte
SP	sulfated polysaccharide
SPR	surface plasmon resonance
SPS	sulfated polysaccharide
SPX	spirolide
SR	scavenger receptors
SR	sulfate reduction
SRA	Sequence Read Archive
SRB	sulfate-reducing bacteria
SRT	solids retention time
SSAP	*Sebastes schlegeli*
SSCI	social sciences citation index
SSCP	single stranded conformation polymorphism
SSF	solid-state fermentation
SSR	short sequence repeats
ssRNA	single-stranded RNA
SSSF	semi-solid state fermentation
SSU	short subunit
ST-PBR	stirred-tank photobioreactor
STS	secondarily treated sewage
STX	saxitoxin

T

T-DNA	transfer DNA
t-PA	tissue plasminogen activator
TAG	triacylglyceride
TAG	triacylglycerol
TALE	transcription activator-like effector
TALEN	transcription activator-like effector nuclease
TAN	total ammoniacal nitrogen
Taq DNA	thermostable DNA polymerase named after the thermophilic bacterium *Thermus aquaticus*
TARC	thymus and activation regulated chemokine
TBA	thiobarbituric acid
TBHQ	*tert*-butylhydroquinone
TBT	tri-*n*-butyltin
TCA	tricarboxylic acid
TCDD	2,3,7,8-tetrachlorodibenzo-p-dioxin

TCP	tricalcium phosphate
TDD	transdermal drug delivery
TDDFT	time-dependent density functional theory
TeBactEn	Text Mining for Bacterial Enzymes
TEM	transmission electron microscope
TEM	transmission electron microscopy
TEOS	tetraethoxysilane
TEOS	tetraethyl orthosilicate
TFA	total fatty acid
TG	triglyceride
TGB	thermal gradient block
TGF-β	transforming growth factor beta
TGI	total growth inhibition
TH	tilapia hepcidin
Th2	T helper 2 cells
Ti(BALDH)	titanium (IV) bis(ammonium lactato) dihydroxide
TLC	thin layer chromatography
TLR	toll-like receptor
TMA	transcription mediated amplification
TMOS	tetramethoxysilane
TMP	transmembrane pressure
TMTD	trimethyltridecanoic acid
TNF	tumor necrosis factor
TNF-α	tumor necrosis factor-α
TOCSY	total correlation spectroscopy
TOF	time of flight
TPA	12-O-tetradecanoylphorbol-13-acetate
TPR	tetratricopeptide repeat domain encoding protein
TR-PBR	tubular recycle photobioreactor
TRAP	total radical antioxidant parameter
TRAP	target of RAP
TRSA	tetracycline-resistant *Staphylococcus aureus*
tsa-FISH	tyramide signal amplification FISH
TSV	Taura syndrome virus
TT	thrombin time
TTE	triethylenetetraamine
TTX	11-[^{3}H]-tetrodotoxin

U

u-PA	urokinase plasminogen activator
UA	urocanic acid
UA	uronic acid
UAC	UA-coupled chitosan
UASB	upflow anaerobic sludge blanket
UCP1	uncoupling protein 1
UDP-sugar	nucleoside sugar diphosphate
UF	ultrafiltration
ULS-RDBR	ultralow speed rotating disk bioreactor
USP	ultra-short pulses
UTR	untranslated region
UV	ultraviolet
UVB	ultraviolet B radiation

V

VDA	vascular disrupting agent
VEGF	vascular endothelial growth factor
VFA	volatile fatty acids
VGCC	voltage-gated calcium channel
VGIC	voltage-gated ion channels
VGSC	voltage-gated Na^+ channel
VHSV	viral hemorrhagic septicemia virus
Vira-A1	Vidarabine
VLC	very long-chain
VLDL	very low density lipoprotein
VLP	virus-like particle
VP	viral protein
VRE	vancomycin-resistant *Enterococcus faecium*
VREF	vancomycin-resistant *Enterococcus faecium*
VS	volatile solid
VSV	vesicular stomatitis virus
VTG	estrogen inducible vitellogenin promoter

W

WAP	whey acidic protein
Wap65	warm temperature acclimation-related protein 65
WAT	white adipose tissue
WBC	white blood cell
WGA	whole genome amplification
WHO	World Health Organization
WoRMS	World Register of Marine Species
WSD	white spot disease
WSSV	white spot syndrome virus
ww	wet weight

X

XANES	X-ray adsorption near edge spectroscopy
XOD	xanthine oxidase

Y

YHV	yellow head virus
YTX	yessotoxin

Z

ZFN	zinc finger protein
ZFN	zinc-finger nuclease
ZFP	zinc finger peptide

1. Introduction to Marine Biotechnology

Se-Kwon Kim, Jayachandran Venkatesan

Marine biotechnology is an innovative field of research in science and technology concerning the support of living organisms with marine products and tools. To understand the *omics* of the living species: it is a novel way to produce genetically modified food, drugs, and energy to overcome global demand. The exploitation of biotechnology for drug discovery, including enzymes, antibiotics, and biopolymers, chemical compounds from marine sources are deliberated in this book. The concepts of marine microbiology and molecular biology are explored extensively in the present book. Biomedical applications of marine biomaterials such as tissue engineering, drug delivery, gene delivery, and biosensor areas are thoroughly discussed. Bioenergy from marine sources is a groundbreaking achievement in the field of marine biotechnology and is also covered in this book. Finally, industrial uses of marine-derived products are explored for mankind.

1.1 Marine Biotechnology – Definition

More than 80% of living organisms on earth are found in the aquatic ecosystem. The largest ecosystem on the planet is the ocean; it can be divided into photic, pelagic, benthic, epipelagic, and aphotic zones. More than 40 000 different kinds of species are present in the marine environment, and they are classified as microorganisms, seagrasses, algae, corals, and animals [1.1]. The marine world is considered as a huge reservoir of various biological active compounds. Marine organisms have the capacity to produce unique compounds due to exposure to exceptionally different oceanic environments, such as temperature, chlorophyll content, salinity, and water quality [1.2, 3]. The oldest known fossils are marine stromatolites, which have been evolving for 3.5 billion years; land fossils are about 450 million years old [1.4, 5]. Although the marine world represents nearly $\frac{3}{4}$ of the earth's surface, it is one of most underutilized biological resources.

Biotechnology is the most powerful tool to discover the many secrets of marine organisms and their compounds. There are numerous definitions and explanations that have been given to marine biotechnology since the day its term was coined [1.6, 7]. According to *Food and Agricultural Organization* (FAO, #8), biotechnology can be defined as [1.8]:

> *any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use.*

J. Grant Burgess suggested that marine biotechnology is [1.4]:

> *biotechnology carried out using biological resources which have come from the marine environment rather than from the terrestrial environment.*

Alternatively, marine biotechnology is also defined as *the industrial use of living organisms or biological techniques developed through basic research*. In another words, The Organization for Economic Cooperation and Development (OECD) defines biotechnology as

> *the application of science and technology to living organisms, as well as parts, products and models thereof, to alter living or non-living materials for the production of knowledge, goods and services.*

Thakur et al. defined the Marine biotechnology as [1.9, 10]

> *the application of scientific and engineering principles to the processing of materials by marine biological agents provide good and services.*

Another possibility to define the marine biotechnology is that it might be derived from marine bio (techno) logy.

1.2 Marine Biotechnology – Tools

In recent years, advances in instrumentation and a combination of proteomic and bioinformatics are accelerating our ability to harness biology for commercial improvement [1.4]. The marine biotechnological process has significant capacity to improve human life. Several biotechnological tools have been developed for cost-effective products that can be used for medical, industrial, and environmental applications. A variety of biotechnological methods have been adopted from marine sources such as transgenic methods, genomics, fermentation, gene therapy, bioprocess techniques, bioreactor methods, etc. Marine biotechnology is more often considered in terms of molecular or genomic biological application to generate desirable products. It encompasses the production and application of living organisms and is expected to have numerous impacts on our economy. Marine biotechnology promises breakthroughs in areas such as aquaculture, microbiology, metagenomics, nutraceuticals, pharmaceutical, cosmeceuticals, biomaterials, biomineraliza-

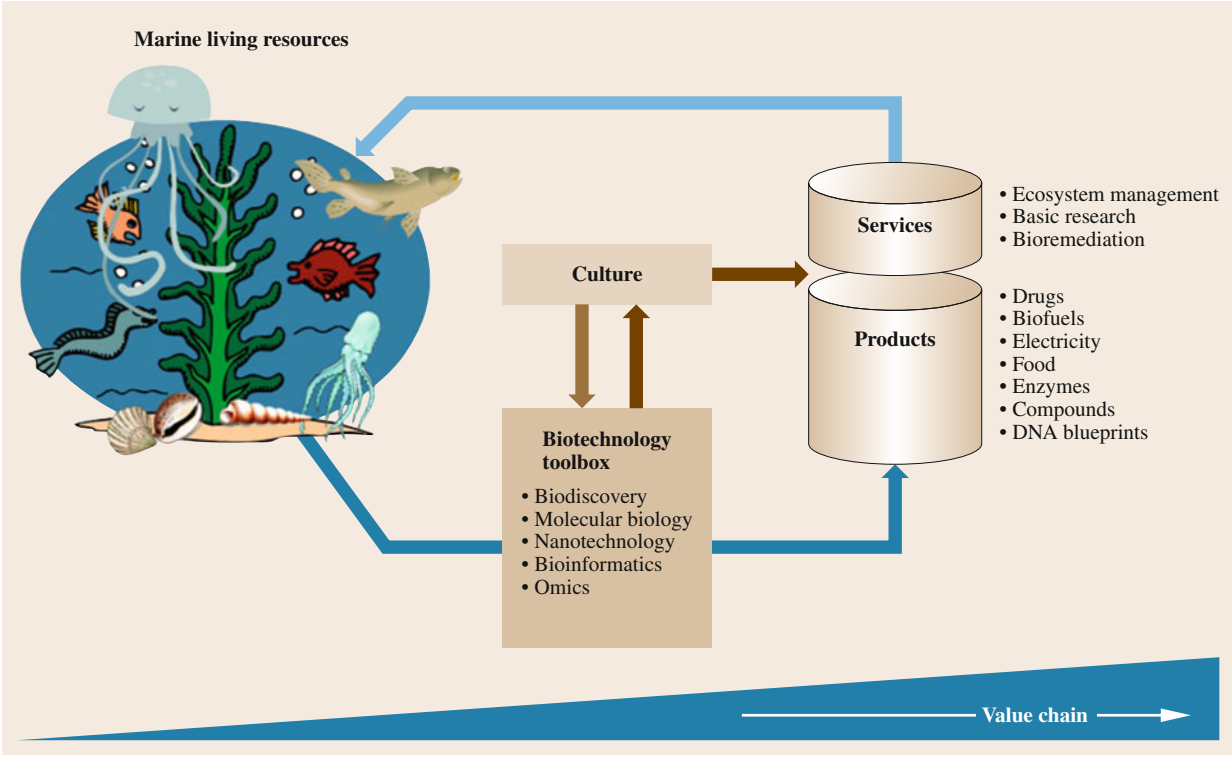

Fig. 1.1 Examples of products and services developed by technological applications using marine bioresources. After [1.11]

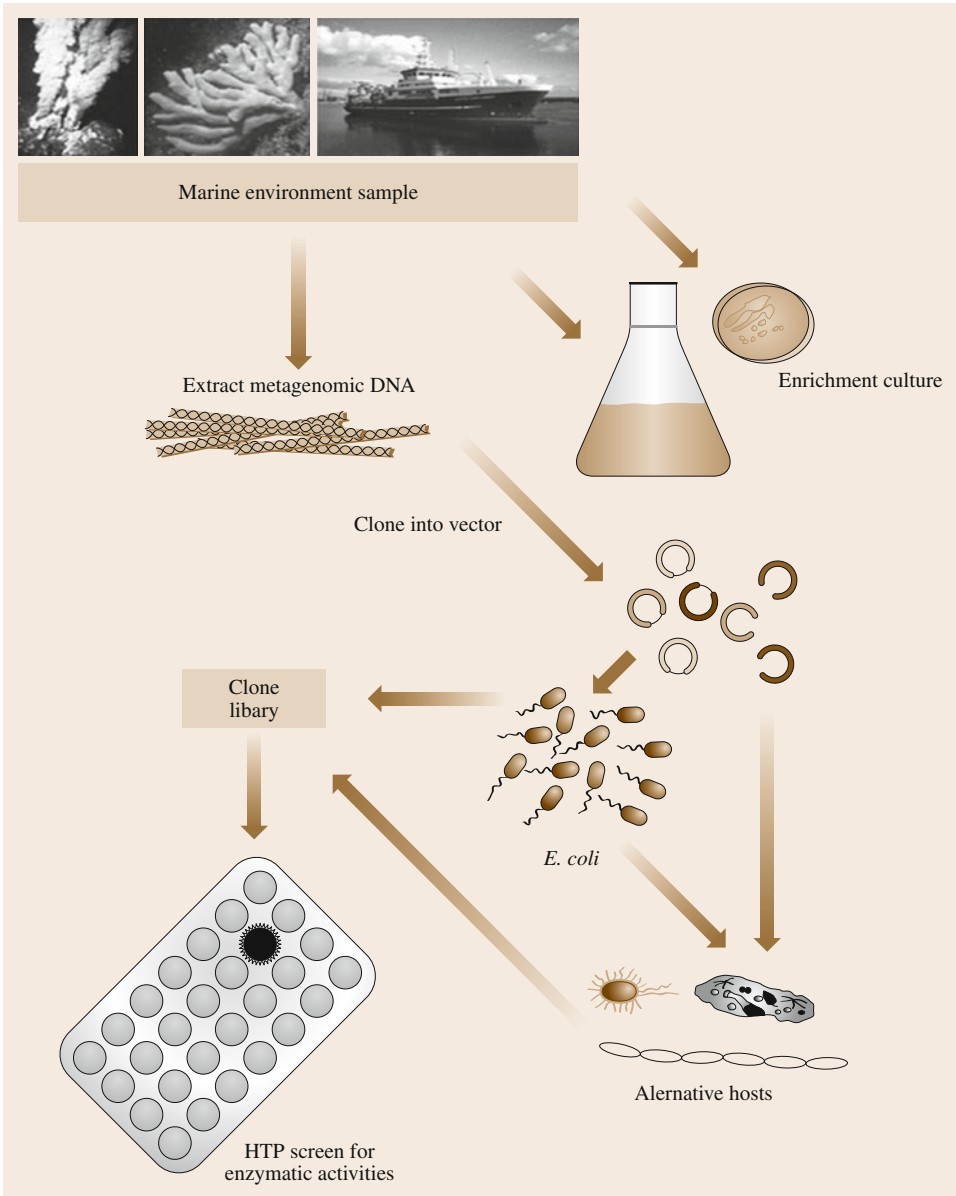

Fig. 1.2 Schematic depiction of functional metagenomic approaches for identification of novel biocatalysts

tion, biofouling, and bioenergy. Products derived by biotechnological methods are commonly more cost efficient with regards to production and also in pure form (Fig. 1.1).

An important consideration in transgenic research is the choice of promoter for regulating the expression of a foreign gene. The discovery of novel processes and techniques in marine biotechnology will create fresh opportunities for the development of innovative materials. The science of biotechnology has given us new tools and tremendous power to create genes and genotypes of plants, animals, and fish. *Lakra* and *Ayyappan* explored the use of synthetic hormones in fish breeding, the production of monosex, uniparental, and polyploid individuals, molecular biology and transgenesis, biotechnology in aquaculture nutrition and health management, gene banking, and marine natural products [1.12].

The biosynthesis and regulation route of many secondary metabolites in marine organisms should be addressed. It is possible, with the recent development of a novel transcriptome profiling methodology that allows for rapid and high-throughput screening of changes in messenger ribonucleic acid (mRNA) sequence pools. The application of genomics-based techniques and the integration of both biochemical and molecular data sets in marine organisms complement ongoing drug discovery efforts [1.13].

Metagenomic-based strategies are powerful tools to isolate and identify enzymes with novel biocatalytic activities from the uncultivable component of microbial communities [1.14]. The recent advances in biotechnological tools such as bioreactors, fermentations, and bioprocessing are useful in the production of functional ingredients, including enzymes that can be used in the food industry [1.15]. Molecular biology is playing a major role in marine biotechnology for an understanding of the genome level. Genomic analysis of marine organisms should be identified to utilize novel genes, proteins, enzymes, and small molecules. The knowledge of metabolic pathways and their genomics is the novel way to understand the mechanism behind the production of the compounds. Metabolic engineering is defined as the optimization of genetic and regulatory pathways to increase the production of compounds by cells (Fig. 1.2).

1.3 Marine Sources and Research Areas

Science and technology continues to move forward in making different technological tools to develop new products from the marine source. Important marine sources in the research are microorganisms, algae, and sponges. Various biotechnological products have been commercialized, ranging from novel drugs, chemicals, and enzymes to bioenergy [1.16–22]. Marine biotechnology plays an important role in the development of various biomaterials, biosensors, seafood safety, aquaculture, bioremediation, and biofouling (Table 1.1). Several drugs are obtained from natural sources, and researchers are still searching for potential organisms from marine sources.

1.4 Applications of Marine Biotechnology

1.4.1 Marine Aquaculture

Marine aquaculture is one of the best examples of marine biotechnology. Fish is one of the most important marine sources for protein supplement in human food. Overfishing and changes in the global environment are contributing to the slow disappearance of this important food resource. By applying marine biotechnological tools, we may be able to provide or improve aquaculture procedures through recombinant technology to develop genetically modified organisms [1.23–26], which could be useful to overcome the global food demand.

1.4.2 Marine Natural Products for Medicine

Marine bioresources are huge reservoirs for various potential biological molecules, which have tremendous potential as human medicines. Natural products are both a fundamental source of a new chemical diversity and an integral component of today's pharmaceutical collection [1.27–33]. Numerous marine compounds are isolated from marine animals, algae, fungi, and bacteria with antibacterial, anticoagulant, antifungal, antimalarial, antiprotozoal, antituberculosis, and antiviral activities. There are now 4 approved products, 13

Table 1.1 Important marine sources and research areas

Research area	Marine source	Aims
Food	Algae, invertebrates, fish	Development of innovative methods, to increase aquaculture production and zero waste recirculation systems
Energy	Algae	Biofuel production, biorefineries
Health	Algae, sponges, microorganisms	To find novel bioactives
Environment	Marine microorganisms	Biosensing technologies for marine environment monitors and non-toxic antifouling technology
Industrial products	Algae	Production of marine biopolymers for food, cosmetics, health

Table 1.2 Examples of market level marine-derived products

Products	Source	Application
Ara-A	Marine sponge	Antiviral
Ara-C	Marine sponge	Anticancer
Okadaic acid	Dinoflagellate	Molecular probe
Manoalide	Marine sponge	Molecular probe
Vent TMA polymerase	Deep-sea hydrothermal vent bacterium	PCR enzyme
Aequorin	Bioluminescent jelly fish	Bioluminescent calcium indicator
Green fluorescent protein	Bioluminescent jelly fish	Reporter gene
Phycoerythrin	Red algae	Conjugated antibodies used in ELISAs and flow cytometry
Cephalosporins	*Cephalosporium* sp., marine fungi	Antibiotic

in clinical trials, and large number of pre-clinical investigations, coming from a wide range of marine sources from many different parts around the world. Prialt ziconotide, a painkiller originally isolated from a Pacific (Philippines) cone snail, Yondelis trabectidin, an anticancer molecule from the Caribbean tunicate *Ecteinascidia turbinata*, and 3-(2,4-dimethoxybenzylidene)-anabaseine (DMXBA) from the ribbon worm *Paranemertes peregrina*, from the Pacific Rim, are a few examples [1.10] (Table 1.2). 59 marine compounds have been reported to affect the cardiovascular, immune, and nervous systems, as well as to possess anti- inflammatory effects. 65 marine metabolites have been shown to bind to a variety of receptors and miscellaneous molecular targets, and thus upon further completion of the mechanism of action studies, will contribute to several pharmacological classes [1.34]. The route to market involves isolation and chemical characterization, followed by synthesis or semi-synthesis of the molecule or an active analog.

Natural product lead compounds from sponges have often been found to be promising pharmaceutical agents. Most of these drugs are used in the treatment of the human immunodeficiency virus (HIV) and the herpes simplex virus (HSV). The most important antiviral lead of marine origin reported thus far is a nucleoside Ara-A (vidarabine), isolated from the sponge *Tethya crypta*. Marine compounds that act on the six hallmarks of cancer presented self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replication, sustained angiogenesis and tissue invasion, and metastasis [1.35–39].

Marine microbes have a huge biochemical diversity and are likely to become a rich source of novel drugs. Marine microbial compounds are an important source for drug development [1.22]. Marine bacteria are one of the important sources for many bioactive compounds, antibiotics, and pharmaceuticals. They are usually found in marine sediments and are also found to be associated with marine organisms [1.40]. Marine fungi are also reported to be a potential source for bioactive compounds. Polyketide synthases are a class of enzymes that are involved in the biosynthesis of secondary metabolites (erythromycin, rapamycin, tetracycline, lovastatin, and resveratrol).

Actinomycetes are one of the most efficient groups of secondary metabolite producers; they exhibit a wide range of biological activities, including antibacterial, antifungal, anticancer, and insecticidal, and enzyme inhibition. Several species have been isolated and screened from the soil in the past decades. Among its various genera, *Streptomyces, Saccharopolyspora, Amycolatopsis, Micromonospora*, and *Actinoplanes* are the major producers of commercially important biomolecules [1.41]. Actinomycetes are virtually unlimited sources of new compounds with many therapeutic applications and hold a prominent position due to their diversity and proven ability to produce novel bioactive compounds; 70% of which are produced by actinomycetes, 20% from fungi, 7% from *Bacillus* sp. and 1−2% by other bacteria [1.42]. Antimicrobial peptides are promising candidates, because their initial interaction with microbes is through binding to lipids [1.43].

Dinoflagellate toxins and bioactives are of increasing interest because of their commercial impact [1.44]. Functional screens to isolate novel cellulases, lipases and esterases, proteases, laccases, oxidoreductases, and biosurfactants have been described [1.45]. Enzyme inhibitors have received increasing attention as useful tools for the study of enzyme structures and their mechanisms. Marine organisms have been documented as a productive source for the enzyme inhibitors. Several commercialized products are shown in Table 1.2. Arebinosyl cytosine (Ara-C) is currently sold by the Pharmacia and Upjohn company under the brand name Cytosar-R [1.10].

1.4.3 Marine Nutraceuticals

Marine nutraceuticals can be derived from a vast array of sources, including marine plants, microorganisms, and sponges. Marine nutraceutical products currently promoted to various countries include fish oil, chitin, chitosan, marine enzymes, chondroitin from shark cartilage, sea cucumbers, and mussels. As mentioned earlier, the marine world represents a largely unexploited reservoir of bioactive substances that can be used for food processing, storage, and protection. Enzymes extracted from fish and marine organisms can provide numerous advantages over traditional enzymes. Fish protein such as collagens and their gelatin derivatives operate at relatively low temperatures and can be used in heat sensitive processes such as gelling and clarifying. Polysaccharides derived from alga, including alginate, carrageenan, and agar types are widely used as thickeners and stabilizers in a variety of food ingredients. In addition, Omega-PUFA (polyunsaturated fatty acid) is an important ingredient in the nutraceutical industry [1.46]. It has been proven that Omega-PUFA, especially eicosapentaenoic acid (EPA) and docosahexenoic acid (DHA) play a significant role in number of aspects of human health [1.47]. The application potential of chitin and chitosan are multidimensional, for example, in food and nutrition, biotechnology, material science, drugs and pharmaceuticals, agriculture and environmental protection, and gene therapy [1.48–52]. Fucoidan is a complex-sulfated polysaccharide, which can be derived from brown algae. Fucoidan has been used in several biological activities and is important for its high bioactive properties, for example, antibacterial, anticoagulant, antiviral, antitumor, etc., and many more yet to be explored [1.53].

1.4.4 Marine Biomaterials

In the recent years, much attention has been paid to marine-derived biomaterials for various biological, biomedical, and environmental applications. A recent report estimates that the global markets for marine biotechnological products might exceed US$ 4.1 billion by 2015, to which the following product segments, marine biomaterials (including food hydrocolloids) could contribute over 40%; marine bioactive substances for healthcare would be the most important and fastest-growing sector. Non-toxic, biocompatible, natural chitin and chitosan from crustaceans have potential use in cosmetics, food, and pharmaceuticals [1.54]. Seaweeds are the abundant source for polysaccharides, which are commercial products (alginate, agar, agarose, and carrageenan) [1.55–61].

1.4.5 Marine Bioenergy

Bioenergy from marine algae is a groundbreaking achievement in the field of marine biotechnology [1.62–67]. Biofuels derived from marine algae are a potential source of sustainable energy that can contribute to future global demands. The realization of this potential will require manipulation of the fundamental biology of algal physiology to increase the efficiency with which solar energy is ultimately converted into usable biomass [1.68]. Anaerobic digestion of microalgae is a necessary step to make microalgae biodiesel and biogas sustainable [1.69, 70]. The potential biomass sources for bioenergy are photosynthetic microalgae and cyanobacteria. There are versatile marine organisms that can be used in the production of biogas, biodiesel, bioethanol, and biohydrogen [1.71–76].

1.4.6 Marine Bioremediation

Bioremediation is also an important area of marine environmental biotechnology. Marine microorganisms have the capacity to degrade the variety of organic pollutants. *Pseudomonas chlororaphis* produces pyoverdin, which catalyzes the degradation of organotin compounds in seawater. Biopolymers and biosurfactants are also applied to environmental waste management and treatment [1.77–81].

1.5 Research Scope

Marine biotechnology plays a vital role in the exploration and study of various marine resources. Marine biotechnology comprises a broad range of subjects: marine bioactive substances, genetics, marine culture, fermentation engineering, and enzyme engineering. The marine biotechnology market is still in the promising stages; during the years 2008 and 2009, the global marine biotechnology market witnessed a slowdown owing to the global economic meltdown. The market gained drive in 2010 with the recovery of the economic situation and is expected to post substantial growth in ensuing years.

Table 1.3 Countries and their marine biotechnology research priorities

Countries		Research priorities
Africa	Mozambique, Nigeria, South Africa, Tunisia and Kenya	Biofuels and bioactives
Central and South America	Brazil, Chile, Argentina, Mexico, Costa Rica	Biodiscovery, bioenergy, bioremediation and biofouling
North America	USA, Canada	Biodiscovery, aquaculture and biofuels
Asia	China, India, South Korea, Japan, Taiwan	Biofuels, biodiscovery for human pharmaceuticals, food, feed, cosmetics
Middle East	Israel	Sponge biotechnology, marine bioactives and biofuels
South East Asia, Indian Islands	Thailand, Vietnam, Indonesia, Malaysia, Singapore, Sri Lanka, the Philippines	Biodiversity for novel bioactives and aquaculture,
Australia Pacific	Australia and New Zealand	Aquaculture and marine bioactives

The research drive on marine biotechnology is high in countries like USA, Brazil, Canada, China, Japan, the Republic of Korea, and Australia, as well as in other countries where activities are grow from a smaller base (Thailand, India, Chile, Argentina, Mexico, and South Africa), and where there are signs that marine biotechnology is increasing in importance as a research priority. It is notable that the major international effort, the Census of Marine Life (CoML), involved 2700 researchers, about 31% from Europe, 44% from USA and Canada, and 25% from the rest of the world, notably Australia, New Zealand, Japan, China, South Africa, India, Indonesia, and Brazil (Table 1.3) [1.82].

The United States is the world leader and represents the single largest region for marine biotechnology worldwide. The marine bioactive substances market is forecasted to register the fastest growth rate of more than 4.0% during the period 2009–2015. Healthcare/biotechnology constitutes the largest, as well as fastest growing, end use for marine biotechnology. Very few countries have initiated national R&D programs to exploit the benefits of biotechnology in the marine sector. However, advances in aquaculture, drug discovery and fisheries are expected to encourage applications of marine biotechnology. The research report titled as *Marine Biotechnology: A Global Strategy Business Report* provides a comprehensive review of the marine biotechnology market, recession on the markets, current market trends, key growth deliverers, introductions of recent products, recent activity in the industry (Aker Bio Marine ASA, CP Kelco US Inc., Cyanotech Corp., Elan Corporation plc, FMC Corp., FMC Biopolymers AS, GlycoMar Ltd., Integrin Advanced Biosystems, International Specialty Products Inc., Lonza Group Ltd., MariCal, Marinova, Martek Biosciences Corp., Mera Pharmaceuticals Inc., New England Biolabs Inc., PharmaMar S.A, PML Applications Ltd., Primex Ltd., Prolume Ltd., Sea Run Holdings Inc., and Tequesta Marine Biosciences), and the profile of major global as well regional market participants. The harnessing of marine resources through biotechnology and development of products and services should be a serious target for any country with significant aquatic biodiversity.

A major task of marine biotechnology is to develop an efficient process for the discovery of novel molecules from the marine environment. The high level of marine biodiversity of marine organisms makes them a prime target for bioprospecting; these are enzymes, bioactive molecules, and biopolymers with varied industrial applications. Biochemical studies of marine organisms are an important task for the discovery of new drug molecules and biological tools and management of biodiversity.

1.6 Organization of the Handbook

This handbook combines the knowledge of sea flora and fauna, biotechnological methods, product development and industrial applications. It is divided into 10 parts. The introduction of the book comprises the definition, history and research scope of marine biotechnology. The first part introduces marine flora and fauna in detail, such as fungi, phototrophs, viruses, microalgae, seaweed, coral, and sponges. In this part, a detailed explanation is given on the production, cultivation, and processing of flora and fauna. The second part of the book introduces the tools and method of marine biotechnology; it covers, bioprocess engineering,

bioinformatics techniques, bioreactors, transgenic technology, quorum sensing, and molecular methods for the detection of invasive species. The third part of the book provides details about marine metagenomics, proteomics, marine metagenomics and supporting technology, microfluidic systems, and genomic mining. The fourth part of the book deals with algal biotechnology, starting with the structure and biological activities of marine algal polysaccharides, two centuries of research on iodine in seaweeds, marine macrophytes, and heavy metal removal by marine algae. The fifth part of the book covers marine microbiology, marine microbial biotechnology, and marine actinomycetes.

The sixth part of the book provides details about marine-derived metabolites, starting with marine natural products, biocatalysts, antimicrobial peptides, marine-derived fungal metabolites, dinoflagellates, carotenoids, Cnidarians, fatty acids, biotoxins, microbial enzymes, and polysaccharides. The seventh part of the book focuses on applications of marine biotechnology, starting with pharmaceuticals, functional food, nutraceuticals and cosmeceuticals. The eighth part of the book covers bioenergy and biofuels; here, the lead authors discuss marine bioenergy, marine algal biotechnology for bioenergy, and biofuels. Biomedical applications are extensively discussed in the ninth part of this book; the topics are marine biomaterials, gene delivery, biosensors, and biomineralization. Finally, the last part of this book focuses on industrial applications of marine biotechnology.

2. Marine Fungal Diversity and Bioprospecting

Kalaiselvam Murugaiyan

Marine fungi are a large group of eukaryotic organisms. Marine fungi, and particularly wood-inhabiting fungi, have been extensively studied since 1944. These have been termed lignicolous fungi and constitute more than 50% of the total 450 species of obligate marine fungi described so far. Marine fungi occur not only in water and sediment, but also as parasites on plants and animals, as well as symbionts in marine lichens, plants, and algae. A rich pool of fungal species is yet to be discovered and investigated over the coming years. About 150 species have been found exclusively on decaying mangrove wood, aerial roots, and seedlings, and are categorized as *Manglicolous fungi*; most of the species belong to the class of *Ascomycetes*. Fungi in mangroves play a significant role in litter decomposition and nutrient cycling, thereby contributing to the fertility of the environment. Fungal biomass along with detritus contributes significantly to the food chain of detritus-feeding organisms found in mangroves. *Aspergillus* and *Penicillium* are the dominant fungi involved in litter decomposition of mangroves. Fungal endophytes are microfungi; they colonize the internal tissues of vascular plants without producing any apparent disease symptoms and are considered as an important component of biodiversity. The distributions of endophytic mycoflora differ with the host and modify the host plants at genetical, physiological, and ecological levels. These modifications induce profound changes in how plants respond to their environments. The environmental and biological factors such as the availability of substrates or hosts, salinity, hydrostatic pressure, temperature, and the availability of oxygen control the distribution of marine fungi. The adaptation of marine fungi in an extreme environment suggests that they are promising sources for screening natural products.

2.1 Preamble

Fungi are eukaryotic and non-vascular organisms. The cells of fungi contain nuclei with chromosomes. A fungus is neither a plant nor an animal. The cell walls of fungi are similar to the structure of the cell walls of plants. The only different is in the chemical composition. The fungi's cell wall is composed mainly of chitin, while plant cell walls are mostly made of cellulose. Their cytoplasmic ultrastructure is also similar to that

of plant cells and differs only in the organelles and their structures. Furthermore, fungi are heterotrophic, feeding on other organisms. Unlike animals (heterotrophic) which ingest and then digest food, fungi will first digest food then ingest it.

Most fungi are multicellular; some are unicellular and are composed of filaments called hyphae. Hyphae may contain internal cross walls called septa. Septa may have pores allowing cytoplasmic contents to flow freely from one cell to another, through which they obtain their nutrients from the host. Hyphae may be branched; a dense mass of hyphae is called a mycelium. To maximize nutrient uptake, filamentous fungi form mats of fine hyphae. Fungi reproduces using spores through wind-dissemination. Both types of spores (sexual and asexual) may be reproduced, depending on the species and conditions. They primarily function as recyclers of organic material.

2.2 Diversity of Fungi

The kingdom Fungi is the second largest group after insects and is widely distributed in nature. A conservative estimate of the total number of fungal species thought to exist is 1.5 million [2.1], with only 71 000 having been described so far [2.2]; the vast majority of all extant fungi is yet to be named. Assuming a relatively constant rate at which new species are described, it will take more than 1100 years to catalog and describe all remaining fungi. However, many of these fungi are likely to become extinct before they are ever discovered, given the current rates of habitat and host loss. For example, up to 2% of tropical forests are destroyed globally each year. These habitats are exceedingly rich in fungal species. It should be considered that this estimate is based only on plant parasitic fungi and does not take into account other ecological groups of fungi such as saprotrophs.

2.2.1 Current Status of Marine Fungi

The first scientific report on marine mycology was published in the early 1900s; therein marine fungi are distinct from their terrestrial and freshwater counterparts [2.3, 4]. 24 species of marine and terrestrial fungi have been found on wood-blocks submerged in water from brackish water lakes in Japan [2.5]. Very little scientific information is available on the occurrence and distribution of fungi inhabiting marine environments, including marine mangroves [2.6]. A saprophytic and facultative parasitic fungus was reported in the coastal waters and adjacent pelagic areas of the Hawaiian Islands [2.7]. More than 800 microorganisms have been isolated from marine sediments in Italy [2.8].

Fungal diversity on prop roots, seedlings, and wood of *Rhizophora apiculata*, and wood, roots, and pneumatophores of *Avicennia* spp. are found in the deltaic mangroves of Godavari and Krishna rivers, on the east coast of India [2.9]. Frequency of occurrence and biodiversity of the fungi have been reported from mangroves of the Godavari and Krishna deltas, on the east coast of India [2.10]. The assemblage and diversity of filamentous fungi on leaf and woody litter accumulated on the floor of two mangrove forests (Nethravathi and Udyavara) on the southwest coast of India have been studied [2.11].

The diversity and ecology of fungi colonizing litter of mangroves in the Bay of Bengal region has been studied in the mangroves of the Godavary and Krishna deltas of Andhra Pradesh, Pichavaram of Tamilnadu, Andaman, and Nicobar islands [2.12]. The occurrence of fungi and a checklist of fungi have been prepared based on the pilot study in the Pichavaram mangroves of southeast India [2.13]. After the tsunami on December 26, 2004, the occurrence of filamentous fungi on woody debris by means of short-term (1 month) and long-term (12 months) damp incubation were investigated along five coastal locations on the southeast coast of India [2.14]. Marine fungi associated with decaying wood samples in the brackish water mangrove ecosystem and shoreline ecosystem was reported in south India [2.15]. Filamentous fungal diversity from the sediments of the continental slope has been investigated along the Bay of Bengal [2.16]. Floristic diversity and phorophyte specificity of lichens have been studied along the southeast coast of India, revealing that the latex bearing *Excoecaria agallocha* bears a maximum of lichen diversity followed by *Rhizophora* sp. [2.17, 18]. The above global and Indian scenario of fungal diversity provides unique opportunities for mycologists to explore fungal diversity and exploit the ecological, medicinal, and industrial potentials of fungi.

2.2.2 Major Groups of Fungi

True fungi belong to the Eukaryota kingdom, which has four phyla, 103 orders, 484 families, and 4979 gen-

era. The Deuteromycotina is not accepted as a formal taxonomic category. About 205 new genera have been described from India. Of these, approximately 27 000 species are reported to colonize diversified habitats. The major groups (phyla) of true fungi are *Ascomycota, Basidiomycota, Chytridiomycota*, and *Zygomycota*. Recently, studies have provided support for the recognition of additional phyla, such as *Glomeromycota*, a group of fungi once placed in *Zygomycota*, which form an association with the roots of most plants. A group of parasitic organisms called *Microsporidia* that live inside the cells of animals are also now considered to belong in the fungal kingdom.

A comprehensive classification of the kingdom Fungi was published as the result of collaboration among many fungal taxonomists [2.19]. This classification is used in the *Dictionary of the Fungi* [2.1] and other fungal references and databases. However, the classification system will undergo additional changes as scientists use new methods to study fungi. For example, *Cryptomycota*, a potentially new phylum of organisms within the fungi kingdom has been described. Recent findings suggest that a total of 625 fungi exist on a global scale (278 *Ascomycetes*, 277 anamorphic taxa, 30 *Basidiomycetes*, and 14 *Oomycetes*) and about 150 species of mangrove fungi have been reported from the mangroves of the Indian subcontinent.

Zygomycotina

Zygomycotina undergo asexual reproduction and are ubiquitous in soil and dung. Most of them are saprophytes and very few are parasitic on plants and animals. Trichomycetous fungi colonize the guts of arthropods. More than 1000 fungal species belonging to *Zygomycotina* have been reported from India, which are of high industrial value. For example, *Saksenea vasiformis*, a unique, indigenous fungus, has received special attention in medical mycology.

Ascomycotina

It is estimated that the *Ascomycetes* form approximately 40–45% of total fungi. Ascomycetous fungi include a number of fungi which have been show variations in their morphological diagnostic features (anamorphes and teleomorphs), an ascus-like organizational nature in ascospores, conidiophores and other characters. *Ascomycotina* forms the largest subdivision with 2700 genera and 28 500 species. Yeasts are of significant importance in industrial fermentations, such as brewing and baking. They are vital in decomposition processes to degrade cellulose and other plant polymers. On other hand, they can parasitize plants and can cause serious damage to the crop which leads to economic loss.

Basidiomycotina

Fleshy fungi, which include toadstools, bracket fungi, fairy clubs, puff balls, stinkhorns, earthstars, bird's nest fungi, and jelly fungi, fall into the category of *Basidiomycotina*. Toadstools exist as a symbiont, as well as parasites, where most of them are saprophytic in nature. They can be poisonous, however, the majority is harmless and some of them have higher nutritive values. More than 2000 species of edible mushrooms are reported from different parts of the world.

Mushrooms and Other Macrofungi

Among fungi, especially *Basidiomycetes* has been exploited more owing to its pharmacological properties such as antibiotic, antiviral, phytotoxic and cytostatic activities. Out of the 41 000 species of mushrooms, 850 species are recorded from India. Isolation of antitumor and immunomodulatory compounds of unusual polysaccharides of these macrofungi are being targeted nowadays.

Rust and Smut Fungi

The rust and smut are largest group of plant parasitic fungi in Basidiomycotina, which could cause drastic damage to economically important crop plants like wheat, corn, cereals, legumes, beans, and grasses. More than 160 genera of rusts have been recorded, out of which 46 are monotypic comprising 7000 species. The maximum number of species is seen in temperate and near temperate regions. Rust fungi occur on dicots rather than monocot plants. They parasitize plants that range from ferns to orchids and mints to composites. Several smuts can also cause considerable economic loss to cultivated plants, mainly on angiospermic monocots. Nearly 1450 smut species are distributed in 77 genera and about 3500 synonyms. Teliospore forming smuts (*Ustilaginomycetes*) are parasites on herbaceous, non-woody plants, while those lacking teliospores (*Microstromatales, Exobasidiales*) mostly parasitize woody (*Microstromatales, Exobasidiales*) plants.

Deuteromycotina

Deuteromycetes constitute an artificial group, which represents the asexual phases of *Ascomycotina* and *Basidiomycotina*. The multiplication occurs through the production of mitotic spores or conidia from special-

ized hyphae called conidiophores. Conidial ontogeny forms the basis for identification and segregation of *Fungi imperfecti*. It comprises 1700 genera of *Hyphomycetes*, and 700 genera of *Coelomycetes* that cover some 20 000 known species. They colonize, survive, and multiply in air, litter, soil, and other substrates and contribute extensively towards bio-degradation and recycling of organic matter, enzyme production, and industrial production including antibiotics, immunoregulators, and bio-control agents, in addition to causing profound mycoses, allergies, and plant diseases. About 8000 *Fungi imperfecti* are reported from India. Very few thermophilic fungi are reported from India with growth optima of around 45 °C.

2.3 Habitats of Fungi in the Marine Ecosystem

Different marine habitats support very different fungal communities. Fungi can be found in niches ranging from ocean depths and coastal waters to mangrove swamps and estuaries with low salinity levels. It is more than five decades since the marine mycology has evolved and it evidently states that marine fungi show a great variance not only in their taxonomy but also in their morphological, physiological and ecological adaptation capabilities from both terrestrial and freshwater fungi. Although *marine fungi* is a common term used to refer all fungi that are present in the sea, they are distinctly referred as marine, oceanic, manglicolous, arenicolous, or estuarine, based on their habitat.

2.3.1 Marine Fungi

Marine fungi form an ecological and not a taxonomic group. According to their origin marine fungi are categorized into two types i. e., obligate marine fungi and facultative marine fungi. Obligate marine fungi grow and sporulate exclusively in seawater, and their spores are capable of germinating in seawater. However, facultative marine fungi are those from fresh water or a terrestrial source that have undergone physiological adaptations that allow them to grow and also sporulate in the marine environment [2.4].

Marine fungi comprise an estimated 1500 species, excluding those that form lichens [2.20]. This number is much smaller when compared to the number of named and undescribed terrestrial fungi, which has been estimated to be 250 000 or more [2.4]. So far less than 500 filamentous higher marine fungi have been described and only 79 are associated with algae as parasites or symbionts, and 18 with animal hosts [2.21].

2.3.2 Fungi in Mangroves

Among the tropical marine ecosystems, mangroves and coral reefs are the major habitats in gross productivity [2.22]. Mangrove forests are spread over 181 000 km^2 in 112 countries in the tropics and subtropics [2.23, 24]. Through detritus production and decomposition mangroves support a variety of planktonic, benthic, and fish communities [2.25–27]. Up to 41% of mangroves exist in South East Asia [2.24]. The Indian subcontinent ranks fourth (6700 km^2) after Indonesia, Bangladesh, and Malaysia in mangrove vegetation cover [2.28]. Mangroves are intertidal forested wetland confined to tropical and subtropical regions, and mangrove vegetation is considered to be a dynamic ecotone (or transition zone) between terrestrial and marine habitats [2.29].

Mangrove ecosystems command intensive attention among coastal ecosystems, not only due to their peculiar habitat characteristics but also due to their rich biodiversity. Mangrove forests are biodiversity *hotspots* for marine fungi because the bases of mangrove trunks and aerating roots are permanently or intermittently submerged. Because the upper parts of roots and trunks are rarely or never reached by salt water, terrestrial fungi and lichens occupy the upper part of the trees and marine species occupy the lower part. At the interface, there is an overlap between marine and terrestrial fungi [2.30]. Mangrove fungi constitute the second largest ecological group of marine fungi. The latest estimate of marine fungi is 1500 species, in which 339 are found in mangrove ecosystems [2.31].

The fungi in mangroves play a significant role in litter decomposition and nutrient cycling, thereby contributing to the fertility of the environment. Fungal biomass along with detritus contributes significantly to the food chain of the detritus-feeding organisms found in mangroves. *Aspergillus* and *Penicillium* are dominant fungi involved in litter decomposition of mangroves. Since 1944, marine fungi have been extensively studied, particularly wood-inhabiting fungi [2.3]. About 150 species are found exclusively on decaying mangrove wood, aerial roots, and seedlings, and are categorized as *Manglicolous fungi*; most of the species belong to the class of *Ascomycetes*.

Of the 150 species, more than 30 species of marine fungi are found in the mangroves in the New World. Only a few seem to be host specific [2.4]. For example, *Avicennia germinans* specifically acts as a host for the fungal species *Rhabdosphora avicenniae* and *Mycosphaerella pneumatophorae*, whereas *Rhizophora mangle* forms another host for *Didymosphaeria rhizophora* and *Leptosphaeria australensis*. They are quite abundant in mangroves due to the easy availability of wood as their bait. Large numbers of fungi are found on *Avicennia marina, A. officinalis, Rhizophora mucronata, R. apiculata*, and *Sonneratia alba*. The fungal biodiversity in mangroves may reflect the age of the plants. A well-developed mangrove habitat provides a larger number of fungal species than new mangrove sites.

2.3.3 Fungi as Endophytes

Fungal endophytes are microfungi, mostly belonging to the family *Ascomycetes*. They colonize the internal tissues of vascular plants without producing any apparent disease symptoms. Fungal endophytes are now considered an important component of biodiversity. The distribution of endophytic mycoflora differs with the host. The fungal endophytes can modify the host plants at genetic, physiological, and ecological levels. It has been suggested that the association of fungi as endophytes with mangrove roots would confer protection from adverse environmental conditions and would allow the latter to successfully compete with saprophytic fungi that decompose senescent roots.

Mangroves are a special kind of host plant and also an abundant resource for endophytic fungi diversity. More than 200 species of endophytic fungi have been isolated and identified from mangroves, this being the second largest community of marine fungi. Most endophytic fungi have wide range of hosts, and a few only have a single host. Although several temperate plants have been studied for their endophyte assemblages, very few tropical plants have been screened for endophytes [2.32, 33]. Recently, endophytic fungi were isolated from mature green leaves of *A. officinalis* along the southeast coast of India and it was observed that the occurrences of dominant endophytic fungi are *Rhizopus* sp. (51.7%), *Penicillium lividum* (45%), and *A. ochraceus* (45%). Species richness and diversity are high in the leaves of *R. mucronata*, and the most dominant endophytes are *P. lividum* (45%) and sterile mycelia (40%). *F. moniliforme* (45%), *Alternaria* sp. (46.7%) are the dominant endophytes in leaves of *R. annamalayana* [2.34]. However, the composition and dominant species on each mangrove plant are different and their colonization varies with different parts (leaves, twigs, and stems), the age of the host plants, and with the seasons [2.35].

Scientists have been astonished at the adaptation of mangrove fungi in extreme environments and have suggested that fungi, in particular endophytes, are promising sources for screening new products. Sampling and characterization of endophytic fungal diversity is an emerging challenge and promises to lead to the discovery of new species, novel compounds, and a better understanding of their role in ecosystems.

2.4 Habitat Characteristics and Their Effect on Fungal Diversity

Despite of the insufficiency of data, generalizations have been made on habitat characteristics [2.2]. Five littoral mycogeographic zones such as arctic, temperate, subtropical, tropical, and Antarctic zones, have been proposed based on the sea-surface temperature. Temperature holds the first position among environmental and biological factors controlling the distribution of marine fungi, and then come the availability of substrates or hosts, salinity, hydrostatic pressure, and the availability of oxygen.

2.4.1 Effects of the Substratum

Marine fungi are commonly colonized in different substrata, which includes leaves and drift mangrove woods, *Avicennia alba, Bruguiera cylindrica*, and *Rhizphora apiculata* [2.35–37]. An abundance of the *Hyphomycetes* group of fungi on marine and mangrove substrates has been reported [2.20]. This might be due to the adaptation of their spores to the marine ecosystem by way of production of appendages, which provide buoyancy in water, entrapment, and adherence to the substrates, as reported in mangrove wood driftwood and animal substrates [2.38–40]. In addition to the above, *Hyphomycetes* also possess an enzyme producing ability and hence, they could potentially colonize lignocellulosic woody substrates. Maximum diversity of fungi on the woody litter of *Rhizophora* (64 spp.) and *Avicennia* (55 spp.) are reported from the Godavari and Krishna deltas of the east coast of India [2.41, 42]. The

nutritional features and persistent nature of the wood of *Avicennia* and *Rhizophora* in mangrove habitats might be responsible for yielding the rich mycoflora [2.43]. It is evident from the frequency distribution of fungi from Malaysian mangroves that driftwood supports a greater diversity of fungi than exposed test panels, e.g., 26 species on driftwood, 9 species on test blocks, while 104 species have been recorded on mangrove driftwood [2.44], yet only 77 on exposed test blocks of mangrove wood [2.45].

Differences in fungal counts may be attributed to a rhizosphere effect, which varies with the mangrove species. The effect of root exudation, which includes both promoters (sugars, amino acids, etc.) and inhibitors (phenolic compounds), and the ratio between the two types of compounds influence the fungal growth and multiplication [2.46]. It is also inferred that distributions of fungal species within the mangrove habitat vary with temperature, salinity, humidity, and organic contents [2.47]. Moreover, the frequency of occurrence and relative abundance of marine fungi from various mangrove forests of the world shows variations. This could be attributed to the difference in the species' diversity of the mangrove ecosystem, age, and preference of the host substrate, ecological factors, high temperature, abrasion, desiccation, variation in salinity, and exposure to UV light [2.48]. Mangrove leaf litter is an important substratum colonized by a very different fungal community to that of lignocellulosic materials [2.49, 50]. Higher marine fungi are not common on such leaf material [2.51].

2.4.2 Effects of Salinity

Salinity is an important factor that profoundly influences the abundance and distribution of fungi in the marine environment [2.52]. There seems to be continuous alterations in the intertidal amplitude and salinity, which can considerably affect fungal biodiversity. Earlier physiological studies of marine fungi led to the conclusion that they require sodium chloride at concentrations found in seawater for their growth. In fact, zoosporic fungi such as *Althornia, Haliphthoros* and *Thraustochytrium* species need sodium for growth at the macronutrient level [2.53]. Generally, changes in salinity in brackish water habitats such as estuaries, backwaters, and mangroves are due to the influx of freshwater from land run-off, caused by monsoons or tidal variations. The effects of salinity on fungal growth have been investigated by various authors, who observed only vegetative growth and depicted that most freshwater fungi cannot reproduce at salinities above 30% seawater and suggest that this is the major reason that they do not grow in the sea [2.19, 21, 54]. Further, it is interesting to note that the species diversity is much greater at the mangrove site when compared with the samples from the open ocean site, and this accounts for the larger number of terrestrial fungi recorded there [2.55].

In higher salinity, some species like *Curvularia lunata, Drechslera* sp., *A. terreus, Cladosporium herbarum*, and *Aurobasidium pullulans* are isolated [2.55]. This may be due to the fact that all these species are salt-tolerant fungi, although these species are mostly found in saltpan and seawater zones [2.56]. These species are mostly isolated from marine zones and rarely in fresh water and mangrove zones. These fungal cells employ two main mechanisms for adaptation to salt stress: accumulation of a polyol, glycerol, and maintenance of ion homeostasis [2.57]. When exposed to NaCl, the cells experience both osmotic stress and ion toxicity. To respond to a low external osmotic potential, the accumulating glycerol seemingly compensates for the difference between the extra and intracellular water potential [2.58]. To reduce sodium toxicity, fungal cells have to maintain low cytosolic Na^+ concentrations, and this is achieved by several mechanisms: by restricting Na^+ influx, rapidly extruding Na^+, and/or efficiently compartmentalizing sodium into vacuoles [2.59, 60]. Genetic evidence indicates that both mechanisms are essential for yeast salt tolerance [2.61].

2.4.3 Effects of Temperature

Temperature is the foremost important physical factor influencing the physicochemical characteristics and also the geographical distribution and abundance of mycoflora [2.52]. This may be due to direct solar heating and penetration of the warm surface water from the sea. Generally, the surface water temperature is influenced by the intensity of solar radiation, evaporation, freshwater influx and cooling, and mix up with ebb and flow from adjoining neritic waters. In general, marine fungi need high temperatures (usually between 25–30 °C) to reproduce [2.62]. At higher temperatures, *A. niger, A. terreus* and *Cladosporium herabrum* have been recorded in the marine zone of the Pichavaram mangrove forest [2.55]. The abundance of this group of fungi in the mangrove environment might be due to their spores, which show adaptation by way of pro-

duction of appendages that provide buoyancy in water, entrapment, and adherence to substrates, as reported in mangrove wood [2.63] and driftwood [2.64]. On the contrary, temperatures below 10 °C support the growth of wood fungi, *Digitatispora marina*, but when the temperature reaches 10 °C and above, the fungi stop fruiting on the wood [2.65]. Likewise, a few marine fungi have been recovered from Antarctic waters such as *Thraustochytrium antarticum, Leucosporidium anatartica*, and *Spathulospora antartica*, which leads us to the conclusion that the low temperature of the seawater and the availability of suitable substrata in the Antarctic region are responsible for the lower numbers of marine fungi [2.66].

There is clear evidence that temperature is responsible for sporulation, deposition, and germination of endophytic fungi. It has been demonstrated that endophytes enhance the thermotolerance of temperate plants, augmenting their potential to colonize extreme environments [2.67]. Further, temperature appears to be a major variable affecting the fluctuation of endophyte frequency in plant tissue [2.68]. Recent studies have provided evidence that the population density of leaves is influenced by summer temperatures; however, the number species of endophytic fungi increases with increasing air temperature [2.69]. It is interesting to note that seven isolates of *Corollospora maritime* have been investigated on the 18S gene [2.70], and it was found that five isolates from temperate localities grouped together; those from subtropical collections formed a separate group, while the strain from Aldabra separated from both groups.

2.5 Collection, Isolation, and Identification of Fungi

The water, sediments, substrates, and any solid material from the habitat can be collected in sterile polythene bags for fungal examination. The samples are transferred to the laboratory for further analysis. Isolation of fungi is performed by using a pour plate method with different fungal agar medium plates. The media is weighed out and prepared according to the manufacturer's specifications, with respect to the given instructions and directions. The isolated fungal species are identified up to species level by referring standard mycological manuals and books [2.4, 71–73]. After identification, the fungal species are maintained on a Sabouraud chloromphenicol agar (SCA) medium at 27 °C and they are subcultured at regular intervals using a sterile cork borer. Mycelial disks are cut at random and used for further studies.

2.5.1 Techniques for Sample Collection

Direct examination method. Fungi are directly examined under a dissection microscope for the presence of ascocarps, basidiocarps, or pycnidia. Such fruit bodies are transferred with a needle to a microscopic slide, torn apart in a drop of water to expose the spores, and carefully squeezed under a cover glass. To allow the development of fruit bodies, the litter samples can be incubated in a sterile moist chamber/petridish/polybag at room temperature. The incubated samples are examined under a microscope for fungal fruit bodies.

Another method is called the *wood baiting technique*, where terrestrial wooden logs measuring 6 × 3 × 2 cm are immersed in mangrove waters for certain period and then collected to examine the fungal colonization. To determine the fungal biota in any habitat, grab samples are satisfactory. At the chosen sites, samples are obtained scooping the water, mud, sand, or soil to be examined into the sample container. Plastic vials, soil cans, or other containers may be used to collect the samples. The container should be clean and the sample should be handled aseptically. It is not possible to obtain samples from the bottom of a body of water without water; to obtain samples from the bottom of a body of water deeper than elbow depth any of the available sampling devices can be used. The container is closed with its proper cover, excess sludge, dirt, etc., is wiped or rinsed off after which it is returned to the laboratory. The container should not be completely airtight.

2.5.2 Media Preparation for Isolation of Fungi

Various culture media are used for the isolation of fungi from the samples. The most commonly used media are Sabouraud dextrose agar or potato dextrose agar, along with chloramphenicol to avoid bacterial contamination. The chemical should be added in proper proportion along with agar (for solidification), autoclaved at 121 °C for 15 min, and plated in a sterile Petri dish that is free from contamination. Media used in plating the samples may be prepared the day before the samples are collected. The most convenient method of storage is in 10 ml lots in culture tubes in culture tube

racks in a hot water bath (45–55 °C). Instead of this, the medium may be placed in agar storage bottles and kept in the refrigerator or on the laboratory shelf. If the latter technique is used, the medium should be remelted just before use and pipetted onto the plate with 10 ml wide-mouth pipettes.

2.5.3 Isolation of Fungi

For the best results in the reading of plates, each plate should contain 40 to 60 colonies of fungi. To accomplish this, the sample must be diluted before it is plated. In general, liquids may be diluted only 1 : 10, a fairly rich sewage may be diluted 1 : 100, sludge containing about 4–6% dry matter and relatively poor clayey soils 1 : 1000, and richer, fairly dry materials (dry matter 30–60%), as much as 1 : 10 000. When the sample reaches the laboratory, a series of dilution flasks is prepared. The samples are then serially diluted and inoculated in the medium, and plating is done by various methods as per convenience. Different culture media are available to culture the yeast and other groups of fungi.

Incubation and Subculture of Isolated Fungi

Commonly, fungi can be grown at room temperature. 25 °C is a standard temperature for the growth of fungi and the temperature can be varied in the case of thermophilic fungi when it requires more than 50 °C to grow. For subcultures of fungi, a sterile cork-borer is used. The media block is taken out and inoculated into an another freshly prepared medium, and incubated at a suitable temperature.

2.5.4 Identification of Fungal Isolates

Several techniques are available for the identification of fungi. Because the nature of spore production apparatus and the spores associated with it is fragile, there are two techniques that are usually used. These are described below.

Direct Mounting Technique or LCB Mount

A small portion of mycelium is taken from the medium with a help of teasing needle. The needle must be incinerated and allowed to cool in laboratory conditions. Care must be taken when the fungus is taken out from the medium for mounting because the spores will be diffused into the environment and this may affect the individual dealing with the fungus; the laminar airflow must be in off mode. A drop of lactophenol cotton blue (LCB) solution is placed on the center part of the microscopic slide. The fungal mycelia should be mounted over the LCB. The mycelia should be gently handled as can break into pieces, which results in difficulties during the identification. Later a cover slip is placed over the mount without air bubbles. The slide is placed under a high power objective and the structure of the fungi is observed and identified.

Agar Block Technique

Fungal media are prepared and cut into 1 × 1 cm blocks with a sterile scalpel blade and placed over a slide. A small piece of mycelia is transferred to the agar block over the slide; a cover slip should be placed. The whole setup is placed inside the petri dish and small cotton soaked in water is also placed inside the dish for maintaining the moisture. The Petri dish is incubated at 25 °C for a certain period of time. Once the spores and mycelia have developed, the cover slip is removed aseptically from the agar block placed over the slide mounted with LCB, and observed under a high power objective. Identification is carried out with the help of a standard atlas and monograph using key characters (Table 2.1).

Macroscopic Morphology of Fungi

1. Rate of growth: slow (7–14 days)
   Rapid (2–7 days)
2. Topography: flat, regularly-folded, tangled
3. Texture: creamy, powdery cottony, mucoid, waxy
4. Color: front color of the colony, back color of the colony.

Microscopic Examination of Slide Cultures

This will be done for the following characteristics:

A. Hyphae-pigmentation of hyphal elements, shapes
B. Asexual spores – simple or specialized asexual spores
C. Conidiophores, conidia, macroconidia, and microconidia
D. Sporangiospores
E. Blastospores or chlamydospores
F. Spore size, shape, attachment to the mycelium, unicellular or multicellular, number of compartments
G. Rhizoids, columella.

2.5.5 Molecular Taxonomical Identification

Assembling taxa based primarily on morphological similarities does not necessarily reflect phylogenetic re-

Table 2.1 Key to the classes of fungi

S. No.	Major classes	Key characters
1.	*Zygomycetes*	Hyphal filaments, usually one-celled, rarely septate usually multinucleate; aquatic species propagating by zoospores, terrestrial species by zoospores, conidia, or conidia-like sporangia; sex cells when present forming oospores or zygospores
2.	*Phycomycetes*	Hyphal filaments, when present, multicellular, cell with one, two, or several nuclei, without zoospores, with or without sporangia, usually with conidia; sexual reproduction absent or culminating in the formation of asci or basidia
2a.	*Ascomycetes*	Sexual spores born in asci
2b.	*Basidiomyctes*	Sexual spores born in basidia
2c.	*Fungi imperfecti* (*Deuteromycetes*)	Without a sexual stage in the life cycle, or with sexual stage rare or obscure; spores born on conidiophores, which may produced at random, in clusters, or within pycnidia

lationships but is rather a convenient scheme which hinders exploration of marine fungi that might produce microbial metabolites for therapeutic use. This necessitates the careful identification and selection of species unique to a particular host before the high-throughput screening of metabolites for desired industrial applications. Therefore, taxonomy of fungi is a formidable challenge for most applications.

Fungal taxonomy is a dynamic, progressive discipline that consequently requires changes in nomenclature. The baseline of traditional fungal taxonomy and nomenclature is morphological criteria or their phenotypes. Numerous alternative approaches have been developed, including nutritional and physiological studies, serologic tests, secondary metabolites, and fatty acids. Although some of these are very useful for identifying poorly differentiated fungi such as yeast and black yeast, in most cases they are only complementary tools of morphological data. The fungus as a whole comprises a teleomorph (sexual state) and one or more anamorphs (asexual states). Traditional fungal classification is possible when the fungus is at its teleomorphic stage (asexual spore morphology also helps); however, the snag occurs in cases of fungi where only the anamorphic stage is available. The dual modality of fungal propagation, i. e., sexual and asexual, has led to a dual nomenclature. The anamorph and the teleomorph generally develop at different times and on different substrates. Species identification by morphological traits is often problematic because mycelial pigmentation, and the shape and size of conidia, which are unstable and highly dependent on the composition of media and environmental conditions. Further, subspecies level of identification is usually based upon pathogenic or physiological race reactions on a set of differential cultivars [2.74]. These processes of identification of fungi are time consuming, labor intensive, and subject to varying environmental or cultural growth conditions during the experiments [2.75], and also lead to inappropriate and unreliable application of species [2.76].

Thus methods are needed to distinguish between closely related species that occur in different habitats. Hence, molecular techniques for fungal identification and to investigate genetic variability within species have been increasingly used during the last decade. Molecular techniques based on polymerase chain reaction (PCR) have been used as a tool in genetic mapping, molecular taxonomy, evolutionary studies, and diagnosis of several fungal diseases [2.77, 78].

Differentiation of the *Fusarium* species/subspecies based on comparison of deoxyribonucleic acid (DNA) sequences of the ribosomal DNA (rDNA) and internal transcribed spacer (ITS) regions have been reported [2.79, 80]. The sequenced rDNA region of *F. oxysporum* (Accession no. JX 840353) isolated from sediments of mangroves along the southeast Indian coast covered the 18S ribosomal ribonucleic acid (rRNA) gene, partial sequence; internal transcribed spacer1; the 5.8S ribosomal RNA gene and ITS2; complete sequences; and the 28S ribosomal RNA gene, partial sequence. In the constructed phylogenetic tree, the strains *F. oxysporum* (GU205817), *F. oxysporum* (EF495237), *F. oxysporum* (EF495230), and *Fusarium* sp., (JF429684) have 98% similarity with the isolated strain *F. oxysporum* (JX 840353) [2.55] and 97% similarity with *Fusarium* sp., (GU973787). Genotypic identification of the 18S ribosomal RNA gene of endophytic *Fusarium* sp. isolated from leaves of *Rhizophora annamalayana* has been analyzed (accession number JN681281) and the fungus was found to be the closest homolog to *Fusarium moniliforme* [2.34]. Ribosomal RNA genes (rDNA) possess characteristics that are suit-

able for the detection of fungi at the species level. These rDNA are highly stable and exhibit a mosaic of conserved and diverse regions within the genome [2.18]. ITS regions have been used successfully to generate specific primers capable of differentiating closely related fungal species [2.81].

2.6 Bioprospecting of Marine Fungi

The need for new and safe bioactive compounds to provide comfort in all aspect of human life is ever increasing. Due the emergence of new diseases, the development of drug resistant pathogenic microorganisms, the appearance of life threatening viruses, the management of post operative complications in patients with organ transplantations are some of the challenges to scientists. Synthetic antibiotics and drugs are extending antibiotic resistant microbes, however it is essential to investigate a new way to treat diseases [2.82]. This situation has forced scientists to explore different natural sources for safe and potent agents to meet the challenges of the twenty-first century. Nature has been a source of medicinal agents for thousands of years and an impressive number of modern drugs have been isolated from natural sources based on their use in traditional medicines or phytomedicines. Due to safety and environmental problems, many synthetic drugs and chemicals have been removed or are currently being targeted for removal from the market, which creates the need to find alternative ways to control farm pests and dermatophytes [2.83–86].

Marine fungi have provided new incentives for research on marine natural products over the past years; this research also continue to be the subject of vigorous chemical investigation [2.87–89]. The diversity of secondary metabolites reported in recent decades is fascinating. This highlights the importance of marine fungi as a source of natural products [2.90–92]. The marine environment is unique in terms of its specific composition in both organic and inorganic substances, as well as temperature ranges and pressure conditions. Ecological niches, e.g., deep-sea hydrothermal vents, mangrove forests, algae, sponge, and fish provide habitats for the evaluation of specific microorganisms.

2.7 Conclusions

Fungi are not only beautiful but play a significant role in the daily life of human beings in addition to their utilization in industry, agriculture, medicine, the food industry, textiles, bioremediation, biodegradation, biogeochemical cycle, biofertilizers, and in many other ways. Fungal biotechnology has become an integral part of human welfare. Fungal biotechnology or *mycotechnology* has advanced considerably in the last five decades. Terrestrial fungi are used in the production of various extracellular enzymes, organic acids, antibiotics, and anticholesterolemic statins. They have been used as expression by hosts, as well as a source of new genes. With modern molecular genetic tools, fungi have been used as *cell factories* for heterologous protein production and human proteins. The focus of future research is oriented towards fungi in special ecological niches, as a basic understanding of the ecology to help reveal the novelty of an organism and its properties. The emphasis is on the following aspects for top priority:

i) Fungi associated with endophytic fungi in marine algae, seagrasses, and mangroves, and the implications.
ii) Fungi associated with marine invertebrates, especially corals and sponges, and their potential for production of bioactive molecules.
iii) Fungi from extreme environments such as the deep sea with elevated hydrostatic pressure and low temperatures, hypersaline waters of the Dead Sea, and anoxic or hypoxic (oxygen deficient) sediments from the marine environment.
iv) Bioremediation of pollutants using salt-tolerant fungi and their salt-tolerant enzymes on a pilot scale and industrial scale.
v) Genomic and proteomic studies with novel organisms such as *Corallochytriumlima cisporum* as a model of animal fungal allies. It is hoped that this will help basic research on evolutionary biology.

3. Diversity of Marine Phototrophs

Hideaki Miyashita

Phototrophs transform the energy of solar irradiation into chemical-bond energy in organic substances. Those organic substances provide biological energy not only for the activities of life on Earth, but also the formation and maintenance of regional and/or global ecosystems. They also provide biotechnological resources for materials, energy, and so on. Since their energy transformation is the starting point of the energy flow in the marine ecosystem, the understanding of *phototrophs* is important not only for the consideration of the homeostasis of the marine environment, but also for the development of new marine biotechnologies. Traditionally, diatoms and flagellates had been understood to be the major primary producers in the ocean. However, the developments of technologies for phytoplankton research within the past three decades revealed a diversity of phototrophs serving as *primary producers* and contributing to the transformation of light-energy into the chemical energy. The contribution by those diverse phototrophs to the energy flow in the ocean seemed much larger than that by diatoms and flagellates, which indicated the necessity of reconsidering energy flow or primary production. In this paper, the author discusses the diversity of planktonic phototrophs that serve as the *primary producers* (the starting point of the energy flow in the marine environments) based on research results in chronological order.

3.1 Traditional Understanding of Primary Producers (≈1970s)

Until the mid 1970s, primary production in marine environments was understood to be performed mainly by diatoms and flagellates [3.1]. It was obvious that they contribute to primary production, since they are the major organisms that can be collected by a phytoplankton net (small mesh-size net). Moreover, phytoplankton are distributed in a wide range of water quality, including eutrophic and oligotrophic environments. Dinoflagellates are also widely distributed as a major member of phytoplankton in the oligotrophic ocean. Symbiotic dinoflagellates in corals at tropical reefs play a significant role as the major primary producer in those oligotrophic environments. Thus, diatoms and flagellates were understood to be the major primary producers in marine environments (Fig. 3.1).

The reason why those two microalgae were considered to be the major primary producers was easily speculated from the approach to phytoplankton sampling and the methods for phytoplankton detection at the time. Except for phytoplankton bloom such as red

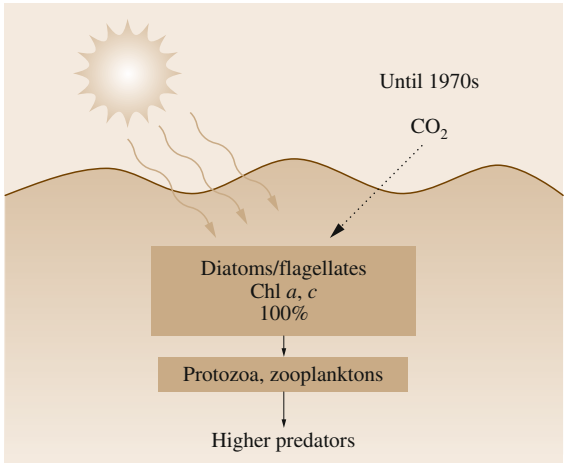

Fig. 3.1 Classical understanding of primary production

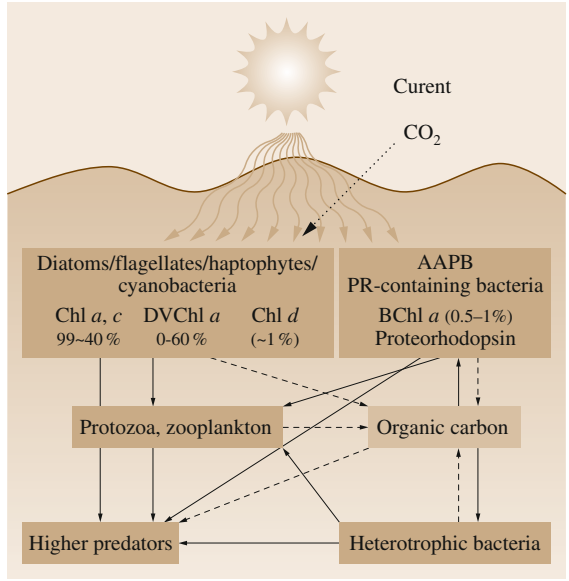

Fig. 3.2 Current understanding of the flow of energy and carbon. AAPB: aerobic anoxygenic photosynthetic bacteria, PR-containing bacteria: proteorhodopsin-containing bacteria

tide or cyanobacterial blooms, plankton nets had been used for phytoplankton sampling. A plankton net is field-equipment used to trap plankton. It is a conical polyethylene net with a defined mesh size and has a collecting bottle attached to the tip end. The mesh size of the net determines the size range of the plankton trapped. In phytoplankton research, nets with mesh sizes of 100 μm (XX13), 70 μm (XX17), and 60 μm (XX25) were used. The result was that only phytoplankton with a cell or colony size of more than 60 μm were used in phytoplankton research until the 1970s (Fig. 3.2).

However recent phytoplankton research using deoxyribonucleic acid (DNA) detection and flow cytometry has shown that the predominant phytoplankton in marine environments is much smaller than those collected by plankton nets. For example, haptophytes including coccolithophores, which are phytoplankton that deposit calcareous plates called coccoliths, are one of the major constituents of primary producers in marine environments. However, most of these pass through a phytoplankton net that is usually used for phytoplankton research, since the cell size of most haptophytes is less than 50 μm. Plankton nets with a smaller mesh size of around 10 μm have been employed for phytoplankton research in recent years. However, the dominant phytoplankton in marine environments has much smaller cell size than the cells that can be caught by those smaller mesh-sized nets.

3.2 Recognition of Picocyanobacteria Dominance (1970s–2000s)

In the late 1970s, the development of observation techniques by fluorescence microscopy and accumulation of knowledge from electron microscopic observations revealed that unicellular cyanobacteria *Synechococcus* spp. are predominantly distributed in the marine environments, especially in tropical and subtropical regions [3.2, 3]. They are very tiny cells with 0.5−2.0 μm in length and 0.5−1.0 μm in diameter, called picocyanobacteria. They play a significant role as a primary producer in those environments. In the late 1980s, the developments of the high performance liquid chromatography (HPLC) technique for pigment analysis and of the cell detection technique using flow cytometry brought new insight in marine picocyanobacteria. Apart from picocyanobacteria, which was recognized as *Synechococcus* spp., it contained divinyl-chlorophyll (DVChl) *a* which had an absorption spectrum slightly different from that of the usual Chl *a* [3.4–6]. Furthermore, those cells did not contain phycobilipigments, which were typical light-harvesting antenna in com-

mon *Synechococcus*. The cyanobacterium named as the genus *Prochlorococcus* is coccoid to ellipsoidal unicellular cells with 0.4–0.6 in diameter and 0.5–0.8 in length. They perform oxygenic photosynthesis using DVChl a/b which can efficiently absorb the blue light dominating in the ocean. They are the dominant picophytoplankton in tropical and subtropical regions between the latitudes of 30° north and 30° south. In several marine regions, the amount of DVChl *a* is three times higher than that of usual Chl *a*, indicating that *Prochlorococcus* play a significant role as a primary producer in those environments.

3.3 Discovery of Ubiquitous Photoheterotrophs (2000–Current Times)

In the early 2000s, two significant findings were reported with respect to the fact that microorganisms other than traditional phytoplankton could possibly contribute significantly to the transformation of light energy into chemical energy in marine environments. One was the wide distribution of aerobic anoxygenic photosynthetic bacteria (AAPB) which contained bacteriochlorophyll (BChl) *a*, that had mainly been recognized as a photosynthetic pigment in anaerobic anoxygenic photosynthetic bacteria (AnAPB) distributed in anaerobic environments [3.7]. The other was the wide distribution of proteorhodopsin-containing bacteria [3.8, 9]. Both bacteria are photoheterotrophs without carbon fixation and had never been recognized as *primary producers*.

APB were first reported in 1979 [3.10]. Phylogenetically, AAPB was derived from non-sulfur purple bacteria [3.11], the anaerobic anoxygenic photosynthetic bacteria (AnAPB) in the α-Proteobacteria. AnAPB had been traditionally understood to distribute in an anaerobic environment and perform photosynthesis without oxygen evolution. They employ bacteriochlorophylls (BChls) for their photosynthesis instead the Chls detected in algae and plants. The amount of primary production by AnAPB reached up to 30% of the total primary production in some specific lakes [3.12]. However, their contribution was negligible on global scale, since such environments were restricted. On the other hand, AAPB grow (photo-)heterotrophycally in an aerobic environment. AAPB are the same with AnAPB on the point that they contain BChl *a*. However, AAPB are aerobic and require molecular oxygen for their growth and BChl *a* synthesis [3.11]. AAPB distributes widely in the euphotic zone of marine environments in amounts with from ranging from 1–24% of the total bacterial count [3.13]. It had been already reported that the phototrophic growth of some APPB was faster than those growing heterotrophically in the dark [3.14]. Moreover, the in situ growth rate of APPB in seawater was faster than that of other heterotrophic bacteria. The detailed physiological role and activity of photosystems in all AAPB have not clarified yet, but AAPB must contribute to the transformation of solar energy in marine environments and act as *primary producer*.

Proteorhodopsin is the rhodopsin-like protein detected in marine Proteobacteria. It is a retial-opsin complex in a member of rhodopsin. Opsin is a bundle of seven transmembrane α-helices. Retinal, vitamin A aldehyde binds to the lysine residue at the central pocket of the opsin. Rhodopsin is well known as a photoreceptor in vertebrates as a light sensor. One rhodopsin-like protein was known to contribute to adenosine triphosphate (ATP) synthesis. Bacteriorhodopsin of *Halobacteria* in *Archea* can transform light energy to transmembrane proton electrochemical gradients ($\Delta\mu H^+$) for ATP synthesis [3.15]. Conformation of retinal molecule changes by absorbing light in synchronization with structure changes of ligand in the central part of opsin. The conformation change lead a serial proton to deliver from cytoplasmic to periplasmic space, and results in a formation of $\Delta\mu H^+$ for ATP synthesis. However, such ATP synthesis using bacteriorhodopsin had been thought to be a special mechanism that is restricted in special Archaean bacterium-distributed extremely salty environments.

However, a large amount and wide variety of rhodopsin-like genes were detected in seawater by metagenomic analysis [3.8, 9]. Moreover the gene was expressed in *E. coli* and acted to form $\Delta\mu H^+$ for ATP synthesis under light [3.16]. The genes of proteorhodopsin are contained in a diversity of bacterial taxa [3.17]. The total amount of proteorhodopsin-containing bacteria is equivalent to 13–80% of the total amount of bacteria and *Archea* in marine environments [3.18, 19]. These results indicate that proteorhodopsin was widely and significantly distributed and play a significant role in light energy transformation in the marine environments. Actually, light-dependent ATP synthesis using proteorhodopsin was

reported in a Flavobacterium strain [3.20]. However, this light-dependent growth was not observed in all proteorhodopsin-containing bacteria. A role of proteorhodopsin other than ATP synthesis was indicated, such as the advantage for the recovery from a starvation situation [3.21]. Detailed research on the roles of proteorhodopsin will clarify its contribution to the light energy conversion process in marine environments.

3.4 Oxygenic Photosynthesis Using Far-Red Light (1990s–2011)

Chl *a* is indispensable for oxygenic photosynthesis, since it plays an essential role in light harvesting, energy transfer, and charge separation in the primary reaction in photosynthesis. This is based on the results from photosynthesis research using land plants and green algae as model organisms. Quantification of the amount of oxygenic phototrophs and the activity of oxygenic photosynthesis are, therefore, estimated based on the amount of Chl *a*. The in situ light absorption range by Chl *a*, from 400 to 700 nm (or from 380 to 710 nm), is defined as photosynthetically active radiation (PAR). PAR is used for the evaluation of light strength for the activity of oxygenic photosynthesis. However, a cyanobacterium *Acaryochloris marina*, which performs oxygenic photosynthesis using Chl *d*, was reported in 1996 [3.22]. Chl *d* is a red-shifted chlorophyll which can absorb far-red light for an almost 30 nm longer wavelength than Chl *a* [3.23]. The cyanobacterium employs Chl *d* not only for the light-harvesting antenna but also for the chlorophyll in the reaction centers [3.24, 25]. As a result, the cyanobacterium can perform oxygenic photosynthesis using far-red light from 700 to 740 nm, which cannot be effectively used by common phototrophs. *Acaryochloris* spp. are widely distributed in coastal areas as epiphytes on seaweed [3.26]. The amount of Chl *d* on the seaweed ranges between about 1−13% versus total Chl *a* content in seaweed. Moreover, chlorophyll was universally detected to be about 1% (versus the Chl *a* amount) in the bottom sediment of coastal areas and lakes in the Antarctic and Arctic [3.26]. The energy transfer efficiency of the photosynthesis using Chl *d* is equivalent to that using Chl *a* [3.27]. Photosynthesis using far-red light, which has not been estimated at all to date, must contribute to primary production in marine environments.

Moreover, in 2010, another red-shifted chlorophyll, Chl *f* was reported from a cyanobacterium isolated from the microbial mat on stromatolite at the coast of Australia [3.28]. Chl *f* has its absorption maximum at around 720 nm and it can absorb far-red light up to around 760 nm in vivo. Because we have to wait for further research to know the contribution of Chl *f* to oxygenic photosynthesis in marine environments, the activity of Chl *f* was not taken into account in the estimation of primary production in marine environments.

These findings on far-red utilization using the red-shifted chlorophylls, Chl *d* or Chl *f*, for oxygenic photosynthesis require reconsideration of the PAR concept and primary production in marine environments.

3.5 Discovery of Picoeukaryotic Phytoplankton (1990s–2011)

In recent years, very diverse eukaryotic picophytoplankton species have been revealed to be widely distributed in significant amounts in marine environments. However, only some dozens of species in chlorophyta, heterokontophyta, and haptophyta were known as eukaryotic phytoplankton until the early 2000s.

Around 2010, several reports on marine picophytoplankton analysis using the techniques of metagenome and flow cytometry were published. These showed that a significant amount of picohaptophytes, including many undescribed species, were widely distributed in marine environments. By pigment composition analysis of marine waters, a carotenoid 19′-hexanoyloxyfucoxanthin (19HF) was predominantly detected in the picoplankton fraction less than 3 μm at a high latitude area from 40° to 60° of both north and south [3.29]. Since picocyanobactria, which is well known as a predominant pico-phytoplankton in tropical and subtropical marine environments, do not contain 19HF, and 19HF is a specific pigment to the algae in the Haptophyta, the amount of picophytoplankton belonging to

Haptophyta accounted for 50% of the total amount of the picophytoplankton fraction [3.29]. A similar estimate was also reported; picohaptophytes formed 5% of the global picophytoplankton biomass and contribute significantly to primary production in the marine environment [3.30].

Furthermore, it was also reported that a significant amount of microalgae in unknown phylum (unisolated phylum to date) also exists in marine environments. In 2007, phytoplankton which did not belong to any known phyla of algae were discovered by metagenomic analysis of a plankton fraction of less than 3 μm in size [3.31]. Its DNA sequence was close to the cryptophycean linage. It was tentatively named *picobiliphytes*. The *picobiliphytes* distribute widely in coastal areas of Europe and the North Atlantic, and the cell number was reaches up to 1.6% of the total eukaryotic phytoplankton. In 2011, the new candidate phylum was also detected by metagenomic analysis targeting plastid DNA. *Rappemonads*, the name tentatively given to the algae in the candidate phylum, were close to haptophytes, but they did not belong to any known phyla phylogenetically [3.32]. *Rappemonads* also widely distribute in coastal areas of Europe, and the Atlantic and Pacific oceans. Since algae in both candidate phyla have not been isolated and cultivated, the characteristics in morphology, physiology, life cycle, photosynthesis, and productivity are not yet known. It might possible to find a further new phylum of photoplankton which has not yet been discovered. The accumulation of knowledge on the diversity of phytoplankton including unknowns might contribute to a better understanding of primary production in marine environments.

3.6 Strange Phototrophic(?) Microorganisms (1990–2011)

The cyanobacterium-like particle UCYN-A was detected by metagenomic analysis of nitrogen-fixing bacteria in marine waters. It was first detected as a cyanobacterium which had a nitrogenase gene for nitrogen fixation in pelagic waters. The wide distribution of UCYN-A indicated that the particle contributes to the nitrogen cycle in pelagic waters. Usual cyanobacteria grow by an oxygenic photosynthesis process photosystems, a respiration system, and genes for a carbon fixation system. However, UCYN-A lacks photosystem II (one of the two photosystems that split water into protons, electrons, and molecular oxygen), RuBisCo (ribulose-1,5-bisphosphate carboxylase-oxygenase), the primary enzyme for fixing CO_2 and the tricarboxylic acid (TCA) cycle for respiration [3.33]. The lacking of these essential genes for free living suggests that UCYN-A might be a symbiont in some organisms. Since it possesses a complete gene set for photosystem I and contains chlorophyll, it must use light energy for some activity of the particle. While it is unclear how the light energy absorbed by photosystem I is used in the particle, it must be contribute to the transformation of light energy into chemical energy.

3.7 Diversity of Light Energy Transformation Systems and Reconsideration of *Photosynthesis*

Organisms that can grow using light as its energy source are called *phototrophs*. Representatives of phototrophs are photosynthetic organisms that can perform *photosynthesis*. *Photosynthesis* is classically the reaction that can reduce carbon dioxide into organic compounds such as sugars using sunlight as a energy source. *Primary producers* are organisms that synthesize organic compounds using inorganic carbon as their carbon source. Their representatives are photosynthetic organisms (such as land plants, algae, cyanobacteria, and some photosynthetic bacteria) and chemoautotrophs. Since the productivity of chemoautotrophs in a general environment is considered to be much smaller than that of photoautotrophs. *Primary producers* has been used synonymously with *photosynthetic organisms*. Similarly, it has been considered that phototrophs and photosynthetic organisms are almost the same so far. However, the recent discoveries of new marine microbes which utilize light energy suggest that the conventional understanding of the terms *phototrophs*, *photosynthetic organisms* and *primary producers* may not necessarily be suitable for

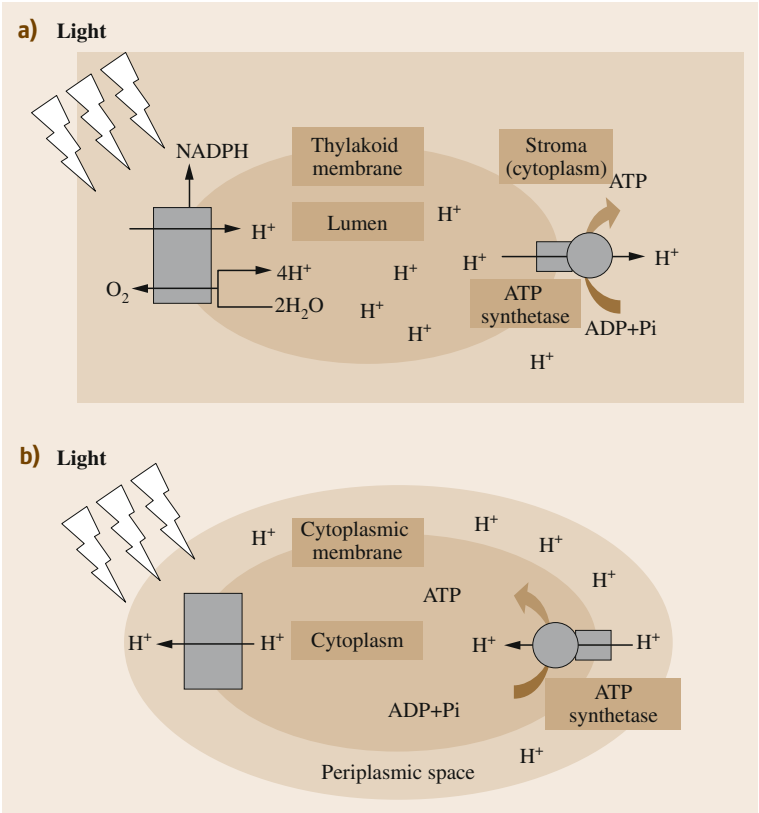

Fig. 3.3a,b Formation of transmembrane electrochemical potential of proton ($\Delta\mu H^+$) using sunlight. **(a)** Cyanobacteria or plastids in algae and land plants; **(b)** photosynthetic bacteria, halorhodopsin and proteorhodopsin-containing bacteria

the understanding of the energy and carbon flow in marine environments.

In this paper, the author defined *phototrophs* as *organisms which can synthesize ATP using light as its energy source*. In another words, phototrophs are

> *the organisms which can synthesize ATP by ATP synthase using the transmembrane electrochemical potential of proton ($\Delta\mu H^+$) by pumping up protons from the membranous one side to another side based on light energy.*

That is, in a chloroplast or cyanobacteria, protons are pumped into thylakoid lumen (the inside of thylakoid) from stroma (cytoplasm in the case of cyanobacteria) (Fig. 3.3a). In cases of non-oxygenic photosynthetic bacteria or proteorhodopsin-containing bacteria, protons are pumped out from the cytoplasmic space to the periplasmic space (Fig. 3.3b). Protons pumped into the thylakoid lumen or pumped out from cytoplasm flow back into the stroma or the cytoplasm, respectively, through ATP synthase, which results in the synthesis of ATP. Here, phototrophs are all organisms that can perform such light-dependent ATP synthesis.

Therefore, photosynthetic organisms are only a part of phototrophs. Primary producers are not only the organisms that can produce organic compounds from inorganic carbon, but also the organisms that can produce ATP using sunlight energy. As a result, phototrophs are almost equal to primary producers in this chapter. Table 3.1 shows primary producers under this concept. Further investigations on how these organisms transform light energy will develop the understanding of energy flows in the marine environment.

Table 3.1 Diversity of phototrophs

Phototrophs	Phylogenetic position	Pigment	Niche	Trophic mode	Carbon source
Anoxygenic phototrophs					
Purple bacteria (including aerobic bacteria)	Bacteria Proteobacteria	Bacteriochlorophyll	Anaerobic ~ Aerobic	Photoheterotroph Photoautotroph	Organic carbon CO_2

3.8 Conclusion

In relation to the food web in marine environments, studies on energy flow are important and relevant to global environment change, preservation and protection of living marine resources, and the diversity of marine microbes. Energy flow in the marine environments has been thought based on the food chain, starting with oxygenic photosynthesis with carbon fixation. However, recent studies have revealed that the energy flow through the microbial loop is very important, in addition to the traditional understanding of the food web, since it is possible that a large amount of bacteria can transform light energy into chemical energy.

To shift to a new paradigm and create a new concept of the energy flow in marine environments, it is required to reveal the diversity of marine phototrophs and their roles in the energy and material flow in marine environments.

4. Marine Viruses

Jeeva Subbiah

Marine viruses are the most abundant *life-forms* in the ocean and exist wherever life is found. The estimated virus count in the ocean is 10^{30}, and every second about 10^{23} viral infections occur in the ocean. These infections are a major source of disease and mortality in organisms ranging from shrimp to whales. Each infection potentially introduces new genetic information into an organism or into progeny viruses. These new genetic changes allow evolution of the host and virus population. Viruses represent the planet's largest pool of genetic diversity. Our understanding of the impact of viruses on global systems, however, is still incomplete. This chapter will present a general review of marine viruses; their impact on marine organisms, such as cyanobacteria, mollusks, and more detailed about shrimp viruses, diagnostics and the control of shrimp viral diseases.

4.1 Viruses

Viruses are more common in air, soil, and water, including the ocean environment, and exist wherever life is found. They are obligate intracellular parasites and infect all living organisms such as vertebrates, invertebrates, plants, fungi, algae, archaea, and bacteria. The marine environment is the major habitat for many living organisms which have a large virus population, and the interaction between virus and their hosts allow the evolution of both viruses and host organisms. Furthermore, each and every progeny virus has the potential to evolve as a new virus, which may involve a huge impact on living organisms or become an emerging virus [4.1]. The evolved new viral strains change in virulence and transfer viruses between ecosystems. In some circumstances, gene transformation between viruses and their hosts may produce dramatic effects on the hosts. For example, the well-known phage cholera toxin (CTX) gene originated from CTXf or CTXφ bacteriophage through horizontal gene transfer. The bacterium *Vibrio cholera* is normally harmless but could become one of humanity's greatest scourges by incorporating CTX genes of filamentous phage (*Inovirus*) from the family *Inoviridae* [4.2, 3]. Marine viruses are not only the major cause of mortality in marine organisms but are also involved in global biogeochemical cycle changes. Moreover, they are a huge reservoir of the greatest genetic diversity on Earth. The estimated virus count in the ocean is

10^{30}, and every second about 10^{23} viral infections occur in the ocean. Therefore, the monitoring of the virus population in the marine environment and an understanding of the virus replication and host specificity are vital and emerging fields in the study of marine viruses. However, our understanding of the impact of viruses on global systems is still incomplete [4.4].

4.2 General Characteristic Features of Viruses

Viruses consist of genetic materials such as nucleic acids, which are either DNA or RNA, surrounded by a protein coat. They can replicate as obligate intracellular parasites by taking on the biosynthetic functions within a host cell. All forms of cellular life are susceptible to virus infection. Therefore, we can speculate that every type of marine organism is host to at least one type of virus [4.5]. The genome of the DNA virus may be single or double-stranded, and the structure may be linear with free 5′ and 3′ ends or the ends have a covalently closed circular form. RNA viruses can also be categorized based on their genome structure: single-stranded RNA (ssRNA), double-stranded (dsRNA), linear, and circular. Single-stranded genomes can be designated as positive (exactly the same as messenger RNA (mRNA) except thymine replaces uracil in the ssDNA genome) or negative (complementary to the mRNA) sense genomes [4.6]. The genome size of viruses varies from a smaller size of about 1.7 kb (Porcine circovirus (ssDNA) and hepatitis delta virus (ssRNA)) to a larger genome size of approximately 1.2 Mb in mimivirus double-stranded DNA (dsDNA) [4.7]. The virus gene expression differs depending on the viral genome nature. For instance, dsDNA viruses encode genes similarly to cellular organisms such as plants, animals, and bacteria. Nevertheless, ssDNA, ssRNA, and dsRNA viruses following a unique gene expression. Furthermore, most prokaryote, plant, and fungal virus genomes are dsDNA, ssRNA, and dsRNA, respectively [4.6]. The structure and morphology of viruses are also comparable with other virus groups. Some of viruses have a lipid layer or compound which is responsible for the development of an envelope along with proteins on the surface of virions. The envelope involves the attachment and entry of virions into the host cells.

4.3 Host Specificity

Every virus has a host specificity and a particular virus can infect a particular species or cells. However, some viruses can infect multiple organisms or a wide range of species. The wide host range suggests that viruses might be involved in different host shift events. Viruses must adapt to the new genetic and immunologic environment of their hosts in order to replicate [4.8]. Furthermore, the interactions between virus and host are crucial for viral replication. Moreover, the proteins or receptor molecules, which are not uniform for all species for virus attachments, may play an important role in host specificity [4.9, 10]. Thus, viruses must often co-evolve with their hosts, which often leads to a species and host specificity [4.8]. Marine environments contain huge life-forms and many different species living in close proximity, which may allow the possibility of viral host shift events.

4.4 Viral Families in Marine Ecosystems

About 15 DNA viral families persist in the marine environment; however, the majority of the families are of the dsDNA virus family rather than ssDNA viruses. *Microviridae* and *parvoviridae* belong to the ssDNA virus family among the DNA virus families in the marine environment. *Microviridae* is one of the families of bacteriophages with single-stranded circular DNA genome. The virions are nonenveloped, icosahedral with spikes and a size of about 25–27 nm in diameter and lack tails. The genome sizes range

from 4.5 to approximately 6 kb, which can encode about 11 genes, and most of them have overlapping reading frames [4.11]. Most of the viruses and morphology are mentioned in Table 4.1. The most common dsDNA viruses include, *Baculoviridae, Herpesviridae, Iridoviridae, Lipothrixviridae, Nimaviridae, Papovaviridae, Phycodnaviridae, Corticoviridae, Tectiviridae, Myoviridae, Podoviridae*, and *Siphoviridae*. *Baculoviridae, Nimaviridae*, and *Parvoviridae* virus families are responsible for infection in crustaceans. Molluscs or mollusks, a large phylum of invertebrates, are the most predominant host for virus families like *Herpesviridae, Birnaviridae* (dsRNA), *Iridoviridae*, and *Papovaviridae*. *Iridoviridae* is a round, icosahedral-shaped virus, which can also infect fish. *Herpesviridae*, an pleomorphic, icosahedral, and enveloped virus, has a wide range of hosts, including mollusks, fish, turtles, and mammals. *Lipothrixviridae* and *phycodnaviridae* infect archaea and algae, respectively. The lipothrixvirus is an envelope and rod shaped, while phycodnavirus is icosahedrally-shaped. *Phycodnaviridae* is a group of large double-stranded DNA viruses and it can infect important taxa of marine primary producers including toxic bloom formers and macroalgae. A marine brown algae infecting phycodnavirus is the *Ectocarpus siliculosus* virus (EsV-1), which can encode about 231 proteins from a 336 kb size of the genome. EsV-1 is a lysogenic virus and the accumulating evidence indicates that the phycodnaviruses and their genes are ancient [4.12]. RNA viruses are a dynamic, widespread, and persistent component of the marine virus community. Although a vast number of marine RNA viruses have not been isolated, the most recognizable marine RNA viruses are positive-sense ssRNA viruses.

4.5 Marine Phages

Viruses can be arranged in terms of the types of cellular organisms that they infect. Marine phages are viruses that live as obligate parasitic agents in marine bacteria. The concentration of viruses is approximately 10^7 viruses/mL of surface seawater and the majority of the viruses are phages. Marine phages control bacterial abundance and impact the biogeochemical cycle through lysing their host (bacteria). In addition, marine phages are extremely diverse and influence their hosts through selection for resistance, horizontal gene transfer, and manipulation of the bacterial metabolism [4.13]. Sometimes, bacteriophages are responsible for altering the bacterial genome, gene expression, and development as emerging bacterial diseases or virulent strain through viral gene transfer. For instance, a major shrimp pathogen *Vibrio harveyi*, converted a nonvirulent strain into a virulent strain by DNA viruses like *Myoviridae* and *Siphoviridae* by transmission of a toxin gene [4.14]. *Corticoviridae, Tectiviridae, Myoviridae, Podoviridae, Siphoviridae, Microviridae, Cystoviridae*, and *Leviviridae* are common marine phages in the marine environment.

4.5.1 Types of Phage Infection

Phage infections can be categorized into the following types: lytic, lysogenic, chronic, pseudolysogenic, restricted, and abortive. In lytic infection, the produced phages release by destroying or lysing the bacterial cells and only the phage can survive. Lysogeny is a phage infection in which the phage genome can replicate continually without phage virion formation; in this case both bacteria and phages survive. The chronic infection effect is similar to lysogeny infection, both bacteria and phage survive, but it is a productive cycle; the produced mature phages are released from infected bacteria by extrusion or budding [4.15]. Some reports suggest that lysogeny is widespread in marine bacteria, and furthermore, up to 50% of bacterioplankton are lysogenic [4.16, 17]. The pseudolysogenic stage is a latent or quiescent state; the infecting phage genome does not replicate and does not produce phage progeny. This phenomenon is usually induced due to the unfavorable growth condition for bacteria, and this cycle ends with either the lytic or the lysogenic cycle, when it turns into favorable condition. This stage indicates phage and bacteria interactions, which may be crucial for the starving viral genome in the host and may involve the virulence of bacteria [4.18]. The bacterium (host) causes death to the infecting phage via host restriction endonuclease activity, thus there is no chance for phage progeny replication and production; this type of infection is called a restricted infection, and only the host only survives not the phage. Abortive infection involves the death of both host and infecting phage without production of phage progeny [4.15].

Table 4.1 Viruses infecting marine organisms

Virus family	Nucleic acid	Morphology	Size (nm)	Host
Baculoviridae	dsDNA	Enveloped, rods	200–450 × 100–400	Crustacea
Herpesviridae	dsDNA	Enveloped icosahedral	150–200	Mollusks, fish, mammals
Iridoviridae	dsDNA	icosahedral	190–200	Mollusks, fish
Lipothrixviridae	dsDNA	Enveloped, rod-shaped	40 × 400	Archaea
Nimaviridae	dsDNA	Enveloped, rod-shaped with tail-like appendage	120 × 275	Crustacea
Papovaviridae	dsDNA	Round, icosahedral	40–50	Mollusks
Phycodnaviridae	dsDNA	Icosahedral	130–200	Algae
Corticoviridae	dsDNA	Icosahedral with spikes	60–75	Bacteria
Tectiviridae	dsDNA	Icosahedral with spikes	60–75	Bacteria
Myoviridae	dsDNA	icosahedral	80–200	Bacteria
Podoviridae	dsDNA	Icosahedral with noncontractile tail	60	Bacteria
Siphoviridae	dsDNA	Icosahedral with noncontractile tail	60	Bacteria
Microviridae	ssDNA	Icosahedral with spikes	25–27	Bacteria
Parvoviridae	ssDNA	Round, icosahedral	20	Crustacea
Birnaviridae	dsRNA	Round, icosahedral	60	Mollusks, fish
Reoviridae	dsRNA	Icosahedral, some with spikes	50–80	Crustacea (?), mollusks, fish
Cystoviridae	dsRNA	Icosahedral with lipid coat	60–75	Bacteria
Bunyaviridae	ssRNA	Round, enveloped	80–120	Crustacea (?)
Caliciviridae	ssRNA	Round, icosahedral	35–40	Fish, mammals
Coronaviridae	ssRNA	Rod-shaped with projections	200 × 42	Crustacea
Dicistroviridae	ssRNA	Round, icosahedral	30	Crustacea
Leviviridae	ssRNA	Round, icosahedral	26	Bacteria
Marnaviridae	ssRNA	Round, icosahedral	25	Algae
Nodaviridae	ssRNA	Round, icosahedral	30	Fish
Orthomyxoviridae	ssRNA	Round, with spikes	80–120	Fish
Paramyxoviridae	ssRNA	Enveloped, filamentous	60–300 × 1000	Mammals
Picornaviridae	ssRNA	Round, icosahedral	27 × 30	Algae, crustacea (?), thraustochytrids
Rhabdoviridae	ssRNA	Bullet-shaped with projections	45–100 × 100–430	Fish

4.5.2 Cyanophages

Cyanobacteria are photosynthetic prokaryotes; they are one of the largest and most important groups of bacteria on earth. Cyanobacteria play an important role as primary producers in the ocean world. Examples are the cyanobacterial genera *Synechococcus* and *Prochlorococcus*, which together account for about 25% of global photosynthesis [4.19]. However, some groups of viruses infect cyanobacteria and cause mortality, that is, those groups of viruses called cyanophages. At the beginning, the causes of cyanobacteria mortality was poorly understood; it was assumed that it was due to protozoan infection rather than viral infection. However, the recent research data suggests that up to 7% of the heterotrophic bacteria and 5% of the cyanobacteria were associated with phages, and approximately 70% of prokaryotes might be infected by viruses [4.20]. In the 1990s, the first viral infection of marine unicellular cyanobacteria was reported and subsequently the cyanophages were isolated and characterized [4.20, 21].

Horizontal Gene Transfer

The interaction of phages and cyanobacteria may possible for new pathways of carbon and nitrogen cycling in marine food webs through gene transfer between marine organisms [4.20]. Metagenomic analysis of viral fractions reveals that cyanophages are widely distributed in the marine environment and interaction between cyanophages and cyanobacteria have been observed in the ocean [4.22]. Especially, most of the

cyanophage genes are involved in cyanobacteria photosynthesis [4.23]. Photosynthesis genes such as high light inducible genes (*hli*), psbA, and psbD are found in cyanophages. These genes encode the photosystem II (PSII) core reaction-center proteins D1 and D2, respectively. PSII, which catalyzes the light-dependent oxidation of water to molecular oxygen in chloroplasts, is a large pigment–protein complex in the thylakoid membrane. The D1 and D2 proteins of PSII bind the pigments and cofactors necessary for primary photochemistry. PSII is very sensitive to photo inhibition, and the D1 protein of the PSII reaction center is the main target for light-induced damage among the PSII proteins. The damaged D1 proteins are degraded and subsequently replaced with newly synthesized polypeptides in a repair cycle. This efficient repair mechanism is crucial to maintain PSII in a functional state. Cyanophages shut down the most of the host's gene expression during the lytic cycle infection and the proton motive force must be maintained if they are to lyse the host. Therefore, it is necessary to prolong photosynthesis of the hosts during the infection cycle. Thus, it is intended that the phage generates the energy for viral production by encoding *psbA* and other genes involved in photosynthesis. The phylogenetic analysis of the cyanophage *psbA* gene provides evidence that the acquisition of these genes by horizontal gene transfer from their cyanobacterial hosts (*Synechococcus* and *Prochlorococcus*) and gene acquisition were not very recent [4.24].

Types of Cyanophages

Cyanophages have been classified into three-tailed phage families: *Myoviridae, Podoviridae*, and *Siphoviridae*; all of them are dsDNA phages. These viruses can be isolated from both marine and fresh water environments [4.25]. Myoviruses and siphoviruses have broad host ranges and have frequently been isolated from a natural marine ecosystem. However, podoviruses have a very narrow host range with a short noncontractile tail. Myoviruses are nonenveloped, have a head with icosahedral symmetry, and a tail with tubular and helical symmetry, which is separated by a neck. The head diameter is 50–110 nm, while the tail is 16–20 nm, and the capsid is made up of 152 capsomers. Furthermore, morphological evidence supports that marine and freshwater myoviruses are more closely related each other than other bacteriophages. Only six cyanophages (S-PM2, P-SSM2, P-SSM4, P-SSP7, P60, and Syn9) infect cyanobacteria in the marine environment and all of these cyanophage sequences are available in GenBank. Interestingly, all those six cyanophages have been isolated either from *Synechococcus* or *Prochlorococcus*. S-PM2, P-SSM2, and P-SSM4 are more similar in morphology to the *Myoviridae*, However P-SSP7 and P60 belong to the *Podoviridae* family. The genomes of podoviral cyanophages are small and compact compared to myoviral cyanophages. For instance, the genome size of P-SSP7 and P60 are found to be about 44 to 47 kb. Nevertheless, myoviral cyanophages have relatively large genomes; 196, 280 bp, 178, 249 bp, and 252, 401 bp are found in S-PM2, P-SSM4, and P-SSM2, respectively [4.26].

4.5.3 Phage Therapy

Natural bacterial viruses or bacteriophages have been applied to control bacterial diseases. For example, instead of antibiotics, phages are used as a common therapy for human gastrointestinal diseases such as salmonellosis in Russia [4.27]. In 1915, the phage was discovered by the English microbiologist F.W. Twort and subsequently by d'Herelle, who introduced the term bacteriophage [4.28]. Phage research was an important field of research in the 1920s and it was desired to treat bacterial diseases [4.28]. Despite phages having been used as an antibacterial agent in the United States and Europe during the 1920s and 1930s, it has been abandoned in the western countries for various reasons, including the discovery of antibiotics. Although the commercial production of therapeutic phages has ceased in most of the Western world, phages continue to be used therapeutically in Eastern Europe and in the former Soviet Union. Moreover, several institutions in these countries are actively involved in therapeutic phage research and production [4.27].

Antibiotics have been widely used as an antibacterial agent. However, antibiotic drugs allow the development of mutated drug-resistant bacteria. Therefore, an effective alternative therapy is necessary to control the rise of anti-drug-resistant bacteria. Bacteria have the tendency to mutate against antibiotics once in every 10^6 divisions, but the antibiotics are immutable chemicals, which are not effective against the new antibiotic resistant bacterium. Although bacteria are also becoming resistant to phages, the rate of developing resistance against phages is approximately once in every 10^7 divisions, which is approximately tenfold lower compared to antibiotics. Furthermore, phages are living organisms and evolve along with hosts by mutation. Thus mutated phages can overcome the bacterial mutations within either a few days or weeks.

Additionally, phages could be the ideal strain for co-therapy along with antibiotics to prevent the emergence of bacterial resistance to antibiotics. Especially lytic phages are the most suitable candidates for phage therapy, due to the fact that they reproduce rapidly within the bacteria and lyse these in their specific host range [4.29].

Since 2006, the United States Food and Drug Administration and United States Department of Agriculture have approved several bacteriophage products for use on all food products. In marine aquaculture, the use of bacteriophages for the control of bacterial diseases in prawns in Asia has been considered. Phage therapy has been applied to control the bacterial pathogen *Vibrio harveyi*, which causes luminous bacterial disease in shrimp larvae [4.30]. Due to their host specificity, this phage therapy may be applicable to control many bacterial diseases in the future.

4.6 Impact of Marine Viruses on Mollusks

Mollusks are invertebrates and one of the largest marine phyla. These bivalve mollusks are filter feeders, thus marine viruses can be easily accumulated in their tissues and may transfer or infect other species, including higher vertebrates and humans, through the food chain. Although the pathogenic viruses are harmful to other species, it gives serious effect on the bivalve mollusks [4.31]. In the 1960s a major epizootic gill necrosis was observed in the oyster *Crassostrea angulata*, and the first report of viral disease in mollusks was reported at the same time. Most mollusks are associated with many different types of viruses including *Herpesviridae, Papovaviridae, Togaviridae, Retroviridae, Reoviridae, Birnaviridae, Picornaviridae*, and the irido-like virus [4.32]. Marine molluscan viruses and their structure morphology and main hosts are given in Table 4.2. Although many viruses are associated with marine mollusks, herpes-like and birnavirus groups are the major threats to mollusks.

4.6.1 Herpesvirus

Herpes-like virus infections have been identified in various marine mollusks throughout the world. As a result of viral disease, European oyster fisheries were destroyed in the 1970s. Since the first observation of the herpesvirus in *Crassostrea virginica*, many reports suggest that mortality is associated with this virus in *Ostreaedulis* and *C. gigas* in France and New Zealand. Herpes-like viruses were also observed in haemocytes of *O. angasi* adults in Australia and in New Zealand in flat oysters, *Tiostreachilensi*. Ostreid herpesvirus 1 (OsHV1); a herpesvirus has been isolated and reported from several species of bivalve mollusks. Moreover, unlike most herpesviruses, this virus has a wide host range of marine bivalves [4.32]. Sequence analysis results have revealed that it has links with groups of herpesviruses isolated from mammals, birds, and fish [4.33].

4.6.2 Birnavirus

Marine birnaviruses (MABV) are icosahedral, non-enveloped viruses, belonging to *Birnaviridae*. The genome of this virus comprises 2 segments of double-stranded RNA designated A and B [4.34]. MABVs had been responsible for the considerable losses in *Pictada fucata*, a commercially important pearl oyster in Japan [4.35]. MABVs infect a wide range of shellfish and fish, and it has been suspected that the mode of transmission may be due to zooplankton [4.36].

Viral diseases in bivalves are a serious concern without any specific chemotherapies and vaccination. According to the bivalve culture, a routine effective diagnostic tool is needed to monitor virus infection, and it is also important to control viral diseases.

4.7 Marine Viruses and Shrimp Aquaculture

Shrimp comprise a main aquaculture commodity worldwide. Many viruses affect shrimps, causing severe mortality of economically important shrimp species. Approximately 60% of disease losses in shrimp aquaculture is associated with viral pathogens, 20% of bacteria, and 20% by fungi and other pathogens [4.37].

Table 4.2 Viruses associated in marine mollusks

Viruses	Host species	Nucleic acid	Morphology	Symmetry
Herpesviridae	*Crassostrea virginicci*	DNA	90 nm capsid; 200 × 250 nm enveloped virion	Icosahedral
Togaviridae	*Ostrea lurida*	RNA	50 nm, enveloped virion	Icosahedral?
Retroviridae	*Crassostrea virginica*	RNA	100–110 nm, enveloped virion	Anisometric
Reoviridae	*Sepia officinalus*	RNA	75 nm, nonenveloped capsid	Icosahedral
Birnaviridae	*Pictada fucata*	RNA	60 nm, nonenveloped virion	Icosahedral
Iridoviridae	*Octopus vulgaris*	DNA	110–120 nm enveloped	Icosahedral
Papovaviridae	*Crassostrea virginica*	DNA	53 nm, nonenveloped virion	Icosahedral

The shrimp industry has grown rapidly and become a major global enterprise that serves the increasing consumer demand for seafood, and it plays an important role in improving food security, poverty mitigation, employment, and other economic activities in many countries [4.38]. Moreover, shrimp aquaculture has contributed significantly to national economies in Southeast Asia and Central and South America.

Since the early 1990s, shrimp aquaculture has expanded rapidly, reaching a worldwide production of 1 million metric tonnes (MT) in 2002 [4.39]. The global production of cultivated shrimp was about 3.5 million MT in 2009 and it continues to represent a vital source of export income for many countries [4.40]. Despite this success, viral diseases have caused billions of dollars' worth of losses for shrimp farmers.

More than 20 viruses, including white spot syndrome virus (WSSV), yellow head virus (YHV), gill-associated virus (GAV), Taura syndrome virus (TSV), infectious myonecrosis virus (IMNV), *Baculoviruspenaei* (BP), monodon baculovirus (MBV), infectious hypodermal and hematopoietic necrosis virus (IHHNV), hepatopancreatic parvovirus (HPV), Mourilyan virus (MoV), Laem–Singh virus (LSNV), spawner-isolated mortality virus (SMV), baculoviral midgut gland necrosis virus (BMNV), and lymphoid organ vacuolization virus (LOVV), have been reported to infect marine shrimp species [4.41]. With the exception of WSSV, YHV, GAV, MBV, IHHNV, and HPV, the genera of many viruses have not yet been assigned due to the poor level of current virus genome characterization [4.41].

4.7.1 RNA Viruses in Shrimp

Seven ssRNA viruses and one dsRNA shrimp virus have been reported to date (Table 4.3). Among the RNA viruses, YHV and TSV are major threats to shrimp aquaculture, with the YHV virus producing 100% shrimp mortality within 3–7 days of infection. YHV is an enveloped, rod-shaped virus measuring 170 nm × 38 nm that belongs to the *Rhabdoviridae* family; it has a genome size of about 22 kb [4.42].

TSV is a highly infectious disease-producing virus which belongs to the *Picornaviridae* family. TSV is a nonenveloped icosahedron with a diameter of 30–32 nm and an ssRNA genome of approximately 10 kb. Infection with this virus is always associated with large economic losses. TSV has a linear positive-sense ssRNA genome of about 10 kb, excluding the 3′-poly (A) tail, which contains two large open reading frames (ORFs). The viral capsid is made up of one minor and three major structural proteins [4.44].

4.7.2 DNA Viruses of Shrimp

Shrimp-infecting DNA viruses are listed in Table 4.4. Two occluded baculoviruses, BP and MBV, have been reported as serious disease-causing viruses and are responsible for major economic losses in the shrimp farming industry. These are both double-stranded viruses belonging to the *Baculoviridae* family. The BP virion is a rod-shaped nucleocapsid surrounded by a trilaminar envelope. The enveloped virion is 312–320 × 75–87 nm with a nucleocapsid of approximately 306–312 × 62–68 nm containing a circular dsDNA genome. MBV is a highly infectious virus that spreads rapidly and causes high mortality rates in juvenile and larval stages. The virus has an enveloped rod-shaped particle 265–282 × 68–77 nm with a nucleocapsid of 250–269 × 62–68 nm containing a genome of approximately 200 kb [4.44].

4.7.3 White Spot Syndrome Virus (WSSV)

WSSV is also a DNA virus that has been responsible for massive mortality rates among penaeid shrimp cultured on the southern and western coasts of Korea [4.45]. WSSV, which belongs to the *Whispovirus* genus of the *Nimaviridae* family [4.46], is a rapidly replicating virulent pathogen. WSSV consists of an enveloped, rod-

Table 4.3 Known shrimp RNA viruses (after [4.41, 43])

RNA Viruses	Abbreviation	Genome	Taxonomic classification	Known geographic distribution
Yellow head virus	YHV	(+) ssRNA	*Reoiviridae/Okavirus*	Asia, Central America
Taura syndrome virus	TSV	(+) ssRNA	*Picornavirale/Dicistroviridae*	Asia, Americas
Infectious myonecrosis virus	IMNV	(+) ssRNA	Totivirus/Unassigned	Asia, South America
Macrobrachium rosenbergii nodavirus	MrNV	(+) ssRNA	Nodavirus/Unassigned	India, China, Taiwan, Thailand, Australia, Caribbean
Laem-Singh virus	LSNV	(+) dsRNA	Luteovirus-like/Unassigned	South and Southeast Asia
Mourilyan virus	MoV	(−)ssRNA	Bunavirus/Unassigned	Australia, Asia
Gill-associated virus	GAV	(+) ssRNA	*Roniviridae/Okavirus*	Australia, Asia, Pacific
Lymphoid organ vacuolization virus	LOVV	(+) ssRNA?	Togavirus-like?/Unassigned	Americas

Table 4.4 Known shrimp DNA viruses (after [4.41, 43])

DNA Virus	Abbreviation	Genome	Taxonomic classification	Known geographic distribution
Monodonbaculovirus	MBV	dsDNA	Baculoviridae/ Nucleopolyhedrosis virus	Asia, Australia, Americas, Africa
Baculoyiral midgut gland necrosis virus	BMNV	dsDNA	Baciloviridae/Unassigned	Asia, Australia
Whit spot syndrome virus	WSSV	dsDNA	*Nimaviridae/Whispovirus*,	Asia, Americas
Baculoviruspenaei	BP	dsDNA	*Baculoviridae*/Unassigned	Asia
Spawner-isolated mortality virus	SMV	ssDNA	*Parvoviridae*/Unassigned	Australia, Asia
Infectious hypodermal and haematopoietic necrosis virus	IHHNV	ssDNA	*Parvoviridae/ Brevidensovirus*	Asia, Australia, Africa, Americas, Pacific
Hepatopancreatic parvovirus	HPV	ssDNA	Densovirus	Asia, Australia, Africa, Americas

shaped nucleocapsid enclosing a large circular dsDNA genome of approximately 293–300 kb, encompassing 181–184 major ORFs [4.47]. The virion contains five major structural proteins, including two envelope proteins and three nucleocapsid proteins [4.48]. White spot disease commonly causes 80–100% mortality within 1 week of the appearance of clinical signs [4.45, 49].

4.7.4 Shrimp Parvoviruses

Two emerging parvoviruses and one parvo-like virus have been reported in shrimp. Of the parvoviruses in crustaceans, HPV and IHHNV have been studied in detail. A third parvo-like virus, SMV, has been reported from *P. monodon* but has not yet been characterized in detail [4.43]. Another virus, lymphoidalparvo-like virus (LPV), consisting of intranuclear particles 18–20 mm in diameter, has been found only in Australia [4.50]. IHHNV and HPV are nonenveloped icosahedral viruses 22–25 nm in diameter, with ssDNA genomes. The morphology, genome structure, and genome organization of both IHHNV and HPV share similarities with members of the *Parvoviridae* family. These two viruses possess three ORFs and belong to the *Densovirinae* subfamily. However, genome analysis of IHHNV indicated that it is closely related to the mosquito densovirus. Therefore, it has recently been classified as belonging to the genus *Brevidensovirus* and the species' name has been changed to *Penaeus stylirosis densovirus* [4.43]. These two viruses also differ in their infection target organ – HPV infects epithelial cells of the hepatopancreas and midgut, while IHHNV infects multiple organs of ectodermal and mesodermal origin [4.43]. However, the classification of HPV is still uncertain due to the wide range of variation in the VP (viral protein) genes and the existence of many subtypes [4.51].

General Characteristics of HPV

HPV is a small (22–24 nm in diameter) nonenveloped icosahedral shrimp-infecting parvovirus, which was recently proposed as a new member of the *Densovirinae* subfamily of ssDNA viruses in the family *Parvoviridae* [4.52]. The genome of HPV is a linear ssDNA molecule about 6 kb in length, the 5′ and 3′ ends of which have a loop-like self-priming hairpin struc-

ture [4.51]. The genome contains three long ORFs: ORF1 (or left ORF), ORF2 (or mid ORF), and ORF3 (or right ORF). ORF1 encodes a putative nonstructural protein-2 (NS2) of 428 amino acids, the function of which is not yet known. ORF2 encodes nonstructural protein-1 of 579 amino acids, which possesses the most conserved region that includes replication initiator motifs, NTP-binding, and helicase domains. ORF3 encodes a polypeptide of 818 amino acids, which is the major capsid protein (VP) [4.51]. The purified viral proteins were detected as a major band at 57 kDa and a minor band at 54 kDa due to posttranslational modification of the deduced 92-kDa polypeptide. However, the function of the minor band is still unknown [4.51].

Hosts and Geographical Distribution of HPV

HPV was first reported in 1984 in the wild shrimp species *F. chinensis* from Singapore [4.53]. HPV was detected in South Korea in 1985 in *F. chinensis* [4.54] and was subsequently observed in wild and farmed shrimp species in many geographical locations, including Australia, China, Thailand, India, Madagascar, Tanzania, New Caledonia, the Philippines, Indonesia, Malaysia, Kenya, Kuwait, Israel, and South and North America [4.43].

HPV infects epithelial cells of the hepatopancreas and shows basophilic inclusions within enlarged nuclei of tubular epithelial cells. HPV infects a wide range of shrimp species including wild and farmed *P. monodon*, *Penaeusesculentus*, *Penaeusjaponicus*, *F. chinensis*, *Penaeussemisulcatus*, *Penaeusindicus*, *Penaeuspenicillatus*, *Penaeusschmitti*, *L. vannamei*, and *Penaeusstylirostris* [4.43, 44].

HPV Genotypes

Viruses are obligate parasites that are normally present in the environment in stable ecological associations with one or more hosts [4.55]. Viruses should have efficient replication and transmission of infection in the environment or host. The environment is constantly changing because of individual differences in host genetics and the immune response of the host. These environmental variables select for mutants or suitable variant phenotypes through the inherent capacity for evasive behavior [4.41].

The HPV genome has greater genetic diversity than those of other shrimp viruses, such as IHHNV and TSV. In total, eight HPV genomes are currently available in GenBank, and among these, complete genome sequence data are available for only four isolates, including the Korean isolates [4.51, 56–58]. However, incomplete or partial genome sequences are available in GenBank for many isolates. The sequencing results of different isolates suggest that HPV isolates from different shrimp species and/or different geographical regions are genetically different [4.59]. Of the three ORFs of HPV, ORF3 (or right ORF), which encodes the major capsid protein, shows greater variability than the other ORFs. Based on the amino acid sequence of the capsid protein gene, it has been divided into three genotypes: genotype I from Korea, Tanzania, and Madagascar; genotype II from Thailand and Indonesia; and genotype III from Australia and New Caledonia. The Korean strains HPVchin and *Fc*DNV were isolated from the shrimp species *F. chinensis*, Australian (*Pmerg*DNV) and New Caledonian isolates were from the host *P. merguiensis*, and Thai isolate (*Pm*DNV) was from *P. monodon*.

4.7.5 Diagnostic Methods for Shrimp Virus Diseases

Microscopy

Most diagnostic methods applied to shrimp have been adopted from other fields of pathology and are slightly different from those used in fish, veterinary, and human pathology. Diagnostic methods for shrimp pathogens include the traditional methods of morphological pathology (direct light microscopy, histopathology, and electron microscopy), traditional microbiology, and the application of serological methods. Initially, diagnosis of shrimp diseases was dependent on microscopic observations, and characterization viruses isolated from infected tissues. Transmission electron microscopy (TEM) was added to the diagnostic toolkit in the mid-1970s and was used to discover the first *Baculovirus-penaei* in shrimp [4.60]. However, electron microscopic methods are not in common use due to their limited sensitivity as well as the long preparation time, specialized equipment, and highly trained personnel requirements.

Hematology and Clinical Chemistry

Hematology and clinical chemistry are principal diagnostic tools for human and veterinary medicine, but they have also been applied to shrimp pathology by examining the changes in hemolymph parameters (hemocyte count, hemolymph clotting time, glucose, nonprotein nitrogen, ammonia, alkaline phosphatase, and total serum protein levels). However, with the exception of hemocyte count and hemolymph clotting time, these tests have not yet been adopted for routine diagnostic purposes [4.61].

Serological Methods

Several serology-based diagnostic methods have been applied for shrimp virus disease diagnosis. Polyclonal antibodies (pAbs) and monoclonal antibodies (mAbs) have also been virus diagnosis. A fluorescent pAb test for BMNV, the ELISA-based pAb test for BP, and pAb for rhabdovirus of penaeid shrimp (RPS) have been reported, and many attempts have been made to develop mAbs against many other viruses, such as HPV, YHV, WSSV, BP, and IHHNV. However, the development of mAbs involves problems related to specificity. Although mAbs may be specific for a particular virus, under some conditions, they may react nonspecifically to shrimp tissue due to the nature of IgM (immunoglobulin M) antibodies [4.62]. Specific mAb-based diagnostic tools are likely to be used because of their good sensitivity, versatility, low cost, speed, and simplicity.

Western blotting is a specific method for detecting antigens using mAb or pAb developed against viral capsid protein. This method requires the separation and transfer of the antigens prior to antibody treatment. Therefore, the component of the pathogen at a particular molecular weight can be identified with a high degree of accuracy. However, this is a time-consuming process that requires specialized equipment for protein separation and transformation. Therefore, this method is not commonly used for pathogen diagnosis [4.63, 64].

Recently, diagnostic lateral flow strip-based kits have been developed for WSSV and YHV using mAbs to VP28 and structural protein p20 [4.65, 66]. An mAb was raised to *Pm*DNV recombinant VP protein, which was applied to detect HPV infection in Thailand. However, the detection sensitivity of this method is not comparable to sensitive molecular diagnostic tools [4.67]. In this method, a pre-coated mouse antiviral protein antibody is used as a capture antibody at the test line (T), an anti-mouse IgG (immunoglobulin G) is used as the capture antibody at the control line (C), and a colloidal gold-conjugated monoclonal antibody pad is located adjacent to the sample pad. The sample is applied to the sample pad located at one end of the strip and allowed to flow by chromatography through the nitrocellulose membrane from one end to the other. Virus particles in test samples bind to the colloidal gold-conjugated monoclonal antibody and the resulting complex is captured by the antiviral antibody at the test line, yielding a reddish-purple band. Any unbound monoclonal antibody conjugated with colloidal gold moves across the test line and is captured by the IgG to form a band at the control line (C). However, this method is about 500 times less sensitive than a one-step real-time polymerase chain reaction, but is slightly more sensitive than dot blotting.

Molecular Diagnostic Methods

Molecular diagnostic methods include radioactive and nonradioactive labeled genomic probes and DNA amplification methods based on polymerase chain reaction (PCR), and additional PCR-based methods are being applied for the development of efficient diagnostic techniques. The first gene probe introduced into shrimp viral detection involved using a radioactive tag for IHHNV. However, it could only be applied in well-equipped laboratories due to the use of radioactive tags. Therefore, an alternative nonradioactive gene probe was developed using digoxigenin 11-dUTP (DIG). This technology allowed the development of many DIG-labeled probes for viral pathogens, such as IHHNV, HPV, TSV, WSSV, MBV, BP, and the ssRNA virus YHV [4.68]. A commercial kit for making DIG-labeled probes is available for IHHNV [4.68].

Dot blot hybridization is a simplification of the Northern, Southern, and Western blotting methods. In dot blot hybridization, the biomolecules to be detected are not first separated by chromatography. Instead, a mixture containing the molecule to be detected or a homogenized tissue sample is applied directly onto a negatively charged nitrocellulose membrane or a positively charged nylon membrane as a dot.

Dot blotting is a quick, convenient, and relatively cheap method to detect pathogens in hemolymph or tissue homogenate. The nitrocellulose membrane is the most common solid matrix used for sample adsorption. However, the major disadvantage of this method is that the sensitivity is limited to 1000 times less than that of PCR, and in most cases, the sensitivity is insufficient for detecting asymptomatic infection and it is usually associated with high background staining due to nonspecific binding of antibodies to the high concentration of shrimp proteins [4.63]. The background staining resulting from the nonspecific binding of antibodies to various shrimp components usually causes difficulty of interpretation in the case of light infection.

In situ hybridization (ISH) is a unique and powerful hybridization technique that uses a labeled complementary DNA or RNA probe to localize a specific DNA or RNA sequence in a portion or section of tissue. This method has been developed to detect shrimp pathogens using nonradioactive DIG-labeled gene probes [4.61].

Several DNA amplification methods based on PCR have been developed, and PCR has been applied in numerous methodologies for pathogen detection. Small,

often otherwise undetectable amounts of DNA can be amplified by PCR to produce detectable quantities of the target DNA. This is accomplished using specific oligonucleotide primers designed for the target DNA sequence [4.68]. Additional PCR-based methods are being applied for the development of efficient diagnostic methodologies. Multiple viral diseases can be simultaneously detected in a single reaction using more than one set of primers. Real-time PCR is especially attractive as it allows real-time analysis, high specificity, quantitative results, and the detection of low copy numbers (even as low as a single copy of a viral genome).

4.7.6 Factors Responsible for Shrimp Viral Diseases

Poor management in the shrimp farming industry leads to severe pollution in shrimp culture ponds, thereby creating a suitable environment for the development of viral diseases. The emergence of disease in shrimp aquaculture has been attributed to three major factors:

1. High density of cultured shrimp in aquaculture ponds
2. Importation or transportation of brood stock of shrimp from one place to another for culture
3. The introduction of wild brood stock into culture ponds.

The introduction of wild brooders carrying pathogens and inadequate information about disease symptoms have been responsible for the emergence of new diseases in the farming system. For example, HPV originated in the Indo-Pacific region but was later spread to America via importation of live Asian shrimp for aquaculture [4.69]. Similarly, TSV was found in Ecuador and spread to America and Southeast Asia [4.70, 71].

Environmental factors and hosts also play important roles in the emergence of shrimp diseases. Poor sanitation conditions, such as high salinity, pH, and nitrogen levels, in culture ponds can cause stress in shrimp, leading to an increased susceptibility to disease. For example, some viruses such as WSSV are highly lethal stress-related viruses. The temperature also plays an important role in virus infection; e.g., WSSV enters the target cell and replicates at 22 °C and thus leads to 100% mortality within 3 days. However, at a reduced temperature of 16–20 °C, 20–35 days were required to reach 100% mortality in experimentally infected crayfish [4.72]. However, high water temperatures from 27–33 °C inhibit the effects of WSSV in shrimp (*L. vannamei*) at the acute infection stage. However, at the chronic stage, increases in water temperature result in rapid disease progression and mortality in WSSV-infected shrimp [4.73].

4.7.7 Control of Shrimp Viral Disease

The most effective means of control or prevention of viral disease is to destroy the infected animals, decontaminate the ponds, and start again with virus-free brood stocks. Viruses, bacteria, protozoa, and fungi have emerged as major causes of disease in farmed shrimp. Bacterial, fungal, and protozoan diseases are manageable by improving culture practices, routine sanitation, and using probiotics and chemotherapeutic agents. However, management of viral diseases is problematic and has been responsible for the most costly epizootic outbreaks reported to date.

Probiotics

Live bacterial cells, referred to as *probiotics*, have been applied in aquaculture farms to improve water quality or prevent disease. The potential benefits of probiotics in aquaculture ponds include enhanced decomposition of organic matter, reduction of nitrogen and phosphorus concentrations, improved control of algal growth, greater availability of dissolved oxygen, less cyanobacteria (blue-green algae), control of ammonia, nitrite, and hydrogen sulfide, lower incidence of disease and greater survival, and improved levels of shrimp and fish production [4.74]. Few detailed studies on disease control using probiotics have been performed [4.75, 76]. However, properly controlled field tests on probiotics revealed no significant effect on measured water quality parameters [4.74]. The use of probiotics in commercial shrimp farming would be beneficial for control of disease only if positive evidence of efficacy with cost benefit analysis is acquired.

Shrimp–Virus Interactions

Shrimp–virus interactions at the molecular and genetic levels are interesting phenomena that may be useful in disease control. Many new shrimp genes have been discovered, some of which may lead to new products for disease control. A study performed in Japan indicated that Kuruma shrimp (*P. japonicus*) survived in a pond after WSSV injection; it was not protected from infection, but showed resistance to disease. This mechanism was designated as a *quasi-immune* response (immune-like system). Recently, a factor was found in shrimp hemolymph that could prevent shrimp from dying upon

injection of WSSV [4.77]. Another phenomenon has been reported that describes protection against WSD (white spot disease) by persistent IHHNV infection in *P. stylirostris*. However, infection was not prevented, although disease severity was reduced [4.78]. We still know very little about the interaction of shrimp with viral pathogens, and a better understanding of shrimp–virus interactions may lead to the development of better methods for viral disease control.

Shrimp Viral Vaccines

The term *vaccine* is applicable to vertebrates because the vertebrate process involves antibodies. However, antibodies do not occur in shrimp. In addition, *vaccinated* shrimp generally become infected but do not develop disease as a result. Therefore, the term *tolerines* has been recommended to describe agents that could be used in the same way as vaccines in shrimp [4.79].

Two types of tolerine have been studied in shrimp; the first type was developed in Thailand in the mid-1990s and is still commercially available under the brand name SEMBVAC, while the second consists of inactivated whole particles of WSSV. Shrimp acquires some degree of tolerance to WSSV and suffer less from the disease after infection due to ingestion of these products [4.80]. Other types of tolerance have also been reported consisting of individual or mixed protein subunits of viral particles that are administered either by injection or by mixing with shrimp feed [4.81, 82].

RNA Interference (RNAi)

RNA interference (RNAi) is a gene silencing technology and the process by which a gene is post transcriptionally suppressed using dsRNA with sequences that match those of viral genes to destroy their homologous mRNA in a sequence-specific manner [4.83]. This technology was recently used in the laboratory to protect shrimp from viral diseases [4.84, 85]. RNAi was used to suppress the replication of YHV and *Pm*DNV [4.83, 86]. However, application of this technology has disadvantages associated with issues of cost, safety, and public acceptance of genetic engineering techniques.

4.8 Conclusion

Viruses, one of the most rapidly evolving genetic agents among all biological entities are involved noncyclic changes in their genetic characteristics. Furthermore, the abundance of both DNA and RNA viruses in the marine environment, viral diversity, and the interaction between their hosts are ecologically important. A disease caused by marine viruses can cause a huge impact on aquaculture practice and aquatic organisms. In some circumstances, the environment pressure or high density of cultured organisms also allows for stress to the organisms, which facilitate virus infections. Moreover, it is challenging to control virus infection in wild marine organisms and viral host shift events in the ocean. Molecular biology-based methods are rapidly advancing the study of virus genomes and their molecular mechanisms. These advanced studies enable the development of rapid diagnostic tools, which could be useful for identifying viral pathogens in marine organisms and marine water samples. The advantages of molecular diagnostic methods are that they are sensitive and beneficial to preventing the spread of viral diseases to other organisms, due to the diagnosis at an early stage of infections in farmed aquaculture systems. Furthermore, therapeutic studies such as virus–host interactions, phage therapy, and RNAi are tools to control viral diseases. Although it is possible to control viral diseases in farmed aquaculture systems by using modern technology, it is still a big question as to how to control viral disease in the ocean. In addition, we must consider the cost of applying new technologies. Despite the fact that the diagnosis and control of known viral pathogens are quite possible, it is an unresolved problem to diagnose an unidentified or unknown virus population in the marine ecosystem. Even though there are a few drawbacks of viral diagnosis or control of virus impacts in aquaculture organisms, it is necessary to characterize the viruses associated with marine organisms for further studies in the future. Moreover, only a tiny fraction of viruses has been discovered and the potential discovery still seems as vast as the ocean itself. Therefore, further research is still needed to analyze the presence of viruses in the marine environment and the new potential hosts of marine viruses yet to be discovered.

5. Marine Microalgae

Tsuyoshi Tanaka, Masaki Muto, Yue Liang, Tomoko Yoshino, Tadashi Matsunaga

Marine microalgae, the largest primary producer in the marine system, have been attracting wide attention as potential resources of new metabolites and biofuels. Whole genome sequencing and genetic modifications of microalgae have been rapidly advancing during the last few decades. In this chapter, the diversity of marine microalgae, the microalgal natural components, and the biotechnologies associated with microalgae are reviewed.

5.1 Overview

Algae are the primary producers of oxygen in the aquatic environment. These microorganisms are widely distributed in marine systems and have a great diversity with respect to size, morphology, life cycle, pigments, and metabolism. About half of the global oxygen production is accomplished by marine microalgae. They play an important role in CO_2 recycling through photosynthesis, which is similar to higher plants in O_2-evolved systems (PSI (photosystem I) and PSII (photosystem II)). In addition to having a long history of use as food and as live feed in aquaculture, microalgae have also been considered as a promising source for high-value added products for pharmaceuticals, cosmetics, and other industrial applications, such as β-carotene, astaxanthin, polyunsaturated fatty acids (PUFAs). The utilization of microalgae as a suitable feedstock for sustainable biofuel production has gained worldwide attention over the last 20 years. In general, microalgal triacylglycerols, hydrocarbons, and polysaccharides are considered as biofuel precursors. Alkanes and short chain fatty acid methyl esters (FAMEs), ranging from C9 to C17, have been considered as the potential alternative jet fuel, while those ranging from C9 to C23 have been mainly recognized as biodiesel. FAMEs are normally generated from the methyl esterification of triacylglycerols. On the other hand, with the degradation and fermentation of microalgal polysaccharides, the generated ethanol can be used as an alternative fuel to gasoline. Compared with higher plants, biofuel from microalgae has two advantages: 1) a relatively higher productivity, and 2) no competition to agriculture.

On the other hand, increased reports of the microalgal whole genome sequence data have been significantly facilitating the better understanding of their evolutionary lineage and the species specificity of the microalgal metabolic pathway. In addition, gene transformation has been achieved in 18 microalgal genera.

In this chapter, we reviewed the fundamental characteristics of marine microalgae, the useful microalgal natural products, as well as the biotechnological aspects of marine microalgae.

5.2 Marine Microalgae

Algae are a very diverse group of photosynthetic organisms other than land plants, which have been classified into many classes, such as *Cyanophyceae*, *Chlorophyceae*, *Rhodophyceae*, *Cryptophyceae*, *Dinophyceae*, *Bacillariophyceae*, *Haptophyceae*, *Euglenophyceae* or *Prasinophyceae*. For convenience, they are referred to as blue-green algae, green algae, brown algae, or red algae due to the difference in composition of photosynthetic pigments. However, it is difficult to make a clear definition of algae because even multicellular eukaryotic microalgae (what is called seaweed) are also included. In this section, some representative marine microalgae are summarized to introduce their biotechnological applications.

Cyanophyceae (cyanobacteria, blue-green algae) are oxygenic photosynthetic prokaryotes that comprise a single taxonomic and phylogenetic group. Chloroplasts in eukaryotes evolved from endosymbiotic cyanobacteria. They show a large diversity in their morphology, physiology, ecology, biochemistry, and other characteristics. Typically, cyanobacteria contain chlorophyll a and phycocyanin. Three genera, i. e., *Prochlorococcus*, *Prochloron*, and *Prochlorothrix*, lack phycocyanin and possess chlorophyll a and b [5.1]. A unicellular cyanobacterium that synthesizes chlorophyll d has also been discovered [5.2]. Marine *Synechococcus* and *Prochlorococcus* contribute largely to global oxygen production. Cyanobacteria have gained attention as a source of bioactive compounds and biopolymers (polyhydroxyalkanoates (PHA)s) [5.3]. Bioactive compounds isolated from marine cyanobacteria were summarized by *Burja* et al. [5.4] and *Takeyama* and *Matsunaga* [5.5]. Several strains of cyanobacteria (*Synechococcus elongates* and *Anabaena variabilis*) have been reported to produce long-chain alkanes and alkenes [5.6]. These findings make cyanobacterial alkane and alkenes a promising source of biofuels [5.7]. Two enzyme families that are responsible for straight-chain hydrocarbon production in cyanobacteria have recently been identified as an acyl–acyl carrier protein reductase (AAR) and an aldehyde-deformylating oxygenase (ADO). These enzymes convert fatty acid intermediates to alkanes and alkenes. This discovery of the cyanobacterial alkane biosynthesis indicates possibilities for optimizing the biodiesel production in cyanobacterial strains with modest gains in alkanes [5.8].

Chlorophyceae, which are one of the classes of green algae, possess chlorophyll a and b, the same predominant photosynthetic pigments as those of land plants. *Chlorophyceae* form starch in the chloroplast as a storage product of photosynthesis. Especially, *Chlamydomonas reinhardtii* has been used as a representative eukaryotic microalgae for biology and molecular biology studies. Chloroplast transformation was firstly achieved in *C. reinhardtii* [5.9]. Some species of *Chlorophyceae* are found in the marine environment. A marine species of *Chlorophyceae*, *Dunaliella* has been cultivated commercially for food supplements and β-carotene production [5.10]. *Chlorella*, which is a genus of single-cell and chlorophyll a/b-containing algae, belongs to the phylum *Chlorophyta*. It has been known as a potential food resource because of its high content of protein and other nutrients. Miura and others [5.11] reported that *Chlorella* sp. NKG 042 401 contains 10% γ-linolenic acid (C18:3), which is present in the cells mainly in the form of galactolipids. In *Euglenophyceae*, the genus *Euglena* is well known. The chloroplast of *Euglena* originated from the eukaryotic green algae and contains chlorophyll a and b. Although most species are found in freshwater environments, some species also occur in marine environments.

Bacillariophyceae (diatoms) possess chlorophyll a and c, and fucoxanthin as the major carotenoid. Diatoms are widely used as feed in mariculture/aquaculture [5.12, 13]. *Chaetoceros calcitrans*, *Chaetoceros gracilis*, *Chaetoceros muelleri*, *Skeletonema costatum*, and *Thalassiosira pseudonana* are commonly used as live feed for all growth stages of bivalve molluscs (e.g., oysters, scallops, clams, and mussels), for crustacean larvae, and for zooplankton used as feed for larvae. The genera *Navicula*, *Nitzschia*, *Cocconeis*, and *Amphora* also are used to feed juvenile abalone. They store energy either as lipids or as chrysolaminarin. Most diatoms have a high content of eicosapentaenoic acid (EPA) 20 : 5 (n-3). *Phaeodactylum tricornutum* and *Nitzschia laevis* have been especially investigated for EPA production. In addition, EPA production by diatoms was reviewed recently by *Lebeau* and *Robert* [5.14, 15]. Recent advances in heterotrophic production of EPA by microalgae were also reviewed by *Wen* and *Chen* [5.16].

The cells of *Haptophyceae* are brownish or yellowish-green and contain chlorophylls a/c and carotenoids such as β-carotene, fucoxanthin, diadinoxanthin, and diatoxanthin. The cells are commonly covered with scales made mainly by carbohydrates or calcium bicarbonate. Many species known as coccol-

ithophorids produce calcified scales called coccoliths. Most are primarily marine species inhabiting tropical seawater. Microalgal biomass of *Haptophyceae* is commonly used as living feed in aquaculture [5.17]. *Isochrysis galbana* and *Pavlova lutheri*, especially, are used as living feed for bivalve molluscs, crustacean larvae, and zooplanktons that in turn are used for crustacean and fish larvae. Some cells can produce PUFAs such as docosahexaenoic acid (DHA), or EPA. In addition, the DHA content in *I. galbana* has been shown to be enhanced by low temperature or incubation of the culture in the dark after reaching the plateau phase growth [5.18]. Furthermore, it was shown that these algae are useful for DHA enrichment of feed such as rotifers for the larvae of several marine fish species [5.19].

In *Dinophyceae*, a genus *Symbiodinium* (dinoflagellate) has been well described. Various marine invertebrates, such as reef-building corals, jellyfish, sea anemones, and bivalves form symbiotic associations with *Symbiodinium*, commonly known as zooxanthellae. *Symbiodinium* strains have been classified into more than three clades using restriction fragment length polymorphism based on 18S rRNA sequence analysis [5.20]. The composition of *Symbiodinium* populations may also play an important role in the tolerance or sensitivity of corals towards bleaching.

5.3 Microalgal Genomes

Sequencing of microbial genomes has become a routine procedure for gene discovery and genetic engineering of microalgae. *Synechocystis* sp. PCC 6803 was the first photosynthetic organism for which the entire genome sequence was determined. Currently, 72 finished cyanobacterial genome sequences are listed in GenBank, and many additional genome analyses are currently in progress. Most cyanobacteria possess a circular chromosome and a small number of additional plasmids. Genome sizes range from a minimum of 1.44 Mb for the marine cyanobacterium UCYN-A [5.21] to a maximum of 11.58 Mb for the *Calothrix* sp. PCC7103 [5.22]. Prokaryotes typically contain a single copy of their chromosome such as *Escherichia coli*, while large differences between cyanobacteria and other prokaryotes have been reported for chromosomal copy numbers. Some cyanobacteria are oligoploid, for example, *Synechocystis* sp. PCC 6803 are highly polyploid, and the motile wild-type strain contains 218 genome copies in exponential phase and 58 genome copies in linear and stationary phases [5.23].

Recently, a comparative genomics-based approach was used to screen cyanobacteria for the direct production of alkanes, the primary hydrocarbon components of gasoline, diesel, and jet fuel [5.8]. Eleven different cyanobacteria with available genome sequences were grown, and their culture extracts were evaluated for hydrocarbon production. Indeed, ten of these strains produced alkanes. The comparison of predicted proteins from these ten genomes against the eleventh finally led to the discovery of two hypothetical proteins as candidates for alkane biosynthesis. This discovery is the first description of genes responsible for alkane biosynthesis and the first example of a single-step conversion of sugar to fuel-grade alkanes by an engineered microorganism. A comparison of the genome sequences of producing and non-producing organisms led to the identification of the responsible genes.

In eukaryotic microalgae genomics, large-scale sequencing has been demonstrated by next-generation sequencing technologies. These have drastically increased the number of bases obtained per sequencing run while at the same time decreasing the costs per base. The first whole genome sequence of *C. merolae* was determined in 2004 [5.26]; this was the first identi-

Table 5.1 Sequenced whole genomes of microalgal strains

Microalgae species	Genome length (Mbp)	References

Ostreococcus tauri	12.6	[5.32]
Coccomyxa subellipsoidea	48.8	[5.33]

fied eukaryotic microalgal genome. Up until November 2012, the whole genome sequence of 11 strains of microalgae had been sequenced, including 2 diatoms (*Thalassiosira pseudonana* [5.24] and *Phaeodactylum tricornutum* [5.25]), a red alga (*Cyanidioschyzon merolae* [5.26]), and 8 green algae (*Chlamydomonas reinhardtii* [5.27], *Ostreococcus lucimarinus* [5.31], *Ostreococcus tauri* [5.32], *Chlorella variabilis* [5.28], *Volvox carteri* [5.30], *Coccomyxa subellipsoidea* [5.33], *Micromonas pusilla* [5.29], and *Micromonas* sp. [5.29]), see Table 5.1. In addition, the draft genome sequences of 17 strains of microalgae can been found in the NCBI GenBank databases [5.34]. With next generation technology, the draft genome sequence of the biodiesel producing microalga *Nannochloropsis gaditana* strain CCMP526 were also identified recently [5.35]. The identified microalgal whole genome sequences provide a powerful tool for the discovery of genes and metabolic pathways. Even though most of the predicted microalgal pathways have been proved to be similar to corresponding pathways in higher plants, the urea cycle identified from genomes of diatoms is absent in higher plants but present in animals [5.24]. The existence of an animal metabolic pathway in microalgal cells further highlights the importance of genome analysis for microalgae.

5.4 Genetic Engineering of Microalgae

5.4.1 Genetic Transformation Methods

Genetic studies on microalgae have been redirected mainly toward analysis of photosynthesis and metabolic pathways. A limited number of microalgae such as cyanobacteria have been used in biotechnological applications. The development of molecular techniques for physiological analysis and enhancement of biotechnological applications is necessary. Many attempts at gene transfer have been made in eukaryotic and prokaryotic microalgae. Genetic manipulation in prokaryotic microalgae cyanobacteria was studied extensively after several transformable unicellular strains were discovered. First, the freshwater cyanobacterium *Synechococcus* PCC7942 was reported to have the ability to take up DNA. Subsequently, several other naturally transformable freshwater strains were found. Gene transfer has been developed mainly in the freshwater strains *Synechococcus, Synechocystis, Anabaeba*, and *Nostoc* [5.69]. Several marine cyanobacterial strains of the genus *Synechococcus* have been also used for heterogeneous gene expression and other genetic applications [5.70, 71]. There are two commonly used gene transfer procedures: transformation using naturally occurring or artificially competent cells, e.g., conjugation with *Escherichia coli*, or physical methods for gene introduction, e.g., electroporation and particle bombardment. Natural transformation has been reported for *Synechococcus* sp. PCC7002 [5.72]. Other strains have been transformed successfully by electroporation or conjugation. Further, plasmids harvested from several marine microalgal species have been used as vector DNA for gene transfer. Marine plasmids have been found in *Synechococcus* sp. NKBG042902, which has a high phycocyanin content and a rapid growth rate. This strain contains more than three cryptic endogenous plasmids, and one of these, the plasmid pSY10 has the unique replication characteristic that its copy number increases under high salinity conditions [5.73]. Plasmids are maintained at a high copy number in cyanobacteria, which suggests the possibility that they act as a shuttle vector between cyanobacteria and *E. coli*. In fact, a shuttle vector with *E. coli* has been constructed using pSY10. Conjugative gene transfer using a broad-host range vector pKT230 was successful for the marine cyanobacterium *Synechococcus* sp. NKBG 15041C [5.74]. It has been demonstrated that this plasmid is stably maintained in cyanobacterial cells [5.75]. In marine cyanobacteria, in addition to the plasmid vector system, the construction of a phage vector system is also required to enable the cloning of large DNA fragments in specific cyanobacterial hosts. Since cyanophages were first reported by *Safferman* and *Morris* [5.76], various types of cyanophages have been found in seawater [5.77, 78] and characterized according to their genetic diversity and phylogenetic affiliations [5.79].

Due to the advance of genome, proteome, and metabolome analyses of microalgae, many attempts at gene transfer to eukaryotic microalgae have been made to enhance the production of useful compounds and biomass. However, because of the stiff cell wall of microalgae, the introduction of exogenous genes into microalgal cells could be challenging. The additional frustules and coccoliths surrounding some species of microalgae cells further increases the difficulty. Thus,

Table 5.2 Microalgal strains achieved for the stable transformation

Phylum species	Organelle	Transformation methods	Gene knock-down	References
Diatom				
Cyclotella cryptica	Nucleus	Biolistic		[5.36]
Cylindrotheca fusiformis	Nucleus	Biolistic		[5.37]

Eustigmatophyte				
Nannochloropsis spp.	Nucleus	Electroporation		[5.35, 68]

the optimization of the gene transformation method for each specific species turns out to be important. Depending on the physiological characteristics of microalgal cells, electroporation, glass beads-mediated transformation, agrobacterium-mediated transformation, and biolistics have frequently been used. Moreover, the level of target protein varied due to multiple insertion, random integration, and (or) gene silencing [5.80]. Stable transformants that have already been reported are summarized in Table 5.2.

Biolistics, also referred to as a gene gun that was originally designed for the delivery of nucleic acid through the cell wall of intact plant cells, has been mostly applied for microalgae gene transformation. The payload in this system is a plasmid DNA-coated tungsten particle (particle size: 0.6−1.6 μm), which can be shot with helium gas. After bombardment, the tungsten particles were shot down to the plant organism or the cell culture on the petri dish. Some cells that are not disrupted by the firing may envelope the DNA-coated tungsten particles and the DNA can then migrate to and integrate into the plant chromosome [5.81]. The transformation efficiency of this methodology is not related to the physical property of the host cell but is highly controlled by the gas pressure at the point of firing. Therefore, theoretically, despite the hard cell wall and frustules, gene transformation can be achieved when the gas pressure is high enough.

Electroporation is a phenomenon when the electrical conductivity and permeability of the cell membrane increase by the externally applied electrical field. If the host cells and plasmids are mixed together, the plasmids can be transferred into the host cells through the transient holes in the cell membrane generated by the electronic shock. Electroporation-based gene transformation methodology has been commonly used to

transform mammalian cells with plasmids. The transformation efficiency was significantly decreased for plant cells due to their thick cell walls. Electroporation-based gene transformation has only been achieved with the *Chlamydomonas reinhardtii* cell wall-deficient mutant and *Dunaliella salina* cells, which have no cell wall [5.46, 57, 82]. However, in the studies mentioned above, the transformation efficiency was tenfold higher than the gene gun method applied to the corresponding strains [5.83].

The glass beads method is a relatively simple transformation procedure that has a higher transformation efficiency than biolistics but it is only capable of transforming cells without cell walls. Both the cell-wall deficient *C. reinhardtii* mutant and *D. salina* have been reported to have been successfully transformed by the glass bead method with a higher efficiency than with the gene gun method [5.56].

Agrobacterium-mediated transformation is based on the characteristic of the soil bacterium *Agrobacterium tumefaciens* that it naturally transfers and inserts its genes into plant chromosomes. Exogenous genes can be transferred into plant cells through *Agrobacterium* transformation using target gene inserted agrobacterium transfer DNA (T-DNA). Although reports of microalgae transferred by agrobacterium transformation are few, *Kathiresan* et al. achieved a twofold transformation efficiency with *Haematococcus pluvialis* over the gene gun method [5.60].

In the transformants generated by the methods mentioned above, it is not rare to find the continuous expression of the target genes in the chloroplast and (or) mitochondria due to the insertion of the target genes into their organelle genome. By using a specific vector containing a homologous sequence in the organelle genome, stable chloroplast and (or) mitochondria transformation can be expected. On the other hand, the target genes are usually found to be randomly inserted into the nucleic genome and even homologous recombination occurs. Thus, it is hardly possible to control the insertion site and the number of the target genes inserted into the nucleic genome, which has made gene functional analysis via gene knock-out difficult. With further consideration of the dual nature of the microalgal life cycle as either haploid or diploid, the possibility of complete knock-out dwindled significantly in diploid cells. The homologous recombination has been applied to the transformation of *C. reinhardtii* and *Volvox carteri*, which maintain an asexual haploid zoospore during the life cycle; their recombination efficiency, however, was inferior [5.84, 85]. Recently, highly efficient homologous recombination was reported in *Nannochloropsis* sp., which suggested the possible use in microalgal gene functional analysis [5.68]. For those diploid microalgae, the knock-down of the target gene via RNAi has been reported and considered as the substitute for knock-out [5.40, 44, 55, 64].

So far, six microalgae including *Phaeodactylum tricornutum*, *Thalassiosira pseudonana*, *Chlamydomonas reinhardtii*, *Chlorella vulgaris*, *Volvox carteri*, and *Cyanidioschyzon merolae* have not only obtained stable transformants but also the whole genome sequence. *P. tricornutum* has been widely used for the studies of metabolic engineering towards enhanced lipid production. Yet, most research in this field has focused on the established stable transformant rather than on high oil-producing strains whose transformation method have not been determined.

5.4.2 Metabolic Engineering

Enhanced production of valuable primary or secondary metabolites in microalgae can be rendered possible by high density cultivation and/or application of genetic manipulation. Recent pharmaceutical interest in unsaturated fatty acids has triggered the search for sources of these valuable compounds. Several eukaryotic microalgae are known to produce highly unsaturated fatty acids such as EPA and DHA, which are valuable dietary components [5.16, 19]. Genetic engineering has been applied to produce EPA in the marine cyanobacterium *Synechococcus* sp. [5.71]. Cyanobacteria do not have the biosynthetic pathway to produce them. The EPA synthesis gene cluster (ca. 38 kbp) isolated from a marine bacterium *Shewanella putrefaciens* SCRC-2738 was cloned to the marine cyanobacterium using a broad-host cosmid vector. The content of EPA grown at 2 °C increased to 0.64 mg g^{-1} dry cells after 24 h incubation at 17 °C. Furthermore, EPA production was improved by partial deletion of the EPA gene cluster to stabilize its expression and maintenance in host cyanobacterial cells [5.86].

Genetic engineering of microalgae for industrial purposes has also been performed in freshwater cyanobacteria where the ketocarotenoid astaxanthin, an extremely efficient antioxidant, was synthesized by the introduction of the β-c-4-oxygenase gene (*crt*O) from the green alga *Haematococcus* [5.87]. Ethylene production was also demonstrated in the cyanobacterium *Synechococcus elongates* PCC7942 by chromosomal insertion of an ethylene forming enzyme [5.88]. How-

ever, the reaction catalyzed by the ethylene forming enzyme induced metabolic stress, which was detrimental to the host cell.

Microalgal biodiesel production is expected to be improved though metabolic engineering. Several transformants have been established for the increased oil content of the microalgal cell, enhanced biomass productivity, and improved quality of the lipids. Acetyl CoA carboxylase (ACCase), which catalyzes the carboxylation of acetyl-CoA to form malonyl-CoA, the primary substrate of fatty acids synthesis, has been overexpressed in diatom cells to elevate the cell lipid content [5.36]. The vector containing the ACCase gene and its 5′ UTR (untranslated region) from the diatom *Cyclotella cryptica* was constructed and introduced into the diatoms *C. cryptica* and *Navicula saprophila*. Stable high ACCase expression transformants were obtained successfully, yet the predicted increase of neutral lipid content was not achieved, which indicates that TAG (triacylglycerol) accumulation in the microalgal cell is much more complex than previously assumed. With the expression of the hexose transporter that transfers the monohexose from the culture medium into the cell, the transformants of green algae *C. reinhardtii* and *V. carteri* as well as diatom *P. tricornutum* have been demonstrated to be capable to grow in the dark in a medium containing glucose [5.89–91]. Especially, the glucose transporter (Glut1) gene transformant of *P. tricornutum* cultured in dark conditions showed an almost threefold higher biomass production than in light conditions [5.91]. On the other hand, the de-regulation of the light-harvesting proteins in *C. reinhardtii* has been demonstrated to be able to elevate the solar energy conversion efficiencies in photosynthesis when the light-harvesting chlorophyll antenna size is minimized [5.92]. This permits a greater photosynthetic productivity under high cell density conditions as well as the possibility of culturing cells under high sunlight conditions. The transformation of *Cinnamomum camphora* (C12-TE) and *Umbellularia californica* (C14-TE) Acyl-ACP thioesterases genes into diatom *P. tricornutum* resulted in an increased lauric (C12:0) and myristic acid (C14:0) accumulation mutant [5.93]. Levels of lauric acid of up to 6.2% of total fatty acids and myristic acid of up to 15% by weight were achieved. Moreover, 75–90% of the shorter chain length fatty acids produced were demonstrated to be incorporated into triacylglycerols.

5.5 Photobioreactors for Marine Microalgae

Microalgae mass cultivation for the production of useful compounds has been widely discussed since the 1950s. Even though large-scale production of astaxanthin, DHA, and EPA from microalgae have been achieved, the industrial production of microalgal biofuel is still under development. Lower cost and higher productivity and efficiency than current bioreactors are necessary due to the extremely low final price of biodiesel (1 dollar L^{-1}) compared with those high value-added microalgal products.

Both the biology and the economics of microalgae mass cultivation are strongly influenced by photobioreactor design. Photosynthetic microalgae can be cultured in photobioreactors as either an open culture system or a closed system. Based on their localization, these photobioreactors can be divided into outdoor culture systems or indoor culture systems.

Outdoor open culture systems are the simplest method of algal cultivation due to the low construction cost and effortless operation. However, the productivity of these systems can be easily affected by several environmental factors such as contamination of other microorganisms, changes of weather conditions, and the disability of transgenic microalgae cultivation. The need to achieve higher productivity and to maintain monoculture of algae led to the development of closed photobioreactors. Despite higher biomass concentration and better control of culture parameters, CO_2 recycling efficiency, energy profit ratio, energy payback time, and cost of production in these enclosed photobioreactors are not better than those achievable in open systems.

The growth rate and maximum biomass yield of microalgal strains are affected by culture parameters (light, temperature, and pH) and nutritional status (CO_2, nitrogen, and phosphate concentration). On the other hand, increasing the density of cultures decreases photon availability to individual cells. Light penetration of microalgal cultures is poor, especially at high cell densities, and such poor photon availability decreases specific growth rates. Higher biomass yields can be expected if sufficient photons are provided in high density cultures of microalgae. Two major types of bioreactors (tubular [5.94, 95] or flat plate [5.96, 97]) are generally applied for the enclosed system (Fig. 5.1).

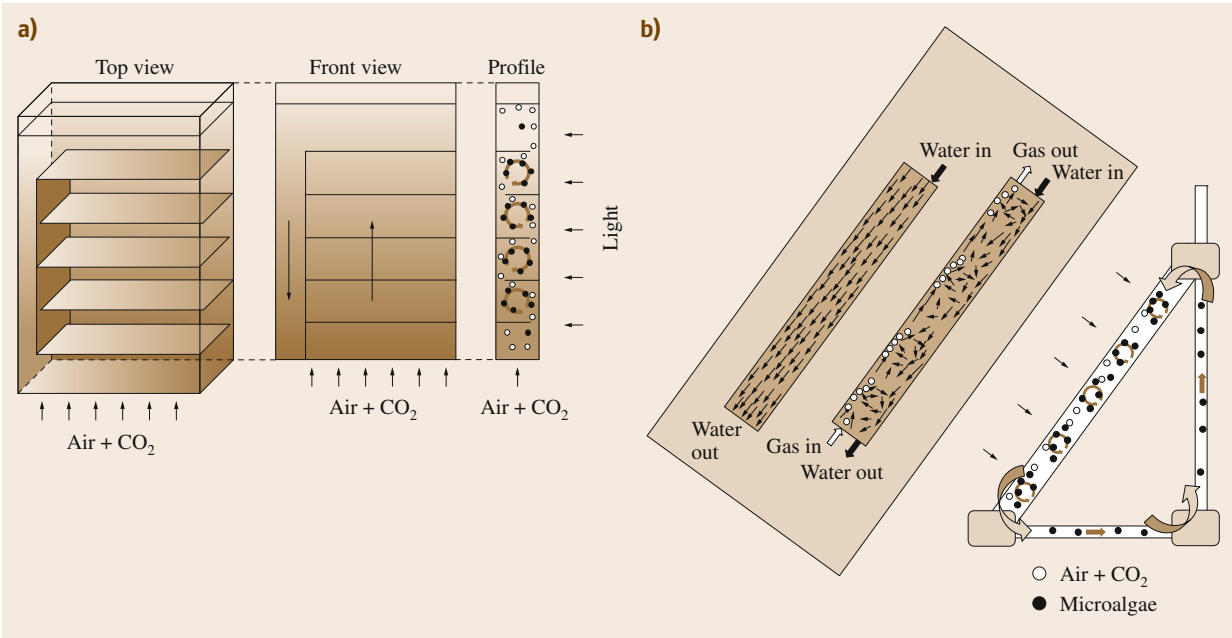

Fig. 5.1a,b Schematics of various photobioreactors. **(a)** After [5.95], **(b)** after [5.96]

Currently these enclosed photobioreactors are industrially applied for biodiesel production, for instance, the outdoor enclosed culture system used in Solix Biofuels Inc. and the indoor enclosed culture system used in Solazyme Inc. In addition, the use of intermittent light instead of continuous illumination can reduce the photoinhibition effect and improve the efficiency of light utilization through the flashing-light effect. On the other hand, the culture medium inside the photobioreactors needs to be stay flowing for mixing the algae and other nutrients. A newly developed flat plate photobioreactor achieved a 1.7-fold increased biomass production for *Chlorella vulgaris* [5.96] by applying the intermittent light from one side of the bioreactor, and the introduction of the air bubbling from the bottom of the bioreactor which generates turbulence inside the container. Recently, based on the flashing-light effect, a triangle bioreactor constructed by three tubular bioreactors with the air bubbling from the hypotenuse has achieved the currently highest volumetric productivity (365 t ha^{-1} a^{-1}) [5.95, 98].

6. Seaweed Flora of the European North Atlantic and Mediterranean

Leonel Pereira

Algae, like most vegetables, have cells with pigments that allow them to perform the photosynthesis. These organisms have a wide geographical distribution, colonizing various sites, but always linked to the presence of water. They can be found floating in the water, on wet rocks, walls, or in association with other organisms, as in the case of lichens, in association with fungi. They are particularly abundant in lakes, rivers, and seas, occupying the euphotic region (or photic), i. e., up to lower penetration of light effective for the realization of photosynthesis of algae (up to 200 m deep). Those that live in water can be planktonic (microalgae) or benthic (macroalgae). The former are small and live suspended in water (microscopic), whereas the latter remain fixed to a substrate (usually rock), are larger in size (macroscopic), and may reach 50 m in length. Seaweeds inhabit the oceans more than 2000 million years and are used as food by people in Asia since the 17th century. Today, seaweed is used in many countries for several purposes: directly as food, phycocolloids extraction (carrageenan, agar, and alginate) used in the pharmaceutical, cosmetic, and food industries. Algae are also used in the extraction of antiviral, antibacterial compounds, and biofertilizers. The larger or macroscopic algae, called macroalgae or seaweed, are mainly found in three of the algal taxonomic groups: Chlorophyta (green algae); Rhodophyta (red algae); and Phaeophyceae (brown algae). In this chapter, the main European seaweed flora and their biotechnological potential are listed.

6.1 Marine Macroalgae (Seaweeds)

Algae, like most vegetables, have cells with pigments that allow them to perform the photosynthesis.

Algae have a wide geographical distribution, colonizing various sites, but always linked to the presence of water. They can be found floating in the water, on wet rocks, walls, or in association with other organisms, as in the case of lichens, in association with fungi.

They are particularly abundant in lakes, rivers, and seas, occupying the euphotic region (or photic), i. e.,

up to lower penetration of light effective for the realization of photosynthesis of algae (up to 200 m deep). Those that live in water can be planktonic (microalgae) or benthic (macroalgae). The former are small and remain suspended in water (microscopic), whereas the latter remain fixed to a substrate (usually rock), are larger in size (macroscopic), and may reach 50 m in length [6.1].

6.1.1 Role of Algae in Nature

Algae are primary producers, i. e., they are able to produce oxygen and organic compounds that serve as food for other living beings, through the process of photosynthesis, using sunlight, atmospheric CO_2, and inorganic substances present in water. Algae are, in fact, fundamental to food chains of all aquatic ecosystems.

6.1.2 Main Taxonomic Groups of Benthic Marine Algae

The coloration of seaweed is the visible expression of the combination of different cellular pigments. Thus, the phyla and classes of macroalgae are essentially defined in practice by their particular pigment composition.

Macroalgae are aquatic photosynthetic organisms belonging to the Domain Eukarya and the Kingdoms Plantae (green and red algae) and Chromista (brown algae). Although classification systems vary over time and according to the authors, it is generally accepted to consider that

1. The green algae are included in the Phylum Chlorophyta; their pigmentation is identical to that of terrestrial plants (chlorophyll a, b, and carotenoids);
2. The red algae belong to the phylum Rhodophyta, their photosynthetic pigments are chlorophyll a, phycobilins (R-phycocyanin and R-phycoerythrin), and carotenoids (β-carotene, lutein, and zeaxanthin);
3. The brown algae are included in the phylum Ochrophyta (or Heterokontophyta), class Phaeophyceae; their pigments are the chlorophylls a, c, and carotenoids, dominated by fucoxanthin, responsible for the brownish color [6.1, 2].

6.1.3 Marine Algae Morphology

The diversity of algae is extraordinary; one can find a multitude of morphological types according to their complexity, structure, and environmental adaptations. Macroalgae show a complex degree of morphological organization, with laminar, cylindrical, tubular, or crustose thalli.

6.1.4 Importance of Algae for Mankind

Today, seaweed is used in many countries for very different purposes: directly as food, phycocolloids extraction, extraction of compounds with antiviral, antibacterial, or antitumor activity and as biofertilizers.

About four million tonnes of seaweed are harvested annually worldwide. The major producers are China and Japan, followed by America and Norway. France used to import Japanese seaweed in the 1970s but 10 years later it went on to produce algae for food and biological products users. Contrary to what happens in East Asia, the West is more interested in thickeners and gelling properties of hydrocolloids extracted from seaweeds: carrageenan, agar, and alginate (E407, E406, and E400, respectively) [6.3, 4].

6.1.5 Historical Overview of Algae Use on Health Treatments

Historically, the algae have been used by coastal communities to prepare home medicines to treat various health problems. Such applications are the product of the empirical knowledge of many generations and, in most cases, their mechanisms are unknown. However, the current research, undertaken in order to analyze the components and causes which affect the proper functioning of our body, are already giving their first fruits. So, we know, for example, that the good results obtained with the use of Kelp (*Laminaria* spp.) in the treatment of goiter are due to the fact that the origin of this disease is a diet low in iodine, chemical element present in significant quantities in brown algae [6.3].

Green algae have been used as anthelmintics, astringent, and to treat gout. Brown algae are used in the treatment of rheumatic processes, arteriosclerosis, menstrual disorders, hypertension, gastric ulcers, goiter, skin diseases, syphilis, and as an anticoagulant. Red algae are used as anticoagulants, anthelmintics, and in treating gastritis and diarrhea [6.3, 5].

6.2 The Marine Algae and Their Biotechnological Potential

Over time, the need to find new paths in search of new sources of energy is evident and relevant, especially the methods independent of fossil fuels, because they will run out one day and have an increasingly higher cost of use, both in terms of economic costs but mainly environmental costs.

One way to achieve it is by taking advantage of the biomass from the cultivation of algae in the oceans and seas, which offer large areas available for that purpose, which does not happen on land, where farmland is occupied for the production of food. The algae can produce, for example, biodiesel and ethanol.

On the other hand, in recent years, several marine organisms have been confirmed as an important source of new compounds potentially useful for the development of chemotherapeutic agents. Previous investigations of the production of antibiotic substances by aquatic organisms point to these forms as a rich and varied source of antibacterial and antifungal agents. Over 15 000 novel compounds have been chemically determined. Focusing on bioproducts, recent trends in drug research from natural sources suggest that algae are a promising group to furnish novel biochemically active substances [6.6].

Seaweeds or marine macroalgae are the renewable living resources which are also used as food and fertilizer in many parts of the world. Seaweeds are of nutritional interest as they contain low calorie food but are rich in vitamins, minerals, and dietary fibers [6.7]. In addition to vitamins and minerals, seaweeds are also potentially good sources of proteins, polysaccharides and fibers [6.8]. The lipids, which are present in very small amounts, are unsaturated and afford protection against cardiovascular pathogens.

Seaweeds are considered as a source of bioactive compounds as they are able to produce a great variety of secondary metabolites characterized by a broad spectrum of biological activities. Compounds with antioxidant, antiviral, antifungal, and antimicrobial activities have been detected in brown, red, and green algae [6.9, 10]. There are numerous reports of compounds derived from macroalgae with a broad range of biological activities, such as antibacterial [6.11], antivirals [6.12], antitumorals [6.13], anticoagulant [6.14], and antifouling [6.15], antihelminthic and antifungal [6.16].

6.3 Taxonomy and Description of Marine Algae with Biotechnological Potential

6.3.1 Domain/Empire Prokaryota, Kingdom Bacteria, Phylum Cyanobacteria (Blue–Green Algae)

- Class: Cyanophyceae
- Order: **Nostocales**

Rivularia bullata (Poir) Berkeley ex Bornet & Flahault

Description. In general, blue-green algae (Cyanobacteria) are not easy to find on the coastline edge (Fig. 6.1). However, one species may be easily confused with a green seaweed (Chlorophyta), whereby described here. This species forms small globular vesicles, dark green, sometimes bluish, gelatinous, and elastic; adherent to exposed rocks, sometimes on *Chthamalus* spp. (Barnacles), together with *Lichina pygmaea* (Lichens), and may attain 5 mm in diameter [6.2, 17].

Habitat. Grows on rocks of the upper littoral zone.

Distribution. NE Atlantic (Ireland and Britain to Portugal); Mediterranean; SW Indian Ocean; SW Pacific; Australia.

Uses and Compounds. Present antibacterial activity [6.18, 19].

6.3.2 Domain/Empire Eukaryota, Kingdom Plantae, Phylum Chlorophyta (Green Algae)

- Class: Bryopsidophyceae
- Order: **Bryopsidales**

Bryopsis hypnoides J.V. Lamouroux

Description. Plants in filamentous tufts, dull or dark green, 10 cm tall, are branching in an irregular, scattered pattern. Primary axes are highly branched. Fronds decrease in diameter with each successive division;

Fig. 6.1 *R. bullata* specimens on *Chthamalus* spp. (Barnacles)

branchlets form irregularly, undifferentiated from axes, constricted at base. Apices rounded; rhizoidal system fibrous, tightly woven [6.20, 21].

Habitat. Common near freshwater and nutrient rich outputs; attaches to hard substrates such as basalt, rocks, or rubble; forms delicate fronds which move with currents.

Worldwide Distribution. Atlantic Ocean, Mediterranean, Caribbean, Indian and Pacific Oceans, Australia.

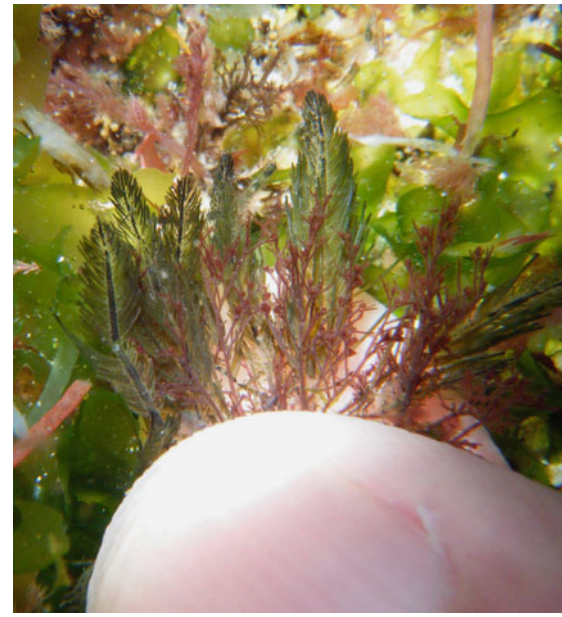

Fig. 6.2 Underwater photo of *Bryopsis plumosa*

Uses and Compounds. The primary structure of bryohealin and of lectin from *Bryopsis hypnoides* had little similarity with any known plant lectin, but rather resembled animal lectins with fucolectin domains [6.20, 22, 23]; Antifouling activity is present [6.24].

Bryopsis pennata J.V. Lamouroux

Description. Thallus filamentous, bushy, in tuft-like mats, to 10 cm high. Fronds feather-like, 8–15 mm wide, pinnately branched; lateral branches of uniform length, constricted at base where joined to main axes. Branchlets in two opposite rows on the upper half of branch, the lower half of branch is bare. The rhizoidal system is fibrous, tightly interwoven. Color is glossy dark green, often with light blue iridescence [6.25].

Habitat. *B. pennata* forms soft, feathery clumps attached to basalt rocks and rubble on shallow reef flats, in tide pools, and in the lower intertidal habitats of coastlines with low wave action.

Distribution. Atlantic Ocean, Mediterranean, Caribbean, Indian and Pacific Oceans, Australia.

Uses and Compounds. *Bryopsis* species are potentially invasive. Like the troublesome *Caulerpa taxifolia*, the genus produces chemical defenses that are toxic to most herbivorous organisms and easily reproduces veg-

etatively from the smallest fragments [6.25, 26]. The extracts of this seaweed have antibacterial [6.27–29], antifungal [6.29], anticancer [6.30], and cardiotonic [6.26] activity.

Bryopsis plumosa (Hudson) C. Agardh

Description. *B. plumosa* is a small, feathery species of green seaweed (Fig. 6.2). The thalli are erect, feather-like, and may reach up to 15 cm in height. It is easily recognized by its delicate branches. All branches are regularly arranged in two rows on opposite sides of the central filament. The lengths of the branches decrease gradually from the base of the plant. It is usually dark to mid-green in color [6.31, 32].

Common Names. Evenly branched mossy feather weed; stoneworts.

Habitat. Not uncommon; in low littoral rock pools and in the sublittoral. Is an epilithic species that is usually found in a deep lower shore pool or subtidally in both sheltered and well-exposed habitats.

Distribution. NE Atlantic (Scandinavia to Mauretania); Mediterranean, Caribbean; SW Atlantic; Indian Ocean; NW Pacific (Japan, China); NE Pacific (Alaska, British Columbia); SE Pacific (Chile); Indo-Pacific (Philippines, Vietnam, Indonesia); Pacific Islands; Australia, New Zealand.

Uses and Compounds. Produces lectins with biological activity [6.23]; present antioxidant [6.33] and antimicrobial [6.34] activity, medicinal and, pharmaceutical uses [6.35].

Caulerpa cupressoides (Vahl) C. Agardh

Description. Erect fronds arise from stolons of up to several diameters in length, anchored to the substratum by rhizoidal structures. Fronds are usually rich forked toward the apex, and at base they are naked (usually three) rows of rounded or flattened, ovoidal to conically pointed, short branchlets with a distinctly pointed tip [6.32, 36].

Habitat. On rocks in the tidal zone at depths of 40 m depth.

Distribution. NE Atlantic (Canary Islands); Caribbean; NW Pacific (Japan, China); West Pacific (Philippines, Indonesia); Pacific Islands; Australia.

Uses and Compounds. This seaweed is reported to be edible, to have antibacterial [6.37–40], antifungal, antioxidant [6.41], anticoagulant [6.41, 42], analgesic [6.43, 44] anti-inflammatory [6.43, 44], and antithrombotic [6.45] properties, and used to treat high blood pressure. However, some *Caulerpa* species produce toxins to protect themselves from browsing fish. This also makes them toxic to humans [6.36].

Caulerpa peltata J.V. Lamouroux

Common Name. Big parasol green seaweed.

Description. This seaweed has structures that look like fleshy umbrellas, with a thick circular portion (about 1−1.5 cm across) on a little stalk. These little umbrellas emerge along the length of a *stem* that creeps over the surface; bright yellowish-green to bluish-green color [6.32, 46].

Habitat. Found on shady rocks or dead corals in infralittoral zones along moderately wave-exposed shorelines. *Caulerpa peltata* grows in tide pools, on lower intertidal coral reefs covered with sand or on soft muddy.

Distribution. Widely distributed in tropical seas; Atlantic Islands.

Uses and Compounds. This seaweed was reported to be edible and used as medicine for its antifungal properties and has ability to lower blood pressure [6.46–48], it is also reported to have larvicidal [6.49, 50], antiplasmodial [6.51], citotoxic [6.52], immunomodulatory [6.53], antioxidant [6.52], antimicrobial [6.40, 54], and anticoagulant [6.55] properties. This species was evaluated for producing biodiesel [6.56].

Caulerpa prolifera (Forsskål) J.V. Lamouroux

Description. Fronds leafy, flat, with a distinct slender stipe and entire margins, at times undulating, oval to longitudinal, spatula-shaped or linear oblong, tapering toward the base, at the apex also narrowing but bluntly rounded (Fig. 6.3). Occasionally, more of these dark-green photosynthetic organs emerge from the stipes as well as from the margins or surfaces of the blades. The sparsely branching, relatively thin (1−2 mm) but wiry stolons are widely spread out, often extensive areas colonizing in this way; rhizoids in intervals of 0.5−2 cm [6.32].

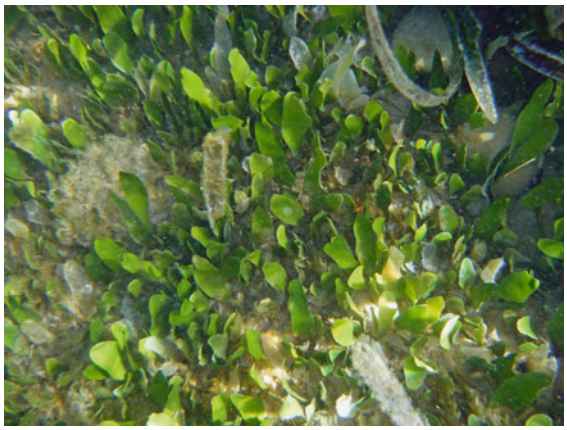

Fig. 6.3 Underwater photo of *Caulerpa prolifera*

Habitat. On sandy or muddy bottoms in sheltered lagoons, only slightly below the low water mark, often among Seagrass; but also on little wave-exposed rocks at depths of several meters.

Distribution. NE Atlantic (S Spain to Canary Islands), Caribbean, Mediterranean; Indian Ocean, SW Pacific (Philippines).

Uses and Compounds. Commonly used in aquaria, to which it is well adapted [6.32, 57], this species produces Caulerpenyne, an acetylenic sesquiterpene, which is specific to *Caulerpa*, as described by *Amico* et al. [6.58, 59] for *C. prolifera*. This seaweed is reported to have antibacterial [6.40, 60, 61], antialgal [6.61], antifungal [6.62], antifouling [6.63], antiproliferative [6.64], antioxidant [6.64, 65], anticoagulant [6.64], and larvicidal activity [6.66].

Caulerpa racemosa (Forsskål) J. Agardh

Common Names. Sea grape; green caviar; grape caulerpa.

Description. It is a bright green seaweed that resembles long skinny vertical bunches of tiny grapes. It can be very similar in appearance to *Caulerpa lentillifera*, though the latter tends to produce denser bunches (though this line can be smudged when *Caulerpa racemosa* grows in wave-exposed waters and develops shorter, stronger branches than normal). *C. racemosa* is quite variable in morphology and has many different growth forms that have been identified and named. A horizontal stolon which is attached to the sediment (usually sand) by descending rhizomes gives rise to erect branches at every few centimeters. These branches can reach as much as 30 cm in height and produce a large number of stalked branchlets which vary in shape from spherical to ovate to disk-shaped, sometimes flattening on top or forming icecream-cone-type shapes. These plants are coenocytic, which means that the entire plant is made up of one giant cell with many nuclei and no cross-walls. It is mainly due to this characteristic, any part of a *C. racemosa* plant that is fragmented, even tiny bits of tissue, can regenerate to form entirely new plants [6.67, 68].

Habitat. Forms intertwined mats in tide pools and on reef flats. Horizontal runners tightly anchor mats to rocks and sand and in calm to moderately heavy surf areas.

Distribution. Eastern Mediterranean; Caribbean, Indian Ocean, NW Pacific (Japan, China), Indo-Pacific (Philippines, Vietnam); Pacific Islands; Australia, New Zealand.

Uses and Compounds. *C. racemosa* is grown commercially in the South Pacific, and harvested wild in other areas [6.67]; edible seaweed, eaten as salad in Polynesia and the Marquesas [6.32]. *C. racemosa*, like *C. lentillifera*, is used commonly in Asian and Island cuisines. It is often used fresh and raw as a salad vegetable and is desired for its peppery flavor which also makes it ideal for use in sauce making [6.69]. This seaweed is common in the Phuket market of Thailand where 10–20 kg of fresh *C. racemosa* is sold per day [6.67].

C. racemosa also contains compounds which function as mild anesthetics, which gives the seaweed clinical value. Traditional medicine of the Philippines uses *C. racemosa* to lower blood pressure and to treat rheumatism [6.67, 68]. This seaweed is reported to have antibacterial [6.39, 60, 70–73], antiviral [6.72, 74, 75], antifungal [6.71], insecticidal [6.76], antioxidant [6.77, 78], anti-inflammatory [6.73, 79], anticoagulant [6.74], analgesic [6.79], hypolipidaemic [6.35, 80], hypoglycemic [6.81] and antitumor [6.77, 82] activity.

Caulerpa taxifolia (M. Vahl) C. Agardh

Description. Plant with widely extending, smooth stolons, about 1 mm in thickness; rhizoid-bearing branches downward and photosynthetic branches growing upward. Erect sections short-stiped and feather-like: the unbranched or sparingly branched axis is covered

Fig. 6.4 Cushion-shaped, dark green, strongly adhered to the rocky substrate (*Codium adhaerens*)

pinnately with 3–6 mm long and 1 mm wide, flattened and upward-bending branchlets. These are compressed, slightly constricted at the base and narrowing toward the mucronate tip [6.32].

Common Names. Killer algae; Aquarium Caulerpa; Folia feathery green seaweed.

Habitat. In sunny locations on sheltered shores, most common in shallow water on sand, mud and rocks, but also in up to 30 m depth.

Distribution. Widely distributed in warmer seas, NE Atlantic (Canary Islands); W Mediterranean; tropical E Atlantic (Ghana); Caribbean; Indian Ocean; NW Pacific (Japan, China); W Pacific and Indo-Pacific (Philippines, Vietnam, Indonesia); Pacific Islands; Australia.

Uses and Compounds. This green seaweed is reported to be edible [6.83], to have antioxidant [6.84], antibacterial [6.83, 85, 86], antiviral [6.87], nematicidal [6.88], and antifungal properties, and used to treat tuberculosis and high blood pressure [6.83]. However, some *Caulerpa* species produce toxins to protect themselves from browsing fish. This also makes them toxic to humans [6.83]; caulerpenyne from *C. taxifolia* which is cytotoxic toward several human cell lines and as such has anticancer, antitumor, and antiproliferative properties [6.35, 89, 90].

Codium adhaerens C. Agardh

Description. Spongy thallus, green light, prostrate, irregularly shaped, and presented with the appearance of a plane carpet firmly fixed to the substrate (Fig. 6.4). It consists of entangled coenocytic filaments and a finished surface by narrow and elongated utricles that are difficult to separate. Firm, gelatinous texture, and smooth to the touch [6.91].

Habitat. Perennial seaweed that can be found on exposed or protected shores under low light conditions, being located mainly in vertical rock faces and gaps.

Distribution. NW Atlantic (common on European bordering countries), Atlantic Islands (Azores, Canary), Africa, Asia, and Australia.

Uses and Compounds. Have vermifuge [6.92], antidiabetic [6.93], antibacterial [6.94], and antiviral [6.95] properties.

Codium bursa (Linnaeus) C. Agardh

Description. Thallus a spongy sphere with a velvety soft, shiny surface; becomes more flattened when increases in size. The internal branched filamentous network becomes looser with increasing size of the sphere, the space fills with water and the surface becomes indented; anchored to substratum by felted filaments [6.32].

Habitat. On rocks, probably prefers sheltered locations; in the infralitoral up to 10 m (−50 m) depth; often in drift.

Distribution. NE Atlantic (Ireland to Canary Islands); Mediterranean.

Uses and Compounds. Have antifungal [6.62], antibacterial [6.96], and antiplasmodial [6.97] activity.

Codium decorticatum (Woodward) M. Howe

Description. Very large, dichotomously branched erect thallus, dark green: from a crustose base rise one to several, up to more than 1 m long ribbons, regularly forking, rounded-flattened (0.5–3 cm wide) and usually visibly compressed at the bifurcations, stretched out like webs, wedge-shaped, and over 6 cm wide at that point [6.32, 98].

Habitat. Inhabits shallow muddy bays and harbors, usually during summer months.

Distribution. NE and E Atlantic (Spain to tropical W Africa), Mediterranean; Caribbean, SW Atlantic (Brazil, Uruguay); Indian Ocean; Hawaii; Antarctica.

Uses and Compounds. Have antibacterial [6.99, 100], antioxidant [6.65, 101, 102], antiviral [6.103], larvicidal [6.104], antifungal [6.105], and antitumor [6.106] activity.

Codium fragile (Suringar) Hariot

Common Names. Dichotomous sponge tang, Forked felt alga, Sea staghorn.

Description. Dark-green alga, ranging from 10 to 40 cm high and consists of repeatedly branching cylindrical segments about 0.5 to 1.0 cm in diameter, and its branches can be as thick as pencil. The segments look like dark green fingers. Its holdfast is a broad, sponge-like cushion of tissue. The tips of segments are blunt and the surface is soft, so it is sometimes mistaken as a sponge. Its body consists of interwoven, filamentous cells with incomplete cross-walls forming the inner part of the branches [6.107, 108].

Habitat. On rocky shores from the upper intertidal rock pools down to the lower intertidal.

Distribution. *C. fragile* is native to the Pacific Ocean in the Sea of Japan, and from Alaska to Baja California, Mexico. Its range has extended southward to South America, on the coasts of Chile and Argentina. It grows along nearly the whole coastline of the eastern North America, from the Gulf of St. Lawrence in Canada to North Carolina. It can be found in the Mediterranean and Adriatic, including the coasts of France, Spain, and Corsica. *C. fragile* ranges from Scandinavia to the Gulf of Gascogne and to the Canaries Islands. It has also been recorded in the Orkneys, Scotland, Ireland, Wales, and England. It can even be found in Australia, Antarctica, and southern Africa [6.107].

Uses and Compounds. *C. fragile* is used for skincare and antiaging products. It is reported to be a regenerating and anti-free radical ingredient, and have rebalancing and energizing properties. Its wealth of macro-elements gives it a remineralizing property [6.109]. One seller claims that *C. fragile* is the ideal ingredient to boost tired and mature skin. It is also used as food in eastern Asia and Chile [6.4, 107, 108, 110]. This species have also antioxidant [6.111, 112], antibacterial [6.112–115], anti-inflammatory [6.116] immunostimulating [6.117], antitumor [6.118], antiangiogenic [6.119], and antifouling [6.115] properties. The bioremediation potential of *C. fragile* has been tested on integrated multitrophic aquaculture (IMTA) [6.118].

Fig. 6.5 Underwater photo of *Codium tomentosum*

Codium tomentosum Stackhouse

Common Names. Spongeweed, Velvet horn.

Description. A small green alga (up to 30 cm long) with a dichotomously branched, cylindrical frond (Fig. 6.5). The frond is solid and spongy with a felt-like touch and has many colorless hairs which can be seen when the plant is immersed in water. The holdfast is disk-like and formed from many fine threads. *C. tomentosum* can be confused with *C. fragile*. However, *C. tomentosum* tends to have a more slender frond with rounded tips whereas *C. fragile* has pointed tips to the frond [6.1, 120, 121].

Habitat. Mainly on rock in the lower shore.

Distribution. *C. tomentosum* is native to the northeast Atlantic Ocean from the British Isles southward to the Azores and Cape Verde. It has also been recorded around the coasts of Africa and in various other parts of the world.

Uses and Compounds. *C. tomentosum* is used in products from the United States, Germany, France, Italy, and the UK. Some of these products are repair and restoration moisturizers, hydration serums, leg and body creams, muds and butters, bath and shower

creams, day creams, night creams, eye creams, anti-aging creams, masks, scrubs, lip balms, and lotions. *C. tomentosum* is a popular food in some parts of Asia [6.120, 122].

This species have antihelminthic and antiprotozoal [6.32, 122, 123], antioxidant [6.124, 125], antigenotoxic [6.124], antitumor [6.126], anticoagulant [6.127–129], antibacterial [6.96, 102, 130, 131] activity.

Halimeda opuntia (Linnaeus) J.V. Lamouroux

Description. Thick, profusely branched clumps of rounded three-lobed or ribbed leaf-like segments, between 10 and 25 cm in height. The branches are numerous and are in different planes, rather than nearly in a single plane as some other species are. This alga can cover larger areas with a dense mat so that individual plants are indistinguishable [6.32, 132].

Habitat. Grow in shallow depressions, cracks and crevices, between hard corals and other somewhat protected areas of the reef, down to 55 m.

Distribution. Mediterranean; Caribbean; SW Pacific and Pacific Islands; Japan; Indian Ocean.

Uses and Compounds. *H. opuntia* show hair-growth-stimulating [6.133], antimicrobial and cytotoxic [6.134–138], antioxidant and hepatoprotective [6.139–141], larvicidal [6.142], antileishmanial [6.143], and antiviral [6.144] activity.

Halimeda tuna (J. Ellis & Solander) J.V. Lamouroux

Description. Thallus calcified, dark green, distinctly segmented with initial branching in one plane; segments disk-like to triangular, up to 2 cm wide. Internodal siphons uncalcified, united in twos or threes, and terminating in pseudodichotomous laterals. Surface cells oppressed to one another in a honeycomb pattern, 25–75 µm in diameter [6.32].

Habitat. Found on hard rocky substratum in shallow water, less than 2 m depth.

Distribution. Globally in warmer seas: NE Atlantic (Morocco, Azores, Canary Islands); Mediterranean; Caribbean; NW Pacific (Japan); SE Pacific (Chile); SW Pacific; Pacific Islands; Indian Ocean; Australia.

Uses and Compounds. This species have antibacterial [6.114, 145, 146], antioxidant [6.65, 147], anticoagulant [6.128], pesticide [6.136, 148], antifungal [6.62], Antitrypanosomal [6.149], cytotoxic and antiproliferative [6.150] activity.

- Class: Dasycladophyceae
- Order: **Dasycladales**

Acetabularia acetabulum (Linnaeus) P.C. Silva

Description. Thallus with a slender stipe, whitish gray or gray-green, merging into a flattened, funnel-shaped cap at the top; this is divided into 20–80 radial rays, navelled, and annulated around navel and below the cap (Fig. 6.6). During growth, delicate filamentous, forking branchlets arise from the uppermost ring and the stipe. These are discarded soon and are therefore lacking in the mature thallus. Only basal parts perennial, plants with fully developed caps between May and August in the Mediterranean [6.32, 151].

Habitat. Mostly forming dense stands on rocks and stones in sheltered bays.

Distribution. NE Atlantic; Mediterranean; Indian Ocean.

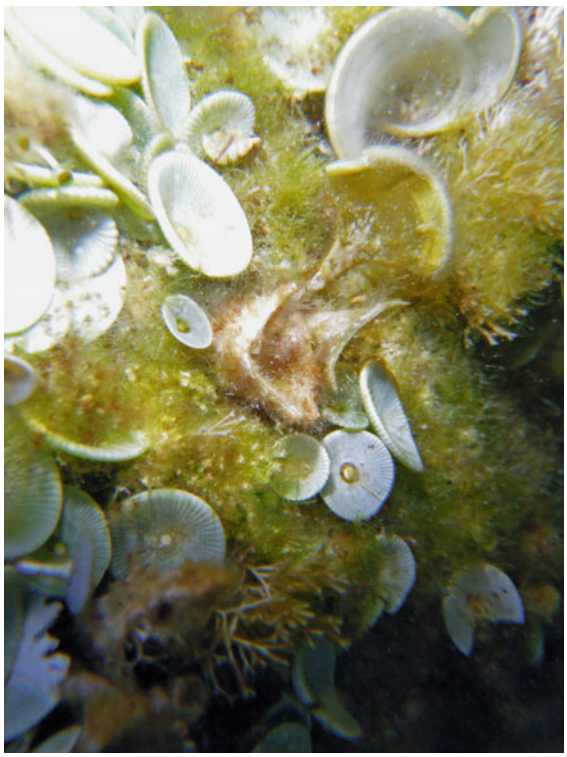

Fig. 6.6 Underwater photo of *Acetabularia acetabulum*

Uses and Compounds. For a time, important researches object in cell biology (cell differentiation, interaction of nucleus and cytoplasm) [6.32].

- Class: Siphonocladophyceae
- Order: **Siphonocladales**

Valonia utricularis (Roth) C. Agardh

Description. Thallus, translucent light- to dark green, primarily consisting of a large (up to 5 mm thick and 20 mm long) bladder- or club- to hose-like *cell*, branching at the base rhizoidally (Fig. 6.7). Later due to outgrowths of this cell cylindrical-clavate branches, often contorted and almost gapless densely packed, thus forming intertwined erect stands [6.32, 152].

Habitat. Plants sessile; at times forming extensive stands beneath other algae. Mostly on rock and reef edges in sheltered locations and shallow water, in up to 2 m depth.

Distribution. Warm NE Atlantic (Portugal to Canary Islands); Mediterranean; Caribbean; Indian Ocean; NW Pacific (Japan, China); Indo-Pacific (Philippines, Vietnam); Pacific Islands; Australia.

Fig. 6.7 *Valonia utricularis* specimen

Uses and Compounds. Show antifungal, antiviral, cytotoxic and atimitotic [6.62] activity.

- Class: Ulvophyceae
- Order: **Cladophorales**

Anadyomene stellata (Wulfen) C. Agardh

Description. *A. stellata* consists of erect, bright green, delicate blades with ruffled edges forming densely packed clumps; blades one cell thick, to 10 cm in height, formed by veins of filaments radiating from base in fan-like branching pattern. Cells between veins arranged in parallel rows. Margins smoothly rounded, formed by small spherical cells; similar to *A. saldanhae* which has cells between veins in random arrangement. Also similar to *A. lacerata* which has lacerated margins formed by elongated vein cells [6.32].

Habitat. Commonly found on rocks or other firm surfaces in the lower intertidal zone.

Distribution. Warmer parts of the NE Atlantic (Azores, Canary Islands), Mediterranean; Caribbean; Indian Ocean; W Pacific (Philippines, Indonesia); Australia.

Uses and Compound. Have anticoagulant [6.153], and antifungal [6.62] activity.

Chaetomorpha aerea (Dillwyn) Kützing

Description. Light green filaments, 10 cm long, growing attached to the substrate, and mostly grouped in tufts. Filament unbranched, growing in flocks or communities attached to sand covered or bare rocky substratum, 2–3 cm in height, yellowish green in color. Cells cylindrical, apical cells 111.2–111.5 µm in length and 110.5–111.6 µm in breadth, middle cells 54.5–62.2 µm in length and 88.8–89.2 µm in breadth, basal cell much longer than the middle and the upper one, showing its length 133.32–144.5 µm and breadth 55.50–58.8 µm, sheath 17–22.5 µm in thickness, sometimes lamellate in mature portion [6.154].

Habitat. Ephemeral species, found in intertidal environment, in both exposed and sheltered stations.

Distribution. Diffused in Mediterranean, Black Sea, NE Atlantic (from Scandinavia to Portugal) NW Atlantic.

Uses and Compounds. Show antibacterial [6.155–157] activity.

Chaetomorpha capillaris (Kützing) Børgesen

Description. Thallus medium green, loose-lying in shade on tidal flats, forming loose, woolly, entangled masses with few if any attachment cells. Filaments unbranched, of similar diameter throughout. Cells (70–) 85–100 (–105) µm in diameter and L/B 1–2, not collapsing on drying; walls 8–12 µm thick; chloroplasts densely reticulate with numerous pyrenoids [6.158].

Habitat. In shade on mangrove pneumatophores or under Samphires on tidal flats.

Distribution. Mediterranean and North Atlantic; Southern Australia and New Zealand.

Uses and Compounds. Have antifungal activity [6.62].

Chaetomorpha linum (O.F. Müller) Kützing

Common Name. Spaghetti algae.

Description. Delicate green seaweed, it grows as a filamentous loosely entangled mass (Fig. 6.8). Plants mostly free floating, sometimes attached to rocks and shells; plant body filamentous, less than 20 cm long, bright green to yellowish green in color, filaments wiry and stiff, unbranched; cell walls thick, appear jointed or articulated with dark green bands; cells constricted at the transverse walls [6.159, 160].

Habitat. Is an intertidal and supralittoral species that can be found in groups of hundreds or thousands of individuals in sandy areas, on rocks or around tide pools.

Distribution. Widespread, including Northern Europe to North Africa Atlantic coasts, North and Baltic; Mediterranean; North American Atlantic Coast (Labrador to Florida); NE Pacific (Alaska to California); SE Pacific (Chile); Indian Ocean, China, Japan, Australia, New Zealand.

Uses and Compounds. Spaghetti algae, though not palatable to many herbivorous species, is popular in reef aquariums for its ability to remove nitrates, assist in buffering pH, uptake carbon dioxide producing oxygen, and assist in balancing trace elements. It also provides hiding spaces for small creatures [6.159]. Possible use on biofuel production [6.161–163], liquid fertilizer [6.164], bioremediation in aquaculture [6.165], and animal feed [6.166]. Extracts of this species have insecticidal [6.167], antimicrobial [6.168–171], antioxidant [6.111, 170], larvicidal [6.171], and antiviral [6.172] activity.

Fig. 6.8 *Chaetomorpha linum* specimens

Cladophora coelothrix Kützing

Description. Thallus medium to dark green, drying brownish, forming dense turfs or cushions to several cm across and to 4 cm high, composed of a basal tangle of branched, often curved, stolon-like filaments giving rise to ascending, more-or-less erect, branch-systems. Growth largely by divisions of conspicuous apical cells, but intercalary cells may divide into shorter cells; feebly to distinctly acropetal at the apices, densely and irregularly branched with many cells (especially lower

ones but often also those near the apices) producing a descending rhizoid from their basal poles, and which attach to the substrate or other filaments with a terminal coralloid holdfast; lateral branches mostly wide-angled (45° or more) arising singly (occasionally two) at or just below a cross wall, with the new wall remaining steeply inclined to the parent cell [6.173].

Habitat. Common in shaded areas or pools near low tide level on rough-water coasts but extending into sheltered areas.

Distribution. Warm temperate to tropical Atlantic coasts of Europe, Africa and America; probably widespread in tropical and warm temperate waters, and in southern Australia.

Uses and Compounds. Have antimicrobial [6.174], and antifungal activity [6.62].

Cladophora fracta (O.F. Müller ex Vahl) Kützing

Description. Filaments branched; attached by rhizoids, pale green, up to 80 cm long, branching irregular or pseudodichotomously divided at wide angles, cells mostly cylindrical; chloroplast parietal net-like with several pyrenoids; main axis up to 85 µm wide, bearing numerous side branches of different lengths; cells of side branches 17–38 µm wide, 5 to 17 times longer than wide, apical cells cylindrical to slightly conical, 16–27 µm wide, 3.5 to 25 times longer than wide [6.175].

Habitat. Frequent in shallow, nutrient-rich ponds and ditches as well as penetrating slightly brackish-water habitats; mostly free floating or unattached and lose lying.

Distribution. NE Atlantic (Sweden to Spain); NW Atlantic; Mediterranean; Australia.

Uses and Compounds. Have antihypertensive [6.176], antimycobacterial [6.177], antioxidant [6.178], antibacterial [6.179, 180], antialgal [6.179], piscidal [6.179] activity, and possible use for biodiesel production [6.181, 182].

Cladophora glomerata (Linnaeus) Kützing

Description. Plants were up to 20 cm high and light to dark green in color. The texture of thallus was soft and slightly mucilage. Plants usually formed in dense tufts well branched. Rhizoids were primary and adventitious and descend from the bases of thallus or from the lower segments of the fronds. Primary branches fused together or not and branched in dichotomous manner. The old branches in the lower portion of the thallus were slight constricted articulations (80–150 µm in width and 160–900 µm in length) and usually branched in dichotomous manner. The branches in the upper portion of thallus were cylindrical (60–120 µm in width and 100–600 µm in length) and branched in dichotomous or trichotomous manner [6.183].

Habitat. Growth of *C. glomerata* usually requires hard substrates for attachment, such as rocks, mussels, and artificial reef structures.

Distribution. Distributed widely around world; NE Atlantic (Sweden to Portugal); NW Atlantic (Canada to Cuba and Mexico); SW Atlantic (Brazil); Mediterranean; Indian Ocean, Pacific.

Uses and Compounds. Used on the treatment of burns [6.184], biosorption of heavy metals [6.185], animal feed [6.186], biodiesel production [6.187], wastewater treatment [6.188], and as food [6.189]. Have antibacterial [6.190–192], antiprotozoal [6.193], antioxidant [6.190, 194], and antifungal activity [6.192, 195].

Cladophora pellucida (Hudson) Kützing

Description. Filaments rigid, erect, setaceous, full dark green, di-tri-chotomous; the axils very acute, the branches erect; articulations many times longer than broad; dissepiments only at the forking of the branches and ramuli [6.196].

Habitat. On the bottoms and sides of deep rock pools, between tide marks, generally near low-water mark.

Distribution. NE Atlantic (from Ireland and Britain to Morocco); Mediterranean; SW Atlantic (Brazil); NE Atlantic (South Africa); Indian Ocean (India); Australia.

Uses and Compounds. Have antitumor [6.197] activity.

Cladophora prolifera (Roth) Kützing

Description. Unattached or basally attached coarse filaments those are usually less than 0.5 mm wide and 3–5 cm long. The filaments are formed of a single row of often swollen cells; if attached then by a discoid base or by rhizoidal outgrowths [6.198].

Fig. 6.9 Herbarium specimen of *Cladophora rupestris* (MACOI no. 2419)

Habitat. Grow fixed to rocks in the upper sublittoral zone.

Distribution. NE and E Atlantic (from Ireland and Britain to Senegal); Mediterranean; NW and SW Atlantic; SE Atlantic; Indo-Pacific Oceans; Australia.

Uses and Compounds. Used on experimental co-culture [6.199]. Have antimicrobial [6.96, 200–203], antifungal [6.200, 204], antiviral [6.103], antioxidant [6.65, 205], and anticoagulant [6.206] activity.

Cladophora rupestris (Linnaeus) Kützing

Description. *C. rupestris* is a densely tufted plant, darkgreen, which grows up to 20 cm in height, with dark green or bluish colored dull fronds. Typical specimens branch profusely upward from the base, in an irregular, whorled or opposite pattern. The stoutness, density, and arrangement of branches give the seaweed a coarse feel (Fig. 6.9).

The morphology of the species is fairly constant over a wide range of habitat conditions and over a wide geographical area. Its morphology is affected by physical damage due to grazing by animals and loss of the apical region on reproduction; both instances are followed by regeneration and proliferation of branches. *C. rupestris* sometimes forms an almost complete cover of stunted growth at high tide level and occasionally in the splash zone where pools are brackish. Filaments are short and branching dense in the most wave exposed locations [6.1, 32].

Habitat. On solid substratum, in all littoral zones, prefers sandy locations in the lower littoral, tolerant to reduced salt content of seawater.

Distribution. NE Atlantic (Scandinavia to N Africa), North Sea and Baltic; Mediterranean; NW Atlantic; NW Pacific (Japan) and SW Pacific; Subarctic.

Uses and Compounds. Contains arabinose, carotenoids, galactose, glucose, polysaccharides, protein, rhamnose, sulfuric acid, and xylose [6.207, 208]. Used for animal feed [6.209], and CO_2 bioremediation [6.210]. Have antimicrobial [6.130, 211], antimycobacterial [6.212], antiprotozoal [6.212], cytotoxic [6.212], and antifouling [6.213] activity.

- Order: **Ulvales**

Ulva clathrata (Roth) C. Agardh

Synonyms. *Enteromorpha ramulosa* (Smith) Carmichael, *Enteromorpha clathrata* (Roth) Greville.

Common Name. Aonori.

Description. Plants less than 30 cm long and soft; thallus repeatedly branched in all directions, cylindrical or compressed with narrow branchlets as much as 40 cm long, light green in color, plants grow first attached to the substratum but later become free floating; cells of the thallus more or less quadrangular in shape with a single cup-shaped chloroplast; pyrenoids 3 to 4.

This species forms tufts, bright green, composed of branched axes, which can reach several centimeters long (20—30 cm). The main axis and branches are covered with conical branchlets very characteristic [6.1].

Habitat. In rocks and stones, from mid-littoral to sublittoral.

Distribution. Entire Atlantic, Mediterranean, Caribbean (Cuba, Mexico), NE and NW Pacific, Australia and New Zealand.

Uses and Compounds. Used as biofilter on shrimp (*Litopenaeus vannamei*) aquaculture [6.214], on shrimp feed [6.215, 216], and for human food [6.4, 217]. Have

antibacterial [6.96, 218–220], anticoagulant [6.221], antifungal [6.217], antiprotozoal [6.123, 218], larvicidal [6.222], analgesic [6.218], anticancer and antiviral [6.217, 218] activity.

Ulva compressa Linnaeus

Synonym. *Enteromorpha compressa* (Linnaeus) Nees.

Common Names. Green nori, Plat darmwier.

Description. *U. compressa* is a green seaweed that can have one of two different growth forms. The first is a flat, narrow sheet with ruffled edges, and the second form (often referred to as *Enteromorpha compressa*) is a hollow tube of tissue, rounded at the top. In both forms the sheets of tissue are very thin; in fact they are exactly one cell thick. Several blades or tubes arise from a common attachment point and can grow up to 200 mm long. *U. compressa* is a shallow water species and is often found in tide pools or on rocks in the intertidal and shallow infra-littoral up to 3 m deep. As a common tidepool species, *U. compressa* is able to withstand great swings in salinity, temperature, and pH [6.223, 224].

Habitat. Marine and estuarine species, rock pools and sandy rocks, particularly in places with widely varying salinities such as upper-shore species.

Distribution. *U. compressa* is widely distributed, found commonly on the NE Atlantic coasts, Pacific coast of North America, throughout the Mediterranean, and also in Africa and Australia.

Uses and Compounds. *U. compressa*, in the same family as *sea lettuce* is a commonly eaten as a sea vegetable, used fresh or dried for both human and animal consumption for its high nutrient levels and good taste; is used dried in cooking, particularly with eggs [6.109, 223, 224]. This seaweed is also utilized as fertilizer to introduce a wide range of minerals to the soil. Many benefits have been associated with *U. compressa* consumption such as cytotoxic [6.225], antimicrobial [6.96, 171, 224, 226–230], antiviral [6.224], and antioxidant [6.224, 225, 231–234] properties. Extracts of *U. compressa* are also added to cosmetics products for a soothing quality that reduces skin itchiness and tautness [6.224].

Ulva fasciata Delile

Description. Thalli thin, sheet-like, up to 50 cm long, consisting of wide blades, 10 – 15 cm wide at base, tapering upward to less that 2.5 cm wide at tip. Basally broadened, but the upper portions divided deeply into many ribbon like segments; margins smooth, often undulate. Holdfast is small without dark rhizoids. Bright grass-green to dark green, gold at margins when reproductive, may be colorless when stressed [6.32, 235].

Fig. 6.10 *Ulva intestinalis* specimens

Habitat. *U. fasciata* is a common species in the intertidal to shallow infra-littoral, often found in tide pools. This species is a quick colonizer and is able to grow very quickly in the right conditions, often reaching bloom levels in the presence of nutrient run-off and fresh water input [6.236].

Distribution. *U. fasciata* has a worldwide distribution in temperate and tropical waters: NE Atlantic; Mediterranean; Caribbean; West coast South Africa; SW Atlantic; entire Pacific; Indiana Ocean; Australia, New Zealand.

Uses and Compounds. *U. fasciata* is a popular edible seaweed in many areas where it grows, such as Hawaii where it is known as *limu palahalala*. *U. fasciata* has a very fine texture and lovely fresh taste and is often chopped into salads or used as a relish, though it can also be cooked and used in soups [6.236]. Green algae extracts are also very nutrient rich and

are a wonderful addition to natural cosmetic products. Have antiviral [6.237, 238], algicidal [6.239, 240] antifungal [6.241] larvicidal [6.242], cytotoxic [6.242], antifouling [6.243], antibacterial [6.241, 242, 244–247], antioxidant [6.246] activity.

Ulva intestinalis Linnaeus

Synonym. *Enteromorpha intestinalis* (Linnaeus) Nees.

Common Name. Gut weed.

Description. *U. intestinalis* is a conspicuous bright grass-green seaweed, consisting of inflated irregularly constricted, tubular fronds that grow from a small discoid base (Fig. 6.10). Fronds are typically unbranched. They may be 10–30 cm or more in length and 6–18 mm in diameter, the tips of which are usually rounded. Like other members of the genus, *U. intestinalis* is a summer annual, decaying and forming masses of bleached white fronds toward the end of the season [6.1, 32].

Habitat. In sheltered as well as exposed locations, on boulders, breakwaters and piers, in pools, also epiphytically; from the upper littoral (also supra-littoral) pools into the sublittoral.

Distribution. More or less globally distributed: entire Atlantic, Mediterranean, Caribbean, NE and NW Pacific, Indian Ocean, Australasia, Antarctica.

Uses and Compounds. This species is used as human food [6.4] and animal feed [6.248, 249], for biomonitoring of heavy metals [6.250, 251], have antimicrobial [6.86, 96, 252, 253], antifungal [6.252], antitumor [6.254, 255], antihemolytic [6.253], larvicidal [6.256], antifouling [6.257], antiplasmodial [6.258], antiprotozoal [6.259], algicidal [6.260], and antioxidant [6.261–263] activity.

Ulva lactuca Linnaeus

Common Names. Sea lettuce, Green laver.

Description. *U. lactuca* is commonly called sea lettuce. Its color can range from light yellowish green to darker green, but is most commonly a vivid green underwater. When exposed at low tide or when washed up on a beach, it is typically darker green. Out of the water the seaweed looks like a rather slimy lime-green mass but in the water the alga actually does look very much like young lettuce leaves. *U. lactuca* is vivid green and cellophane thin (only two cell layers thick), and forms light yellowish green to dark-green translucent sheets. The soft frond grows as a single, irregular, but somewhat round-shaped blade with slightly ruffled edges which are often torn. There can be numerous small holes or perforations scattered throughout. The frond is connected to rocks with a small, almost invisible discoid holdfast, and does not have a stipe. *U. lactuca* may grow to a diameter of 20–30 cm, although it is frequently much smaller, with larger sheets feeling slightly thicker than smaller specimens [6.1, 32, 264].

Habitat. From the tidal zone to the sublittoral, often free floating in pools.

Distribution. *U. lactuca* is ubiquitous, common to most shorelines around the world.

Uses and Compounds. *U. lactuca* is available in different forms from companies in countries which include the UK, Ireland, France, Germany, Vietnam, China, Canada, and the United States. It is sold both in fresh and dried form, in flakes, powders, and salad mixes. It is a delicate seaweed with a mild flavor. *U. lactuca* is sometimes eaten as *green laver*, but it is considered inferior to *purple laver*. It is used as a seasoning by itself and in blends, and can be found in soups and salads [6.32]. This species is also used in animal feed [6.265]. It also a key ingredient in many cosmetic and personal care items such as soap, lotion, toner, lifting cream, eye cream, lip cream, makeup remover, body polish, bath soaks, antiaging products, shaving lotion, shampoo, conditioner, and serums [6.264, 266]. It is also a component in gardening and fertilizer products [6.3].

This species have antioxidant [6.267, 268], antibacterial [6.70, 72, 115, 145, 171, 228, 269–271], antitumor [6.72, 126], anti-inflammatory [6.272], antifouling [6.115, 273], antifungal [6.72, 115], antiviral [6.72, 263], antialgal [6.115] activity.

Ulva linza Linnaeus

Synonym. *Enteromorpha linza* (Linnaeus) J. Agardh.

Common Names. Breed darmwier, Bright grass kelp, Welded green nori.

Description. *U. linza* is a large, ribbon-like species of green seaweed that may reach up to 30 cm in length.

The thalli are unbranched and often have a frilled margin. The thalli taper into a distinct stipe below and are highly compressed. The width of the thallus is greater in the middle than at the base and may reach 5 cm in width. *U. linza* is bright light to dark green in coloration [6.32, 274].

Habitat. Usually found on rocks or in rock pools, usually marine but occasionally found under brackish conditions.

Distribution. *U. linza* is found worldwide in bays and sheltered coasts.

Uses and Compounds. *U. linza* is used as an edible seaweed in many cultures for its high nutrient content and silky texture. Green algae extracts are also very nutrient rich and make a beneficial addition to natural cosmetic products [6.274]. Have antibacterial [6.60, 96, 228, 269, 275, 276], anti-inflammatory [6.277], and antiviral [6.278].

Ulva prolifera O.F. Müller

Synonym. *Enteromorpha prolifera* (O.F. Müller) J. Agardh

Common Name. Green ribbon plant.

Description. The fronds are tubular, though often more or less flattened, little to much branched. The arrangement of the cells, in longitudinal and transverse rows in the central part of the frond, is characteristic of this species, as are the cylindrical chloroplasts seeming to fill the cell and the usually single, central pyrenoids [6.279].

Habitat. A common green alga near the top of the shore, on rocks or other algae, on open coasts or in estuaries and harbors, where it may grow mixed with *U. intestinalis* or other species of the same genus.

Distribution. NE Atlantic (Britain to Senegal); Atlantic Islands, Mediterranean; NW and W Atlantic; Caribbean; SE Atlantic; Pacific; China, Australia.

Uses and Compounds. Used for food [6.280] and animal feed [6.281, 282]; potential use for the production of biofuels [6.283]. Have also antibacterial [6.171, 284], antifouling [6.285], antioxidant [6.101], antifungal [6.226, 286], antitumor [6.126], immunomodulatory [6.287] activity.

Ulva rigida C. Agardh

Common Name. Green laver.

Description. *U. rigida* is a bright green seaweed with a variety of growth forms. The two cell layer thick, sheet-like blades can grow as tiny blades forming carpet-like turfs, or as clumps of several larger blades, or solitarily. In its largest form, *Ulva rigida* can reach up to 10 cm in height, but size and blade shape are both highly variable. Blades may be flat or ruffled, sometimes bearing many small holes (perforations) and sometimes not. However, the defining characteristics of *U. rigida* are common among all its growth forms: the two cell layers of the blades are easily separable, like a deflated balloon, and the holdfasts are composed of many small, tough, dark rhizhoids that are absent in other *Ulva* species. *U. rigida* is common in intertidal and shallow sublittoral waters, often found in tidepools. This seaweed is able to withstand high variation in salinity and water chemistry and actually seems to prefer areas with freshwater input [6.32, 288].

Habitat. Epilithic, in the entire littoral zone to the sublittoral.

Distribution. *U. rigida* has a worldwide distribution in temperate and warm seas.

Uses and Compounds. *U. rigida* is often utilized as a fresh sea vegetable by many island cultures for its high nutrient content and fresh taste [6.288, 289]. This species is used to for animal feed [6.290, 291].

Green algae extracts are also very nutrient-rich and make a beneficial addition to natural cosmetic products. The polysaccharide ulvan is easily extracted from *U. rigida*. It is composed of β-(1,4)-xyloglucan, glucuronan, and cellulose in a linear arrangement. It corresponds to a water-soluble dietary fiber and is resistant to both human digestive tract enzymes and degradation by colonic bacteria. This polysaccharide cannot therefore be considered prebiotic; however, it could potentially be hydrolyzed to bioactive oligosaccharides [6.288, 292].

U. rigida have antigenotoxicity [6.293, 294], antihyperglycemic [6.293], immunomodulating [6.295],

antibacterial [6.201, 296–300], antioxidant [6.300–302], antileishmanial [6.303] activity.

Ulvaria obscura (Kutzing) Gayral
Synonym. *Monostroma obscurum* (Kützing) J. Agardh

Description. Thallus widely bladed, similar to that of *Ulva*, turning brown on dying; monostromatic blade; occurring not often; bipolar species [6.304].

Habitat. In sublittoral, at 3−17 m depth.

Distribution. NE Atlantic (Iceland and Norway to Portugal); Atlantic Islands; NW Atlantic (Alaska and Greenland to Washington); SW Atlantic (Argentina).

Uses and Compounds. *Ulvaria obscura* produces a dopamine that functions as antiherbivore defense [6.305, 306], and flavonoids with protective effect action against free radicals, protecting collagen surrounding of blood vessels. This species have antioxidant [6.307] activity.

- Order: **Ulotrichales**

Gayralia oxysperma (Kützing) K.L. Vinogradova
Synonym. *Monostroma oxyspermum* (Kützing) Doty

Description. Thalli forming leafy monostromatic blades from a few centimeter to a meter or more in length. Cells in the upper portion of blade polygonal and isodiametric, becoming more elongate toward base with long rhizoidal projections in holdfast region. In surface view, cells in groups of two or four; cells uninucleate with parietal chloroplast and single prominent pyrenoid traversed by thylakoids [6.32, 308].

Habitat. On rocks, boulders or on other seaweeds, older free floating; common through the entire littoral to sublittoral boundary, preferably in sheltered sites; tolerant to changing salinity.

Distribution. European coastlines (Atlantic, North Sea and Baltic); Atlantic coasts of North, Central and South America; Caribbean; East Pacific coastlines (Alaska to California), Japan, Mauritius, S Australia.

Uses and Compounds. Consumed as *green vegetable* (SE Asia, China) and used for animal feed [6.32, 109]. Have antiviral activity [6.309].

6.3.3 Domain/Empire Eukaryota, Kingdom Plantae, Phylum Rhodophyta (Red Algae)

- Class: Bangiophyceae
- Order: **Bangiales**

Bangia fuscopurpurea (Dillwyn) Lyngbye
Description. Gelatinous, unbranched, blackish-purple filaments, at first uniseriate later multiseriate, attached by rhizoidal outgrowths from basal and adjacent cells; cells with central star-shaped rhodoplast with pyrenoid [6.310].

Habitat. On rocks, wood, etc., as fleecy mat, especially at high tide level on exposed coasts in autumn and winter, disappearing in spring or early summer, at other times present as sparse filaments.

Distribution. NE Atlantic (Iceland to Senegal)); W Atlantic (Brazil and Argentina); Caribbean; W Pacific (Japan, China); NE Pacific (California, Mexico); Indo-Pacific/Indian Ocean; Australia.

Uses and Compounds. Consumed as *vegetable* [6.310]. Have antioxidant, antibacterial, antiviral, cytotoxic [6.205, 311] activity.

Porphyra leucosticta Thuret
Synonym. *Pyropia leucosticta* (Thuret) Neefus & J. Brodie

Description. Delicate membranous monostromatic reddish-brown fronds, becoming pink on drying, to 150 mm long, with very short stipe from basal holdfast [6.1, 2, 312].

Habitat. Usually epiphytic on larger algae, littoral to shallow sublittoral, spring to autumn, widely distributed, common.

Distribution. NE Atlantic (Norway to Portugal); Mediterranean; NW Atlantic (Canada and USA); SW Atlantic (Brazil); SE Atlantic (Angola).

Uses and Compounds. Produces high percentage of vitamin C and natural carotenoids, and therefore *P. leucosticta* could become a valuable source of raw material to obtain such compounds, which have mul-

tiple uses in the pharmaceutical field, cosmetic and food industry [6.313]; used for food [6.3, 314], and for IMTA aquaculture [6.315]. Extracts have high antioxidant [6.316], and low antiprotozoal, antimycobacterial, and cytotoxic [6.317] activity.

Porphyra linearis Greville

Description. Delicate, linear, membranous, purple-brown fronds, 20–40 mm (–200) mm long and 5–10 (–25) mm broad, usually simple with short stipe from basal holdfast; orange patches when reproductive [6.1, 318].

Habitat. Marine species, zone forming on rock in the upper intertidal and splash zone of semiexposed and exposed shores, generally distributed; a winter and spring annual appearing on semiexposed and exposed.

Distribution. Recorded throughout Northern Europe, from Norway to Portugal, Azores. Canada (Labrador) to USA (at least Connecticut).

Uses and Compounds. Used for food [6.3, 4, 319, 320], and for aquaculture [6.321–323]. Extracts have antimicrobial activity [6.130].

Porphyra umbilicalis (Linnaeus) Kützing

Common Names. Purple laver, Pink laver, Laver, Nori.

Description. A red alga (up to 40 cm across) with a circular (*P. umbilicalis*) or irregularly shaped (*P. leucosticta*), broad frond that is membranous but tough (Fig. 6.11). The plant attaches to rock via a minute discoid hold-fast, is greenish when young gradually changes into purplish red, and has a polythene-like texture. Another species is the *P. linearis*, with narrow stem that attaches the base and appears mainly in winter [6.1, 324, 325].

Habitat. On rocks, mussels, etc., in the littoral to splash zone, generally distributed, abundant, especially on exposed coasts.

Distribution. *P. umbilicalis* occurs in the North Atlantic. In the east, it is found in Iceland and has been recorded from Norway to Portugal and in the Western Mediterranean. In the West, *P. umbilicalis* is found from Labrador in Canada to the mid-Atlantic coast of the United States.

Fig. 6.11 Herbarium specimen of *Porphyra umbilicalis* (MACOI no. 110)

Uses and Compounds. *P. umbilicalis* is rich in protein, vitamins A, C, E, and B, and trace minerals, and also rich in omega-3 polyunsaturated fatty acids (EPA and DHA). It contains special compounds named *mycosporine-like amino acids* (MAAs) which are valuable in certain types of personal care products. Some of the favorable properties associated with compounds from *P. umbilicalis* are that it [6.3, 324, 325]: acts as a natural bio-protector against UVA-induced damage; prevents the formation of *sun burn cells* and premature photo-aging; protects cell structures, especially membrane lipids and DNA from damage by UV-induced radicals; helps in the re-equalization of lipid deficient skins; increases epidermal hydration; protects against *Trans Epidermal Water Loss*; improves intercellular cohesion; reinforces the skin barrier function; restores cell membrane structure after irritant damage; has oxygenating properties that helps revitalize stressed and fatigued skin; able to diminish the appearance of fine lines and wrinkles.

As a result, it is used in many different product applications, such as [6.325, 326]: antioxidant; daily UV protective skin care, sun care; anti-photo-aging care; cares for dry, reactive and sensitive skins; lip care; after sun care.

Specific products identified so far from France, Ireland, Italy, Spain, and United States utilizing *P. umbilicalis* include regenerating face creams and antiaging facial creams, facial masks, and aftershave balm. For food, it is sold in flaked and whole leaf form, as a nori substitute, as laver, and is used as an ingredient in several snack mixes and condiments. It is also used as a pet nutrition supplement [6.3, 4, 320, 325].

- Class: Florideophyceae
- Order: **Ahnfeltiales**

Ahnfeltia plicata (Hudson) E.M. Fries

Description. Perennial red seaweed which forms dense, tangled tufts (Fig. 6.12). The fronds are very fine, tough, and wiry with irregular or dichotomous branching and up to 21 cm in length. The holdfast is disk-like or encrusting, 0.5–2 cm in diameter. The fronds are dark brown when moist and appear almost black when dry. The uppermost branches are often green [6.327].

Habitat. On rocks, mid-littoral to sublittoral, especially common on sand-covered rocks, widely distributed, common.

Distribution. N and NE Atlantic (Greenland to Azores); SW Atlantic (Uruguay); NE Pacific (Alaska to Mexico); NW Pacific (Russia); SE Pacific (Chile); Indian Ocean; Antarctica and the Sub-Antarctic Islands.

Uses and Compounds. A source of so-called *Russian Agar* (agar of high quality and low sulfate content) [6.32, 328, 329]. *A. plicata* is one of the major seaweeds harvested for commercial colloid production as it produces a very high quality, low sulfate and used for many purposes. It forms a major component of Asian cooking, often showing up in soups and jellies. As a nonanimal derived thickening agent, *A. plicata* is also widely used for vegan products (such as marshmallows, gummy bears, cosmetics, etc.) in place of gelatin [6.330].

Fig. 6.12 *Ahnfeltia plicata* specimens

- Order: **Bonnemaisoniales**

Asparagopsis armata Harvey

Common Names. Harpoon weed, Harpoon-alga.

Description. Thallus of the gametophyte tufted, main axes cylindrical, denuded at the base, densely tufted apically, tufts with pyramidal outline, forming lateral brush-like tassels; some lateral branches develop into unbranched, elongated-pointed harpoon-like anchoring structures covered with barbed hooks (a characteristic feature of the species) which are usually pinnately arranged (Fig. 6.13). The tetrasporophyte (*Falkenbergia*

Fig. 6.13 Underwater photo of *Asparagopsis armata*

phase) is small, almost spherical tufts (similar to cotton balls) of multiseriate branching threads (microscope required) [6.32].

Habitat. Both phases readily reproduce vegetatively. Drift specimens of gametophyte readily attach to other algae by barbed branchlets, and produce new shoots; introduced from Southern Hemisphere [6.331].

Distribution. *A. armata* is native to the Southern Hemisphere (Australia and New Zealand) but has been introduced to the Northern Hemisphere, first recorded in Europe in 1925 and since spreading throughout the Channel Islands and all around Great Britain. *A. armata* is now found globally, from the Canary Islands to Morocco and throughout the Pacific and Indian Oceans [6.32, 331].

Uses and Compounds. *A. armata* extract is a powerful antioxidant with antibacterial qualities and is a valued ingredient in many cosmetic products. Present strong cytotoxicity against human cancer cell lines [6.62, 316, 332]. *A. armata* is also harvested or grown for the production of phycocolloid [6.333, 334].

The species has also been examined for its potential as a source of pharmaceutical and bioactive agents since its extracts contain anti-*Leishmania* [6.335], antioxidant [6.336], antiviral [6.337, 338], antifungal [6.62], antimicrobial [6.62, 336, 339, 340] compounds.

Asparagopsis taxiformis (Delile) Trevisan de Saint-Léon

Common Name. Cat's tail red seaweed.

Description. Thallus fluffy, fine, filamentous creeping mats or tufts, to 4 cm high, pale red to gray-pink; branching irregular to alternate. Branches cylindrical, occasionally moniliform (with segments swollen or bead-like), 30–80 µm diameter, central axial filament surrounded by 3 pericentral cells; cells commonly pointed at tips, twice as long as broad, each set rotated approximately 60°; apex with single prominent apical cell cutting off lens-shaped cell basally; holdfast initially disk-like, later becoming branched, tangled, creeping, forming filamentous mass. Tetrasporangia solitary on outer filaments, not in groups or series, formed from one pericentral cell of segment. Fluffy appearance and shaped like a Christmas tree. Grows 3–15 cm high [6.32, 341].

Habitat. A tropical/subtropical species; thalli are epilithic; in shallow sublittoral habitats with heavy water motion.

Distribution. Globally distributed in tropical and subtropical seas: E Atlantic (Azores, Madeira, Canary Islands, W Africa, Cape Verde Islands to Nigeria); W Atlantic (Brazil); Caribbean; W Pacific (Japan, China); NE Pacific (California, Mexico); Pacific Islands (Hawaii); Indo-Pacific/Indian Ocean; Australia, New Zealand.

Uses and Compounds. The species has been examined for its potential as a source of pharmaceutical and bioactive agents since its extracts contain antifouling and anticyanobacterial [6.342], antifungal [6.341], anticoagulant [6.343], and antimicrobial [6.341, 344, 345] compounds.

Used fresh in Hawaii as *limu kohu* (generic name for seaweed) to flavor meat and fish dishes [6.341, 346].

Bonnemaisonia hamifera Hariot

Common Names. Bonnemaison's Hook Weed; Pink cotton wool.

Description. Gametophyte plants occurring from March–June, brownish red, fronds feathery, with a slightly flattened axis to 1 mm wide and 350 mm long, attached to *Cytstoseira* and other algae by crosier-shaped, hook-like modified branches. Tetrasporophyte (*Trailliella* phase) plants occurring all year round, but most obvious in October–March, brownish red, much branched, filamentous, in dense cotton-wool-like tufts to 25 mm in diameter [6.347].

Habitat. Probably introduced from Japan at the end of the last century; gametophyte first found in Europe (Isle of Wight) in 1893, on rocks and other algae, lowest littoral and sublittoral.

Distribution. NE Atlantic (Scandinavia to Canary Islands); SE Atlantic (South Africa); Mediterranean; NW Pacific (Russia, Japan); NE Pacific (California, Mexico).

Uses and Compounds. Extracts of this species have antibacterial [6.348, 349], antioxidant [6.350], and antihypertension [6.351] activity.

- Order: **Ceramiales**

Alsidium helminthochorton (Schwendimann) Kützing

Common Name. Corsican moss.

Description. Upright radially organized polysiphonous thalli, up to 15 cm high, with cylindrical axes and progressively narrower distal branches. Branch apices abruptly tapering; trichoblasts spirally arranged on axis, present on every segment but soon deciduous; parenchymatous cortication occurs to near branch apex 6–8 pericentral cells. Lateral polysiphonous branches originate from trichoblast basal cell [6.352].

Habitat. Found on calm, shallow, photophilic biotopes.

Distribution. Mediterranean.

Uses and Compounds. In Mediterranean, the Greek physician, Stephanopoli, discovered in 1775 that the red seaweed *Alsidium helminthochorton*, found on the rocky shores of Corsica, have an efficient anthelmintic action [6.353–355].

Boergeseniella thuyoides (Harvey) Kylin

Description. Cylindrical, cartilaginous, tufted, deep brownish-purple fronds, to 150 mm high, from creeping rhizoidal base; fronds distichously bi-tripinnate, patent, short, of nearly uniform length giving branches a linear appearance; ramuli short, spinelike; polysiphonous, central siphon with 8–12 pericentral siphons and outer cortication of small, colored cells; articulations as broad as long, barely visible [6.356].

Habitat. On rock and epiphytic in shallow, wave-exposed pools in lower intertidal.

Distribution. NE Atlantic (Ireland and Britain to Morocco).

Uses and Compounds. Extracts of this species have antiviral [6.337, 357], and antibacterial [6.358] activity.

Bornetia secundiflora (J. Agardh) Thuret

Description. *B. secundiflora* is dark red in color, firm and rigid when fresh. The thallus is 5–20 cm high when erect, fan shaped with blunt tips (apices), much branched and tufted, with branches often curved over. The plant has a jelly-like texture. Branches are sparse at the base becoming denser toward the apices [6.359].

Habitat. *B. secundiflora* grows on boulders and bedrock, often under overhangs, from just below extreme low water to 3 m depth. It tolerates sand on rocks and moderately to extreme wave exposure.

Distribution. NE Atlantic (England to the Canary Islands, W Africa); Mediterranean.

Uses and Compounds. Extracts have antifouling activity [6.360, 361].

Bostrychia scorpioides (Hudson) Montagne

Description. Frond flexuous, dull purple, filiform, much branched, inarticulate, dotted, subdichotomous; the branches three or four times pinnated; pinnae and pinnulee patent; apices strongly rolled inward [6.362].

Habitat. On muddy shores near high-water mark, on lower stems of saltmarsh flowering plants, widely distributed, locally abundant.

Distribution. Atlantic shores of Europe, from England to Spain.

Uses and Compounds. Produces Sorbitol; the polyol sorbitol is known to occur naturally in the Rosaceae family especially in *Sorbus aucupria* and in the algae, e.g., *Bostrychia scorpioides*. It is used in the pharmaceutical industry for the treatment against constipation and it known to stimulate vascular contraction as well. Its use in the cosmetics industry, especially in the manufacture of toothpaste is an example of a well established use of carbohydrate and its derivatives in this sector [6.363].

Brongniartella byssoides (Goodenough & Woodward) F. Schmitz

Description. Soft, tufted, deep purplish red fronds, to 300 mm long; main axis well-defined, bi- or tripinnate, bearing alternate, distichous branches. Branches and branchlets articulated, with central siphon and 5–7 pericentral siphons, clothed with short, slender, repeatedly dichotomously branched, monosiphonous ramuli. Its color is light red brown to almost black when dry [6.32, 364].

Habitat. On stones and shells and epiphytic, lower littoral and sublittoral, spring and summer, generally distributed, common in NE Atlantic.

Distribution. NE Atlantic (Scandinavia to Portugal, North Sea, E Baltic Sea), Mediterranean Sea.

Uses and Compounds. Great antioxidant potential; strong cytotoxicity against human cancer cell lines [6.316].

Ceramium virgatum Roth

Synonym. *Ceramium rubrum* C. Agardh.

Common Names. Hornweed, Red hornweed.

Description. Small red seaweed growing up to 30 cm tall. It has a filamentous frond that is irregularly and dichotomously branched, with the branches narrowing toward pincer-like tips. The holdfast is a minute conical disk that extends into a dense mass of rhizoidal filaments. The plant is reddish brown to purple in color and has a banded appearance when viewed closely [6.1, 365].

Habitat. *C. virgatum* is both epilithic and epiphytic, often growing on the stipes and fronds of *Fucus* spp., *Mastocarpus stellatus*, and *Laminaria hyperborea* as well as on the leaves of *Zostera marina*.

Distribution. *C. virgatum* is common worldwide from the Americas to Europe (Atlantic), through the Mediterranean, down to South Africa, Asia, and Antarctica.

Uses and Compounds. *C. virgatum* is used as an extract for cosmetic products [6.313, 366], produces an agar-type polysaccharide [6.367], and have antiviral [6.368], antibacterial [6.276, 369–371], antioxidant [6.372], antialgal [6.373], antiprotozoal, antimycobacterial and cytotoxic activity [6.317].

Chondria capillaris (Hudson) M.J. Wynne

Synonym. *Chondria tenuisssima* (Withering) C. Agardh

Description. Thallus bushy, vivid purple to pale yellowish red, upright cylindrical main axes cartilaginous-firm, with numerous long, softer irregularly spirally arranged lateral axes, branching to the fourth degree; the recent branches also stand rather loosely, spindle-shaped tapering at both ends, the apices pointed and crowned by hair-thin filamentous tufts (magnifying glass required); plants with reproductive bodies appear more densely branched peripherally; discoid holdfast, on prostate axes additional rhizoids [6.32].

Fig. 6.14 *C. coerulescens* specimen (note the blue iridescence in water)

Habitat. On rocks, pebbles, and shells, in shallow water at wave-protected sites, at depths to about 6 m.

Distribution. NE and E Atlantic, Mediterranean, Caribbean, Indian Ocean (India, East Africa, Mauritius).

Uses and Compounds. Extracts have antioxidant and vermifuge [6.335] activity.

Chondria coerulescens (J. Agardh) Falkenberg

Description. *C. coerulescens* has bluish or yellowish fronds with blue iridescence (Fig. 6.14). The fronds are flexible and cartilaginous in texture, turning black when dry. Young axes show a striking turquoise iridescence when alive; the thalli consist of cylindrical erect axes or trailing tufts, and is 3–8 cm high when erect. The distinct main axis is 0.4–0.5 mm in diameter, branching sparsely at irregular intervals in a spiral pattern to 1–3 orders of branching. Branches are linear, often long and curve downward gradually tapering to a slender point, and reattach by secondary holdfast. The morphology shows relatively little variation except that some thalli consist only of inconspicuous isolated erect axes whereas others form dense tufts [6.1, 374].

Habitat. *C. coerulescens* is a sublittoral species, growing on pebbles in mud from extreme low water to 4 m depth.

Distribution. NE Atlantic (Ireland and Britain to Senegal); Mediterranean.

Uses and Compounds. Produces hemagglutinins [6.375].

Chondria dasyphylla (Woodward) C. Agardh

Description. The thallus is 10–21 cm high, reddish brown in color, with the primary erect axis initially arising from a discoid holdfast to 4 mm diameter, subsequently further erect axes arising from the same holdfast giving a clumped appearance. Short creeping branchlets are produced from the lowermost parts of erect axes, and become attached to the substrate by small rhizoidal haptera about 0.5 mm diameter. The thallus branching is irregularly radial, erect-patent with 3–4 orders of branching, ultimate branches arising every two to six (eight) axial cells. Ultimate branchlets are 250–500 µm diameter, the variation being a reflection of the robustness of the plant [6.376].

Habitat. Usually found in mid-littoral pools.

Distribution. NE Atlantic (Ireland to W Africa); Mediterranean, Caribbean, Indian Ocean.

Uses and Compounds. According to the results of *Khanavi* et al. study [6.377], hexane fraction of *Chondria dasyphylla* could contain phytosterols (fucosterol) with cytotoxicity against breast and colon cancer cell line. Extracts of this seaweed have larvicidal [6.378], antibacterial, antifungal, antiprotozoal, antiviral, antifertility, and hypoglycemic [6.218] activity.

Cryptopleura ramosa (Hudson) L. Newton

Description. A short thallus with a stout midrib arises from a discoid holdfast, widening as it branches into flattened red-brown or red-purple fronds to a height of 20 cm (Fig. 6.15). The fronds are thin and membranous, around 2.5 cm in width and may have a slight blue iridescence under water. Repeated branching gives it a bushy tangled appearance with the branches tapering to rounded tips. Morphology is variable and blades can be either erect or prostrate and broadly wedged or strap shaped. Margins may be smooth, undulating, and denticulate or hooked, frequently with a blue iridescence underwater [6.379].

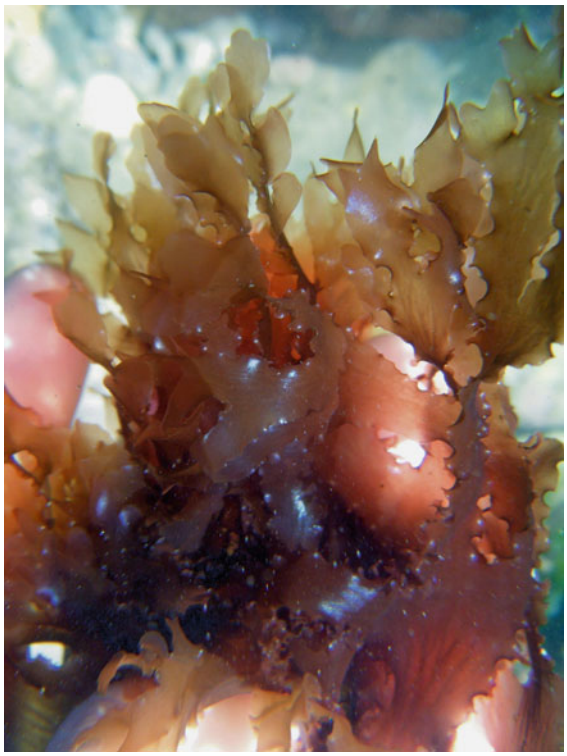

Fig. 6.15 Underwater photo of *C. ramosa*

Habitat. On rocks and often as epiphyte on stipes of *L. hyperborea*, lower intertidal and sublittoral, generally distributed, common.

Distribution. NE Atlantic (Scandinavia to Canary Islands); SW Atlantic (Brazil, Uruguay), Mediterranean Sea.

Uses and Compounds. Tested for biodiesel production [6.380]. Have antifouling [6.373], antiviral [6.381], algicidal [6.382], and antifouling [6.361] activity.

Dasya rigidula (Kützing) Ardissone

Description. Present irregular subdichotomous branching; variable cortication among the thallus; ocellate apex; and stichidia with four tetrasporangia per segment. Traditionally, the species of this genus are diagnosed depending on the branching pattern, presence of ocellate apex, and degree of cortication [6.383, 384].

Habitat. From the mid-littoral to deep waters.

Distribution. NE and E Atlantic (From France to Senegal); Atlantic Islands; West Atlantic; Caribbean; SW Atlantic (Brazil); Mediterranean.

Uses and Compounds. Have antibacterial activity [6.60].

Delesseria sanguinea (Hudson) J.V. Lamouroux

Common Name. Sea beech

Description. Membranous, bright crimson fronds, with cartilaginous, cylindrical, branched stipe, from thickened discoid holdfast, to 300 mm long (Fig. 6.16). Branches bearing spirally arranged, leaflike, ovate-lanceolate blades, each with short stipe and pinnately branched midrib, membranous portion monostromatic, margin undulate (on mature blades), entire; reproductive structures in small oval, stalked blades, borne on midribs in winter [6.385].

Habitat. On rocks, in deep shady lower intertidal pools and in the sublittoral.

Distribution. NE Atlantic (Scandinavia to Portugal, North Sea, Baltic Sea); Mediterranean (sporadically).

Uses and Compounds. *D. sanguinea* is used in the cosmetics industry for its anticoagulant properties and vitamin K content; the active principle being termed *Delesserine* [6.386, 387]. Have also anti-inflammatory and antiskin aging [6.387–389] activity.

Fig. 6.16 Herbarium specimen of *Delesseria sanguinea* (MACOI no. 2549)

Digenea simplex (Wulfen) C. Agardh

Description. Cylindrical axes (1 mm in diameter) rigid, with short secondary branches of the same diameter, carrying dense tufts of thin, straight ramuli; 5–25 cm. Cartilaginous at the apices. Light red (the naked base) to dark red (the branches). The gametophyte and the sporophyte are similar [6.390].

Habitat. Found year round in photophyle sheltered biotopes, from surface down to a few meters; frequently covered by epiphytes.

Distribution. Worldwide distribution in tropical and temperate waters: Mediterranean (with the exception of the Lion Gulf), tropical Atlantic, Red Sea, and Indo-Pacific.

Uses and Compounds. The active agent (Kainic acid), originally isolated in Japan from this species, but now manufactured commercially [6.32], has anti-helminthic activity. The extracts from these red algae have antifungal [6.204] activity.

Halopithys incurva (Hudson) Batters

Description. Tough, cylindrical, cartilaginous, shaggy, dark red fronds, 250 mm long. Main branches alternate or subdichomous, simple or pectinate in lower parts, much branched above, often curved and hooked. Branches with usually double row of short, pointed ramuli on the upper side, ramuli straight, curved or hooked, slightly narrowed at base; axis of 1 central, 5 pericentral siphons, with several layers of cortical cells, outermost small, colored; articulations visible, shorter than broad [6.32].

Habitat. On rocks, mid-littoral pools to subtidal.

Distribution. Warmer NE Atlantic (Ireland to Canary Island); Mediterranean.

Uses and Compounds. Have antibacterial [6.358, 391, 392], antioxidant [6.393], antitumor [6.394], and antiviral [6.357] activity.

Heterosiphonia plumosa (J. Ellis) Batters

Description. *H. plumosa* is a red to deep crimson seaweed which appears black when dried. This species has a flattened, fern-like appearance with a hairy thallus

growing from a discoid holdfast. The fronds are flat or slightly cylindrical up to 20 cm in length and 0.5 cm in diameter at the base, tapering toward the apex. The primary branching from the main frond occurs in a single plane, and is alternately, yet irregularly spaced with up to 1 cm between each branch. Each branch is bare at the base, with the rest bearing an irregular and alternately arranged series of smaller secondary branches. The secondary branches are progressively shorter toward the apex, and each branch bears numerous pointed branchlets giving an overall tufted and feather-like appearance [6.395].

Habitat. On rocks and epiphytic, low intertidal pools and sublittoral, southern and western shores, common in the south, rare in the north.

Distribution. NE Atlantic (Scandinavia to Portugal).

Uses and Compounds. Have high antioxidant activity [6.316].

Hypoglossum hypoglossoides (Stackhouse) F.S. Collins & Hervey

Description. Membranous, rose-pink fronds, 20–200 (300) mm long, arising from a discoid base. Frond linear-lanceolate, with well-marked midrib and thin membranous margins, 1–5 (8) mm wide, repeatedly branched irregularly from midrib; fronds with pointed apices, margins without microscopic veins, monostromatic except in midribs [6.396].

Habitat. On rocks and epiphytic, lower intertidal and sublittoral to 30 m, most abundant in *L. hyperborea* forests.

Distribution. NE and E Atlantic (Scandinavia to Portugal, Azores, Canary Islands, Cap Verde Islands); NW and W Atlantic (North Carolina to West Indies): Mediterranean.

Uses and Compounds. Have antimicrobial activity [6.397].

Laurencia microcladia Kützing

Description. Thallus erect, flexible, soft texture, forming dense tufts up to 15 cm in length. The thallus has greenish-yellow and pinkish apices easily visible. Flaccid consistency does not adhere completely to the herbarium sheet when dry; thalli fully cylindrical with 385–410 µm in diameter; branching irregularly, alternating, dense in the upper two-thirds of the plant, to three branching orders. Adhered to the substrate by rhizoids, from which emerge branches ending in small secondary locking disks [6.398].

Habitat. Present in the mid-littoral rock bottom and up to 1–2 feet deep in the sublittoral exposed coasts. Often found in very beaten but has also been collected in puddles of lower mid-littoral and sublittoral.

Distribution. NE Atlantic (from France to Mauritania); Atlantic Islands (Azores, Canary Islands); Mediterranean; NW Atlantic (USA); Caribbean; SW Atlantic (Venezuela, Brazil).

Uses and Compounds. Have antimitotic and cytotoxic, [6.62, 399–403], antiparasitic [6.402, 404, 405], and antifungal [6.62] activity.

Laurencia obtusa (Hudson) J.V. Lamouroux

Description. Plants 1.5–2.5 cm tall, bushy, with green or yellow axes and rose branchlets, main stems long, which are sparingly alternately branched, 0.75–1.50 cm, but above are increasingly closely paniculately branched and spreading, the smallest branches and the short, truncate, ultimate branchlets opposite or subverticillate, 0.5–0.75 mm diameter; tetrasporangia in a band below the apex of the hardly modified branchlets [6.406].

Habitat. On solid substrata, in extremely shallow locations in calm shallow water, also in exposed locations within the intertidal zone.

Distribution. Worldwide in warm temperate to tropical seas.

Uses and Compounds. Have antibacterial [6.32, 407–410], antimalarial [6.411, 412], antitumor [6.316, 413, 414], antioxidant [6.316, 410, 415], and antifouling [6.416] activity.

Laurencia pyramidalis Bory de Saint-Vincent ex Kützing

Description. Globose tufts of brittle, cartilaginous, narrow, cylindrical, reddish brown to yellowish-red fronds, 150 mm long, from small discoid base (Fig. 6.17). Axis simple, branches patent, often opposite, spirally arranged, shorter toward apex giving regular pyramidal outline [6.417].

Fig. 6.17 Underwater photo of *Laurencia pyramidalis*

Habitat. Usually epiphytic, annual, lower intertidal.

Distribution. NE Atlantic (From Ireland and Britain to Portugal); NW Mediterranean.

Uses and Compounds. Have antioxidant and antimicrobial activity [6.410].

Laurencia viridis Gil-Rodríguez & Haroun

Description. Thallus annual, cartilaginous, mainly greenish with pink tips, with erect axes averaging 4–8 cm (range 2–15 cm) long, having alternate or helicoid branching only in the upper two-third of the thallus; ovoid spermatangia produced in cup-shaped receptacles; cystocarps urceolate, and sessile; tetrasporangia in parallel abaxial rows [6.418].

Habitat. Mainly restricted to exposed low intertidal sites, growing on rocks with strong wave action.

Distribution. Macaronesian region (Azores, Madeira, Selvages, Canaries, and Cape Verde).

Uses and Compounds. Have cytotoxic and antitumor [6.419–423] activity.

Nitophyllum punctatum (Stackhouse) Greville

Description. Delicately membranous, rose-pink fronds with an elongate fan-shaped outline, margins distinctly frilly, to 40 mm or, exceptionally, to 1 m, sessile or shortly stipitate (< 2 mm long); frond veinless, undivided or deeply subdichotomously divided to the base; apices blunt or rounded, often ribbon-like (Fig. 6.18). Gametophyte plants form rounded spots to 5 mm in diameter whilst tetrasporophyte plants form characteristically elongated spots [6.424].

Habitat. In littoral pools in winter and early spring and in the sublittoral (15 m) on cobble or other mobile surfaces and on bedrock in the lower parts of kelp forests from spring to summer.

Distribution. NE Atlantic (Norway to Canary Islands); NW Atlantic (N America); Caribbean, Mediterranean and Indian Ocean (India, Egypt); Sub-Antarctic.

Uses and Compounds. Potential bio-insecticides against mosquito larvae [6.66].

Osmundea hybrida (A.P. de Candolle) K.W. Nam

Description. Cylindrical, cartilaginous, tufted, dark purple to greenish-yellow fronds, 150 mm long; main axis with repeatedly pinnate branching, branches mostly alternate, shorter toward apex giving pyramidal outline; ultimate ramuli short, patent, truncate; axis monosiphonus with elongated pericentral cells and 1–2 outer layers of rounded colored cells; apex con-

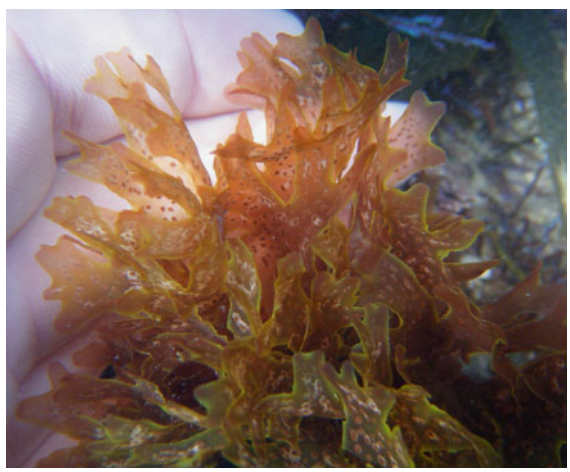

Fig. 6.18 Underwater photo of *N. punctatum*

cave, with ephemerally colorless dichotomous hairs surrounding apical cell [6.425].

Habitat. On stones and shells, sometimes epiphytic, upper intertidal, widely distributed, locally common.

Distribution. NE Atlantic (Britain to Morocco); SW Atlantic (Brazil).

Uses and Compounds. Perform antibacterial activity [6.340, 391].

Osmundea pinnatifida (Hudson) Stackhouse

Common Name. Pepper dulse.

Description. A small red alga (up to 8 cm in length), it is tough and cartilaginous with flattened fronds (Fig. 6.19). Branching is alternate and occurs in one plane only, with branches becoming shorter toward their apex and broadly rounded. The plant is highly variable in size and coloration depending upon its location on the shore. Higher shore plants are generally dwarfed and yellow green in color, owing to exposure to high levels of sunshine while on the lower shore they are reddish brown [6.1, 426].

Habitat. On rocks, perennial, throughout intertidal, often as flattened rosettes covering exposed rocks, also sublittoral, generally distributed, abundant.

Fig. 6.19 *Osmundea pinnatifida* specimen

Distribution. NE Atlantic (Ireland and Britain to Senegal); Atlantic Islands; SW Atlantic (Brazil); Mediterranean (Turkey); SW and East Asia, North America, South America, Australia, and New Zealand.

Uses and Compounds. The marine polyether triterpenoid dehydrothyrsiferol 298, originally isolated from the red alga *Laurencia pinnatifida* was shown to induce apoptosis in estrogen-dependent and independent breast cancer cells [6.419, 420]. Have antibacterial [6.27, 358, 427, 428], antioxidant [6.234, 429], antileishmanial [6.430, 431], anticancer [6.225, 432], antifouling [6.257, 275], insecticidal, and antifungal [6.226] activity.

This aromatic seaweed is dried and used as a pepper- or curry-flavored spice in Scotland, Ireland, and Portugal (Azores Islands) [6.3, 426].

Osmundea truncata (Kützing) K.W. Nam & Maggs

Description. *O. truncata* is much less common than *O. pinnatifida*, is more pinnately branched, generally grows epiphytically, and rapidly degenerates on collection [6.433].

Habitat. On rocks, perennial, throughout intertidal, often as flattened rosettes covering exposed rocks.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antimicrobial activity [6.130].

Pterosiphonia complanata (Clemente) Falkenberg

Description. Thallus with prostate and erect axes, the erect ones flat-compressed and with distichous, alternate pinnate branching (Fig. 6.20); brownish-red color, flexible, and cartilaginous texture; attached by rhizoids which form discoid adhesive structures [6.434].

Habitat. On rocks and as epiphyte on other algae, in the entire intertidal zone and below.

Distribution. Warm to tropical regions of the Atlantic and Mediterranean.

Uses and Compounds. Extracts have antiviral [6.357], and antibacterial [6.358, 435] activity.

Fig. 6.20 *Pterosiphonia complanata* specimen

Ptilota serrata Kützing

Synonym. *Ptilota pectinata* (Gunnerus) Kjellman

Description. *P. serrata* is a typically dark red and less than 5 cm tall seaweed. It is branched in opposite pairs, often with wavy spandrels protruding from the ends of the branches. Simple branchelets with serrated margins on one side stand opposite to composite-pinnately divided lateral branches on the other [6.32].

Habitat. Understory alga in the shallow sublittoral becoming dominant beyond 10 m.

Distribution. North Atlantic (Greenland, Svalbard, Faroe Islands, Norway), and N Pacific (Alaska to Washington).

Uses and Compounds. Has hemagglutinating activity [6.375].

Rhodomela confervoides (Hudson) P.C. Silva

Description. Cylindrical, cartilaginous, bushy, brownish-red fronds, to 300 mm long. Much branched, repeatedly, irregularly. Branches clothed with small, pinnate branchlets and simple, pointed ramuli. In winter, branchlets are shed and frond appears bare, spiky, and very different from summer appearance. Central siphon surrounded by elongated cells with the outer band of small colored cells, articulations not visible [6.436].

Habitat. On rocks and shells, intertidal pools at all levels; widely distributed, common.

Distribution. Warmer NE Atlantic (Ireland to Canary Islands); Mediterranean.

Uses and Compounds. Extracts have antibacterial [6.437], antifungal [6.438], antihyperglycemic [6.439], cytotoxic [6.440], and antioxidant [6.441–443] activity.

Rytiphlaea tinctoria (Clemente) C. Agardh

Description. Thallus red, very dark, cartilaginous, abundantly branched, formed on the principal axes, flattened branches alternate provided in turn with short ramuli ends more or less curved. Structure–uniaxial quickly becoming complex by recloisonnement; in cross section showing the axial cell medulla sometimes indistinct, surrounded by 5 pericentral cells; thallus with apical growth [6.444].

Habitat. In the upper sublittoral, occasionally in the mid-littoral.

Distribution. NE Atlantic (France to Mauritania); Atlantic Islands; Mediterranean.

Uses and Compounds. Extracts are used as colorant [6.445]. Extracts have antimicrobial activity [6.130].

Spyridia filamentosa (Wulfen) Harvey

Common name. Feathery seaweed.

Description. Plants, dull brown to pale pink, usually less than 20 cm tall when in low turf mats, up to 18 cm tall in areas of good water motion; fastened by small discoid holdfast, the lower portions of plants and the lower branches tending to entangle; one to several erect axes, branching irregularly dichotomous or completely irregular, at times also alternate or unilateral; axes crisp, brittle, branching to 4–5 or more orders, the last orders short, becoming matted and giving plants fuzzy appearance; plants often look whitish or lightly calcified, but calcification from crustose coralline algae or sediment, not inherent in plants [6.446].

Habitat. On solid substrates in calm protected areas or adrift; to 8 m deep; common on eroded coral in sandy areas, but occurring in sandy mud as well, in matted intertidal turfs on coral and basalt.

Distribution. NE and E Atlantic (from Ireland and Britain to Sierra Leone); Atlantic Islands; NW and W

Atlantic (USA, Mexico); Caribbean; SW Atlantic; Indian Ocean; SE Pacific; Australia and New Zealand.

Uses and Compounds. Extracts have antibacterial [6.60, 421, 447–449], and antitumor [6.421] activity.

Vertebrata lanosa (Linnaeus) T.A. Christensen

Synonym. *Polysiphonia lanosa* (Linnaeus) Tandy.

Common Names. Wrack siphon weed, Many tubed gable weed.

Description. *V. lanosa* is a filamentous red alga that grows as an obligate epiphyte on *Ascophyllum nodosum*. The short, cylindrical, cartilaginous fronds form beautiful dense reddish purple tufts along the ochre colored thalli of their host. Branches of this alga are dichotomous with pointed tips. Formerly classified as *Polysiphonia lanosa*, it lacks the distinctive banded pattern typical of *Polysiphonia* species. As an obligate epiphyte, *V. lanosa* cannot grow except attached to other seaweed species by tiny structures called rhizoids that grow into the tissue of the algal host. *A. nodosum* is the most frequent host, though *V. lanosa* is sometimes found on *Fucus* species such as *F. vesiculosus* as well, so it is abundant where these species thrive [6.450].

Habitat. Hemi-parasitic on *A. nodosum*, more rarely on *F. vesiculosus*, never on rock (appearances can be deceptive as it can grow on old stalks of both species) in the sheltered mid-littoral, generally distributed, usually abundant where *Ascophyllum* occurs. *Vertebrata* is generally infected with a tiny, more or less colorless parasitic red alga called *Choreocolax polysiphoniae*, to which it is closely related [6.451].

Distribution. *V. lanosa* is fairly common in the N. Atlantic, along the coasts of North America and Europe.

Uses and Compounds. *V. lanosa* is valued for its strong antioxidant and anticancer properties, used in supplements and health and beauty products [6.450]. Extracts of this species have cytotoxic [6.452], antioxidant [6.453], antibacterial [6.454], antifungal [6.455], and antifouling [6.373, 454] activity.

- Order: **Corallinales**

Amphiroa beauvoisii J.V. Lamouroux

Description. More or less erect, sometimes bushy. Size: 2–5 cm high. Branching: dichotomous, occasionally irregular. Intergenicula: tapered toward the base and flattened at the apices (up to 3 mm long, the lower diameter 0.6–0.65 mm, the upper diameter 0.4 mm) apices characteristically knife-like and striped. Geniculа: with 2 (3–4) rows of cells. Color of living specimen: pink, pink-violet. Color of dried specimen: pink-violet to white [6.456].

Habitat. Like that of *A. rigida*, species of sheltered environments, on sublittoral, from surface to 30 m deep.

Distribution. Widely distributed in tropical and subtropical seas.

Uses and Compounds. Extracts have antibacterial activity [6.457].

Amphiroa cryptarthrodia Zanardini

Description. Thallus erect, bushy; endophytic base on other calcareous algae (particularly on *Lithophyllum* species). Size: 2–4 cm high. Dichotomous branching, regular and *geometric* (angle of about 90°); branch junctions usually not coinciding with intergenicula. Branches lying on different planes, slightly swollen apices. Intergenicula cylindrical with rare annular swellings, tapered on the upper part of fronds 1–4 (4.5) mm long, 0.25–0.6 mm in the lower diameter, upper diameter 0.15–0.18 mm. Dark red to pink violet (rare), apart from lighter apices due to annular ridges [6.458].

Habitat. On the rocks in sheltered waters where they often form large lawns, in the same station of *A. rigida* (but less frequently); also reported in tide pools.

Distribution. NE Atlantic (from France to Senegal); Mediterranean.

Uses and Compounds. Used on functional foods and pharmaceuticals [6.205]; extracts have antifungal and antimitotic activity [6.62].

Amphiroa fragilissima

Description. Thalli with dense cushion-like tufted growth, very brittle to strong calcification; branches cylindrical, thin, segmented, rather regularly forking, sometimes also trichotomous, the angles between two fork branches usually rather wide (broadly Y-shaped); the segments are slightly swollen at the endings; yellowish red to whitish pink [6.32].

Habitat. Common in shallow water, especially in seagrass meadows and rock hollows; to 10 m depth.

Distribution. Widely distributed in tropical and subtropical seas.

Uses and Compounds. Used on functional foods [6.109], and the extracts have antiviral [6.237], antibacterial [6.40], cytotoxic and antioxidant [6.459], oxytocic and espamogenic [6.460] activity.

Amphiroa rigida J.V. Lamouroux

Common Name. Twig algae.

Description. Thallus growth lawn-like, segmented branches terete, brittle (calcified), usually forking and simultaneously laterally branching, narrowing toward the tip, segments distally inconspicuous (Fig. 6.21); purple-like conceptacles mostly numerous, especially on peripheral branches [6.32].

Habitat. Species recorded in shallow and deep waters in sheltered and shaded sites; sometimes found on rocky pools in exposed areas; mainly on sublittoral.

Distribution. Cosmopolitan species, present in warmer and tropical seas.

Fig. 6.21 *Amphiroa rigida* specimens

Uses and Compounds. Extracts have antimicrobial [6.391], antifungal, cytotoxic, and antimitotic [6.62] activity.

Corallina elongata J. Ellis & Solander

Description. Whitish pink to reddish lilac, calcified, articulated fronds, fish-bone-like arrangement, to 50 mm high, axis compressed, repeatedly pinnate from discoid base, more abundantly and regularly branched than *C. officinalis*; articulations small [6.1].

Habitat. On rocks, exposed coasts, lower intertidal, southern and western coasts, occasional.

Distribution. NE Atlantic (Ireland and Britain to Senegal); Mediterranean.

Uses and Compounds. Used for R-phycoerythrin extraction and for functional foods [6.461]. Extracts have antimicrobial [6.228], antifungal and antiviral [6.62] activity.

Corallina officinalis Linnaeus

Common Name. Coral weed.

Description. Whitish pink to lilac, calcified, articulated fronds, 60–70 (–120) mm high, axis cylindrical to compressed, repeatedly pinnate from and expanded discoid base, branching often irregular (Fig. 6.22). Growth form very variable often stunted. In unfavorable habitats erect system vestigial, but extensive base may be present [6.1].

Habitat. On rocks, mid-littoral pools and drainage runnels, lower intertidal and shallow sublittoral, widespread and abundant, especially on exposed coasts.

Distribution. *C. officinalis* has been recorded widely in the north Atlantic, from northern Norway to Morocco and from Greenland to Argentina. It is found along the Atlantic coasts of North America from Labrador south to Connecticut and Maryland in the United States. *C. officinalis* has been reported in Japan, China, Australasia, South Africa, and the Arctic Sea.

Uses and Compounds. *C. officinalis* is a very popular ingredient among cosmetics and health and personal care companies. There are known sellers of *C. officinalis*-based products in the United States, China, Italy, France, Switzerland, and Ger-

Fig. 6.22 Underwater photo of *C. officinalis*

many. These are products for men and women, and include toners, moisturizers, cleansers, emulsions, essences, astringents, eye creams, wash gels, shower gels, shave balm, hydration sprays and creams, and masks [6.462]. Extracts have antimicrobial [6.201], anthelmintic [6.354], and antioxidant [6.335, 463] activity.

Haliptilon attenuatum (Kützing) Garbary & H.W. Johansen

Description. Thallus habit: erect, bushy with dense not entangled fronds (D). Size: 2–2.5 cm high. Branching: alternate, dichotomic-pinnate (D-A) (whorled); distal dichotomous branchlets. Intergenicula: cylindrical, tapered near apices, 0.2–0.4 (0.5) mm long, 0.07–0.1 mm in diameter. Genicula: 60–200 µm long. Color of living specimen: from red scarlet to purple. Color of dried specimen: from white to ivory yellow [6.464].

Habitat. Epiphytic species often on *H. virgatum*; mainly on sublittoral.

Distribution. Alboran Sea: Morocco; Middle Western Mediterranean Sea: Italy; North Adriatic Sea: Italy, Croatia.

Uses and Compounds. Extract has antibacterial activity [6.60].

Jania adhaerens J.V. Lamouroux

Description. This species is small (4–5 mm high), heavily calcified, and forms intricately entwined clumps. The branches are pinkish-red color, regularly dichotomous, terete or slightly compressed, and slightly curve downward. Terminal segments are acuminate. This is an epiphytic species, decumbent on other seaweeds such as the species of Sargassaceae, growing in the sublittoral zones along shorelines moderately exposed to water movement [6.465].

Habitat. Growing in the sublittoral zones along shorelines moderately exposed to water movement.

Distribution. Atlantic Islands; Mediterranean; SW and SE Atlantic; Caribbean; Indo-Pacific Oceans; Australia.

Uses and Compounds. Extracts have antigenotoxic [6.466], antifungal, antiviral, and antimicrobial [6.62, 103] activity.

Jania rubens (Linnaeus) J.V. Lamouroux

Description. Slender, rose-pink, articulated, calcified fronds, to 50 mm high; repeatedly dichotomously branched, luxuriant specimens secondarily pinnate (Fig. 6.23). Segments cylindrical, to 120 µm diameter, those bearing branches somewhat compressed, to 180 µm diameter. Fixed by small conical disk,

Fig. 6.23 *Jania rubens* specimens

but spreading vegetatively by developing attachment disks from branches in contact with solid substratum [6.467].

Habitat. Epiphytic, found only growing epiphytically on the brown algae *Cladostephus* and *Cystoseira* lower littoral, often abundant.

Distribution. The range of *J. rubens* stretches from the Baltic Sea and Norway in the north to Portugal, Senegal, East Africa, and the Azores in the south; it is also found in the Mediterranean, the Canary Islands, Indian Ocean, Black Sea, and China Sea, as well as around Brazil.

Uses and Compounds. *J. rubens* has recently starting to be used by cosmetic companies as an extract in natural beauty products. It is prized for its ultra-moisturizing and protective properties due to the high concentration of minerals and trace elements present in its tissue. One provider notes that *J. rubens* is characterized by a concentration of minerals and trace elements 20 000 to 40 000 times greater than that of seawater, thus giving it re-mineralizing properties. It is also used in skin whitening and hydrating products [6.468].

Extracts of this species have antitumor [6.126], bio-insecticide [6.463], antimicrobial [6.469, 470], antihelmintic and cytotoxic [6.354, 471], antifouling [6.472], and antifungal [6.62] activity.

Jania rubens var. *corniculata* (Linnaeus) Yendo

Description. Thallus erect, bushy, attached by a basal crustose disk. Size: 1–4 cm high; dichotomous branching, abundant, and entangled branches. Intergenicula: cylindrical, slightly compressed, bearing basal, sometimes articulated projections (horn-like); becoming wider at distal apex, 0.40–0.75 mm long (times) 0.10 mm in diameter. Genicula: irregular filaments 90–160 µm. Color of living specimen: from violet pink more or less intense. Color of dried specimen: white to yellow ivory [6.473].

Habitat. Epilithic or epiphytic on other algae (particularly *Cladostephus* species), in well-lit sites. Bathymetric

Distribution. From surface to shallow waters (3 m).

Distribution. NE Atlantic (from Ireland and Britain to Morocco); Mediterranean.

Uses and Compounds. Extracts have antioxidant and antimicrobial activity [6.474].

Lithophyllum byssoides (Lamarck) Foslie

Synonym. *Lithophyllum lichenoides* Philippi

Description. *L. byssoides* commonly grows in the intertidal zone. Living specimens, gray–violet in color, form characteristic cushion-like clumps, composed of densely interweaving and anastomosing lamellae which are more or less smooth on the dorsal surface and ridged on the ventral one. Growth form with spiniform lamellae has also been observed. Thalli grow by forming concretions of approximately 10 to 20 cushion-like dumps [6.475].

Habitat. It grows on rocky substrata at mid-littoral.

Distribution. NE Atlantic (Spain, Portugal to Senegal); Mediterranean (Italy).

Uses and Compounds. Extracts have antifungal activity [6.62].

Lithothamnion corallioides (P.L. Crouan & H.M. Crouan) P.L. Crouan & H.M. Crouan

Common Name. Maerl.

Description. An unattached, fragile, alga with a calcareous skeleton. It is very similar to and often confused with *Phymatolithon calcareum*. Its form is very variable but it commonly occurs as highly branched nodules forming a 3D lattice. Individual plants may reach 4–5 cm across and are bright pink in color when alive but white when dead [6.476].

Habitat. Typically found at less than 20 m depth on sand, mud or gravel substrata in areas that are protected from strong wave action but have moderate to high water flow. Usually found as unattached plants.

Distribution. NE Atlantic (Norway to Mauritania); Mediterranean.

Uses and Compounds. Used as fertilizer and as a constituent of pharmaceutical preparations [6.477, 478]. Extracts have antifungal activity [6.62].

Lithothamnion glaciale Kjellman

Common name. Knobby coralline-crust algae.

Description. Bright pink to purplish, minutely white-speckled calcareous crust, becoming very thick, usually with abundant regular or irregular branches, free or attached to substratum [6.479].

Habitat. On rocks, pebbles, shells or free-living, lower intertidal (north-east coasts) and sublittoral to deeper waters.

Distribution. In the NE Atlantic from the British Isles north to Arctic Russia including the Faeroe Isles, Iceland and western Baltic; in the NW Atlantic from Cape Cod north to Arctic Canada and Greenland; also northern Japan and China in the western Pacific.

Uses and Compounds. Commercial extraction for use as a soil conditioner on acidic ground, as an animal food additive, for the filtration of acid drinking water and in pharmaceutical and cosmetic products [6.386, 479]. Extracts promote the induction of metamorphosis of the sea urchin larvae (*Strongylocentrotus droebachiensis*) [6.480].

Mesophyllum lichenoides (J. Ellis) M. Lemoine

Description. Pale to dark purple thin, brittle, leafy calcified fronds, attached at base, margins free, lobed. Fronds semicircular, concentrically banded (Fig. 6.24). Reproduction takes place in winter and spring in small, wart-like conceptacles [6.481].

Habitat. Epiphytic on *C. officinalis* in mid-littoral pools.

Distribution. NE Atlantic (from Ireland to Mauritania); Mediterranean.

Uses and Compounds. Used as a soil conditioner on acidic ground [6.386]. Extracts have antifungal, cytotoxic and antimitotic activity [6.62].

- Order: **Gelidiales**

Gelidiella acerosa

Description. *G. acerosa* is a red algae with yellowish brown, tufted, entangled, erect, cylindrical thalli reaching 6 cm tall. The ends of the fronds are pinnately divided, giving it a feathered appearance. Branch tips of *G. acerosa* terminate in a single apical cell. Short, thick branches attached to the substratum by stoloniferous rhizoids form dense mats along shallow reefs. *G. acerosa* is found on surf-exposed and moderately wave-sheltered rocks and reefs in the lower mid-littoral and the sublittoral zone, and in tide pools at higher levels on the shore [6.482, 483].

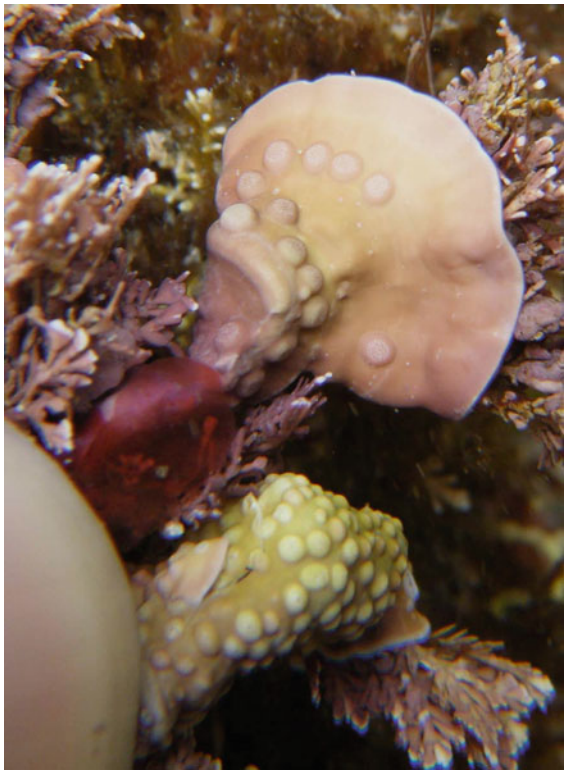

Fig. 6.24 Underwater photo of *Mesophyllum lichenoides*

Habitat. In tide pools, attached to rock reefs at depth of 0–1 m; in association with *Gelidiopsis* and *Gelidium* species.

Distribution. Atlantic Islands: Azores and Cape Verde Islands.

Uses and Compounds. *G. acerosa* is an important commercial species for agar production [6.484–487]. It has also been used traditionally for the preparation of agar-forming hard jellies, or eaten fresh and also prepared as a salad vegetable or cooked and eaten mixed with rice [6.4]. However, over recent years, *G. acerosa* has become a key ingredient in a staggering number of products [6.109]. It is used in nearly 150 hair products, including: hair color and bleaching; shampoos and conditioners; styling mousse, foam, gels, sprays, and lotions; hair relaxers and detanglers; antidandruff hair masks [6.483].

Extracts have antifungal [6.488], contraceptive [6.489], antioxidant [6.490], antifungal, and antibacterial [6.490–493] activity.

Gelidiella ramelosa (Kützing) Feldmann & G. Hamel

Description. Plants occur as turfs to 1–2 cm in height, with prostrate stolons attached by clusters of rhizoids to rock. Erect axes are irregularly pinnately branched and terete to slightly compressed. Structurally, the medulla is pseudoparenchymatous with no discernible central axis, and rhizines are absent. Spermatangia occur in surface sori. Tetrasporangia are borne in irregular whorls in terete, basally constricted stichidia that are lateral on erect axes [6.494].

Habitat. Growing as sparse turf amongst coralline algae.

Distribution. NE Atlantic (from France to Portugal); Mediterranean; Australia.

Uses and Compounds. Extracts have cytotoxic and antimitotic activity [6.62].

Gelidium corneum (Hudson) J.V. Lamouroux

Synonym. *Gelidium sesquipedale* (Clemente) Thuret.

Common Name. Kanteen.

Description. Dark red, hard consistency, cartilaginous, and may reach 30 cm in length thalli. Branches with obtuse apex and attenuated at the base (Fig. 6.25).

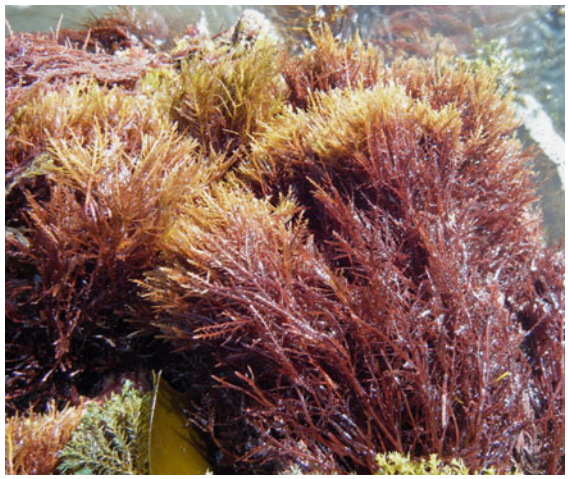

Fig. 6.25 *Gelidium corneum* specimens

This species typically forms dense stands of clumped fronds, often under a kelp canopy [6.1].

Habitat. On rocks and tide pools in exposed areas.

Distribution. E Atlantic (Britain to South Africa); W Atlantic (USA to Brazil); Mediterranean; Indo-Pacific zone; Australia.

Uses and Compounds. One of the main sources of Agar [6.495, 496]. Extracts are used for the production of edible films containing carvacrol for ham packages, and other edible films with antimicrobial effect [6.497–500]. The antimicrobial and antioxidant activity was demonstrated in several studies [6.269, 501, 502].

Gelidium pulchellum (Turner) Kützing

Description. Cartilaginous, regularly or irregularly bipinnate, dark red-brown fronds, 50–100 mm high, arise from a creeping base. Main axes narrow, cylindrical, somewhat flattened above. Ultimate branches short, pointed at first, later ± spathulate, particularly when reproductive; appearance variable with Habitat and time of year [6.503].

Habitat. Abundant in and around tidal pools in mid- and lower littoral in high-light situations; generally epiphytic on *C. officinalis*; widely distributed, common.

Distribution. NE Atlantic (Ireland and Britain to Portugal and Morocco). Australia.

Uses and Compounds. Source of agar [6.3, 503, 504]. Extracts have antibacterial [6.358], and antiviral [6.357] activity.

Gelidium pusillum (Stackhouse) Le Jolis

Description. Cartilaginous, purplish, or blackish red, turf-forming, 2–10 mm high, arising from extensive creeping base and incorporating shell debris and small mollusks; erect fronds flattened and leaf-like and 0.5–2 mm broad [6.505].

Habitat. Marine and estuarine species, on rock pools and sandy rocks, particularly in places with widely varying salinities such as upper shore species.

Distribution. NE and E Atlantic (from Norway to Benin); Mediterranean; EW Atlantic; Caribbean; SE Atlantic; SW Atlantic; Indian Ocean; SW Pacific.

Uses and Compounds. Source of agar [6.505]. Extracts have antibacterial [6.358], and antifungal [6.62] activity.

Gelidium spinosum (S.G. Gmel.) P.C. Silva

Description. Small alga, cartilaginous, crimson to purplish red, 20–60 mm long. Main axes distinctly flattened, often narrower at base, ultimate branches short, often opposite, spine-like or spathulate [6.32].

Habitat. In sheltered locations below the tidal mark.

Distribution. NE Atlantic (Ireland and Britain to Canary Islands); Mediterranean; Indo-Pacific (Indonesia).

Uses and Compounds. Source of Agar [6.506]. Extracts have antiviral, cytotoxic, and antibacterial activity [6.205, 507].

Pterocladiella capillacea (S.G. Gmelin) Santelices and Hommersand

Synonym. *Pterocladia capillacea* (S.G. Gmelin) Bornet.

Common Name. Small agar weed.

Description. Thallus dark brownish red, commonly grows in dense tufts about 4 cm high, and composed of prostrate axes that give rise to the flattened erect axes: branching pinnate to irregularly opposite with uniaxial growth from single apical cells; inner structure pseudoparenchymatous, with long, slender, thick-walled rhizine cells filling the spaces between elongated medullary cells that are surrounded by a three-layered cortex of smaller pigmented cells [6.508].

Fig. 6.26 *Ahnfeltiopsis devoniensis* specimen

Habitat. In large pools and lagoons in the lower littoral and shallow sublittoral, widely distributed, never common.

Distribution. Europe, Atlantic Islands, N America, Caribbean Islands, S America, Africa, SW and SE Asia, Australia and New Zealand, Pacific Islands.

Uses and Compounds. Source of agar [6.509, 510]. Extracts have antioxidant [6.234], antibacterial [6.470], antinociceptive and anti-inflammatory [6.511], anticoagulant [6.512], and antitumor [6.126] activity.

- Order: **Gigartinales**

Ahnfeltiopsis devoniensis (Greville) P.C. Silva & DeCew

Synonym. *Gymnogongrus devoniensis* (Greville) Schotter

Description. *A. devoniensis* is a small red marine alga that grows to only several centimeters in length from a disk-like holdfast (Fig. 6.26). It forms a medium-sized flattened frond with regular dichotomous branching. The branches have parallel sides. The reproductive structures (cystocarps) are internal [6.513].

Habitat. Generally found in the very lower intertidal or shallow sublittoral, in salty areas protected from strong wave action. As far as it is known, it can be found anytime.

Distribution. NE Atlantic (Britain to Portugal).

Uses and Compounds. Source of carrageenan [6.514–516]. Extracts have antihypertensive and antioxidant activity [6.501, 517].

Calliblepharis ciliata (Hudson) Kützing

Common Name. Eyelash weed.

Description. *C. ciliata* is bright to dark red in color. The main blade is erect and forms into a wedge shape

or ovate lobe that expands into a dichotomous or irregularly divided blade up to 7 cm broad and 30 cm long and 350–650 µm thick. Small branches arise from the main blade. It can vary considerably in blade width and degree of subdivision. In southeastern England its blades are often only 10–15 µm thick. The branchlets (proliferations) that arise from the margins of the blade are either pointed or rounded. Patches of encrusting bryozoans are very common on old specimens [6.518, 519].

Habitat. In larger lower intertidal pools and sublittoral (0–25 m) on stones, maerl, and shells, widely distributed, common in south and west, sometimes frequent in drift.

Distribution. NE Atlantic (Ireland and Britain to Mauritania); W Mediterranean.

Uses and Compounds. Source of carrageenan [6.520, 521], and hemagglutinins [6.375].

Calliblepharis jubata (Goodenough & Woodward) Kützing

Description. *C. jubata* is brownish red in color. It has a thallus consisting of a branched holdfast that gives rise to an erect frond that expands into a dichotomous or irregularly divided blade (Fig. 6.27). The outline of the frond is variable but it commonly has a cylindrical or very slightly compressed stipe. Its blades are about 6 mm broad and 30 cm long with narrow branches. The branches appear long and tendril like. Long branchlets (proliferations) arise from the blade surface and margins of the branches [6.1].

Habitat. On rocks and epiphytic, especially on *C. officinalis* in large open pools, mid-littoral to shallow sublittoral (5 m).

Distribution. NE Atlantic (Ireland to Mauritania); W Mediterranean.

Uses and Compounds. Source of carrageenan [6.514–516, 521–523], and hemagglutinins [6.375]. Extracts have antimycobacterial [6.317], anticoagulant [6.524], antiprotozoal, and cytotoxic [6.525] activity.

Caulacanthus ustulatus (Mertens ex Turner) Kützing

Description. Thalli forming small dense entangled tufts of up to 5 cm, reddish-brown color, which blackens

Fig. 6.27 *Calliblepharis jubata* specimen

Fig. 6.28 Underwater photo of *Chondracanthus teedei* var. *lusitanicus*

by desiccation, with rough touch; fixed to the substrate by cylindrical, crawling axes from which derive others, also with circular section, irregularly branched; ramifications with acute apices and behaving small triangular-shaped spines [6.526].

Habitat. It lives on rocks and clams in well-lighted areas with little inclination at mid-littoral zones in semiexposed shores.

Distribution. NE and E Atlantic (Ireland and Britain to Guinea); Mediterranean; NW Atlantic (Canada to Mexico); SW Atlantic (Brazil); SE Atlantic (Angola to South Africa); Indian and Pacific Oceans; Australia.

Uses and Compounds. Produces a kappa/iota-hybrid carrageenan [6.527]. Extracts have antibacterial activity [6.358].

Chondracanthus acicularis (Roth) Fredericq

Description. Cartilaginous, cylindrical, or compressed, purple-red or blackish fronds, sometimes with greenish or whitish spots, to 100 mm long, irregularly bipinnately branched, branches curved, sharply pointed [6.1].

Habitat. On rocks, lower intertidal, generally uncommon but may be locally common on sheltered, silty shores in the lower intertidal.

Distribution. NE and E Atlantic (Ireland and Britain to Cameroon); Mediterranean; NW and SW Atlantic; Caribbean; Indian Ocean; Pacific (Hawaii); E Australia.

Uses and Compounds. Source of carrageenan [6.514–516]. Extracts have antiviral [6.103], antibacterial [6.269, 357], antioxidant [6.429], antifungic [6.204], and anticoagulant [6.512] activity.

Chondracanthus teedei var. *lusitanicus* (Rodrigues) Bárbara & Cremades

Description. The fronds of this alga are cartilaginous-membranous, with purple-violet color that darkens by desiccation, becoming greenish yellow with decay (Fig. 6.28). The main axes of the fronds, as their ramifications are wide, reaching 1 cm in the older portions. This species is confused sometimes with *Calliblepharis jubata* [6.1].

Habitat. On rocks in mid-littoral zone.

Distribution. NE Atlantic (Spain and Portugal).

Uses and Compounds. Produces carrageenan [6.514–516, 528]. Extracts have cytotoxic activity [6.529].

Chondrus crispus Stackhouse

Description. Cartilaginous, dark purplish red, red, yellowish or greenish fronds of 150 mm high, gametophyte plants are often iridescent under water when in good condition; stipe compressed, narrow, expanding gradually to a flat, repeatedly dichotomously branched frond, in tufts from a discoid holdfast. Axils rounded, apices blunt or subacute, frond thicker in center than margins; breadth of segments varies frequently; branching, color, and thickness also vary frequently.

Highly variable (polymorphous) thalli may reach 15 cm long, cartilaginous consistency and reddish-pink or -brown color and iridescent in water. These algae are fixed by a disk whose first unbranched stipe gradually expands into a fan-like blade, repeatedly dichotomously divided, with ends rounded or truncated. Small dilations (2–3 mm in diameter), which are the reproductive structures may appear on the surface of the blades [6.1].

Common Names. Irish moss, Carrageen moss, Jelly moss.

Habitat. On rocks, lower intertidal and shallow sublittoral, in pools in the mid-littoral in some locations; widely distributed in the northwestern and northeastern Atlantic, often abundant.

Distribution. *C. crispus* has a wide distribution. It includes the northwest Atlantic from Labrador and the Maritime Provinces in Canada southward to New Jersey and Delaware in the United States. It can be found to a limited extent in the western Baltic Sea, from northern Russia and Norway to southern Spain, spanning the northeast Atlantic, the North Sea, and the English Channel. It can be found in the Mediterranean, Portugal, the Azores, the Faroes, and West Africa, as well as in the Bering Sea from Russia to Alaska.

Uses and Compounds. *C. crispus* is harvested as a common source of the polysaccharide carrageenan, which is extracted from cell walls and forms a gel that is used commercially as a thickener [6.4, 514–516].

The gelling and thickening properties of carrageenan are used widely in the cosmetics, food, and

pharmaceutical industries. Examples of applications include making ice cream and air fresheners, beer clarification, and treatment for coughs and diarrhea [6.109, 530, 531].

Extracts have antifouling and antibacterial [6.61, 532], antioxidant, and antimicrobial [6.205, 373, 533].

Cystoclonium purpureum (Hudson) Batters

Description. Rather soft, cylindrical, dull-purplish pink fronds, 3 mm wide, to 600 mm long. Branches numerous, alternate, branchlets tapered at both ends; branches sometimes drawn out into long twisting tendrils; multiaxial, medulla a cordlike strand of loosely interwoven, narrow filaments, surrounded by large, rounded cells, with outer layer of small, angular, assimilatory cells; said to have an onion-like smell shortly after collection [6.534].

Habitat. On rocks and stones in mid-littoral and in shallow sublittoral, generally distributed, abundant.

Distribution. North Atlantic (Arctic Canada to Spain); North Sea (Helgoland); Baltic, Mediterranean (Greece), Indian Ocean (Pakistan), Australia (Queensland).

Uses and Compounds. Source of carrageenan [6.32, 521, 535]. Extracts have nematicide [6.536], antibacterial [6.86, 358, 537], and anticoagulant [6.375] activity.

Dilsea carnosa (Schmidel) Kuntze

Common Name. Red rags.

Description. One of the larger red seaweeds, *D. carnosa* is tough and leathery (Fig. 6.29). Several dark reddish brown, flat, blades gradually expand from a single disk-shaped holdfast, and have short cylindrical stipes. The blades do not have a midrib or veins and are simple wedge or spoon shaped. The blades can be 15–30 cm long and 5–20 cm wide. Older blades may be split from the margin toward the base but the rounded oblong (obovate) shape of the blade is never quite lost [6.1, 538].

Habitat. On rocks in shady pools, lower intertidal on rock, and shallow sublittoral to 25 m, usually on rock in kelp forests; widely distributed, common.

Distribution. NE Atlantic (Iceland and Spitsbergen to Portugal).

Fig. 6.29 *Dilsea carnosa* specimens

Uses and Compounds. Produces carrageenan [6.539, 540], and extracts antisettlement [6.257], antiprotozoal [6.525], antifungal [6.541], and antifouling [6.542] activity.

Dumontia contorta (S.G.Gmelin) Ruprecht

Description. Erect thallus, cylindrical when young, compressed when older, tubular-hollow, brownish red to crimson-purple, often yellow-brown at the tips. Thallus with irregular simple lateral branches, tapering at both ends, sometimes slightly swollen, often twisted around the longitudinal axis; soft, gelatinous. Holdfast a small, persistent disk, expanding with age [6.32].

Habitat. On rocks and pebbles, shallow open pools, upper intertidal to shallow sublittoral, common, widely distributed.

Distribution. NE Atlantic (Spitsbergen to Portugal, North Sea); NW Atlantic; NW Pacific (Russia, Japan); NE Pacific (Alaska).

Uses and Compounds. Extracts have antiviral [6.543], and antioxidant [6.429] activity.

Furcellaria lumbricalis (Hudson) J.V. Lamouroux

Common Names. Clawed fork weed, black carrageen.

Description. Cartilaginous, cylindrical, brownish-black fronds, repeatedly dichotomously branched,

fastigiate, to 2 mm diameter and 300 mm long, with acute apices; attached by much-branched rhizoids. Multiaxial, medulla of cylindrical cells interspersed with rhizoids, cortex of irregular filaments, inner cells elliptical, outer cells narrow, elongated, in radial rows [6.544].

Habitat. On rocks, lower intertidal and shallow sublittoral, in pools and runnels, in open situations, often on sandy and muddy shores, tolerating lowered salinities.

Distribution. North Atlantic (Nova Scotia, Greenaland); NE Atlantic (Faroe Islands, Ireland and Britain to Spain), North Sea (Scandinavia, Hegoland), Baltic; W Mediterranean (Spain, Sardinia, Sicily); Indian Ocean (India, Pakistan).

Uses and Compounds. Source of hybrid carrageenan (Furcellaran) [6.32, 545]. The sulfated polysaccharides of this species have immunostimulation activity [6.546].

Gigartina pistillata (S.G. Gmelin) Stackhouse

Description. *G. pistillata* (Fig. 6.30) is the type species of the genus *Gigartina* and their thalli are erect, up to 20 cm tall, dark red or red-brown, cartilaginous, elastic, dichotomously branched, attached to the substrate through a small disk [6.1].

Habitat. On firm substrata in the intertidal zone, to 12 m depth.

Distribution. NE Atlantic (Ireland and Britain to Senegal); SE Atlantic (South Africa).

Uses and Compounds. Source of carrageenan – (female gametophytes) produces a hybrid carrageenan, 48.7 kappa, 44.5 iota (% mol). *G. pistillata* (tetrasporophytes) produces a hybrid carrageenan xi-lambda [6.547]. The sulfated polysaccharides of this species have antitumor [6.548], antiviral [6.549], anti-inflammatory [6.550], and antioxidant [6.429, 551] activity.

Gymnogongrus crenulatus (Turner) J. Agardh

Description. Cartilaginous, fleshy, flattened, dark red fronds, to 100 mm high, with short cylindrical stipe from basal disk; repeatedly dichotomous, branches strap-shaped, apices rounded, often paler than rest of frond. Reproductive structures appear as external, wart-like excrescences [6.552].

Fig. 6.30 Underwater photo of *Gigartina pistillata*

Habitat. Epilithic, lower littoral in pools and emergent, and sublittoral to 13 m, tolerant of sand cover; plants typically encrusted with species of Bryozoa, Foraminifera, and calcareous algae.

Distribution. NE Atlantic (Ireland and Britain to Mauritania, Canary Islands, Cap Verde Islands); NW Atlantic (New Brunswick to Massachusetts); Australia.

Uses and Compounds. *G. crenulatus* produce a hybrid carrageenan (64.1 kappa, 30.8 iota %mol) [6.547]. The sulfated polysaccharides of this species have antibacterial activity [6.130].

Gymnogongrus griffithsiae (Turner) Martius

Description. Cartilaginous, cylindrical to compressed, brownish red to blackish-purple fronds, to 75 mm high, from an expanded discoid base; repeatedly dichotomous, fastigiate, with rounded, somewhat flattened apices [6.553].

Habitat. Epilithic, littoral in pools and emergent, upper sublittoral; tolerant of sand cover. On sand-covered rocks, lower intertidal, rare [6.518].

Distribution. NE and E Atlantic (Ireland to W Africa); Mediterranean; NW to SW Atlantic (North and South Carolina, Brazil, Uruguay); Caribbean; Australia.

Uses and Compounds. Produces sulfated galactans – carrageenans [6.554] with antioxidant [6.205], and antiviral [6.555–557] activity.

Hypnea cornuta (Kützing) J. Agardh

Description. Plants caespitose or loosely intricate-caespitose, up to 30 cm in length, soft in texture and reddish brown in color; axes subterete, up to 1 mm in diameter at the base, pointed at the apex, spirally branched up to the fourth order; branching angle less than 90°; axes and branches loosely clothed with stellate processes; branches up to 550 µm in diameter, and spinous ultimate branchlets, 60–70 µm in diameter, slightly constricted at their base; extensive basal system of prostrate axes attached by secondary discoid holdfasts produced by the cortical cells at any axis level [6.558].

Habitat. In mid-littoral rock pools exhibit the habit of free-floating plants, while in the open sea it throve attached on rocks within −50 cm.

Distribution. W Atlantic (USA to Brazil); Mediterranean; Caribbean (Cuba); Indian Ocean; NW Pacific (Japan); Indonesia; Australia.

Uses and Compounds. Produces carrageenan [6.559].

Hypnea musciformis (Wulfen) J.V. Lamouroux

Common Names. Hook weed, Hooked seaweed, Hypnea.

Description. *H. musciformis* is a red alga with loosely intertwined cylindrical branches that form clumps or masses up to 20 cm tall, though plants are often broken by wave action before they reach full size (Fig. 6.31). Branches are firm and highly irregularly branched, narrowing to broad, flattened, tendril-like hooks. These hooks make *H. musciformis* easily distinguished from all other *Hypnea* species found in similar Habitats. Holdfasts are small or lacking because the plants usually anchor themselves by attaching to other species such as *Sargassum* (for example, *Sargassum muticum*). The tissue is usually a dark reddish brown, though when growing in nutrient poor water color can pale to yellowish brown. It is found abundantly in shallow coastal waters where it prefers calm, shaded sublittoral reef flats, though it also grows in tide pools and rocky intertidal areas. In bloom stage, it may be found free floating. *H. musciformis* is also a highly opportunistic invader [6.560].

Fig. 6.31 Herbarium specimen of *Hypnea musciformis* (MACOI no. 3733)

Habitat. Common on calm intertidal and shallow sublittoral reef flats, tide pools and on rocky intertidal benches. Most often found low intertidal to shallow sublittoral reef flats, attached to sandy flat rocks.

Distribution. NE Atlantic (Spain and Portugal to Canary Islands), E and SE Atlantic (W Africa); NW Atlantic (Georgia, N. Carolina); SW Atlantic (Brazil, Uruguay); Caribbean; Mediterranean; Red Sea, Indian Ocean and Indo-Pacific; Pacific Islands (Hawaii; Fiji); Australia.

Uses and Compounds. In some areas, *H. musciformis* is grown for harvest of kappa carrageenan [6.561, 562]. It also contains a high amount of natural occurring antioxidants, and is nourishing to the skin. *H. musciformis* is used in over 100 hair color and hair care products such as shampoos, conditioners, and styling gels, it is used in more than 20 sunless tanning products, and in many antiaging creams and applications. *H. musciformis* is used in facial treatments, toners, and moisturizers, makeup and cosmetics, and eye treatments. *H. musciformis* is also commonly joined by *Gelidiella acerosa* and *Sargassum filipendula* as an effective seaweed ingredient set for personal care products [6.109, 560].

Extracts have antiviral [6.238], antifungal [6.563, 564], antitumoral [6.421, 565], antihelminthic [6.566], psychotropic and anxiolytic [6.567], antibacterial [6.38, 70, 242, 421, 568, 569], cytotoxic, antioxidant, larvicidal, and antifeed [6.242, 570, 571] activity.

Hypnea spinella (C. Agardh) Kützing

Description. Fragile, upright, or in tangled mats, to 15 cm high, light brown-red, rose-red or bleached; branching in all directions; branches 0.4–1.0 mm diameter, cylindrical. Branchlets spine-, spur-, or tendril-like, numerous, spirally arranged, to 2.5 mm long, occasionally longer; apices tapering, pointed, slightly up-curved. Cortex 1–2 cells thick; cells rounded to irregular, 7.5–25.0 µm diameter, densely pigmented; medullary cells thick-walled, irregular to ovoid, 100–320 µm diameter, surrounding obvious thick-walled central filament (70–80 µm diameter); holdfast initially disk-like. Tetrasporangia ovoid, 10–23 µm diameter, 25–49 µm long, zonately divided, in swollen sori (nemathecia) girdling middle part of lateral branchlet; cystocarps spherical, 100–900 µm diameter, solitary or clustered at base to middle of branchlet [6.572].

Habitat. Attached to small shells or rubble, often entangled in seagrass beds; lower intertidal to 7 m (reported to 27 m) deep.

Distribution. Warm E Atlantic (Atlantic Islands, W coast of Africa); Mediterranean; Caribbean; NW Pacific (Japan, China); Pacific Islands (Hawaii); Indo-Pacific (Philippines, Vietnam); E Pacific (Mexico, Ecuador); Australia.

Uses and Compounds. This is an edible species, being commonly eaten (boiled in coconut milk) in other parts of the Pacific and Asia [6.573]. Extracts have antifungal [6.204], and immunomodulatory [6.394] activity.

Mastocarpus stellatus (Stackhouse) Guiry

Common Name. False Irish moss.

Description. A small red alga (up to 17 cm in length), the fronds are channeled with a thickened edge and widen from a narrow stipe with disk-like holdfast (Fig. 6.32). The channeling is often slight and is most noticeable at the base of the frond. Mature plants have conspicuous growths of short, shout papillae (reproductive bodies) on the fronds. The plant is dark reddish brown to purple in color and may be bleached. The common name false Irish moss is used as it may be confused with *C. crispus* (Irish moss); the main features separating the two species being the channeled frond and appearance of reproductive bodies on mature plants [6.1].

Fig. 6.32 *Mastocarpus stellatus* specimen

Habitat. This alga is found on rocky shores, particularly in very exposed areas where it grows among barnacles and mussels, on less exposed shores it is often abundant under fucoids.

Distribution. NE Atlantic (Scandinavia to Mauritania, North Sea); NW Atlantic (Newfoundland and Nova Scotia to Rhode Island).

Uses and Compounds. Source of carrageenan [6.514–516]. Extracts have antioxidant activity [6.205, 373, 429, 574].

Phyllophora crispa (Hudson) P.S. Dixon

Description. Bright red or pink seaweed. Each plant has a small disk-shaped base and erect fronds. The fronds consist of short cylindrical stipes (stalks) rarely longer than 1 cm long and blades which may be up to 15 cm long and 10 mm wide. The fronds are dichotomously branched, with undulating margins and an indistinct midrib. The tip of each frond is distinctly rounded. The fronds are perennial and in some case five or six new periods of growth can be identified. Regeneration occurs following erosion or animal

grazing. Continual regeneration leads to great variation in the appearance of individual plants as each new growth could come from the end, margin or surface of the blade. Fronds are frequently encrusted with the spiral tube worm *Spirorbis spirorbis* or bryozoans [6.575].

Habitat. Frequent in shady pools in lower intertidal and on rock subtidally to 30 m.

Distribution. NE Atlantic (Scandinavia to Canary Islands, North Sea); W Mediterranean; Black Sea; Free-floating forms in the Baltic Sea.

Uses and Compounds. Raw material for the agar production on the Black Sea [6.32]. Extracts have antifungal activity [6.62].

Polyides rotundus (Hudson) Gaillon

Common Names. Discoid forked weed, Goat tang.

Description. Dark red or blackish seaweed with smooth, cartilaginous, cylindrical fronds, branching dichotomously in roughly the same plane. The fronds rise from a fleshy, discoid holdfast up to 2 cm in diameter. The reproductive bodies occur as oval-shaped swellings along the sides of the branches or occasionally encircling them. The seaweed grows up to 20 cm in length [6.576].

Habitat. On rocks and stones in open sandy pools and runnels, lower intertidal and shallow sublittoral.

Distribution. N and NE Atlantic (Arctic Ocean to Iberian Peninsula, Baltic); NW Atlantic (Arctic Canada to New York).

Uses and Compounds. Extracts have antifouling activity [6.532].

Solieria chordalis (C. Agardh) J. Agardh

Description. Thallus tufted, vividly red, axes cylindrical, thin, only sparsely branching at first, later characteristically with relatively long, unilaterally inserted appendices, height to 20 cm [6.577].

Habitat. In sheltered localities below the mid-littoral zone on rocks.

Distribution. NE Atlantic (from N France to S Morocco), Mediterranean.

Uses and Compounds. Source of carrageenan [6.521, 578–581]. Extracts have hemagglutinating [6.375], and Immunostimulation [6.581] activity.

Sphaerococcus coronopifolius Stackhouse

Common Name. Berry wart.

Description. Narrow, compressed, two-edged, cartilaginous, scarlet fronds, main axes dark brownish red, to 300 mm long; branching abundant, distichous, subdichotomous or alternate, terminal branchlets acute, fringed with short marginal proliferations. Tetrasporophyte is *Haematocelis fissurata*, a thick crust with oily fissures, with which it is sometimes found [6.582].

Habitat. Rarely on rocks in lower littoral, often common in the shallow sublittoral to 15 m.

Distribution. E Atlantic (Ireland and Britain to Canary Islands); Mediterranean, the Black Sea.

Uses and Compounds. Extracts have antifouling [6.583], cytotoxic and antimitotic [6.62, 332, 584, 585], antiviral [6.586], antibacterial and antifungal [6.62, 275], activity.

Stenogramma interruptum (C. Agardh) Montagne

Description. Cartilaginous, flattened, bright-red fronds, to 70 mm high, shortly stipitate from the discoid base. Lamina fan-shaped, ±dichotomously divided, segments about 10 mm wide, with rounded apices, margin usually smooth, rarely proliferous; reproductive structures often occurring in a clearly visible, often discontinuous, *midrib* over the surface of the fronds [6.587].

Habitat. Epilithic, sublittoral to 13 m, in sheltered areas on small stones among gravel and mud [6.518]. On rocks, stones, etc., sublittoral, southern and western coasts, occasional.

Distribution. NE Atlantic (Ireland and Britain to Morocco); West of Atlantic (Canada to Brazil); E and W Pacific (Japan, Mexico, Ecuador, Chile, Peru); Australia and New Zealand.

Uses and Compounds. Produces carrageenan – polysaccharides from tetrasporic plants (lambda-carrageenan) of *S. interruptum* showed higher anticoagulant activity than those isolated from cystocarpic

Fig. 6.33 Underwater photo of *Gracilaria gracilis*

(kappa/iota-carrageenan) plants [6.512, 588]. Extracts have also antiviral activity [6.35, 549].

- Order: **Gracilariales**

Gracilaria bursa-pastoris (S.G. Gmelin) P.C. Silva

Description. Growing in tufts to 30 cm long, much branched usually simply forked or alternate rarely opposite; somewhat compressed, but not flat. Thallus greenish red, yellow greenish to dark brownish red, with cylindrical axes, forking and with lateral branching, tufted, erect, branches gradually tapering off, not narrowing at their origins, the cystocarp-bearing plants are densely covered with hemispherical reproductive structures (cystocarps); texture cartilaginous-meaty, stiff, bristly; discoid holdfast [6.32].

Habitat. Epilithic, on calmer water of the upper sublittoral.

Distribution. NE Atlantic (Ireland to Cape Verde Islands, Kenya); Mediterranean, Indo-Pacific Oceans (India, Sri Lanka, Philippines, Singapore, Japan, China, Hawaiian Islands, Florida, Mexico); Caribbean (Cuba) and SW Atlantic (Brazil).

Uses and Compounds. Source of agar [6.589] and used directly as food and for animal feed [6.32, 290]. Extracts have antibacterial [6.171], anticoagulant [6.375] activity.

Gracilaria gracilis (Stackhouse) Steentoft, L.M. Irvine & Farnham

Common Name. False Ceylon moss.

Description. Cartilaginous, cylindrical, dull-purple fronds, to 500 mm long, one or several are arising from small, fleshy, perennial discoid holdfast (Fig. 6.33). Branching very irregular, sparse or profuse, branches to 2 mm diameter, apices pointed; intertidal tissue of large thin-walled cells with narrow outer cortical zone of small colorless cells [6.2, 590].

Habitat. On rocks and stones, intertidal and sublittoral, especially on sandy shores, generally distributed, common.

Distribution. Temperate-warm to warm NE and E Atlantic (Ireland to Canary Islands, W Africa); SE Atlantic (South Africa); Mediterranean; Caribbean; W Atlantic (Brazil); NW Pacific (Russia, Japan); NE Pacific (Alaska to California, Mexico); Pacific Islands; Indo-Pacific Ocean; Australia; Antarctica.

Uses and Compounds. Source of agar [6.32, 523, 591–593] and used directly for animal feed [6.594]. Extracts have antimicrobial [6.276, 569], and antioxidant [6.350, 595] activity.

Gracilaria multipartita (Clemente) Harvey

Description. *G. multipartita* is a translucent, dull purple or reddish-brown alga which has fronds that measure up to 25 cm long. It is cartilaginous, very brittle, and has a compressed stipe [6.1].

Habitat. Grows on rocks or other hard substrata, tolerating a wide degree of wave exposure. Recorded from the upper sublittoral to a depth of 15 m. *G. multipartita* is also tolerant of sand.

Distribution. NE Atlantic (Britain to Senegal); Atlantic Islands; Mediterranean (Italy, Spain).

Uses and Compounds. Source of agar [6.596]. Extracts have antibacterial [6.269, 358, 597, 598], and antifungal [6.284, 286] activity.

Gracilaria vermiculophylla (Ohmi) Papenfuss

Common Name. Komulkosiraegi.

Description. *G. vermiculophylla* is a red macroalga that is cartilaginous, cylindrical, and up to 50 cm long. It is coarsely branched, often profusely so. It can be found as loose-lying thalli or attached to small stones or shells. Red algae are often found in the vegetative state, and the characterization of reproductive structures is often necessary for correct identification of *Gracilaria* species [6.599–601].

Habitat. Estuarine habitats, marine habitats, mainly in salinity lagoons. It is well adapted to low energy, shallow-bottom bays, lagoons, estuaries, harbors, and inslets [6.602].

Distribution. Native range – NW Pacific ocean including Japan and E Asia [6.601]; Introduced range – N American E and W coasts, Europe, NE Atlantic coast extending from Morocco to SW Sweden, E Pacific [6.603, 604].

Uses and Compounds. *G. vermiculophylla* is widely collected for the production of Agar, which is used extensively in the pharmaceutical and food industries [6.592, 605–607]. Extracts have antibacterial [6.449], and antioxidant [6.335, 608] activity.

Gracilariopsis longissima (S.G. Gmelin) M. Steentoft, L.M. Irvine & W.F. Farnham

Description. Thalli are from almost simple to profuse and irregularly branched, with the slender cylindrical axis throughout the plant. Cystocarps are scattered throughout the thallus, protruding from the thallus surface. Spermatia are formed in near the surface of the thallus. Tetrasporangia are cruciate and are scattered in the cortex [6.609].

Habitat. Usually lives in the sublittoral environment, on loamy or sandy funds shells or gravel.

Distribution. NE Atlantic (Britain to Portugal); SE Atlantic (Namibia, South Africa).

Uses and Compounds. Source of agar [6.592, 605]. Extracts have antibacterial [6.569, 610, 611] activity.

- Order: **Halimeniales**

Grateloupia filicina (J.V. Lamouroux) C. Agardh

Description. Compressed, tufted, dark purplish brown fronds, to 120 mm high, main axis 1–4 mm broad. Once or twice pinnate, axes and branchlets tapered at base and apex. This is a soft limp and slippery smooth seaweed with somewhat flattened branches that can be red green brown or almost black. Size and shape vary greatly from 0.5–5 mm wide to 2–30 cm long, with either few or many branches [6.612].

Habitat. On rocks in pools; mid-littoral to shallow sublittoral, sporadic, often locally common.

Distribution. Worldwide in warm and temperate-warm seas.

Uses and Compounds. Used as food and source of Carrageenan [6.613–615]. Extracts have antioxidant [6.350, 595, 615–617], antimicrobial [6.34], antiviral [6.615, 618, 619], anticoagulation [6.615, 620, 621] activity.

Grateloupia turuturu Yamada

Description. Thallus flat, membranous, with short stipe, the single fronds linear to broad-lanceolate, undivided or irregularly dividing from the base, narrowing toward the base as well as the tip (Fig. 6.34); sometimes proliferating on the margins and the surface; consistency gelatinous-slippery but firm; discoid holdfast; violet- to crimson-red, often greenish at the top thallus [6.32].

Habitat. Epilithic in shallow tide pools and on sand-covered rocks near coast.

Distribution. SE Pacific (Chile), SW Atlantic (Peru), *G. turuturu* is considered native to Japan, China, and Korea, but has spread to the NE Atlantic, the Mediterranean, South America, Australia, and New Zealand.

Uses and Compounds. In Japan, this seaweed is commonly used as a sea vegetable [6.622]. *G. turuturu* is characterized by its richness in dietary fiber (nearly 60% DW) and therefore appears to be a good source of food fiber for human consumption. This is very interesting because the beneficial effect of fiber on health is already well known [6.623, 624]. This seaweed is also rich in proteins, like *Palmaria palmata*, another red alga

Fig. 6.34 Underwater photo of *Grateloupia turuturu*

now authorized in France as a sea vegetable. Its lipid content is low, like all red seaweeds used in human nutrition, and its eicosapentaenoic acid content is similar to those reported for edible red seaweeds such as *Chondrus cripus* or *Gracilaria verrucosa* [6.625].

Extracts have antifouling [6.586], antibacterial [6.626], anticoagulant [6.512], antioxidant [6.627], and antiviral [6.278] activity.

- Order: **Nemaliales**

Galaxaura rugosa (J. Ellis & Solander) J.V. Lamouroux

Synonym. *Galaxaura elongata* J. Agardh.

Description. Thallus bushy, stiff, compact, forming hemispherical mounds, 5–7 (–12) cm high, dark red-brown; branching irregularly dichotomous; calcification moderate. Branches cylindrical, 0.5–1.5 (–3) mm diameter, densely but evenly covered by stiff hair-like filaments; holdfast inconspicuous. Tetrasporangia at apex of surface filaments, occasionally lateral near tip, spherical to oval, to 32 µm diameter, cruciately divided [6.628].

Habitat. On firm substrata in calmer shallow water; found in up to 18 m depth.

Distribution. E Atlantic (Madeira, Canary Islands, Cap Verde to Gabon); W Atlantic (Brazil); Caribbean; Indian Ocean; NW Pacific (Japan, Philippines, Indonesia); Pacific Islands; Australia, New Zealand.

Uses and Compounds. Extracts have anti-inflammatory [6.629], antimicrobial [6.72, 391], antifungal, cytotoxic, and antiviral [6.72] activity.

Ganonema farinosum (J.V. Lamouroux) K.C. Fan & Yung C. Wang

Synonym. *Liagora farinosa* J.V. Lamouroux

Description. This alga is soft, smooth and about 13 cm tall. It is pinkish, lightly calcified, farinose and attached by small discoid holdfasts. The branching pattern is basically dichotomous, with interdichotomal lengths decreasing toward terminal portions of the thallus. The branches are numerous, cylindrical, measuring about 1.5 mm in diameter, with forking apices into very short, acute and terminal branchlets [6.630].

Habitat. *G. farinosum* is found attached to rocky substrate among other algae in the sublittoral and intertidal areas exposed to air during low tides.

Distribution. *G. farinosum* is widely distributed in the tropical waters of the Atlantic, Pacific, and Indian Oceans; Mediterranean; In SE Asia, it has been recorded from Thailand, Vietnam, Malaysia, Indonesia (Irian Jaya) and the Philippines.

Uses and Compounds. Extracts have antibacterial [6.449], antifungal [6.204], cytotoxic, and antiviral [6.72] activity.

Liagora ceranoides J.V. Lamouroux

Description. Thallus to 11 cm high, pale pink to gray, lightly calcified, mucilaginous, irregularly or dichotomously branched every 2–20 mm, with many proliferous lateral branches to 10 mm long; pressed specimens strongly adherent. Main axes to 2.5 mm in diameter basally, tapering to 0.2 mm near apices [6.631].

Habitat. From intertidal pools to 27 m depth, epilithic on *Lobophora variegata*; widespread in tropical seas.

Distribution. NE Atlantic (from France, Spain): Atlantic Islands; Mediterranean; NW Atlantic; Caribbean; SW and SE Atlantic; Indo-Pacific Oceans; Australia.

Uses and Compounds. Extracts have anticoagulant [6.206], and antioxidant [6.65] activity.

Liagora viscida (Forsskål) C. Agardh

Description. Thallus tufted, gray-purple to greenish white or pink, repeated dense branching at almost the same length, branches terete, tapering toward the top (Fig. 6.35); terminal branches usually spreading as wide-angled bifurcations, moderately calcified, texture flexible-firm [6.32].

Habitat. On firm substrata in shallow water to 5 m depth.

Distribution. NE and North Atlantic (France to Cap Verde Islands); Mediterranean; Indian Ocean (India, Sri Lanka); Pacific Islands (Fiji).

Uses and Compounds. Their endophytic fungi have antitumor and antimicrobial activity [6.632, 633].

Nemalion helminthoides (Velley) Batters

Description. Thallus cylindrical, reddish to purple brown, softly gelatinous, simple or sparingly dichotomously branched, to 2 mm wide, to 250 mm long, with discoid holdfast [6.634].

Habitat. On exposed rocky shores, generally growing on barnacles and limpets.

Distribution. NE Atlantic (Scandinavia to Canary Islands, W Africa); SW Atlantic (Brazil, Uruguay); Mediterranean; NW Pacific (Japan); NE Pacific (Alaska to Mexico); Australia, New Zealand.

Uses and Compounds. Used as food [6.634] and with dietary antioxidants [6.65, 205, 429]. *N. helminthoides* showed appreciable antiherpetic activity [6.635].

Scinaia furcellata (Turner) J. Agardh

Common Name. Southern scinà's weed.

Description. Cylindrical, gelatinous but firm, clear pink to purplish-red fronds, 10 mm wide, 250 mm long, dichotomously branched from small discoid base (Fig. 6.36); constrictions at irregular intervals in mature plants [6.32].

Fig. 6.35 *Liagora viscida* specimen

Fig. 6.36 *Scinaia furcellata* specimen

Habitat. On stones, shells, and mal in the sublittoral (30 m), mainly in clear, unpolluted water; not common.

Distribution. NE and E Atlantic (S Norway to Morocco, Canary Islands to Congo); NW Atlantic; Mediterranean; Indian Ocean.

Uses and Compounds. Extracts have cytotoxic [6.636], antibacterial [6.130], and anticoagulant [6.637] activity.

- Order: **Neamatomales**

Schizymenia dubyi (Chauvin ex Duby) J. Agardh

Description. Erect leaf-like flat fronds, brow-red (liver-colored), translucent, gradually widening from the base, simple or irregularly split or lobed, then at a narrow angle, overlapping; often noticeably sickle-shaped, with smooth margin, not proliferating texture soft-slippery; cystocarps very small and sunken; very short stunted stipe, small discoid holdfast [6.32].

Habitat. Pools and on rock mid lower intertidal zone.

Distribution. NE Atlantic (Iceland to Morocco); Mediterranean; NW Pacific (Japan, China, Korea); Australia.

Uses and Compounds. Extracts have antioxidant [6.350], antitumor [6.638], antiviral, and anticoagulant [6.205, 546, 639, 640] activity.

- Order: **Palmariales**

Palmaria palmata (Linnaeus) Weber & Mohr

Common Name. Dulse, Grannogh, Dillisk, Handed focus.

Description. Reddish brown, membranous or leathery, flattened fronds, 50–300 (–1000) mm long, arising from a discoid base, usually with a small stipe expanding gradually to form simple or dichotomously and palmately divided fronds, often with characteristic marginal leaflets (Fig. 6.37); blade very variable in shape, having broadly ovate to narrowly linear segments [6.641].

Habitat. On rocks, mussels, and epiphytic on several algae, intertidal (at all levels but particularly near low water) and shallow sublittoral, especially on the upper part of *L. hyperborea* stip.

Distribution. *P. palmata* grows along the northern coasts of the Atlantic and Pacific oceans, as far north as Arctic Canada and Russia, and as far south as Portugal in Europe, and New Jersey and California in the United States. In the western Pacific, the southern range of *P. palmata* includes Japan and Korea.

Uses and Compounds. Dulse is good to eat, but only after being dried. In a fresh state it is leathery and unpalatable. After sun drying and proper storage, it is a very pleasant plant to chew. It has very little fat and only a small amount of proteins and cellulose, but is very rich in trace elements and vitamins, particularly vitamin A. Dulse contains large amount of several unusual carbohydrates including an unusual short-chained one, floridoside, and this can form up to 30% of the dry weight. This may account for its palatability [6.642].

Fig. 6.37 *Palmaria palmata* specimen

P. palmata is a good source of dietary requirements; it is rich in potassium, iron, iodine and trace elements, and relatively low in sodium. A small amount can provide more than 100% of the daily amount of Vitamin B_6, 66% of Vitamin B_{12}, iron, and fluoride. It has a slight nutty flavor, and has a long tradition in the cuisines of many Northern European cultures. *P. palmata* is also a traditional food in maritime North America, used in condiments, soups, and appetizers. Younger parts of the fronds are considered the most tender and edible. It can be eaten raw. *P. palmata* is also used as fodder for a variety of animals in many countries, as pet supplements, and sometimes as an agricultural fertilizer [6.4, 642, 643].

Extracts of this species have antioxidant [6.533, 644–647], and antitumor [6.432, 644, 645] activity.

Rhodothamniella floridula (Dillwyn) Feldmann

Description. *R. floridula* is perennial brownish-red seaweed found on the lower shore. It usually covers large areas of rock in sandy habitats. At the base of the seaweed, filaments bind with sand to form a spongy, carpet like mass. The filaments are well-spaced and branch out up to 3 cm in length. Upright filaments of the seaweed uncovered by the ebbing tide appear as tufts of hair; when plants dry out they have a purplish tinge [6.648].

Habitat. Turf-forming on sand-covered rocks, mid- and lower intertidal, often under *Fucus serratus*; widely distributed, very common.

Distribution. NE Atlantic (Ireland and Britain to Portugal); SE Atlantic (Namibia, South Africa); SW Atlantic (Argentina).

Uses and Compounds. Used for the production of pharmaceuticals and functional foods [6.205]. Extracts have antioxidant activity [6.205].

- Order: **Plocamiales**

Plocamium cartilagineum (Linnaeus) P.S. Dixon

Common Names. Cock's comb, Kammtang, Kamwier, Red comb weed.

Description. Bright scarlet seaweed up to 30 cm in length with branching fronds (Fig. 6.38). The branching occurs alternately along the fronds and becomes more frequent toward the tips. The general appearance of these seaweeds can greatly vary from very compact and closely branched to a much broader appearance with widely separated branching. The tips are incurving and ultimate branching occurs only to one side, giving a distinctive feathery or comb-like appearance [6.649].

Habitat. Temperate seas throughout the world; found on coasts of strong to moderate wave action and known from depths of 2–26 m. Growing on *L. hyperborea* stipes and on other algae.

Distribution. NE Atlantic (Scandinavia to Senegal, North Sea), SE Atlantic (Namibia); Mediterranean; Indian Ocean (Pakistan, Mauritius); NW Pacific (Japan); Pacific Islands; NE Pacific (Alaska to California); SE-Pacific (Chile); Australia, New Zealand; Antarctica.

Fig. 6.38 Underwater photo of *Plocamium cartilagineum*

Uses and Compounds. Extracts with a red color are said to have been used for cosmetic purposes in ancient Rome [6.32].

P. cartilagineum is harvested commercially as the main raw material for the agar production on the Pacific coast of North America. Agar is widely used not only in laboratories as a growth medium for bacteria and other cultures, but in food and cosmetics as a gelling agent and stabilizer. It is a very pure, natural, firm gel. *P. cartilagineum* extracts are also high in lypolitic (lipid-digesting) sterols and as such is useful as an additive in slimming applications such as creams and massage products where it is able to provoke the release of fatty acids and eliminate surface fat, acting as a skin-firmer [6.650].

Extracts have antimicrobial [6.651], insecticidal [6.652], cytotoxic and antitumor [6.653], antioxidant [6.125], and antiviral [6.357, 549] activity.

- Order: **Rhodymeniales**

Botryocladia botryoides (Wulfen) Feldmann

Description. Plants rose-red to honey pink, erect, up to 11 cm in length, with irregular pseudodichotomous branching. Main axis and branches terete, 9–2.5 mm in diameter, of solid construction, composed of small pigmented, round to oval, cortical cells (5 µm diameter) that gradually increase in size thallus inward; medullary cells larger, hyaline, and ovoid, up to 50 µm. Axis and branches bearing pyriform vesicles [6.654, 655].

Habitat. Epilithic in depths up to 7 m.

Distribution. NE Atlantic (Atlantic Islands), Western Atlantic [6.654].

Uses and Compounds. Extracts have antifungal activity [6.62].

Champia parvula (C. Agardh) Harvey

Description. Soft, gelatinous, pinkish red, much-branched fronds, densely matted, with blunt apices, to 100 mm high. Axes segmented, with nodal diaphragms, segments about as broad as long, filled with watery mucilage [6.656].

Habitat. Epiphytic on smaller algae in lower intertidal pools and sublittoral, South West England and Ireland, Channel Islands, locally common.

Distribution. Worldwide in tropical to subtropical and warmer seas with bordering warm-temperate zones.

Uses and Compounds. Extracts have anticoagulant [6.637], and antiherpetic [6.657] activity.

Chylocladia verticillata (Lightfoot) Bliding

Description. Soft, gelatinous, cylindrical, pinkish to brown-red fronds (often bleached yellow or almost white in sunny Habitats), to 300 mm high, filled with a watery mucilage. Main axis simple, jointed, with nodal diaphragms, very slightly constricted at nodes, 2-several branches per node, themselves often branched, with small beaded ultimate ramuli. Very variable in branching pattern, plants of exposed coasts often simple with small terminal tufts of ramuli [6.658].

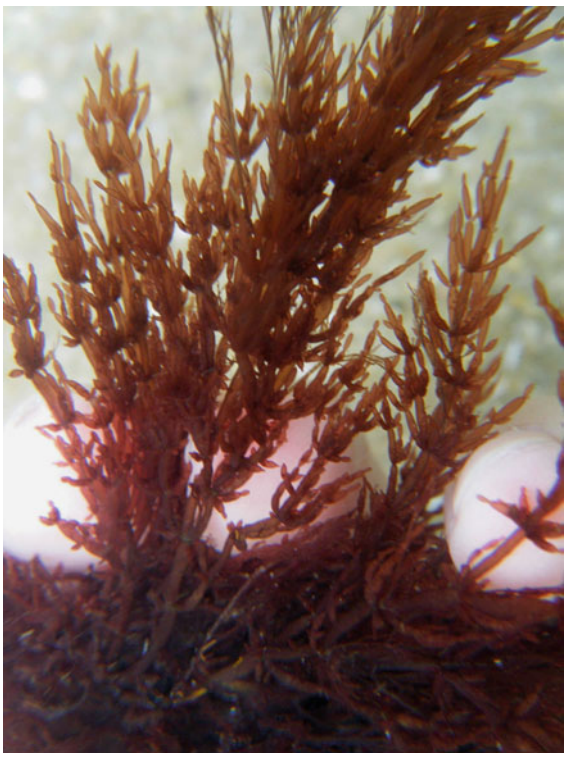

Fig. 6.39 Underwater photo of *Lomentaria articulata*

Habitat. On rocks and stones and epiphytic, lower intertidal and sublittoral, generally distributed, common.

Distribution. NE Atlantic (Norway to Sierra Leone); Mediterranean.

Uses and Compounds. Extracts have cytotoxic activity [6.659].

Lomentaria articulata (Hudson) Lyngbye

Description. A small (up to 20 cm tall, but usually much shorter) dark brown to red alga (Fig. 6.39). The thallus is conspicuously constricted giving a segmented appearance. Starting almost at the base, many branches grow out of each constriction, the bead-like segments becoming gradually smaller toward the tip of the branch. The plant is very shiny and the tips of branches may be bleached pink or orange [6.1].

Habitat. On rocks and stones in pools, lower intertidal and sublittoral, generally distributed, frequent.

Distribution. NE and E Atlantic (Scandinavia to Cameroon), Mediterranean, Black Sea, Indian Ocean (India), W Pacific (Philippines).

Uses and Compounds. Extracts have antioxidant [6.316], and antimicrobial [6.660] activity.

Rhodymenia pseudoplamata (J.V. Lamouroux) P.C. Silva

Description. Flattened, fan shaped, rather stiff, rose-red fronds, to 100 mm high, with long or short stipes arising from a discoidal base. Fronds repeatedly dichotomously lobed, axils wide, apices rounded, margin smooth [6.32].

Habitat. On rocks, shady pools lower intertidal and sublittoral, also epiphytic on *L. hyperborea* stipes.

Distribution. NE Atlantic (Scandinavia to Cap Verde Islands), E Atlantic (W Africa), SE Atlantic

(Namibia, South Africa); NW Atlantic (N and S Carolina), Caribbean, SW Atlantic (Brazil, Uruguay); Mediterranean.

Uses and Compounds. Extracts have antibacterial activity [6.358].

6.3.4 Domain/Empire Eukaryota, Kingdom Chromista, Phylum Ochrophyta; Class Phaeophyceae (Brown Algae)

- Order: **Cutleriales**

Cutleria multifida (Turner) Greville

Description. Only the morphologically more conspicuous *Cutleria*-phase is described: thallus erect, light to yellow-brown, also olive-brown, flattened, membranous, with smooth margins, deeply incised and repeatedly irregular forking, with linear to wedge-shaped sections, gradually narrowing toward the tip and dissected apices, fringed by a tuft of hair-like filaments; without stipe, rhizoidal discoid holdfast [6.32].

Habitat. On rocks, usually isolated, sublittoral to 10 m.

Distribution. NE Atlantic (Scandinavia to Canary Islands); Mediterranean; Indian Ocean; NW Pacific (Japan); SE Pacific (Chile); Pacific Islands; Australia.

Uses and Compounds. Extracts have anticoagulant activity [6.661].

Zanardinia typus (Nardo) P.C. Silva

Common Name. Penny weed.

Description. *Z. typus* is a fairly small brown seaweed with flat fronds that may be either round or fan-like and possibly irregular in shape. The appearance may change with age, varying in color from olive to dark brown or black and in texture from smooth to leathery. The edge of the fronds may be smooth or ruffled, and has a distinct fringe of hairs [6.662].

Habitat. Found mainly on silty boulders or bedrock, rarely on living substrata, on sublittoral from shallow water to about 20 m depth.

Distribution. NE Atlantic (SW Ireland and SW Britain, Canary Islands); Mediterranean (Italy).

Uses and Compounds. Extracts have antifouling [6.663], antioxidant [6.664], antibacterial and antifungal [6.62, 311, 665], antiviral cytotoxic, and antimitotic [6.62, 507].

- Order: **Desmarestiales**

Desmarestia aculeata (Linnaeus) J.V. Lamouroux

Description. This species of brown seaweed looks like a flattened cactus; a flat main axis approximately 2 cm wide with obvious midrib arises from a discoid holdfast. Numerous thinner opposite growing flat side branches are attached to the main axis. *D. ligulata* grows low to sublittoral and reaches 80 cm in length. Other species of flattened *Desmarestia* have been described for our area and there is ongoing discussion about the relationships of these species and their exact number. *D. munda* is described as growing to over 120 cm with side branches as wide as the main axis (4–10 cm), but strictly sublittoral. Beach Watchers have observed individuals that match both descriptions and a combination of the two [6.1].

Habitat. On rocks in pools in the lower intertidal; however, mostly sublittoral, to 15 m depth often abundant.

Distribution. NE Atlantic (Iceland to Morocco); NW Pacific (Japan); NE Pacific (Alaska to California); SE Pacific (Chile); Pacific Islands (Hawaii); Australia, New Zealand.

Uses and Compounds. Source of Laminaran and Alginic acid [6.666].

Desmarestia ligulata (Stackhouse) J.V. Lamouroux

Description. This species of brown seaweed looks like a flattened cactus (Fig. 6.40); a flat main axis approximately 2 cm wide with obvious midrib arises from a discoid holdfast. Numerous thinner opposite growing flat side branches are attached to the main axis. *D. ligulata* grows low to sublittoral and reaches 80 cm in length. Other species of flattened *Desmarestia* have been described for our area and there is ongoing discussion about the relationships of these species and their exact number. *D. munda* is described as growing to over 120 cm with side branches as wide as the main axis

Fig. 6.40 Underwater photo of *Desmarestia ligulata*

(4–10 cm), but strictly sublittoral. Beach Watchers have observed individuals that match both descriptions and a combination of the two [6.1].

Habitat. On rocks in pools in the lower intertidal; however, mostly sublittoral, to 15 m depth often abundant.

Distribution. NE Atlantic (Iceland to Morocco); NW Pacific (Japan); NE Pacific (Alaska to California); SE Pacific (Chile); Pacific Islands (Hawaii); Australia, New Zealand.

Uses and Compounds. The brown algae *D. ligulata* and *D. viridis* accumulate sulfuric acid until their average internal pH is 0.5 – 0.8. A related species, *D. aculeata*, does not accumulate acid [6.667]. Extracts have antimicrobial [6.668], antioxidant, and antitumor [6.316, 421] activity.

- Order: **Dictyotales**

Canistrocarpus cervicornis (Kützing) De Paula & De Clerck

Synonym. *Dictyota cervicornis* Kützing

Description. Thallus tufted, yellow-brown, erect, somewhat intertwined; branches screw-like twisted, narrow ribbons, mostly forking, but asymmetrically branching (one fork longer than the other), widening at the fork-base (to 4 mm), the upper thallus parts narrow (1–2 mm wide), slightly tapering upward, tips acute, margins smooth; anchored to right substrata by a discoidal holdfast [6.669].

Habitat. Grows on rocks and epiphytically in shallow water of warmer seas, but also in up to 20 m depth.

Distribution. Warm E Atlantic; Caribbean; SW Atlantic (Brazil); NW Pacific (Japan, China); Indian Ocean.

Uses and Compounds. Extracts have antisnake [6.670], antifouling [6.671], antifungal [6.204], antiproliferative [6.672], antiviral [6.673], antioxidant and anticoagulant [6.64, 674] activity.

Dictiopteris polypodioides (A.P. De Candolle) J.V. Lamouroux

Synonym. *Dictyopteris membranacea* (Stackhouse) Batters

Description. Thallus flat and leaf-like, to 300 mm long and 20–30 mm broad; fronds olive to yellow-brown, translucent, and ± regularly dichotomously forked with a prominent midrib extending to the apices (Fig. 6.41). Margins sometimes split to the midrib. Initially with an unpleasant smell shortly after collection, and degenerating quickly [6.1].

Habitat. In low-light calm water, to 40 m depth.

Distribution. Cold temperate to warm NE Atlantic (Ireland to Canary Islands); Mediterranean; W Pacific (Philippines); NW Pacific (Japan); Caribbean; Indian Ocean.

Uses and Compounds. Extracts have anti-inflammatory [6.675], antibacterial [6.276, 675], antitumor [6.676], antioxidant [6.675], and cytotoxic [6.62] activity.

Fig. 6.41 Herbarium specimen of *Dictiopteris polypodioides* (MACOI no. 260)

Dictyopteris delicatula J.V. Lamouroux

Description. *D. delicatula* has erect, light-brown, strap-shaped blades attaching to substratum at basal holdfast or to adjacent branches, creating a tangled mass 2–8 cm in height. Dichotomous to irregularly branched bilayered blades, 0.5–5.0 mm wide, have a distinctly raised midrib that may be several cells thick. Cells of blades are arranged in parallel rows at acute angles to midrib. Scattered clusters of hyaline hairs in dense tufts arise along midrib on only one surface of midrib [6.677].

Habitat. Attached to rock-sand coral fragments, also as an epiphyte on larger seaweeds; from the lower sublittoral to ≈ 10 – 30 m depth.

Distribution. Tropical and Sub-tropical Atlantic (Canary Islands), Gulf of Mexico, Caribbean, Indian Ocean, Red Sea, Central Pacific, Costa Rica; Pacific.

Uses and Compounds. Extracts have antifungal [6.204], cytotoxic [6.459], antibacterial [6.449], antiproliferative and antitumor [6.672], antioxidant and anticoagulant [6.459, 678, 679] activity.

Dictyopteris plagiogramma (Montagne) Vickers

Common Name. Limu lipoa

Description. Thalli dark olivaceous green to light tan or almost yellowish, occurring as dense often intertwined tufts of multiple axes arising from a common matted holdfast; fronds 2–8 cm long, 1–8 mm wide, usually crisp in texture and pungently aromatic when fresh; branching of juvenile thalli basically dichotomous, becoming pseudomonopodial at maturity and then highly irregular as wing tissue wears away to leave midribs as several orders of stalks. Blades from apex to base traversed from midrib to margin by regularly spaced microscopic to faintly visible veins that arise at angles of 10–20° and form broad arches bending away from the apices [6.680].

Habitat. Uncommon, on hard substrates, often attached to coral fragments or scattered rocks on deep sand plains; 9–55 m deep.

Distribution. Widespread in the subtropical to tropical waters of the Atlantic, Caribbean, Mediterranean, Indian Oceans, and in the Pacific Ocean.

Uses and Compounds. Produces Laminaran and Alginic acid and is used as food [6.681]. Extracts have antioxidant activity [6.682].

Dictyota ciliolata Sonder ex Kützing

Description. Thallus erect, light brown with yellow green iridescence, sometimes with dark brown striations; branching irregular to dichotomous; branches strap-shaped, margin with teeth, often spirally twisted; medullary cells one layer thick, rectangular [6.683].

Habitat. Attached to rock in seagrass bed, and in intertidal pools in moderately high energy Habitats.

Distribution. Warm E Atlantic (Madeira, Canary Islands, W Africa); Caribbean; SW Atlantic (Brazil); SW Pacific; Indian Ocean; Australia.

Uses and Compounds. Extracts have antifungal [6.204], and antioxidant [6.65] activity.

Dictyota dichotoma (Hudson) J.V. Lamouroux

Description. Thallus flat, homogenous yellow-brown to darker brown, with fairly regular dichotomous branches (Fig. 6.42) with parallel sides to 30 cm long, the tips usually bifid; branches 3 to 12 mm wide, membranous, without a mid-rib [6.1].

Fig. 6.42 Underwater photo of *Dictyota dichotoma*

Habitat. In shallow water on firm substrata, found in >50 m depth.

Distribution. Common and globally distributed.

Uses and Compounds. A chlorine-containing perhydroazulene diterpene, dictyol J 146, was isolated from the brown alga *D. dichotoma* along with two known diterpenes, dictyolactone and sanadaol [6.684, 685]. All three metabolites were algicidal [6.686] to the bloom-forming species *Heterosigma akashiwo* and *Karenia mikimotoi*. Dictyolactone also displayed a moderate activity against the dinoflagellate *Alexandrium catenella*.

Extracts of this seaweed have also anticoagulant [6.512, 637, 687], cytotoxic [6.62, 688, 689], antitumor [6.126, 690], anti-inflammatory [6.691], antifungal [6.62], larvicidal [6.51], antimicrobial [6.18, 40, 692], and antifouling [6.693, 694] activity. Extracts have also used for a liquid fertilizer [6.695].

Dictyota fascida (Roth) J.V. Lamouroux

Synonym. *Dilophus fasciola* (Roth) M.A. Howe

Description. *D. fasciola* has a ribbon-like opaque thallus with a height of 100–150 mm, and width of 1–6 mm. The thalli are flattened, and highly branched in a dichotomous pattern; it is three cells thick and without midrib. The branches are attenuated with forked tips; it has a yellowish-brown coloration [6.696].

Habitat. On firm substrata in the intertidal.

Distribution. Warmer E Atlantic (Madeira, Canary Islands); E Africa); Mediterranean; Indian Ocean.

Uses and Compounds. Extracts have antimicrobial [6.130], antioxidant [6.664], and antifouling [6.697] activity.

Dictyota implexa (Desfontaines) J.V. Lamouroux

Synonyms: *Dictyota dichotoma* var. *implexa* (Desfontaines) S.F. Gray; *Dictyota linearis* (C. Agardh) Greville

Description. Thallus bushy, brown, consisting of intertwined, erect fascicles; thallus regularly forking, width at the base 2–3 mm, abruptly narrowing toward the tipe, then filamentous (< 0.5 mm) [6.32].

Habitat. From 0 to 10 m depth.

Distribution. Atlantic Islands (Azores and Canary Islands); Mediterranean.

Uses and Compounds. Extracts have antibacterial [6.40, 276, 698], antifungal [6.276], and antioxidant [6.112] activity.

Dictyota mertensii (Martius) Kützing

Description. Thallus bushy, brown, often iridescent blue-green under water, erect, robust and stately; the flattened fronds show a branching pattern atypical for the genus: distinct main axes branch repeated-alterning, terminal forkings of the latitudinal axes turn into spur-like, 1–2 mm long, pointed or rounded tips [6.32].

Habitat. On rocks in shallow (about 2 m deep) water, in moderately wave-exposed sites in the intertidal, also in up to approx. 15 m depth.

Distribution. Warm E Atlantic (Canary Islands to Gabon); Caribbean; SW Pacific and Pacific Islands.

Uses and Compounds. Extracts have antibacterial [6.699] and feeding-deterrent [6.700, 701] activity.

Dictyota spiralis Montagne

Synonym. *Dilophus spiralis* (Montagne) G. Hamel

Description. Thallus bushy, erect; lamina segments ribbon-like, regular forking, spiralling around the longitudinal axis, tips straight, pointed. 10–20 cm long, brown, tips a lighter shade [6.702].

Habitat. Near the surface on rocks, also as an epiphyte.

Distribution. NE Atlantic (W Ireland and SW Britain to Mauretania); Mediterranean.

Uses and Compounds. Extracts have antimicrobial activity [6.18, 130, 703].

Lobophora variegata (J.V. Lamouroux) Womersley ex E.C. Oliveira

Description. These algae occur in orange brown to dark brown in colour and bear a leathery feel. The blades may appear as fan shaped, flabellate or as crusts. They are often tightly adhered to the substrate [6.704].

Habitat. Grow in most reef environments, encrusting great areas of shaded, rocky substrates. Especially abundant on undercut wall faces along deep drop-offs.

Distribution. Warm E Atlantic (Madeira, Canary Islands, W Africa); Caribbean (Trinidad); Hawaii; Indian Ocean, Australia.

Uses and Compounds. Lobophorolide was isolated from the common brown alga *L. variegata* and displayed a potent and highly specific activity against the marine filamentous fungi *Dendroyphiella salina* and *Lindra thalassiae* and a potent activity against *C. albicans* and antineoplastic [6.705]. Extracts have also antiprotozoal [6.706, 707], antimicrobial [6.65, 260, 707], anti-inflammatory [6.708], hypoglycemic [6.81], antifungal [6.61, 62], antifouling [6.260], anti-inflammatory, antioxidant, and anticoagulant [6.65, 709, 710] activity.

Padina gymnospora (Kützing) Sonder

Description. Usually the blades are 10–12 cm long and broad, but plants with 15 cm long and to 20 cm broad blades may be found; the frond has three layers of cells except near the enrolled edge where two cell layers occur; the hair lines alternate on both sides of the blade and the dark lines of sporangia are found just above every second hair-line; plants tufted, 5–10 cm tall, the blades 5–20 cm broad rounded or split into narrower portions, the lower parts stalk like and stupose, usually rather moderately calcified on the upper surface [6.711, 712].

Habitat. On rocks and other firm substrata (mangrove-roots), in calm or only moderately wave-exposed locations in the intertidal, found in up to 14 m depth.

Distribution. Warm E and SE Atlantic (Canary Islands to Angola); SW Atlantic (Brazil); Caribbean; W Pacific and Indo-Pacific (Philippines, Vietnam); Pacific Islands; Indian Ocean; Australia.

Uses and Compounds. Extracts have anti-inflammatory [6.713], antibacterial [6.114, 493, 714, 715], antifungal [6.715], anticoagulant [6.716], antioxidant [6.717], neuroprotective [6.718], antiviral [6.172, 719] activity.

Padina pavonica (Linnaeus) Thivy

Common Name. Peacock's tail

Description. The fronds are thin and leafy, flattish and entire when young, but often concave, or almost funnel shaped in mature specimens, with a lactiniate or irregularly lobed margin (Fig. 6.43). The inner (or upper) surface is covered in a thin coating of slime, and the outer (or lower) surface is banded with zones of light brown, dark brown, and olive green. Small, fine hairs form concentric lines, 3–5 mm apart, from the outer margin continuing down the outer (colored) surface of the fronds [6.32].

Habitat. On rocks in sheltered locations near the surface, to 20 m depth.

Distribution. NE Atlantic (S Britain to Canary Islands, W Africa); Mediterranean; Caribbean; W Pacific (Philippines), Pacific Islands; Indian Ocean.

Uses and Compounds. Cosmetic uses for skin antiaging [6.720]. High anticoagulant activity has been reported for purified fucan sulphates from *P. pavonica* (xylofucomannoglucuronan) [6.721]. Extracts have also allelopathic [6.722], antifungal [6.204, 286, 438, 722], antibacterial [6.72, 284, 421, 723, 724], anticoagulant [6.512], antitumor [6.126, 421], antiviral [6.72], cytotoxic, and antimitotic [6.62, 72, 725] activity.

Taonia atomaria (Woodward) J. Agardh

Description. Thallus erect, flat ribbon-shaped, paper-like thin, irregularly branching into wedge-shaped segments and/or deeply dividing into narrower, almost linear bands, the upper margin appearing frayed; without midrib; dark, slightly undulating zones of transverse stripes on both sides (hairs and reproductive structures). Stipe-like at the bottom anchored by a dense rhizoidal felt [6.32].

Fig. 6.43 *Padina pavonica* specimens

Habitat. In pools on rocky and sandy substrata in semiwave-exposed situations up to 10 m depth.

Distribution. NE Atlantic (Britain to Mauretania), Mediterranean.

Uses and Compounds. Used as functional foods ingredient [6.205, 726, 727].

T. atomaria was a source of meroditerpenes atomarianones A 123 and B 124, the cytotoxic agents against the NSCLC-N6 and A-549 cell lines [6.728]. The brown alga *T. atomaria* was also a source of meroditerpenes atomarianones, the cytotoxic agents against some cell lines [6.728].

Sargaquinone were isolated from the brown alga *T. atomaria* and were anti-inflammatory agents by inhibition of leukotriene biosynthesis [6.729].

Extracts have also antioxidant [6.102, 205, 685], antitumor [6.730], and antimicrobial [6.130] activity.

Zonaria tournefortii (J.V. Lamouroux) Montagne

Description. Thallus erect, with flat lobed sections divided into. Wedge-shaped segments, often incised and proliferating; lamina inconspicuously banded by distant, concentric rows of hairs which are parallel to the distal margin; additionally, delicate lines which run radially from the base to the upper margin; margins not enrolled, lamina not calcified; basally thickened, stipe-like, branching, stipe extending like a midrib into the segments; cushion-like rhizoidal network [6.32].

Habitat. In shady locations, from the surface to 40 m depth.

Distribution. Warm NE Atlantic (Madeira, Canary Islands, W Africa); Mediterranean; Caribbean; SW Atlantic (Brazil); SW Indian Ocean (South Africa).

Uses and Compounds. Extracts have antibacterial activity [6.391].

- Order: **Ectocarpales**

Asperococcus bullosus J.V. Lamouroux

Description: Thallus simple, membranous, hollow and irregularly bladder-like bloated; with short stipe which abruptly widens into the hollow inflated thallus body; reproductive structures on the surface are visible as dark dots; discoid holdfast [6.32].

Habitat. Lower intertidal and shallow sublittoral; mainly epiphytic.

Distribution. Widely distributed in temperate seas.

Uses and Compounds. Extracts have antioxidant and antitumor activity [6.205, 731].

Chordaria flagelliformis (O.F. Müller) C. Agardh

Common Name. Black whip weed.

Description. Thallus string-like, with divaricated branches, slippery, solid, dark brown to black, 10–30 cm high; branching irregular, alternate from all sides; branches cylindrical, or slightly compressed, to 3 mm wide, slightly tapering toward the base. Branch apices blunt. Medulla composed of longitudinal filaments of long cylindrical cells to 50–600 µm decreasing toward periphery to 16–18 µm. A layer of assimilative unbranched filaments (of 4–9 cell rows) develop from the peripheral cells [6.732].

Habitat. Growing on stony bottom, in low intertidal to sublittoral, in calm shores and exposed to wave action.

Distribution. NE Atlantic (from Greenland, Scandinavia to Britain, North Sea and Baltic)); NW Atlantic; SE Atlantic; NE Pacific; Antarctica and Sub-Antarctic Islands.

Uses and Compounds. Used as food [6.546, 732], and extracts have antitumor [6.733], anticoagulant and

antithrombotic [6.732, 734], and antioxidant [6.546] activity.

Colpomenia peregrina Sauvageau

Common Name. Oyster thief.

Description. Sometimes regularly spherical (*C. peregrina*) or more or less irregular outline (*C. sinuosa*), yellowish-brown color, fixed to the substrate by filamentous rhizoids. Internally, the thallus is characterized by an outer cortex composed of small colored cells and inner pith composed of large pigmented cells [6.1].

Habitat. On moderately wave-exposed rocks and (mostly) on other algae in the lower intertidal.

Distribution. NE Atlantic (Norway to Canary Islands); W Mediterranean; NW Pacific (Japan); NE Pacific (Alaska to California); Australia, New Zealand.

Uses and Compounds. Extracts have cytotoxic and antibacterial activity [6.735].

Colpomenia sinuosa (Mertens ex Roth) Derbès & Solier

Description. Thallus bladder-like, smooth, slick, hollow, crisp, spherical to sac-like, irregularly expanded or somewhat lobed, to 30 cm diameter, 10 cm high, golden-brown (Fig. 6.44); often covered with fine colorless hairs; reproductive sori as dark raised patches on surface. Membrane 300–500 µm thick, of 4–6 cell layers; medullary cells to 240 µm diameter; cortex 1–2 cells thick; surface cells 3.7–8.0 (–16) µm diameter, darkly pigmented; surface-phaeophycean-hairs transparent, in scattered clusters; holdfast not apparent, attachment at many points [6.1].

Habitat. Firmly attached to hard surfaces or epiphytic on other organisms; lower intertidal to 15 m deep.

Distribution. NE Atlantic (Portugal to Canary Islands); Mediterranean; E and SE Atlantic (W to South Africa); Caribbean; SW Atlantic (Brazil, Uruguay); Indian Ocean; NW Pacific (Japan, China) NE Pacific (California); SE Pacific (Galapagos, Chile); W Pacific and Indo-Pacific (Vietnam, Malaysia, Philippines); Pacific Islands (Hawaii, Polynesia); Australia, New Zealand.

Uses and Compounds. Edible, used as food [6.32], fertilizer, and source of alginic acid [6.109]. Extracts have antibacterial [6.86, 228, 692], antifungal [6.204], antioxidant [6.736, 737], antitumor [6.126], antileukemic, antiprotozoan, and hypolipidemic [6.698] activity.

Fig. 6.44 Underwater photo of *Colpomenia sinuosa*

Ectocarpus siliculosus (Dillwyn) Lyngbye

Description. Plants tufted, often only one to a few cm tall, but in exceptional cases up to 20 cm. Axes freely branched, main axis not distinguishable; filaments up to 30 µm in diameter, tapering toward the apices. Sometimes forming terminal pseudohairs, forms soft beards on larger plants or other firm substrata, and grows up to 2 feet long [6.738].

Habitat. On various firm substrata near the low-tide mark or below, later often free floating; also epiphytic.

Distribution. Almost globally distributed: NE Atlantic (Greenland to Canary Islands; North Sea; Baltic); Mediterranean; NW Atlantic (Canada, USA); SE and SW Atlantic; Caribbean; NW Pacific (Japan, China); NE Pacific, Australia and New Zealand; Sub-Antarctica.

Uses and Compounds. Extracts have antibacterial [6.248, 276, 454], and antioxidant [6.595] activity.

Hydroclathrus clathratus (C. Agardh) M.A. Howe

Common Name. Perforated brown seaweed.

Description. *H. clathratus* is a very interesting brown seaweed, appearing as a 6 – 10 cm yellow-brown clump of very porus, chain-like tissue. The plant

has a very open, sponge-like structure with a complex series of holes perforating narrow, fleshy strips. Its name, *clathratus,* means *latticed,* an apt description. *H. clathratus* is found worldwide in warm seas but is an uncommon species on hard reefs. *H. clathratus* is more often found on in calm, shallow areas where it is anchored in bare sand [6.32, 739].

Habitat. In mid-littoral, often on wave-exposed rocks, more rarely in depths of apertures 1–3 cm, of the bridges 1–3 mm.

Distribution. The worldwide distribution of *H. clathratus* includes Europe, both coasts of Africa, the Pacific Islands, Asia, Australia, North and South America from California through Chile and the Gulf of Mexico.

Uses and Compounds. *H. clathratus* has been used for centuries in traditional cuisine and medicine of island cultures, such as Hawaii. Hydroclathrus clathratus is known to possess anticancer, anti-herpetic, anti-inflammatory, and anticoagulant properties and is now used as a mineral supplement in cosmetics and as a soil-additive (fertilizer) for its high concentration of micronutrients [6.32, 739].

Extracts have antiviral [6.740, 741], antitumor [6.742–747], cytotoxic and antiviral [6.72], and antimicrobial [6.72, 230, 248, 692, 715] activity.

Leathesia marina (Lyngbye) Decaisne

Synonym. *Leathesia difformis*

Common Names. Sea cauliflower, Sea balls.

Description. Thallus round in young stages, light brown, firm-fleshy and slimy-smooth, later hollow, and with an irregularly convoluted surface [6.32].

Habitat. Mostly epiphytically on larger algae or sessile on rocks.

Distribution. Nearly worldwide; NE Atlantic (Iceland to Canary Islands); Mediterranean; NW Atlantic; SE Atlantic (Namibia, South Africa); Indian Ocean (South Africa); NW Pacific (Japan, China); NE Pacific (Alaska to California); SW Pacific (Philippines); Australia; New Zealand, Antarctica and Sub-Antarctica.

Uses and Compounds. Extracts have agricultural bio-control and bio-stimulating [6.748], antifouling [6.749], antiviral [6.750], antioxidant [6.111], and antitumor [6.751] activity.

Petalonia fascia (O.F. Müller) Kuntze

Description. Thallus consists of erect, light to dark brown, dorsoventrally flattened lamina, arising from a holdfast singly or in clusters; linear or broadly lanceolate to almost elliptical, abruptly or gradually narrowing toward the base and merging into a elliptical, abruptly or gradually narrowing toward the base and merging into a short stipe, only slightly narrowing at the tip, rounded and often frayed; thallus undivided, membranous and thin when young, later leathery-tough with smooth, sometimes undulating, margins (Fig. 6.45). The species is very polymorphic especially in relation to thallus width [6.752].

Habitat. Found growing on rock in the mid intertidal to shallow sublittoral from protected to semiexposed Habitats.

Distribution. N NE Atlantic (Greenland to Canary Islands); Mediterranean; NW Atlantic (Arctic to New Jersey; SE Atlantic (Senegal, Namibia, South Africa); SW Atlantic (Brazil, Uruguay); Indian Ocean (Pakistan, South Africa); NW Pacific (Japan, China); NE Pacific (Alaska to California); SE pacific (Chile); Australia, New Zealand; Antarctica, and Sub-Antarctica.

Fig. 6.45 Herbarium specimen of *Petalonia fascia* (MACOI no. 292)

Uses and Compounds. Used as directly food, and the extracts have antimicrobial and antioxidant [6.203, 698] activity.

Punctaria latifolia Greville

Description. Frond oblong or obovate, medium brown, complanate, simple, ovate to ligulate, thickish, gelatinous and tender, usually 5–20 (–30) cm long and (1–) 2–6 cm broad, margin smooth to undulate, with a short, slender, stipe and cuneate base, arising from a small, discoid, rhizoidal holdfast (0.5–) 1–2 (–3) mm across; epiphytic (usually on *Posidonia* or *Heterozostera*) or epilithic; growth diffuse. Structure (2–) 4–6 cells and 80–120 µm thick, with a medulla 2–4 cells thick with few phaeoplasts, and a monostromatic cortex of isodiametric cells mostly of similar size to the medullary cells, 15–25 µm across in surface view, each with several discoid to irregularly shaped phaeoplasts each with a pyrenoid; phaeophycean hairs scattered, single or in small groups, 7–10 µm in diameter [6.753].

Habitat. On rocks in the upper intertidal down to several meters depth.

Distribution. Widely distributed in cooler temperate waters.

Uses and Compounds. Extracts have antibacterial [6.735], antiviral [6.735], cytotoxic, and antitumor [6.102, 735, 751, 754] activity.

Scytosiphon lomentaria (Lyngbye) Link

Common Name. Sausage weed

Description. *S. lomentaria* has cylindrical, shiny, olive brown, unbranched fronds up to 400 mm long. They have short stalks and a large number may arise from a single discoid holdfast. They widen to 3–10 mm and narrow again near the tip. They are hollow and often have irregular constrictions [6.755].

Habitat. It occurs in the littoral zone on wave-exposed shores and rock pools. Small plants are often found growing on limpets and pebbles.

Distribution. Cosmopolitan in temperate and cold seas.

Uses and Compounds. Used directly as food, and the extracts have antioxidant [6.111, 112, 335, 756, 757], antiviral [6.278], antimicrobial [6.421, 698], antitumor [6.421, 758], and antifouling [6.759] activity.

- Order: **Fucales**

Ascophyllum nodosum (Linnaeus) Le Jolis

Common Names. Knotted wrack, Asco, Sea Whistle, Bladderwrack, Egg wrack.

Description. *A. nodosum* is a perennial brown intertidal seaweed species most abundant on sheltered rocky shores in the mid-intertidal zone of the North Atlantic. Olive green in color, *A. nodosum* generally grows upward in the water column anchoring to hard substrates using a disk-shaped holdfast (Fig. 6.46). A single specimen resembles an intertwined mass of shoots and branches. Incoming tides gradually refloat vast stands of *A. nodosum*, until it becomes an expansive swaying undersea forest. Its thallus can measure from 30 to 60 cm, and is flexible to decrease breakage that may result from strong wave action. Its long, thick, leathery, branching strap-like fronds are typically between 0.5 and 2 m in length, and have large egg-shaped air bladders (*pneumatocysts*) at regular intervals along their length which keep the plant floating upright when submerged at high tide, and hang downward, draping over intertidal rocks in a thick, tangled, and glistening mat at low tide. The large air bladders take it toward the light for maximum photosynthesis. The fronds have no midrib.

It is present and grows all year round, and has no resting period. The species grows slowly and can live to be several decades old in wave-sheltered locations of temperate waters, and it has the capability to survive low temperatures. It can eventually grow to three and four meters; individual fronds can become up to 15 years old before breakage. The holdfasts of *A. nodosum* are thought to persist for several decades from which new fronds regenerate. Another interesting attribute of *A. nodosum* is that it repeatedly sloughs its entire outer epidermis, a phenomenon not exhibited by other related seaweeds.

A. nodosum attaches to rocks and boulders on the middle shore in a range of habitats, from estuaries to relatively exposed coasts. These sites can have low, moderate, and high wave action across low-, mid- and upper littoral heights, although some sublittoral populations have been reported. The upper limits of *A. nodosum* distribution are controlled by its ability to resist desiccation and high temperatures [6.1, 760].

Fig. 6.46 *A. nodosum* specimen

Habitat. On rocks in sheltered locations of the mid- to the lower littoral zone.

Distribution. Distribution is confined to the North Atlantic basin, found in the Arctic Ocean, Baltic Sea, Belt Sea, Northern Europe, Gulf of Maine, North Sea, and Northwest Atlantic. Its northern limits are northern Norway and the White Sea in the east, and Baffin Island in the west. Southern distributions extend to northern Portugal and New Jersey.

Uses and Compounds. *A. nodosum* is very effective at accumulating nutrients and minerals from the surrounding seawater, and this is what makes them a valuable resource for human enterprise. This species is harvested for use in items such as food, fertilizer, soil conditioners, animal feed, skin and hair care products, cleaners, degreasers, equestrian products, and nutritional supplements. It is also popular in cosmetology and thalassotherapy. The Industry has more than 200 product types from over 100 companies which include *A. nodosum* as an ingredient [6.3, 4, 760].

Extracts of this species have anticoagulant [6.761], antiviral, and anti-inflammatory [6.762, 763], antibacterial [6.764, 765], antioxidant [6.763, 766], nematicidal [6.767], agricultural biostimulant [6.768], antitumor [6.432], antifouling [6.61], and phytobiotic [6.769] activity.

Bifurcaria bifurcata R. Ross

Common Names. Brown tuning fork weed, Brown forking weed

Description. Up to 30 cm in length; olive-yellow in color, but much darker when dry (Fig. 6.47); holdfast expanded and knobby; frond cylindrical, unbranched near base then branching dichotomously. Elongate reproductive bodies present at ends of branches. Rounded air bladders sometimes present [6.1].

Habitat. Epilithic in intertidal tide pools, occasionally exposed at low tide and extending into the shallow sublittoral.

Distribution. Temperate NE Atlantic (from W Ireland to Morocco).

Uses and Compounds. A linear cytotoxic diterpene bifurcadiol was isolated from the brown alga *B. bifurcata* by *Di Guardia* et al. [6.770] which exhibit cytotoxicity against cultured human tumor

Fig. 6.47 *Bifurcaria bifurcata* specimen

cell lines. Extracts have also antifouling [6.771, 772], antibacterial [6.96, 269, 773], antiprotozoal [6.525], antioxidant [6.429, 731], and antitumoral [6.774] activity.

Cystoseira abies-marina (S.G. Gmelin)

Description. At the base a branching, gnarled stem with teeth-like appendages. Upper thallus tufted, forking or lateral branching at more or less the same length, single branches thin, covered with scattered dark dots, and conspicuous bilateral saw-teeth-like; conceptacles as wart-like swellings in the upper parts of the thallus; without swim bladders [6.32].

Habitat. It is mostly present in the Macronesian islands. Widely spread out in the sublittoral zone, in places subject to wave action.

Distribution. E Atlantic (Azores, Madeira, Canary Islands, Cap Verde Islands); Mediterranean (Spain, Sardinia, Libya, Italy).

Uses and Compounds. This species is used directly for food and as fertilizer [6.775]. Extracts have antioxidant [6.225, 776, 777], antimicrobial [6.778], and cytotoxic [6.225] activity.

Cystoseira baccata (S.G. Gmelin) P.C. Silva

Common Name. Bushy berry wrack

Description. Fronds usually solitary, 1 m or more in length, attached by a thick, conical attaching disk (Fig. 6.48). Axis simple or branched, up to 1 m in length, flattened, about 1×0.4 cm in transverse section; apex smooth and surrounded during periods of active growth by incurred young laterals. Lateral branch systems distichous, alternate, radially symmetrical, and profusely branched in a repeatedly pinnate fashion and bearing sparse, filiform, occasionally bifurcate appendages on the branches of higher orders; deciduous, leaving decurrent bases which give an irregular, zigzag outline to the axis. Aerocysts present in axes of branches of higher order, sometimes in chains; seasonal, particularly numerous in Autumn. Receptacles 1–5 cm long, formed from axes of ultimate ramuli, irregularly nodose and bearing simple, filiform appendages [6.779].

Habitat. Lower intertidal in large sandy pools or lagoons, mostly in persistent stands.

Fig. 6.48 Underwater photo of *Cystoseira baccata*

Distribution. Widely distributed in the NE Atlantic (Baltic, Netherlands, Belgium, Ireland, Britain, N France, N Spain, Portugal, Mauretania, and Canary Islands).

Uses and Compounds. Extracts have antifouling [6.780], antibiotic [6.781, 782], antiplasmodial, and cytotoxic [6.783] activity.

Cystoseira barbata (Stackhouse) C. Agardh

Description. The thallus is 15–20 cm tall-each branch ends with a conic foot (sole); in most cases the basement branches are joined together in a common base. The stem is narrow enough, 3–5 mm thick, cylindrical, the final side is smooth and unequal. The main branches are alternatively or chaotically branched from the stem, very long, cylindrical shape, plenty of small branches whose number gradually decreases, leaving a few singular cylindrical small branches, much shorter than the initial ones; the small branches are uni-

formly distributed along the main branches or come together as brooms nearest their tops. In winter and spring, there are many (air) bladders on branches. Cryptostoma are numerous on the surface of the branches and (air) bladders. The receptacles are spare shaded or cylindrical 0.2−1 cm long, strongly stressed on the scaphidia surface and with thready sterile tops; gathered in dense installments on the lateral surface of the branches: often in the receptacles the (air) bladders are metamorphosed and are distributed close the top branches [6.784].

Habitat. Rocky bottoms on pebbly grounds in sublittoral areas at 0.5−10 m depths.

Distribution. NE Atlantic (France to Portugal); Mediterranean, India and Russia.

Uses and Compounds. Source of alginic acid and the extracts have antioxidant, antibacterial, antifungal, anti-HIV, and hypoglycemic activity [6.130, 192, 201, 784–788].

Cystoseira brachycarpa J. Agardh

Synonym. *Cystoseira balearica* Sauvageau

Description. Plant caespitose, to 20−25 cm in height, attached to the substratum by a more or less compact discoid base formed of haptera; axes numerous, 2 –6 with 8 cm high; apices of the axes not very prominent, flattened and smooth; tophules absent. Primary branches cylindrical, seasonally either with smooth bases or covered with small spinose; conical appendages, some of witch can give rise to smaller branches; secondary and tertiary branches also cylindrical and covered with spinose appendages [6.789].

Habitat. Occurs in the upper sublittoral zone, from the surface to several meters depth, in moderately exposed and high light-intensity places.

Distribution. Mediterranean.

Uses and Compounds. The linear diterpenes eleganolone and elegandiol, isolated from *C. brachycarpa*, inhibit contractile activities of acetylcholine and histamine on ileum musculature of guinea pigs [6.790, 791]. Extracts have antimicrobial and antiviral [6.62, 136, 792, 793], antifungal, cytotoxic, and antimitotic [6.62] activity.

Cystoseira compressa (Esper) Gerloff & Nizamuddin

Description. *C. compressa* has a discoid base with several spined axes; the axes have denticulate margins. It is irregularly branched with compressed primary ramifications, and compact crawling receptacles; the axes have a height of 10−100 mm, and a thickness of 2−5 mm. This alga lacks any leaves, tophules, and air vesicles; *C. compressa* has an olive-brown coloration [6.794].

Habitat. On rocky substrata, especially in the shallow sublittoral of light exposed, sheltered locations, to 30 m depth.

Distribution. NE Atlantic (Azores, Canary Islands); Mediterranean.

Uses and Compounds. Extracts have anti-inflammatory and antiproliferative [6.795], antimicrobial [6.72, 248], antiviral, and cytotoxic [6.72] activity.

Cystoseira crinita Duby

Description. *C. crinita* has an upright, bushy thallus with smooth axes; it reaches a height of 50−350 mm, and a width of 200−500 mm. The main branches are rough, thin, and alternate; the upper section is particularly densely branched. The secondary ramifications are lacking spines, and the terminal receptacles are long, and compact. This alga lacks tophules and the gas vacuoles are either missing or few. *C. crinita* has a light-brown to blackish coloration [6.796].

Habitat. Rocky bottoms on pebbly grounds in sublittoral areas.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antibacterial [6.114, 474, 735], antioxidant [6.717, 797, 798], antiviral and cytotoxic [6.735], anti-inflammatory, and antiproliferative [6.798] activity.

Cystoseira foeniculacea (Linnaeus) Greville

Description. Plant caespitose, to 30 cm, attached to the substratum by a wide and irregular basal disk. Axes to 10 cm high, with a circular cross-section (to 5 mm), normally spinose and with small scars from dehisced primary branches; apices of the axes not very prominent, with small spines [6.799].

Habitat. Occurs in mid-littoral pools and sheltered places.

Distribution. NE Atlantic (Scotland and Ireland to Senegal, Cap Verde Islands); Mediterranean.

Uses and Compounds. Extracts have antibacterial activity [6.60].

Cystoseira humilis Schousboe ex Kützing

Description. Characterized by highly differentiated basal and apical regions and the presence of catenate pneumatocysts (air vesicles). In old plants they have an elongated main axis, and in time the primary laterals become proportionally elongated. Their lower parts are strongly flattened into *foliar expansions* or basal leaves. Fertile regions which bear conceptacles are known as receptacles. These are normally found at the tips of the branches. Their basal and apical regions are highly differentiated. They have catenated pneumatocysts (air vesicles). The aerocyst or air vesicles keep the organism erect, by causing it to float in strong currents [6.800].

Habitat. Occurs in mid-littoral pools and sheltered places.

Distribution. One of the most widely distributed genera of the Fucales order and provides an essential habitat for many epiphytes, invertebrates, and fish. Found mostly in temperate regions of the Northern Hemisphere, such as the Atlantic, Mediterranean, Indian, and Pacific Oceans.

Uses and Compounds. Extracts have antibacterial activity [6.96, 171, 269].

Cystoseira mediterranea Sauvageau

Description. *C. mediterranea* has an upright thallus, with a single cylindrical main axis; irregular ramifications are present with the alga reaching a height of 400 mm. The receptacles are short and cylindrical, and whilst it has gas-filled vesicles, it is lacking in tophules. The main axis has a relatively soft texture, whilst the outer extremities are rough, almost spiny. It is a brown to olive green color and displays a bluish green iridescence when submerged [6.801].

Habitat. Grows in wave-exposed or moderately exposed places, in the upper sublittoral zone, always near the surface.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antitumor [6.62, 421], antimicrobial [6.96, 276, 284, 421], andantifungal [6.62, 276] activity.

Cystoseira nodicaulis (Withering) M. Roberts

Common Name. Bushy noduled wrack.

Description. Thallus to 1 m long, usually solitary, attached by a irregular conical disk. Axis cylindrical usually branched, with smooth, rounded apex immersed between bases or tophules of developing laterals. Lateral branch systems (below) radial or distichous, with greenish-blue iridescence when first formed, about 50 cm long, repeatedly branched in a pinnate manner, either regularly or irregularly, with infrequent cryptostomata and bearing spine-like appendages; deciduous in summer; first-formed laterals of the season with tophules, later without; tophules ovoid, to 15 mm long, smooth or covered with small tubercles, persistent on axis after rest of lateral has been shed. Receptacles formed in the ultimate branchlets, simple or branched, nodose, usually bearing spine-like appendages; air vesicles inconspicuous, dilations of ultimate branchlets, solitary, in series or confluent; sometimes absent [6.802].

Habitat. Found in large intertidal rock pools and lagoons, often with *C. tamariscifolia* and *C. baccata*.

Distribution. Southern and western shores of Britain and Ireland, north to the Argyll in Scotland; Atlantic France and Spain, Portugal, Canary Islands, Morocco, south to Mauritania.

Uses and Compounds. Extracts have antileukemia activity [6.803].

Cystoseira spinosa Sauvageau

Description. Plant with a single axis, to 30–40 cm in height. Axis simple, to 20–30 cm hight: Apex of the axis not prominent and with spines; tophules spinose and oblong; branches both cylindrical and completely flattened, the latter with a pronouced midrib. Spinose appendages more abundantly present in the cylindrical than in the flattened branches; aerocysts absent [6.799].

Habitat. Occurs in the lower sublittoral zone.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antifungal and antimicrobial activity [6.62, 804].

Cystoseira tamariscifolia (Hudson) Papenfuss

Common Name. Rainbow wrack

Description. *C. tamariscifolia* is a bushy seaweed, up to 60 cm in length but usually 30–45 cm. It has a cylindrical frond and branches irregularly (Fig. 6.49). The reproductive bodies on the end of branches are long, oval and spiny. Small air bladders are usually found below the reproductive bodies. *C. tamariscifolia* is olive green in color, almost black when dry. When the plant is seen underwater it has a blue-green iridescence [6.805].

Habitat. Found in rock pools and on the lower shore; grows on both rocky shores and gravelly flats.

Distribution. NE Atlantic (United Kingdom to Mauritania); Mediterranean (France to Turkey).

Uses and Compounds. Extracts have antibacterial and antifungal [6.269, 438, 806–808], antioxidant and antitumor [6.731], and cytotoxic [6.317] activity.

Fig. 6.49 Underwater photo of *C. tamariscifolia*

Cystoseira usneoides (Linnaeus) M. Roberts

Description. Large sized thallus, formed by a central axis and lateral branches with secondary branches – the ones which are closer from basis are flattened and have a foliaceous aspect (Fig. 6.50); presents numerous vesicles [6.809].

Habitat. Is present in relatively deep rocky areas crossed by currents.

Distribution. NE and E Atlantic (France, Spain, Portugal, Morocco, Senegal); Mediterranean (France, Spain, Algeria, Italy).

Uses and Compounds. Extracts have hypoglycemic and hypocholesterolemic [6.810], neuropharmacological [6.811, 812], anticancer, antioxidant, and anti-inflammatory [6.813] activity.

Cystoseira zosteroides C. Agardh

Description. Plant with a single axis, to 30 cm in height, attached to the substratum by simple or branched unfused haptera; axis branched or simple, to 10 cm high; apex of axis smooth and prominent; tophules cylindrical or ovoid, completely smooth, blackish or yellowish brown, sessile or with a sort peduncle; primary branches cylindrical or slightly flattened; secondary and tertiary branches foliaceous, several centimeters long and 1–1.5 mm wide, with an unpronounced midrib and with flattened and triangular spinose appendages, 1 mm long; aerocysts absent [6.799].

Fig. 6.50 *Cystoseira usneoides* specimen

Habitat. Occurs in the lower sublittoral zone.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antifungal and antimitotic activity [6.62].

Fucus ceranoides Linnaeus

Common Name. Horned wrack

Description. Large brown intertidal seaweed, restricted to growing in estuaries or near freshwater streams on the shore. *F. ceranoides* does not have airbladders, but the side of the fronds is often inflated. Frond thin with smooth margin, fan shaped with prominent midrib, without air bladders but frond on either side may be inflated, reproductive bodies' narrow, pointed fronds at ends of branches [6.814].

Habitat. On estuaries or near freshwater streams on the shore, it attaches to stones, rocks, or gravel.

Distribution. *F. ceranoides* is widely distributed in NE Europe but is only common in brackish water. It is characteristic of estuaries and is often abundant where freshwater streams run onto the shore.

Uses and Compounds. Extracts have antioxidant and antitumor activity [6.205].

Fucus distichus Linnaeus

Common Name. Rock weeds

Description. A small tufted brown alga. It has narrow fronds without airbladders and short receptacles. The species has a life span of 3 years and grows up to 30 cm long [6.815].

Habitat. Occurs in rock pools and on rock faces in the upper mid-littoral at wave exposed locations.

Distribution. NE Atlantic (Arctic to Britain and Ireland); NE Pacific (Alaska); Japan.

Uses and Compounds. Extracts have antimicrobial activity [6.816].

Fucus evanescens C. Agardh

Common Name. Arctic wrack

Description. Brown to olive green in color, broad blades, obvious midrib, with Y-shaped forks. Can grow up to 3–90 cm and can be difficult or to distinguish from *F. vesiculosus*, sometimes indistinguishable [6.817].

Habitat. Occurs in rock pools and on rock faces in the upper mid-littoral at wave exposed locations.

Distribution. NE Atlantic (Arctic to Britain and Ireland); NE Pacific (Alaska); Japan.

Uses and Compounds. Source of alginic acid, fucoidan, and used for animal feed [6.817, 818]. Extracts have antiviral [6.819, 820], antibacterial [6.821], antitrypanosomal [6.822], anti-inflammatory, antiangiogenic and antiadhesive [6.823], antithrombotic and hemorrhagic [6.824], anticoagulant [6.823, 825], antitumor [6.826–828], and immunostimulating [6.829–831] activity.

Fucus serratus Linnaeus

Common Names. Toothed wrack, Black wrack, Blackweed

Description. *F. serratus* is a robust, olive-brown shrubby seaweed. It can grow in high densities low on the shore, forming dense mats of long ribbons up to 1 meter long and 2–5 cm across. It attaches to rocks via a discoid holdfast about 3 cm in diameter. Though technically a brown alga, it can vary in color from olive green through reddish brown (though it often has a greenish tint). It typically grows up to 70 cm but has been recorded at over 2 m in length in very sheltered environments. The flat, strap-like fronds have a forward-pointing serrated edge, a distinct midrib, and grow from a short stipe. The fronds are bifurcating (splitting in two repeatedly) [6.832].

Habitat. On firm substrata in the lower mid-littoral; often zone forming.

Distribution. *F. serratus* is a seaweed of the North Atlantic Ocean. It extends from the Canary Islands and northern Portugal along the Atlantic coast of France, into the British Isles and North Sea coasts, and into the W Baltic. It is found in Scandinavia up to Novaya Zemlya, around Iceland, and over to the Gulf of St. Lawrence in the NW Atlantic, ranging from Chaleur Bay and the tip of Cape Breton to Bar Harbor, Maine.

Uses and Compounds. *F. serratus* survives by filtering the ocean for nutrients and as a result, amasses

a huge amount of minerals and vitamins. Used for hundreds of years in seaweed baths, the oils from this seaweed have positive effects on skin, hair and body. The antioxidant [6.766] compounds found naturally in this seaweed have long been known to have pronounced antiaging, skin conditioning, and repair and hydrating effects. This seaweed is used as a food, and is harvested for cosmetics, and it is harvested to make fertilizer. Its edible properties are very similar to that of bladderwrack and interest in this plant is growing, as, being a thyroid stimulant it might could counter obesity by increasing the metabolic rate. It is also known to help women with abnormal menstrual cycling patterns and/or menstrual-related disease histories. It can be stored dried to make a nutritious tea as well as for use in soups and stews as a flavoring [6.833].

This species is collected, dried, and used as a soil additive as well. *F. serratus* is used by over a dozen businesses across the United States, Australia, France, Italy, Ireland, and the United Kingdom in a wide variety of products, such as: antiaging and eye serums, facial moisturizers and sunscreens, dental care compound, revitalizing compound used in skin and hair products, hair shampoos and conditioners, bath soak products, cleansing lotions, body buffs and gels, hand creams, facial, washes, cleansers, and toners, and fertilizers [6.833].

Fucus spiralis Linnaeus

Common Name. Spiral wrack

Description. Well-grown fronds are usually easily recognizable by the flattened, twisted, dichotomously branched thallus, lacking bladders, and the large, oval receptacles at the frond tips, each receptacle being surrounded by a narrow rim of vegetative frond. Nevertheless, younger plants are not always so easy to identify, and even mature plants can be confused with *F. ceranoides* or with bladderless forms of *F. vesiculosus*. Both of these species, however, have narrower, more pointed, rimless receptacles [6.834].

Habitat. Attaches to rocky substrata on sheltered to moderately exposed shores.

Distribution. *F. spiralis* is common on the coasts all around the British Isles, Iceland, W coasts of Europe, Canary Islands, Azores and Northeast North America from New Jersey to Nova Scotia. There are also isolated reports in the N Pacific.

Uses and Compounds. *F. spiralis* has been used historically for treatment of obesity, gout, goiter, and corns, and also in weight reducing and revitalizing bath treatments. It has been used for cattle feed, and as an organic manure. This alga, regularly exposed to sun radiation and its oxidative consequences, has developed optimal bioelectronics characters. It has a high concentration of phloroglucinol derivatives, including phenol acid, and in turn has been used in products from companies in France and the UK such as nutritional supplements, skin serum, body lotion, and compounds and extracts used as ingredients in other skin and hair products [6.835].

Extracts of this species have also antifouling [6.275], antimicrobial [6.269], antioxidant [6.225, 836, 837], anticoagulant [6.55], and antiproliferative [6.225] activity.

Fucus vesiculosus Linnaeus

Common name. Bladder wrack

Description. *F. vesiculosus* varies in color from olive green to olive brown to reddish brown to almost black and is typically about 40 cm in length (although fronds can grow longer). It attaches to rocky substrates by means of a small disk-shaped holdfast. *F. vesiculosus* is characterized by the small nearly spherical gas-filled vesicles (bladders) which look like bubblewrap and occur in pairs one on either side of an obvious central midrib running along the center of the strap-like frond (Fig. 6.51). The flattened, branching fronds can grow from one to two meters in length, and the air-filled bladders which keep the seaweed floating upright in its rocky anchorages increase its ability to photosynthesize. Typically it grows gregariously, forming dense mats of long ribbons up to one meter long and five centimeters across. The appearance of *F. vesiculosus* varies depending on the environmental conditions in which it occurs; in more sheltered areas there are many air bladders, whereas there are fewer in more exposed conditions. Also, in small plants, air bladders may be entirely absent. In exposed areas, it is beneficial for *F. vesiculosus* to lack bladders, as this decreases the potential for severe damage, and minimizes the risk of it being detached and swept away [6.1, 838].

Habitat. On rocks and stones in the mid-littoral; often zone forming.

Distribution. *F. vesiculosus* is found on the coasts of the North Sea, the western Baltic Sea, and the Atlantic

Fig. 6.51 *F. vesiculosus* specimens

and Pacific Oceans. It occurs around the coastline of Greenland, Britain, Ireland, Norway, the Atlantic coast of France, Spain and Morocco, and the Atlantic coasts of Canada and the United States from Hudson Bay to North Carolina.

Uses and Compounds. Primary chemical constituents of *F. vesiculosus* include mucilage, alginic acid, mannitol, beta-carotene, zeaxanthin, iodine and iodine salts, bromine, potassium, volatile oils, and many other minerals, as well as polysaccharides. When used in hot seawater baths or steamed the plants are said to release certain substances that promote good skin, the lower blood pressure and ease arthritic and rheumatic pains. *F. vesiculosus* has been shown to help women with abnormal menstrual cycling patterns and menstrual-related disease histories. A popular use of *F. vesiculosus* in herbal medicine is as a source of iodine (it was the original source of iodine, discovered in 1811), an essential nutrient for the thyroid gland; it can be used in the treatment of underactive thyroid glands (hypothyroidism) and goiter, a swelling of the thyroid gland related to iodine deficiency [6.3, 4, 838].

Extracts of this species have genotoxic and antigenotoxic [6.839], antioxidant [6.717, 766, 840, 841], antithrombotic [6.842], antibacterial and antifouling [6.275], antiviral [6.843], antitumor [6.844, 845], and anticoagulant [6.512] activity.

Halidrys siliquosa (Linnaeus) Lyngbye

Common Name. Sea oak, Pod weed

Description. A large sturdy brown alga 0.3–1 m in length (occasionally up to 2 m) rising from a strong, flattened cone shaped holdfast. The main stem is flattened and branches alternately to give a distinctly zigzag appearance. The stem bears a few, flattened ribbon-like *leafy* fronds. The ends of some branches bear characteristic pod-shaped air bladders (about 0.5 cm wide by 1–4 cm long) that are divided by transverse septa into 10 or 12 compartments. The branches also bear reproductive bodies that appear similar to the bladders but lack the septa. Young plants are olive-green in color while older specimens are dark brown and leathery. This species is perennial [6.846].

Habitat. Distinctive and common rock pool seaweed from the middle to the lower shore (may be found in the upper mid-littoral but only in rock pools). It may also form a zone in the sublittoral below the lower limit.

Distribution. NE Atlantic (from Faroe Islands to Portugal, North Sea, Baltic).

Uses and Compounds. Source of alginic acid. Extracts have antibiotic [6.847, 848], antifouling [6.849], antioxidant, and antitumor [6.421, 731] activity.

Himanthalia elongata (Linnaeus) S.F. Gray

Common Names. Sea spaghetti, Sea thong

Description. Common brown seaweed, which has a two stage morphology. Small button-like thalli are first produced, from which long strap-like reproductive fronds (receptacles) are formed in autumn (Fig. 6.52). The strap-like reproductive fronds grow quickly between February and May, reaching a length of up to 3 m. The plant releases gametes from June until the winter when it starts to decay. Plants commonly live for 2–3 years and reproduce once before dying [6.1].

Habitat. *H. elongata* is common on gently shelving rocky shores attached to hard substrata such as bedrock, or large to very large boulders. It is found on the lower

Fig. 6.52 *Himanthalia elongata* specimen

shore flourishing at the low tide limit with moderate wave exposure where its thallus is typically always submerged, and is considered a sublittoral species.

Distribution. *H. elongata* can be found from the Arctic Ocean south to the Iberian Peninsula, in the waters of the Baltic Sea, the North Sea and the northeast Atlantic Ocean. It is seen on the shores of Norway, the Faroes, Britain, Ireland, the western coast of France, northern Spain, and Portugal.

Uses and Compounds. *H. elongata* is known to provide high levels of Vitamins A, C, and E along with essential amino acids and other natural minerals. It has several properties which make it attractive as an ingredient in personal care and cosmetic products, such as that it is absorbent, viscosity controlling, skin protecting, and can be used as a binding agent. It has a natural ability to help restore balance to skin's moisture levels. It is used in dozens of products made in Ireland, France, Spain, Italy, Canada, and the United States [6.3, 4, 850].

H. elongata is used in shampoos and hair treatments, facial cleansers and skin care products, and also as a fertilizer. It can be sold and eaten fresh when in season, but it is typically sold dried or pickled, and is eaten most commonly in France and Ireland. It is used as an alternative to both traditional semolina spaghetti and green beans. It is found in popular tartar (sauce), *tahini*, pâté and cream products, and also in sea vegetable mixes [6.3, 4, 850].

Extracts of this species have hypoglycemic [6.851], antibiotic [6.852, 853], neuropharmacological [6.854, 855], antimicrobial, and antioxidant [6.429, 533, 765, 766, 856, 857] activity.

Pelvetia canaliculata (Linnaeus) Decaisne & Thuret

Description. *P. canaliculata*, often called channeled wrack, is a very common brown alga (Phaeophyceae) of Europe. It is the only species remaining in the monotypic genus *Pelvetia*. It is relatively small, not growing longer than 15 cm. When viewed underwater, its color can be light olive green, and sometimes yellowish brown (Fig. 6.53). *P. canaliculata*'s color can range from dark brown to dark olive to very dark or blackish green when dried. Its extremities can appear swollen and with orange during spring and summer. These bumpy, irregularly v-shaped swellings with forked tips at the ends of the fronds are its reproductive structures. It appears bushy and grows in dense tufts. Each frond is curled longitudinally (rolled lengthwise) to form a distinct channel. It is irregularly dichotomously branched; each tough and thick branch is of uniform width up to 1 cm, lacks a midrib, and lacks air vesicles or bladders. *P. canaliculata* is a perennial species; it is at least two years old before it reaches maturity, and has a life span of up to 4 or 5 years, growing 3 – 4 cm per year [6.1, 858].

Habitat. *P. canaliculata* grows attached to hard substrata with a small basal disk on the upper shore, and forms the uppermost zone of algae growing at or above high water mark. It needs periods of exposure to the air, and sometimes grows so high up a beach that coarse grass and other long-shore angiosperms grow among it. *P. canaliculata* is found right at the top of the beach in sheltered to moderately exposed areas where it can dry out completely to become black and crispy.

Fig. 6.53 *Pelvetia canaliculata* specimens

Distribution. One can find *P. canaliculata* in the northeast Atlantic, from the Arctic Ocean to the Iberian Peninsula, in the English Channel, and in the North Sea. It is common on the Atlantic shores of Europe from Iceland to Spain, including Norway, Ireland, the UK, the Netherlands, France, and Portugal (southern limit of this species).

Uses and Compounds. *P. canaliculata* was historically harvested for use as animal fodder, and in certain areas there are still animals which graze on the growing plants. It has also been collected historically as a source of food for people. It is included in dozens of products from Italy, France, United Kingdom, and the United States. According to one leading cosmetics producer, *P. canaliculata* stimulates the synthesis of collagens and proteoglycans, which are responsible for giving connective tissue its elastic properties. Using it as a compound can increase the skin's firmness and reduce the appearance of lines and wrinkles. It is reported from another leading cosmetics company that it increases microcirculation and can help reduce fat and cellulite. *P. canaliculata* can be found on ingredient labels for moisturizing lotions, masks and creams, and in body creams, day creams, and night creams. It is found in quality restorative and hydrating serums, and in compounds and extracts used in different products. For food, it is sold in different dried forms, and as a seasoning mix [6.858].

Source of alginic acid and fucoidan [6.859], and the extracts of this species have antioxidant [6.860, 861], anticoagulant [6.862], antifungal [6.863], antifouling [6.275], and antibiotic [6.864] activity.

Sargassum filipendula C. Agardh

Description. The habit of *S. filipendula* is so like that of other species which have been described that it needs but slight attention. This species grows attached to rocks below low water mark, and therefore, unlike *Fucus* and A*scophyllum*, is never exposed to the air. Vegetative plants and reproductive plants bearing all stages of conceptacles are plentiful in summer. Sporelings are abundant also and easily collected, for the discharged eggs and their products, the sporelings, remain attached for some time by mucilage to the surface of reproductive branches near the parent conceptacles. The stem arises from a small disk-shaped holdfast and passes into long cylindrical branches which bear spirally arranged leaves, berry-like floats, which seem to be modified portions of leaves, as generally stated, and short reproductive branches. This form may attain a height of 60 cm, but is commonly shorter [6.865].

Habitat. On firm substrata in the shallow sublittoral, to 6 (−30) m depth.

Distribution. NE Atlantic (Spain and Portugal to Gabon), Caribbean (Cuba), SW Atlantic (Mexico to Brazil).

Uses and Compounds. Extracts have antitumor [6.866–869], antioxidant [6.679, 866, 868, 869], and antifungal [6.863, 870] activity.

Sargassum hornschuchii C. Agardh

Description. Differs from the *S.vulgare* for the shape of the *leaves*: laminated in *S. vulgare* and triangular section in *S. hornschuchii* [6.871].

Habitat. On firm substrata in the shallow sublittoral, to 6 (−30) m depth.

Distribution. Mediterranean.

Uses and Compounds. Extracts have antifungal [6.62], cytotoxic, and antitumor [6.197] activity.

S. muticum (Yendo) Fensholt

Common Names. Japanese seaweed, Japanese brown alga, Japweed, Wire weed, Strangle weed.

Description. *S. muticum* is a large brown seaweed, varying in color from dark brown to pale, yellowish brown depending on the season and the growing conditions. *S. muticum* has regularly alternating lateral shoots or branches, on a central perennial stem (Fig. 6.54). It attaches to the substrate with a disk-shaped holdfast. It has numerous small 2–3 mm round or pear-shaped air-bladders which sit on small stems and cause the alga to stand upright in the water or float if parts of the alga are detached from the basal stem. *S. muticum* has a frond which may be 75–120 cm long in its native range, but normally reaches a length of 1.5–2 m in Swedish waters, 6–7 m in French waters, and up to 8.5 m in Norwegian waters. Lateral branches detach in the summer or autumn, leaving a short perennial basal stem to overwinter [6.872]. During the summer, cigar-shaped reproductive receptacles develop in the areas where the annual shoot or *branch* attaches to the stem, but may also sit on top of the branch [6.1, 873].

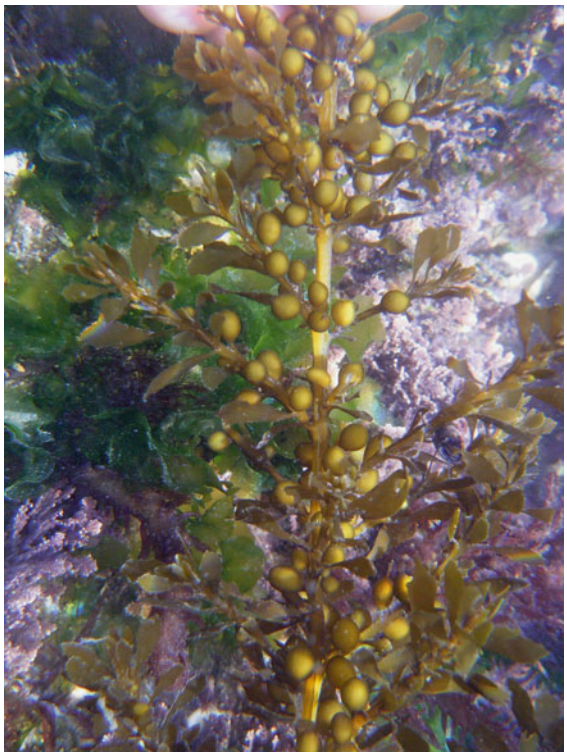

Fig. 6.54 Underwater photo of *S. muticum*

Habitat. In the mid-littoral and to below the tidal mark (3–5 m).

Distribution. Highly invasive: originally from Japan, it now colonizes large parts of the NE Atlantic (Norway to Portugal, North Sea), the W Mediterranean, and the N Pacific: NW Pacific (Japan), NE Pacific (Alaska to Mexico).

Uses and Compounds. Source of Laminaran [6.873], and extracts have antitumor and antibacterial [6.113], antioxidant [6.874], antialgal [6.257], antifungal [6.863], antibiotic [6.875], and antifouling [6.876–880] activity.

Sargassum natans (Linnaeus) Gaillon

Description. *S. natans*, unlike the many benthic *Sargassum* species (i. e., those that live attached to the sea bottom), is a pelagic (free-floating) brown seaweed that occurs mainly far out in the North Central Atlantic Ocean, but washes ashore regularly. It is often associated with the Sargasso Sea, a very large region situated offshore from the southeastern United States, approximately south and east of Bermuda and seaward from the Gulf Stream. The Sargasso Sea, which accumulates large masses of *Sargassum*, results from a ring of prevailing ocean currents that enclose an enormous eddy (about 5.2 million km^2) which rotates clockwise as a result of the Earth's eastward rotation. *S. natans* apparently reproduces only asexually, by fragmentation. *Gower* and *King* [6.881, 882] used satellite imagery to track the origin, distribution, and fate of floating *Sargassum*. Using this approach, they analyzed data from 2002 to 2008 and were able to present the first mapping of the full distribution and movement of pelagic *Sargassum* in the Gulf of Mexico and western Atlantic. Their results revealed a seasonal pattern in which *Sargassum* typically shows strong growth in the northwest Gulf of Mexico in the spring of each year, is transported into the Atlantic in about July, appearing east of Cape Hatteras as a *Sargassum jet*, and ends up northeast of the Bahamas in February of the following year.

Habitat. On firm substrata in the shallow sublittoral, to 6 (–30) m depth.

Distribution. NE Atlantic (Spain); Atlantic Islands; NW Atlantic; Caribbean; SW Atlantic; Pacific Ocean (Indonesia); Australia.

Uses and Compounds. Source of alginic acid [6.883] and extracts of this species have antimicrobial [6.136, 884, 885], antifouling [6.275], and antitrypanosomal [6.822] activity.

Sargassum vulgare C. Agardh

Description. *S. vulgare* has a bush-like thalli reaching 15–70 cm high; the fronds are oval, flattened, olive-green to brown and possess a central rib and undulated edge. The base of the fronds has hollow, spherical vesicles, of 5–8 mm, and clusters of reproductive bodies; these are held in place by a pedicle. The alga is attached to the substrate with irregular rhizoidal branches. *S. vulgare* has an olive brown to dark brown coloration [6.886].

Habitat. On firm substrata in the shallow sublittoral, to 6 (–30)m depth.

Distribution. NE Atlantic (Portugal, S Spain to Canary Islands); Mediterranean; Caribbean; SE Atlantic (W Africa); W Pacific (Philippines); Indian Ocean.

Uses and Compounds. Source of alginic acid [6.765, 886, 887] and extracts of this species have antihelminthic [6.886], antioxidant, antimicrobial and antifungal [6.336, 888, 889], antitumor [6.765, 890, 891], antilipemic [6.892], antifouling [6.893, 894], antimicrobial [6.228], anticoagulant, antithrombotic, and anti-inflammatory [6.889] activity.

- Order: **Laminariales**

Alaria esculenta (Linnaeus) Greville

Common Name. Dabberlocks.

Description. Fronds with olive or yellow-brown fronds to 4 m long and 25 cm wide. Attached by a root-like holdfast at the base from which a narrow flexible stipe arises which continues into the leafy part of the plant as a distinct mid-rib (Fig. 6.55). The reproductive structures, apparent as dark-brown areas, are confined to unbranched leafy appendages borne on the stipe, usually in two rows. This is the only kelp-like plant in Ireland and Britain with a distinct midrib and is the only one with sporangia borne at the base of the frond in special leaflets called sporophylls [6.895, 896].

Fig. 6.55 Herbarium specimen of *Alaria esculenta* (MA-COI no. 2664)

Habitat. Generally grows on rock in very exposed places, often forming a band at low water and in the shallow sublittoral, but also occurs in tidal pools in the lower shore.

Distribution. Coasts of the North Atlantic (France, Scotland, Ireland, Greenland, Iceland, northeastern United States, northeastern Canada), the N Sea (England, Norway, Netherlands), Novaya Zemlya to the N Pacific (Bering Sea and Sea of Japan).

Uses and Compounds. *A. esculenta* can be used for a variety of purposes from human consumption and alginate production to fodder and body-care products. It is rapidly gaining popularity in the natural foods market. It can be ordered from many sellers as whole, flaked, milled, or powdered. It is used

for antiaging body creams, foot creams, bath soaks, body and face masks, body polish, UV-protecting facial moisturizers, self-tanning lotions, lip balm, day- and night-creams, and nutritional supplements to name a few. In Canada and the United States, this seaweed is sometimes sold as *Atlantic Wakame* and is presented as an alternative to traditional Japanese Wakame (*Undaria pinnatifida*). *A. esculenta* also has potential as a foodstuff in aquaculture for herbivorous molluscs such as abalone. Over 20 sellers with over 70 *A. esculenta*-based products have been identified. These sellers are from Germany, Italy, France, Ireland, United Kingdom, Canada, and the United States [6.4, 896, 897].

Chorda filum (Linnaeus) Stackhouse

Common Names. Sea lace; dead man's rope; mermaid's tresses; Cat gut.

Description. *C. filum* is a brown seaweed with long cord-like fronds, only 5 mm thick in diameter. The fronds are hollow, slippery, unbranched, and grow up to 8 m long. The species is attached to the substratum using a small discoid holdfast. It is an annual species, disappearing in winter [6.898, 899].

Habitat. It is found in rock pools on the low shore and in the sublittoral down to 5 m. It is most commonly found in the sheltered bay.

Distribution. Abundant throughout the North Atlantic, on the shores of Europe and America, coast of Brazil, and also in the North Pacific, at Sitka, Unalaschka, and Kamtschatka.

Uses and Compounds. *C. filum* is used fresh as a foodstuff, and for animal feed [6.898]. This species produces alginate and fucoidan, and have antimicrobial [6.474, 546, 844, 898, 900], algicidal [6.257], anticoagulant [6.524], and antioxidant [6.474] activity.

Laminaria digitata (Hudson) J.V. Lamouroux

Description. A large conspicuous kelp growing up to 2 m in length commonly found at low water during spring tides on rocky shores. The frond is broad and digitate, glossy and dark brown in color and lacks a midrib. The stipe is oval in cross section, smooth and flexible and is usually free of epiphytes, although old stipes which has become slightly roughened may support a few epiphytes, notably *Palmaria palmata*. The kelp is attached to freely branched haptera, which spread out to form a shallow dome-shaped holdfast. *L. digitata* may be confused with young *L. hyperborea* plants. However, the stipe of *L. hyperborea* is circular in cross section, is stiff, and snaps easily when bent (although you would not see that in younger fronds) [6.901, 902].

Habitat. On rocks from the low water spring tide level to the shallow sublittoral. In some locations, *L. digitata* may be found in deeper water.

Distribution. *L. digitata* is a North Atlantic Arctic-cold-temperate species which does not occur in the North Pacific. It is found along both coasts of the English Channel; the southernmost occurrence of this species in European waters is on the southern coasts of Brittany. It grows along most coasts of Britain and Ireland, and along the North Sea coasts of Scandinavia. Its northerly range includes into the Barents Sea and the western shores of Novaya Zemlya, and has been reported to occur in the Svarlbard Archipelago. *L. digitata* also grows in Iceland, the Faeroes, southern Greenland, and the eastern coasts of North America, as far south as Cape Cod.

Uses and Compounds. *L. digitata* plants contain minerals, vitamins, and trace elements. These include iodine, calcium, potassium, iron, carotene, alginic acid, laminaran, fucoidan, mannitol, protein, carotene, niacin, phosphorus, the B complex vitamins, vitamin C, and many other trace elements. This species stores flavor-enhancing glutamic acid, or sodium glutamate, which imparts a mellow, silky taste to dishes. The slight sweet background is mannitol, a natural sugar. In terms of relatives, *L. digitata* is closely related to the five species (*Saccharina latissima*, *S. japonica*, *L. angustata*, *L. longissima*, and *L. ochotensis*) typically harvested as *Kombu* in Japan, and is frequently harvested and sold as Kombu in North America. Many recipes calling for Kombu could be made with this form of kelp [6.901–906].

Extracts of this species have antibacterial [6.371], and antioxidant [6.766] activity.

L. hyperborea (Gunnerus) Foslie

Common Name. Oarweed.

Description. *L. hyperborea* is often difficult to distinguish from *L. digitata*, particularly when plants are young (Fig. 6.56). However, the stipe of *L. digitata* is darker and usually oval in cross section instead of cylindrical, is not thicker at the base, does not snap easily,

Fig. 6.56 *Saccorhiza polyschides* (*left*) and *L. hyperborea* (*right*)

and does not have epiphytes on the stipe. Also, the belt of *L. hyperborea* is nearly always below (in deeper water) any belt of *L. digitata*. *L. ochroleuca* is a similar species, but has a smooth stipe (not rough like *L. hyperborea*), and its fronds are typically more golden or yellow. *Saccorhiza polyschides*, another commercially utilized kelp, appears similar to *L. hyperborea* from the frond, but has a twisted stipe near a bulbous haptera, which is very different from *L. hyperborea*'s bird claw holdfast [6.1, 907].

Habitat. Found on bedrock or other stable substrata from extreme low water to depths dependent on light penetration and sea urchin grazing (typically about 8 m depth in coastal waters to 30 m in clear coastal).

Distribution. *L. hyperborea* is a European North Atlantic cold-temperate species which does not extend into areas influenced by Arctic waters; its range is the NE Atlantic Ocean, from Scandinavia south to Spain and the Canary Islands, the Baltic Sea, and the North Sea.

Uses and Compounds. In Europe, *L. hyperborea* is one of the two kelp species commercially exploited by the hydrocolloid industry, the other being *L. digitata*. *L. hyperborea* is also utilized by the cosmetic and agrochemical industries and for biotechnological applications, and by the food industry for emulsifiers and gelling agents. Drift kelp has long been collected as an agricultural fertilizer and soil conditioner. *L. hyperborea* is still harvested and used in popular kelp meal fertilizer products. *L. hyperborea* is a source of laminarin and mannitol, which are used in industrial and other applications. Because of its ability to absorb and retain water, it has been used in wound dressings to prevent adhesions, and has also been used to help dilate the cervix during childbirth [6.3, 907].

Extracts have antifungal [6.863], anticoalgulant [6.512], antibacterial [6.765], antioxidant [6.860], and anticoagulant [6.524] activity.

Laminaria ochroleuca Bachelot de la Pylaie

Common Names. Kelp, Kombu.

Description. *L. ochroleuca* is a glossy, yellow-brown kelp that is prevalent along the intertidal zones. This kelp is quite conspicuous as it grows quite large under the right conditions. The maximum length recorded is 4 m long, but this length is rarely attained and occurs only in specific areas. Under normal conditions *L. ochroleuca* is more likely to reach a maximum length of about 2 m. It has a large heavy holdfast made up of thick haptera (up to 18 cm in diameter) that support the plant and anchor it to rock. This holdfast gives rise to a fairly long, rigid, round, epiphyte-free stipe that tapers somewhat as it approaches the blade. This stipe is so strong and stiff that it stands erect when the plant is out of the water. The blade of this kelp is large, flat, and leathery, and is divided into 5–20 strap-like digits. This kelp is easily distinguished by the distinct yellow area at the junction of the stipe and the blade. The entire plant actually has a very lovely yellowish hue to its smooth, bright, glossy tissue. *L. ochroleuca* is a perennial kelp that retains its stipe and holdfast year long but regenerates a new blade each year [6.1, 908].

Habitat. This species is found on rocks from the low water spring tide level to the shallow sublittoral. In some locations *L. ochroleuca* may be found in deeper water.

Distribution. *L. ochroleuca* is a warm-temperate species of kelp, and is most common in the NE Atlantic from the British Isles to the Sahara and the Atlantic zones of the Mediterranean.

Uses and Compounds. Extracts of *L. ochroleuca* have been found to act as a central nervous system depressant with a slight analgesic activity. It is also able to effectively guard DNA against UV rays and premature aging. With these properties, it is becoming more widely used in cosmetics and in natural therapeutic medicine. Applied topically, *L. ochroleuca* helps reduce inflammation and, like many forms of seaweed, has some amount of moisture-binding properties due to its sterol content. It is used in products from Spain, Germany, France, and the United Kingdom; these include rescue balms, repairing and antiaging moisturizers, as well as dried and packaged foods [6.3, 4, 908, 909].

Extracts have also antimicrobial [6.224, 269, 910–913], antifungal [6.913], and antialgal [6.257] activity.

Saccharina latissima (Linnaeus) C.E. Lane, C. Mayes, Druehl & G.W. Saunders

Synonym. *Laminaria saccharina* (Linnaeus) J.V. Lamouroux

Common Names. Sugar kelp, Sea belt, Sugar wrack.

Description. Just like most kelps, *S. latissima* has blades (lamina), stipes, and holdfasts, which is attached to substrates. The sporophytes of *S. latissima* have a rich medium brown color, a long undivided frond without a midrib and a profusely branched holdfast (Fig. 6.57). Mucilage ducts are absent from stipe; the blade often has two rows of bullations formed in two longitudinal rows parallel to the central axis. The frond of *S. latissima* has a distinctive frilly undulating margin. The stipe of *S. latissima* may be up to 50 cm long [6.1, 914].

Habitat. *S. latissima* is usually found from the sublittoral fringe down to a depth of 30 m. More rarely, it occurs in rock pools. The species usually occurs in sheltered conditions and may be attached to unstable substrata such as boulders and cobbles.

Distribution. N and NE Atlantic (Greenland to Portugal, North Sea, Baltic); NW Atlantic (Canadian Arctic to Massachusetts); NE Pacific (Alaska to California).

Uses and Compounds. Kelp harvesting is also an important industry around the world. Kelp products, alginic acid and fucoidan, are used for different purposes [6.915]. Alginic acid is a common polysaccharide constituent of kelp cell walls and it can be used to form gels. Alginic acid is used as a stabilizer in the food, cosmetic, and pharmaceutical industries: yogurts, shampoos, skin creams, lotions as well as ice creams. Alginic acid is also being used in many dietary products because human body cannot absorb it. In lots of biotechnological research experiments, alginic acid is used to separate substances [6.3, 4].

Fig. 6.57 *Saccharina latissima* specimen

People eat Sugar kelp (also called Kombu in Japanese dishes), which contains appreciable amount of vitamin C and is high in iodine, protein, and calcium. The blade is usually chopped and cooked as a savory garnish (Tororo Konbu) for rice and other dishes, as a vegetable, and as snacks (such

as Tsukudani). Kombu is also used to add flavor to broths (Dashi stock) and stews but it removes itself removed from the liquid at the end of cooking and discarded. It can be used to soften beans during cooking, and to help convert indigestible sugars [6.4].

Extracts of this species have anticoagulant [6.512, 524], antifouling [6.916], antimicrobial [6.533, 816, 917], and antioxidant [6.429, 533, 860] activity.

Saccharina longicruris (Bachelot de la Pylaie) Kuntze

Description. *S. longicruris* is a particularly tall species of kelp. The hollow, cylindrical stipe itself can reach up to 10 m long, plus the frond which adds another 1–2 m. The large branched holdfast grips firmly to the rocky substrate allowing a single long, thin, olive-brown, leafy blade to float near the surface. The midsection of these blades is somewhat thicker, but the edges spread and thin and become wide and ruffled. *S. longicruris* is limited to the sublittoral zone, but can be found either in shallow or in much deeper waters, often preferring areas with a strong flow. In this environment, it is a dominant part of the seaweed community and forms dense multistory forests with older plants forming a canopy of fronds floating on the surface and younger plants protected underneath [6.918].

Habitat. Horizontal distribution is determined to a large extent by substratum type and salinity. In very sheltered sites the species can occur on an unstable substratum of gravel and small stones.

Distribution. The species occurs widely throughout the NW Atlantic and eastern Arctic Oceans, mostly within Canadian territorial waters, and along the west coast of Greenland north of 62° N. The species is rare on the east coast of Greenland, but has been recorded from Iceland, the Faeroes and as far south as Long Sound on the Shetland Islands at the latitude of 60° N. *S. longicruris* has not been recorded from the European mainland.

Uses and Compounds. *S. longicruris* is an edible species of kelp that is related to traditional Japanese Kombu, but is thinner, tenderer, and cooked fastly. It is high in minerals and micronutrients and is particularly delicious as it contains naturally occurring monosodium glutamate – a little known feature of many kelp species [6.918, 919].

Extracts have immunostimulatory [6.920], and skin antiaging [6.921] activity.

Saccorhiza polyschides (Lightfoot) Batters

Common Name. Furbelows.

Description. *S. polyschides* is kelp species with a distinctive large warty holdfast and a flattened stipe with a frilly margin (Fig. 6.56). The stipe is twisted at the base and widens to form a large flat lamina, which is divided into ribbon-like sections. The species is an annual, and very fast growing. It is opportunistic and colonizes available hard substrata in the sublittoral [6.1, 922].

Habitat. In the lower littoral, in calm shallow water to 19 m.

Distribution. NE Atlantic (Norway to Morocco), W Mediterranean.

Uses and Compounds. Source of alginic acid, and possible source of biofuel [6.380]. Extracts of this species have hypoglycemic [6.923], antisettlement [6.360], cytotoxic, and antiplasmodial [6.924] activity.

U. pinnatifida (Harvey) Suringar

Common Name. Wakame.

Description. *U. pinnatifida* belongs to the order Laminariales, with three clearly recognizable parts comprising its visible thallus: blade, stipe, and holdfast. The thallus can reach 1–3 m in length. The blade is lanceolate and broad with a prominent midrib, and translucent with color ranging from green to yellowish brown to dark brown. The blade could also be described as triangular and lobed (Fig. 6.58). The appearance of the blade evolves and changes over time; it is initially simple, flattened, and broad with a pronounced or distinct midrib; older plants have thicker blade tissue which splits horizontally down to the midrib to form fingers or straps, becoming more transversally lobed, and becomes pinnate with age. The margins of the blade can also be described as wavy. The distal portion of the blade and the straps eventually become tattered. The stipe of *U. pinnatifida* is wavy or corrugated above the holdfast. The stipe is also usually short (10–30 cm) in length and up to 1 cm in diameter) and in mature plants bears convoluted wing-like reproductive outgrowths or frills (sporophylls). The stipe is

Fig. 6.58 *U. pinnatifida* specimen

Fig. 6.59 Herbarium specimen of *Cladostephus spongiosus* (MACOI no. 3509)

also flattened, and transitions into the midrib which extends through the middle of the length of the blade. *U. pinnatifida* is attached to its substrate by a branched holdfast comprised of haptera. It may be confused with *A. esculenta*, as it also has a prominent midrib, but the corrugated stipe of *U. pinnatifida* (which contains its sporophylls) is distinctive. Also, *A. esculenta* grows in more exposed and wave-battered locations than *U. pinnatifida* [6.1, 4, 925].

Habitat. Wakame is economically important as a food crop but is also a fouling organism. It is able to compete with native Kelp species in the shallow sublittoral zone.

Distribution. Worldwide distribution.

Uses and Compounds. *U. pinnatifida* is economically important as a food crop, next to Nori, on the Japanese menu, and is eaten both dried and fresh. In East Asian countries the seaweed is known as Wakame and is treated as a delicacy, often added to miso soup. It can be considered a sea vegetable, or edible seaweed. *Wakame* fronds are green and have a subtly sweet flavor and slippery texture. In Asia and Europe, Wakame is distributed either dried or salted, and used in soups (particularly miso soup), and salads (such as tofu salad), or often as a side dish to tofu and a salad vegetable like cucumber. Goma wakame, also known as seaweed salad, is a popular side dish at some sushi restaurants; literally translated, it means *sesame seaweed*. In Korea, *U. pinnatifida* is used in salads or soup such as Miyeokguk. Many women consume *U. pinnatifida* during pregnancy, and *Miyeokguk* is popularly consumed by women after giving birth as Miyeok contains a high content of calcium and iodine, nutrients that are important for nursing new mothers. It is also traditionally eaten on birthdays for this reason, a reminder of the first food that the mother has eaten and passed on to her newborn through her milk, thus bringing good fortune for the rest of the year. After the species was accidentally introduced in 1971 in the Mediterranean via farming of Japanese oysters (*Crassostrea gigas*), *U. pinnatifida* was grown in the French Bretagne as food, which increased exposure of this seaweed to Europeans. *U. pinnatifida* is also used in a wide variety of topical beauty treatments and personal care products, due to its high polysaccharide content and ability to provide moisture [6.3, 4, 925].

Extracts of this species have antihypertensive [6.926], immunomodulating [6.927], antidiabetic [6.928], antiviral [6.929, 930], cytotoxic [6.931], antioxidant [6.932], antitumor [6.933, 934], antiedema

[6.935], antiplasmodial [6.936], anti-osteoporotic [6.937], anti-inflammatory [6.938], antiobesity [6.939, 940], antihypertensive [6.941], and antithrombotic [6.942] activity.

- Order: **Ralfsiales**

Ralfsia verrucosa (J.E. Areschoug) J.E. Areschoug

Description. *R. verrucosa* is an olive brown to khaki encrusting brown seaweed that occurs abundantly in low shore tide pools. Here it often forms large, flat, smooth expanses giving the impression that someone had accidentally dropped khaki paint into the tide pools. *R. verrucosa* can occur in high abundance because of its relatively fast growth rate and also because it produces a chemical which seems to deter most grazers [6.943].

Habitat. Saxicolous, mid-littoral.

Distribution. NE Atlantic (Ireland and Britain to Morocco); SE Atlantic (South Africa); NW Atlantic (Canada, USA); SW Atlantic (Argentina); Mediterranean; Indo-Pacific; Australia.

Uses and Compounds. Extracts have antibacterial and antifouling activity [6.944].

- Order: **Sphacelariales**

Cladostephus spongiosus (Hudson) C. Agardh

Description. Fairly stiffly branched fronds growing from a crust-like discoid holdfast, covered with small branchlets arranged in whorls (Fig. 6.59); maximum length is usually about 15 cm [6.945].

Habitat. On firm substrata in the intertidal zone.

Distribution. NE Atlantic (Iceland to Morocco); Mediterranean, Indian Ocean; Australasia; Antarctica, Sub-Antarctic Islands.

Uses and Compounds. Extracts have antibacterial activity [6.171, 201].

Halopteris filicina (Grateloup) Kützing

Description. Compressed, tufted, dark purplish brown fronds, to 120 mm high, main axis 1–4 mm broad. Once or twice pinnate, axes and branchlets tapered at base and apex [6.946].

Habitat. On rocks in pools, mid-littoral to shallow sublittoral, sporadic, often locally common.

Distribution. NE Atlantic (Ireland and Britain to Morocco); Mediterranean; NW Atlantic (USA); SW Atlantic (Brazil); NE Pacific (South Korea, Japan).

Uses and Compounds. Extracts have antihelminthic [6.946], antimicrobial [6.40, 130, 201, 203], antifouling [6.947], antifungal and antimitotic [6.62] activity.

Stypocaulon scoparium (Linnaeus) Kützing

Synonym. *Halopteris scoparia* (Linnaeus) Sauvageau.

Common Name. Sea broom.

Description. *S. scoparium*, previously known as *H. scoparia*, is a dark brown algae that forms beautiful fluffy clumps in shallow rocky-bottomed water. Growing only up to 15 cm in length, *S. scoparium* has a main axis with alternate plumed branches which are more or less fan shaped when flat, though when buoyed up by water they form inverted cone-shaped tufts with a very delicate appearance due to the many filamentous branches. Plants are usually attached to rocks with small to extensive disks often obscured by many matted rhizoids; though these are lacking in free-living plants. These plants are characterized by pure, sheltered waters with high light levels. *S. scoparium* often forms clumps on cobble in the shallow sublittoral zone, though they are just as likely to be found in shallow tide pools or sandy-bottomed areas [6.32, 948].

Habitat. On rocks and epiphytically on other seaweeds; in sheltered zones of the upper littoral and in up to 5 m depth.

Distribution. NE and E Atlantic (Scandinavia to Cap Verde Islands); Mediterranean.

Uses and Compounds. *S. scoparium* is known to be an ingredient in compounds used in personal care products; it contains growth substances (phytohormones) that include auxins, gibberellins, cytokinins, abscissic acid, and betaines [6.948].

Extracts of this species have antiprotozoal [6.193], antifungal and antimitotic [6.62], antioxidant [6.949], antileukemia [6.950], and antimicrobial [6.296] activity.

7. Corals

Mohammad Kazem Khalesi

Almost 50% of cytotoxic compounds are isolated from marine organisms such as sponges and corals. Symbiotic corals, mainly soft corals, are potential sources of many unique metabolites including cytotoxic and anticancer compounds. This review focuses on secondary biochemicals with potential biomedical properties extracted from both soft and hard coral species. The coral-derived compounds and extracts, for which biological activities have been reported, are discussed in this review, which covers the years from 1975 to late 2012. For distinction, members of each coral family, and the relevant genera and species have been surveyed separately. A total of 244 compounds (excluding crude extracts) have been introduced from 15 and 6 families each with 139 and 16 species of soft and hard corals, respectively. The majority of introduced compounds are promising as potential cancer therapeutics.

7.1 Background

The marine environment represents a treasure of useful products that await discovery to used for the treatment of infectious diseases [7.1]. Medicines derived from marine organisms, specifically invertebrates, as a source of novel compounds have been investigated because of their potential for producing new drugs (e.g., toxins with high potency and low solubility), which makes them particularly suitable for consideration as sources of antineoplastic agents [7.2]. Almost 50% of cytotoxic compounds have been isolated from marine organisms such as sponges and corals (reviewed in [7.3]). In comparison with the other life-forms, bioactive compounds have been detected frequently, albeit after sponges, in symbiotic corals, mainly soft corals.

There are two subclasses in *Anthozoa*, namely, *Hexacorallia* (zoantharia) and *Octocorallia*. Soft corals (octocorals: phylum *Cnidaria* (formerly *Coelenterata*), class *Anthoza*, subclass *Octocorallia*) are multicellular

marine animals, most of which form colonies mainly in tropical waters composed of hundreds or thousands of polyps; polyps cover a soft skeleton composed of a protein/calcium carbonate material (> 60% of organic matter). *Cnidaria*, one of the largest phyla consists of three classes, among which *Anthozoa* is the largest [7.4, 5]. Among *Cnidaria*, 21% of the species contain potential marine biomedical compounds [7.6]. Almost 50% of octocorals as members of *Cnidaria* have been reported to produce toxins; about 60% of their extracts are bioactive molecules with medicinal potential [7.7–10]. Published records state that 11–17% of potential new drugs undergoing preclinical stage from 1998 to 2002, originate from octocorals. From the soft coral species investigated up to 2008, more than 30% exhibited cytotoxic activity [7.11], suggesting production of potential medicinals. A similar percentage (30%) was presented in [7.12], where crude extracts were screened from 20 octocorals displaying cytotoxic and antimycobacterial activities (60%, Figs. 7.1–7.10).

7.2 Potential Pharmaceuticals from Soft Corals

Octocorals lack toxic stinging nematocysts, as well as a rigid protective skeleton common to scleractinians, but possess allelopathic capabilities [7.13]. Using allelopathic chemicals, sessile soft corals compete for space, reduce their palatability by producing terpenoids, and reduce fouling by chemical substances and mucus [7.14]. These allelopathic secondary metabolites, especially terpenes, also protect against predators, infections and injuries, and play a range of physiological roles [7.5, 15].

Structurally diverse compounds including diterpenes, prostaglandins, and steroids described in octocorals [7.16–18] render these animals rich sources of steroids, terpenoids, and other types of secondary metabolites, including a large variety of sesquiterpenoids and diterpenoids [7.8, 19]. Octocorals, unlike sponges, are capable of rapidly synthesizing terpenes de novo [7.19]. Similarly, it was reported in [7.20] and [7.21] that toxins are secreted more or less continuously in several species of soft corals.

In a comprehensive study, the antimicrobial activity of extracts of several of the most dominant stony (scleractinian) and soft (alcyonacean) coral species from the coral reef of Eilat (northern Red Sea) was compared against indigenous bacteria. The results revealed substantial variability in antimicrobial activity of the extracts from hard and soft corals. Five out of six (83%) Red Sea alcyonacean soft corals showed considerable antimicrobial activity against the test bacteria, whereas none of the extracts of the six stony corals tested inhibited the test bacteria. It, therefore, appears that soft and hard corals have developed different means to combat potential microbial infections. Antibiotic compounds in alcyonacean soft corals are used to combat microbial attack, whereas stony corals seem to rely on other means [7.22]. Nonetheless, further research on hard (scleractinian) corals revealed bioactive compounds and the biological role of terpenes in hard corals as well. Hence, in this chapter, the pharmaceutical potential of soft and hard coral species will be described separately.

De novo biosynthesis of sterols has also been stated as an important mechanism in octocorals [7.23]. Until early 2009, 561 new polar steroids had been reported from 16 families of octocoral species. Soft corals contribute predominantly as containers of the largest number of marine polar steroids; *unusual sterols* are the only extensive products of a large number of coral species. Particularly, the Alcyonarian corals of the genera *Sarcophyton*, *Sinularia*, and *Lobophytum* are very rich in sterols [7.24].

Soft (octo)corals (order *Alcyonacea*) and gorgonians (order *Gorgonacea*), with fewer examples from zoanthids (order *Zoantharia*) and sea pens (order *Pennatulacea*), have presented the majority of interesting metabolites. Of the six orders in the subclass *Octocorallia*, the *Alcyonacea*, which are fleshy soft corals, and *Gorgonaceae* (sea fans and sea whips) are by far the most widely distributed and studied. In *Alcyonaceae*, *Alcyoniidae* and *Nephtheidae* are the largest families. *Alcyonaria* possess a diverse array of chemical compounds and are particularly rich in isoprenoids, including terpenes, carotenoids, and steroids [7.25–27]; hence, they were one of the first marine groups to be systematically screened for secondary metabolites [7.28]. Each species of octocorals seems to have its own specific set of compounds [7.29].

Potential therapeutics identified in soft corals include anticancer agents, immunomodulators, and useful antifouling agents. The striking presence of cembranoid diterpenes in soft corals outnumbers the occasional occurrence in other taxa, which are also interesting in terms of pharmacological research. They show significant biological activity, including antimicrobial,

Ca-antagonistic and anti-inflammatory properties; the antitumoral effect of cembranes is, however, the most important activity. The ability of soft corals to produce a wide array of diversified cembranoid structures is remarkable (this is reviewed in [7.30]). Furthermore, a particular class of cembranes, namely furanocembranolides are exclusive to octocorals, which were found only in the families *Gorgoniidae* and *Alcyonidae* (see [7.31, 32] and earlier reviews referred to therein). The concentrations of various secondary metabolites vary in different genera of octocorals and hard coral species; therefore, this review first introduces the richest, most studied genera, for which potential pharmaceutical properties have been reported.

7.2.1 Family *Alcyoniidae* (Subclass *Octocorallia*)

Genus *Sinularia*

Extensive studies on the *Sinularia* revealed that about 60% of this genus contains toxins [7.35]; it is a rich source of cembranoid diterpenes and shows a large variation in chemical elaboration [7.11, 24, 36]. Secondary metabolites of *S. flexibilis* marked the presence of terpenoids associated with the following bioactivities: antifouling [7.37, 38], antimicrobial [7.39, 40], cytotoxicity [7.17, 41], and feeding deterrence [7.42]. Of these compounds, sinulariolide, flexibilide, and dihydroflexibilide are the most significant, whose concentrations vary depending upon the site of collection [7.37]. They ranged from 7.5–32.0 mg terpenoid/g tissue (0.75–3.2% dry mass, mean = 1.7%) in the field (see [7.37]). Sinulariolide and flexibilide showed marked antimicrobial activity and inhibited growth of Gram-positive bacteria at effective concentrations as low as 5 and 10 ppm, respectively; hence, they show potential as antibiotics [7.17]. The anti-inflammatory potency of flexibilide was stated to be similar to phenylbutazone [7.43]. One metabolite of low concentration in *S. flexibilis*, 7,8-deoxyflexibilide, was responsible for ichthyotoxicity against the Japanese medaka fish (*Oryzias latipes*: [7.44]). Diterpene cembranoids, sinularin and its dihydro congener, obtained from *S. flexibilis* were found to be effective (ED_{50} = 0.3–16 $\mu g\,mL^{-1}$) in the NCI's screens of potential anticancer agents [7.41]. 11–Episinulariolide from *S. flexibilis* exhibited strong algacidal properties [7.38]. *S. flexibilis* also yielded cembrane-type diterpenoids, sinulaflexiolides A–K, among which sinulaflexiolides D and E showed selective inhibitory activity against gastric gland carcinoma cell line BGC-823 at 8.5 and 0.12 μM, respectively [7.45].

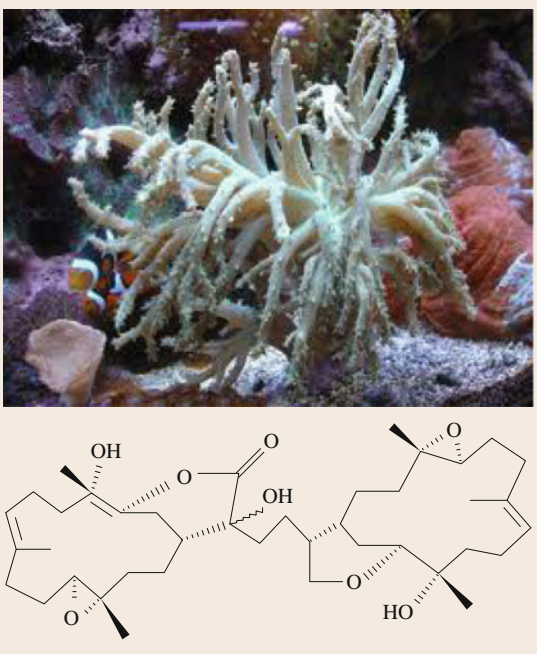

Fig. 7.1 *Sinularia flexibilis* (after [7.33]) and one of its terpenes, sinuflexlin (after [7.34])

The cembranoid sinulariol D obtained from *Sinularia* sp. [7.46] was mildly cytotoxic (reviewed by [7.47]). A sesquiterpene furanoic acid isolated from *Sinularia* sp. was found to inactivate bee venom, phospholipase AZ (bvPLA) in vitro [7.48]. *S. ovispiculata* from Andaman and Nicobar Islands (India) presented a cytotoxic sterol [7.49]. A study of *S. gardineri* from the Red Sea revealed a heptacyclic norcembranoid dimer singardin, which showed cytotoxicity to murine leukemia (P-388), human lung carcinoma (A-549), human colon carcinoma (HT-29), and human melanoma cells (MEL-28) [7.50]. A cembranolide, capillolide, from the Chinese *S. microclavata* exhibited potent cytotoxic activity against tumor cell lines (A-549) with an IC_{50} value of 0.5 $\mu g\,mL^{-1}$; *S. microclavata* also yielded microclavatin with cytotoxicity against tumor cell lines KB and MCF (Michigan Cancer Foundation-7) with IC_{50} values of 5.0 and 20.0 $\mu g\,mL^{-1}$ [7.51]. A cytotoxic lobane diterpene, ineleganene, was isolated from the Formosan *S. inelegans* [7.52]. Three cytotoxic acylspermidines were reported from a Japanese *Sinularia* sp. [7.53]. Extract of an Okinawan *Sinularia* sp., containing norcembrenolide and sinuleptolide, demonstrated potent inhibition of tumor necro-

sis factor-α (TNF-α) production dose-dependently (IC_{50} = 20 and 15 $\mu g\,mL^{-1}$, respectively); it showed a more potent effect than prednisolone at a concentration of 33 $\mu g\,mL^{-1}$ [7.54]. β-Caryophyllene-type terpenoids from the Taiwanese *S. nanolobata* presented cytotoxicity against the growth of a limited panel of cancer cell lines [7.55]. Scabrolides, as two epimeric norditerpenoids, isolated from the Taiwanese *S. scabra*, were found to show significant cytotoxicity against KB and Hepa59T/VGH cancer cell lines (ED_{50}s 2.3–2.6 $\mu g\,mL^{-1}$) [7.10]. The sphingosine derivative from *S. crassa* [7.56] produced maximum anti-inflammatory effect at a dose of 10 $mg\,kg^{-1}$, which was comparable to that of indomethacin (2 $mg\,kg^{-1}$). *S. crassa* also yielded crassarosterol A and four steroidal glycosides, crassarosterosides A–D, which significantly inhibited the expression of pro-inflammatory iNOS protein at 10 μM, and some also showed cytotoxicity toward selected human liver cancer cells [7.57].

Sinularolides from *S. gibberosa* exhibited cytotoxicity against HL-60, Hela, BGC-823, MDA-MB-435, Bel-7402, and PC-3MIE8 tumor cell lines [7.36]; *S. gibberosa* also produced sesquiterpene peroxygibberol, which showed mild cytotoxicity [7.59]. Gibberoketosterol from *S. gibberosa* of Taiwan was shown to significantly inhibit the up-regulation of the pro-inflammatory proteins of macrophage cells [7.60, 61]. Novel norditerpenoids and diterpenoids extracted from the Formosan *S. gibberosa* showed weak cytotoxicity in vitro toward a few cancer cell lines [7.62]. *S. firma* from coastal Indian Ocean waters yielded two glycosides named Firmacosides A and B, previously found to possess significant antibacterial activity [7.63]. Two polyhydroxylated steroids from a Formosan *Sinularia* sp. showed significant inhibition of the accumulation of the pro-inflammatory COX-2 protein of RAW264.7 macrophage cells at 10 μM [7.64]. Five novel cytotoxic steroids, and four new hydroxycembranes isolated from the Formosan *S. facile*; one of the hydroxycembranes exhibited cytotoxicity toward Hep G2 cancer cell line with IC_{50} value of 12.9 $\mu g\,mL^{-1}$ [7.65, 66]. Anti-inflammatory cembranoids querciformolides A–D and granosolides A and B were reported from *S. quercifformis* and *S. granosa* [7.67]. *S. gyrosa* yielded three diterpenoids, gyrosanols A–C, with antiviral activity against HCMV (human cytomegalovirus) at IC_{50}s of 2.6 and 3.7 μM; the compounds also showed significant anti-inflammatory activity by reducing the levels of the COX-2 protein in RAW 264.7 macrophages [7.68]. Reference [7.69] reviewed the latest progress in the chemistry and pharmacological activities of terpenoids from *Sinularia* soft corals providing a perspective on future areas of research interest.

Genus *Sarcophyton*

Two cembranoids isolated from the hexane extract of the *Sarcophyton trocheliophorum* (Pacific Ocean) were cytotoxic to Ehrlich ascites tumor cells [7.71]. A new macrocyclic diterpenoid lactone, sartrochine, was also reported from *S. trocheliophorum*, which showed cytotoxic activity against S180 cells and an antibiotic effect on *Streptococcus* [7.72]. A sarcophine-related cembranoid from an Australian *Sarcophyton* species showed convulsant activity [7.73]. A cembranoid diterpene possessing antifouling activity was reported from a Thai *Sarcophyton* sp. [7.74]. Two new cytotoxic tetraterpenes, methylsarcophytotate and methylchlorosarcophytoate, were isolated from a species in Japanese seawater [7.75]. Reference [7.76] deals with a discovery of tubulin stabilizing activity of sarcodictyin A derived from a Mediterranean stolonifer *Sarcodictyon roseum*; accordingly, this compound was re-

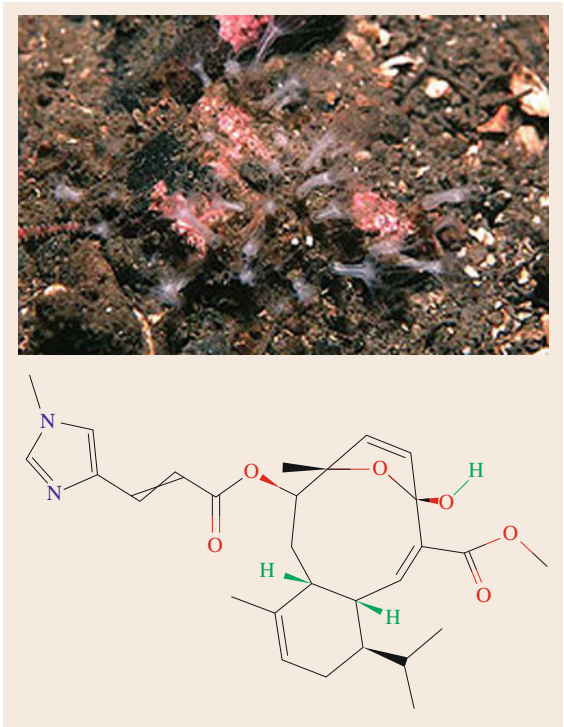

Fig. 7.3 Sarcodictyin A and *Sarcodictyon roseum* (after [7.70])

ported to be in preclinical development [7.77]. However, sarcodictyin showed relatively weak antiproliferative activity (e.g., the IC_{50} values for growth inhibition of the human ovarian carcinoma cell line 1A9 were 300 nM for both sarcodictyin A and B versus 4 nM for taxol; [7.78]. The Australian *S. crassocaule* contained cembranoids, sarcophine and sarcophytoxide, which were released into the seawater as allelochemicals [7.35]. Three cytotoxic cembrenolide diterpenes, sarcocrassolide, crassolide, and 13-acetoxysarcocrassolide, with two cytotoxic steroids were isolated from the Formosan *S. crassocaule* [7.79]. The cytotoxicity of crassocolides A–M from a Taiwanese *S. crassocaule* was determined against a limited panel of cancer cells [7.80, 81]. Sarcophytol A (from *S. glaucum*), due to its cancer preventive activity, was extensively studied by the National Cancer Institute at preclinical trials level [7.82]. Sarcophytol A and its analogs isolated from *S. glaucum* were shown to inhibit the development of large bowel cancer in female rats, to suppress carcinogenesis in liver, breast, thymus, and skin in mice, and to prevent skin cancer [7.83, 84]. Sarcophine, obtained from red *S. glaucum* has been investigated since 1998 for its potential as a chemopreventive, cytotoxic, and antimicrobial agent, as well as competitive cholinesterase inhibitor, noncompetitive phosphofructokinase inhibitor, and a Na^+, K^+-ATPase inhibitor [7.85]. A study on *S. glaucum* resulted in 7β-acetoxy-8α-hydroxydeepoxysarcophine showing cytotoxicity against HepG2 (Hepatoma Growth2), HCT-116 (human colorectal tumor), and HeLa (Henrietta Lacks) cells with IC_{50} values of 3.6, 2.3, and 6.7 $\mu g\,mL^{-1}$, respectively [7.86]. Sarcotriol is a derivative of sarcophine, which displayed a potent chemopreventive activity against skin cancer [7.87]. Three furano-cembranoids and sarcoglaucol from *S. cherbonnieri* collected from the Great Barrier Reef [7.88] were found to be cytotoxic towards several tumor cell lines (IC_{50} values ranged from 0.15 to 8.6 $\mu g\,mL^{-1}$). Moreover, two tetraterpenoids, methyltortuoates A and B from the soft coral *S. tortuosum* showed cytotoxicity on human nasophyringeal carcinoma (CNE-2) and murine lymphocytic leukemia (P-388) tumor cell lines [7.89]. 7β-hydroxy-8α-methoxydeepoxysarcophytoxide reported from the Vietnamese *S. mililatensis*, was found to stimulate the growth of preosteoblastic MC3T3-E1 cells, suggesting the compound to be a potential cure for osteoporosis [7.90]. Sarcostolide E extracted from *S. stolidotum* [7.91] exhibited weak to moderate cytotoxic activity against human WiDr and Daoy tumor cell lines.

Genus *Lobophytom*

Lobophytum depressum from the Red Sea is one of the earliest corals studied [7.92]. Denticulatolide, an ichthyotoxic cembranoid diterpene, was isolated from the *L. denticulatum* [7.93]. Later, [7.94] presented evidence that extract of the Indian *L. strictum* showed promising hypotensive activity in *in vitro* tests (25 $mg\,kg^{-1}$, 27–30 min). Subsequently, it was reported in [7.95] that one of the two amine chlorides from the same species exhibited hypotensive and vasodilator activities. A cembranolide diterpene from *L. cristagalli* was identified as a potent (IC_{50} 5.3 μM) inhibitor of farnesyl protein transferase [7.96]. A sterol that was active against human ovarian tumor and human leukemia cell lines was isolated from an Indonesian *Lobophytum* sp. [7.97]. A cembrenoid diterpene, lobohedleolide, derived from *Lobophytum* sp. [7.56] produced maximum anti-inflammatory effect at a dose of 10 $mg\,kg^{-1}$, which was comparable to that of indomethacin (2 $mg\,kg^{-1}$). Lobohedleolide was also reported to have cytotoxic [7.98] and anti-HIV activities (EC_{50} approximately 3–5 $\mu g\,mL^{-1}$) [7.99]. Ex-

tracts obtained from *L. crassum* indicated ceramideas, a moderately antibacterial component [7.100]. The Formosan *L. crassum* yielded three glycolipids, all of which exhibited cytotoxicity against the growth of cancer cells of HepG2, Hep3B (human liver carcinoma), MDA-MB-231 (human breast carcinoma), and Ca9-22 (human gingival carcinoma) with IC_{50}s from 9.2 to 15 $\mu g\,mL^{-1}$ [7.101]. In [7.102] crassumolides A and B and D–F, which were cytotoxic toward Ca9-22 cancer cells, and broadly cytotoxic toward all six test cancer cell lines used were also isolated. *L. crassum* also produced a cembrane-type diterpenoid, lobocrassin F, which displayed a significant inhibitory effect on the release of elastase by human neutrophils [7.103]. Investigations on the *L. durum* [7.104] led to the isolation of three hemiketal cembranolides, durumhemiketalolides A–C with anti-inflammatory activities. Moreover, *L. durum* succumbed anti-inflammatory durumolides F–L (10 μM), which significantly reduced the levels of the iNOS and COX-2 proteins, and also exhibited weak antibacterial activity against *Salmonella enteritidis* [7.105].

Recently, six new cytotoxic cembranolides from *L. michaelae* were isolated and their anti-HCMV activity as well as cytotoxicity against selected cell lines were evaluated [7.106].

Genus *Eleutherobia*

Anti-inflammatory activity was observed for three related xenicane diterpenes, 9-deacetoxy-14,15-deepoxyxeniculin isolated from specimens of the South African octocoral, *Eleutherobia aurea* [7.107]. In reference [7.108] initially isolated eleutherobin, a tricyclic diterpene from the Australian soft coral *Eleutherobia* sp. was reported. Later, in reference [7.109] it was shown that eleutherobin was a potent inducer of tubulin polymerization *in vitro*. Eleutherobin showed selective cytotoxicity toward breast, renal, ovarian, and lung cancer cell lines and was found to be generally more inhibitory than sarcodictyin A (reviewed in [7.110]). Treatment of cancer cells with eleutherobin produced all the characteristic effects associated with those observed with taxol (reviewed by [7.111]. The Carribbean octocoral *Erythropodium caribaeorum* (family Anthothelidae) and the soft coral *Bellonella albiflora* (family Alcyoniidae) provided alternative sources for eleutherobin [7.112, 113].

Genus *Alcyonium*

The valdivones, anti-inflammatory diterpene esters, from the South African *Alcyonium valdivae* were introduced by [7.114]. *A. fauri* from the southeast coast of southern Africa yielded a sesquiterpene, hydroquinone rietone, which exhibited moderate activity in the NCI's in vitro anti-HIV bioassays [7.115]. *A. patagonicum* from the South China Sea succumbed a sterol cytotoxic against the P-388 cell line with an IC_{50} value of 1 $\mu g\,mL^{-1}$ [7.116]. Identified steroids in the Korean *A. gracillimum* exhibited moderate cytotoxicity and antiviral activity [7.117]; its glycoside was found to be toxic to the larvae of *Balanus amphitrite* [7.118].

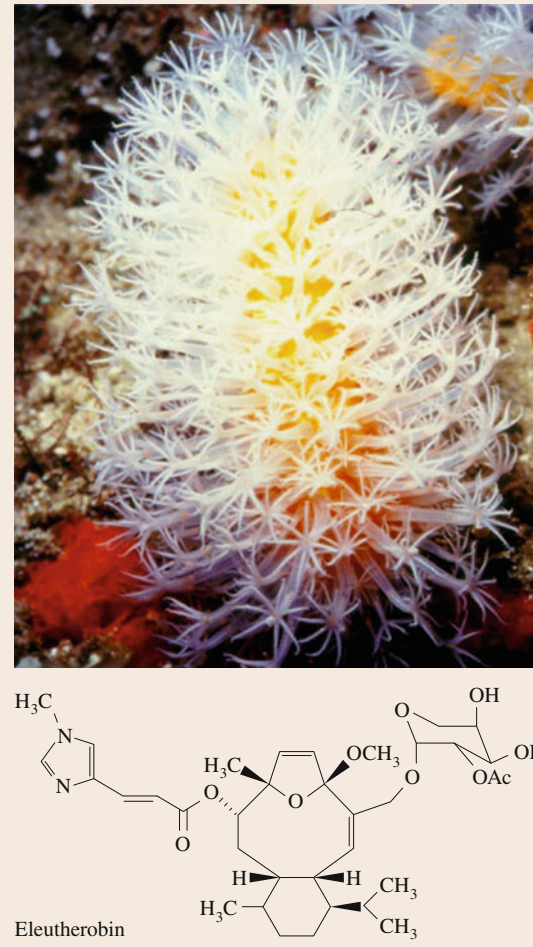

Fig. 7.4 *Eleutherobia* sp. and its tricyclic diterpene eleutherobin (after [7.70])

Genus *Cladiella* (= *Microspiculariа*)

Cladiella sp. surrendered a new dienone sterol, named cladiellin A, with antioxidant activity [7.119]. An aus-

tralins A–D isolated from Taiwanese *C. australis* was mildly cytotoxic [7.59]. Most diterpenoids, hirsutalins A–H, isolated from *C. hirsuta* exhibited cytotoxicity toward several cancer cell lines with two hirsutalins being significantly anti-inflammatory in vitro [7.120]. An Indonesian *Cladiella* sp. produced cladielloides A and B; the latter exhibited moderate cytotoxicity toward CCRF-CEM (Human Caucasian acute lymphoblastic leukaemia) tumor cells as well as significant inhibitory effects on superoxide anion generation and elastase release by human neutrophils [7.121]. From the same species, cladieunicellin H was purified with moderate inhibitory effects on the generation of superoxide anion and the release of elastase by human neutrophils [7.122].

Genus *Klyxum*

Nine diterpenoids, simplexins A–I, from *Klyxum simplex* were found to be cytotoxic toward a limited panel of cancer cell lines, or to significantly inhibit the accumulation of the pro-inflammatory iNOS and COX-2 proteins in RAW264.7 macrophage cells [7.123]. Three novel diterpenoids, namely klysimplexin sulfoxides A–C, were isolated from the cultured soft coral *K. simplex*, which significantly inhibited the accumulation of the pro-inflammatory iNOS protein in RAW264.7 macrophage cells [7.124]. Diterpenoids from Taiwanese *K. molle* named klymollins A–H displayed a similar activity together with significant in vitro anti-inflammatory activity by inhibiting the expression of the iNOS protein [7.125].

Genus *Paraminabea*

The Formosan *Paraminabea acronocephala* yielded withanolides, paraminabeolides A–F along with minabeolides, which were either cytotoxic toward Hep G2 cancer cells, or significantly inhibited the accumulation of the pro-inflammatory iNOS protein, or could effectively reduce the expression of COX-2 protein [7.126].

Genus *Parerythropodium*

Extracts of the Red Sea *Parerythropodium fulvum fulvum* exhibited antimicrobial activity against several co-occurring and potentially pathogenic marine bacteria [7.40].

Genus *Anthomastus*

3-oxo-sterols were reported as moderately cytotoxic metabolites of Antarctic *Anthomastus bathyproctus* [7.127].

Genus *Bellonella*

The cytotoxic diterpene sarcodictyin A, which was reported in the stoloniferan soft coral *Sarcodictyon roseum* [7.76], was also isolated from *Bellonella albiflora* [7.113]. Sarcodictyin A showed strong cytotoxicity against HeLa human cervix cells.

7.2.2 Family *Anthothelidae*

Genus *Erythropodium*

The Caribbean octocoral *Erythropodium caribaeorum* provided methyl-caribaeorane, which was active in a cell-based assay for antimitotic activity at 10 mM [7.112].

7.2.3 Family *Gorgoniidae*

Both soft corals and gorgonians are abundant in tropical reef habitats, with the Indo-Pacific being dominated by soft corals and the western Atlantic reefs by gorgonians. Both are prolific producers of terpenoids, especially diterpenes [7.128]. Gorgonians (horny corals) from the Caribbean were the first octocorals studied for antimicrobial activity of corals [7.129]. In the late 1960s and early 1970s, it was discovered that some gorgonians contain large quantities of prostaglandins rendering, in part, the rapid growth of the field of marine natural products. The corals that were found to possess antibacterial activity were *Antillogorgia turgida*, *A. americana*, *Rhipidogorgia flabellum*, *Briareum asbestinum*, *Plexaura homomalla*, *P. dichotoma*, and *Plexauropsis crassa*. In reference [7.27] the absolute configuration and species distribution of 28 terpenoid compounds isolated from 19 species of gorgonians were described. Over 200 novel secondary metabolites isolated from gorgonians were discussed in [7.25], for many of which the pharmacological effects were described in [7.130]. Extracts from eight coral species from San Blas Islands, Panama, [7.131] displayed intermediate levels of antimicrobial activity against five marine and nonmarine bacteria. It was found that nonpolar fractions were much more active than polar fractions. Extracts of several species of 39 Caribbean gorgonians were broadly studied against 15 strains of marine bacteria, including marine opportunistic pathogens, and strains isolated from healthy and decayed gorgonians inhibited the growth of bacteria [7.132], hence, as the source of a number of bioactive terpenoids. Nine of ten gorgonian extracts from the four families tested showed antimicrobial activity against Gram-positive bacteria [7.133]. These corals, therefore, maintain a wealth of novel

Fig. 7.5 *Pseudopterogorgia elizabethae* and its major diterpene pseudopterosin A (courtesy of NSF (Natural Products Science), Oregon State University)

structures with potentially useful biological activities, from which 602 new compounds have been reviewed by [7.134].

Genus *Pseudopterogorgia*

The genus *Pseudopterogorgia* was considered as one of the most chemically defended among gorgonians. This ability seems to derive from high concentrations of secosteroids present in these gorgonians [7.25]. The anti-inflammatory potential of pseudopterosins was found to be superior to that of standard drugs such as indomethacin [7.135]. The extracts from *P. elizabethae* (containing pseudopterosins) and *Eunicea fusca* (containing fucoside-A or fuscol) could possibly be used in cosmetic industries [7.136–138]. A semisynthetic pseudopterosin derivative, methopterosin, also displayed anti-inflammatory activity [7.139], hence it has successfully completed Phase II clinical trials as a topical anti-inflammatory agent [7.140]. Therefore, and because the pseudopterosins are potent anti-inflammatory and analgesic agents (ED_{50} ca. $3.0\,mg\,kg^{-1}$ [7.141]), they have been licensed to a small pharmaceutical firm for medical use as potential anti-inflammatory drugs [7.142]. A furanogermacrene isolated from the *P. americana* inhibited both diatoms *Nitzchia salinicola* and *Nitzchia* spp. at naturally occurring concentrations in in situ experiments [7.143]. Up until 1999, 12 different congeners, pseudopterosins A–L, were reported in *P. elisabethae* from various geographic locations around the West Indian region [7.141]; pseudopterosins A–D were reported as the primary metabolites in their collections of *P. elisabethae* from the Bahamas, being major metabolites in the gorgonian; pseudopterosins C comprised as much as 7.5% of the lipid extract. Furthermore, pseudopteroxazole, a benzoxazole diterpene alkaloid isolated from the West Indian *P. elisabethae*, induced 97% growth inhibition for *Mycobacterium tuberculosis* H37Rv at a concentration of $12.5\,g\,mL^{-1}$ [7.144]. In reference [7.145] the synthesis of elisabethatriene, a diterpene cyclase, from *P. elisabethae*, was reported. Similarly, ergorgiaene, a diterpene (also known as biflorane) was isolated from the hexane extract of the same West Indian gorgonian, which induced 96% growth inhibition for *M. tuberculosis* H37Rv at a concentration of $12.5\,g\,mL^{-1}$ [7.146]. A partially purified extract of *P. elisabethae*, containing pseudopterosin E, is being used as an additive in a cosmetic preparation, a face cream under the brand name Resilience (see the review in [7.30]). In reference [7.142] elisabethin H from the southwestern Caribbean *P. elisabethae* with anti-inflammatory properties was further isolatedİt was also demonstrated that the compounds isolated from *P. elisabethae*, collected in the southwestern Caribbean, were promising molecules with an anti-inflammatory activity both in vivo and in vitro [7.147].

An analog of lophotoxin (from the genus *Lophogorgia*), bipinnatin-B, isolated from the gorgonian *P. bipinnata* [7.148] was found to be a potent neurotoxin (at concentrations of $10\,\mu M$); *P. bipinnata* also produced caucanolides A–F, which exhibited mild activity towards *Plasmodium falciparum*, and cytotoxicity towards a panel of tumor cell lines [7.149]. Providencin and kallolide A were isolated from the West Indian gorgonian *P. kallos*; providencin showed moderate anticancer activity against human breast (MCF7), lung (NCI-H460), and CNS (SF-268) cancer cell lines [7.150]. This octocoral also yielded seven cembranolides, including bipinnatin Q, which displayed significant cytotoxic activity against the NCI (Na-

tional Cancer Institute) tumor cells MCF breast cancer, NCI-H460 nonsmall cell lung cancer, and SF-268 CNS cancer [7.151]. In reference [7.150] the isolation of the structurally intriguing diterpenes providencin, intricarene, and bielschowskysin from *P. kallos* was also reported. Bielschowskysin exhibited strong activity against certain human cancer cell lines and was also effective against *Plasmodium falciparum*, the cause of malaria [7.152].

Pseudopterolide, an unusual diterpene from the gorgonian *P. acerosa* showed unusual cytotoxic properties [7.155]. The genus *pseudopterogorgia* also yielded pseudopetrocin-E, a tricyclic diterpene pentoside with anti-inflammatory and analgesic activities equal in potency to industrial standard indomethicine [7.156].

Genus *Pterogorgia*

Pterogorgia guadalupensis was reported to contain a cristaline lactone that exhibited mild antibiotic activity against bacterial species [7.157].

Genus *Gorgonia*

Crude extracts from the sea fan coral *Gorgonia ventalina* showed antibacterial activity against the bacterium *Listonella anguillarum* [7.158]. In reference [7.159] exochitinase activity against the fungal pathogen, *Aspergillus sydowii* in *G. ventalina* from the Florida Keys was also explored.

Genus *Eunicella*

Spongouridine previously isolated from the sponge *Cryptotethia crypta* and found to possess antiviral activity, was also isolated from the gorgonian *Eunicella cavolini* (reviewed in [7.160]). *E. verrucosa* from Spain gave the cytotoxic verrucoside [7.161].

7.2.4 *Subergorgiidae*

Genus *Subergorgia*

The gorgonian coral *Subergorgia suberosa* occurs widely in Indo-Pacific waters. Subergorgic acid, a cardiotoxin obtained from the Pacific *S. suberosa* [7.162] inhibited neuromuscular transmission at $0.16\,\mu g\,mL^{-1}$ in isolated guinea-pig heart assay. A further study of *S. suberosa* yielded the sesquiterpene suberosols A–D as well as a subergane-based sesquiterpene, subergorgiol, which exhibited cytotoxicity towards the P-388 murine leukaemia and the A-549 and HT-29 tumor cell lines; subergorgiol was moderately cytotoxic against the growth of HeLa cancer cells [7.163, 164]. A sesquiterpene alkaloid, 6-(9′-purine-6′,8′-diolyl)-2β-suberosanone, was also reported from *S. suberosa* as a mildly cytotoxic metabolite ($IC_{50} = 8.87\,\mu g\,mL^{-1}$ [7.165]. Reference [7.166] reported that the most potent antifoulant produced by *S. suberosa* was subergorgic acid.

7.2.5 Family *Briareidae*

Genus *Briareum (= Solenopodium)*

Solenolides as anti-inflammatory and antiviral diterpenoids were introduced from the gorgonian *Briareum* (*Solenopodium*) sp. [7.167]. A study of *B. excavatum* resulted in briantheln A [7.168], which was shown to reverse multidrug resistance in human carcinomas, and in briaexcavatolides, one of which shown to exhibit significant cytotoxicity toward P-388 and HT-29 cancer cells [7.169]. A diterpenoid, excavatoid L, from the cultured *B. excavatum* moderately inhibited superoxide anion generation and elastase release by human neutrophils [7.170]. Violides O, briarlides I–R and briviolides derived from *Briareum* sp. showed mild cytotoxicity toward Vero and MDCK cells [7.171, 172]. In addition, diterpenes briarenol A and briaranolides A–J were isolated from Taiwanese and Okinawan collections of *Briareum* sp., respectively [7.173, 174]. Very recently, briarenolide F from *Briareum* sp. was reported to show significant in vitro anti-inflammatory effect on the generation of superoxide anions by human neutrophils [7.175].

7.2.6 Family *Plexauridae*

Genus *Pseudoplexaura*

Horny gorgonians *Pseudoplexaura porosa*, *P. wagenaari*, *P. flagellosa*, and *P. crucis* provided a lactonic cembrane diterpene, the antineoplastic crassin acetate, which is reported to be toxic to *Entamoeba histolytica* at $20\,\mu g\,mL^{-1}$ in vitro [7.176]. Crassin acetate may constitute as much as 1.5% of the dry weight of the cortex of *P. porosa* [7.177], which was cytotoxic ($1-10\,\mu g\,mL^{-1}$) to mouse fibroblasts and human leukemic and HeLa cells in vitro [7.178]. Both crassin acetate and eunicin also inhibited the growth of *Clostridium feseri* and *Staphylococcus* species [7.179]. Furthermore, two cytotoxic antitumor cembranes, named 14-deoxycrassin and pseudoplexaurol were isolated from the Caribbean *P. porosa* [7.180].

Genus *Plexaura*

Two prostaglandins, 15-epi-PGA2 and its diester and PGA2α were isolated from the air-dried cortex of the

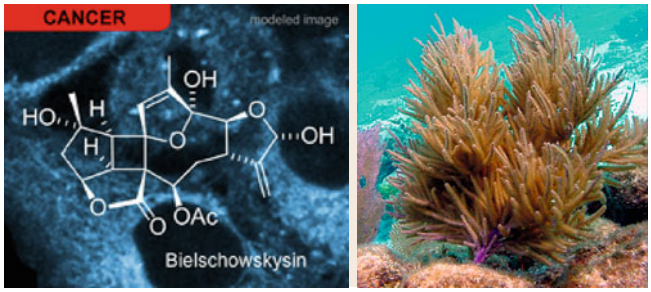

Fig. 7.6 Bielschowskysin, a diterpene isolated from the Caribbean gorgonian octocoral *Pseudopterogorgia kallos* (after [7.153, 154])

Caribbean gorgonian *Plexaura homomalla* (Esper) in high yields of 0.2 and 1.3%, respectively [7.16, 18]; hence, there is a great interest in *P. homomalla* as a potential commercial scale source of prostaglandins either by pruning in a natural way or by marine farming [7.19]. These findings stimulated a worldwide survey of prostaglandins in *Cnidaria* (formerly coelenterates), with an eye toward the commercial harvesting of these important metabolites from marine *Cnidaria*, resulting in extensive harvesting of wild corals. An antimalarial inhibitor of plasmepsin II (enzyme belonging to Plasmodium family) was detected in *P. homomalla*, which showed 5.9-fold specific inhibitory activity [7.181].

Genus *Eunicea*

A diterpene, eunicin exhibiting antibacterial activity has been isolated from the gorgonian *Eunicea mammosa* [7.182, 183]. Seven sesquiterpenoid metabolites including elemane, eudesmane, and germacrane types were reported as mildly antiplasmodial constituents of a Caribbean *Eunicea* species [7.184], which are among the most abundant octocorals of the region. Eupalmerin acetate, a novel anticancer agent from Caribbean gorgonians *E. succinea* and *E. mammosa* induced apoptosis in human malignant glioma cells ($IC_{50} = 5.1–6.9\,\mu mol\,L^{-1}$), hence it was suggested to be promising as a clinical anticancer agent [7.2]. A diterpene, fuscoside E, extracted from *E. fusca* showed strong anti-inflammatory in ear edema bioassay and also presented antifouling activity against bacterial strains [7.185]. A dilophol diterpene, eunicidiol, along with fuscol and eunicol were isolated from the crude extract of *E. fusca*, collected from Hillsboro Ledge, Florida. Topical application of a 100 µg/ear dose of these diterpenes significantly reduced ear edema by 44, 46, and 54%, respectively, which was superior to the effect of indomethacin, a known anti-inflammatory [7.186].

Genus *Euplexaura*

Guaiazulene from the gorgonian *Euplexaura erecta* [7.187] exhibited mild activity against *Pseudomonas aeruginosa*. New tetraprenylated purine alkaloids, nuttingins A–E, and new closely related malonganenones D–G were isolated from the gorgonian *E. nuttingi* collected on Pemba Island, Tanzania, displayed inhibitory activity against both K562 and UT7 tumor cell lines, and also induced apoptosis in transformed mammalian cells at a concentration of $1.25\,\mu g\,mL^{-1}$ [7.188]. *E. robusta* collected from Weizhou Island, China, yielded malonganenones I–K; the compounds showed moderate cytotoxicities against K562 and HeLa tumor cell lines with IC_{50} values ranging from 0.35–10.82 µM, and one with moderate inhibitory activity against c-Met kinase at a concentration of 10 µM [7.189].

Genus *Muricea*

Muricea species such as *M. californica* and *M. fruticosa* provided four new esterified aminogalactose saponins called muricins, which inhibited the growth of the diatom *Phaeodactylum tricornum* at 100 ppm concentrations, suggesting that it has a significant role in reducing fouling due to the diatoms [7.190]. From *M. austere* collected on the Pacific coast of Panama, eight compounds including three tyramine derivatives, two steroidal pregnane glycosides, and three sesquiterpenoids were isolated, and their antiprotozoal activities were evaluated in vitro against a drug-resistant *Plasmodium falciparum* and intracellular form of *Trypanosoma cruzi* [7.191].

Genus *Anthoplexaura*

The dimorphosides from the gorgonian *Anthoplexaura dimorpha* inhibited the development of fertilized eggs of sea urchins [7.192].

Genus *Paramuricea*

Linderazulene and two congeners were isolated from a deep-sea collection of the gorgonian *Paramuricea*

sp. in Curaçao and found to be mildly cytotoxic against the P388 murine leukemia cell line with IC_{50}s of 18.8, 2.7, and 15.6 $\mu g\,mL^{-1}$, respectively [7.193]. The Mediterranean gorgonian *P. clavata* resulted in two new alkaloids bufotenine and 1,3,7-trimethylisoguanine, which showed significant antiadhesion activity against one bacterial strain while being nontoxic [7.194].

Genus *Plexaurella*

Plexaurella grisea from the Caribbean (Dominican Republic) produced sterols and sesquiterpenes with selective activity against the HT 29 ($ED_{50} = 0.1\,\mu g\,mL^{-1}$) and P-388 tumor cell lines, respectively [7.195, 196].

Genus *Echinomuricea*

A xanthine derivative, named caffeine, isolated from the gorgonian *Echinomuricea spendens* displayed mild antifouling activity against marine fouling organisms [7.197]. A new halimane-type diterpenoid, echinohalimane A, was isolated from *Echinomuricea* sp.; the compound exhibited cytotoxicity toward various tumor cells and displayed an inhibitory effect on the release of elastase by human neutrophils [7.198]. Echinoclerodane A from *Echinomuricea* sp. exhibited moderate cytotoxicity toward MOLT-4 (molybdate uptake transporter), HL-60, DLD-1 (dihydrolipoamide dehydrogenase), and LoVo (human colon adenocarcinoma) tumor cells, and inhibitory effects on the generation of superoxide anions and the release of elastase by human neutrophils [7.199].

Genus *Calicogorgia*

Calciferols first reported from Japanese *Calicogorgia* sp. Calciferols A and B were found to be toxic to brine shrimp; calciferol D exhibited potent antiviral activity and calciferols F–I showed cytotoxicity and PLA2 inhibitory behavior [7.117, 200].

Genus *Menella*

A south China Sea gorgonian, *Menella* sp., resulted in menellins A–C, which exhibited modest anti-inflammatory inhibition effects against RAW264.7 macrophages with IC_{50} of 71.3, 33.9 μM [7.201]. A sesquiterpenoid, menelloide A, isolated from *Menella* sp. inhibited generation of superoxide anions by human neutrophils [7.202].

7.2.7 Family *Acanthogorgiidae*

Genus *Astrogorgia*

Astrogorgiadiol from *Astrogorgia* sp. inhibited cell division in starfish eggs [7.203]. Five compounds of astrogorgols A–N from Chinese *Astrogorgia* sp. showed significant inhibitory activities against human tumor related protein kinases, including ALK, AXL, FAK, IGF-1R, MET wt, SRC, and VEGF-R2 [7.204]. Twelve new eunicellin-based diterpenoids, astrogorgins B–M, were isolated from the Chinese gorgonian *Astrogorgia* sp., among which significant antifouling activity was observed for 14-deacetoxycalicophirin B against the larval settlement of the barnacle *Balanus amphitrite* at nontoxic concentrations with an $EC_{50} = 0.59\,\mu g\,mL^{-1}$, while the other analogs were effective within an EC_{50} range of 5.14–17.8 $\mu g\,mL^{-1}$ [7.205].

Genus *Acalycigorgia*

Xenicane diterpenoids including acalycixeniolide H and D–G, and five further xenicanes isolated from the gorgonian, *Acalycigorgia inermis* inhibited cell division of fertilized starfish eggs and significant cytotoxicity against a human leukemia cell line [7.192, 206, 207].

Genus *Muricella*

A sterol, calicoferol D, from the Korean gorgonian *Muricella* sp. showed antiviral activity and brine shrimp lethality [7.117, 200].

7.2.8 Family *Nephtheidae*

Genus *Nephthea*

Cytotoxic sterols were isolated from the soft coral *Nephthea erecta* [7.208]. Another Formosan *N. brassica* yielded two new cytotoxic cembranoid diterpenes, brassicolide and brassicolide acetate; a new cytotoxic sesquiterpene, (−)-4*R*-*O*-acetyl-selin-11-en; and six cytotoxic terpenoids, (−)-selin-11-en-4*R*-ol, 2-hydroxynephthenol, nephthenol, cembrene A, epoxycembrene A, and (−)-β-elemene, all of which showed significant cytotoxicity in A549 (human lung adenocarcinoma), HT-29 (human colon adenocarcinoma), KB (human epidermoid carcinoma), and P-388 (mouse lymphocytic leukemia) [7.209]. An isolate from *Nephthea* sp. (called decaryiol) collected from the Fiji Islands was found to be cytotoxic towards several tumor cell lines with IC_{50} values ranging from 0.15–8.6 $\mu g\,mL^{-1}$ [7.88]. The Taiwanese *N. armata* yielded two new cytotoxic 19-oxygenated ergosterols, armatinols A and B [7.210].

Chabrolonaphthoquinone B, chabrolobenzoquinones E–H and chabrolohydroxybenzoquinones E–G were isolated as mildly cytotoxic constituents of *N. chabrolii* [7.211]. Furthermore, three new steroids, chabrolosteroids A and B, and C, were isolated from the Taiwanese *N. chabrolii* [7.212], from which chabrolosteroid B exhibited weak cytotoxicity toward the Hep 3B ($IC_{50} = 19.9\,\mu g\,mL^{-1}$) cancer cell line. The diterpene pacificins, isolated from Taiwanese *N. pacifica* were mildly cytotoxic [7.213]. The extract of the Formosan *Stereonephthya crystalliana* showed significant cytotoxicity to A549, HT-29, and P-388 cell cultures [7.214]. A novel unusual pentacyclic hemiacetal sterol, nephthoacetal, was isolated from *Nephthea* sp.; it exhibited a significant inhibitory effect with an EC_{50} value of $2.5\,\mu g\,mL^{-1}$ and moderate cytotoxicity against HeLa cells with IC_{50} values of $12.3\,\mu g\,mL^{-1}$ [7.215].

Genus *Dendronephthya (= Spongodes)*

Isogosterones found in *Dendronephthya* sp. were reported to inhibit larvae settlement at low concentrations (ca. $2.2\,\mu g\,mL^{-1}$), which makes them promising as nontoxic antifoulants [7.118]. Dendronesterol B from the Japanese *D. gigantia* was shown to be mildly cytotoxic [7.216]. Tissue extracts of *Dendronephthya* sp. showed antibacterial activity against epibiont bacteria [7.217]. Two steroids, 3-oxocholest-1,22-dien-12β-ol and 3-oxocholest-1,4-dien-20β-ol from *D. gigantea* showed notable inhibitory activity against farnesoid X-activated receptors (FXR) with IC_{50}s of 14 and 15 µM [7.218]. The Chinese *Spongodes* (*Dendronephthya*) sp. yielded a steroid, methyl spongoate, found to have cytotoxicity against BEL-7402 at a moderately low concentration [7.219]. The Chinese *Dendronephthya* sp. resulted in the isolation of 18 new cembranoid diterpenes, namely, dendronpholides A–R, along with 11-episinulariolide and an enantiomer of sandensolide; the cytotoxicity of several compounds against human tumor cell lines was also evaluated [7.220]. *D. griffini* yielded griffinisterones F–I, which were found to significantly inhibit the accumulation of the pro-inflammatory iNOS protein of the LPS-stimulated RAW264.7 macrophage cells at 10 µM [7.221].

Genus *Gersemia*

Gersemia fruticosa, a cold water species of the White Sea (Arctic Ocean), presented polar sterols, among which 9,11-secosterol was found to be endowed with cytotoxicity and 5,6-epoxy sterol was highly antiproliferative [7.222, 223]. Antibacterial effects were observed in the extract of sub-Arctic *G. rubiformis* [7.224]. The Antarctic *G. antarctjca* released metabolites containing a 1 : 1 mixture of homarine and trigonein that served antibacterial roles to the surrounding seawater [7.225].

Genus *Capnella*

Capnella thyrsoidea yielded a series of xenicane diterpenes, e.g., the anti-inflammatory tsitsixenicin A [7.226]. *C. imbricata* is known for producing a range of sesquiterpene alcohols known as capnellenes [7.227]. All the capnellene compounds identified by [7.228] were cytotoxic in all cell lines, including renal leiomyoblastoma, ovarian, promyelogenous leukaemia, and HL-60 as well as K562 leukaemia cancer cell lines (IC_{50} values 0.7–4500) with the greatest activity against K562 leukaemia. A study on the Formosan *C. imbricata* revealed three anti-inflammatory capnellenes and a calamenene, which showed more specific inhibition ($IC_{50} = 10\,\mu M$) against the up-regulation of the pro-inflammatory iNOS and COX-2 proteins of LPS-stimulated RAW264.7 macrophage cells [7.229]. Capnellenes, GB9 and GB10, were also found to have antineuroinflammatory and antinociceptive properties in IFN-gamma-stimulated microglial cells and in neuropathic rats, respectively [7.230].

Genus *Litophyton*

Litosterol, a C-19 hydroxysteroid, was isolated from an Okinawan octocoral *Litophyton viridis*. It inhibited 90% of the growth of *M. tuberculosis* with an MIC (minimum inhibitory concentration) of $3.13\,\mu g\,mL^{-1}$ [7.231]. Litophynols A, B, and litophynins E, H, and I monoacetate isolated from the mucus secreted by *Litophyton* sp. were reported to possess hemolytic activity [7.232].

Genus *Lemnalia*

The Kenyan *Lemnalia flava* yielded lemnaflavoside and three monoacetate derivatives [7.233]. Lemnalol isolated from the Formosan *L. cervicorni* produced anti-inflammatory and analgesic effects in carrageenan-injected rats. As a potential therapeutic agent for neuropathic pain, lemnalol, in a single intrathecal administration (0.05–10 µg) was demonstrated to significantly attenuate thermal hyperalgesia and mechanical allodynia induced by chronic constriction injury (CCI) in a well-established rat model, 14 days postsurgery. Lemnalol (10 µg) also significantly inhibited CCI-induced

up-regulation of microglial and astrocytic immunohistochemical activation markers in the dorsal horn of the lumbar spinal cord. Additionally, intrathecal injection of lemnalol (10 μg) markedly inhibited spinal pro-inflammatory mediator tumor necrosis factor-α expression in microglial cells and astrocytes in neuropathic rats [7.234]. It was recently reported in reference [7.235] that treatment with lemnalol (intramuscular: 30 mg kg^{-1}, for 6–168 h) significantly attenuated mechanical allodynia, paw edema, and knee swelling induced by monosodium urate; the elevated expression of c-Fos and pro-inflammatory proteins observed in synovial tissue were also significantly inhibited by lemnalol administration rendering the compound a promising candidate for the development of a new treatment for gouty arthritis and other acute neutrophil-driven inflammatory diseases [7.235].

Genus *Scleronephthya*

Scleronephthya pallida from Thailand produced a fucoside steroid that exhibited moderate antimalarial activity and cytotoxicity [7.236].

7.2.9 Family *Clavulariidae*

Genus *Clavularia*

Kericembrenolides from *Clavularia koellikeri* were shown to display growth inhibition against B-16 melanoma cells (IC_{50}s of 1.2–3.8) [7.237]. A cembrane diterpene isolated from the Okinawan *C. koellikeri* [7.238] showed cytotoxic activity against human colorectal adenocarcinoma cells (DLD-1, IC_{50} 4.2 μg mL^{-1}) and strong growth inhibition against human T lymphocytic leukemia cells (MOLT-4, IC_{50} 0.9 μg mL^{-1}). *C. koellikeri* also yielded a new diterpenoid with modest growth-inhibition effect in vitro toward tumor cells [7.239]. Six cytotoxic dolabellane diterpenes were isolated from the Formosan soft coral *C. inflata*, and their cytotoxicity against selected cancer cells was measured in vitro [7.240]. Three cytotoxic prostanoids, claviridenone E–G, and three cytotoxic steroids, stoloniferone E–G, were isolated from the Formosan *C. viridis* [7.241]. A cytotoxic cembranoid, claviolide, was also isolated from the Formosan *C. violacea*, as reported in reference [7.241]. Clavubicyclone from *C. viridis*, a common western Pacific coral, exhibited mild cytotoxicity towards MCF-7 and OVCAR-3 tumor cell lines [7.242]. Extract of *C. viridis* further afforded seven new prostanoids [7.243], the pharmacological study of which revealed that bromovulone III and chlorovulone II exhibited the most promising cytotoxicity (0.5 μg mL^{-1}) against human prostate (PC-3) and colon (HT29) cancer cells. Antitumor and anticarcinogenic compounds were isolated from the symbiont of the Okinawan soft coral *C. viridis* and showed significant growth-inhibitory activity in vitro toward cancer cells [7.244].

Corals obviously produce various prostaglandins as an antipredatory defense [7.245]. Prostaglandins including chlorovolones, clavulones, claviridenones (antitumor prostanoids), and C-20 acetoxy clavulones were also reported to have been isolated from the stoloniferan *C. viridis*, which exhibited unique antineoplastic activity and were potent growth inhibitors in a variety of cultured cells; thus, they may represent a new chemical class of cancer therapeutics [7.246]. A prostanoid and steroids of *C. viridis* were also found to inhibit the up-regulation of the pro-inflammatory iNOS and COX-2 proteins of LPS-stimulated RAW264.7 macrophage cells [7.227].

Genus *Telesto (= Carijoa)*

Diverse collections of *Carijoa* (*Telesto*) *riisei* produce a variety of natural products geographically. *C.* (*Telesto*) sp. presented extracts with high cytotoxic activity [7.12]. The Brazilian *C. riisei* yielded the known 18-acetoxypregna-1,4,20-trien-3-one, which displayed cytotoxic activity against the cancer cell lines SF295, MDA-MB435, HCT8, and HL60, as well as antimicrobial activity against *Staphylococcus aureus, Pseudomonas aeruginosa, Enterobacter* spp. and *Proteus* spp., all of which are resistant to antibiotics [7.247]. Unusual prostanoids named punaglandins with antiviral and anticancer activities (e.g., an antitumor that inhibits leukemia cell proliferation) from the octocoral *T.* (*Carijoa*) *riisei* have been reported [7.248]. A steroid (18-acetoxipregna-1,4,20-trien-3-one) isolated from *C. riisei* displayed a strong antileishmanial activity, with an IC_{50} value of 5.5 μg mL^{-1} against promastigotes and 16.88 μg mL^{-1} against intracellular amastigotes [7.249]; the antitrypanosomal activity of the steroid resulted in an IC_{50} value of 50.5 μg mL^{-1}. The steroid also displayed mammalian cytotoxicity (IC_{50} of 10.6 μg mL^{-1}). Pregnane compounds from the Indopacific octocoral *Carijoa* sp. showed a strong activity in the preliminary biological assay for the inhibition of the integrated electron transfer chain (NADH oxidase activity) in beef heart submitochondrial particles [7.250]. Inhibitory concentration 50% (IC_{50}) ranged from 1.1–1.9 μM, with full inhibition at approximately 21 μM. Riiseins A and B from *C. riisei* showed *in vitro* cytotoxicity toward HCT-

Fig. 7.7 *Capnella imbricata* Quoy and Gaimard, 1833 and capnellene

116 human colon adenocarcinoma with IC_{50} values of $2.0\,\mu g\,mL^{-1}$ [7.251]. Cytotoxic amides found in the Micronesian *C. riisei*, were reported to be mildly toxic to murine leukemia cells (P-388) in culture [7.252].

7.2.10 Family *Tubiporidae*

Genus *Pachyclavularia*

Pachyclavulariolide F derived from *Pachyclavularia violacea* collected in Papua New Guinea showed in vitro cytotoxicity [7.253]. Organic extract from *P. violaceae* exhibited significant cytotoxicity toward P-388 tumor cells ($ED_{50} = 0.3\,mg\,mL^{-1}$) [7.254]. Pachyclavulariaenone G was shown to exhibit significant cytotoxicity toward P-388 and HT-29 cancer cells [7.163]. Five new briarane-type diterpenoids, pachyclavulides E–I, were isolated from the Okinawan *P. violacea* [7.255]; pachyclavulides B and E showed weak cytotoxicity in vitro toward the CNS (SNB-75; $IC_{50} = 5.2\,\mu M$) and the lung (A549; $IC_{50} = 5.1\,\mu M$) cancer lines.

Genus *Leptogorgia* (= *Lophogorgia*)

Lophotoxin from Pacific sea whips of the genus *Lophogorgia* was found to be an irreversible inhibitor of the nicotinic acetylcholine receptor [7.256]. Lophotoxin, a neurotoxin originally isolated from the Pacific gorgonian *L. rigida*, was the most potent feeding deterrent among the furanocembranolides isolated from the Brazilian gorgonian *L. violacea* [7.257]. The steroids found in the gorgonian *L. sarmentosa* of the Gibralter Strait, exhibited significant cytotoxicity against four tumor cell lines ($ED_{50} = 1\,\mu g\,mL^{-1}$) [7.258]. *Lophogorgia* sp. presented extracts with high cytotoxic activity [7.259]. The common sea whip *L. virgulata*, a temperate/subtropical coral of the western Atlantic Ocean, yielded antimicrobial extracts named homarine [7.260].

7.2.11 Family *Ellisellidae*

Genus *Ctenocella*

Ctenocella pectinata from New Caledonia produced pectinoacetals A–C [7.263], of which their two analogs from *Ctenocella* sp. of the same region were cancer cell antiproliferative [7.264].

Genus *Ellisella*

Two briarane diterpenes from the gorgonian *Ellisella* sp. inhibited cytokinesis, causing multinuclei formation on NBT-II cells [7.265]. *E. robusta* sucumed robustolides J and K, which displayed inhibitory effects on superoxide anion generation by human neutrophils [7.266].

Genus *Rumphella*

A fraction isolated from the gorgonian *Rumphella aggregata* was studied in vitro on asynchronous cells of a human non-small-cell-bronchopulmonary-carcinoma line, which appeared to irreversibly inhibit cell growth in the G1 phase of the cell cycle [7.267]. Two norsesquiterpenoid alcohols, designated as rumphellatins B and C, were obtained from the Formosan gorgonian coral *Rumphella antipathies*. Rumphellatin B showed antibacterial activity toward the Gram-positive bacterium *Staphylococcus aureus* [7.268].

Genus *Junceella*

Junceellonoids C and D from *Junceella fragilis* exhibited cytotoxicity toward human breast carcinoma MDA-MB-231 and MCF-7 cells at a concentration of $100\,\mu M$ [7.269]. The sea whip gorgonian *Junceella juncea* led to the isolation of five new 8-hydroxybriarane diterpenoids, junceols D–H [7.270]; junceols D and F–H exhibited cytotoxicity toward CCRF-CEM and DLD-1 tumor cells, and junceols E–H displayed weak inhibitory effects on superoxide anion

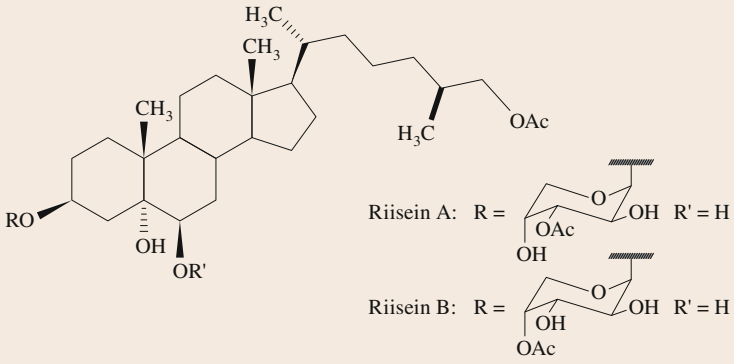

Fig. 7.8 *Carijoa riisei* and riiseins A and B (after [7.261, 262])

generation by human neutrophils. Structures, names, biological activities, and references of 137 briarane-type diterpenoids from various octocorals are summarized in [7.271].

7.2.12 Family *Xeniidae*

Genus *Xenia*

The soft coral *Xenia macroscopiculata* was shown to be the most active species among the Red Sea corals examined, with the highest and most potent antimicrobial activity. This characteristic, based upon bioassay-directed fractionation, was due to the presence of a range of compounds of different polarities. One of the isolated antibiotics was identified as desoxyhavannahine with an estimated volumetric concentration of ca. $590\,\mu g\,mL^{-1}$ (assuming 100% recovery) in tissues of *X. macroscopiculta*. The MIC of purified desoxyhavannahine was $48\,\mu g\,mL^{-1}$ against a marine bacterium; it is about tenfold lower than its estimated natural concentration, whereas the MIC of the crude extract of *X. macroscopiculta* was $25\,\mu g\,mL^{-1}$. This may suggest that the extract of this coral contains additional antimicrobial compounds [7.272]. Furthermore, eight diterpenoids were isolated from the Formosan *X. blumi*, and their cytotoxicity against selected cancer cells was measured in vitro [7.273]. Xenicane diterpenes and xeniolactones A–C were reported from Taiwanese *X. blumi* and *X. florida*, for which mild cytotoxicity was observed [7.273]. *X. florida* also afforded florxenilides A and B, which exhibited cytotoxicity against human colon cancer (WiDr) cells at 4.5 and 3.7 μM, respectively [7.274]. The cytotoxic sesquiterpenes, xenitorins A–F, were isolated from *X. puerto-galerae*; xentorins A and E exhibited cytotoxicity towards the A and P388 tumor cell lines [7.275]. Seven cytotoxic xenicane-type diterpenoids, 9-deoxyxeniloide-E, 9-deoxy-7,8-epoxyxeniloide-E, xeniolide-G, 9-deoxyxenialactol-C, xenibecin, xeniolide-H, and xenitacin, were isolated from the methylene chloride solubles of the Formosan *X. umbellata* [7.276]. An extract from Taiwanese *X. umbellata* led to the isolation of mildly cytotoxic diterpenoids, xenibellols A and B, and umbellactal [7.277]. The norxenicane metabolite xenibellal was reported as

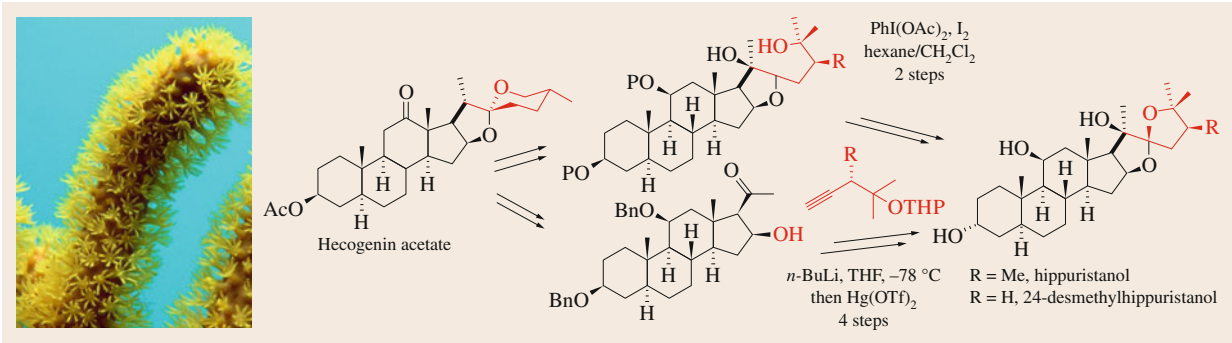

Fig. 7.9 *Isis hippuris* and its cytotoxic polyoxygenated steroid, hippuristanol

a mildly cytotoxic component of Taiwanese *X. umbellata* [7.278].

Genus *Heteroxenia*

The *Heteroxenia* sp. collected in the Philippines yielded biologically active sarcoaldosterol, which was active against the phytopathogenic fungus *Cladosporium cucumerinum*; it was also found to be cytotoxic [7.279]. The venom of *H. fuscescens* was found to be lethal (LD_{50}: 0.7 mg kg^{-1}) in dermonecrosis and vasopermeability potency assays in mouse skin, with one prominent 97 kDa protein fraction (LD_{50}: 0.55 mg kg^{-1}) [7.280]. The Egyptian Red Sea *H. ghardaqensis* led to the isolation of a gorgostane sterol that showed moderate activity as growth inhibitor of human colon tumor cell lines [7.281].

Genus *Cespitularia*

Cespitularia hypotentaculata yielded diterpene cespitularins A–H and I–Q, for which variable potency and selectivity was observed towards tumor cell lines A-549, HT-29, and P388 [7.282, 283]. Alcyonolide from an Okinawan *Cespitularia* sp. was cytotoxic against HCT 116 cells (IC_{50} 5.85 μM) [7.284]. Cespitulin G produced by *C. taeniata* displayed significant activities on superoxide-anion generation and elastase release by human neutrophils [7.285].

Genus *Asterospicularia*

An investigation of *Asterospicularia laurae*, collected on the Great Barrier Reef, Australia, afforded the cytotoxic diterpenes 13-epi-9-deacetoxyxenicin and 13-epi-9-deacetoxyxenicin [7.286]. The compounds showed cytotoxicity against a cultured suspension of P388D1 mouse lymphoma cells, with IC_{50}s of 0.1 and 1.0 μg mL^{-1}, respectively. Asterolaurins A–F, xenicane diterpenoids were extracted from Taiwanese *A. laurae*; asterolaurin A exhibited moderate cytotoxicity against HepG2 cells with an IC_{50} of 8.9 μM, while asterolaurin D showed potent inhibition of elastase release and superoxide anion generation in vitro [7.287].

7.2.13 Family *Melithaeidae*

Genus *Acabaria*

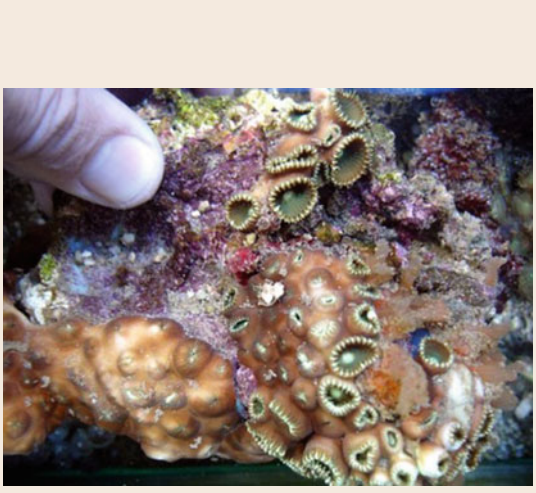
Extracts of *Melitodes ornata* exhibited spasmolytic activity [7.288]. Three sterols from the Korean *Acabaria undulata* exhibited moderate cytotoxicity and inhibitory activity against phospholipase A_2 [7.289].

7.2.14 Family *Isididae*

Genus *Isis*

Isis hippuris has proven to be a rich source of new cytotoxic polyoxygenated steroids. The authors of reference [7.291] worked on Okinawan the gorgonian *I. hippuris* and found that hippuristanol and 2R-hydroxy hippuristanol were potent anticancer agents. Epihippuristanol from the same species [7.292] was stated to be in the patenting process for its cytotoxic properties [7.293].

I. hippuris also yielded polyoxygenated gorgosterols showed moderate activity for reversal of multidrug resistance with cancer cells [7.294]. Several hippuristanol steroids were reported from the Taiwanese *I. hippuris*, including isishippuric acids A and B; isishippuric acid B was shown to exhibit potent cytotoxicity toward a limited panel of cancer cells [7.295]. Hippuristanol was further shown to be a selective and potent inhibitor of eIF4A RNA-binding activity that can be used to distinguish between eIF4A-dependent and eIF4A-independent modes of translation initiation in vitro and in vivo [7.296]. From the extracts of the South China Sea gorgonian *Isis minorbrachyblasta*,



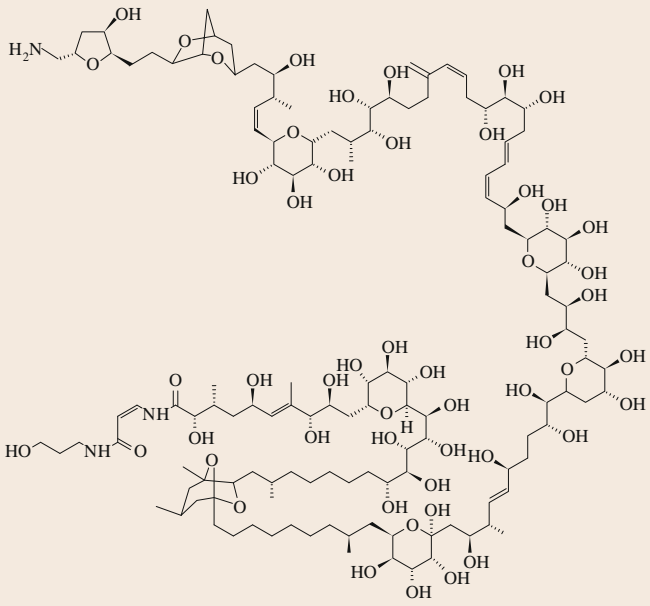


Fig. 7.10 Structure of palytoxin and a zoanthid *Palythoa* sp. (after [7.290])

two polyoxygenated steroids, gorgost-5-ene and 11-*O*-acetyl-22-epihippuristanol were isolated; they showed weak and moderate cytotoxicities against the examined cancer cell lines [7.297].

Genus *Dasystenella*

The first Antarctic gorgonian to be reported to contain polyoxygenated steroids was *Dasystenella acanthina* of the eastern Weddel Sea. All steroidal compounds from this species showed significant activities as growth inhibitors of several human tumor cell lines, as well as cytostatic and cytotoxic effects on selected tumor cell lines [7.225, 298].

Genus *Ainigmaptilon*

Ainigmaptilone A, extracted from the Antarctic gorgonian *Ainigmaptilon antarcticus* was one of two sesquiterpenes showing antibiotic activity [7.299].

7.2.15 Family *Zoanthidae* (Subclass *Hexacoralia = Zoantharia*)

Zoanthids containing palytoxins are reportedly among the most toxic marine organisms known [7.300, 301]. The extremely poisonous palytoxin, as one of the most potent known toxins, was originally found in the zoanthid *Palythoa toxica* (for a review, see [7.6]). Its intravenous lethality (LD_{50}), which ranges from $0.025\,\mu g\,kg^{-1}$ in rabbits to $0.45\,\mu g\,kg^{-1}$ in mice, is exceeded only by certain proteins and polypeptides [7.302]

Palythoa liseia yielded several punaglandins exhibiting antineoplastic properties [7.246]. The zoanthid, *Gerardia savaglia* was found to be an unexpected new rich source of the molting hormone, ecdysterone [7.303], which was found to be effective in inducing contractions in guinea pig uterus due to the active component oxytocin, reported as 2-deoxyecdysterone in *Zoanthus* sp. as well [7.304]. Prostaglandins such as PGA_2 isolated from the zoanthid *Palythoa kochii*, stabilize microtubules in a manner similar to paclitaxel (Taxol) [7.305]. The isolated zoanthamine and norzoanthamine alkaloids produced by the *Zoanthus* spp. [7.306] and *Z. nymphaeus* showed antitumor and antiplatelet activities, restrained the growth of murine leukemia cells, inhibited inflammation in mouse ears, and were suggested as promising candidates for antiosteoporotic drugs [7.307, 308]. The suppressive effect of norzoanthamine hydrochloride ($2\,mg\,kg^{-1}\,d^{-1}$) on osteoporosis was confirmed in vivo [7.309]. These findings suggest that norzoanthamine may act as both a suppressor of bone resorption and an enhancer of bone formation. In addition, a high concentration of norzoanthamine was detected to be present in the epidermal

tissue of *Zoanthus* sp. [7.310]; it was also found to be a collagen-strengthening function for norzoanthamine. Parazoanthoxanthin A, a related structure of zoanthoxanthin isolated from the zoanthid *Parazoanthus axinellae* [7.311] showed anticholinesterase activity [7.312]. *Zoanthus* sp. was also reported to produce a steroidal hormone, 2-deoxyecdysterone, which exhibited promising oxytocic activity compared to that of clinical standards, oxytocin and prostaglandin $F_{2\alpha}$ [7.304].

An alkaloid, antipathine A, together with three known zoanthoxanthin alkaloids extracted from the South China Sea black coral *Antipathes dichotoma* (zoanthid, family *Antipathidae*). Two alkaloids showed moderate cytotoxicity against human stomach carcinoma SGC-7901 cell line with IC_{50} of 67.38 and 86.40 $\mu g\,mL^{-1}$, respectively; the other two alkaloids also showed weak cytotoxicity toward human liver carcinoma Hep_G2 cell line [7.313].

7.3 Potential Pharmaceuticals from Hard Corals

Stony corals (hard coral/scleractinian) have rather been disregarded as a source of bioactive compounds; this may be because many secondary metabolites assumedly function in defense, and the calcareous skeleton of these animals is supposed to satisfy the defensive role [7.314]. Growth inhibition of smaller soft corals by some hard corals revealed the biological role of terpenes in hard corals [7.315].

7.3.1 Family *Poritidae*

A vasoactive and cardiotonic peptide (12 000 Da) from *Goniopora* sp. was reported to prolong action potential in amphibian and mammalian atria caused by delayed inactivation of Na^+ current, analogous to the mechanism of the action of ATX-II [7.316]. Extracts of *Porites lichen* and *P. lutea* exhibited antifertility at 80 and 100%, respectively ($LD_{50} > 1000\,mg\,kg^{-1}$ in mice) [7.288]. Aqueous extracts from the Hawaiian *Porites lobata* revealed antibacterial activity against nine bacterial strains [7.317].

7.3.2 Family *Dendrophylliidae*

A compound, tubastrene, with antiviral activity was found in the scleractinian *Tubasterea aurea* [7.318]. Sponge-derived aplysinopsins, with anticancer and antimicrobial properties that were first reported from *Astroides calycularis* collected in the Mediterranean Sea [7.319], were also isolated from the Indo-Pacific corals, *T. aurea* and *Tubastraea* sp., as inhibitors of the development of fertilized sea urchin eggs [7.320]. The isolation of two cytotoxic macrolides, mycalolides D and E, was reported from a collection of *T. faulkneri* [7.321]. The extract of *T. faulkneri* had previously been found to be cytotoxic in the antitumor screening of the NCI. Chemical extracts from *T. faulkneri* were also tested for deleterious effects on competent larvae of 11 other species of coral belonging to seven genera of four scleractinian families. Larvae exposed to extract concentrations from 10–500 $mg\,mL^{-1}$ consistently suffered higher mortality than larvae in solvent controls [7.322]. These compounds could, therefore, function as allelochemicals.

7.3.3 Family *Milleporidae*

A calcium-dependent smooth muscle excitatory effect was elicited by the venom of the hydrocoral *Millepora complanata* [7.183]. The nucleoside 1-methylisoguanosine isolated from some marine animals, including the coral *Madracis mirabilis*, showed potent muscle relaxant, blood pressure lowering, cardiovascular, and anti-inflammatory activity [7.323, 324].

7.3.4 Family *Acroporidae*

Extracts from *Acropora formosa* and *A. millepora* exhibited weak and strong hemolytic activity, respectively, and were also toxic to mice [7.325]. *Acropora corymbosa*'s extracts showed 100% antifertility ($LD_{50} > 1000\,mg\,kg^{-1}$, in mice). *Montipora divaricata* showed spasmolytic activity, LD_{50} more than 1000 ($mg\,kg^{-1}$, in mice) [7.288]. *Montipora* sp. and *M. mollis* succumbed polyacetylene compounds that exhibited ichthyotoxicity and inhibited the growth of some bacteria and fungi [7.326]. Six acetylenic compounds of *Montipora* sp. exhibited significant cytotoxicity against a small panel of human solid tumor cell lines, with Montiporyne A found to induce apoptosis in human colon tumor cells [7.314, 327]. The Korean *Montipora* spp. yielded three diacetylenes, one of which was the most potent cytotoxin towards a range of tumor cell lines [7.328]. Antimicrobial activity was found in the eggs of *Montipora digitata* [7.329], which had previ-

ously been reported to produce montiporic acids [7.330] and other cytotoxic diacetylenes [7.327]. Antibacterial activity against 9 bacterial strains was revealed in crude aqueous extracts from the Hawaiian *M. capitata* [7.317].

7.3.5 Family *Pocilloporidae*

Extracts from *Pocillopora demicornis* exhibited hypotensive activity (LD_{50} 681 mg kg^{-1} in mice) [7.288]. The Hawaiian *P. meandrina* displayed antibacterial activity in crude aqueous extracts against nine strains of bacteria including coral pathogens [7.317].

7.3.6 Family *Oculinidae*

From the coral *Galaxea fascicularis*, a crude mucus-like extract and subsequently its purified component were found to contain a DNase-like activity. It indiscriminately digested λDNA, as well as naked genomic DNAs isolated from a multiple-drug-resistant murine leukemia cell line, P388/VCR, and a nontransformed liver cell line, BL8L. Their apoptotic actions indicate their potential role in the development of an anticancer agent [7.331].

7.3.7 Family *Helioporidae*

Seven diterpenes, helioporins A–G, were isolated from the blue coral *Heliopora coerulea*; helioporins A and B showed antiviral activity against HSV1 and C-G cytotoxicity against P388 [7.332].

7.3.8 Family *Pectiniidae*

A polyacetylene from *Pectinia lactuca* exhibited ichthyotoxicity and inhibited the growth of some bacteria and fungi [7.326].

7.3.9 Family *Mussidae*

The extracts of *Lobophyllia corymbosa* showed 100% anti-implantation activity in female mice as the most promising activity observed [7.325].

7.4 Mycosporine-Like Amino Acids (MAAs)

Above all, because they are inhabitants of shallow waters exposed to ultraviolet radiation, symbiotic corals also produce mycosporine-like amino acids (MAA) that, as UV-absorbing compounds, possess photoprotective properties [7.333]; they also manufacture other mycosporines referred to as true *multipurpose* secondary metabolites against detrimental UV effects, in combination with other functionalities such as prevention of oxidation reactions [7.334]. *Palythoa tubereulosa* was the initial source of the mycosporine-like amino acids as natural sunscreens [7.335]. The unique physical and chemical properties of MAAs as natural sunscreens prompted an investigation of their use in healthcare applications and in the formulation of cosmetic products [7.336]. As an example, the commercially available synthetic fungicide, clotrimazole (mycosporin) is a chemical analog of naturally occurring mycosporine-like amino acids [7.337]. MAAs were also separated from the *Acropora formosa*, *Stylophora pistillata* [7.338–341], *Pocillopora damicornis*, and *Montipora verrucosa* [7.342].

Moreover, the microscopic algal symbionts of corals, referred to as zooxanthellae, and not coral cells are in some cases the likely source of the secondary metabolites of interest [7.343]. For example, anti-inflammatory pseudopterosins were shown to be produced by the endosymbiotic algae [7.344]. Ultimately, it is worth mentioning that antitumor and anticarcinogenic activities have also been reported for the unique pigment of dinoflagellate symbionts of corals, namely peridinin and related compounds [7.345]. The genus *Symbiodinium*, for instance, a symbiont of the Okinawan soft coral *Clavularia viridis* containing abundant antitumor marine prostanoids (e.g., clavulones), yielded compounds with significant growth-inhibitory activity in vitro toward cancer cells (IC_{50} of 2.0−2.8 g mL^{-1}) [7.244].

7.5 Conclusion

Table 7.1 summarizes various coral-derived compounds with diverse therapeutic properties, most of which necessitate further preclinical examinations to be commercialized. The substances in Table 7.1 account

Table 7.1 Componds with various properties extracted from soft and hard coral species

Compounds	Coral species	Properties	References
Alcyoniidae			
Flexibilide and dihydroflexibilide	*Sinularia flexibilis*	Antibacterial, cytotoxic, cardiac vasorelaxant, anti-inflammatory, anti-arthritic	[7.17, 37, 39, 41, 43]
Sinulariolide and 11–episinulariolide	*S. flexibilis*	Cytotoxic, algicide	[7.17, 28, 38]
Sinuflexlin	*S. flexibilis*	Cytotoxic	[7.11]
2-Phenylethylamides	*S. flexibilis*	Atrial stimulants	[7.43]
Sinulaflexiolides A−K	*S. flexibilis*	Anticancer	[7.45]
Scabrolides	*S. scabra*	Cytotoxic	[7.10]
Sinularolides, gibberosins, norhumulene, xeniaphyllane and gibberoketosterol	*S. gibberosa*	Cytotoxic, anti-inflammatory	[7.36, 60–62]
β-Caryophyllene terpenes	*S. nanolobata*	Cytotoxic	[7.55]
Sphingosine derivative, crassarosterol A and crassarosterosides A–D	*S. crassa*	Anti-inflammatory, cytotoxic	[7.56, 57]
Querciformolides A–D, granosolides A and B	*S. querciformis*, *S. granosa*	Anti-inflammatory	[7.67]
Gyrosanols A–C	*S. gyrosa*	Anti-inflammatory and antiviral	[7.68]
24-Methylenecholest-4-ene-3β,6β-diol, singardin	*S. ovispiculata*, *S. gardineri*	Cytotoxic	[7.49, 50]
Microclavatin and capillolide	*S. microclavata*	Cytotoxic	[7.51]
Sinuleptolide, sinulariol D and acylspermidines	*Sinularia* spp.	Anticancer, cytotoxic	[7.46, 53, 54]
Furanoic acid	*Sinularia* sp.	Bee venom inactivator	[7.48]
Firmacosides A and B	*S. firma*	Antibacterial	[7.63]
Polyhydroxylated steroids	*Sinularia* sp.	Anti-inflammatory	[7.64]
Polyoxygenated steroids and hydroxycembranes	*S. facile*	Cytotoxic	[7.65, 66]
Methylsarcophytotate and methylchlorosarcophytoate	*S. glaucum*	Cytotoxic	[7.75]
Sarcodictyins	*S. roseum*	Cytotoxic	[7.76]
Sarcophine, sarcophytol A, sarcotriol and hydroxydeepoxysarcophine	*Sarcophyton glaucum*	Antitumor, Anticancer, cytotoxic	[7.83, 84, 86, 87]
Sarcoglaucol, methyl tortuoates A and B, sarcostolides A–G	*S. cherbonnieri*, *S. tortuosum*, *S. stolidotum*	Cytotoxic	[7.88, 89, 91]
Sarcophine, sarcophytoxide, sarcocrassolide, crassolide, 13-acetoxysarcocrassolide and crassocolides A−M	*S. crassocaule*	Allelochemicals, cytotoxic	[7.35, 79–81]
7β-Hydroxy-8α-methoxydeepoxy sarcophytoxide	*S. mililatensis*	Antiosteoporosis	[7.90]
Neocembrenes and sartrochine	*S. trocheliophorum*	Cytotoxic, antibiotic	[7.71, 72]
Denticulatolide	*Lobophytum denticulatum*	Ichthyotoxic	[7.93]
Amine chlorides	*L. strictum*	Hypotensive and vasodilator	[7.94, 95]
Cembranolide deterpenes	*L. cristagalli*	Farnesyl inhibitor	[7.96]
Secosterol and lobohedleolide	*Lobophytum* spp.	Antitumor, anti-inflammatory, anti-HIV, cytotoxic	[7.56, 97, 99]
Ceramideas, lobocrassin F, glycolipids, crassumolides	*L. crassum*	Anti-inflammatory, antibacterial, anti-cancer	[7.100, 101, 103]

Table 7.1 (continued)

Compounds	Coral species	Properties	References
Alcyoniidae			
Durumhemiketalolides A−C and durumolides	*L. durum*	Antibacterial, anti-inflammatory	[7.104, 105]
Cembranolides	*L. michaelae*	Antiviral	[7.106]
Eleutherobin	*Eleutherobia sp.*	Cytotoxic	[7.109]
9-Deacetoxy-14,15- deepoxyxeniculin	*Eleutherobia aurea*	Anti-inflammatory	[7.107]
Sarcodictyin A	*Bellonella albiflora*	Cytotoxic	[7.113]
Cladiellin A, Cladielloides A and B, cladieunicellin H	*Cladiella* sp.	Antioxidant, cytotoxic and anti-inflammatory	[7.119, 120, 122]
Australins A–D	*C. australis*	Cytotoxic	[7.59]
Hirsutalins A–H	*C. hirsuta*	Cytotoxic	[7.120]
Valdivones	*Alcyonium valdivae*	Anti-inflammatory	[7.114]
Rietone	*A. fauri*	Anti-HIV	[7.115]
Sterol	*A. patagonicum*	Cytotoxic	[7.116]
Steroids	*A. gracillimum*	Cytotoxic and antiviral	[7.117]
Klysimplexin sulfoxides A–C, klymollins A–H, simplexins A–I	*Klyxum simplex*, *K. molle*	Cytotoxic, anti-inflammatory	[7.123–125]
Paraminabeolides A–F	*Paraminabea acronocephala*	Cytotoxic	[7.126]
Extracts	*Parerythropodium fulvum fulvum*	Antimicrobial	[7.40]
Anthothelidae			
Caribaeorane	*Erythropodium caribaeorum*	Anticancer	[7.112]
Plexauridae			
Crassin acetate	*Pseudoplexaura porosa* and *P. wagenaari*	Antibacterial and antineoplastic	[7.176–178]
14-Deoxycrassin and pseudoplexaurol	*P. porosa*	Antitumor	[7.180]
Guaiazulene	*Euplexaura erecta*	Antibacterial	[7.187]
Nuttingins A–E and malonganenones D–G	*E. nuttingi*	Antitumor, cytotoxic	[7.188]
Malonganenones	*E. robusta*	Cytotoxic	[7.189]
Muricins	*Muricea californica* and *M. fruticosa*	Antifouling	[7.190]
Steroids and sesquiterpenoids	*M. austere*	Antiprotozoal	[7.191]
Dimorphosides	*Anthoplexaura dimorpha*	Cytotoxic	[7.192]
Linderazulene	*Paramuricea* sp.	Cytotoxic	[7.193]
Sterols and sesquiterpenes	*Plexaurella grisea*	Anticancer	[7.195]
Caffeine	*Echinomuricea spendens*	Antifouling	[7.197]
Echinohalimane A and echinoclerodane A	*Echinomuricea* spp.	Antitumor, cytotoxic	[7.198, 199]
Calicoferols A–H, menelloide A	*Muricella* sp., *Calicogorgia* sp.	Antiviral, cytotoxic	[7.117, 200, 202]
Menellins A–C	*Menella* sp.	Anti-inflammatory	[7.201]
Eunicin	*Eunicea mammosa*	Antibacterial	[7.182, 183]
Fucoside-A (fuscol), fuscoside E, and eunicidiol	*E. fusca*	Skin care, anti-inflammatory, antifouling	[7.137, 185, 186]
Sesquiterpenoids	*Eunicea* sp.	Antimalarial	[7.184]
Eupalmerin acetate	*E. succinea* and *E. mammosa*	Anticancer	[7.2]

Table 7.1 (continued)

Compounds	Coral species	Properties	References
Plexauridae			
Spongouridine	*Eunicella cavolini*	Antiviral	[7.160]
Verrucoside	*E. verrucosa*	Cytotoxic	[7.161]
Prostaglandins	*Plexaura homomalla*	Hormon-like	[7.16]
Ellisellidae			
Briarane diterpenes	*Ellisella* sp.	Antitumor	[7.265]
Robustolides J and K	*E. robusta*	Anti-inflammatory	[7.266]
Rumphellatin B	*Rumphella antipathies*	Antibacterial	[7.268]
Pectinoacetal analogs	*Ctenocella* sp.	Anticancer	[7.264]
Junceols D and F–H	*Junceella juncea*	Cytotoxic	[7.270]
Gorgoniidae			
Pseudopterolide	*Pseudopterogorgia acerosa*	Cytotoxic	[7.155]
Bipinnatin-B and caucanolides A–F	*P. bipinnata*	Neurotoxin, cytotoxic, antimalarial	[7.148, 149]
Pseudopterosins, elisabethin H and methopterosin	*P. elisabethae*	Anti-inflammatory	[7.135, 139, 142]
Pseudopteroxazole and ergorgiaene (biflorane)	*P. elisabethae*	Antimycobacterial	[7.144, 146]
Providencin, kallolide A, Bielschowskysin and bipinnatin Q	*P. kallos*	Anticancer and antimalarial	[7.150–152]
Pseudopetrocin-E	*Pseudopterogorgia* sp.	Anti-inflammatory	[7.156]
Ancepcenolide, furanogermacrene	*Pterogorgia guadalupensis*, *P. americana*	Antibacterial	[7.143, 157]
Antikinases, crude extracts	*Gorgonia ventalina*	Antibacterial, antifungal	[7.158, 159]
Briareidae			
Solenolides	*Briareum* (*Solenopodium*) sp.	Anti-inflammatory and antiviral	[7.167]
Briantheín A, briaexcavatolides and excavatoid L	*B. excavatum*	Cytotoxic, anti-inflammatory	[7.168–170]
Violides Q–V, briarlides I–R, briviolides, biarenol A, briaranolides A–J, and briarenolide F	*Briareum* spp.	Cytotoxic, anti-inflammatory	[7.171–175]
Nephtheidae			
Naphthoquinones, chabrolidiones, chabrolosteroid B and armatinols	*Nephthea chabrolii* and *N. armata*	Cytotoxic	[7.210–212]
Elongatols	*N. elongate*	Cytotoxic	[7.106]
Brassicolide and brassicolide acetate	*N. brassica*	Cytotoxic	[7.209]
Erectasteroids and various sterols	*N. erecta*	Cytotoxic	[7.208, 346]
Pacificins, decaryiol	*N. pacifica*, *Nephthea* sp.	Cytotoxic	[7.88, 213]
Dendronesterone A, dendronesterol B, 3-oxocholest-1,22-dien-12β-ol and 3-oxocholest-1,4-dien-20β-ol	*Dendronephthya gigantea*	Cytotoxic	[7.216, 218, 347]
Dendronpholides A−R, isogosterones and tissue extracts	*Dendronephthya* sp.	Cytotoxic, antibacterial, antifoulant	[7.118, 217, 220]
Methyl spongoate	*Spongodes* (*Dendronephthya*) sp.	Cytotoxic	[7.219]
Griffinisterones F–I	*D. griffin*	Anti-inflamatory	[7.221]
9,11-Secosterol and 5,6-epoxy sterol	*Gersemia fruticosa*	Cytotoxic, antiproliferative	[7.223]
Extract, homarine, and trigonein	*G. rubiformis*, *G. antarctjca*	Antibacterial	[7.224, 225]

Table 7.1 (continued)

Compounds	Coral species	Properties	References
Nephtheidae			
Lemnalol, cervicol and isolemnalol	*Lemnalia cervicorni*	Cytotoxic	[7.347]
Lemnalol	*L. cervicorni*	Antinociceptive	[7.234, 235]
Laevinols	*L. laevis*	Cytotoxic	[7.348]
Lemnaflavoside	*L. flava*		[7.233]
Tsitsixenicin	*Capnella thyrsoidea*	Anti-inflammatory	[7.226]
Capnellenes, calamenene and cytotoxic, capnellenes GB9 and GB10	*C. imbricata*	antineuroinflammatory and antinociceptive	[7.228–230]
Fucoside steroid	*Scleronephthya pallida*	Antimalarial and cytotoxic	[7.236]
Litosterol	*Litophyton viridis*	Antimycobacterial	[7.231]
Stereonsteroids	*Stereonephthya crystalliana*	Cytotoxic	[7.214]
Clavulariidae			
Krecembrenolides and sesquiterpenoids	*Clavularia koellikeri*	Cytotoxic, antitumor	[7.237–239]
Prostadienoate, prostanoids, stoloniferones A–D and E–G, claviridenones, clavubicyclone, bromovulone III, clavulones, and chlorovulone II	*C. viridis*	Anticancer, antitumor, cytotoxic	[7.238, 241–243, 246, 296, 349]
Claviolide, dolabellane diterpenes	*C. violacea*, *C. inflata*	Cytotoxic	[7.240, 241]
Amides, riiseins and 18-acetoxypregna. . .-one	*Carijoa riisei*	Antiprotozoan, cytotoxic, antimicrobial	[7.247, 249, 251, 252]
Punaglandins	*Telesto* (*Carijoa*) *riisei*	Antitumor	[7.248]
Pregnane compounds	*Carijoa* sp.	Cytotoxic	[7.250]
Subergorgiidae			
Suberosols, subergorgic acid, and suberosanone	*Subergorgia suberosa*	Cardiotoxin, antifoulant, cytotoxic	[7.162, 163, 165, 166]
Acanthogorgiidae			
Astrogorgiadiol, astrogorgols, and astrogorgins B–M	*Astrogorgia* sp.	Anticancer, antitumor, antifouling	[7.203–205]
Acalycixeniolides	*Acalycigorgia inermis*	Cytotoxic	[7.206, 207]
Xeniidae			
Desoxyhavannahine	*X. macroscopiculta*	Antimicrobial	[7.272]
Xenitorins A and E	*X. puerto-galerae*	Cytotoxic	[7.275]
Xenicanes, xeniolactones, and florxenilides A and B	*X. blumi*, *X. florida*	Cytotoxic	[7.273, 274]
Xenibellols A and B, umbellactal and xenibellal	*X. umbellata*	Cytotoxic	[7.276–278]
Sarcoaldosterol	*Heteroxenia* sp.	Cytotoxic and antifungal	[7.279]
Gorgostane	*H. ghardaqensis*	Antitumor	[7.281]
Cespitularins A–Q	*Cespitularia hypotentaculata*	Antitumor, cytotoxic	[7.282, 283]
Alcyonolide, cespitulin G	*Cespitularia* sp., *C. taeniata*	Cytotoxic	[7.284, 285]
13-Epi-9-deacetoxyxenicin, 3-epi-9-deacetylxenicin and asterolaurins A–F	*Asterospicularia laurae*	Cytotoxic	[7.286, 287]
Isididae			
Polyoxygenated gorgosterols, epihippuristanol, isishippuric acid B and hippuristanols	*I. hippuris*	Anticancer, cytotoxic	[7.291, 293–296]

Table 7.1 (continued)

Compounds	Coral species	Properties	References
Isididae			
Polyoxygenated gorgosterols, epihippuristanol, isishippuric acid B and hippuristanols	*I. hippuris*	Anticancer, cytotoxic	[7.291, 293–296]
Gorgost-5-ene- and 11-*O*-acetyl-22-epihippuristanol	*I. minorbrachyblasta*	Cytotoxic	[7.297]
Steroids	*Dasystenella acanthina*	Cytotoxic	[7.225, 298]
Ainigmaptilone A	*Ainigmaptilon antarcticus*	Antibacterial	[7.299]
Tubiporidae			
Pachyclavulariolide F and pachyclavulariaenone G	*Pachyclavularia violacea*	Cytotoxic	[7.253, 254]
Lophotoxin	*Lophogorgia* sp.	Paralytic (neuro)toxin	[7.256]
Steroids	*L. sarmentosa*	Cytotoxic	[7.258]
Homarine	*L. virgulata*	Antimicrobial	[7.260]
Melithaeidae			
Polyhydroxysteroids	*Acabaria undulata*	Cytotoxic	[7.289]
Zoanthidae			
Palytoxin	*Palythoa toxica* and *P. tuberculosa*	Cytotoxic	[7.6]
Punaglandins	*Palythoa liseia*	Antineoplastic	[7.246]
2-Deoxyecdysterone	*Zoanthus* sp.	Oxytocic	[7.304]
PGA2 (Prostaglandin)	*P. kochii*	Microtubules stabilizer	[7.305]
Zoanthamine alkaloids	*Zoanthus* spp.	Anti-inflammatory and antiosteoporotic	[7.306]
Norzoanthamine	*Zoanthus* sp. and *Z. nymphaeus*	Antiplatelet and antiosteoporotic	[7.307, 308, 350]
Parazoanthoxanthin	*Parazoanthus axinellae*	Anticholinesterase	[7.312]
Antipathine A	*Antipathes dichotoma*	Cytotoxic	[7.313]
Acroporidae			
Polyacetylenes	*Montipora* sp., *M. mollis*	Ichthyotoxic, antibacterial	[7.326]
Montiporyne A	*Montipora* sp.	Anticancer	[7.327]
Diacetylene	*Montipora* spp.	Antitumor	[7.328]
Montiporic acids	*M. digitata*	Antimicrobial	[7.329, 330]
Poritidae			
Peptide	*Goniopora* sp.	Vasoactive and cardiotonic	[7.316]
Helioporidae			
Helioporins A–G	*Heliopora coerulea*	Antiviral and cytotoxic	[7.332]
Dendrophylliidae			
Tubastrene	*Tubasterea aurea*	Antiviral	[7.318]
Mycalolides	*T. faulkneri*	Cytotoxic	[7.321]
Aplysinopsins	*Tubasterea* spp. and *Astroides calycularis*	Anticancer, antimicrobial	[7.319]
Milleporidae			
1-Methylisoguanosine	*Madracis mirabilis*	Cardiovascular and anti-inflammatory	[7.323, 324]
3-Oxo sterols	*Anthomastus bathyproctus*	Cytotoxic	[7.127]
Venom	*Millepora complanata*	Muscle excitatory	[7.183]

Table 7.1 (continued)

Compounds	Coral species	Properties	References
Mussidae			
Extracts	*Lobophyllia corymbosa*	Antiimplantation activity	[7.325]
Pocilloporidae			
Extract	*Pocillopora demicornis*	Hypotensive	[7.288]
Pectiniidae			
Polyacetylene	*Pectinia lactuca*	Antibacterial and antifungul	[7.326]
Oculinidae			
Crude extract	*Galaxea fascicularis*	Anticancer	[7.331]
Mixed hard corals			
Crude extracts	*M. capitata*, *Porites lobata* and *Pocillopora meandrina*, *M. divaricata*, *Acropora formosa*, *A. millepora*, *A. corymbosa*, *Porites lichen*, and *P. lutea*	Antibacterial, spasmolytic, hemolytic, anti-implantation activities	[7.288, 317]
Mycosporine-like amino acids (MAAs)	Various soft and hard corals	Photoprotective (sunscreens)	[7.338]

Table 7.2 Distribution of bioactive compounds among members of soft and hard corals

Soft corals				***Hard corals***			
Family	Genera	Species	Compounds	Family	Genera	Species	Compounds
Alcyoniidae	14	43	75	Acroporidae	2	6	4
Plexauridae	11	23	27	Dendrophylliidae	2	4	3
Nephtheidae	7	21	36	Milleporidae	3	3	3
Zoanthidae	5	8	8	Poritidae	1	1	1
Gorgoniidae	4	8	16	Helioporidae	1	1	1
Xeniidae	4	10	16	Pectiniidae	1	1	1
Ellisellidae	4	5	5	Total	10	16	13
Acanthogorgiidae	3	2	4				
Isididae	3	3	7				
Tubiporidae	2	4	5				
Clavulariidae	2	6	17				
Briareidae	1	3	10				
Subergorgiidae	1	1	3				
Melithaeidae	1	1	1				
Anthothelidae	1	1	1				
Total	63	139	231				

for ≈ 32% cytotoxic, ≈ 11% anticancer and antitumor, ≈ 11% anti-inflammatory, > 13% antibacterial, antiviral, antifungual, antiprotozoan and antimicrobial, and 33% other bioactivities including antifouling and anti-HIV properties. Accordingly, the majority of the tabulated compounds are promising as potential cancer therapeutics.

Table 7.2 shows that a total of 244 compounds (excluding crude extracts) have been introduced from 15 and 6 families each with 139 and 16 species of soft and hard corals, respectively. These compounds have mostly been identified in *Alcyoniidae* (soft corals) and *Acroporidae* (hard corals), in which the genera *Sinularia* and *Montipora* are prominent, respectively, with regard to bioactive compound production. This survey scores the *Alcyoniidae* family as the first followed by the families, *Nephtheidae*, *Plexauridae*, *Clavulariidae*, *Xeniidae*, and *Gorgoniida* as the most prolific among the octocorals studied (Fig. 7.11). Corals and in particular soft corals are, therefore, outstanding among marine

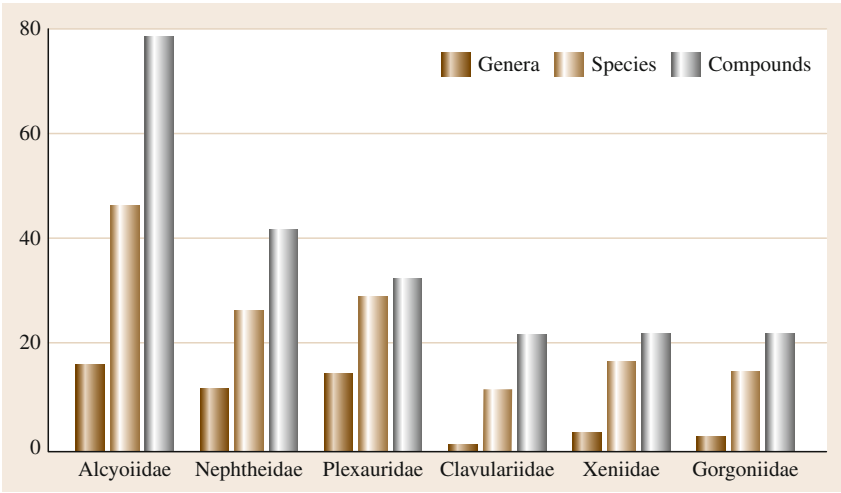

Fig. 7.11 Prolific families of soft coral species

organisms in the quantitative investment they make in terpenoid-based defence and competition. This wealth of bioactive substances renders these invertebrates potential with a variety of therapeutic agents.

8. Marine Sponges – Molecular Biology and Biotechnology

Stephen A. Jackson, Jonathan Kennedy, Lekha Menon Margassery, Burkhardt Flemer, Niall O'Leary, John P. Morrissey, Fergal O'Gara, Alan D. W. Dobson

Marine sponges are an ancient and diverse animal phylum that host well-established symbiotic microbial communities. The vast majority of the microbial genetic diversity in sponges is, however, currently inaccessible by traditional methods. This large genetic resource may be of use for biotechnological applications, particularly as the physicochemical parameters under which the genes within these microbes function are likely to dictate that they may be significantly different from similar genes or gene products currently in use in industry, offering in some instances improved performance. Emerging tools and technologies in the field of metagenomics offer enormous potential for the discovery and exploitation of new biosynthetic entities. Both sequence-based and function-based technologies have to date been employed to identify genes with novel or improved functions. Marine sponges, as well-recognized sources of novel marine natural products with varied applications, are the ideal target for the implementation of these new technologies. We detail here some successes in the discovery and development of marine natural products for industrial or pharmaceutical applications and we also highlight some technical impediments to gene and gene product exploitation which as yet still need to be overcome.

8.1 Marine Sponges

Marine sponges (phylum *Porifera*) are the oldest extant metazoan animals (Fig. 8.1), with the oldest fossils dating back almost 630 million years [8.1]. Sponges are globally distributed (Fig. 8.2) and are impor-

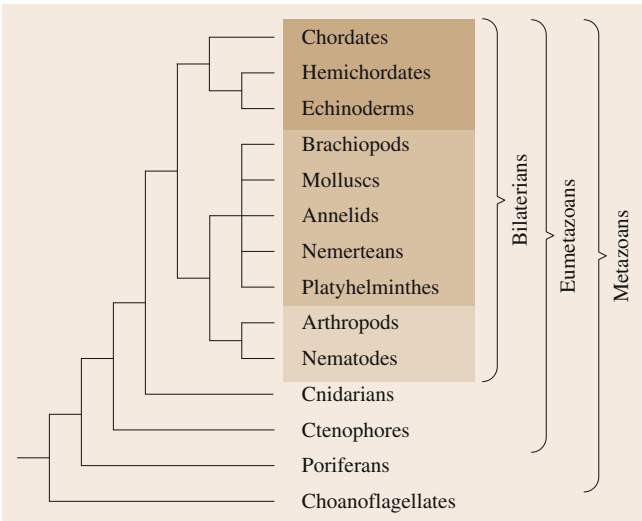

Fig. 8.1 Phylogeny of metazoa

tant members of all benthic communities. Sponges have been reported to be more abundant (area coverage/biomass/volume) than other benthic organisms [8.2], with sponge species diversity often outnumbering all other benthic species combined [8.2]. Sponges play vital roles in marine nutrient cycling as important sources of dissolved inorganic nitrogen (DIN), mediated by nitrifying endosymbiotic microbes resulting in high concentrations (40 μM) of nitrate near the ocean floor. They are also important sinks and sources of particulate organic carbon (POC), dissolved organic carbon (DOC), and dissolved organic nitrogen (DON) [8.3].

The World Porifera Database [8.5] currently lists > 8370 valid sponge species, which are distributed amongst 680 genera in four distinct classes: *Calcarea*, *Hexactinellida*, *Demospongiae*, and the recently recognized *Homoscleromorpha* [8.6]. *Demospongiae* is by far the largest class, comprising ≈ 83% of valid species. Almost all sponges are found in seawater, however, one suborder of *Demospongiae* (*Spongillina*) comprising ≈ 250 species is freshwater in origin [8.4].

8.1.1 Sponge Anatomy and Physiology

Although marine sponges exhibit a wide range of morphologies, the basic physiological features are common to all filtering sponges. Anatomical features, particularly different sponge skeleton types have traditionally been used to aid taxonomic classification of sponges.

8.1.2 Sponge Skeletons

Porifera exhibit a wide range of morphologies, from encrusting, through branching to barrel types. Sponge skeletal systems are comprised of spicules which may be calcareous, composed of calcium carbonate ($CaCO_3$); siliceous, composed of silicon dioxide (SiO_2); or spongin – a collagenous protein. The class *Calcarea* have calcareous spicules, *Hexactinellida* have siliceous spicules, while *Demospongia* and *Homoscleromorpha* can be spiculate, with a combination of siliceous spicules and spongin, or aspiculate, which contain spongin skeletons.

8.1.3 Sponge Cell Types

The sponge body is composed of very few differentiated cell types. The sponge epidermis (pinacoderm) is composed of pinacocyte cells interspersed with porocyte cells, which form a porous aquiferous system throughout the sponge body. Choanocyte cells line choanosome *chambers*, where these flagellated cells, through a whipping action, create a water current which flows from outside the sponge body, through ostia – pores in the pinacoderm, through the sponge aquiferous system and is expelled through the osculum (Fig. 8.3). The sponge body is composed of a mesohyl – collagenous material through which archaeocytes travel. These archaeocyte cells play a role in the phagocytosis of food and can also differentiate into oocytes for sexual reproduction or gemmules for asexual reproduction. Pinacocyte cells are also capable of digesting food particles while sclerocyte cells produce and excrete spicules.

8.1.4 Sponge Physiology

Sponges do not possess distinct systems or organs; with the aquiferous system serving a role that is analogous to the circulatory, digestive and excretory systems found in higher metazoans. Most adult sponges are sessile filter-feeding animals that filter bacteria, micro-eukaryotes and particulate matter from ambient seawater, which they then pump through the canal systems in their bodies. Oxygen is delivered to cells by diffusion, food is engulfed and digested by phagocytosis in the mesohyl, and metabolic waste is removed in the constant water current generated throughout the body of the sponge. Sponges can pump remarkable volumes of seawater through their bodies with reports of 24 000 $L\,kg^{-1}\,d^{-1}$ in some sponge

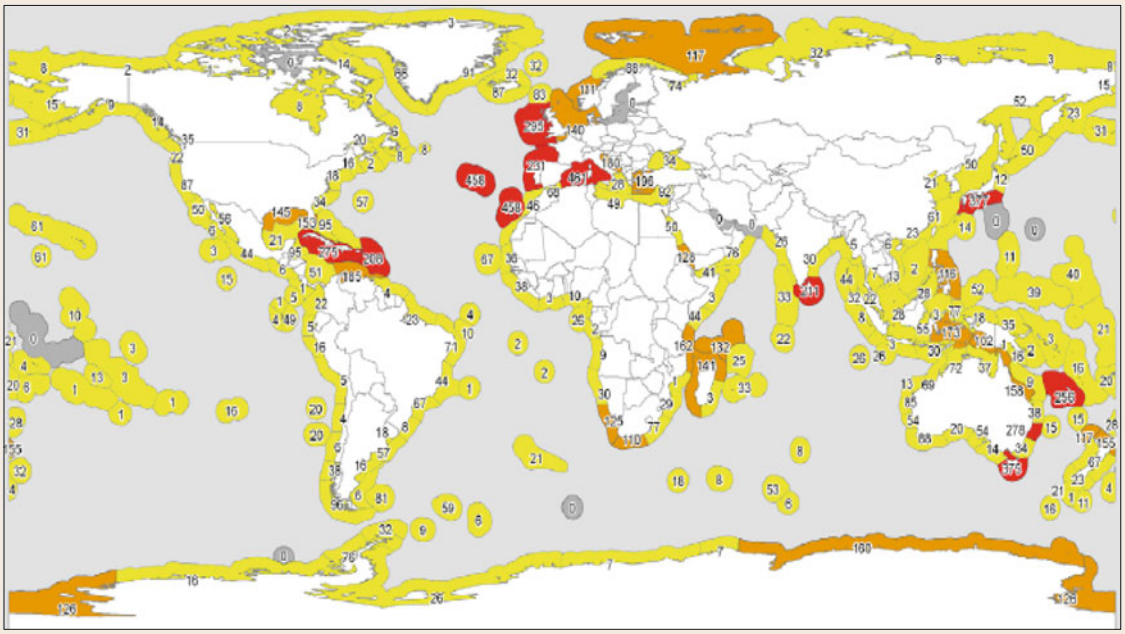

Fig. 8.2 Global distribution of marine sponges [8.4]

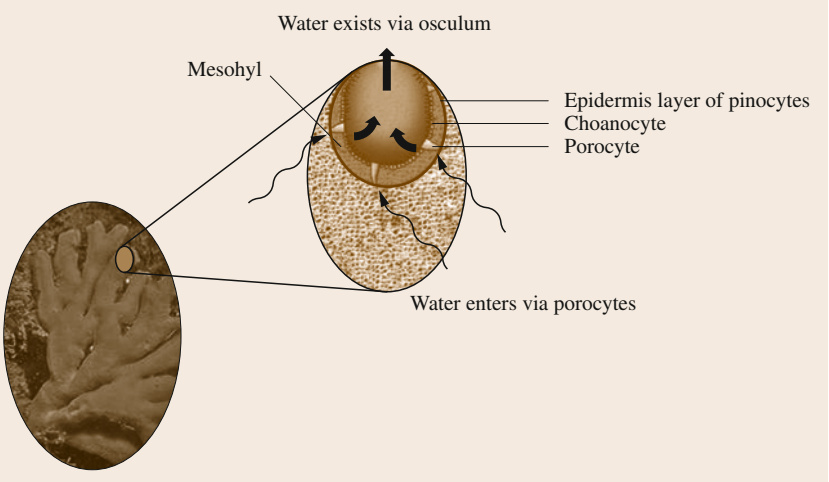

Fig. 8.3 Anatomy of a marine sponge

species [8.7]. Some sponges (≈ 120 species) do not possess aquiferous canal systems and thus are not filter feeders. Instead, they are carnivorous, capturing prey on *hooks* on the outer surface of the body where specialized cells migrate to the captured prey and phagocytose and digest the food prey. Carnivorous sponges have to date only been found in the deep sea [8.4].

Sponges do not possess adaptive immunity although innate immunity featuring an interferon-like 2′,5′-adenylate-synthetase system, a variable immunoglobulin-like system, and lipopolysaccharide LPS activated

kinase cascades are all present [8.8], and compounds with antimicrobial and anti-inflammatory properties have been extracted from sponge tissues. The primary producer of sponge-derived secondary metabolites is, however, still quite unclear although many of the sponge-derived compounds identified to date strongly resemble compounds that are known to be produced by microbes [8.9].

8.2 Sponge-Associated Microorganisms

Marine sponges play host to microbes from all domains of life; *Eukarya* [8.10, 11], *Archaea* [8.12, 13], and *Bacteria* [8.7]. Viruses and bacteriophages have also been detected in sponge tissues [8.14, 15]. These close and consistent associations are thought to be based on various symbiotic relationships including commensalist and mutualist [8.16], as well as parasitic. Microbes are also a significant food source for marine sponges [8.17] which, as sessile animals, must derive their nutrition by active filter-feeding from ambient seawater. This water filtering activity results in a remarkable enrichment of microbes in sponge tissues where 10^8–10^{10} bacteria/g wet weight have been recorded [8.18], with microorganisms constituting up to 35% of the total sponge biomass and densities exceeding 10^9 microbial cells/cm of sponge tissue; which is three to four orders of magnitude greater than the density of bacteria in the surrounding seawater (10^6 mL^{-1}).

8.2.1 Sponge-Associated Bacteria

Bacterial associates of sponges have been investigated through the use of both culture-dependent and culture-independent methods. Culture isolation from sponges is, like all other environmental sources, hampered by *the great plate anomaly* where less than 1% of taxa observed through other methods have proven amenable to culture under laboratory conditions through traditional or, indeed, more novel innovative approaches [8.9].

Researchers have used a wide range of culture conditions (including various growth media and different incubation temperatures) in attempts to access as wide a variety of bacterial diversity as possible [8.19–25]. Others have targeted the isolation of particular taxa of interest [8.26–40]. In addition, a number of innovative culture isolation methods have been employed, including the manipulation of bacterial communities through antibiotic administration prior to isolation [8.41], or other quite imaginative approaches such as liquid culturing and floating-filter culturing methodologies [8.42].

Despite these efforts the same bacterial phyla repeatedly appear following culture isolations, with members of only seven bacterial phyla (*Proteobacteria*, *Firmicutes*, *Actinobacteria*, *Planctomycetes*, *Verrucomicrobia*, *Cyanobacteria*, and *Bacteroidetes*) [8.7] to date being isolated in culture from sponge tissues; despite the observation that > 30 phyla or candidate phyla can be found in close association with sponges through molecular methods [8.9]. Notwithstanding this, diverse novel bacterial taxa are regularly isolated from sponge species worldwide (Table 8.1).

Culture-Independent Analyses

Microscopy. The presence of bacteria in the mesohyl of sponges was first confirmed in the early 1960s [8.69] by use of electron microscopy (EM). Subsequently, EM studies reported various cell types, including *Cyanobacteria*, in sponge tissues [8.70], and later still dense bacterial cell populations in sponge mesohyl tissues [8.71] were estimated to comprise 30% of the sponge biomass. Scanning electron microscopy (SEM) was subsequently employed to report the presence of unicellular cyanobacteria and non-photosynthetic filamentous cyanobacteria in the tissues of *Theonella swinhoei* [8.72]. The development of fluorescence in situ hybridization (FISH) allowed subsequent investigators to identify particular bacterial taxa and their spatial distribution within sponge tissues by designing probes to target particular 16S ribosomal ribonucleic acid (rRNA) genes. This allowed for the identification of *Cyanobacteria* [8.73, 74], *Actinobacteria*, *Bacteroidetes*, *Planctomycetes* as well as γ- and β-*Proteobacteria* [8.38] in sponges, and also demonstrated the vertical transmission of eubacteria and archaea in sponge larvae [8.75].

16S rRNA Clone Libraries. Polymerase chain reaction (PCR)-based approaches involving the amplification of 16S ribosomal deoxyribonucleic acid (rDNA) molecules and their subsequent cloning and analysis have been successfully employed to allow the species' composition of unculturable sponge-associated bacte-

rial communities to be conducted, as well as studies on other aspects of sponge microbial ecology to be undertaken. In this way, the bacterial community structures in many sponges have to date been elucidated [8.13, 31, 37, 40, 76–81]. In addition both inter and intra-sponge species microbial community comparisons have been performed [8.18, 82, 83]. The structures of communities within taxa of particular interest have been examined including: *Actinobacteria* [8.34], *Chloroflexi* [8.84], and *Cyanobacteria* [8.73, 85–87]. Differences in community profiles between inner and outer sponge tissues have also been explored [8.88–90]. Cloning of 16S rRNA genes led to the discovery of a novel candidate bacterial phylum, *Poribacteria* [8.91], which is common to many sponge species [8.92] but almost exclusively known from sponges.

These investigations have spanned a large range of sponge species from all of the worlds' oceans (Table 8.2). The sequencing of 16S rRNA clone libraries initially led to the identification of 16 bacterial phyla or candidate phyla (*Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, *Chloroflexi*, *Cyanobacteria*, *Deinococcus-Thermus*, *Firmicutes*, *Gemmatimonadetes*, *Lentisphaerae*, *Nitrospira*, *Planctomycetes*, *Poribacteria,* *Proteobacteria* [8.α-, β-, δ- and γ-], *Spirochaetes*, TM6, and *Verrucomicrobia*), which have been found in close association with sponges [8.7]. Subsequently, sequencing of sponge-derived denaturing gradient gel electrophoresis (DGGE) bands [8.78] added the phyla *Aquificae*, *Dictyoglomi*, and *Deferribacteres*, and the candidate phylum TM7 to the list of taxa found in association with sponges.

Pyrosequencing. Next generation sequencing allows for the generation of hundreds of thousands of sequencing reads from metagenomic deoxyribonucleic acid (DNA) samples. Barcoding of samples allows for the pooling and parallel processing of samples, and very robust and comprehensive descriptions of bacterial community structures from diverse sources can thus be generated. The large datasets generated by pyrosequencing analyses have allowed for the identification of members of the *rare-biosphere* [8.107]. Also, more accurate descriptions of community structures and rank-abundance profiles of bacterial communities from a huge diversity of biomes have been made.

Various aspects of the aquatic bacterial consortia from lakes [8.108, 109], seawater [8.110], and hydrothermal vents [8.111], for example, have been reported; together with the bacterial communities associated with marine animals (fish [8.112], squid [8.113], corals [8.114, 115], and a marine polychaete [8.116]). The same is true for marine sponges. A recent re-

Table 8.3 Sponge species from which pyrosequencing of bacterial 16S rRNA genes has been reported

view of publicly available sponge-associated 16S rRNA sequences [8.117] analyzed a dataset of ≈ 7500 sequences. However, pyrosequencing analyses have generated > 700 000 sponge-derived bacterial 16S rRNA gene sequences which were not included in that study. These datasets have investigated various aspects of sponge-bacterial associations, including bacterial community structures [8.118–121], seasonal variations in community composition [8.122], bacterial-archaeal relative abundances [8.118], vertical symbiont transmission [8.119], and core variable and species-specific bacterial communities from a range of sponge species [8.84]. These pyrosequencing studies have thus far investigated 15 sponge species (Table 8.3) leading to the identification 35 bacterial phyla or candidate phyla which have been found in close association with sponges. Taxa identified in sponges for the first time by pyrosequencing include BRC1, *Chlamydiae*, *Fibrobacteres*, *Fusobacteria*, *Tenericutes* and WS3 [8.119], *Chlorobi*, *Chrysiogenetes*, OD1, *ε-Proteobacteria* and *Thermodesulfobacteria* [8.118], OP10, OS-K [8.84] and *Thermotogae*, *Elusimicrobia*, and *Synergistetes* [8.121]. Many of these extra taxa are amongst the rarest members of the sponge-associated communities. Highly diverse communities described at genus, family, order, and class levels have been described with ≈ 3000 OTUs (95% sequence identity) reported from the marine sponge *Rhopaloides odorabile* [8.119].

8.2.2 Sponge-Associated Archaea

Archaea were first reported in association with marine sponges in 1996 when *Cenarchaeum symbiosum* was found in the tissues of *Axinella mexicana* [8.123], and it has subsequently been reported to be consistently found in sponges of the family *Axinellidae* [8.12]. Many reports of sponge-associated archaea followed [8.13, 38, 124–131] and included studies which demonstrated the vertical transmission of archaea in sponge larvae, suggesting a very close co-evolutionary relationship [8.75, 132]. In a recent study using the aforementioned pyrosequencing-based approaches the relative abundance of bacteria and archaea in sponges from the Red Sea was assessed with values of between 4–28% in different sponges being reported, but significantly all were comprised almost exclusively of *Crenarchaeota* [8.118].

8.2.3 Sponge-Associated Eukaryota

Sponge-Associated Fungi

Although an as yet quite underexplored group of microorganisms, marine fungi are known in some cases to form symbiotic relationships with sponges, although the function of these associations remains largely unknown. While the majority of fungi recovered from marine sponges to date appear to be halotolerant, few, if any, appear to have a growth requirement for dissolved sea salts. Many of these halotolerant fungi are believed to have originated from the terrestrial environment and may have been washed from the terrestrial environment into the sea and subsequently adapted to the marine environment. Indeed, many of the fungi reported to have been isolated from sponges are closely related to terrestrial species with *Penicillium* sp. and *Aspergillus* sp. in particular being commonly found in marine sponges.

Despite the discovery that marine fungi are often derived from terrestrial environments, a coherent case for fungal involvement in a symbiotic relationship with marine sponges has also been advanced. A yeast has been shown to be maternally transmitted in a *Chondrilla* sponge, while putative fungal genes have been detected in sponge mitochondria, and yeasts have been proposed as a potential source of vitamins for marine sponges. In addition, transmission electron microscopy (TEM) has been employed to observe the close association of a filamentous fungus with sponge oocytes, while six fungal species have been reported to be cultured from in vitro cultures of sponge primmorphs and

single cells, further suggesting that fungi may, in fact, be true sponge symbionts and might, therefore, play an important role in host physiology.

Sponge-associated fungi have been shown to display a range of quite diverse biological activities through the production of a wide range of chemically diverse compounds with novel antibacterial, anti-inflammatory, antiviral, and anticancer activity. Some examples include *Fusarium oxysporum* DLFP2008005 isolated from *Hymeniacidon perlevis*, which has been reported to exhibit antibacterial and antifungal activities against *Staphylococcus epidermidis*, *Bacillus subtilis*, *Pseudomonas fluorescens*, *Pseudomonas aeruginosa*, and the yeast *Candida albicans*. *Penicillium* cf., *montanense* isolates obtained from *Xestospongia exigua* from the Bali Sea in Indonesia have been reported to produce xestodecalactone B, a novel decalactone metabolite which displays antifungal activity against *Candida albicans*. *Aspergillus versicolor*, isolated from *Petrosia* sp. in Korea is known to produce the cytotoxic lipopeptide fellutamide C, while *Emericella variecolor* isolated from a Venezuelan sponge, has been shown to produce varitriol, which displays activity against breast cancer cell lines and varixanthone, which has antimicrobial activity. In addition, the fungus *Microascus longirostris* SF-73 isolated from a New Zealand sponge has been shown to produce the protease inhibitors cathestatin A, B, and C, which may potentially be used in inactivating target proteases in the pathogenic processes of various human diseases such as emphysema, arthritis, pancreatitis, thrombosis, and many others. Finally, extracts from the fungus *Engyodontium album* isolated from the Mediterranean sponge *Suberites domuncula* have been shown to display cytotoxicity against murine lymphoma cells.

As a result there has been an increased recent interest in molecular-based approaches to assess the fungal biodiversity of sponges with a view to assessing their overall chemical potential. These studies have primarily involved the use of 18S rRNA to phylogenetically analyze the fungal ecology of these sponges, resulting in fungi from 32 orders, from three phyla (*Ascomycota* [8.22] orders, *Basidiomycota* [8.8] orders, *Zygomycota* [8.2] orders), representing > 120 genera having to date been found in or on sponges. In addition, at least 18 orders of fungi have been isolated in culture. Examples of phylogenetic studies include the analysis of 80 fungi isolated from *Haliclona simulans* which were assessed by using both culture-dependent and metagenomic approaches. With the use of different fungal media containing either agar or gellan gum, a total of 19 different genotypes were detected, which were subsequently classified as members of *Agaricomycotina*, *Mucoromycotina*, *Saccharomycotina*, and *Pezizomycotina*; with the majority of the isolates being associated with the latter class. Some of these fungal isolates showed antimicrobial activity against *Escherichia coli*, *Bacillus* sp., *Staphylococcus aureus*, and *Candida glabrata*. Fungal 18S rRNA gene sequences belonging to *Eurotiales*, *Calosphaeriales*, and *Chaetothyriales* were amplified from deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) extracted from this marine sponge. Further studies have reported on the isolation of fungi from three Hawaiian sponges, from the Mediterranean sponges *Psammocinia* sp. and *Tethya aurantium* and from China Sea sponges. The secondary metabolic potential of these fungal isolates is reflected in the fact that 15 polyketide synthase (PKS) genes and 4 NRPS (non-ribosomal peptide synthase) genes were identified in the fungi isolated from the Chinese sponges.

It is fair to say that, in general, fungal associations with marine sponges are less well understood than their microbial counterparts. This may be due in part to the fact that metagenomic 18S rRNA-based studies typically encounter problems with respect to contamination with sponge rRNA coupled with difficulties in extracting fungal DNA. Even though sponge specific clusters have recently been detected in the genus *Penicillium* and 530 possibly obligate marine fungi have to date been described, many if not most sponge-derived fungal isolates or 18S rRNA clones which have been classified as genera typically found in terrestrial environments, and many compounds derived from those isolates, have also been shown to be present in their terrestrial counterparts. Nonetheless, the tremendous biochemical potential of fungi and the lack of understanding of sponge-fungi ecology should ensure that an ongoing and active research interest is maintained in this area.

Other Sponge-Associated Eukaryotes

Other eukaryotes have been reported to be present in close association with sponges. Polychaetes (annelid worms) and shrimp have been reported from Caribbean sponges [8.133]. *Ophiuroidea* (brittle stars), *Cnidaria* (sessile *Anthozoa*), *Turbellaria* (flatworms), *Nemertinia* (ribbon worms), *Sipuncula* (sipunculid worms), *Polychaeta*, *Mollusca*, *Crustacea*, *Pycnogondia* (sea spiders), *Echinodermata* (sea cucumbers), *Ascidiacea* (sea squirts), and *Pisces* (fish) have all been observed in association with the Brazilian sponge *Zygomycale*

parishii over a 5 year study period [8.134]. *Ophiuroidea* were also found to be consistently associated with sponges, but the authors suggest that this relationship is species-specific between *Callyspongia vaginalis* and *Ophiothrix lineata* [8.135]. Although many of these phyla are known parasites, their precise roles within their sponge hosts are as yet not known. A mutualist relationship between a sponge (*Halichondria panicea*) and a scallop (*Chlamys varia*) has, however, been reported, where the sponge obtains increased suspended nutrients while the scallop gains protection from predation [8.136].

8.2.4 Sponge-Specific Microorganisms

In a meta-analysis performed in 2002 of all the then publicly available ($n = 190$) sponge-derived 16S rRNA gene sequences, including 5 sponge species from different geographical regions such as the Mediterranean Sea (France, Israel and Croatia), the Red Sea, the North Pacific (Japan and USA), Australian waters (Davies Reef), and from the Philippine Sea (Palau), researchers revealed monophyletic clusters of sponge-derived sequences more closely related to each other than to sequences of the same taxa derived from non-sponge sources; leading to the hypothesis of sponge-specific microbes [8.82]. That study established that 14 monophyletic sequence clusters from 7 bacterial phyla, representing 70% of all sponge-derived sequences, were termed as *sponge-specific*. This term was defined to apply to groups of at least three sequences, which were (i) recovered from different sponge species and/or from individuals of the same species from different geographic locations, (ii) more closely related to each other than to sequences from non-sponge sources, and (iii) clustered together independently of the tree-building algorithm used.

Further interrogation of this hypothesis followed with the subsequent analysis in 2007 of $\approx$ 1700 sponge derived publicly available 16S rRNA sequences, with reports that 32% of all sponge-derived sequences from at least 10 bacterial phyla and also from a major archaeal lineage (*Crenarchaeota*) recruited to sponge-specific clusters [8.7]. These sponge-specific clusters included 100% ($n = 21$) of all sequences, then available, from the putatively sponge-specific candidate phylum *Poribacteria*. High proportions of sponge-derived sequences from *Chloroflexi* (62%), *Cyanobacteria* (79%), *Nitrospira* (57%), and *Spirochaetes* (67%) were classified as being sponge-specific. Notable proportions of sequences from *Actinobacteria* (38%), *Gemmatimonadetes* (25%) and *β-/γ-Proteobacteria* (34%) were assigned to sponge-specific clusters. Conversely, only 5% of *Acidobacteria* sequences, 9% of *Firmicutes* sequences, and 0% of *Bacteroidetes* sequences were determined to be sponge-specific.

In a subsequent study in 2011, by which time the number of publicly available (non-pyrosequencing-derived) sponge-derived 16S rRNA sequences had risen to $\approx$ 7500, *Simister* and colleagues found that 27% of sponge-derived sequences could be assigned to sponge-specific clusters from 14 bacterial phyla and one major archaeal lineage (*Thaumarchaeota*) [8.117]. Similar to previous findings, large proportions of sponge-derived *Chloroflexi* (61%), *Cyanobacteria* (53%), *Nitrospirae* (39%), and *Spirochaetes* (92%) were classified as being sponge-specific. While this study analyzed a dataset of $\approx$ 7500 sponge-derived sequences, it like the previous study, only considered relatively long sequencing reads. However, with the emergence of pyrosequencing $\approx$ 700 000 sponge-derived 16S rRNA sequences are currently available in public databases, with reads varying in length from 50–60 bp [8.119] up to an average 430 bp [8.120]. Recent reports which have analyzed $>$ 110 000 sponge-derived sequences derived by pyrosequencing, assigned between 36–65% of sequences from sponge individuals to previously described sponge-specific clusters [8.118].

8.3 Symbiotic Functions of Sponge-Associated Microorganisms

While the diversity and abundance of microbes found associated with sponges is well established, little experimental evidence exists to elucidate the symbiotic roles of those microbes in the sponge hosts. Instead, indirect evidence is used to support the hypotheses of commensal, mutualistic, or parasitic activities in the sponge holobiont.

8.3.1 Molecular Methods to Elucidate Sponge Symbiont Functions

The detection of microbial biomarker gene sequences from sponge metagenomes has led to speculation about possible symbiotic functional roles for those taxa. While known physiological functions of microbes may

be used to predict possible functions, empirical conclusions cannot be conclusively drawn from phylogenetic biomarker data analyses. In addition, such predictions can only be made for microbes which have been cultured and from which physiological characterizations have been elucidated. Other methods which can be employed to determine sponge symbiont functions include genome reconstruction [8.137], single-cell genomics [8.138, 139], metatranscriptomics [8.94, 140], shotgun cloning and sequencing of sponge metagenomic DNA [8.141], shotgun pyrosequencing [8.121], and the targeted PCR amplification of functional genes from sponge metagenomes [8.20, 105, 142–148].

A good example of the successful application of single-cell genomics to predict sponge symbiont functionality from uncultured microbes is the recent work on the genome of *Cenarchaeum symbiosum* derived from the marine sponge *Axinella mexicana* [8.138] and on Poribacteria from the sponge *Aplysina aerophoba* [8.139]. While a shotgun sequencing-based approach has also been used in the reconstruction of an unidentified δ-proteobacterium from shotgun sequence data from the sponge *Cymbastela concentrica* [8.137], pyrosequencing of cDNA has also recently been used to elucidate the diversity and abundance of actively transcribed genes from the sponge *Geodia barretti* ([8.140]; while shotgun approaches (cloning – [8.141]; pyrosequencing – [8.121] have identified functional genes in the sponges *Cymbastela concentrica* and *Arenosclera brasiliensis*, respectively.

Researchers have also targeted functional genes of particular interest for PCR amplification and sequencing, with genes involved in ammonia-oxidation, nitrification, and putative host defence in particular being targeted. Ammonia-oxidation (amoA) genes have been identified in the metagenomes of *Aplysina aerophoba* [8.145], *Ircinia strobilina*, *Mycale laxissima* [8.147], and *Phakiella fusca* [8.105]; and nitrification genes (nirS) have been amplified from the sponge *Astrosclera willeyana* [8.148]. Genes involved in the production of bioactive secondary metabolites which may contribute to sponge defence have also been targeted, with PKS genes being identified from the sponges *Pseudoceratina clavata* [8.143], *Discodermia dissoluta* [8.142], *Theonella swinhoei*, *Aplysina aerophoba* [8.1–6], and *Haliclona simulans* [8.77].

8.3.2 Discrimination Between Food Microbes and Symbiotic Microbes

A long-standing question in the sponge microbiology area centers on how sponges discriminate between food and symbionts when both occur in the sponge mesohyl. Some recent progress has been made in this regard, with genomic, metagenomic, and metatranscriptomic analyses being employed to identify factors which may play crucial roles in the symbiosis between sponges and microbes. These include factors associated with cell recognition, adhesion, and signalling. Gene transcripts for cell recognition factors such as polycystic kidney domain-like (PKD) factor have been identified in the *Geodia barretti* metatranscriptome [8.140], while Ig-like domain protein encoding gene sequences have been found in the genome of *Candidatus Poribacteria* [8.139]. Adhesion related genes (ankyrin repeat, tetratrico peptide repeat, fibronectin type III, and laminin-G domain proteins) were also noted in the genomes of sponge-derived *Poribacteria* [8.139] and δ-proteobacteria [8.137], and adhesion related gene transcripts (ankyrin repeat domain proteins, tetratrico repeat domain proteins, TonB-dependent receptors, and collagen binding surface proteins) were observed from the metatranscriptome of *Cymbastela concentrica* [8.141] and *Geodia barretti* with cell signalling related protein transcripts also being noted [8.140].

Transposable insertion elements have been identified in the metagenome of *Cymbastela concentrica* [8.141] with transposase gene transcripts being reported from the metatranscriptome of *Geodia barretti* [8.140]. These elements are thought to play roles in microbial genomic rearrangements and streamlining to help with adaptation to a symbiotic lifestyle [8.141]. Factors with possible roles in the maintenance of a symbiotic relationship including tetracycline resistance genes and gene encoding for multidrug resistance proteins were found in the genome of a sponge-associated unidentified δ-proteobacterium [8.137], while clustered regularly interspaced short palindromic repeat (CRISPR) gene sequences with possible roles in resistance to viral infection have been found in the metagenome *C. concentrica* [8.141]. Genes and gene transcripts involved in the biosynthesis of essential vitamins (B_2 or B_{12}) have been noted in the genomes of *Cenarchaeum symbiosum* [8.138], *candidatus Poribacteria* [8.139], and a sponge-associated δ-proteobacterium [8.137],

in the metagenome of *C. concentrica* [8.141] and in the metatranscriptome of *G. barretti* [8.140], suggesting that symbiotic microbes may be an important source of these essential vitamins for their hosts. Sponge-associated microbes have also been noted to be a remarkably rich source of various classes of chemicals with a wide range of bioactive properties and are thought to potentially play important roles in sponge host defence ranging from infection to predation [8.7].

8.4 Biotechnological Potential of Marine Sponges – Pharmacological Potential

Much of the recent research interest in the area of marine sponges and marine sponge-associated microbes has been primarily driven due to the pharmacological potential of many of the diverse chemical entities, with wide ranging biological activities which have been and continue to be discovered from this quite unique marine ecosystem [8.149]. The physicochemical properties of the marine environment (pH, pressure, temperature, osmolarity) in which many marine sponges reside means that any bioactive substances produced in that environment may have sufficiently different properties to terrestrially produced products to make them of interest for novel drug discovery [8.150]. While the search for novel drugs has involved many phyla of marine invertebrates, the phylum *Porifera* has proved to be the most promising (Fig. 8.4) [8.151]. As previously mentioned, sponges are sessile filter feeders, with no adaptive immunity, and thus rely on the production of chemical entities to defend themselves against infection, parasitism, and disease, and also to gain a competitive advantage [8.150].

Quite a diverse range of chemical classes with bioactive properties have to date been obtained from sponges and sponge-derived microbes, and include alcohols [8.152], alkaloids (Table 8.5), amino acid derivatives [8.153–155], aromatic compounds [8.156], fatty acids [8.157–159], lactones [8.160–162], peptides (Table 8.6), polyacetylenes [8.163, 164], polyketides (Table 8.7), quinones, and quinolones [8.165–168], sphingolipids [8.169, 170], and sterols [8.171–173], together with terpenes and terpenoids (Table 8.8). These bioactivities have been identified from bacterial or fungal isolates from sponges or from aqueous or organic extracts from the sponge tissues. In many cases, the bioactive compounds have been identified, purified, and characterized.

Numerous compounds and small molecules with activities against important human infections and diseases have been reported. Important bioactive compounds which have been reported include antibacterial compounds (including anti-methicillin-resistant *Staphylococcus aureus* (anti-MRSA) and antituberculosis) (Table 8.4), antifungal compounds (Table 8.5), antiparasitic compounds (including antimalarial) (Tables 8.5–8.8), antiviral compounds (including anti-HIV) (Tables 8.5, 8.6 and 8.8), anticoagulant compounds [8.174, 175], antihelminthic compounds [8.176], antibiofouling compounds [8.177–179], anti-inflammatory compounds (Tables 8.7 and 8.8), neuromodulatory compounds [8.162, 180, 181], a UV-A protectant compound [8.173], and a large array of cytotoxic compounds with potential uses as anticancer drugs (Tables 8.5–8.8).

8.5 Exploiting the Pharmacological Potential of Marine Sponges

Although many novel bioactive compounds have been, and continue to be, isolated from sponges and/or their symbiotic microbes, these compounds are typically produced in minute quantities and the potential utility of these compounds to the pharmaceutical industry is, therefore, often somewhat limited [8.231]. For example, when halichondrins were isolated from the marine sponge *Halichondria okadai* [8.232], they were identified as very potent antitumor compounds with enormous clinical potential. However, it was estimated that 1 t of sponge biomass would need to be harvested to obtain 300 mg of a mixture of the halichondrin analogs [8.233]. With 1–5 kg of the drug being potentially required annually for the treatment of cancer patients, natural harvest was obviously unrealistic. To help overcome supply problems such as this, much recent effort has focused on marine products of potential bacterial origin. Indeed, evidence continues to emerge

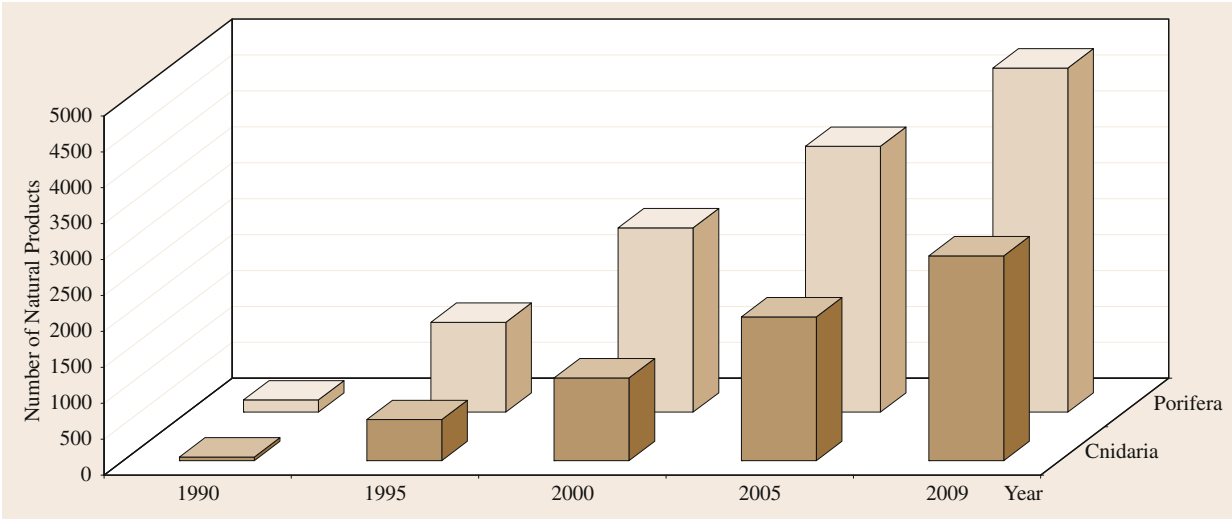

Fig. 8.4 Marine natural product discovery from marine phyla from 1990–2009

to suggest that many of the bioactive compounds isolated from sponges may, in fact, be secondary metabolite products of symbiotic bacteria [8.9, 234]. Given that bacteria have long been used for industrial products and that systems and tools for the manipulation of bacteria for industrial purposes are well established, then where marine natural products are of bacterial origin, industrial, and biotechnological manipulations are likely to be readily available for the production of sufficient quantities for clinical trials.

The extensive search for pharmaceutical products from marine sponges has led to some success stories. The nucleosides Ara-A (Acyclovir) and Ara-C (Cytarabine) from the sponge *Cryptotethya crypta* are commercially available as antiviral and antitumor drugs, respectively [8.235]. The chemical synthesis of Halichondrin B (Eribulin) has been achieved and was recently approved for breast cancer treatment [8.236, 237]. The synthetic tripeptide Hemiasterlin first identified in the marine sponge *Cymbastela* sp. has entered phase I clinical trials for cancer treatment [8.234], while a derivative of the hydroxamic acid, psammaplin [8.Panobinostat (LBH-589)], from the sponge *Psammaplysina* sp. is also currently in phase II clinical trials.

8.6 Metagenomic Strategies for Natural Product Discovery

It is now well established that in most environments, including marine environments, only $< 1\%$ of microbes present within these ecosystems can currently be isolated using traditional culturing techniques, thereby leaving the vast majority of these potentially biotechnologically important microorganisms and their biochemical pathways inaccessible and, therefore, unexploitable. The emergence of culture-independent and metagenomic techniques has, however, provided us with additional tools to allow us to determine the full extent of the uncultured microbial diversity within these ecosystems, thereby allowing access to the biochemical pathways within these as yet uncultured microorganisms. The term *metagenome* was first coined by Handelsman and colleagues [8.238] in the context of a description of the collective genomes of soil microbes. Metagenomic analyses involve describing either the sequence-based or function-based characteristics of a particular metagenome. Where the sequence of particular gene of interest is known, PCR primers or hybridization probes can be designed to interrogate a metagenome for the presence of the desired genes [8.239]. When focusing on genes and/or gene products for which sequence data is not known, a functional metagenomics approach can be employed [8.240]. This involves the extraction of total DNA from the metagenome of choice, fractionating the DNA to provide DNA fragments large enough to

include complete gene clusters and/or operons, and cloning the large fragments via bacterial artificial chromosomes (BACs) or fosmids into a heterologous host such as *E. coli* (Fig. 8.5). The generation of large metagenomic libraries in this way allows for the high-throughput functional screening of the libraries for desired functions, by culturing the clones on media incorporating appropriate substrates to reveal phenotypic functions [8.238]. Large-insert BAC and fosmid clone libraries have to date been constructed from a wide variety of different marine environmental niches, including: marine plankton [8.241], seawater [8.242–

atina clavata [8.143], together with novel NRPS genes from the sponges *Haliclona okadai* [8.252] and *A. aerophoba* [8.253]. With respect to novel biocatalysts, quite a diverse range of enzymes has been discovered from a wide variety of marine metagenomic libraries, including esterases, lipases, and chitinases, amongst others.

8.6.1 Functional Screening of Large-Insert Metagenomic Clone Libraries

Such strategies involve screening the library for functional activities which result from the expression of genes within the bacterial metagenomic DNA. In many instances, this involves phenotypic-based detection methods which employ chemical dyes and substrates of the enzyme, which are often linked to chromophores. When the products of the individual metagenomic clones act upon these dyes or chromophores the product can be detected either visually or spectrophotometrically. The clone(s) displaying the relevant activities can then be genetically characterized, and following identification of the gene encoding the putative activity, cloned in *E. coli*, allowing subsequent purification and biochemical characterization studies on the enzyme to be undertaken. A number of routinely used functional assays will be described later in this chapter. The major advantage of functional screening-based approaches is given that sequence-based information is not required, no bias is introduced into the screening process, thereby increasing the likelihood of identifying entirely new classes of genes encoding either known or more likely novel functions.

One of the most commonly used functional screens currently employed to screen terrestrial metagenomic libraries and which is now finding increased utility in marine metagenomic studies has been for the identification of lipase/esterase activity. These are an important group of biocatalysts which are frequently used in organic synthesis strategies primarily due to their enantio/stereoselectivity and high level of activity in the presence of organic solvents. Metagenomic clones exhibiting lipolytic activity can be readily identified by the formation of clear halos surrounding the positive clones following growth on agar plates containing tributyrin as the indicator substrate (Fig. 8.6). Tributyrin-positive clones can then subsequently be tested on trioleinrhodamine B agar, which is used to detect lipolytic activity against long-chain fatty acids (C18).

With the use of this screen quite a large number of lipases have been reported from marine environments. Examples include novel lipolytic enzymes from *Aplysina aerophoba* and *Hyrtios erecta* marine sponge metagenomic libraries, as well as 15 different lipolytic genes from a metagenomic library constructed from South China Sea marine sediment. Esterases that appear to be particularly adapted to high hydrostatic pressure and salinity have also been isolated using this screen from metagenomic libraries constructed from the brine interface of a deep-sea hypersaline anoxic basin. More recently, this screen was successfully used by the authors' group to identify a novel halo tolerant li-

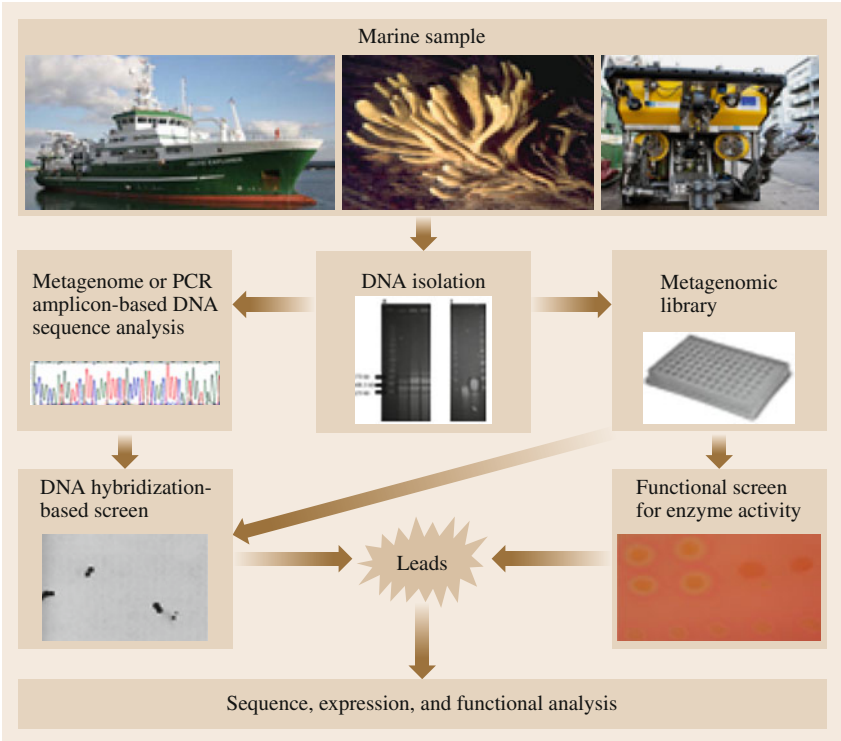

Fig. 8.5 Metagenomic strategies

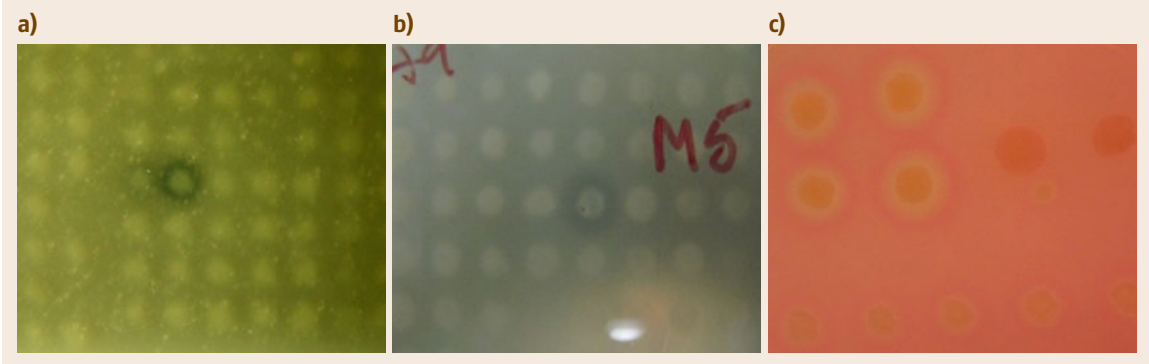

Fig. 8.6a–c Identification of a metagenomic clone exhibiting **(a)** lipase activity on 1% tributyrin agar, **(b)** protease activity on 1% skimmed milk agar and **(c)** cellulase activity on 0.1% Ostazin Brilliant Red hydroxyethyl cellulose

pase from a *Haliclona simulans* metagenomic library. Heterologous expression of the recombinant lipase in *E. coli* and subsequent biochemical characterization of the recombinant protein, showed an enzyme with the highest substrate specificity for long-chain fatty acyl esters, with optimal activity with p-nitrophenyl palmitate (C16) at 40 °C, in the presence of 5 M NaCl at pH 7. The lipase was also active over a broad temperature (4–60 °C) and pH (3–12) range and displayed high levels of stability at NaCl concentrations as high as 5 M and at temperatures ranging from 10–80 °C.

Another functional screen which is also now being increasingly used in marine metagenomics is the use of Luria Bertani agar supplemented with 1% skimmed milk, with a clear halo around the metagenomic clone being indicative of protease activity (Fig. 8.6). Using

this approach two proteases have been identified from the aforementioned *Haliclona simulans* library [8.255], while a zinc-dependent metalloprotease has also been isolated from a deep-sea sediment metagenomic library using this screen [8.256]. Interestingly, this enzyme also displayed an ability to hydrolyze both fibrin and azocasein, thereby raising the possibility of its utility as a potential therapeutic agent in the treatment of thrombosis. A novel subtilisin-like serine protease has also recently been cloned from an Antarctic coastal sediment metagenomic library [8.257]. This protease displayed good thermostability with an optimum temperature of 60 °C with approximately 73% of its activity being retained after incubation at 50 °C for 2 h.

The fluorogenic analog of chitin 4-methylumbelliferyl β-D-*N*,*N*′-diacetylchitobioside (MUF-diNAG) can also been successfully employed in function-based screens to identify chitinases in marine metagenomic libraries; it has been successfully employed to identify two cloned chitinase genes from coastal seawater metagenomic samples [8.242].

Metagenomic clones displaying cellulase activity can be detected by using colorimetric assays involving a cellulosic substrate. An example is the dye Congo red, which interacts with intact β-D-glucans and can thus be used to screen for β-D-glucan-hydrolase activity. Cellulolytic metagenomic clones can be identified on carboxymethylcellulose containing Luria Bertani (LB) and subsequently staining with Congo red. Metagenomic clones exhibiting activity can be visualized due to the formation of a yellow halo, which is due to the formation of the dye-glucan complex (Fig. 8.6). While a large number of cellulases have to date been isolated from metagenomic libraries constructed from different terrestrial and in particular mammalian gut microbiomes [8.258], to the authors' knowledge there are no reports to date of cellulases being isolated from marine metagenomic libraries. This is surprising, given the recent increased interest in this family of enzymes from a bioenergy perspective, particularly with respect to production strategies involving lignocellulose containing plant material/biomass, coupled with the fact that a number of cellulases have been isolated from marine bacteria, including a *Marinobacter* strain associated with the marine sponge *Dendrilla nigra*. Therefore, it appears highly likely that marine sponge metagenomic libraries do contain large numbers of novel cellulase genes; a fact reinforced by the recent cloning of a novel cellulase from a metagenomic library constructed from the gut microflora of abalone [8.259].

Laccases are a family of blue multicopper oxidases, which are mostly known from fungi but which have been found in all domains of life. Bound copper atoms catalyze the oxidation of aromatic compounds while reducing molecular oxygen to water. Fungal laccases are known to play a key role in lignin degradation, while bacterial laccases are involved in the production of spore coat pigment production for UV production and in copper homeostasis. Laccases possess significant biotechnological potential, including degradation and detoxification of industrial dyes, particularly azo dyes which are used extensively in the textile industry and are thus present in many wastewater discharges. Laccases are known to degrade azo dyes and thus constitute a promising, environmentally friendly method for the treatment of azo dye containing waste streams. These discharges are typically alkaline in nature and contain high concentrations of salts such as NaCl, which limits the use of fungal laccases. Thus, there is an increased interest in new laccases from marine sources, particularly of bacterial origin, given that bacterial laccases have been shown to possess excellent activity under alkaline conditions and to be very salt tolerant [8.260].

A number of functional screens are thus potentially available for the detection of laccase activity in marine metagenomic libraries. These include the polyphenol dye Remazol Brilliant Blue R (RBBR), guiacol and 2′,2′-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS). RBBR is typically incorporated into standard growth media such as LB at a final concentration of 0.04 w/v %, together with 250 µM copper chloride ($CuCl_2$). The copper chloride is added as laccases require copper ions to work and activity is indicated by a clear or brown halo around the colony displaying the activity. Guaicol $C_6H_4(OH)(OCH_3)$ is a colorless natural organic compound which when oxidized by laccases produces an amber color. The inclusion of guaicol at levels of around (0.01 w/v %) in standard bacterial growth media coupled with the addition of copper chloride (250 µM) ensures the ready detection of laccase activity. ABTS can also be employed to functionally screen for laccase activity. ABTS is an aromatic compound, which can be used to determine the antioxidant capacities of foodstuffs. When ABTS is incorporated to standard bacterial growth at a concentration of 1 mM, together with copper chloride (250 µM), laccase activity can be detected by the appearance of a green-blue color. Finally, syringaldazine [8.*N*,*N*′-bis (3,5-dimethoxy-4-hydroxybenzylidene) hydrazine] is also a good a good substrate that can be used to detect laccase activity. The incorporation of syringal-

dazine (50 μM) to standard bacterial growth allows the detection of laccase activity due to the appearance of a purple halo resulting from the oxidation of the substrate.

Syringaldazine has been successfully employed in the functional screening of a bovine rumen metagenomic library to clone a novel laccase gene [8.261], while guaicol has similarly been used in a functional screen to clone a novel laccase from a mangrove soil metagenomic library [8.262]; detailed protocols have been developed for the functional screening of metagenomic libraries from numerous environmental sources by the Golyshin group [8.263]. Thus, with the availability of these functional screens coupled with the fact that sequence-based screens have already resulted in the cloning of novel sponge-derived laccases, which will be discussed later in this chapter, it is likely that metagenomic libraries constructed from marine sponges will contain large numbers of novel laccases, many with potentially biotechnologically important biochemical characteristics.

Function-based screens continue to be developed as evidenced by the recent functional screen involving the use of chrome azurol S (CAS) as an indicator. This screen involves CAS changing color from orange to blue in the presence of iron and has recently been used in the cloning of gene clusters for two known siderophores, namely vibrioferrin and bisucaberin from marine metagenomic libraries [8.264].

8.6.2 Problems Associated with Functional Screening of Metagenomic Libraries

A number of problems continue to hamper the discovery of novel genes and gene products from metagenomic clone libraries. These include the choice of an appropriate heterologous host system and appropriate screens for the detection of activities. *E. coli* is the heterologous host of choice in most cases [8.265]. Uchiyama and colleagues reported that ≈ 40% of foreign genes can successfully be expressed in *E. coli* [8.224]. However, the expression of foreign genes can be impeded by host codon usage preferences, problems with gene promoter recognition, transcription initiation factors, improper protein folding, and the inability to export gene products from the host cell [8.265]. In addition, the expression of foreign gene products can sometimes be toxic to the heterologous host [8.266]. The abundance of genes of interest in the source environment and the cloned insert size and library size can also have an effect on the probability of cloning particular genes [8.266].

Efforts to increase the rate of gene and product discovery can be improved by the use of alternative heterologous host expression systems other than *E. coli*. In this respect, an increasing number of host systems are now becoming available, including *Agrobacterium tumefaciens*, *Bacillus subtilis, Burkholderia graminis, Caulobacter vibrioides, Pseudoalteromonas haloplanktis, Pseudomonas putida*, *Ralstonia metallidurans, Rhizobium leguminosarum*, *Streptomyces* spp., *Sulfolobus solfataricus*, *Thermus thermophilus*, and *Thiocapsa roseopersicina* [8.267, 268]. In addition, increases in the rate of novel gene discovery are likely to be improved through the use of multiple heterologous host expression systems, such as through the use of shuttle vectors that can be transformed from *E. coli* into different hosts, thereby increasing the likelihood of expression [8.265]. In this respect, the authors' group has developed a novel cloning vector pCCERI (Fig. 8.7), which incorporates elements from *Streptomyces* phage φC31 for chromosomal integration into alternative hosts and an inducible replicon for ease of handling. pCCERI incorporates the φC31 integrase gene and attachment site for site specific integration into hosts containing the cognate *att*B site. The vector also incorporates the *ori*V from the inducible copy number system developed by *Wild* et al. [8.269], allowing induction from single to multicopy in a modified *E. coli* host. In addition, the vector has apramycin and chloramphenicol resistance genes for selection in different hosts, and *ori*T for conjugal transfer. A helper plasmid pERI3-50-1 was also constructed to allow efficient high-throughput conjugation of entire metagenomic libraries to the alternative host strains *Pseudomonas putida* and *Streptomyces lividans*, thereby increasing the likelihood of obtaining the expression of metagenomic inserts.

While, as previously mentioned, functional screening of marine sponge metagenomic libraries has been successful in the isolation of numerous industrially relevant biocatalysts, primarily involving the use of screens that employ colony color or colony appearance changes. However, many enzymes are not amenable to identification using these types of approaches. In an attempt to overcome this problem approaches involving the use of *gene-expression* reporter-based assays have been developed. This involves the use of a transcriptional regulator that responds to the product of a reaction, which is catalyzed by the enzyme being targeted, resulting in the transcription factor-dependent

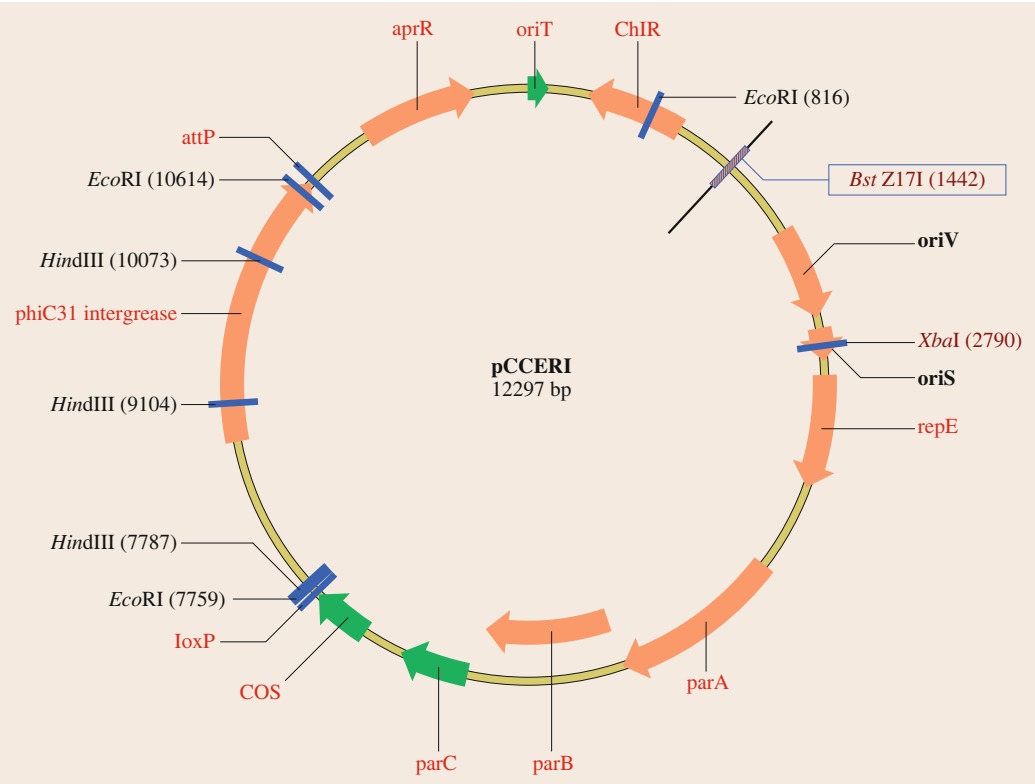

Fig. 8.7 Cloning vector pCCERI

activation of a promoter which is itself fused to a reporter gene, with a readily available phenotype such as β-galactosidase activity. The idea is to employ bacteria containing reporter systems such as this as *hosts* for a sponge metagenomic library. Hereby clones encoding enzymes, which catalyzes a reaction, which produces the desired reaction product, would activate the reporter gene. Other similar approaches that have been successfully employed for screening terrestrial-based metagenomic libraries which may also prove useful in the context of marine metagenomic libraries include the substrate-induced gene expression (SIGEX) assay, which was originally designed for the identification of quorum sensing attenuation in *Pseudomonas* and specific catabolic enzymes [8.264]. Another novel approach that may also prove useful is the use of complementation to identify novel enzymes, where the ability of the product of a metagenomic clone to complement a mutation in a reporter is used in the detection of the expression of the enzyme being targeted. This was previously used to clone novel DNA polymerases from a glacial ice metagenomic library. Another major problem with heterologous expression of genes, irrespective of the particular host system employed, centers on the decreased sensitivity due to the likelihood of intracellular accumulation of the enzymatic activity. This can be overcome by facilitating enzyme release from the cell by ensuring cell lysis using detergents such as Tween or Triton X, allowing release while still ensuring that the heterologously expressed protein retains its native configuration. This approach is particularly suited to high-throughput screens, where metagenomic libraries can be functionally screened in a microtiter plate format in the presence of substrate, allowing the use of liquid handling and colony-picking robots, together with microtiter readers.

8.6.3 Sequence-Based Screening of Metagenomic Libraries to Identify Novel Biocatalysts

Sequence-based approaches involves targeting the presence of specific gene encoding proteins of interest by

Fig. 8.8 Partial amino acid alignment of bacterial laccase genes including gene sequences derived from metagenomic studies (ADV52199 – drained peat soil metagenome, ADM87301: South China Sea marine microbial metagenome, SNB11 and SNB12: marine sponge metagenome). Histidine-rich copper binding domains are indicated by vertical boxes. ZP 01036720: multicopper oxidase domain protein *Roseovarius* sp. 217, ZP 00964414: multicopper oxidase domain protein *Sulfitobacter* sp. NAS14.1, ZP00961617: multicopper oxidase domain protein *Roseovarius nubinhibens*, YP 002289160: CumA *Oligotropha carboxidovorans* OM5, ADV52199: laccase uncultured bacterium, YP 004619745 cueO *Ramlibacter tatouinensis* TTB310, ZP 02186341: alpha proteobacterium BAL 199, ADM87301: laccase uncultured bacterium, SNB11 and SNB12: sponge metagenome-derived sequences

using either hybridization probes or PCR primers for these genes. This involves the design of DNA probes or PCR primers typically derived from conserved regions of already well-characterized genes or protein families. Using the homology-based approach, PCR amplification is performed, following which the putative gene is sequenced and then subsequently cloned into an appropriate expression vector where the heterologously expressed protein is then purified and biochemically characterized to ascertain its function. While such ap-

proaches are often successful, they at best lead to the identification of new variants of already well-known classes of proteins, with very few really novel genes being detected.

Notwithstanding this, such homology-based strategies have led to the identification of genes encoding novel enzymes from marine metagenomic libraries. Examples include the use of degenerate PCR primers designed based on the conserved regions of alkane hydroxylase gene sequences, to clone two alkane hydroxylase (*alkB*) genes from a Pacific deep-sea sediment metagenomic library [8.270]. Moreover, the recent cloning of four unique $FADH_2$-dependent halogenases from the metagenome of the Mediterranean sponge *Aplysina aerophoba* using PCR primers designed based on conserved sequences from previously cloned halogenases indicates that the microbial consortia of sponges are likely to be a valuable source for novel halogenases [8.271].

Other examples include the cloning of a novel peptidase encoding gene using PCR primers designed to amplify cellulase genes, from the metagenome of the western Arctic Ocean [8.272]. In addition, a new laccase gene was cloned from a marine microbial metagenomic library from the South China Sea, using PCR primers based on the relatively highly conserved sequence coding for copper binding sites in bacterial laccases (Cu1F ACMWCKGTTCAYTGGCACGG; Cu4R TGNTCNAGNAWGTGRCARTG) [8.260]. This novel laccase shared less than 40% sequence identity with previously characterized multicopper oxidases and when heterologously expressed in *E. coli* resulted in the production of a recombinant protein that exhibited alkalescence-dependent, chloride tolerant laccase activity. Similar primers were employed by the authors' group to clone two candidate laccase encoding genes (SNB11 and SNB12) from the metagenomic library of the sponge *Stelletta normani*, which was collected from a depth of 1348 m from the Atlantic Ocean in Irish waters. Basic Local Alingment Search Tool (BLAST) analyses and sequence alignments of the cloned sequences show that although the copper binding domains in these novel genes are conserved, the overall gene sequences are quite divergent from known gene sequences (Fig. 8.8). The quite marked difference between these newly cloned SNB11 and SNB12 genes from *S. normani* and already known genes suggests that marine sponges and those from deep sea ecosystems in particular may prove a valuable source for laccases with potentially new and improved functionality.

8.6.4 Sequence-Based Screening of Metagenomic Libraries to Identify Genes Involved in the Biosynthesis of Natural Products

As previously mentioned, sponges are a rich source of natural products, many of which are now widely believed to be metabolites, which are, in fact, synthesized by symbiotic bacteria. There are a number of examples of marine sponge-associated bacterial isolates which produce compounds that are similar and in many cases identical to sponge-derived compounds. These include jasplakinolide (jaspamide) from the sponge *Jaspis* sp. and cyclodepsipeptide chondramide D isolated from the myxobacterium *Chrondromyces crocatus* and salicylihalamide A produced by *Haliclona* sp., which is almost identical to the myxobacterial metabolite apicularen A. In addition, there are a number of sponge-associated bacteria that synthesize important natural products, including the *Salinispora* spp., which produces rifamycins and a *Micromonospora* sp., from *Acanthostrongylophora* sp., which produces the antimalarial compound manzamine A.

Many of the structurally diverse classes of natural products most commonly associated with microorganisms include polyketides, non-ribosomal peptides, or hybrid peptide-polyketides, which are synthesized by polyketide synthases (PKS), non-ribosomal peptide synthetases (NRPS), or hybrid PKS-NRPS synthases which are encoded in gene clusters in the producing bacteria. These multifunctional biosynthetic enzymes typically consist of a series of modules which are usually distributed among several polypeptides. These modules consist of a series of enzymatic domains each of which is involved in the catalysis of individual biosynthetic steps. Biosynthesis occurs in an *assembly line*-like process with the nascent polyketide or peptide chain passing from module to module, with each module adding extender units until synthesis of the compound is complete. Polyketide-derived natural products which are believed to be produced by symbiotic sponges microbes include halichondrin B, discodermolide, peloruside, and laulimalide; while polyketide/non-ribosomal peptides include hemiasterlins, the aforementioned jaspamide, and the salicylihalimides. Thus, perhaps it is not surprising that numerous sequence-based screens, many of which have been PCR-based, have been undertaken on sponge metagenomic libraries; specifically targeting PKS and NRPS gene clusters as a means of assessing overall diversity and the secondary metabolite/chemical

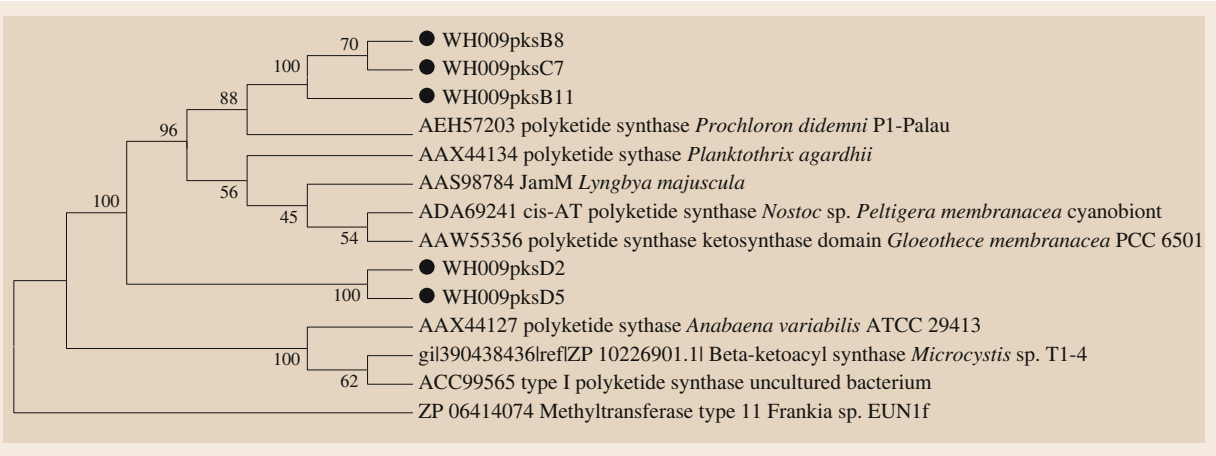

Fig. 8.9 UPGMA bootstrap-consensus tree showing the evolutionary relationship of inferred amino acid sequences from translated putative PKS gene fragments cloned from the metagenome of the marine sponge *R. ramosa*. Included are the closest BLAST relatives and a methyltransferase outgroup. • – denotes sponge-derived sequences

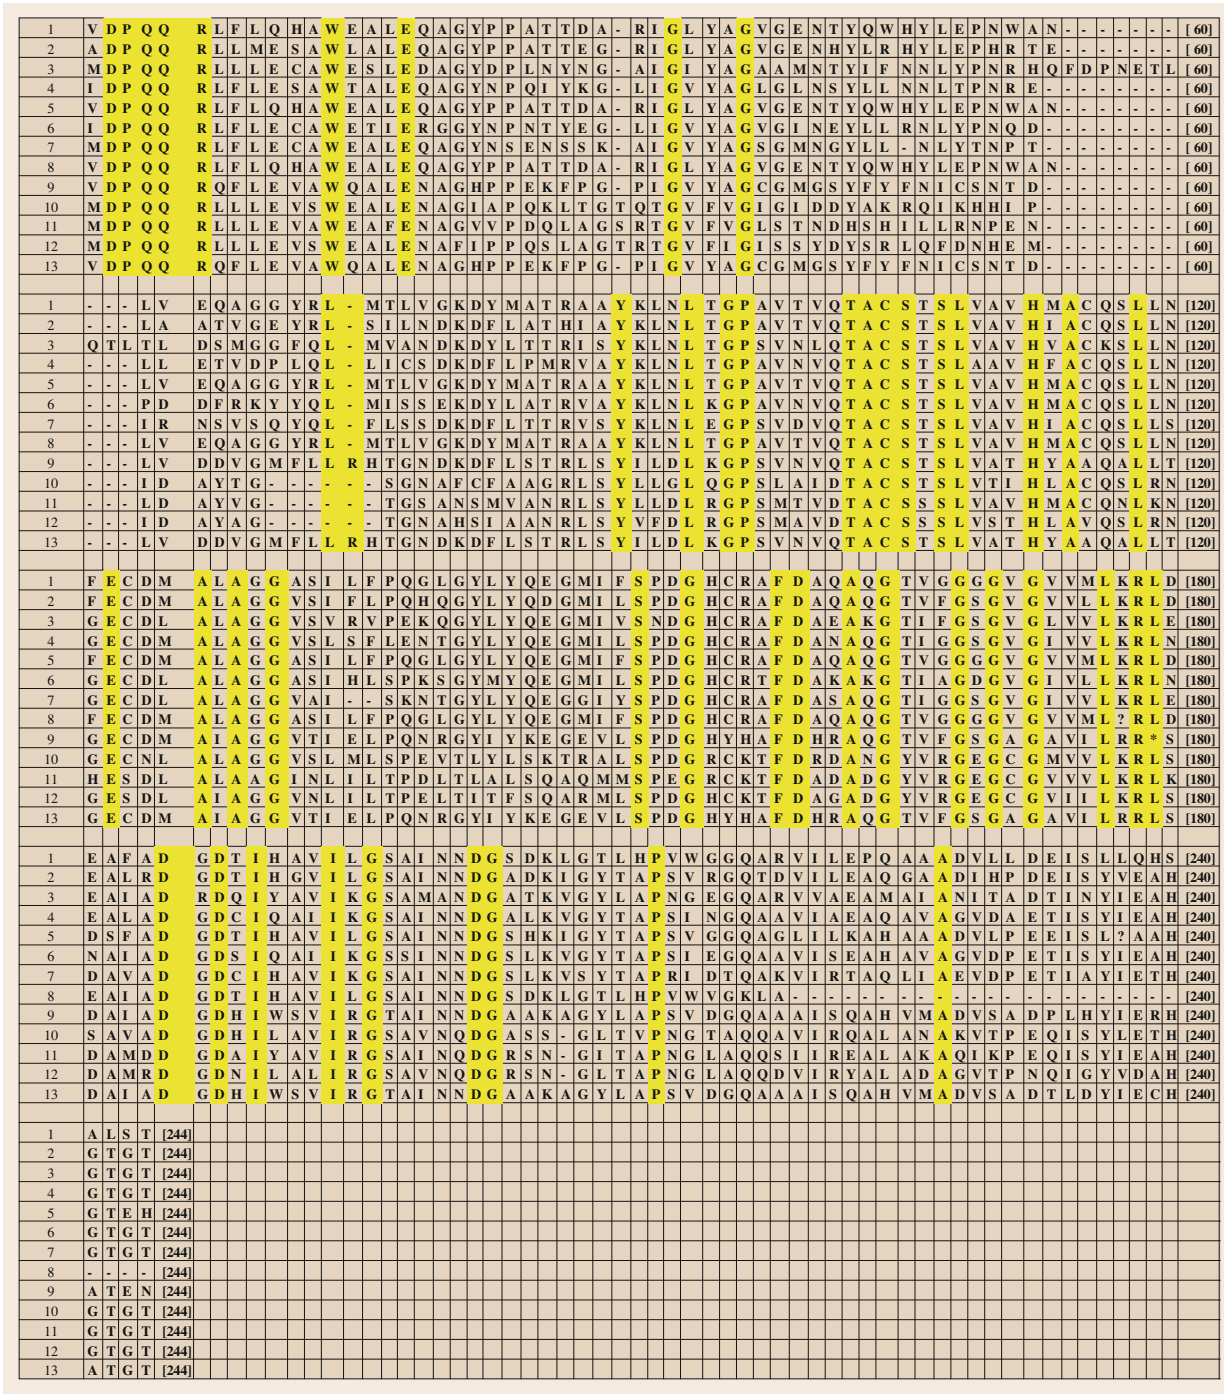
potential of the microbiota associated with these sponges. With this approach, PKS genes have been identified in a number of sponges including *Pseudoceratina clavata*, *Discodermia dissoluta*, *Theonella swinhoei*, *Aplysina aerophoba*, *Haliclona simulans*, *Arenosclera brasiliensis*, amongst others, together with novel NRPS genes from the sponges *Haliclona okadai* and *A. aerophoba*.

We also employed such an approach to assess the metabolic potential of the marine sponge *Raspailia ramosa*, which we isolated from the Lough Hyne Marine Nature Reserve in Cork, Ireland. Many bioactive secondary metabolites and bioactivities have previously been reported from sponges of this genus [8.273]. The authors' group also previously identified antimicrobial activities from cultured isolates from *R. ramosa* [8.267]. These data combined suggest that there is a high likelihood that the metagenome of this sponge might be a good source of potentially exploitable bioactivity. Thus using degenerate primers targeting the ketosynthase domains of Type I PKS genes namely (MDPQQRf 5′-RTRGAYCCNCAGCAICG-3′ and HGTGTr 5′-VGTNCCNGTGCCRTG-3′ [8.143]), we analyzed metagenomic DNA from the sponge. This resulted in the cloning of five partial putative polyketide synthase genes, which, following blast analyses of the deduced amino acid sequences of these putative PKS and subsequent sequence alignment and phylogenetic tree construction, indicated the likely presence of two distinct types of PKS (Fig. 8.9). One tree branch included two highly similar ketosynthase gene fragments which were found to be only distantly related (40–45% amino acid sequence identity) to previously known genes, with the closest known related sequences being derived from cyanobacterial (*Anabaena* sp., *Microcystis* sp.) PKS genes. The other clade included 3 sequences more related to each other than to any other known gene sequence, with significant amino acid sequence homology (58–73% similar) to known ketosynthase genes, including genes involved in the biosynthesis of Jamaicamide, a neurotoxic polyketide from *Lyngbya majuscula*. In all cases a highly conserved cysteine residue (residue 104, Fig. 8.10) at the enzyme active site was present.

A similar approach was subsequently employed to identify putative non-ribosomal peptide encoding gene fragments from the *R. ramosa* metagenome by

Fig. 8.10 Alignment of inferred amino acid sequences of cloned putative PKS gene fragments from the metagenome of the marine sponge *R. ramosa* with the closest known BLAST relatives. Conserved residues are highlighted in yellow. (1) WH009pksB8, (2) *Prochloron didemni* P1-Palau polyketide synthase, (3) *Planktothorix agardhii* polyketide synthase, (4) *Nostoc* sp. cis-AT polyketide synthase, (5) WH009pksB11, (6) JamM *Lyngbya majuscula*, (7) *Gloeothece memranacea* polyketide synthase ketosynthase domain, (8) WH009pksC7, (9) WH009pksD2, (10) *Anabaena variabilis* polyketide synthase, (11) *Microcystis* sp. β-ketoacyl synthase, (12) type I polyketide synthase, uncultured bacterium, (13) WH009pksD5. Sponge-derived sequences are denoted WH009 ►



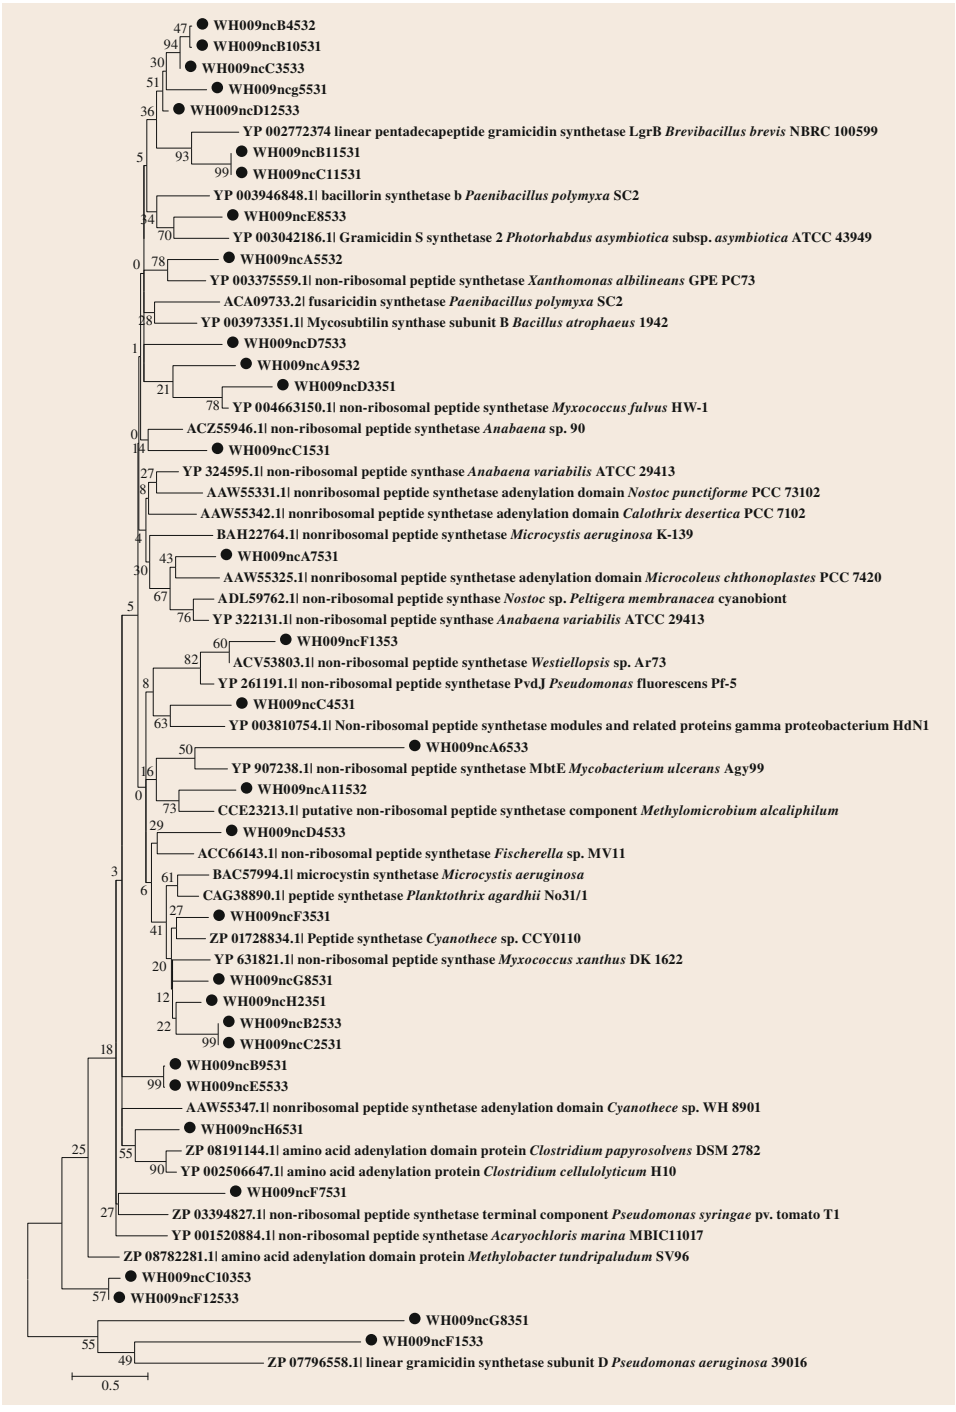


Fig. 8.11 Maximum likelihood bootstrap-consensus tree showing the evolutionary relationships between inferred amino acid sequences of partial putative NRPS gene sequences cloned from the metagenome of the marine sponge *R. ramosa* and their closest BLAST relatives. • – denotes sponge-derived sequences

employing degenerate primers to target the adenylation domain of potential NRPS genes (MTF2 5′-GCNGGYGGYGCNTAYGTNCC-3′ and MTR 5′-CCNCGDATYTTNACYTG-3′ [8.274]). This resulted in the cloning of 32 putative partial NRPS genes which, following BLAST analyses and phylogenetic tree construction, revealed a high level of diversity with many sharing homology (amino acid sequence identities ranging from 40–99%) with genes known to be involved in antimicrobial compound biosynthesis, and the cloned PCR products being related to varying degrees to gene products from at least 21 bacterial genera from 4 bacterial phyla. Examples of partial genes cloned here, which were similar known antimicrobial biosynthetic genes, include a sponge-derived gene sequence with similarity to the biosynthetic genes responsible for the production of the cytotoxic cyanobacterial product, microcystin and putative NRPS genes, which shared significant homology with genes involved in the biosynthesis of antibacterial (fusaricidin) and antifungal (bacillomycin L, mycosubtilin) compounds.

The high levels of bacterial diversity associated with *R. ramosa* together with the identification of diverse biosynthetic gene fragments of interest and the previous isolation of bacteria showing antimicrobial activities from *R. ramosa* make this species of particular research interest. Moreover, the wide diversity of potential non-ribosomal peptides that may be produced by bacteria associated with the sponge is also especially interesting. A PCR-based approach has recently also been employed to demonstrate a ribosomal origin for the bioactive metabolites polytheonamides A and B isolated from the marine sponge *Theonella swinhoei*. The biosynthetic gene cluster was cloned from the sponge metagenome, revealing a bacterial gene architecture involving six candidate enzymes which appear capable of carrying out up to 48 posttranslational modifications. This work, together with the work reported here, further highlights the biosynthetic scope of ribosomal systems within sponge metagenomes, and may ultimately provide further opportunities for peptide bioengineering strategies [8.275].

8.7 Conclusions

The results presented here clearly identify the considerable promise of metagenomic technologies and techniques to discover and exploit novel genes and gene products with potential commercial value. However, much work remains to be done to determine if the enzymes and compounds discovered here can realize that potential.

9. Bioprocess Engineering of Phototrophic Marine Organisms

Gregory L. Rorrer

Phototrophic marine organisms, particularly photosynthetic marine algae, are a diverse source of natural products ranging from lipid-based biofuels to pharmacologically-active compounds. The engineered production of both biomass and natural products is accomplished within enclosed, illuminated bioreactor systems called photobioreactors. This chapter describes the basic principles of photobioreactor analysis and design, and the biological factors that limit photobioreactor performance for the controlled cultivation of phototrophic marine organisms. There are three parts to this chapter. First, the quantitative growth characteristics of photosynthetic marine organisms in liquid cell suspension culture are described, including the use of photosynthetic biomass stoichiometry to describe nutrient incorporation into cellular biomass, and the combined effects of dissolved nutrient concentration and light intensity on cell growth rate. Second, the basic elements of photobioreactor design and operation are presented, focusing on models for predicting biomass production in batch or continuous cultivation modes within common photobioreactor configurations. Third, the limiting factors in photobioreactor design and operation are critically assessed from a quantitative point of view, focusing on light and carbon dioxide transfer limitations, and their effects on biomass production. Finally, future directions for the design and applications of enclosed photobioreactors are overviewed.

9.1 Introduction to Marine Process Engineering

Marine bioprocess engineering focuses on the design and analysis of processes that manufacture valuable compounds from marine organisms within an enclosed, controlled environment. Marine bioprocesses use liv-

ing marine organisms as *cell factories* for biological synthesis of these compounds. Marine organisms can be broadly classified into two categories, those requiring an organic carbon source for growth (heterotrophs) and those that rely on photosynthesis for growth (phototrophs). This chapter focuses solely on phototrophic marine organisms. Phototrophic marine organisms comprise a vast group that includes photosynthetic bacteria, cyanobacteria, microscopic algae (microalgae), and seaweeds (macroalgae).

9.1.1 Phototrophic Marine Organisms: A Diverse Source of Valuable Natural Products

A marine natural product is defined as any valuable material that is biologically produced by a marine organism. This section overviews natural products of current or future value commercial value from phototropic marine organisms, with a particular focus on marine algae.

Phototrophic marine algae are particularly diverse sources of natural products, as detailed in several reviews [9.1–8]. The biosynthesis of natural compounds by phototrophic marine organisms falls into two categories. The first category comprises organic compounds biologically synthesized through primary metabolism. Primary metabolism represents a system of biochemical pathways that are essential for cell growth and reproduction. For example, the biosynthesis of sugars, amino acids, nucleic acids, proteins, ribonucleic acid (RNA), and deoxyribonucleic acid (DNA), are usually associated with primary metabolism in phototrophic marine organisms. The second category comprises organic compounds derived from secondary metabolism. Biochemical pathways within secondary metabolism are not essential for cell growth or reproduction but serve some specialized function in time of need, for example, lipids for chemical energy storage, or bioactive chemical defense compounds to avoid being eaten by other organisms. In general, secondary metabolites are the source of pharmacologically-active compounds. Natural products derived from marine organisms do not have to be in a pure form. Often, the cell biomass itself or extracts of the cell biomass are valuable. These extracts, which can include both primary and secondary metabolites of human nutritional value, are called *nutraceuticals*.

Microalgae are a promising future platform for the production of advanced biofuels, as discussed in several recent reviews and papers [9.9–15]. Microalgae are single-celled photosynthetic organisms that grow, reproduce themselves, and biosynthesize energy-dense molecules through metabolic processes that utilize only sunlight, atmospheric CO_2, water, and macronutrients – principally nitrogen and phosphorous – as inputs. The variety of lipids biosynthesized within the algae, which can constitute up to 50 wt% of the algal biomass, can be chemically converted to liquid transportation fuels such as biodiesel ($\approx C_{14}--C_{22}$ fatty acid methyl esters) or green diesel by catalytic processes [9.16]. Relative to oil-bearing land plants for biodiesel production, algae can thrive on saline waters not suitable for food production, and have much higher production rates. Furthermore, algal biofuel production systems can be sited on non-arable land because the organisms are grown in water within engineered systems (e.g., open ponds or enclosed photobioreactors), not in soil.

Other than algal biofuels, commercially important natural products from phototrophic marine organisms fall into five categories:

1. Nutritional supplements or nutraceuticals
2. Specialty pigments
3. Industrial polysaccharides
4. Products for aquaculture
5. Pharmaceutical compounds.

Examples of commercial natural products from phototrophic marine organisms are provided in Table 9.1. Commercial natural products include beta-carotene, the polyunsaturated fatty acids (PUFAs) EPA and DHA, *Spirulina* dried biomass, astaxanthin (an aquaculture feed supplement), and the hydro-colloids. Most of the products listed in Table 9.1 are primary metabolites, although some polyunsaturated fatty acids and polysaccharides can also be produced as a consequence of secondary metabolism. Discussions of the metabolic pathways associated with the biological synthesis of each of these compounds within the cell are beyond the scope of this chapter.

Phototrophic marine organisms will play a major role in emerging marine biotechnology revolution because they are a rich source of novel drugs for the future. Below, a few exciting new pharmaceutical candidates from cyanobacteria, microalgae, and macroalgae are overviewed.

Marine cyanobacteria and microalgae offer a diverse array of pharmaceutical candidates. For example, a sulfolipid from the filamentous marine cyanobacteria *Lyngbya* sp. is in preclinical trials for treatment against the human immunodeficiency virus (HIV). The thiazoline-containing lipid Curacin A from *Lyngbya*

Table 9.1 Commercial high value products from phototrophic marine organisms

Product area	Product class	Examples	Representative organisms Species	Classification
Nutritional supplements	Carotenoids	Beta-carotene	*Dunaliella salina*	Green microalga
	PUFAs	Eicosapentaenoic acid (EPA) Docosahexanaeoic acid (DHA)	*Nannochloropsis* sp. *Phaeodactylum tricornutum* *Isochrysis galbana*	Green microalga diatom Green microalga
	Foodstuffs	Dried biomass rich in vitamins & proteins	*Spirulina platensis*	Cyanobacteria, green micoalga
Specialty pigments	Phycobiliproteins	Red phycoerythrin, blue phycocyanin	*Porphyridium cruentum* *Spirulina platensis*	Red microalga Cyanobacteria
Industrial polysaccharides	Hydro-colloids	Sulfated polysaccharides	*Porphyridium cruentum*	Red microalga
		Agars, alginates, carrageenans	*Gracilaria* sp., *Laminaria* sp., *Eucheuma* sp.	Red, brown macroalgae
Aquaculture	Carotenoids	Astaxanthin for fish aquaculture	*Haematococcus* sp.	Green microalga
	Feedstock	Fresh biomass for bivalve and shrimp larvae	*Isochrysis, Dunaliella* sp.	Green microalgae

is also under research and development as an anticancer drug. Other cyanobacteria contain linear peptides that act as immunosuppressive agents. Brevetoxins from various dianoflagellates possess potent antiinfective properties. These are just a few examples of the broad spectrum of pharmacologically active compounds found in marine cyanobacteria and microalgae.

Many red and brown marine macroalgae (seaweeds) biochemically oxidize simple complex polyunsaturated fatty acids to complex compounds called eicosanoids. In eicosanoid biosynthesis, the stereochemically specific oxidation of arachidonic acid is accomplished through lipoxygenase, epoxygenase, and cyclooxygenase pathways to produce a variety of pharmacologically important compounds, including hydroxy fatty acids, prostaglandins, hepoxlins, and leukotrienes. Eicosanoids are important in maintaining normal physiological conditions in mammals, and aberrant production of these metabolites underlies several diseases, including inflammation, asthma, heart disease, and cancer. Unique eicosanoids produced by marine macroalgae possess potent pharmacological properties as well, and may ultimately lead to the development of new pharmaceutical agents to treat these diseases.

Halogenation of secondary metabolites, while rare in land plants and microorganisms, occurs frequently in marine organisms due to the abundance of chlorine and bromine in seawater. Red macroalgae in particular have evolved several unique biosynthetic pathways for the production of organohalogen compounds, primarily as a means for chemical defense against predation by herbivores. A novel pathway is the stereoselective halogenation of terpenoids. Monoterpenes and their biohalogenated derivatives have emerged as a class of chemopreventive agents for alleviating the proliferation and progression of cancer-related tumors. However, bioprocess technologies are needed for securing future supplies of these drug candidates in the quantities required for product development, testing, and eventual commercial production. Toward this end, research in marine biotechnology has focused on the development of cell and tissue suspension cultures of macroalgae that biologically synthesize pharmacologically active compounds in vitro [9.7].

9.1.2 Marine Bioprocess Engineering and the *Cell Factory*

Many of the natural products derived from phototrophic marine organisms are complex organic compounds that possess unique structures and stereochemistry. Often, these compounds are so complex that they cannot be duplicated by chemical synthesis in the laboratory. In this case, the phototrophic marine organism itself must serve as the living *cell factory* for the biological synthesis of these compounds. The living cell factory can assume the form of an intact organism, a tissue culture derived from the organism, or a liquid cell suspension culture derived from the organism. The liquid cell suspension culture is the most desired form for process

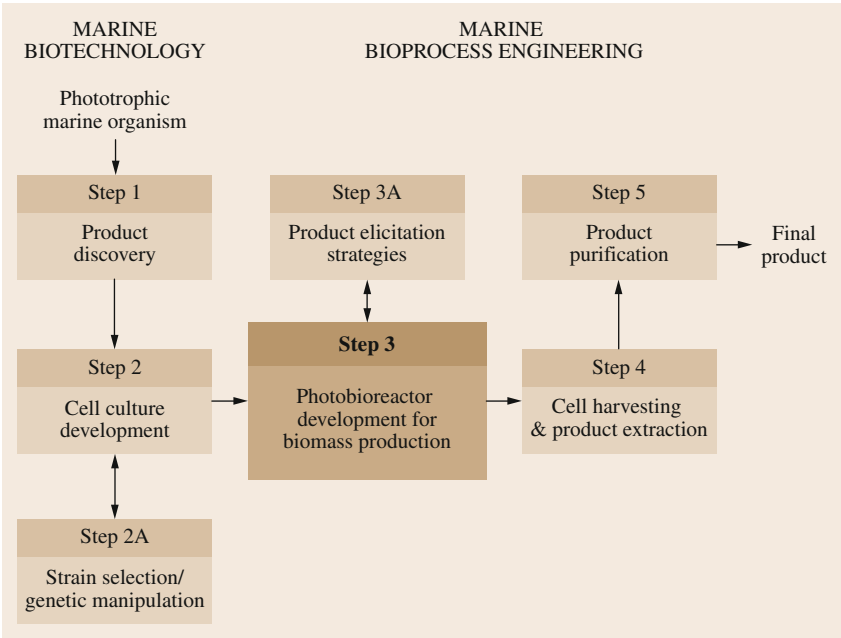

Fig. 9.1 The development of bioprocess technology for phototrophic marine organisms requires five steps, spanning both marine biotechnology and marine bioprocess engineering

biotechnology applications, as it resembles a fermentation broth. The cell factory can produce compounds resulting from primary metabolism, which are essential to cell growth, or compounds from secondary metabolism, which are not essential for cell growth but may serve some special function in time of need. Primary and secondary metabolites are often produced by a complex series of reactions within the cell – pathways that cannot be easily duplicated by other means. So how can the microscopic *cell factory* serve as a macroscopic *real factory* on a large scale? The answer lies in understanding how marine bioprocesses are developed, which is described below.

All bioprocesses include biomass production and product purification stages. The development of marine bioprocesses requires five steps, as illustrated in Fig. 9.1. In step 1, a valued natural product within a given marine organism is identified and characterized. In step 2, the specific marine organism that naturally produces the target compound is isolated and cultured. From the culture isolates, a cell suspension culture that grows on a nutrient medium is established. Often, several cell lines within a pure culture are established in order to find the one that biosynthesizes the most desired compound in the highest amount, a process called strain selection.

In step 3, a biological reactor is developed for cultivation of the marine organism under tightly controlled conditions on a process scale. In essence, the biological reactor, or bioreactor, houses the cell factories that produce cellular biomass containing the valued natural compounds. Usually, if cell biomass is produced, the target compounds are produced as well. However, often, elicitation strategies specific to the marine organism or its class of compounds must be developed. Elicitation strategies seek to coax metabolic pathways within the living *cell factory* to produce more of a desired compound or compounds. For example, the concentration of polyunsaturated fatty acids within an algal cell can often be improved by switching the culture medium from a nutrient-rich growth medium to a nitrogen-limited medium. This forces cell metabolism to produce compounds that do not contain nitrogen, such as fatty acids.

In step 4, the cell biomass in the liquid suspension culture is harvested by various techniques including any combination of flocculation, de-watering, sedimentation, centrifugation, or filtration. This step is often very costly, because often 100–5001 of water must be processed for each gram of dry cell mass harvested! Sometimes, the product is excreted from the cells to the surrounding liquid medium, but more often the product is retained within the cellular biomass. After harvesting, the desired natural product is then extracted from the cellular biomass with the appropriate aqueous or organic solvent. In step 5, established chemical process technologies such as liquid–liquid ex-

traction or chromatography are used to fractionate the cell extract into the final purified compounds. Topics related to *downstream bioseparation processes* such as biomass extraction and chromatography are beyond the scope of this chapter because they are generic to all forms of bioprocess technology, not just marine bioprocess technology. Excellent references on bioprocess engineering fundamentals and bioseparations are available [9.17–19].

This chapter focuses on the cultivation of phototrophic marine organisms in enclosed photobioreactor systems. However, it is also possible to cultivate phototrophic marine organisms outdoors in tanks or ponds. In open pond or tank cultures, the liquid surface is exposed to ambient air and direct sunlight. The open pond or tank culture is industrially practiced species of photosynthetic microalgae that can grow under conditions of salinity or pH where potential airborne contaminants cannot survive. A prominent example is the cultivation of the green microalga *Dunaliella* at elevated salinity in raceway ponds for production of beta-carotene. The two major limitations on open pond culture are sterility and process control. The manufacture of bioproducts requires a *GMP* or *good manufacturing practices* environment. Therefore, bioreactors must be enclosed and sterilizable to control contamination. Furthermore, bioreactor cultivation must be carried out with pure cultures under precisely controlled environmental conditions to ensure that the same product is reliably produced in the cell culture from batch to batch. Simultaneous control of contamination, temperature, pH, nutrient composition, aeration, and light is impossible to achieve in open pond or tank cultures.

9.2 Growth Characteristics of Phototrophic Suspension Cultures

Phototrophic marine organisms in liquid suspension culture share common growth characteristics. Below, concepts underlying photosynthetic biomass stoichiometry and specific growth rate are used to estimate the amounts and rates of photosynthetic biomass production.

9.2.1 Nutrient Requirements and Photosynthetic Biomass Stoichiometry

Photosynthetic Biomass Production

Phototrophic liquid suspension cultures utilize dissolved carbon dioxide as the carbon source and light as the energy source for photosynthesis. A detailed discussion of the complex biochemistry behind photosynthesis is beyond the scope of this chapter, and so the reader is encouraged to consult any of the excellent textbooks that cover photosynthesis, particularly in algal systems [9.20–22]. However, the basic idea of photosynthesis is to convert carbon dioxide to carbohydrates and ultimately to cellular biomass by an array of reduction reactions. Within the cell, photosynthesis is localized within organelles called chloroplasts. Within the chloroplasts are thylakoid membranes that contain complex molecules called chlorophylls that absorb light in the photosynthetically active radiation (PAR) range of 400–700 nm wavelength. The absorption of light by chlorophyll induces electron flow and transport that is used to drive reactions within two photosystems (I and II). Photosystem I carries out the reduction of the chemical energy carrier $NADP^+$ to NADPH (nicotinamide adenine dinucleotide phosphate) whereas Photosystem II splits water into O_2 and hydrogen ions (H^+). The proton gradient generated by Photosystem II produces the chemical energy carrier adenosine triphosphate (ATP) through the process of photophosphorylation. The NADPH and ATP generated by these processes subsequently reduce CO_2 to carbohydrates by a series of non-light requiring (dark) reactions collectively called the Calvin cycle. The overall stoichiometric equation for photosynthesis is

$$6CO_2 + 6H_2O \xrightarrow{h\nu} C_6H_{12}O_6 + 6O_2 \,, \qquad (9.1)$$

where $h\nu$ is the light energy. Note that CO_2 is consumed and O_2 is generated in a 1 : 1 stoichiometric ratio. However, this stoichiometric equation ignores the incorporation of other elements such as nitrogen and phosphorous into cellular material.

Medium Components

In phototrophic liquid suspension cultures, carbon dioxide is supplied to the culture by placing the liquid medium into contact with an aeration gas containing CO_2. The CO_2 dissolves into the liquid phase from the gas phase. In addition to dissolved CO_2 and light, phototrophic liquid suspension cultures require both

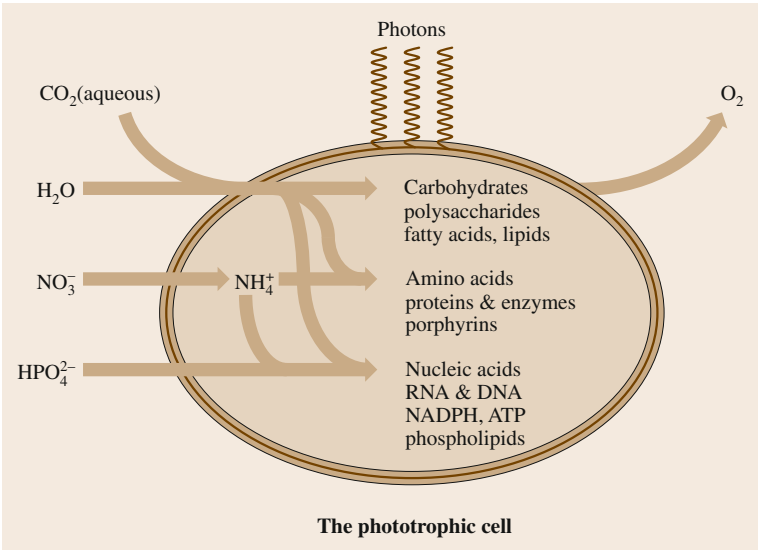

Fig. 9.2 Simplified schematic of macronutrient inputs to a phototrophic cell

macronutrients and micronutrients for growth. A very simplified schematic of the assimilation of macronutrients and CO_2 into the phototrophic cell is presented in Fig. 9.2. Both macronutrients and micronutrients are dissolved in a liquid base medium. The liquid base medium mimics the composition of seawater, which contains salts of sodium (Na), magnesium (Mg), potassium (K), and calcium (Ca) in order of decreasing abundance.

Macronutrients include nitrogen and phosphorous, usually supplied as inorganic salts. Nitrogen is typically supplied to the liquid medium as salt containing the nitrate anion NO_3^- or the ammonium cation NH_4^+. Nitrogen is assimilated into amino acids and ultimately protein. Phosphorous is typically supplied to the liquid medium as sodium or potassium salt containing the phosphate anions HPO_4^{2-} or $H_2PO_4^-$. Phosphorous is assimilated into nucleic acids, genetic material (RNA, DNA), chemical energy carriers (ATP, NADPH), and phospholipids.

Inorganic micronutrients include elements such as boron (B), cobalt (Co), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), and zinc (Zn), supplied as salts. Organic micronutrients, if used, are most commonly vitamins. Micronutrients usually serve as cofactors for enzymatic processes within the cell. The generic roles of macronutrients and micronutrients in the primary metabolism of phototrophic marine organisms and their typical concentrations in the liquid medium are summarized in Table 9.2. Liquid medium formulations also typically contain metal ion chelators such as ethylenediaminetetracetic acid (EDTA) to maintain iron solubility and alkaline buffers such as sodium bicarbonate to adjust the medium pH to the typical ambient seawater pH of 8.0.

Biomass Stoichiometry

The overall biomass stoichiometry approximates the incorporation of externally supplied carbon, nitrogen, and phosphorous (the macronutrients) into cellular material. The elemental composition of phototrophic marine organisms in a nutrient-rich environment typically follows the well-known Redfield ratio of 106C : 16N : 1P. Assuming that the elemental composition of phototrophic biomass follows the Redfield ratio, the photosynthetic biomass stoichiometry for incorporation of CO_2, nitrate (NO_3^-), and phosphate (PO_4^{3-}) into cellular material is

$$106\,CO_2 + 122\,H_2O + 16\,NO_3 + PO_4 \xrightarrow{h\nu} |\,(CH_2O)_{106}(NH_2)_{16}(PO_4)\,|_{\text{biomass}} + 138\,O_2\,. \tag{9.2}$$

Note that the CO_2 consumed and O_2 generated are not in a 1 : 1 stoichiometric ratio. The biomass stoichiometry for a specific organism can be proposed if the elemental composition ($C_x\,H_y\,O_z\,N_r\,P_s$) of the cellular biomass is known and the type of nutrients dissolved in the liquid medium is also specified.

The biomass yield coefficient relates biomass production to nutrient consumption. Biomass yield coefficients can be estimated from photosynthetic biomass

Table 9.2 Typical growth medium composition for phototrophic marine organisms

Typical medium component & concentration				Major cellular constituents/role or function
Macronutrients				
Nitrogen (nitrate)	N	$NaNO_3$	1–10 mM NO_3^-	Amino acids and proteins (enzymes), purines, porphyrins, amino sugars, amines
Phosphorous (phosphate)	P	Na_2HPO_4	0.05–0.5 mM HPO_4^{2-}	Nucleic acids and genetic material, chemical energy carriers (ATP, NADPH), phospholipids
Sulfur (sulfate)	S	$MgSO_4$	40 mM SO_4^{2-}	Amino acids (methionine, cysteine), sulfated polysaccharides, sulpholipids
Macrosalts				
Sodium	Na	NaCl	450 mM Na^+	Major component of seawater/water balance
Magnesium	Mg	$MgSO_4$	40 mM Mg^{2+}	Major component of seawater, component of chlorophyll
Potassium	K	KCl	10 mM K^+	Osmotic regulation, pH balance, protein conformation
Calcium	Ca	$CaCl_2$	10 mM Ca^{2+}	Major component of seawater/enzyme activation, ion transport
Micronutrients – trace elements a				
Boron	B	H_3BO_3	0.4 mM BO_4^{3-}	Diverse roles in primary metabolism and reproduction
Cobalt	Co	$CoCl_2$	0.2 µM Co^{2+}	Constituent of vitamin B_{12}
Copper	Cu	$CuCl_2$	0.2 µM Cu^{2+}	Constituent of plastocyanin/enzyme co-factor, electron transport (photosynthesis)
Iron	Fe	$FeCl_3$	0.02 mM Fe^{3+}	Constituent of ferredoxin and cytochrome/enzyme co-factor for redox reactions including nitrate reductase
Molybdenum	Mo	Na_2MoO_4	5 µM MoO_4^{2-}	Enzyme co-factor: nitrate reductase
Manganese	Mn	$MnCl_2$	5 µM Mn^{2+}	Constituent of photosystem II, maintenance of chloroplast membranes
Silicon	Si	Na_2SiO_3	0.5 mM SiO_3^{2-}	Cell wall component (diatoms)
Zinc	Zn	$ZnCl_2$	5 µM Zn^{2+}	Enzyme co-factor: carbonic anhydrase
Micronutrients – vitamins				
Cyanocobalamin		B_{12}	0.001 µM	Enzyme co-factor/growth factor
Thiamin		B_1	1 µM	Enzyme co-factor/growth factor
Biotin			0.001 µM	Enzyme co-factor/growth factor

stoichiometry. For example, the biomass yield coefficients based on CO_2 consumption and for nitrate consumption for the biomass stoichiometry given in (9.2) are

$$\begin{aligned} Y_{X/CO_2} &= \frac{\text{g cellular biomass produced}}{\text{mol } CO_2 \text{consumed}} \\ &= \frac{1\text{ mol biomass produced}}{106\text{ mol CO }_2\text{consumed}} \frac{3531\text{ g biomass}}{1\text{ mol biomass}} \\ &= \frac{33.3\text{ g cells}}{1\text{ mol } CO_2}\,, \end{aligned} \tag{9.3}$$

$$\begin{aligned} Y_{X/N} &= \frac{\text{g cellular biomass produced}}{\text{mol nitrate consumed}} \\ &= \frac{1\text{ mol biomass produced}}{16\text{ mol } NO_3^- \text{consumed}} \frac{3531\text{ g biomass}}{1\text{ mol biomass}} \\ &= \frac{221\text{ g cells}}{1\text{ mol } NO_3^-}\,. \end{aligned} \tag{9.4}$$

It cannot be inferred from (9.3) and (9.4) that the molecular weight of biomass is 3531 $gmol^{-1}$, as this value simply represents the biomass composition referenced to the stated biomass stoichiometry. Published values of biomass yield coefficients must be interpreted with caution, as they often change at high N:P ratios in the liquid medium or under nitrogen limitation. Nevertheless, biomass yield coefficients are very useful for material balance calculations. For example, biomass yield coefficients can be used to predict the maximum cell density for a given dissolved nutrient composition, as detailed in Sect. 9.3.2.

CO_2 Speciation

Dissolved CO_2 speciates to bicarbonate and carbonate ions if the medium is alkaline. Phototrophic marine organisms grow best in a seawater-based medium at pH 8 to 9, where CO_2 speciates to bicarbonate (HCO_3^-) and

carbonate (CO_3^{2-})

$$CO_2(g) \leftrightarrow CO_2(aq)\,,$$
$$CO_2(aq) + H_2O \leftrightarrow HCO_3^- + H^+\,,$$
$$HCO_3^- \leftrightarrow CO_3^{-2} + H^+\,,$$
or
$$CO_2(aq) + OH^- \leftrightarrow HCO_3^-\,. \qquad (9.5a)$$

It must be emphasized that the speciation of CO_2 is a gas–liquid equilibrium process. The equilibrium absorption of CO_2 from the gas phase to the liquid phase is described by Henry's law

$$P_A = H[CO_2]_{aq} \qquad (9.5b)$$

where P_A is the partial pressure of CO_2 in the gas in contact with the liquid, $[CO_2]$ is the concentration of CO_2 dissolved in the liquid medium that is in equilibrium with the CO_2 partial pressure in the aeration gas, and H is the Henry's law constant. The subsequent mass action expressions for dissolved CO_2 speciation in a liquid medium are

$$K_1 = \frac{[H^+][HCO_3^-]}{[CO_2]_{aq}}\,,$$
$$K_2 = \frac{[CO_3^{2-}][H^+]}{[HCO_3^-]}\,. \qquad (9.6)$$

From the mass action expressions and Henry's law for absorption of CO_2, it can be shown that the predicted equilibrium concentrations of bicarbonate $[HCO_3^-]$ and carbonate $[CO_3^{2-}]$ ions are

$$[HCO_3^-] = 10^{-(+pK_{a,1}-pH)}\frac{P_A}{H}[CO_3^{2-}]$$
$$= 10^{-(+pK_{a,2}-pH)}[HCO_3^-]\,. \qquad (9.7)$$

The total dissolved carbon concentration ($C_{A,T}$) is the sum of all specie concentrations

$$C_{A,T} = [CO_2]_{aq} + [HCO_3^-] + [CO_3^{2-}]\,. \qquad (9.8)$$

The pK_a values for dissociation of HCO_3^- and CO_3^{2-} are 6.05 and 9.23, respectively, in seawater of 35 ppt salinity at 15 °C. The Henry's law constant (H) for dissolution of CO_2 is 0.026 L atm mmol^{-1} at the same conditions. Selected equilibrium properties of CO_2 and O_2 in fresh water and seawater are presented in Table 9.3.

Representative plots of equilibrium species concentration versus pH are shown in Fig. 9.3. The dissolved concentration of CO_2 in seawater is a function of temperature and CO_2 partial pressure but is not a function of pH, whereas the ionic bicarbonate and carbonate species concentrations are also a function of pH. For example, if ambient air containing 350 ppm CO_2 (CO_2 partial pressure P_A of 0.00035 atm CO_2) is bubbled into a seawater medium at 15 °C, then at pH 8.0 the equilibrium dissolved CO_2, HCO_3^- and CO_3^{-2} concentrations are 0.014 mM, 1.2 mM, and 0.071 mM respectively. However, at pH 7.0 the equilibrium concentrations of CO_2, HCO_3^- and CO_3^{2-} are 0.014 mM, 0.12 mM and 0.00071 mM, respectively. At high pH, this bicarbonate reservoir can serve as ballast for dissolved CO_2.

9.2.2 Specific Growth Rate

The specific growth rate is a convenient tool for characterizing the intrinsic biomass production rate in the exponential phase of growth. It is defined as the derivative of the cell density (C_x, g cells/L^{-1} culture) versus cultivation time (t) curve divided by the cell density

$$\mu = \frac{1}{C_x}\frac{dC_x}{dt}\,. \qquad (9.9)$$

The specific growth rate (μ) is a normalized parameter with units of reciprocal time, e.g., h^{-1}, similar to a first-order rate constant associated with a first-order chemical reaction.

The specific growth rate of a particular phototrophic marine organism in a liquid suspension culture is affected by both intrinsic environmental conditions (pH, temperature, salinity, light intensity) and the available nutrient composition. At optimal pH, temperature, and salinity, the specific growth rate is principally affected by three variables: 1) the dissolved carbon dioxide concentration in the liquid medium; 2) the dissolved limiting nutrient concentration in the liquid medium; and 3) the incident light intensity to the cell surface for photosynthesis. Like most living organisms, the specific growth rate of phototrophic cells exhibits saturation with respect to each of these variables. The Monod model is most commonly used to describe saturation growth kinetics. By the Monod approach, the combined effect of these three variables on the specific growth rate is given by

$$\mu = \frac{C_A}{K_A + C_A}\frac{C_N}{K_N + C_N}\frac{I}{I_k + I}\mu_{max}\,, \qquad (9.10)$$

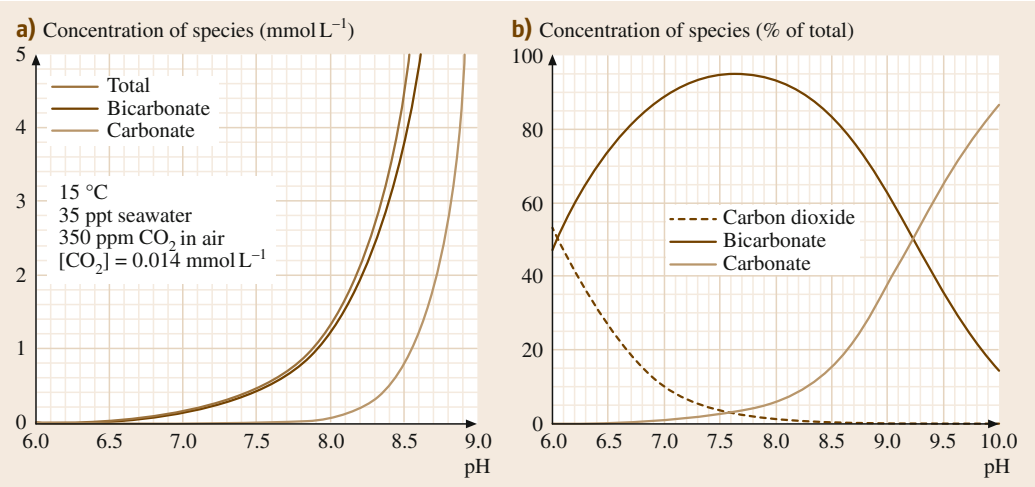

Fig. 9.3a,b Calculated speciation of dissolved carbon dioxide to carbonate and bicarbonate ions as a function of pH in a seawater-based liquid medium using air as the aeration medium. Conditions: 15 °C, 35 ppt seawater, CO_2 partial pressure of 0.00035 atm (350 ppm CO_2 at 1 atm total pressure), Henry's law constant for CO_2 of 0.026 L atm mmol^{-1}, equilibrium dissolved CO_2 concentration of 0.014 mM. **(a)** Molar concentrations of bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) versus pH; **(b)** molar percentage of dissolved CO_2, bicarbonate, and carbonate versus pH

Table 9.3 Equilibrium properties for the speciation of CO_2 in fresh water and seawater. All values are obtained from *Raven* [9.21]

Equilibrium property	Variable name	T (°C)	Value		Units
			fresh water	35 ppt seawater	
Dissolved CO_2 concentration in equilibrium with 35 Pa gas phase CO_2	(CO_2) or C_A*	5.0	22.43	18.75	μmol L^{-1}
		15.0	15.95	13.46	
		25.0	11.90	10.18	
		35.0	9.27	8.06	
Henry's law constant for CO_2	$H(CO_2)$	5.0	0.0154	0.0184	L atm mmol^{-1}
		15.0	0.0217	0.0257	
		25.0	0.0290	0.0339	
		35.0	0.0373	0.0428	
Dissolved O_2 concentration in equilibrium with 20.95 kPa gas phase O_2	(O_2)	5.0	391.5	310.8	μmol L^{-1}
		15.0	298.3	240.8	
		25.0	236.0		
Henry's law constant for O_2	$H(O_2)$	5.0	0.5280	0.6651	L atm mmol^{-1}
		15.0	0.6930	0.8584	
		25.0	0.8759	1.0683	
Dissociation constant for bicarbonate (HCO_3^-)	$pK_{a,1}$	5.0	6.52	6.11	
		15.0	6.42	6.05	
		25.0	6.35	6.00	
		35.0	6.31	5.97

		15.0	10.43	9.23	
		25.0	10.33	9.10	
		35.0	10.25	8.95	

where C_A is the dissolved carbon dioxide concentration ($\mathrm{mol\,L^{-1}}$), C_N is the dissolved limiting nutrient concentration ($\mathrm{mol\,L^{-1}}$), I is the light intensity incident to the cell surface ($\mu\mathrm{mol\ photons\,m^{-2}\,s^{-1}}$), I_k is the half-saturation constant for light intensity ($\mu\mathrm{mol\ photons\,m^{-2}\,s^{-1}}$), K_A is the half-saturation constant for dissolved carbon dioxide ($\mathrm{mol\,L^{-1}}$), K_N is the half-saturation constant for the dissolved nutrient concentration, and μ_{max} is the maximum possible specific growth rate of the phototrophic organism ($\mathrm{h^{-1}}$). It is important to note here that the dissolved nutrients are expressed as concentration in the liquid surrounding the cell whereas light is expressed as the photon flux incident to the cell. If the culture is not illuminated ($I = 0$), then the specific growth rate is zero. Furthermore, if the dissolved limiting nutrient concentration C_N or the dissolved CO_2 concentration C_A are zero, the specific growth rate is zero.

For many phototrophic marine organisms, values for K_A and K_N are typically very small, often in the range of only 10–100 $\mu\mathrm{mol\,L^{-1}}$. The specific growth rate is assumed to follow zero-order kinetics with respect to the dissolved carbon dioxide concentration C_A. A zero-order process means that as long as C_A is finite, the specific growth rate μ is not affected by C_A. However, if C_A is zero, then μ is zero even if sufficient dissolved nutrients and light are present. For zero-order kinetics with respect to CO_2, (9.10) reduces to

$$\mu = \frac{C_A}{K_A + C_A}\frac{C_N}{K_N + C_N}\frac{I}{I_k + I}\mu_{max} \cong \frac{C_N}{K_N + C_N}\frac{I}{I_k + I}\mu_{max}\,. \tag{9.11}$$

A short-hand form of (9.11) is

$$\mu \cong \frac{C_N}{K_N + C_N}\mu'\,, \tag{9.12}$$

where μ' represents the effect of light intensity alone on the specific growth rate. Often, in liquid suspension culture the dissolved carbon dioxide concentration C_A is much higher than K_A, *and* the limiting nutrient concentration C_N is much higher than K_N. Under these conditions, the growth kinetics are zero-order with respect to both of these variables and (9.12) becomes

$$\mu \cong \mu_{max}\frac{I}{I_k + I}\,. \tag{9.13}$$

The effect of light intensity on the specific growth rate deserves special attention, as this variable has the most profound effect on the specific growth rate. Light intensity is formally referred to as photosynthetically active radiation (PAR or irradiance) in the range of 400–700 nm wavelength. Irradiance is best expressed as quantum photon flux with units of $\mu\mathrm{mol\ photons\,m^{-2}\,s^{-1}}$. Further details on units of irradiance are provided in Sect. 9.3.3. The specific growth rate exhibits saturation growth kinetics with respect to light intensity. A representative plot of specific growth rate versus light intensity is shown in Fig. 9.4. At low light intensities, the specific growth rate linearly increases with increasing light intensity. At high light intensities, the specific growth remains constant at its maximum value with increasing light intensity, as all photoreaction centers within the cell are saturated by incident photons. At light saturation, the growth is CO_2 fixation rate limited. At very high light intensities above light saturation, oxidation processes resulting in a reduction in growth rate can occur, a process known as photoinhibition.

Four models that quantify the effect of I on μ are compared in Table 9.4. The parameters I_k and μ_{max} and photoinhibition constant K_i are unique for a given phototrophic marine organism and are determined experimentally by fitting I versus μ data to the desired model. Values of I_k range widely but typically vary from about 10–200 $\mu\mathrm{mol\ photons/m^{-2}\,s^{-1}}$. Published values of I_k and μ_{max} for a given phototrophic marine organism must be used with extreme caution since they

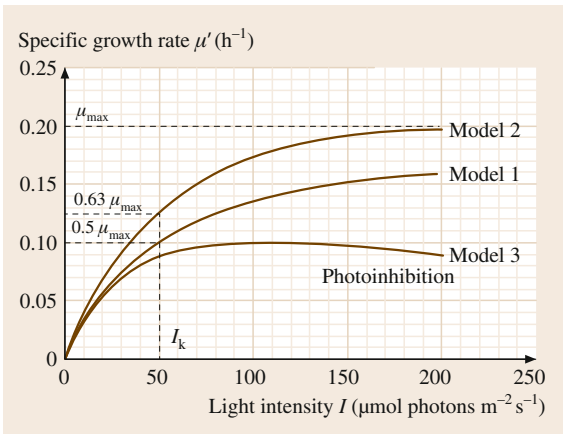

Fig. 9.4 Specific growth rate (μ') versus light intensity (I): comparison of Monod model (Model 1) with the exponential model (Model 2) and the photoinhibition model (Model 3). Model input parameters: $I_k = 50\,\mu$ mol photons $\mathrm{m^{-2}\,s^{-1}}$, $\mu_{max} = 0.2\,\mathrm{h^{-1}}$, $K_i = 0.005\,\mathrm{m^2\,s\,\mu}$ mol photons^{-1}

Table 9.4 Common light-saturation growth models for phototrophic marine organisms

Light-saturation growth model	Equation	Adjustable parameters	Limiting cases
Monod model (Model 1)	$\mu' = \frac{\mu_{max} I}{I_k + I}$	μ_{max}, I_k	$I \ll I_k$, $\mu' = \mu_{max}\frac{I}{I_k}$; $I = I_k$, $\mu' = 0.5\,\mu_{max}$; $I \to \infty$, $\mu' \to \mu_{max}$
Exponential model (Model 2)	$\mu' = \mu_{max}\left(1 - e^{-\frac{I}{I_k}}\right)$	μ_{max}, I_k	$I \ll I_k$, $\mu' = \mu_{max}\frac{I}{I_k}$; $I = I_k$; $\mu' = 0.632\mu_{max}$; $I \to \infty$, $\mu' \to \mu_{max}$
Monod model with photoinhibition (Model 3)	$\mu' = \frac{\mu_{max} I}{I_k + I + K_i I^2}$	μ_{max}, I_k, K_i	$I \ll I_k$, $\mu' = \mu_{max}\frac{I}{I_k}$; $I \to \infty$, $\mu' \to 0$
Bannister–Monod model (Model 4)	$\mu' = \frac{\mu_{max} I}{(I_k^m + I^m)^{1/m}}$	μ_{max}, I_k, m	$m = 1$, Monod model; $I \to \infty$, $\mu' \to \mu_{max}$

are usually dependent on the conditions under which the organism is maintained. Specific factors include the cell line of the organism, maintenance conditions for pH, temperature, salinity, and light intensity, and finally the particular constituents of the liquid medium formulation.

Phototrophic marine organisms are often subjected to an illumination cycle, commonly known as a photoperiod. Usually, the photoperiod is referenced with respect to a 24 h day and abbreviated as, for example, 16 : 8 LD, which refers to 16 h of light to 8 h of dark for one cycle on a 24 h photoperiod. During the dark phase of the photoperiod, it is assumed that no photosynthetic biomass production occurs. Therefore, the net specific growth rate over the entire photoperiod can be estimated by

$$\mu_{photoperiod} = \mu_{continuous\ light} f\,, \tag{9.14}$$

where f is the fractional photoperiod, defined as the time of culture illumination divided by the total time of the photoperiod, e.g., for a 16 : 8 LD photoperiod, f is equal to 0.67.

9.3 Basic Elements of Photobioreactor Design and Operation

Photobioreactors can assume many configurations. The common requirements and process material balances for well-mixed and tubular photobioreactors in batch and continuous operation are described below.

9.3.1 Common Requirements

A photobioreactor is an enclosed, illuminated culture vessel designed for the controlled biomass production of phototrophic liquid cell suspension cultures. All photobioreactor systems, regardless of configuration, must provide illumination, gas exchange, and mixing. Phototrophic cultures need light as the energy source to drive photosynthesis, and so the photobioreactor must deliver sufficient light to the culture vessel. Phototrophic cultures also use dissolved CO_2 as the inorganic carbon source for photosynthetic biomass production and evolve O_2.

Gas exchange is the process of adding CO_2 to the culture and removing evolved O_2 from the culture. Usually, gas exchange is accomplished by sparging an aeration gas into the liquid suspension culture. The aeration gas contains CO_2 that dissolves into the liquid. For example, ambient air contains about 350 parts per million (ppm) CO_2. The aeration gas also removes evolved O_2 by stripping the dissolved O_2 from the culture liquid to the aeration gas stream. The aeration gas stream exits the culture and carries out the evolved O_2 along with it.

Mixing of the liquid culture is required to suspend the biomass and to promote contact between the liquid nutrient medium and the cells. Mixing also promotes the process of gas exchange. A uniform biomass suspension allows light to uniformly penetrate the culture.

9.3.2 Biomass Production in Well-Mixed Batch or Continuous Operation

Photobioreactors can be operated in either batch or continuous modes, as illustrated in Fig. 9.5. The concepts underlying biomass production in batch and continuous bioreactors are described below.

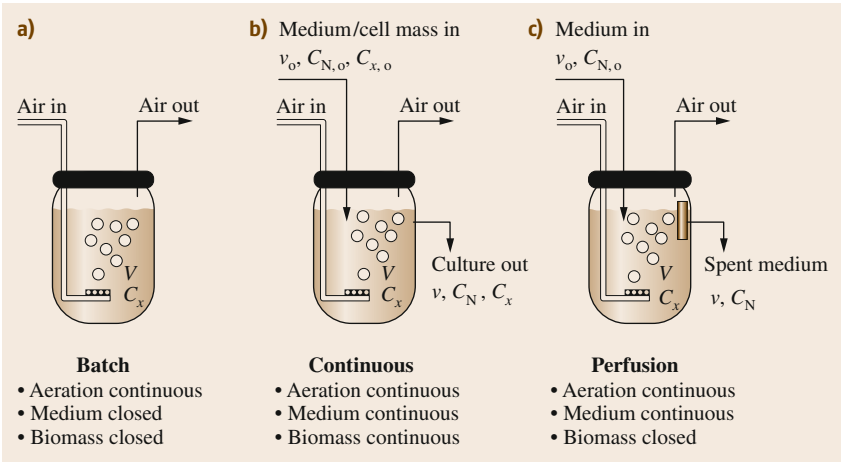

Fig. 9.5a–c Comparison of (**a**) batch, (**b**) continuous, and (**c**) perfusion bioreactors

Well-Mixed Batch Cultures: Unsteady-State Material Balances

In a batch bioreactor, the biomass suspension is retained within the cultivation vessel. Initially, a small amount of suspension culture is added to the vessel containing a liquid medium, which is a process called inoculation. As long as adequate amounts of carbon dioxide and light are continuously provided to the liquid suspension culture, the cell mass grows and consumes the macro and micronutrients dissolved in the liquid medium. The cell density within the culture vessel increases with time until a limiting nutrient within the liquid medium is completely consumed, as illustrated in Fig. 9.6. After the limiting nutrient is completely consumed, cell growth moves to a stationary phase. Other processes can also lead to the stationary phase of growth. For example, the buildup of toxic components in the liquid medium produced by the cells can halt further growth.

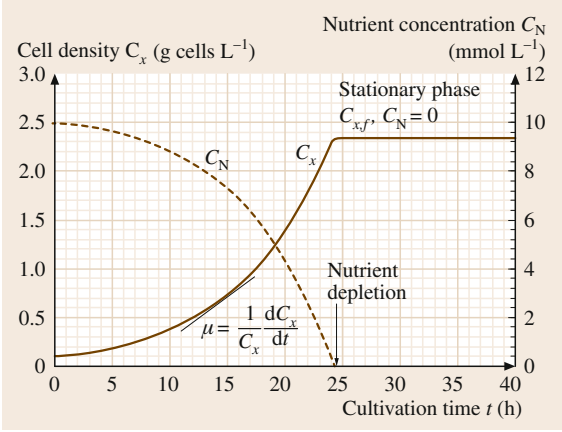

Fig. 9.6 Computed cell density (C_x) and limiting nutrient concentration (C_N) versus cultivation time in a well-mixed batch culture with light-saturated growth showing the final cell density at nutrient depletion. Model input parameters: $K_N = 0.1\,\text{mmol}\,L^{-1}$, $Y_{X/N} = 224\,\text{g cell mol}^{-1}\,\text{N}$, $\mu_{max} = 0.2\,h^{-1}$, $I_k = 50\,\mu\,\text{mol photons}\,m^{-2}\,s^{-1}$, $I = 100\,\mu\,\text{mol photons}\,m^{-2}\,s^{-1}$, $C_{N,i} = 10\,\text{mmol N}\,L^{-1}$, $C_{x,i} = 0.1\,\text{g cell}\,L^{-1}$

Material balances on cell biomass and the dissolved limiting nutrient describe the rates and amounts of biomass production within the batch bioreactor. Here, the cell suspension within the culture vessel is well mixed and the total culture volume is constant. The rate of biomass production is determined from a differential material balance on the cell mass, described in words as

$$\begin{pmatrix}\text{rate of cell mass}\\ \text{added to vessel}\end{pmatrix} - \begin{pmatrix}\text{rate of } \textit{cell} \text{ mass}\\ \text{removed from vessel}\end{pmatrix} + \begin{pmatrix}\text{rate of generation of}\\ \text{cell mass within vessel}\end{pmatrix} = \begin{pmatrix}\text{rate of accumulation of}\\ \text{cell mass within vessel}\end{pmatrix}. \tag{9.15}$$

In a batch reactor, the rates of cell mass addition and removal from the vessel are zero. Mathematically, the differential material balance on cell mass in the batch bioreactor is given by

$$0 - 0 + \mu C_x V = \frac{d\,(C_x V)}{dt}. \tag{9.16}$$

Simplification of (9.16) and combination with (9.12) yields

$$\frac{\mathrm{d}C_x}{\mathrm{d}t} = \mu C_x = \mu' \frac{C_\mathrm{N}}{K_\mathrm{N} + C_\mathrm{N}} C_x \,, \tag{9.17}$$

where C_x is the cell density in the liquid suspension culture (g cells L^{-1} culture), V is the total culture volume, and μ/describes the dependence of specific growth rate on light intensity as presented earlier in (9.11). Equation (9.17) is subject to an initial condition $C_x = C_{x,\mathrm{i}}$ at $t = 0$, the beginning of the cultivation cycle. For now, (9.17) is left in differential form because μ also depends on the delivery of light and CO_2 to the photobioreactor. Detailed methods on how to estimate growth rate in light-limited or CO_2-limited growth are described in Sects. 9.4.2 and 9.4.3.

In a batch bioreactor, the cell mass will not grow forever because at some point the limiting nutrient will be exhausted ($C_\mathrm{N} = 0$). The cell density at nutrient depletion is determined by an integral material balance on the cell mass, which is described in words as

$$\begin{pmatrix} \text{final cell mass} \\ \text{at end of cultivation} \end{pmatrix} - \begin{pmatrix} \text{initial cell mass} \\ \text{at beginning of cultivation} \end{pmatrix} - \begin{pmatrix} \text{amount of cell mass produced} \\ \text{by limiting nutrient consumption} \end{pmatrix} = 0 \,. \tag{9.18}$$

Mathematically, (9.18) is expressed as

$$C_x V - C_{x,\mathrm{i}} V - (C_{\mathrm{N,i}} - C_\mathrm{N}) V Y_{X/\mathrm{N}} = 0 \,, \tag{9.19}$$

where $C_{\mathrm{N,i}}$ is the initial concentration of the limiting nutrient (mol $\mathrm{N\,L}^{-1}$), and $C_{x,\mathrm{i}}$ is the initial biomass concentration (g cells L^{-1}), and $Y_{X/\mathrm{N}}$ is the biomass yield coefficient for the limiting nutrient (g cell produced mol^{-1} N consumed). At nutrient depletion ($C_\mathrm{N} = 0$), (9.19) reduces to

$$C_{x,\mathrm{f}} = C_{x,\mathrm{i}} + C_{\mathrm{N,i}} Y_{X/\mathrm{N}} \,, \tag{9.20}$$

where $C_{x,\mathrm{f}}$ is the final cell density at $C_\mathrm{N} = 0$.

Well-Mixed Continuous Cultures: Steady-State Material Balances

In a continuous bioreactor, the biomass suspension is continuously removed from the culture vessel. Fresh liquid medium enters the culture vessel at a constant volumetric flow rate equal to the volumetric flow rate of the suspension culture exiting the vessel so that the total liquid volume within the vessel is constant. The aeration gas and light are also continuously delivered to the culture vessel. Continuous bioreactors are designed to operate at steady state, meaning that the rate of biomass production within the vessel equals the rate of biomass removal from the vessel. In steady-state operation, the cell density in the vessel does not change with time, and there is no accumulation of cell mass within the culture vessel. If the liquid suspension culture is well mixed within the vessel, then the cell density inside the vessel equals the cell density of liquid suspension culture exiting the vessel.

Material balances on cell biomass and the dissolved limiting nutrient describe the rates and amounts of biomass production within the continuous bioreactor. Again, the cell suspension within the culture vessel is well mixed and the total culture volume is constant. Using (9.15) as a template, the mathematically stated material balance on the cell mass in the continuous bioreactor is given by

$$C_{x,\mathrm{o}} v_\mathrm{o} - C_x v + \frac{\mu' C_x C_\mathrm{N} V}{K_\mathrm{N} + C_\mathrm{N}} = 0 \,. \tag{9.21}$$

In a similar manner, the material balance on the limiting nutrient is

$$C_{\mathrm{N,o}} v_\mathrm{o} - C_\mathrm{N} v + \frac{\mu' C_x C_\mathrm{N} V}{(K_\mathrm{N} + C_\mathrm{N})\, Y_{X/\mathrm{N}}} = 0 \,. \tag{9.22}$$

In continuous culture, D is the dilution rate (h^{-1}), defined as

$$D = \frac{v_\mathrm{o}}{V} \,. \tag{9.23}$$

Usually, there are no cells in the liquid inlet ($C_{x,\mathrm{o}} = 0$) and the volumetric flow rates of the inlet and outlet are equal ($v_\mathrm{o} = v$). In this case, (9.21) and (9.22) are rearranged to yield the following:

$$D = \mu = \frac{K_\mathrm{N}}{K_\mathrm{N} + C_\mathrm{N}} \mu' \,, \tag{9.24}$$

$$C_x = Y_{X/\mathrm{N}} \left(C_{\mathrm{N,o}} - \frac{D K_\mathrm{N}}{\mu' - D} \right) \,, \tag{9.25}$$

$$C_\mathrm{N} = \frac{D K_\mathrm{N}}{\mu' - D} \,. \tag{9.26}$$

Note that (9.25) and (9.26) depend on the dilution rate D. However, D cannot exceed μ'. If D exceeds μ' then

Table 9.5 General comparisons of enclosed photobioreactor configurations

Photobioreactor configuration	Mixing and biomass suspension	Aration and gas exchange	Light transfer	Shear damage to cells	Scale-up difficulty	Comments
Bubble or airlift aerated – planar vessel	Poor–adequate	Excellent	Good	Low	Moderate	Simple design
Bubble or airlift aerated – cylindrical vessel	Good	Excellent	Adequate	Low	Moderate	Simple design

a phenomenon known as *washout* occurs, where the residence time of the cells within the vessel is not sufficient to sustain culture growth at constant cell density. In this instance, the cells leave the vessel faster than new cells can be formed, and the cell density C_x goes to zero. Therefore, continuous flow bioreactors have a limit on the range of dilution rate D. Furthermore, as detailed later in Sect. 9.4.2, within photobioreactor vessels the cell density C_x reduces μ' by a process known as light attenuation. Finally, with C_x known by (9.25), the volumetric biomass production rate of continuous bioreactors is given by

$$r_x = DC_x \,. \tag{9.27}$$

The design equations above all assume that the CO_2 transfer to the culture is always provided at a sufficient rate to avoid CO_2-limited growth, and that the culture growth within the photobioreactor is not subject to light attenuation. It will be shown in Sects. 9.4.2 and 9.4.3 how these equations are used under conditions of light or CO_2-limited growth.

The perfusion bioreactor is the intermediate case between batch and continuous operation (Fig. 9.5). In a perfusion operation, the fresh medium inflow and waste medium outflow are continuous, but the cell mass is retained within the vessel. Therefore, cell density still increases with time. There are many methods to achieve perfusion operation, but the simplest is to put a retaining screen on the culture output line to retain the biomass. Since nutrients are continuously added to the bioreactor, perfusion operation is commonly used to avoid nutrient depletion until some other variable becomes limiting. Thus perfusion operation can increase final cell density.

9.3.3 Enclosed Photobioreactor Configurations

A myriad of elaborate and elegant photobioreactor configurations have been developed. Each configuration seeks to provide the best venue for illumination, aeration, and mixing of the photosynthetic cell suspension culture to promote optimal growth. In general, photobioreactors fall into three configurations, each with several variations on a given theme. These three configurations are the bubble-column/airlift photobioreactor, the stirred-tank photobioreactor, and the tubular photobioreactor. The general characteristics of each configuration are compared in Table 9.5. The photobioreactor vessel can be externally or internally illuminated. Specific examples of externally illuminated photobioreactors are provided in references [9.23–28], and examples of novel internally illuminated photobioreactor configurations are described in references [9.29–33].

Table 9.6 Approximate conversion factors for flux irradiance in the photosynthetically active range (PAR). For example, to convert PAR flux irradiance from energy units of $W\,m^{-2}$ to quantum units of $\mu mol\ photons\,m^{-2}\,s^{-1}$, multiply the numerical value for $W\,m^{-2}$ by 4.6, e.g. $10\,W\,m^{-2}$ multiplied by $4.6\,\mu mol\,m^{-2}\,s^{-1}$ per $1.0\,W\,m^{-2}$ gives $46\,\mu mol\ photons\,m^{-2}\,s^{-1}$

Required units conversion	Light source conversion factor		
	Natural sunlight	Metal halide lamp	White fluorescent lamp
$W\,m^{-2}$ to $\mu mol\ photons\,m^{-2}\,s^{-1}$	4.6	4.6	4.6
klx to $\mu mol\ photons\,m^{-2}\,s^{-1}$	18	14	12
klx to $W\,m^{-2}$	4.0	3.1	3.1

Illumination System and Vessel Material Requirements

Illumination of photobioreactors can be either external or internal. The light source for the externally illuminated photobioreactors is positioned outside the culture vessel. Therefore, the culture vessel wall is constructed of a transparent material to allow the transfer of light to the photosynthetic liquid suspension culture. The light source for internally illuminated photobioreactors is placed within the culture vessel.

Light sources for illumination of photobioreactors can be either artificial or natural. Common artificial light sources include fluorescent lamps and metal halide lamps, which provide irradiance in the photosynthetically active range of 400–700 nm. Irradiance is best expressed in terms of quantum photon flux, with common units of $\mu mol\ photons\,m^{-2}\,s^{-1}$. Common conversion factors that relate quantum photon flux to energy flux or other units of light measurement for common light sources are provided in Table 9.6. Fluorescent lamps are relatively inexpensive and can easily provide incident light intensities up to $150\,\mu mol\ photons\,m^{-2}\,s^{-1}$, whereas halogen lamps are more expensive but provide higher incident light intensities up to about $500\,\mu mol\ photons\,m^{-2}\,s^{-1}$. The lamps are arrayed on a grid to uniformly illuminate the vessel surface. More exotic and expensive artificial light sources include light emitting diodes or Xenon lamp sources with fiber optic light delivery systems. These light sources are used for internally illuminated photobioreactors. References on fiber optic illumination systems are provided in the Suggested Reading section at the end of this chapter.

Natural sunlight obviously provides the best quality PAR at high irradiance near $1000–2000\,\mu mol\ photons\,m^{-2}\,s^{-1}$ and is free. However, natural sunlight also has many drawbacks for bioprocess technology applications. First, the photobioreactor must be placed outdoors, which places severe constraints on sterility and temperature control. Second, it is very difficult to achieve reproducible light delivery as the light intensity of natural sunlight is dependent on several variables, including the weather, the time of day, the time of year, and geographic location.

Wasted light energy input to photobioreactors is dissipated as heat, and so the vessel must be temperature controlled. Usually, a heat exchanger is installed into the culture vessel to control the temperature of the liquid suspension culture. The heat exchanger usually consists of coiled metal tube bank that contacts the liquid culture within the vessel. Cold water pumped through the heat exchanger tubes cools the culture. Alternatively, hot water or steam pumped through the heat exchanger tubes heats the culture. Principles of heat exchanger design are beyond the scope of this presentation.

In general, externally illuminated photobioreactors are easier to design, fabricate, and operate than internally illuminated photobioreactors. This presentation of photobioreactor configurations focuses on externally illuminated photobioreactors with a uniform light source. A parameter common to all externally illuminated photobioreactors is the illumination surface area to volume ratio

$$S/V = \frac{\text{illuminated surface area of vessel exposed to culture}}{\text{culture volume inside vessel}} . \qquad (9.28)$$

The externally illuminated photobioreactor configurations described below seek to maximize S/V while providing adequate mixing and gas exchange.

Suitable materials for externally illuminated photobioreactor culture vessels depend on the vessel configuration. Furthermore, phototrophic marine organisms are cultivated in a salt water medium which is highly corrosive. Therefore, wetted parts are constructed of stainless steel or inert plastics such as polyethylene, polypropylene, Plexiglass, or clear polyvinylchloride (PVC). The transparent portions of column and planar photobioreactor vessels are constructed of glass or plexiglass sheets. Tubular photobioreactors are constructed of transparent rigid plexiglass tubing, translucent rigid

or flexible PVC tubing, or translucent flexible silicone tubing. The plastic materials also must be resistant to UV radiation from the illumination source.

Bubble-Column and Airlift Photobioreactors

The basic features of bubble-column and airlift photobioreactors in both cylindrical and planar vessel configurations are provided in Figs. 9.7 and 9.8 respectively. Aeration provides both mixing and gas exchange. The aeration gas stream is continuously injected to the bottom of the vessel through a sparger. The sparger forms small bubbles in the liquid medium. The bubbles rise through the culture and generate liquid convection currents, which mix and suspend the cells in the liquid medium. In the bubble column configuration, air is uniformly injected across the bottom of the vessel, and the rising bubbles fill the liquid volume. In the airlift configuration, air is injected only into the riser section. The air bubbles break up at the liquid surface, and the upward liquid flow generated by the rising air bubbles now moves downward through the downcomer section. Although the airlift configuration only aerates a portion of liquid in the vessel, the overall liquid circulation pattern within the vessel is uniform and promotes mixing and suspension of biomass. Airlift or bubble column aeration is a gentle means of mixing and biomass suspension and thus is appropriate for marine organisms that are fragile and easily damaged by fluid shear forces. Bubble-column and airlift photobioreactors can be operated in either batch or continuous biomass production modes.

Light delivery to bubble-column or airlift photobioreactors determines the vessel configuration. The two most basic vessel configurations are planar and cylindrical. The planar photobioreactor configuration (Fig. 9.8) is designed to minimize the path length for light penetration into the suspension culture and maximize the illumination surface area to culture volume ratio. The flat surface of the vessel is illuminated, either from one or both sides. The aeration gas is injected uniformly across the bottom of the vessel. Although light transfer is generally good, mixing is often

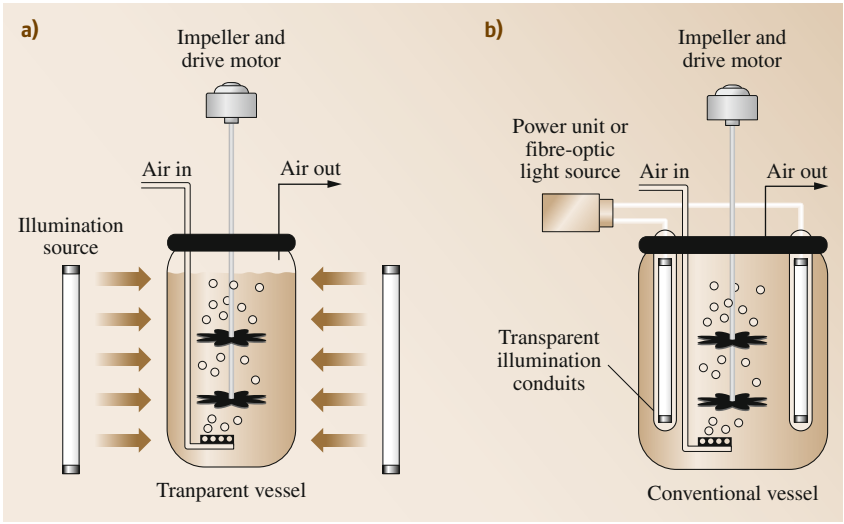

Fig. 9.9a,b Comparison of externally and internally illuminated stirred-tank photobioreactors. **(a)** External illumination, **(b)** internal illumination

non-uniform and dead zones occur where cell mass settles to the bottom corners of the vessel. Non-uniform mixing becomes more problematic as the culture volume increases upon process scale-up, particularly above 2000 L. The cylindrical photobioreactor configuration (Fig. 9.7) is designed to promote mixing and biomass suspension while maintaining an acceptable illumination surface area to culture volume ratio. The illumination source is aligned around the outside surface of cylindrical vessel or placed within an annular space in the center of the vessel. There are many variations to these basic planar and column photobioreactor configurations.

Stirred-Tank Photobioreactors

Externally and internally illuminated stirred-tank photobioreactor configurations are illustrated in Fig. 9.9. Stirred-tank photobioreactors provide the best venue for mixing and gas exchange because the impeller mechanically agitates the culture to suspend the biomass and to break up and disperse the aeration gas bubbles into the liquid phase. Stirred tank bioreactors of cylindrical vessel geometry typically have a height to diameter ratio of less than 3. Consequently, externally illuminated stirred tank photobioreactors are not practical at culture volumes exceeding 100 L because the path length for light penetration to the suspension culture is too large. Internal illumination can circumvent this light transfer constraint but complicates mixing and vessel design. Transparent glass or plastic tubes sealed at one end are mounted through the head plate of the vessel to accommodate fluorescent lamps. The lamps can be removed or replaced without opening the vessel. More advanced internally illuminated photobioreactors use fiber optics to deliver light to the culture [9.29–33].

Tubular Photobioreactors

The tubular photobioreactor is designed to minimize the path length for light penetration into the suspension culture and concurrently maximize the illumination sur-

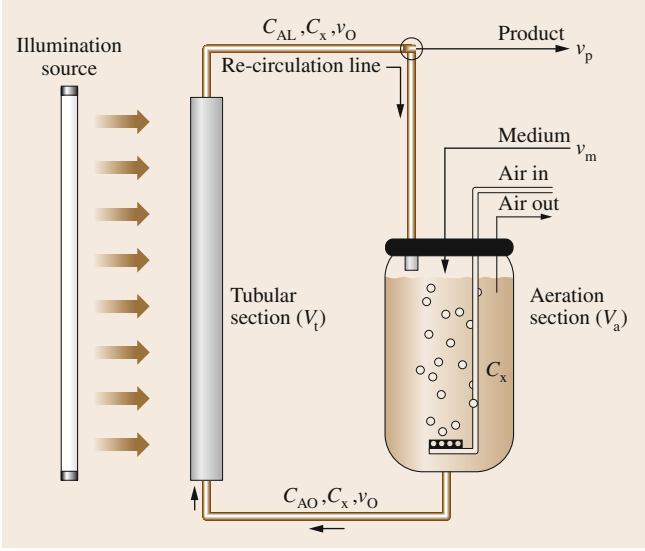

Fig. 9.10 Basic configuration of the externally illuminated tubular photobioreactor, featuring tubular section, aeration tank, and re-circulation line for batch or continuous operation

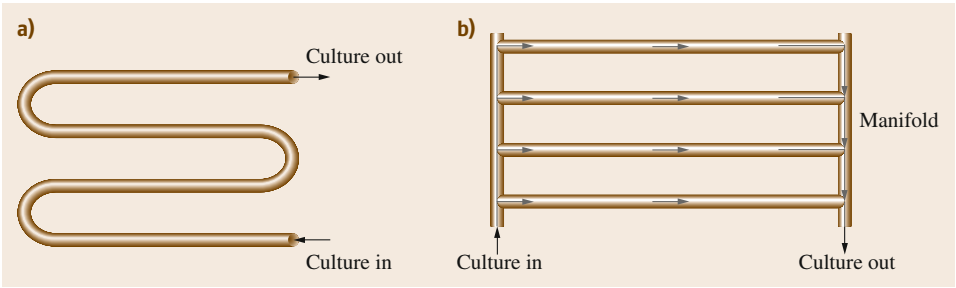

Fig. 9.11a,b Tubular photobioreactors: comparison of **(a)** single-tube bank and **(b)** parallel tube bank with manifold

face area to culture volume ratio. Tubular photobioreactors are much easier to scale up to large culture volumes exceeding 2000 L. Tubular photobioreactors can also be operated in batch or continuous biomass production modes, as described at the end of this section.

Most tubular photobioreactors have an aeration section connected to a tubular section, as shown in Fig. 9.10. The aeration section carries out the gas exchange processes for the entire photobioreactor. The aeration section is usually not illuminated. The tubular section is illuminated to promote photosynthetic biomass production. The tubular section is not usually aerated, as it is often difficult for air bubbles to travel down the length of tube. Therefore, the aeration section delivers CO_2 to the liquid suspension culture, whereas the culture within the tubular section consumes CO_2 by photosynthesis. Since the tubular section is not aerated, the CO_2 concentration in the liquid medium decreases and the dissolved O_2 concentration increases as the suspension culture moves down the length of the tube. Consequently, the phototrophic suspension culture is continuously re-circulated between the aeration section and the tubular section to replenish the suspension culture with CO_2 consumed by photosynthesis and to remove the O_2 buildup created by photosynthesis. Carbon dioxide-limited growth occurs when the dissolved CO_2 concentration inside the tube goes to zero. In order to avoid CO_2-limited growth, the residence time of the culture within the tube is short and so the biomass cell density is essentially constant for a single pass through the tubes. Cumulative biomass production occurs over many passes between the aeration tank and tubular section.

Light delivery to tubular photobioreactors is usually excellent because the maximum path length for light transfer is the diameter of the tubing. Typically, even for large-scale systems exceeding 1000 L, tubing diameters are below 6 cm. The light path length for the tubular photobioreactor is the shortest of all photobioreactor systems. The configuration of a particular tubular photobioreactor is determined by the arrangement of the tubing bank relative to the external illumination system. Three common tubular photobioreactor configurations are the horizontal tube bank, the vertically stacked tube bank, and the helical tube bank. Most tubing banks use a manifold to distribute the culture flow between several tubes running in parallel (Fig. 9.11). Manifold tube banks also reduce the pressure drop associated with frictional losses as the culture moves through the tubing, since the tubing length is reduced proportional to

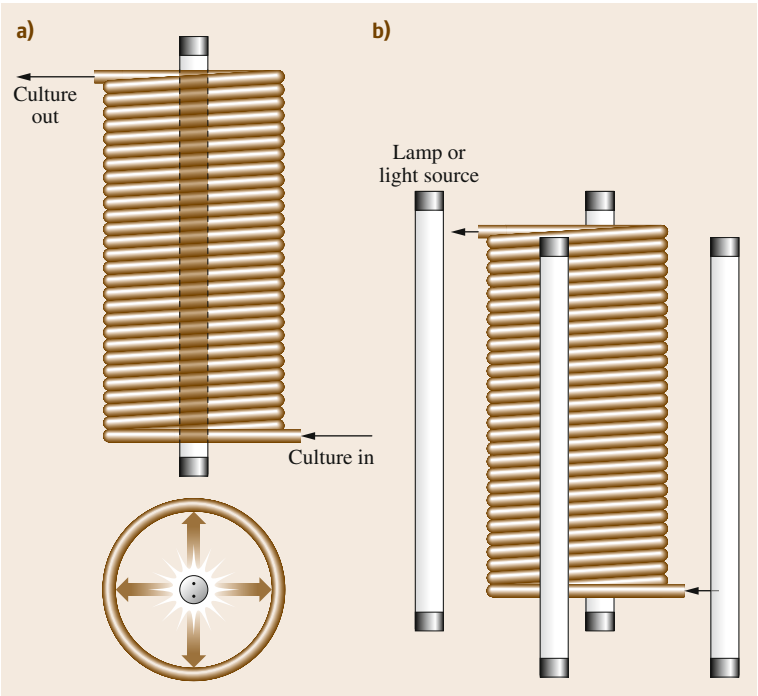

Fig. 9.13a,b Tubular photobioreactors: **(a)** internal versus **(b)** external illumination of helically wrapped tube array

the number of manifolds. The horizontal tube bank is illuminated from only one side (Fig. 9.12a), whereas the vertically stacked tube bank can be illuminated from two sides (Fig. 9.12b), similar to the planar photobioreactor. The helical tube bank is wrapped around a cylindrical support, and the tubing is essentially vertically stacked (Fig. 9.13). The lamps are placed within the tubing coil (Fig. 9.13a) or outside of the tubing coil (Fig. 9.13b).

There are two important parameters that characterize the flow of the liquid suspension culture inside the tube. The culture flow rate inside the tubing should be turbulent to adequately suspend the cell suspension as it travels down the length of the tube. The Reynolds number is a dimensionless parameter that defines the conditions for turbulent flow. The Reynolds number for flow of the liquid suspension culture through a tube is given by

$$\mathrm{Re} = \frac{v\rho_c d}{\mu_c} , \tag{9.29}$$

where d is the inner diameter of the tubing, v is the bulk linear velocity of the liquid culture (volumetric flow rate divided by cross-sectional area, $\mathrm{m\,s^{-1}}$), μ_c is the apparent viscosity of the liquid suspension culture ($\mathrm{kg\,m^{-1}\,s^{-1}}$), and ρ_c is the overall density of the liquid suspension culture ($\mathrm{kg\,m^{-3}}$). For simplicity, μ_c and ρ_c approximate the properties of the liquid medium, which in turn approximate the properties of water. Turbulent flow occurs at $\mathrm{Re} \geq 2000$. If the tube diameter is 2 cm, then the linear velocity for turbulent flow begins at about $10\,\mathrm{cm\,s^{-1}}$. Common linear velocities in tubular photobioreactors range from $30–50\,\mathrm{cm\,s^{-1}}$. Another important flow parameter for tubular photobioreactors is the culture residence time inside the tube

$$\tau_{\mathrm{tube}} = \frac{V_t}{v_o} , \tag{9.30}$$

where V_t is the volume of the culture in the tube.

There are two basic methods for circulating the liquid suspension culture between the aeration tank and the tubular section, as illustrated in Fig. 9.14. In Fig. 9.14a, the culture is mechanically pumped from the exit of the aeration tank to the entrance of the tubular section. The culture flow exiting the tubular section is returned to the aeration tank. In Fig. 9.14b, the culture exiting the tubular section is sent to an airlift riser. Air injected into the bottom of the riser section moves the culture up to a holding tank and simultaneously promotes gas exchange. The liquid suspension culture exits the holding tank and flows by gravity through the

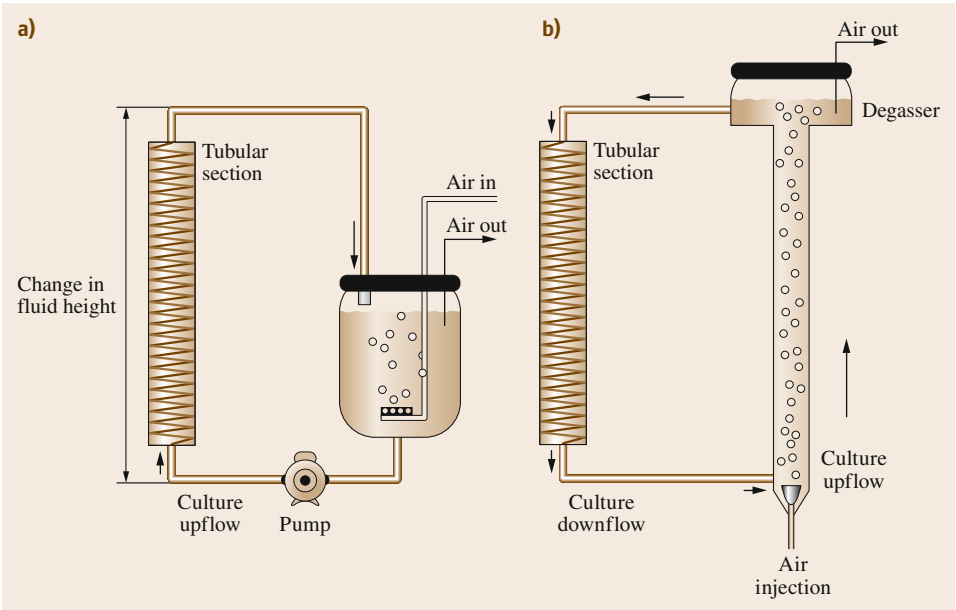

Fig. 9.14a,b Tubular photobioreactors: **(a)** mechanical versus **(b)** airlift pumping

tubular section. In both configurations, the culture recirculation system must compensate for pressure drop due to friction of the culture with the tubing walls and the difference in elevation between the tubular section entrance and exit points. The airlift system is relatively gentle on the cells and has no moving parts, but cannot accommodate high flow rates or pump against high fluid heads. The mechanically pumped system can provide high flow rates against high pressure drops. However, the pump can potentially damage the culture if the cells are fragile towards hydrodynamic or mechanical shear forces. In this context, volumetric pumps, where the pump rotor speed is proportional to flow rate, are preferred over centrifugal pumps, where the rotor speed is fixed independently of culture flow rate. Diaphragm pumps also provide relatively low shear.

A variant of the airlift pumping system for the tubular photobioreactor is the airlift tubular photobioreactor. It combines the elements of an airlift and tubular bioreactors into one system, as illustrated in Fig. 9.15. In the airlift tubular photobioreactor, the tube is inclined upward at an angle. Air is injected into the bottom of the tube to provide gas exchange and to move the suspension culture up the tube. Since the aeration gas is inside the tube, the tubing diameter is larger than that for conventional tubular reactors. Furthermore, the reactor volume must be increased to compensate for the space occupied by the bubbles. At the top of the tube is a degassing vessel where the aeration gas exits the system, and the culture flows back down to the bottom of the tube.

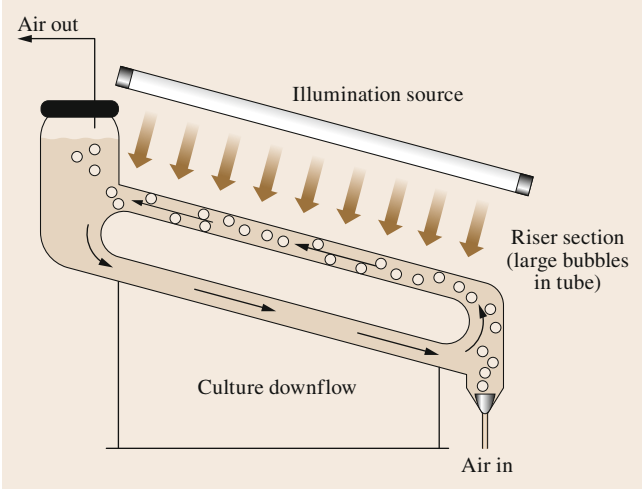

Fig. 9.15 The inclined tubular airlift photobioreactor

Tubular Recycle Photobioreactors

The tubular photobioreactors described above are designed for batch operation. Even though the culture is continuously flowing in and out of the tubing bank, it is still recirculating between the tubular section and

the aeration section and so there is no net flow of the culture out of the system. However, the tubular photobioreactor can be converted from batch operation to continuous operation by adding a product line to the re-circulation loop, as shown in Fig. 9.10. In the continuous recycle mode of operation, the liquid suspension culture exiting the tubular section is divided into two streams. The first stream, called the recycle line, is returned to the aeration section. The second stream, called the product line, is withdrawn from the system at a constant volume flow rate. The recycle ratio is defined as

$$R_p = \frac{v_o}{v_p} , \tag{9.31}$$

where v_o is the culture volumetric flow rate in the recycle line and v_p is the volumetric flow rate in the product line. As described earlier in Sect. 9.3.2, to maintain steady-state, constant cell density operation, fresh liquid medium is added to the aeration section at a volumetric flow rate equal to the volumetric flow rate of culture removal (i. e., $v_p = v_m$).

9.4 Limiting Factors in Photobioreactor Design and Operation

There are three major processes that limit photosynthetic biomass production in a photobioreactor. The first process, macronutrient limitation, was discussed in Sect. 9.3.2. The second process is the delivery of light for photosynthesis. The third process is the delivery of CO_2 for photosynthesis. Light delivery is traditionally seen as the limiting process to biomass production. However, CO_2 delivery limitations can be significant and are often overlooked in photobioreactor design and operation. In this section, methods are presented to estimate the combined effects of light delivery and CO_2 delivery on biomass production in photobioreactors. The modeling of light and CO_2 limitations in enclosed photobioreactors is described in several excellent references [9.34–40]. Process scale-up, measurement, and control issues in photobioreactor design and operation are also described, as they follow from the presentation of light and CO_2 delivery limitations.

9.4.1 Five Steps for Photobioreactor Design

Successful photobioreactor design depends on understanding light and CO_2 limitations. In this context, photobioreactor design has five major steps:

1. Use biomass stoichiometry to calculate the limiting nutrient concentration in the liquid medium necessary to achieve the desired final cell density in the vessel (Sect. 9.2.1).
2. Select a batch or continuous biomass production process. For relatively low rates of biomass production (e.g., $10–100\,kg\,d^{-1}$), consider a batch process. For higher biomass production rates, consider a continuous process (Sect. 9.3.2).
3. Select the photobioreactor configuration and incident light intensity which provides sufficient light delivery to the culture, and then compute the path length for light transfer so that the mean light intensity $I_m \geq I_k$ (Sect. 9.4.2).
4. Based on *step 3* above, design the aeration system to provide a CO_2 transfer rate (CO_2-TR) that is sufficient to avoid CO_2-limited growth at the final cell density in the culture vessel (Sect. 9.4.3).
5. Based on *step 3*, above, determine the cultivation time (batch process) or the culture residence time (continuous process) and the vessel volume required to satisfy the biomass production schedule.

Engineering analysis falls into two primary categories: design and performance analysis. Design starts with a set of process performance targets, e.g., required biomass production rate or cell density, and determines the photobioreactor design parameters necessary to achieve the production target. Specific design parameters include nutrient concentration in the liquid medium, vessel size and configuration, illumination system settings, and aeration system settings. In contrast, performance analysis usually begins with a photobioreactor system already in place that is operating at a given set of medium, illumination, and aeration conditions. Performance analysis estimates the biomass production at this set of process conditions. Below, the quantitative relationships needed for both process design and performance analysis are presented.

9.4.2 Light-Limited Growth

Light Attenuation

The specific growth rate of phototrophic organisms exhibits saturation growth kinetics with respect to incident light intensity. Therefore, the delivery of light to the photobioreactor in part determines the biomass pro-

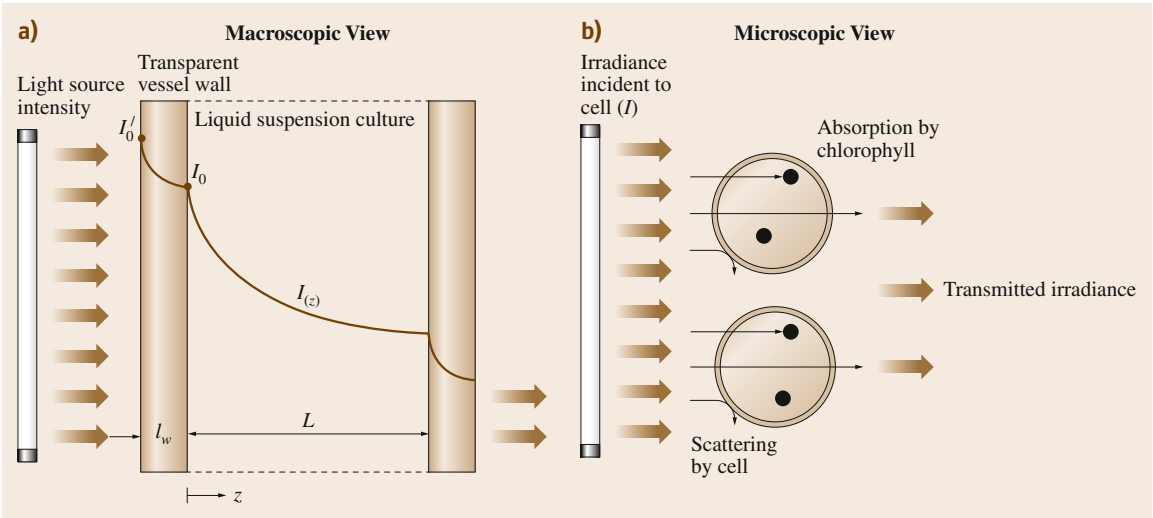

Fig. 9.16a,b Light attenuation for one-dimensional light transfer through the vessel wall and liquid suspension culture. **(a)** Macroscopic view, **(b)** microscopic view

ductivity in the photobioreactor. Consider a simple case illustrated in Fig. 9.16, where a transparent vessel of planar configuration is uniformly illuminated from one side. Recall that light intensity is expressed in units of flux. Light transfers through the transparent vessel wall and then penetrates the suspension culture (Fig. 9.16a). As the light penetrates into the suspension culture, photons are absorbed by the chlorophyll in the cells for photosynthesis or scattered by the cells in the suspension (Fig. 9.16b). The superimposing effects of absorption and scattering reduce the light flux. The light intensity decreases with increasing path length for the light flux and increasing biomass concentration in the liquid suspension. The reduction in light intensity is called light attenuation. The Beer–Lambert law for one-dimensional light transmission approximates the light intensity $I(z)$ as a function of path length z and biomass concentration C_x

$$I(z) = I_o e^{-k_c C_x z}\,, \tag{9.32}$$

where k_c is the specific attenuation constant of the phototrophic cell suspension culture (L(g cells cm)$^{-1}$). Values for k_c can range from 0.1–2.0 L(g cells cm)$^{-1}$ and are linear function of the specific chlorophyll concentration (Y_c) in the cell. Values for k_c are unique for a given phototrophic organism and must be experimentally determined, since the concentration of light absorbing pigments and the size of the cell aggregates can vary considerably even within a given species.

As seen in Fig. 9.17, light attenuation follows an exponential decay function. At long path lengths and high cell densities, the local light intensity $I(z)$ can approach zero. In this situation, the specific growth rate will also go to zero and no growth will occur. This behavior suggests three basic regimes for light attenuation within the vessel. Each regime can be referenced with respect to the I_k value for a given organism. In the first regime,

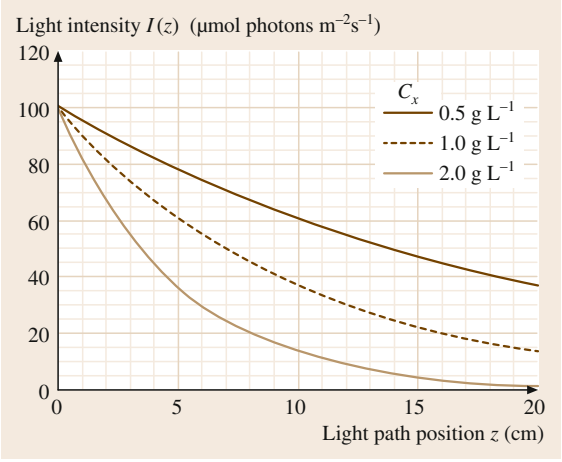

Fig. 9.17 Calculated light intensity (I) versus light path position (z) and cell density (C_x) for one-dimensional light transfer through well-mixed cell suspension culture of total light path length $L = 20$ cm. Model input parameters: $I_o = 100\,\mu$mol photons m^{-2} s^{-1}, $k_c = 0.1$ L (g cell cm)$^{-1}$

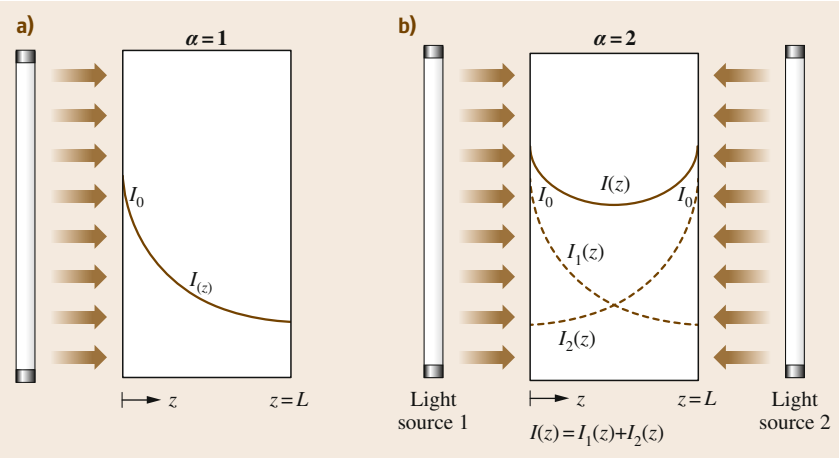

Fig. 9.18a,b Superposition of light intensity distribution for one-dimensional light transfer: comparison of **(a)** single-plane ($\alpha = 1$) versus **(b)** dual-plane ($\alpha = 2$) external illumination

$I(z) \gg I_k$, and the specific growth rate is not significantly affected by light intensity as the light intensity is near saturation. In the second regime, $I(z)$ is on the same order of magnitude as I_k, and the specific growth rate is now affected by the reduction in light intensity. In the third regime, $I(z) \ll I_k$, and the specific growth rate is now close to zero, the so-called dark zone.

Mean Light Intensity

It follows from the above discussion that the light intensity distribution sets the specific growth rate distribution of the phototrophic suspension culture within the photobioreactor. If the suspension culture is well mixed, then the cells circulate between areas of relatively high light intensity near the surface of the vessel and relatively low light intensities deeper within the vessel. In essence, all the cells within the suspension culture experience a mean light intensity that, in turn, sets the average specific growth rate of the culture. The mean light intensity is best determined by integrating the light distribution function over path length for light transfer. For the one-dimensional transfer of light across the width of a planar vessel shown in Fig. 9.18, the mean light intensity I_m is

$$I_m = \frac{1}{L}\int_0^L \alpha\, I(z)\,\mathrm{d}z = \frac{1}{L}\int_0^L \alpha\, I_o \mathrm{e}^{-k_c C_x z}\,\mathrm{d}z$$
$$= \frac{\alpha\, I_o}{k_c C_x L}\left(1 - \mathrm{e}^{-k_c C_x L}\right) , \qquad (9.33)$$

where α is the view factor for one-dimensional light transfer, representing the number of planes of light delivery: $\alpha = 1$ for one-sided illumination, $\alpha = 2$ for two-sided illumination.

Basic concepts for light attenuation in the one-dimensional system described by Fig. 9.18 and (9.33) can be extended to photobioreactors with more sophisticated vessel geometry and view factors for light delivery to the vessel surface. The mathematical aspects of these analyses can become quite complicated and are beyond the scope of this chapter. However, three cases are considered here. First, consider the photobioreactor vessel of planar geometry with two planes of light delivery shown in Fig. 9.18b. In this configuration, light is symmetrically delivered to the vessel surface from opposite sides. The light flux incident to the cells superimposes, so that the light flux from the left side and the light flux from the right side are simply added together at a given position within the path length for light transfer. In this illumination arrangement, α is equal to 2. Second, consider a photobioreactor vessel of cylindrical geometry of radius R uniformly illuminated around the vessel circumference with incident light intensity I_o (Fig. 9.19). In this more complicated case, the cross-sectional area for light transfer is a function of radial position within the vessel. The mean integral for I_m is given by

$$I_m = \frac{4 I_o \mathrm{e}^{-k_c C_x R} \sinh(k_c C_x R)}{k_c C_x R} . \qquad (9.34)$$

Finally, consider a parallel array of narrow cylindrical tubes, where the entire bank of tubes is uniformly illuminated from one side (e.g., Fig. 9.12). The diameter of the tube represents the longest light path for light. If the bank of tubes is approximated by a flat plate with the

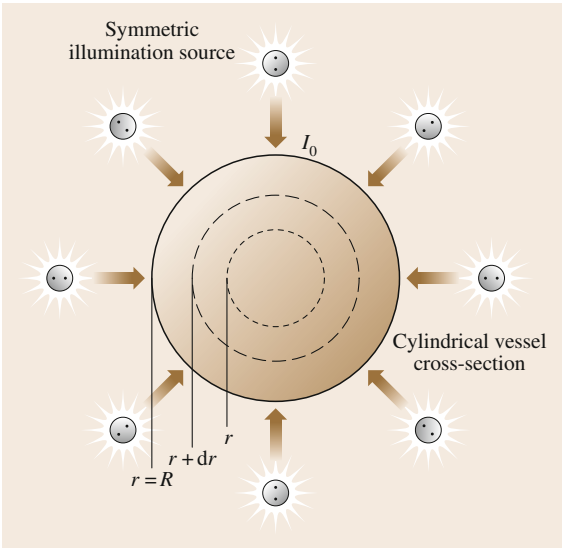

Fig. 9.19 Symmetrical, external light delivery to a cylindrical photobioreactor vessel

tubing diameter as path length for light transfer, then (9.33) can still be used to provide the most conservative approximation for the mean light intensity I_m.

Often the vessel wall material itself is not perfectly transparent and attenuates light, as illustrated in Fig. 9.16. Therefore, the transfer of light from the outer surface of the vessel to the culture encounters two resistances in series: the vessel wall and the liquid suspension culture itself. From the Beer–Lambert law, the light intensity incident to the outer vessel surface is related to the light intensity incident to the culture on the inner vessel surface by

$$I'_o = I_o e^{-k_w l_w} , \tag{9.35}$$

where k_w is the specific light attenuation constant for the vessel wall material (cm $^{-1}$), I'_o is the light intensity incident to the outer vessel wall surface, and l_w is the thickness of the vessel wall. Typical values of k_w for a transparent Plexiglass sheet and translucent silicon rubber tubing are 0.05 and 0.5 cm^{-1}, respectively. Values for k_w are best determined experimentally. The mean light intensity in terms of I'_o can be estimated by simply inserting (9.35) into (9.33).

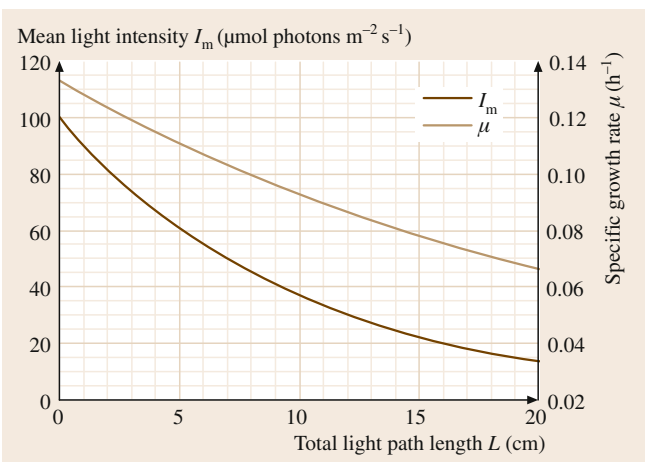

Fig. 9.20 Calculated effect of total light path length (L) on mean light intensity (I_m) and specific growth rate (μ) for one-dimensional light transfer. Model input parameters: $I_o = 100\,\mu mol\ photons\ m^{-2}\ s^{-1}$, $k_c = 0.1\,L\,(g-cell-cm)^{-1}$, $C_x = 2\,g\,cell\,L^{-1}$, $\alpha = 1$

Effects of Mean Light Intensity on Growth Rate and Biomass Production

Light attenuation reduces the mean light intensity (I_m) experienced by the phototrophic liquid suspension culture within a photobioreactor vessel. If the culture is uniformly mixed, the mean light intensity sets the specific growth rate. Therefore, in (9.11) the light intensity (I) is replaced with I_m, so that

$$\mu = \frac{C_N}{K_N + C_N} \frac{I_m(C_x)}{I_k + I_m(C_x)} \mu_{max} . \tag{9.36}$$

Recall from (9.33) that I_m is a function of the incident light intensity I_o, the path length for light transfer into the photobioreactor, and the cell density C_x. During phototrophic cultivation, the incident light intensity and path length for light transfer are fixed. However, as cell density C_x increases, I_m decreases and hence the specific growth rate μ decreases. The process of light attenuation therefore reduces biomass production. In particular, if the culture is not CO_2-limited, then biomass production for the well-mixed batch bioreactor described by (9.17) now becomes

$$\frac{dC_x}{dt} = \mu C_x = \frac{C_N}{K_N + C_N} \frac{I_m(C_x)}{I_k + I_m(C_x)} \mu_{max} C_x , \tag{9.37a}$$

with

$$\frac{dC_N}{dt} = -\frac{\mu}{Y_{X/N}} C_x . \tag{9.37b}$$

Equations (9.37a) and (9.37b) are subject to the initial conditions $C_x = C_{x,i}$, $C_N = C_{N,i}$ at $t = 0$.

The output cell density and limiting nutrient concentration for the well-mixed continuous-flow bioreactor described by (9.25) and (9.26) now become

$$C_x = Y_{X/N}\left(C_{N,o} - \frac{DK_N}{\frac{I_m(C_x)}{I_k + I_m(C_x)}\mu_{max} - D}\right) \tag{9.38}$$

and

$$C_N = \frac{DK_N}{\frac{I_m(C_x)}{I_k + I_m(C_x)}\mu_{max} - D}\,. \tag{9.39}$$

If the path length L is increased, then I_m and μ also decrease. To illustrate, the effect of light path length L on I_m and μ for a planar vessel with one-sided illumination ($\alpha = 1$) is presented in Fig. 9.20.

Biomass production for light-limited growth of phototrophic liquid suspension cultures in tubular photobioreactors follows from the equations described above. In the tubular photobioreactor, the tubular section improves the access of the culture to light. However, in order to avoid CO_2-limited growth, the residence time of the culture within the tube is short and so the biomass cell density is essentially constant for a single pass through the tubes. Cumulative biomass production occurs over many passes between the aeration tank and tubular section. Consequently, for batch operation of the tubular photobioreactor, the material balance development parallels that of (9.37a), but with one important modification. In the tubular photobioreactor, the aeration tank is not illuminated, and so only the tubular section culture volume V_t can promote photosynthetic growth. In this case, the biomass production rate for batch growth of the photosynthetic tubular photobioreactor under light-limited conditions is given by

$$\frac{dC_x}{dt} = \frac{V_t}{V}\mu C_x = \frac{V_t}{V}\frac{C_N}{K_N + C_N}\frac{I_m(C_x)}{I_k + I_m(C_x)}\mu_{max}C_x\,. \tag{9.40}$$

Model predictions reveal how light transfer affects biomass productivity in photobioreactors. The effect of light attenuation on cell growth kinetics is shown in Fig. 9.21. The batch cultivation is carried out in a well-mixed planar photobioreactor illuminated from one side. The growth curve (C_x versus t) and substrate consumption curve (C_N versus t) are generated by numerically integrating (9.37a) and (9.37b) over time using the model input parameters given in the caption of Fig. 9.21 and (9.20) as the limiting nutrient balance for estimation of C_N. As the cell density (C_x) increases with time, the mean light intensity I_m decreases, and the biomass production rate slows down. When the limiting nutrient is completely consumed the cell density becomes constant. As the path length for light transfer in the planar photobioreactor is increased from 5 to 20 cm, the biomass production rate decreases markedly. The effect of light attenuation on cell growth kinetics in a well-mixed continuous photobioreactor is shown in Fig. 9.22. Increasing dilution rate D (9.23) by increasing the volumetric flow rate of feed medium increases biomass productivity until washout is observed. Increasing the light path length L from 5 to 10 cm markedly decreases the optimum biomass production rate. Therefore, increasing light attenuation by increasing the path length for light transfer significantly lowers the performance of both batch and continuous photobioreactors in light-limited growth.

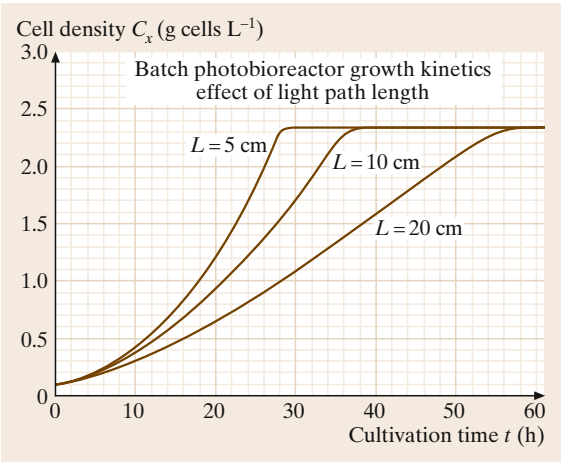

Fig. 9.21 Calculated effect of total light path length (L) on the cell density versus time curve within a well-mixed planar photobioreactor under *batch*, light-limited growth. Model input parameters: $\mu_{max} = 0.2\,h^{-1}$, $I_k = 50\,\mu mol\ photons\ m^{-2}\ s^{-1}$, $K_N = 0.1\,mmol\,L^{-1}$, $Y_{X/N} = 224\,g\ cell\ mol^{-1}\ N$, $k_c = 0.5\,L(g\,cell\,cm)^{-1}$, $C_{x,i} = 0.1\,g\,cells\,L^{-1}$, $C_{N,i} = 10\,mmol\,N\,L^{-1}$, $I_o = 150\,\mu mol\ photons\ m^{-2}\ s^{-1}$, $\alpha = 1$ (one-sided illumination)

9.4.3 Carbon Dioxide–Limited Growth

Phototrophic liquid suspension cultures utilize dissolved CO_2 as the sole inorganic carbon source for photosynthetic biomass production. Carbon dioxide is supplied to the culture by contacting the liquid medium with an aeration gas containing CO_2, for example by

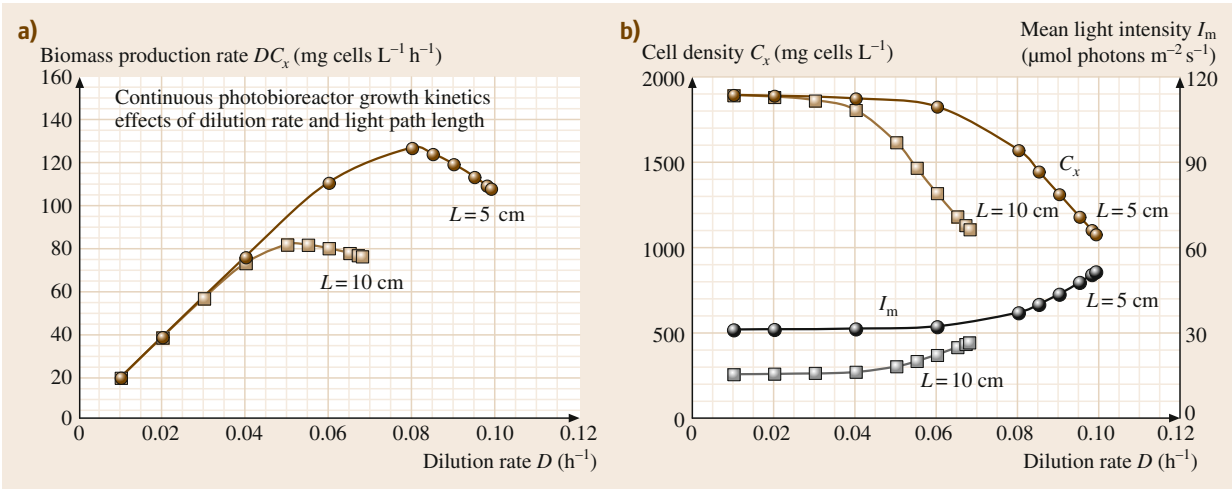

Fig. 9.22a,b Calculated effect of total light path length (L) and dilution rate on biomass productivity in well-mixed planar photobioreactor under *continuous*, light-limited growth. Model input parameters: $\mu_{max} = 0.2\,h^{-1}$, $I_k = 50\,\mu mol\ photons\ m^{-2}\ s^{-1}$, $K_N = 0.1\,mmol\,L^{-1}$, $Y_{X/N} = 224\,g\,cell\,mol^{-1}\,N$, $k_c = 0.5\,L\,(g\,cell\,cm)^{-1}$, $C_{x,o} = 0\,g\,cells\,L^{-1}$, $C_{N,o} = 10\,mmol\,N\,L^{-1}$, $I_o = 150\,\mu mol\ photons\ m^{-2}\ s^{-1}$, $\alpha = 1$ (one-sided illumination). **(a)** Biomass productivity, DC_x; **(b)** cell density C_x, and mean light intensity I_m at C_x

bubbling air containing CO_2 directly into the liquid suspension culture. The CO_2 entering the photobioreactor with the aeration gas can transfer from the gas phase to the liquid phase and become consumed by the photosynthetic cells, or simply exit with the aeration gas, as shown in Fig. 9.23.

The CO_2 is transferred from the gas phase to the liquid phase by a process known as interphase mass transfer. The CO_2 dissolved in the liquid phase is then consumed by the photosynthetic cells and incorporated into cellular biomass. If the CO_2 transfer rate provided by aeration and interphase mass transfer (i. e., the CO_2-TR) is not sufficient to meet the CO_2 consumption demand by the photosynthetically active culture, then the biomass production rate is CO_2 limited. Therefore, the rate at which CO_2 is delivered to the culture can have a significant impact on biomass productivity. The purpose of this section is to quantitatively define conditions that result in CO_2-limited growth and to identify strategies that avoid CO_2 limitations in photobioreactors.

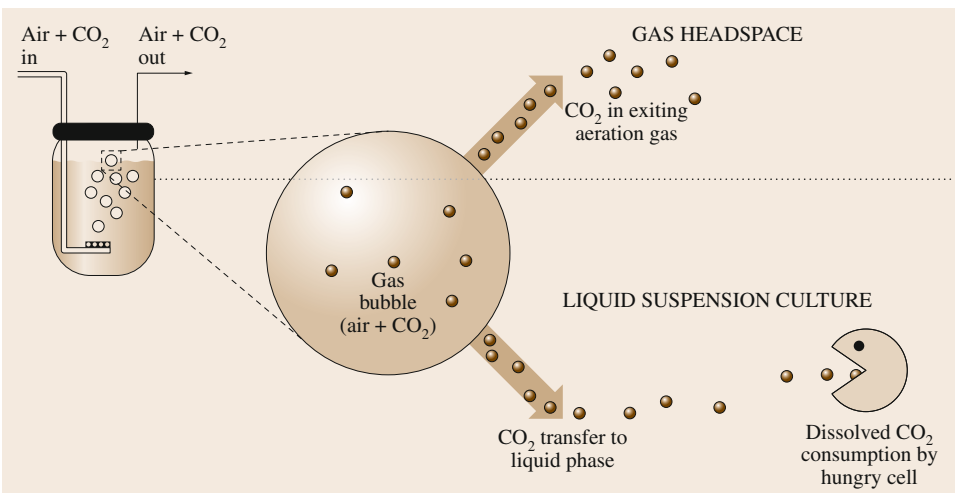

Fig. 9.23 Modes of CO_2 delivery and consumption in phototrophic culture

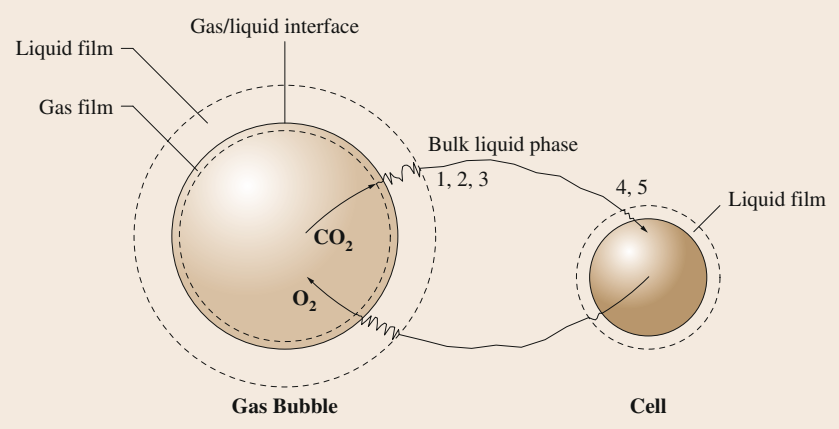

Fig. 9.24 Interphase mass transfer of CO_2 from the aeration gas bubble to the photosynthetic cell, and the concurrent transfer of O_2 evolved by the cell to the aeration gas bubble. The interphase mass transfer and consumption of CO_2 occurs in five steps: 1) mass transfer of gas-phase CO_2 through gas film inside gas bubble; 2) dissolution of CO_2 at the gas bubble/liquid interface; 3) mass transfer of dissolved CO_2 through the liquid film surrounding the gas bubble; 4) mass transfer of dissolved CO_2 through the liquid film surrounding the cell; 5) consumption of CO_2 by the cell

CO_2 Transfer Processes

The transfer of CO_2 from the aeration gas stream to the photosynthetically active cell occurs in five steps, as illustrated in Fig. 9.24:

1. Flux of CO_2 through the stagnant gas film inside the gas bubble to the gas/liquid interface (gas film mass transfer).
2. Equilibrium partitioning of CO_2 between the gas and liquid at the interface (absorption).
3. Flux of dissolved CO_2 through the stagnant liquid film surrounding the bubble (liquid film mass transfer).
4. Flux of dissolved CO_2 through the stagnant liquid film surrounding the cell.
5. Uptake and consumption of CO_2 by the cell for photosynthesis.

Thus the aeration gas serves as the source for CO_2 mass transfer and the photosynthetically active cells serve as the sink for CO_2 mass transfer.

Four assumptions and conditions on the CO_2 transfer processes described above are invoked to make the system more tractable for bioprocess engineering calculations. First, the equilibrium absorption of CO_2 from the gas to the liquid is described by Henry's law

$$P_A = H\, C_A^{*}\,, \tag{9.41}$$

where P_A is the partial pressure of CO_2 in the gas, C_A^{*} is the concentration of CO_2 dissolved in the liquid in equilibrium with the CO_2 partial pressure in the gas, and H is the Henry's law constant in units of pressure/concentration. Henry's law is valid for dilute solutions where the gas is sparingly soluble in the liquid. Such is the case for CO_2 dissolved in seawater. Second, for a sparingly soluble solute, it is commonly accepted that the solute flux is limited by the transport of the dissolved solute across the stagnant liquid film surrounding the bubble, i. e., the interphase mass transfer process is liquid phase controlled. Third, the partial pressure of CO_2 remains relatively constant inside the bubble. Fourth, the dissolved CO_2 consumption rate is assumed to follow zero-order kinetics with respect to dissolved CO_2 concentration, and so the volumetric consumption rate of CO_2 is given by

$$Q_A = \frac{\mu C_x}{Y_{X/CO_2}}\,. \tag{9.42}$$

Photosynthetic O_2 evolution and transfer follows the same processes as CO_2 transfer and consumption, only in reverse order, as illustrated in Fig. 9.24. The photosynthetically active cell is the source for O_2, whereas the aeration gas is the sink for O_2 mass transfer. If air is used as the aeration gas, then typically the dissolved O_2 concentration is near its saturation value for the partial pressure of O_2 in air.

Material Balances for CO_2 Delivery and Consumption

Carbon dioxide limitation during growth of phototrophic cell suspension cultures in a given photobiore-

actor configuration is assessed by performing a material balance on CO_2 dissolved in the liquid culture. The CO_2 material balance is

$$\begin{pmatrix}\text{rate of } CO_2\\ \text{added to culture}\end{pmatrix} - \begin{pmatrix}\text{rate of } CO_2\\ \text{removed from culture}\end{pmatrix} + \begin{pmatrix}\text{rate of generation of}\\ CO_2 \text{ by culture}\end{pmatrix} = \begin{pmatrix}\text{rate of accumulation of}\\ CO_2 \text{ within culture}\end{pmatrix} . \quad (9.43)$$

Liquid-phase CO_2 material balances are developed for batch and continuous photobioreactors. The batch and continuous photobioreactors are well mixed and continuously aerated. Although the cell density (C_x) increases with time in batch culture, CO_2 consumption and mass transfer rates are at a nominal steady state for a given value of C_x. At these conditions, the CO_2 material balance for the culture in the batch photobioreactor is

$$k_L A_i (C_A{}^* - C_A) - \frac{\mu C_x V}{Y_{X/CO_2}} = 0 , \quad (9.44)$$

where A_i is the gas/liquid interfacial surface area of all the bubbles, and k_L is the liquid phase mass transfer coefficient for dissolved CO_2 flux across the liquid film surrounding the bubble ($m\,s^{-1}$). The first term in (9.44) represents the interphase mass transfer flux of CO_2 from the gas to the liquid phase. Note that $C_A{}^*$ is dependent on the gas phase CO_2 partial pressure P_A by (9.41). The second term in (9.44) represents the consumption rate of CO_2 by the culture. Note the sign is negative to denote consumption rather than generation. Similarly, the CO_2 material balance on the continuous photobioreactor is

$$v_o C_{A,o} + k_L A_i (C_A{}^* - C_A) - v_o C_A - \frac{\mu C_x V}{Y_{X/CO_2}} = 0 . \quad (9.45)$$

Usually, the $v_o C_{A,o}$ term is small in magnitude with respect to the other terms and is neglected.

At the point of CO_2 limitation, the CO_2 that is delivered to the liquid culture is immediately consumed by the cells, and so C_A will be near zero, but not at zero. In this case, equations (9.44) and (9.45) both reduce to

$$CO_2 - TR = k_L a\, C_A{}^* \geq \frac{\mu C_x}{Y_{X/CO_2}} , \quad (9.46)$$

where a is the gas–liquid interfacial area per unit volume of culture A_i/V ($m^2\,m^{-3}$). Therefore, to avoid CO_2-limited growth, the CO_2-TR must always be higher than the CO_2 demand. If the growth is CO_2-limited, then the biomass productivity μC_x is set by the CO_2-TR.

The CO_2 demand given by (9.42) is a function of both specific growth rate μ and cell density C_x. Recall from (9.36) that light attenuation lowers μ as C_x increases and so μ' is also implicitly a function of C_x. At a fixed aeration rate and CO_2 partial pressure in the aeration gas, as the cell density increases, the process moves closer to CO_2 limitation. Therefore, the critical cell density ($C_{x,c}$) at which CO_2 limitation occurs in a well-mixed, continuously aerated photobioreactor is found by combination and rearrangement of equations (9.46) and (9.36) to yield

$$C_{x,c} = \frac{k_L a C_A{}^* Y_{X/CO_2}}{\mu_{max} I_m(C_{x,c})/(I_k + I_m(C_{x,c}))} , \quad (9.47)$$

where $C_N \gg K_N$. Since I_m is a function of C_x, (9.47) must be solved implicitly for $C_{x,c}$ using the appropriate relationship for I_m, e.g., (9.33).

Effects of Aeration on CO_2 Transfer Rate

Equation (9.46) contains a new parameter, a, which is defined as

$$a = \frac{A_i}{V} = \frac{\text{gas–liquid interfacial area } (m^2)}{\text{volume of culture}(m^3)} . \quad (9.48)$$

The parameter a is difficult to determine independently. Therefore, a and k_L are usually lumped together into a single parameter called the volumetric mass transfer coefficient $k_L a$, which has units of reciprocal time (e.g., h^{-1}). Generally, $k_L a$ increases with increasing aeration rate and decreasing bubble size. Many correlations exist for estimation of $k_L a$ in aerated systems, including enclosed algal photobioreactors [9.41–44]. The $k_L a$ for CO_2 transfer can be readily scaled from $k_L a$ for O_2 transfer. Specifically, $k_L a$ for CO_2 is related to the $k_L a$ for O_2 using penetration theory for mass transfer, for example,

$$(k_L a)_{CO_2} = (k_L a)_{O_2} \left(\frac{D_{CO_2}}{D_{O_2}}\right)^{\frac{1}{2}} , \quad (9.49)$$

where D_{CO_2} and D_{O_2} are the liquid-phase diffusion coefficients for dissolved CO_2 and O_2 dissolved in seawater, respectively. The diffusivity ratio D_{CO_2}/D_{O_2} is

0.8 for seawater. It should be noted here that (9.49) should be used at pH 7.5 and higher, as speciation of CO_2 provides a chemical reaction within the liquid film that is described by penetration theory.

Values of k_La for O_2 transfer in various bioreactor configurations are determined by well-established correlations or by direct measurements within the bioreactor. For example, a simple but very approximate k_La correlation for O_2 transfer in a bubble-column bioreactor presented by *Chisti* and *Moo-Young* [9.41] is

$$k_La = 0.76\, u_{gs}{}^{0.8}\,, \tag{9.50}$$

where k_La has units of s^{-1} and u_{gs} is the superficial gas velocity in units of $m\,s^{-1}$, defined as the volumetric flow rate of the entering aeration gas divided by the cross-sectional area of the bioreactor vessel. Well-established experimental methods also exist for estimating k_La directly in the photobioreactor culture by measurement of the dissolved oxygen versus time profile induced by a step change in aeration gas composition. A detailed presentation of the many correlations available to measure or estimate k_La for a particular bioreactor configuration and aeration system is beyond the scope of this chapter, but representative approaches are provided in [9.41–44].

Models for CO_2-Limited Growth

Carbon dioxide-limited growth occurs if C_x is greater than $C_{x,c}$ ((9.47)). Under CO_2-limited growth, the volumetric biomass production rate μC_x is set by (9.46). Therefore, *if* $C_x > C_{x,c}$ then biomass production for CO_2-limited growth in a well-mixed batch photobioreactor is

$$\frac{dC_x}{dt} = \mu C_x = \frac{C_N}{K_N + C_N} k_La C_A{}^* Y_{X/CO_2} \approx k_La C_A{}^* Y_{X/CO_2} (\text{if } C_N \gg K_N)\,. \tag{9.51}$$

If the simplification $C_N \gg K_N$ is made, the right-hand side of (9.51) is a collection of constant terms. In this case, (9.51) is readily integrated from $t = t_c$ at $C_x = C_{x,c}$ to yield

$$C_x(t) = C_{x,c} + k_La\, C_A{}^* Y_{X/CO_2}(t - t_c)\,, \tag{9.52}$$

where C_x increases with time until nutrient limitation ($C_N = 0$) is reached. Note that (9.52) is linear. A hallmark of CO_2-limited growth in batch photobioreactors is that the cell density versus time profile assumes a straight line. Furthermore, in CO_2-limited growth, the biomass production rate is directly proportional to CO_2–TR. However, even in CO_2-limited growth biomass production eventually becomes limited by some other variable, such as complete consumption of the limiting nutrient, as described by (9.20).

Similarly, with some algebra it can be shown that the material balances in the well-mixed continuous photobioreactor under CO_2-limited growth conditions where $C_x > C_{x,c}$ are

$$C_x = \frac{C_N}{K_N + C_N} \frac{k_La C_A{}^* Y_{X/CO_2}}{D} \approx \frac{k_La C_A{}^* Y_{X/CO_2}}{D}\,, \tag{9.53}$$

for the cell biomass, and

$$C_N = C_{N,o} - \frac{C_N}{K_N + C_N} \frac{k_La C_A{}^* Y_{X/CO_2}}{DY_{X/N}} \approx C_{N,o} - \frac{k_La C_A{}^* Y_{X/CO_2}}{DY_{X/N}}\,, \tag{9.54}$$

for the limiting nutrient. Simultaneous solution of equations (9.53) and (9.54) for outlet cell density C_x and outlet nutrient concentration C_N is required if C_N is comparable in magnitude to K_N. However, if $C_N \gg K_N$, then cell density C_x and biomass productivity DC_x increase linearly with increasing CO_2-TR. Equations (9.53) and (9.54) are only valid if C_x is greater than $C_{x,c}$ and if the dilution rate D is below the washout condition.

The CO_2 mass transfer analysis assumes that the aeration gas flow rate is high and CO_2 is slightly soluble in the liquid, so that only a small fraction of the CO_2 in the gas phase is actually transferred to the liquid phase. However, if the liquid medium is alkaline (pH > 8.5), then CO_2 in the aeration gas can be absorbed more efficiently since dissolved CO_2 speciates to bicarbonate and increases the total dissolved inorganic carbon concentration. Furthermore, if the aeration rate is very low and the CO_2 demand is high, it is possible that the liquid medium can capture all of the gas phase CO_2 delivered to the culture so that no CO_2 exits with aeration gas. Under these limiting conditions, CO_2-TR is

$$CO_2 - TR = \frac{F_A}{V} = \frac{v_a P_A}{RTV}\,, \tag{9.55}$$

where F_A is the molar flow rate of CO_2 in the aeration gas ($mol\,CO_2\,min^{-1}$), R is the gas constant (e.g., $0.08206\,L\,atm\,(mol\,K)^{-1}$), T is the temperature (K) of the aeration gas, v_a is the volumetric flow rate of the aeration gas at T ($L\,min^{-1}$), and V is the culture volume.

9.4.4 Process Scale-Up and Other Limiting Factors

Process *scale-up* seeks to preserve the performance of a given photobioreactor design as it is moved from a laboratory scale to a process scale. Conservatively, process scale-up is carried out in increments of ten. For example, a 100 L laboratory photobioreactor is first scaled up to a 1000 L pilot-plant photobioreactor, which is then scaled up to a 10 000 L process-scale photobioreactor. The scale-up design of the photobioreactor follows a few simple guidelines if the five-step process for rational photobioreactor design described at the beginning of this section is followed. Scale-up guidelines for bubble-column airlift photobioreactors and tubular photobioreactors are suggested below.

Process scale-up for bubble-column and airlift photobioreactors requires that the mean light intensity (I_m) and volumetric CO_2 transfer rate (CO_2-TR) are kept constant as the vessel size is increased. Therefore, the width of the planar vessel or the diameter of the cylindrical vessel is usually kept constant as the vessel size is increased from the pilot scale to the process scale to preserve I_m. The incident light intensity to the vessel surface is also kept constant. The other vessel dimensions (height or length of the planar vessel, height of the cylindrical vessel) are increased until the vessel size reaches 2000 L. If culture volumes in excess of 2000 L are required, then it is best to construct multiple units operating in parallel. Once the final vessel size is determined, the aeration rate is increased to keep the aeration rate per unit volume constant from the pilot scale to the process scale. For example, if the required aeration rate is 20 L air min^{-1} for a 100 L vessel, then the required aeration rate for a 1000 L vessel is 200 L min^{-1}, so that the aeration rate per unit volume of culture is kept constant at 0.2 L air (L culture $min)^{-1}$. All other aeration parameters are kept constant, including the sparger design and the CO_2 partial pressure in the aeration gas, so that the volumetric CO_2-TR is preserved upon scale-up.

Process scale-up for tubular photobioreactors requires that six process parameters be kept constant, including:

1. The mean light intensity inside the tube
2. The culture residence time within the tube
3. The Reynolds number for culture flow within the tube
4. The pressure drop in the tube
5. The CO_2-TR in the aeration tank
6. The ratio of the aeration tank culture volume to the tubular section culture volume.

The simplest way to keep parameters 1–4 constant is to keep the diameter and length of the tube constant and then manifold the tubes in parallel until the desired culture volume is achieved. The culture flow rate to a given tube is equal to the total flow rate divided by the number of parallel tubes.

Following scale-up, there are several other potential limiting factors and problems associated with biomass production in photobioreactors that deserve a brief mention. These include cell damage due to agitation, particularly pumping operations, cell adhesion to vessel surfaces, and cell clumping. Cell damage due to pumping was already discussed in Sect. 9.3.3.

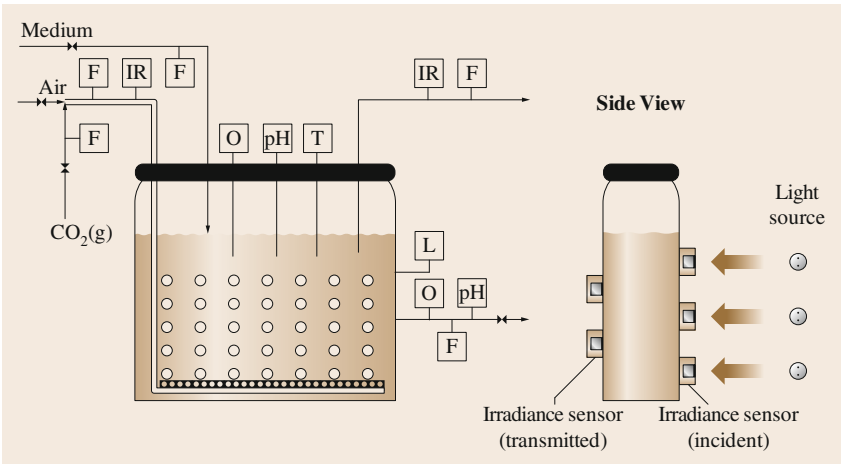

Fig. 9.25 Arrangement of bioprocess sensors for photobioreactor operation. F = flow meter, IR = gas phase CO_2 infrared sensor, L = liquid level, O = dissolved oxygen probe, pH = pH probe, T = temperature

9.4.5 Process Monitoring and Control

Photobioreactors require online process measurement sensors common to most bioprocess equipment for cell cultivation, including dissolved oxygen electrodes, pH electrodes, temperature probes, gas and liquid flowmeters, and liquid level indicators. Photobioreactors also require sensors for gas phase CO_2 concentration and light intensity. The suggested arrangement of process sensors is provided in Fig. 9.25.

Photosynthetic liquid suspension cultures produce oxygen and so the dissolved O_2 concentration in the liquid medium is usually near 100% of its saturation value with respect to the oxygen partial pressure in the aeration gas. However, if the culture is not adequately aerated, oxygen can build up in the liquid medium to higher concentrations which may be toxic to the cells, a phenomenon called oxygen toxicity. Therefore, the dissolved oxygen concentration should be monitored in all aerated vessels as well as the entrance and exit points to tubular sections of tubular photobioreactors. The consumption of dissolved CO_2 by photosynthesis can shift the equilibrium of dissolved organic carbon species by dissociating bicarbonate to dissolved CO_2 and OH- ions, which raises the pH. Therefore, the pH should be monitored at all points common to dissolved oxygen concentration measurement. Several commercially available dissolved oxygen (DO) and pH electrodes are suitable for these bioprocess measurements. The CO_2 ultimately consumed by photosynthesis is delivered to the photobioreactor by the aeration gas. Therefore, the total aeration gas flow rate and the gas-phase concentration entering and exiting the photobioreactor should be monitored. Online infra-red (IR) sensors are suitable for measurement of gas-phase CO_2 concentration in the inlet and exhaust aeration gas streams.

Online culture pH and gas-phase CO_2 concentration measurements can also be used to control photobioreactor operation during culture growth. For example, if CO_2 demand by actively growing culture is high, the pH will rise. The pH can be lowered by increasing the CO_2 concentration in the aeration gas or by direct injection of CO_2 to the culture. Both methods improve the CO_2 transfer rate and lower the culture pH by shifting the dissolved inorganic carbon equilibrium back to bicarbonate. For process controller operation, the gas phase CO_2 concentration serves as the manipulated variable and the pH serves as the response variable.

Photobioreactors should also be equipped with online irradiance sensors that measure the PAR (400–700 nm) light intensity in units of μmol photons $\cdot m^{-2} s^{-1}$. Irradiance sensors should be placed on the illuminated vessel surface with the face of the sensor pointed toward the light source. Other irradiance sensors should have the face of the sensor pointed to the culture to measure the light intensity transmitted through the culture vessel. If possible, several irradiance sensors should be laid out in a grid pattern along the illuminated vessel surface to monitor temporal distributions of both incident and transmitted light intensity. Irradiance sensors can also be used to control semi-continuous processes. For example, if the transmitted light intensity through the culture falls below a target value indicative of a certain cell density, then a portion of the suspension culture is pumped out and fresh medium is added to dilute the suspension culture and raise the transmitted light intensity back up to the setpoint value.

9.4.6 Illustration of a Photobioreactor Design Problem

This section illustrates the design of an enclosed photobioreactor system using concepts given in Sects. 9.2–9.4.

9.4.7 Design Needs Statement

It is necessary to design and scale up an aerated planar photobioreactor for cultivation of a phototrophic algal cell suspension culture. The cell mass contains an expensive antibiotic compound in the concentration of 25 mg per 1.0 g cell mass. The cultivation will be carried out as a batch process with an inoculum cell density of 0.10 g cells (L culture)$^{-1}$. To achieve the needed antibiotic production rate of 0.5 kg day^{-1}, the target biomass productivity is 20 kg cells d^{-1}, and a final cell density of 2.0 g cells (L culture)$^{-1}$ is desired to facilitate downstream processing. The intrinsic growth parameters for the organism, including biomass yield coefficients, are Monod parameters for light and limiting nutrient at 25 °C and pH 8.0, and a specific light attenuation coefficient for the cell suspension. These characteristic growth parameters are summarized in Table 9.7. The cell suspension culture becomes photo-inhibited at light intensities exceeding 300 μmol photons m^{-2} s^{-1}. To complete the photobioreactor design, specify the required nutrient loading in the culture medium, the illumination system delivery, the vessel dimensions, and the required CO_2 transfer rate necessary to avoid CO_2-limited growth.

Photobioreactor Process Design

The photobioreactor design process has five steps.

Step 1. Determine the initial concentration of limiting nutrient ($C_{N,i}$) necessary to achieve the target cell density ($C_{x,f}$) of 2 g cell L^{-1}. Using (9.20) and the $Y_{X/N}$ value provided in Table 9.7, $C_{N,i}$ is

$$\begin{aligned} C_{N,i} &= \frac{(C_{x,f} - C_{x,i})}{Y_{X/N}} \\ &= \frac{(2.0 - 0.1)\ \text{g cell l}^{-1}}{224\ \text{g cell mol}^{-1}\,\text{N}^{-1}} \frac{1000\,\text{mmol}}{1\,\text{mol}} \\ &= 8.48\,\text{mmol N L}^{-1}\,. \end{aligned}$$

Steps 2 and 3. Determine the light path length L. An aerated planar photobioreactor in the batch cultivation mode of operation must be used. Also, the vessel must be artificially illuminated since it will be located indoors. The light path width for the planar vessel configuration, the incident light intensity to the vessel surface, and the mode of light delivery (one or two-sided illumination) must be specified. With respect to the mode of light delivery, the two-sided illumination system improves light delivery and biomass productivity and hence reduces vessel size, but has a higher operating cost than the one-sided illumination system since the electricity to run the illumination system is a utility cost. First, the mean light intensity (I_m) at the final cell density in the process of 2 g cell L^{-1} is set to I_k for the culture of 50 μmol photon $m^{-2}\,s^{-1}$ so that $I_m \geq I_k$. Second, to avoid photoinhibition of cells residing near the wall of the vessel, the incident light intensity I_o is set to 150 μmol photon $m^{-2}\,s^{-1}$, which is one half the observed photoinhibition threshold of 300 μmol photon $m^{-2}\,s^{-1}$. Finally, the path length L is backed out from (9.33) for both $\alpha = 1$ (one-sided illumination) and for $\alpha = 2$ (two-sided illumination)

$$\begin{aligned} I_m &= \frac{\alpha I_o}{k_c C_x L}\left(1 - e^{-k_c C_{x,f} L}\right) \\ &= \frac{\alpha\ 150\,\mu\text{mol m}^{-2}\,\text{s}^{-1}}{0.21\,(\text{g cm})^{-1} 2.0\,\text{g l}^{-1} \cdot L} \\ &\quad \times \left[1 - \exp\left(-0.21\,\text{cm g}^{-1} 2.0\,\text{g l}^{-1} \cdot L\right)\right] \\ &\geq 50\,\mu\text{mol m}^{-2}\,\text{s}^{-1}\,. \end{aligned}$$

The required path length L is calculated using the root-solving function on any scientific calculator or spreadsheet program (e.g., Solver on Microsoft Excel). For $\alpha = 1$, L is 7.05 cm, and for $\alpha = 2$, L is 15 cm. Therefore, a path length of $L = 15$ cm with two-sided illumination is selected to make the final vessel size practical.

Step 4. Determine the volumetric CO_2 transfer rate (CO_2-TR) necessary to avoid CO_2-limited growth. According to (9.42), the CO_2 demand increases as cell density C_x increases and μ' increases. The maximum CO_2-TR required for the aeration process is determined at peak CO_2 demand. As the cultivation proceeds, C_x increases but μ' decreases because I_m, which determines μ', decreases as C_x increases. The magnitude of C_x increase is higher than the magnitude of μ decrease, and so the design is based on $C_{x,f}$. At final cell density $C_{x,f}$ of 2.0 g cell L^{-1}, I_m is 50 μmol photon $m^{-2}\,s^{-1}$, and μ' is 0.1 h^{-1} based on Model 1 in Table 9.4. Therefore, the maximum CO_2-TR at $C_{x,f}$ is determined by (9.46) in the form of

$$\begin{aligned} \text{Peak CO}_2 - \text{TR} = k_L a C_A{}^* &= \frac{\mu' C_{x,f}}{Y_{X/CO_2}} \\ &= \frac{0.1\,\text{h}^{-1} 2.0\,\text{g l}^{-1} 1000\,\text{mmol mol}^{-1}}{33.8\,\text{g mmol}^{-1}\text{CO}_2} \\ &= 5.92\,\text{mmol CO}_2\,(\text{L} - \text{h})^{-1}\,. \end{aligned}$$

Now, the aeration system itself can be further specified. First, consider that ambient air serves as the aeration gas, which contains 350 ppm CO_2 (0.00035 atm CO_2). Using a Henry's law coefficient of $H = 0.0339$ L atm $mmol^{-1}CO_2$ (Table 9.3), the required volumetric mass transfer coefficient $k_L a$ to achieve this CO_2-TR is

$$\begin{aligned} k_L a &= \text{CO}_2 - \text{TR}\frac{H}{P_A} \\ &= 5.92\,\text{mmol CO}_2\,\text{l} - \text{h}^{-1} \\ &\quad \times \frac{0.0339\,\text{l} - \text{atm mmol}^{-1}}{0.00035\,\text{atm}} \\ &= 573\,\text{h}^{-1}\,. \end{aligned}$$

A $k_L a$ value of 573.1 hr^1 is too large to accomplish within a bubble-column bioreactor. However, if the partial pressure of CO_2 in the aeration gas is increased to 3500 ppm (0.0035 atm CO_2), i. e.,

$$\begin{aligned} k_L a = \text{CO}_2 - \text{TR}\frac{H}{P_A} &= 5.92\,\text{mmol CO}_2\,\text{l} - \text{h}^{-1} \\ &\quad \times \frac{0.0339\,\text{l} - \text{atm mmol}^{-1}}{0.0035\,\text{atm}} \\ &= 57.3\,\text{h}^{-1}\,, \end{aligned}$$

Table 9.7 Example values of intrinsic growth characteristics of a phototrophic suspension culture

Input parameter	Value and units
μ_{max}	$0.2\,h^{-1}$
I_k	$50\,\mu mol\ photons\ m^{-2}\,s^{-1}$
K_N	$0.1\ mmol\,N\,L^{-1}$
$Y_{X/N}$	$224\ g\ cell\ mol^{-1}\ N$
Y_{X/CO_2}	$33.8\ g\ cell\ mol^{-1}\ CO_2$
k_c	$0.2\,L(g\ cell\ cm)^{-1}$

then the required k_La to avoid CO_2-limited growth is reduced to $57.3\,h^{-1}$, which is readily achievable. There are many ways the aeration rate and bubble size can be set to achieve this k_La value.

Finally, the sodium bicarbonate loading in the liquid medium necessary to maintain a pH of 8.0 at a CO_2 partial pressure of 3500 ppm must be calculated. From (9.7) and Table 9.3, at 25 °C the bicarbonate concentration needed in the liquid medium is

$$\begin{aligned}[HCO_3^-] &= 10^{-(pK_{a,1}-pH)}\frac{P_A}{H}\\ &= 10^{-(6.0-8.0)}\frac{0.0035\ atm}{0.03391-atm\,mmol^{-1}}\\ &= 10.3\ mmol\,l^{-1}\,.\end{aligned}$$

Step 5. Determine the cultivation time and photobioreactor vessel dimensions necessary to achieve the production schedule of 20 kg of biomass per day with a final cell density of $2.0\ g\ cell\,L^{-1}$ and initial cell density of $0.1\ g\ cell\,L^{-1}$. The cultivation time to achieve $C_{x,f}$ is determined from the computed growth curve of C_x versus cultivation time. The prediction of C_x versus t in the photobioreactor is determined by integrating equations (9.37a) and (9.37b) with respect to t using the input parameters given in Table 9.7 and $L = 15$ cm, $\alpha = 2$, and $C_{N,i} = 8.5\ mmol\,N\,L^{-1}$.

$$\frac{dC_x}{dt} = \mu C_x = \frac{C_N}{K_N + C_N}\frac{I_m(C_x)}{I_k + I_m(C_x)}\mu_{max}C_x\,,$$

with the initial condition $t = 0$, $C_x = C_{x,i} = 0.1\ g\ cell\,L^{-1}$. At at a given value for C_x, I_m and C_N are estimated by

$$I_m(C_x) = \frac{\alpha I_o}{k_c C_x L}\left(1 - e^{-k_c C_x L}\right),$$

$$C_N = \frac{(C_x - C_{x,i})}{Y_{X/N}}\,.$$

The differential equation can be numerically integrated without much trouble using differential equation solver utilities found in software packages such as MathCad or MatLab. Plots of C_x, C_N, I_m, and CO_2 demand versus cultivation time are presented in Figs. 9.26a,b. From Fig. 9.26a, the final cultivation time (t_f) is 22.0 h at the point where the limiting nutrient is consumed and the cell density becomes constant. Based on this cultivation time, the total culture volume to achieve the biomass

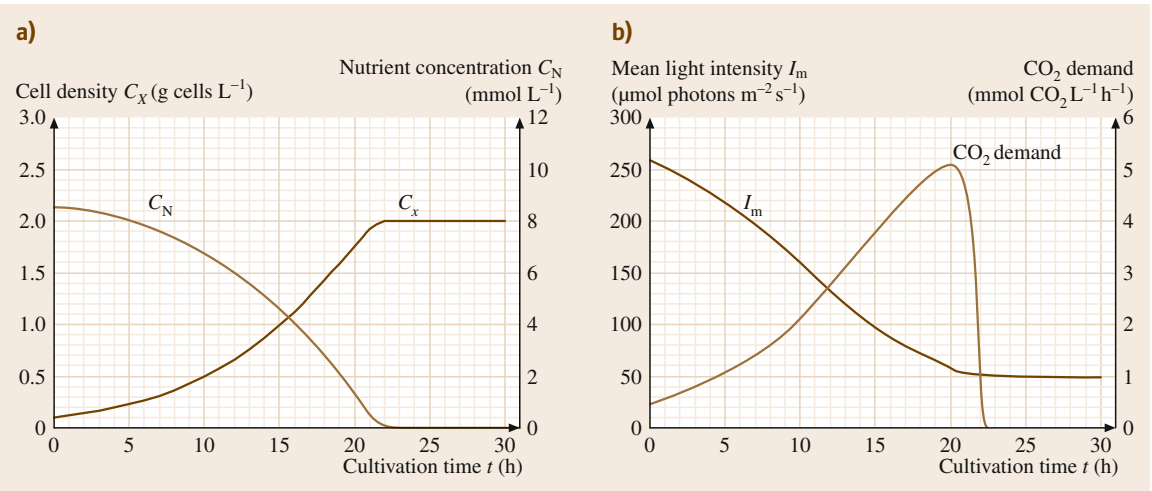

Fig. 9.26a,b Planar photobioreactor design illustration: model simulation results. **(a)** Cell density (C_x) and limiting nutrient concentration (C_N) versus cultivation time; **(b)** mean light intensity (I_m) and volumetric CO_2 demand versus cultivation time

Table 9.8 Summary of planar photobioreactor design parameters necessary to achieve 20 kg per day biomass production schedule

Parameter	Value and units
Initial cell density $C_{x,I}$	0.1 g cell L^{-1}
Final cell density $C_{x,f}$	2.0 g cell L^{-1}
Cultivation time in batch culture t_f	22 h
Initial nutrient concentration $C_{N,i}$	8.5 mmol N L^{-1}
Incident light intensity I_o	150 μmol photons m^{-2} s^{-1}
Mean light intensity at $C_{x,f}$ I_m	50 μmol photons m^{-2} s^{-1}
Planes of illumination α	2
Light path length L	15 cm
Total cultivation volume V	9648 L (five 2000 L units)
Single vessel width W	6.67 m
Single vessel height H	2.0 m
Peak CO_2-TR	5.69 mmol CO_2 $L^{-1}h^{-1}$
CO_2 partial pressure P_A	0.0035 atm (3500 ppm)
Bicarbonate concentration at P_A for pH 8.0, $[HCO_3^-]$	10.3 mmol L^{-1}
Aeration gas flow rate at P_A for peak CO_2-*TR* v_a/V	0.69 min^{-1}
Mass transfer coefficient for peak CO_2-*TR* k_La	57.3 h^{-1} (with 3500 ppm CO_2)

production rate (r_p) of 20 kg d^{-1} is

$$V = \frac{r_p t_f}{C_{x,f} - C_{x,i}} = \frac{20\,\text{kg}\,\text{d}^{-1}\,22\,\text{h}\,1\,\text{d}(24\,\text{h})^{-1}}{(2.0-0.1)\,\text{g}\,\text{l}^{-1}\,1\,\text{kg}(1000\,\text{g})^{-1}} = 9649\,\text{l}.$$

A culture volume of 9649 L may be too large for a single planar vessel, and so it is decided to build five 2000 L photobioreactors operating in parallel for a total cultivation volume of 10 000 L. For a single planar vessel, the light path length L or *thickness* of the vessel is fixed at 15 cm. Furthermore, the height of each vessel (H) is set at 2 m for the culture, 2.4 m for the entire vessel to accommodate the gas headspace. The width of each vessel is, therefore, 6.67 m. The final recommended design parameters are summarized in Table 9.8.

Based on these design parameters, chemical and energy inputs can be calculated. For example, the inlet mass flow rate of CO_2 in the aeration gas (F_A) based on the peak CO_2-TR and the required culture volume is

$$\begin{aligned} F_A &= \text{CO}_2 - \text{TR} \cdot V \\ &= 5.92\,\text{mmol}\,\text{CO}_2\,\text{l}-\text{h}^{-1}\,\frac{44\,\text{mg}\,\text{CO}_2}{1\,\text{mmol}^{-1}}\,\frac{1\,\text{kg}}{10^6\,\text{mg}}\,9649\,\text{l} \\ &= 2.51\,\text{kg}\,\text{CO}_2\,\text{h}^{-1}, \end{aligned}$$

which includes both CO_2 supplied by ambient air and the CO_2 addition to the aeration gas. The total aeration gas flow rate at this CO_2 molar flow rate of 2.51 kg CO_2 h^{-1} (0.95 mol CO_2 min^{-1}) at 25 °C and 3500 ppm CO_2 partial pressure is

$$\begin{aligned} v_{a,min} &= \frac{F_A RT}{P_A} \\ &= \left(0.95\,\text{mol}\,\text{CO}_2\,\text{min}^{-1}0.082061-\text{atm}\,\text{mol}^{-1}\,\text{K}^{-1}\right. \\ &\quad \left.\times(273+25)\,\text{K}\right)/\,0.0035\,\text{atm} \\ &= 6652\,\frac{1}{\text{min}}, \end{aligned}$$

and the minimum aeration rate per unit volume (*vvm*) at this peak CO_2-TR is

$$vvm = \frac{v_a}{V} = \frac{6652\,\text{l}\,\text{min}^{-1}}{9649\,\text{l}} = 0.68\,\text{min}^{-1}.$$

To achieve a k_La of 57.3 h^{-1} at a minimum aeration rate of 0.68 *vvm*, the bubble size of the aeration system is adjusted to achieve this value.

9.5 Future Directions for Process Scale Enclosed Photobioreactors

There are two pathways that will drive the future development of process scale photobioreactors.

First, high-value compounds from phototrophic marine organisms will drive the development of artificially illuminated photobioreactors. New process biotechnologies for the production of high-value compounds by phototrophic marine organisms in a GMP environment will require artificially illuminated photobioreactors located indoors within climate-controlled manufacturing facilities, similar to those used by fermentation processes. Furthermore, photobioreactors operating in a GMP environment must be easily sterilized and fully

controllable. Under controlled conditions for light and CO_2 delivery, cell densities exceeding 5 g dry cells L^{-1} of culture are possible. If 1) the achievable cell density is high, 2) the product is extremely valuable (> \$1000 kg^{-1}), and 3) required production slate of the target compound in the biomass is small (e.g., less than 1 kg d^{-1}), as is the case with many high-value specialty chemicals or pharmaceutical compounds, then photobioreactor culture volumes for process-scale units will most likely be under 20 000 L. Consequently, for process biotechnology applications, photobioreactor development is likely to move toward internally illuminated, stirred-tank photobioreactors, or batteries of externally illuminated bubble-column/airlift photobioreactors.

Second, environmental and renewable energy applications will drive large-scale photobioreactor development using natural illumination. The future development of photobioreactors will also focus on environmental or renewable energy applications, including CO_2 mitigation, waste water cleanup, and hydrogen gas production, and the production of biofuels. In the future, CO_2 emissions from industrial processes may be capped in the attempt to reduce the release of greenhouse gases to the atmosphere. One way to reduce CO_2 emissions is to capture the CO_2 and convert it to something else. Phototrophic marine organisms are ideal for this purpose because they convert CO_2 into biomass and lipids which can be processed into biofuels. However, there are several challenges to photobioreactor design for biological CO_2 mitigation. Stack gases from combustion processes typically contain at least 10% CO_2 by volume. In the simplest process, the stack gas is bubbled directly into an open pond or tank culture. However, this process is not efficient because only a fraction of the CO_2 in the stack gas is transferred to the liquid culture. In contrast, tubular photobioreactors may be more effective for CO_2 capture, but the residence time of the culture in the tubular section must be designed to completely consume the CO_2.

Whether the process application for cultivation of phototrophic organisms in enclosed photobioreactors is for high-value compounds at a small scale or CO_2 mitigation at large scale, this chapter has shown simple but effective approaches for the successful design of the cultivation system that incorporates nutrient consumption, light transfer, and CO_2 delivery into the process analysis.

9.6 Notation

a	Interfacial area of aeration gas bubbles in liquid suspension per unit culture volume, $m^2\ m^{-3}$
A_i	Total interfacial area of aeration gas bubbles in liquid suspension, m^2
C_A	Concentration of dissolved CO_2 in culture medium, mol L^{-1}
$C_A{}^*$	Concentration of dissolved CO_2 in equilibrium with the CO_2 partial pressure in the aeration gas, mol L^{-1}
C_{AL}	Concentration of dissolved CO_2 exiting tubular section or entering aeration tank (tubular photobioreactor), mol L^{-1}
C_{AO}	Concentration of dissolved CO_2 exiting aeration tank or entering tubular section (tubular photobioreactor), mol L^{-1}
$C_{A,T}$	Total dissolved carbon concentration, mol L^{-1}
C_N	Concentration of dissolved nutrient in liquid medium, mol L^{-1}
$C_{N,i}$	Initial concentration of dissolved nutrient in batch bioreactor liquid medium, mol L^{-1}
$C_{N,o}$	Concentration of dissolved nutrient in inlet flow stream of well-mixed continuous flow bioreactor, mol L^{-1}
C_x	Cell density in liquid suspension culture, g cells L^{-1} culture
$C_{x,c}$	Cell density where growth kinetics become CO_2 transfer rate limited at a given set of process conditions, g cells L^{-1} culture
$C_{x,f}$	Final cell density at nutrient depletion, g cells L^{-1} culture
$C_{x,i}$	Initial cell density in batch bioreactor, g cells L^{-1} culture
$C_{x,o}$	Cell density of inlet flow stream of well-mixed continuous flow bioreactor, mol L^{-1}
d	Inner diameter of tubing, cm or m
D	Dilution rate for well mixed continuous flow bioreactor, s^{-1} or h^{-1}
D_{CO_2}	Diffusion coefficient for CO_2 dissolved in seawater, $m^2\ s^{-1}$
D_{O_2}	Diffusion coefficient for O_2 dissolved in seawater, $m^2\ s^{-1}$

f Fractional photoperiod for illumination, h light on (24 h)$^{-1}$

F_A Molar flow rate of CO_2 in the inlet aeration gas, mol CO_2 h^{-1}

H Henry's law constant for dissolved CO_2 in seawater medium, atm L mol^{-1}

k_c Light attenuation constant for liquid cell suspension culture, L (g cells cm)$^{-1}$

$k_L a$ Volumetric mass transfer coefficient for CO_2, h^{-1}

k_w Light attenuation constant for transparent or translucent vessel wall material, cm^{-1}

K_A Dissolved CO_2 concentration at half saturation, mol L^{-1}

K_i Photoinhibition constant, m^{2}s μmol^{-1} photons

K_N Dissolved limiting nutrient concentration at half saturation, mol L^{-1}

I Light intensity incident to photosynthetic cell, μmol photons m^{-2} s^{-1}

I_k Light intensity at half saturation, μmol photons m^{-2} s^{-1}

I_m Mean light intensity delivered to liquid suspension culture, μmol photons m^{-2} s^{-1}

I_o Light intensity incident to liquid suspension culture inside vessel, μmol photons m^{-2} s^{-1}

I'_o Light intensity incident to outer vessel wall surface, μmol photons m^{-2} s^{-1}

$I(z)$ Light intensity distribution in response to light attenuation, μmol photons m^{-2} s^{-1}

L Light penetration path length for planar photobioreactor, or length of tubing in the tubular section, cm or m

l_w Wall thickness of transparent or translucent vessel material, cm or m

P_A Partial pressure of CO_2 in the aeration gas, Pa or atm

Q_A Volumetric consumption rate of dissolved CO_2 by cell suspension culture, mol L^{-1}h^{-1}

r Radial position within cylindrical vessel, cm or m

R Outer radius of cylindrical vessel, cm or m

R_p Recycle ratio in continuous flow tubular recycle photobioreactor, v_o/v_p

r_X Biomass production rate, g cells L^{-1}h^{-1}

t Cultivation time, h or day

u_{gs} Superficial gas velocity, volumetric aeration gas flow rate divided by bioreactor cross-sectional area, m s^{-1}

v Bulk linear velocity of the liquid culture flowing through the tube (volumetric flow rate divided by cross-sectional area), m s^{-1}

v_a Volumetric flow rate of the aeration gas, L h^{-1}

v_m Fresh medium addition to continuous flow tubular recycle photobioreactor, L h^{-1}

v_o Volumetric flow rate of liquid suspension culture through tubular section (tubular photobioreactor), L s^{-1}

v_o Volumetric flow rate of liquid medium added to continuous photobioreactor, L h^{-1}

v_p Volumetric flow rate of product suspension withdrawn from continuous flow tubular recycle photobioreactor, L h^{-1}

V Total liquid volume of culture, L

V_a Liquid volume of culture in aeration tank of tubular photobioreactor, L

V_t Liquid volume of culture in tubular section of tubular photobioreactor, L

Y_c Specific chlorophyll content of biomass, mg chl a g^{-1} cells

Y_{X/CO_2} Biomass yield coefficient based on CO_2 consumption, g cells mol^{-1} CO_2

$Y_{X/N}$ Biomass yield coefficient based on limiting nutrient consumption, g cells mol^{-1} nutrient

z Position along light path in planar photobioreactor or axial position down length of tubing for tubular photobioreactor, m

Greek Letters.

α Number of illumination planes

μ Specific growth rate of liquid suspension culture, h^{-1}

μ' Specific growth rate defined in (9.12), h^{-1}

μ_c Apparent viscosity of liquid suspension culture, g cm^{-1} sec^{-1}

μ_{max} Specific growth rate of liquid suspension culture at saturation light intensity, h^{-1}

ρ_c Apparent density of liquid suspension culture, g cm^{-3}

τ_{tube} Residence time of culture inside tubular section, h

10. Bioinformatic Techniques on Marine Genomics

A. Mir Bilal, H. Mir Sajjad, Inho Choi, Yoon-Bo Shim

Marine biotechnology is the industrial, medical or environmental application of biological resources from the sea. Since the marine environment is the most biologically and chemically diverse habitat on the planet, marine biotechnology has in recent years delivered a growing number of major therapeutic products, industrial and environmental applications, and analytical tools. These range from the use of a snail toxin to develop a pain control drug to metabolites from a sea squirt to develop anticancer therapeutic and marine enzymes to remove bacterial biofilms. In addition, well-known and broadly used analytical techniques are derived from marine molecules or enzymes, including green fluorescence protein gene tagging methods and heat resistant polymerases used in the polymerase chain reaction. Advances in bacterial identification, metabolic profiling, and physical handling of cells are being revolutionized by techniques such as mass spectrometric analysis of bacterial proteins. Advances in instrumentation and a combination of these physical advances with progress in proteomics and bioinformatics are accelerating our ability to harness biology for commercial gain. Single cell Raman spectroscopy and microfluidics are two emerging techniques that we try to touch a bit in this chapter. In this chapter, we provide a brief survey and update of the most powerful and rapidly growing analytical techniques as used in marine biotechnology, together with some promising examples of less well-known earlier stage methods which may make a bigger impact in the future.

10.1 Background

Genomics is the study of the structure, function, and diversity of genomes; genome is the collective term for all the genetic information contained in a particular organism. Genomics has brought about a revolution in all fields of biology. Genomic analysis, from originally limited to one or a small number of genes to large numbers of genes or even to the complete set that make up a genome, differentiates the genomic approach from the classical biological approach. High throughput methodologies adapted for the analysis of multiple gene sets has led to substantial technical advances and to the development of new ways of thinking about bi-

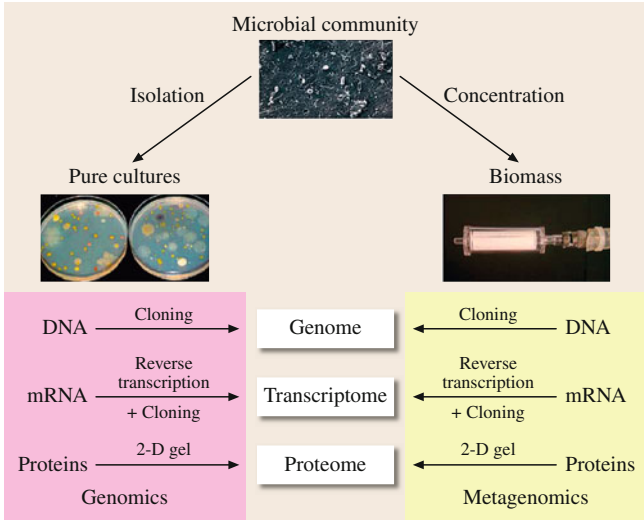

Fig. 10.1 Molecular and genomic approaches to the study of natural communities of microorganisms

ology. Genomics as a discipline began with the first attempts to obtain large-scale sequence data for individual organisms, either by sequencing the genomic DNA (deoxyribonucleic acid) or, where this was not practical, by sequencing large numbers of cDNA (complementary deoxyribonucleic acid) [10.1]. The availability of extensive sequence data for a large number of organisms has facilitated the development of additional genomic tools such as microarray systems for the analysis of gene expression and collections of sequence-tagged mutants.

Marine organisms were very poorly represented amongst these early genomic models and were to some extent left behind as the application of genomic approaches to several terrestrial models allowed an acceleration of our understanding of the biology, ecology, and evolutionary history of these species. Now the situation is different and, to a certain extent, advancements have been made in recent years, essentially due to the reduced cost of DNA sequencing and associated enhanced capacity for analysis of very large datasets. This cost reduction has not only allowed the application of genomic approaches to a much broader range of species but has also opened up new fields of genomics such as metagenomics and metatranscriptomics, in which sequencing methodologies are used in novel and groundbreaking ways. The rapid development of platforms for high-throughput experiments at lower costs can be observed in the fields of transcriptomics, proteomics, and metabolomics as well, providing scientists with a more holistic view of microbes in their natural, environmental context through multiomic studies. Multiomic studies not only significantly increase the size and complexity of genomic data; they demand the integration of diverse data to maximize scientific insights. Marine biology has been at the pole position of many of these new applications.

Novel genomic approaches are currently being applied to exploit the enormous phylogenetic diversity of marine organisms in order to explore the evolution of developmental processes, characterizing the marine ecosystems that play key roles in global geochemical cycles, searching for novel biomolecules, and understanding ecological interactions within important marine ecosystems. Genomics including ecological genomics is being transformed into a data-intensive science with an exponential increase of data [10.2]. The rate of sequence data generation is far outpacing the rate of increase in central processing units (CPU), and the cost of analyzing large datasets produced by, for example, Solexa, already exceeds the cost of generating them [10.3–6]. This situation is often characterized by fear-inducing metaphors such as *data tsunami*, *data avalanche*, and *data deluge*. Rather than being a threat to humankind, however, the technological improvements open challenging, but excellent opportunities for marine biology and biotechnology [10.7].

The burgeoning development of platforms for high-throughput experiments at lower costs can be observed in the fields of transcriptomics, proteomics, and metabolomics, providing scientists with a more all-inclusive view of microbes in their natural, environmental context through multiomic studies. Furthermore, these multiomic studies are extended to metatranscriptomics and metaproteomics, involving analysis of entire microbial communities. Modern marine microbial ecology can be considered to have started in the 1970s, when it was shown that most respiration in the oceans was in the bacterial size fractions [10.8], and that bacteria were very abundant [10.9, 10] (Fig. 10.1).

Nowadays marine microorganisms are known to be responsible for half of the total primary production on the planet [10.11], and the 1030 microbial cells present in the oceans [10.12] account for more than 95% of the total respiration [10.13]. The application of genomic approaches to marine microbial ecology in the past few years has caused a kind of Copernican revolution. Thanks to such techniques, novel functions have been discovered, a large diversity of microorganisms has been discovered, and the meaning of concepts such as species, genome, and niche has been challenged [10.14].

10.2 Marine and Bacterial Fluorescence Shining Light on Biological Questions

One of the most widespread and remarkable analytical techniques to be used in biology in recent years is the use of a green fluorescent protein (GFP) from a jellyfish (Fig. 10.2) to tag and study biological molecules under the microscope in vivo. The natural function of GFP in the jellyfish is unknown, although it has been suggested that the protein may act as a light driven electron transfer. Different GFP-like proteins have been discovered in a variety of marine organisms, including the marine chordate Amphioxus, underlying marine biodiversity as a rich source of biologically useful molecules which can have a major impact on the development of new analytical methods. It will be interesting to monitor the discovery of new fluorescent proteins from bacteria which may provide better markers or markers that allow the visualization of different processes (e.g., redox state) to be visualized in addition to the localization of specific proteins. One example is the development of fluorescent proteins as markers which emit light in the infrared region of the electromagnetic spectrum, allowing visualization of processes that occur deeper in tissues, which are impenetrable to visible light. One of these is an engineered phytochrome, named IPF1.4 from the bacterium *Deinococcus radiodurans*, a bacterium which is highly resistant to ionizing radiation. More recently, the photosynthetic bacterium *Rhodopseudomonas palustris* has provided a phytochrome, which has been engineered to produce the protein near-infrared fluorescent protein (iRFP for improved infrared imaging.

Fig. 10.2 The jellyfish *Aequoria victoria* source of green fluorescent protein which sparked an increase in the availability of fluorescent proteins as biological markers

10.3 Recent Advances in Imaging Techniques for Marine Biotechnology

The invention of the microscope in 1595 and its development and use by Van Leeuwenhoek, a Dutch draper, in his scientific observations of the first bacterial cells is a classic example of the need for new analytical tools as a prerequisite to the opening up of vast new areas of science that were hitherto invisible to us. Whilst this special issue covers a number of key metabolic and genomic breakthroughs which are also promising to reveal new worlds, there have also been some advances in imaging techniques that are proving useful for our ability to analyze biological systems in ever greater detail. One of these is super resolution microscopy. The resolution of images using light microscopy is limited by the physics of light diffraction and is $\approx 250\,\text{nm}$; however, super resolution microscopy has been developed to enable imaging at wavelengths below this limit. In addition to increasing the resolution of images obtained, three-dimensional imaging or subcellular structure is now becoming widely applied.

10.4 Chemical Analysis of Volatile Microbial Metabolites

Quorum sensing as a means by which bacterial cells can carry out the ultimate and original approach to crowdsourcing and collective decision-making for their ecological benefit was a major breakthrough in our understanding of the complexity of bacterial life, and provides the lead idea for the development of novel antibacterial compounds. Quorum sensing was discovered in bioluminescent marine bacteria and later found to regulate a wide variety of physiological responses, including virulence. There is no doubt that other cell–cell communication mechanisms exist and remain to be discovered. One thoroughly studied communica-

tion system occurring in higher animals and plants is through airborne volatile odorous molecules (olfaction). The evolutionary origins of olfaction are interesting, although unclear. Yeast cells, and more recently also bacteria, have been showed to respond physiologically to airborne odorous molecules produced by other bacteria, representing a new category of cell–cell communication in prokaryotes. The ability to quickly detect nearby competing life forms and/or nutrient sources by sensing of odorous molecules (unlike, for example, oxygen or carbon dioxide, which are not directly indicative of other life forms, which is probably why they do not have an odor) would have been an essential ability for survival even in the first bacterial cells to have evolved. In addition, a molecule of ammonia gas is one of the simplest molecules to be indicative of other living cells and would, therefore, have been a good candidate molecule for the first olfactory systems to sense and respond to. Indeed, sensing of ammonia by bacteria also appears to be connected not just to nitrogen metabolism but as a general signal which regulates a number of physiological responses such as biofilm formation and antibiotic resistance and chemotaxis. This, therefore, raises the question as to the use of new and powerful analytical techniques for detecting and analyzing volatile molecule production and function in interbacterial systems. Methods such as targeted metabolomics with mass spectrometry are increasingly being used not only to understand these volatile compounds but to develop artificial olfactory systems of the future.

10.5 Bioinformatics Resources

The sequencing value is realized only through its annotation, which expresses a scientific understanding of the raw data. Currently, a range of annotation systems exists for single-genome analysis. These systems support the management and integration of data from computational analyses using diverse sets of bioinformatics algorithms and software tools [10.15]. This is reflected by examples including sequence assembly [10.16], gene finding, protein domain prediction [10.17], protein function assignment [10.18, 19], prediction of gene expression, and gene regulation accompanied by data from laboratory studies. Until few years ago, most sequenced genomes belonged to bacteria of medical interest. However, thanks to the initiative of the Gordon and Betty Moore Foundation, over hundreds of genomes of marine bacteria have been sequenced in the last 2 years.

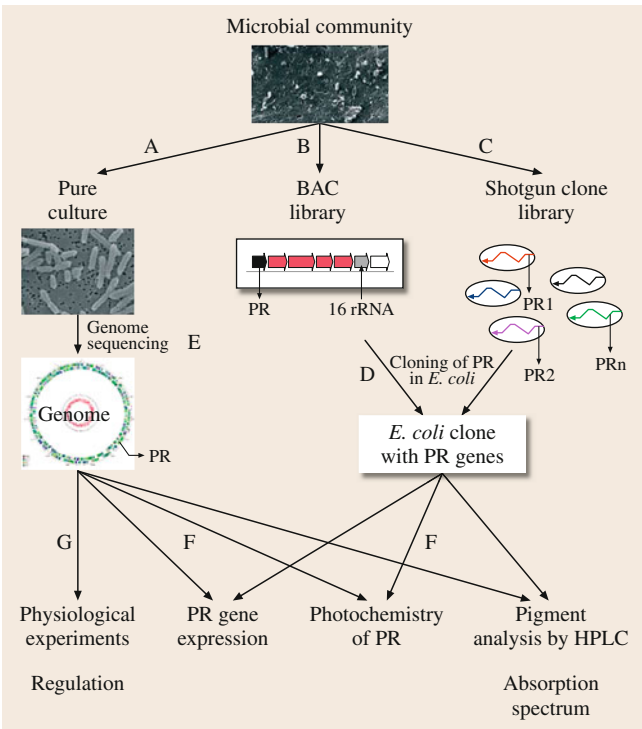

Fig. 10.3 Different approaches to environmental genomics

Of course, the ultimate genome project has surely been the 15-year effort to sequence the 3 billion base pair human genomes [10.20] The large investment in resources and people ($2.7 billion 1991) was paired with a period of rapid development in the technology of sequencing. The chemistry involved was basically the same as that originally developed by Sanger and colleagues (1977) [10.21], but the technology became hugely automated, largely due to the parallel non-governmental effort led by the Celera Corporation [10.22]. Similarly, corresponding advances in computational infrastructure and bioinformatics making sense of sequence data made it feasible to pair together millions of individual sequence reads by massively parallel pair-wise comparison techniques. Applications of these new methodologies helped spur on an explosion in the study of microbes and microbial communities. To date, sequence-based metagenomic analyses of ma-

rine microbiota have attempted to describe: *who is there?*; *what are they doing?*; *who is doing what?*, and *what evolutionary processes determine these parameters?* Recent conceptual and technological advances have allowed the increased use of sequence-guided metagenomic investigations of the marine environment. Recent advances in high-throughput sequencing technology and lower cost sequencing technologies have made random shotgun sequencing of environmental DNA economically feasible. The majority of metagenomic investigations to date have employed whole metagenome shotgun sequencing approaches for the cloning and sequencing of microbial DNA from marine environments. This involves the generation of small insert DNA clone libraries, and their subsequent analysis using Sanger dideoxy sequencing, generating sequences that can then be used to query databases, whereby phylogeny can be inferred or putative functional genes identified. Where putative protein encoding sequences are detected proximal to phylogenetic marker genes on a single cloned fragment, function can be linked to taxonomy. This approach can give read lengths ranging from 600–900 bp in length, which can be extended through the entire fosmid clone. The contigs generated using this approach give a fuller context for any given gene detected, thus giving a greater probability of reconstructing the metabolic pathways of individual members within a particular marine microbial consortium. While the benefits of the technology both from a sequence data generation and cost standpoint (25–40 Mb of DNA sequence per run at an accuracy of ≈ 98%) are obvious, the limitations of lower read lengths of between 200–300 bp can be problematic [10.23]. Read lengths achievable using pyrosequencing are currently around 450 bp, and this is likely to continue to improve, which should improve the amount of useful data generated from pyrosequencing of metagenomics samples (Fig. 10.3).

10.6 Large-Scale Sequence Analysis

With the advent of the *omics* era, more and more metagenomic and metatranscriptomic datasets are being generated from marine environments. While the computational needs for single-genome analysis are solved and can be performed on today's commodity hardware, the new large-scale metagenomic sequencing projects which generate 2000–3000 genome equivalents of sequence information per project bring new challenges. On the one hand, the challenge is the sheer amount of sequence data per metagenome. On the other hand, all metagenome sequences are mere fragments of unknown organismal origin. Taken together, these challenges demand further development of software for assembly, gene calling, and annotation. Recently, several new and dedicated data processing and database resources have emerged to address the current need for large-scale metagenomic data analysis and management, for example, the community cyber infrastructure for advanced marine microbial ecology research and analysis (CAMERA) and the meta genomics-rapid annotation using subsystems technology (MG-RAST) platform [10.24]. However, just a *simple* automatic annotation based on the basic local alignment search tool (BLAST) sequence similarity searches poses a severe computational bottleneck. Consider the following example: in November 2009, the MG-RAST server processed 278 metagenomes with an average of 33 Mbp of sequence data per project. On a single high-end server (Xeon E5540, 8 cpu's, 2.53 GHz, 16 GB ram) a complete BLAST analysis of a single project against

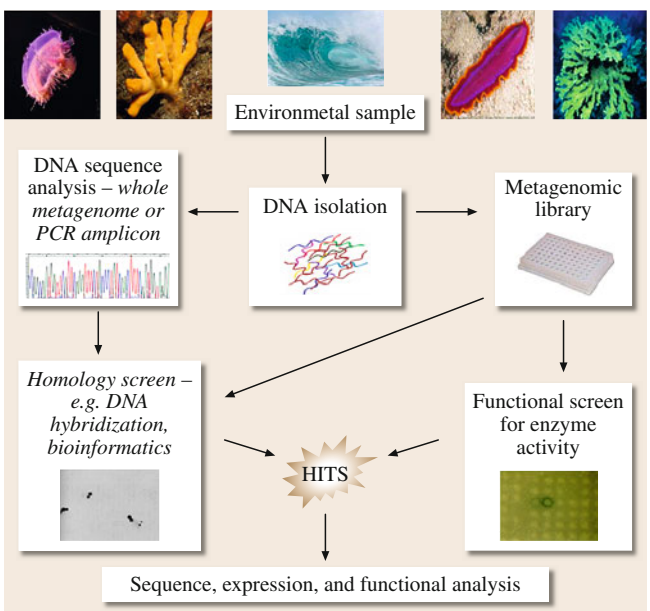

Fig. 10.4 Enzyme discovery from metagenomes: functional and sequence-based approaches

a 2 Gbp nonredundant reference database would take 3 days. Because BLAST computing time grows linearly with the reference database size, and the reference databases double every year, a comparable growth in the number of servers is needed. In other words, any institution that aims to keep pace with the growth of sequence data needs to double its budget each year. Even when accounting for the 15% yearly increase in CPU speed, a 1.7 factor budget growth is needed. This simplified example does not yet incorporate concomitant costs incurred as a result of increases in memory consumption, storage capacities, and network bandwidth for data exchange, as well as power consumption and cooling. The issue becomes even more severe when one considers that, unlike BLAST, several analysis tools have nonlinear computational time consumption and the growth of metagenomic datasets continues steadily.

The rapidly developing field of sequence-based metagenomic analysis of marine microbiota promises much for the future of marine biotechnology. While sequence-based metagenomic approaches rely on comparing sequence data, which is obtained with sequences deposited in databases, functional metagenomics focuses on screening DNA library clones directly for a phenotype, i. e., the genes are recognizable by their function rather than by their sequence. The power of such an approach is that it does not require the genes of interest to be recognizable by sequence analysis, ensuring that this approach has the potential to directly identify entirely new classes of genes for both known and, indeed, novel functions [10.25, 26]. Another advantage of such an approach is that while sequence-based approaches can result in the incorrect annotation of sequences with weak similarities to biochemically characterized gene products or of sequences similar to gene products with multiple functions, the results from a functional metagenomics approach are unambiguous. Data from the Global Ocean Sampling (GOS) expedition indicates that despite current large-scale sequencing efforts the rate of discovery of new protein families from the marine environment is linear, implying that marine microorganisms will continue to be a source of novel enzymes in the foreseeable future [10.27]. As many of these gene products are entirely novel, their activity cannot be inferred from comparison to known protein databases; thus a functional metagenomics approach has the ability to identify novel genes on the basis of phenotypes which lend themselves to high throughput screens Fig. 10.4.

10.7 Integrating Sequence and Contextual Data

From the time of field sampling to final step of sequence analysis, a range of diverse data is produced among different scientific communities, where individual researchers process the samples with different protocols in different time frames. Often, the data is not deposited in public resources at all, or the submitters have the choice of up to a dozen repositories. Therefore, current molecular, environmental and diversity data is fragmented, imprecise, or lost in lab books or proprietary private archives. Moreover, environmental data, such as temperature, cannot be stored consistently in the current records of sequences in the INSDC databases [10.28], nor can a genome sequence be stored in databases dedicated to environmental data. Unfortunately, even conceptually simple contextual data-driven requests, such as *Give me the temperature at the sampling site of the microbial isolate of interest* or *Give me all unknown genes sampled at temperatures greater than* 80 °C, are far from trivial. The reason is as simple as it is profound.

An important source of contextual data is the data taken in the field (on site), such as the geographic and environmental origin of the sample, as well as information about subsequent processing to obtain the DNA, and the sequencing itself. Given that each DNA sequence from the marine environment is properly georeferenced, with geographic location, depth in the water column or sediment, and time of sampling, the environmental context can be significantly complemented with data from environmental databases. Only recently have bioinformatic resources begun to invest in better management and integration of contextual data. CAMERA hosts the fully georeferenced GOS data set. IMG/M integrates rich details about the hosted genomes and metagenomes. Megx.net is the first resource to provide a comprehensive annotation of the environment of microbial genomes Kottmann et al., The Barcode of Life initiative [10.29] successfully collaborated with INSDC to store latitude and longitude in the public sequence repositories. Classical ecological and conservation marine studies focused on species and communities; the emphasis has now shifted to enhancing our understanding of the relationships among the various components

of biodiversity, especially their role in ecosystem services, such as global nutrient recycling and climate. Here, we highlight the significance of genomics and genetic principles in elucidating the interactions among different biological levels of diversity, from genetic and cellular, to community and ecosystem-level processes. Genomic methods are especially powerful in disclosing previously undetected taxonomic (e.g., DNA barcoding), genetic (e.g., 454 sequencing), and functional (e.g., gene expression, analysis of metabolites) diversity, including the identification of new species and metabolic pathways.

10.8 Proteomics as Potential Tool for Survey in Marine Biotechnology

Currently, newer regulations have been introduced to ensure that marine resources are exploited in a rational way, thus preventing depletion of the available resources. Accordingly, proteomic tools are aimed at the investigation of the proteome, which includes all changes in the quantities and post-translational modifications of all the proteins in cells. The changes may be brought about by growth, differentiation, senescence, changes in the environment, genetic manipulation, or other events. To date, the application of proteomic tools for the investigation of seafood and other marine products has been scarce. An idea of the current limited impact of proteomics in this research field can also be gained if one considers that SWISSPROT, EXPASSY, NCBI, and other databases include fewer than 23 000 amino acid sequences from teleost fish proteins, most of which correspond to the Euteleostei group. By contrast, there are nearly 610 000 nucleotide sequences reported for this group of aquatic vertebrates. Thus, the relative amount of information about protein sequences in this field is below 4% with respect to the number of DNA sequences available. Nevertheless, it should be stressed that proteomics has been useful in some biomedical applications of marine proteins. Additionally, proteomics has afforded valuable tools for the investigation of fish physiology and pathology. Among the research areas in which proteomics may have applied interest for the investigation of teleost fish, the following should be noted: antifreeze proteins, immunoglobulins, and enzymes. Note should also be taken of the application of proteomics to the sequencing of parvalbumins and to the characterization of their allergenic potential or calcium transport properties.

10.9 Proteomics and Seafood

From the nutritional and functional points of view, proteins are the basic components of seafood. The wide variability of proteins present in seafood and their highly variable composition offers a strong potential to originate a large variety of different products. In addition, the denaturation levels of seafood proteins are closely related to the sensory and technological properties of seafood products. Proteomic tools have seldom been applied to food nutritional analysis and, in the particular case of seafood technology, the shortage is even more relevant. Thus, MS methods have been considered in nutritional studies on milk and egg products. The application of proteomics to marine biotechnology began in the past decade. Important fields such as investigation of the expression of selected exogenous features introducing rough DNA manipulation techniques in transgenic fish have only been recently initiated. Although fish transgenesis involves gene integration and transmission steps achieved by gene mapping and other genomic tools, follow-up of the expression of such genes and the subsequent biosynthesis of recombinant proteins involves the use of proteomic tools. It should be noted that although the genomes of both wild-type and transgenic marine organisms are well-defined and not subject to variation; the proteome of these organisms may depend on several intracellular and/or extracellular factors and is hence subject to variation, thus being in a dynamic state. Accordingly, the follow-up of the advanced steps of gene expression by proteomic tools allows research scientists to elucidate the effect of such factors on the proteome, thereby providing valuable information aimed at obtaining the optimum levels of a target protein involved in prototrophy and growth, or in other features of technological interest. From the biotechnological point of view, traits of interest in aquaculture have focused on, amongst

other things, the improvement of the growth rate or the increase in thermotolerance. Growth enhancement strategies have been successfully applied to several fish species, such as carp, catfish, tilapia, and salmon, through the incorporation of homologous or heterologous growth hormone (GH) genes or cDNAs. The monitoring of gene expression in genetically modified marine organisms is thus a crucial step in the optimization of the use of such organisms in aquaculture and seafood technology. It should also be noted that the cross-effect of transgene expression on the biosynthesis of host proteins in genetically improved fish species is another relevant issue in which proteomics will surely play a significant role soon. In both issues, proteomics represents a valuable tool of remarkable applied interest.

10.10 Present Status and Future Trends of Proteomics in Marine Biotechnology

Proteomic tools, mainly 2-D PAGE (polyacrylamide gel electrophoresis) and mass spectrometry, represent a robust analytical strategy for the phenotypical investigation of marine organisms of industrial interest. These tools afford specific information about expression patterns, post-translational modifications, or protein interaction mechanisms. This information is extremely useful for the optimization of specific biotechnological processes. It should be stressed that high-throughput proteomics techniques have recently been coupled with newer bioinformatic tools, thus affording more robust and powerful strategies for both protein identification and characterization purposes. Recently, proteomic tools were successfully applied for the isolation and characterization of a calponin-like protein from the mussel *Mytilus galloprovincialis* 68 kDa polypeptide, a polypeptide involved in muscle contraction processes. The protein, isolated from the retractor muscle of this mollusc, was successfully separated from actin by 2-D PAGE and was identified by N-terminal amino acid sequence analysis. Likewise, the investigation of mussel adhesive proteins which have been reported to harbor an extraordinary biotechnological potential as a biodegradable adhesive material is another promising field in which proteomics may play a significant role. It is noteworthy that the protein can be readily obtained from mussels, a marine source characterized by their wide availability and low price. Thus, proteomic tools should play a significant role when undertaking optimization strategies aimed at achieving the highest yields of such proteins, mainly by elucidating the biochemical modifications to be considered in the process design step. The investigation of marine bacteria by proteomic techniques is also still in its early days. Although the protein profiles of the thermophilic microorganism *Pyrococcus abyssi* were investigated when the organism was subjected to different levels of pressure and temperature, other authors applied 2-D PAGE to investigate the level of protein biosynthesis and expression in *Sphingomonas* sp. cultivated under different conditions. Earlier reports considered high-resolution 2-D PAGE to elucidate the mechanisms of UV protection in cyanobacteria, concluding that this technique had greater power of resolution than conventional SDS-PAGE (SDS: sodium dodecyl sulfate) to detect proteome changes. The relationship between symbiotic marine bacteria and their hosts is another field in which proteomics may represent a valuable tool. In this sense, 2-D PAGE has also been successfully applied to the elucidation of proteome changes in the squid *Euprymna scolopes* due to the presence of the symbiotic marine luminous bacterium *Vibrio fischeri*. These authors described the usefulness of 2-D PAGE in following up protein changes in the host soluble proteome in colonized organs of the squid specimens in comparison with uncolonized specimens.

10.11 Pharmacophore Model Hypo1, Virtual Screening for Identification of Novel Tubulin Inhibitors with Potent Anticancer Activity

Microtubules are cytoskeletal filaments consisting of R/β-tubulin heterodimers and are involved in a wide range of cellular functions, including shape maintenance, vesicle transport, cell motility, and division. In the mitotic phase of the cell cycle, microtubules are in dynamic equilibrium with tubulin dimers by assembling the tubulin into microtubules or, conversely, disassembling microtubules to tubulin. Disruption of the dynamic equilibrium can induce cell cycle arrest and ultimately lead to apoptosis. Therefore, compounds that could in-

hibit tubulin polymerization or interrupt microtubule depolymerization would be useful in the treatment of cancer. In recent decades, several compounds, mostly natural products, targeting tubulin have been discovered and developed; some of them are already in clinical use, such as epothilone, paclitaxel, and vindesine.

Recent studies reveal that the antitubulin agents targeting the colchicine sites could, in addition to their antimitotic action, shut down the blood supply to tumors by disassembling the microtubules of abnormal vasculatures and changing the endothelial cell morphology, which would consequently cause nutrient starvation of tumor cells and eventually lead to apoptosis. These vascular-disrupting agents, e.g., combretastatin (CA4), provide a promising new approach in the treatment of cancer and are currently under clinical evaluation for single-drug cancer therapy or multidrug treatment in combination with other cytotoxic drugs and antiangiogenic agents.

10.11.1 CBM4-2 Carbohydrate Binding Module from a Thermostable *Rhodothermus marinus* Xylanase

The family of CBM4-2 structures was calculated using hybrid distance geometry/simulated annealing protocol following methods similar to those used by *Sorimachi* et al. [10.30] and *Simpson* et al. [10.31]. The final set of restraints contained 1654 nonredundant unambiguous NOEs and ambiguous NOEs, 93 æ, 72 ø1, and 1 ø2 restraints, and 65 pairs of hydrogen bond restraints, plus 177 backbone dihedral restraints based on chemical shifts from TALOS. Almost all hydrogen bond restraints were limited to those expected from the regular secondary structure, except for Ala4-Ile164 and Asn79-Ala4, which contribute to tertiary structure, together with Trp28-Val25, Val36-Gly33, and Trp69-Asn67, which are involved in â-turns. The final restraint set had 12.8 restraints per residue. The first 12 models had a very similar energy and showed no NOE violations greater than 0.2 Å and no angle violations greater than 5°. Hence, these models were selected to represent the solution structure of CBM4-2. The average structure was calculated from these 12 structures (by selecting the lowest energy structure and superimposing the remaining 11 on this one) and was subsequently subjected to restrained energy minimization to yield the minimized average structure. The 12 best structures and the average structure have been deposited with the Research Collaboratory for Structural Bioinformatics Protein Data Bank (PDB ID 1k42 (ensemble) and 1k45 (minimized average)).

10.12 The Polymerase Chain Reaction: A Marine Perspective

A major step in the widespread application and development of the polymerase chain reaction was undoubtedly the early use of the heat stable DNA polymerase Taq. Owing to commercial interest in manufacturing different heat stable polymerases, a larger number of enzymes from hot springs and marine environments were subsequently reported. The fidelity of these enzymes also differed, and one enzyme, that from the marine thermophile *Pyrococcus furiosus*, named Pfu, was found to have superior copying fidelity and is now a widely used polymerase chain reaction PCR reagent. *P. furiosus* was isolated from geothermally heated marine sediments on Vulcano Island, Italy, and is a good example of marine biodiversity providing useful solutions to analytical methods. The widespread use of PCR and high throughput sequencing has allowed us to realize that the vast majority of marine microbes remain to be isolated and studied even though their genes are now accessible.

10.13 Conclusions and New Frontiers

It is clear that once a significant advance has been made in physics, mathematics or chemistry, it is often decades before optimization, improved instrumentation, and increased awareness allow the use of these new techniques in biotechnology. It would, therefore, be interesting to look into the world of physics and mathematics today and asks our colleagues in those disciplines what the key breakthroughs have been in the last few years, so that we might deliberately accelerate their uptake into both mainstream biotechnology and biotechnology of the sea. Recent reports have highlighted the problems arising from the need to handle,

manage, and utilize so-called *big data* in all sectors of the economy, not just biotechnology. It is difficult to extract biological meaning from such data sets. Each of the many new analytical techniques described in this chapter will involve rapid data acquisition accelerating the problem still further, and it may, therefore, be in the fields of mathematics and computing where the most interesting breakthroughs will occur in the coming years.

11. Microbial Bioprospecting in Marine Environments

Mariana Lozada, Hebe M. Dionisi

During evolution microorganisms accumulated a remarkable physiological and functional heterogeneity as a result of their adaptation to various selective environmental pressures. Marine microorganisms have been evolving and diversifying for billions of years in contrast microorganisms from terrestrial habitats, which possess a much shorter evolutionary history. In addition, the oceans harbor unique habitats that are mostly unexplored, making them exciting targets for bioprospecting of new microbial capabilities. Over the last years, novel and more complex approaches for the screening of molecules and activities from marine microorganisms with biotechnological potential have been developed and successfully applied. In this chapter, we explore methodological approaches that are currently being used for microbial bioprospecting, with emphasis in the marine environment. These include, among others, high-throughput and other advanced cultivation techniques aiming to recover a larger fraction of culturable microbes, as well as culture-independent, *omics* and *meta-omics* approaches for mining the microbial metabolic potential.

11.1 Bioprospecting

The term bioprospecting refers to the systematic search for novel biological products and activities with biotechnological applications in natural habitats [11.1]. The course of search and discovery in biotechnology starts with the selection of the most appropriate environments and sampling methods from previous information, continues with the retrieval of the biological materials and their correct storage, moves through screening for desired attributes in the form of microbial assemblages, cells, macromolecules, metabolites, or bioactive compounds using an ever-growing toolkit, and culminates with the development of a commercial product or process ([11.2], Fig. 11.1). This workflow represents a value-adding chain that ends with the addition of products and services that respond to society's needs [11.3]. The biotechnological potential of microbial diversity can be further improved by tools such as enzyme engineering, metabolic engineering and directed evolution [11.4]. Due to their exceptional microbial biodiversity, marine habitats represent fertile grounds for bioprospecting. In this chapter, we will explore the state-of-the art and emerging approaches that can be used to search for biological products and activities with applications in all biotechnological fields.

11.2 Marine Microbial Habitats and Their Biotechnologically-Relevant Microorganisms

The marine environment covers more than 70% of the Earth's surface and contains 97.5% of the water of our planet. Marine habitats contain a rich variety of distinctive life forms, the majority of them represented by microorganisms. Salinity is the major environmental determinant of microbial community composition, clearly distinguishing marine habitats from terrestrial ones [11.5]. Moreover, marine sediments constitute the most phylogenetically diverse environments on Earth, in contrast with soil, which bears high species-level diversity but has below-average phylogenetic diversity [11.5]. Marine microorganisms are progressively recognized as a promising source of biotechnologically valuable products and capabilities. Over the last years, many biomolecules with unique structural features and unique molecular mode of action have been identified in marine environments [11.6]. However, many marine microbial habitats still remain largely unexplored, understudied, and underexploited in comparison with terrestrial ecosystems and organisms.

Through billions of years of evolution, marine microorganisms have developed unique metabolic and physiological capabilities to thrive in a variety of marine habitats. In fact, oceans include the greatest extremes of temperature, light, and pressure encountered by life [11.7]. In recent years, marine microorganisms living under extreme conditions have been the focus of bioprospecting efforts as novel sources of biomolecules with biotechnological potential [11.8, 9]. For example, hydrothermal vents comprise microorganisms with distinct metabolisms based on chemosynthesis. The high diversity and abundance of these communities are comparable to those found in shallow tropical seas, and thus they are recognized as potentially rich sources of biologically active natural products [11.10]. Piezophilic microorganisms inhabiting deep-sea habitats are also of interest, as they can provide enzymes for high-pressure bioreactors, among other applications [11.11]. Interestingly, these microorganisms can be either psychrophilic or thermophilic due to the cold temperatures of the deep ocean or to their proximity to hydrothermal vents, respectively.

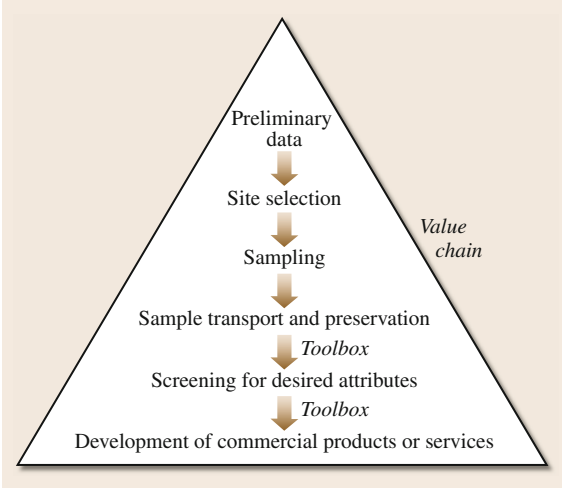

Fig. 11.1 Workflow of search and discovery in biotechnology

Other types of marine microorganisms with potential biotechnological capabilities include those living under epiphytic, epibiotic, and symbiotic lifestyles. Competition and defence strategies characteristic of surface-associated microorganisms, such as the production of toxins, signaling molecules, and other secondary metabolites, constitute an unparalleled reservoir from a biotechnological perspective [11.12, 13]. Bacteria living in symbiotic associations with marine invertebrates often produce complex metabolites as a consequence of coevolution with their host [11.14]. Sponges and corals are examples of habitats where symbiotic microorganisms with interesting capabilities have been found [11.15]. In many cases, microorganisms have been found to be the producers of metabolites previously assigned to their hosts [11.16].

Microorganisms from intertidal zones must be able to tolerate rapid and repeated fluctuations in environmental conditions. These include temperature, light, and salinity, as well as wave action, ultraviolet radiation, and periods of drought [11.17]. Intertidal microbial communities preferentially grow as biofilms on natural and artificial surfaces. Within these protective microenvironments, they are subjected to intense biological and chemical interactions, leading to the production of various interesting secondary metabolites [11.18]. For example, in response to intense solar radiation, cyanobacteria and other microorganisms inhabiting intertidal or supratidal zones produce UV-absorbing/screening compounds, which present potential for the development of novel UV blockers for human use [11.19].

There are certain phylogenetic groups which per se constitute interesting targets for bioprospection. Actinomycetes (within the phylum Actinobacteria) are widely known for their capabilities of producing metabolites, which include antibiotics, antitumor and immunosuppressive agents and enzymes, among others [11.20]. Novel compounds with biological activities have already been isolated from marine actinomycetes [11.6]. Culture-independent studies have shown that the majority of actinomycetes from marine environments are not recovered by cultivation-based methods, and that marine actinomycetes are very different phylogenetically from their terrestrial counterparts [11.21, 22]. Deep-sea sediments and marine flora and fauna allow the access of true marine actinomycetes, away from the influence of land wash-offs [11.6]. Given the fact that 45% of all microbial bioactive secondary metabolites currently derive from actinomycetes and that only 10% of these metabolites is estimated to have been discovered so far, it becomes evident that advances in the ability to access this yet unexploited diversity will provide a new source for the discovery of secondary metabolites [11.23].

11.3 Methods for Microbial Bioprospecting in Marine Environments

Both culture-dependent and independent methods have uncovered an incredible diversity of microorganisms whose metabolisms largely have yet to be characterized [11.24, 25]. These methods have been further empowered by genomic-level information, which in turn is supported by sequencing technologies and bioinformatics [11.26, 27]. In the next sections, traditional, state-of-the-art and emerging approaches used for bioprospecting marine microorganisms with biotechnological potential will be reviewed.

11.3.1 Culturing Techniques

Microbial bioprospection and biodiscovery is currently severely limited by the lack of laboratory cultures [11.28]. Although culture-independent approaches have revolutionized environmental microbiology, the development of biotechnological applications from the genetic potential of microbial communities as well as fundamental environmental research must be anchored by the corresponding study of pure cultures. Furthermore, this novel diversity needs to be deeply characterized and adequately preserved in order to guarantee its future availability [11.29]. Novel cultivation methods, fortunately, continue to emerge as alternatives to overcome culture limitations [11.30]. These methods rely on advances in basic biological and ecological knowledge in order to best simulate the natural environment, as well as on the development of new technologies for more efficient screenings (Table 11.1). With the aid of sophisticated high-throughput cultivation techniques, the proportion of microorganisms from marine environments represented in culture has increased significantly over the last years [11.31].

High-throughput dilution-to-extinction culture is one of the most powerful and sensitive approaches for the culture of marine microorganisms such as bacterioplankton. This technique led to the cultivation of the first member of the widespread but yet uncultured marine SAR11 clade [11.40]. This method consists in dilution of bacteria up to 1–10 cells per well in microtiter plates, using low-nutrient filtered seawater. High-throughput screening based on fluorescence microscopy clearly improved the technique over conventional methods, allowing rapid and sensitive detection of growing cells [11.35]. In later studies, this approach was coupled to long-term incubation at low temperatures to allow the recovery of new microbial variants [11.39].

The diffusion chamber [11.32] is a device in which microbial cells are inoculated in an agar matrix separated from the source environment by membranes, isolating the cells but allowing nutrients and growth factors to pass through. The use of this device greatly improved the proportion of culturable bacteria from marine sediments [11.32]. Another version of this approach is the microbial trap, which selectively enriches for filamentous bacteria (e.g. actinomycetes) by allowing the filament colonization of the sterile agar through membranes with 0.2 µm pores [11.34]. Microdroplet encapsulation in an agarose matrix, combined with growth detection by flow cytometry, led to the recovery of new clades from the marine environment [11.36, 37]. This approach is similar to the diffusion chamber in the sense that the agarose is porous, and nutrients and signaling molecules can diffuse into the growing colony and waste metabolites can diffuse out. Another advantage of the approach is that the microdroplets are physically separated and, because they are much larger than bacterial cells, they can be manipulated [11.28, 36].

Currently, second-generation high-throughput automated methods are being developed from these environ-

Table 11.1 Limitations encountered with the culturing of marine bacteria and solutions implemented through novel culturing techniques

Limitation	Solution	References
Lack of knowledge on physiological needs	Culture in situ or in simulated natural media	[11.32–34]
Oligotrophy (particularly bacterioplankton)	Use of low-nutrient filtered seawater	[11.35]
Overgrowth of fast growers	Dilution, encapsulation	[11.35–37]
Slow growth	Long-term incubation	[11.38, 39]
Poor cell density	Highly sensitive screening techniques (e.g. fluorescence microscopy, flow cytometry)	[11.35–37, 40]
Dormancy	Long-term incubation, repeated short-term incubations	[11.41]
Special needs of chemical or physical parameters	Chemical gradient systems, high-pressure reactors, flow-through devices, gas-lift reactors	[11.42–44]
Need of attachment to a solid surface	In situ colonization carriers	[11.44–46]
Loss of interactions between interdependent microorganisms (e.g. syntropy, cell-to-cell signaling)	Diffusion devices, microdroplet encapsulation, co-culture of *helper* strains, addition of growth factors	[11.30, 32, 36, 47, 48]
Complexity of bacterial communities	High-throughput cultivation and screening	[11.40, 49–51]

mental cultivation devices. One example is the development of the isolation chip (Ichip), a culture/isolation device composed of several hundreds of miniature diffusion chambers, each inoculated with a single environmental cell [11.50]. Another example is the micro-Petri dish, a device supported by porous material and reaching a million growth compartments [11.49]. An interesting method that couples high-throughput culture to rapid chemical screening was recently developed to identify symbiotic microbes producing secondary metabolites [11.51]. The screening is chemically based, by means of the use of ultra high-performance liquid chromatography/mass spectrometry. In this approach, a 96 multi-well plate format is utilized in rounds of successive culturing steps [11.51]. This strategy prevents spending significant resources on isolating, culturing, and analyzing microbes that do not possess the capability to produce the compounds of interest.

Various factors are thought to contribute to the low rate of culture recovery of environmental microbes (Table 11.1). The lack of knowledge of the environmental and nutritional requirements of yet unknown microorganisms is the most obvious. Another is the loss of biological cell-to-cell interactions in the isolation process [11.44]. For example, most of the strains able to grow on Petri dishes after recovery in diffusion chambers were, indeed, mixed cultures, highlighting the importance of chemical signaling for microbial growth [11.32]. The co-culturing with *helper strains*, followed by the identification of an oligopeptide signal, allowed previously uncultured strains to be successfully isolated in the laboratory [11.30, 48]. These authors have also reported problems in the successful adaptation to laboratory conditions or *domestication* of the cultured strains, as many of the strains forming microcolonies in diffusion chambers could only undergo a limited number of divisions in Petri dishes [11.32]. In further experiments, successive rounds of in situ cultivation in the chambers allowed for a larger recovery of isolates [11.30].

Advances in the understanding of basic microbiological principles can greatly help us to overcome the limitations of culturing environmental microbes. The theory of *scouting* of dormant cells proposes that any microbial population consists of a mixture of active and dormant cells [11.41, 52]. Individual cells periodically exit dormancy, although these events are not related to the onset of favorable environmental conditions, but are rather essentially random. Moreover, this happens independently of the nature of the microbial species (sporulating vs. nonsporulating, or fast versus slow growers). Indeed, the importance of the slow growers in environmental samples may be lower than previously thought, as many of the microbes regarded as slow growers in culture are, in fact, late awakening events [11.52]. One practical implication of this theory is that the success in discovering novel species depends on the overall amount of cultivation effort rather than the length of in-

cubation (i. e., the same amount of effort focused either on many short-term or fewer long-term cultivation experiments) [11.41]. This theory could explain previous findings, such as why, for example, representatives of the phylum Verrucomicrobia that had been considered unculturable for many years, were eventually cultivated using rather conventional techniques. Dilution cultures were used to separate the very fast growers, but long incubation times were not necessary [11.41, 53].

11.3.2 Culture Independent Gene-Targeted Methods

In spite of the recent advances in microbial culturing, the majority of environmental microorganisms are still unculturable. Out of the more than 100 bacterial divisions that have been proposed to date, only 30 possess a cultivated representative [11.29]. Moreover, marine microbes are at the top of the list of those unculturable by conventional methods [11.26]. Since the landmark studies of *Woese* and *Pace* [11.54, 55], which stated the basis for molecular phylogeny, culture-independent methods have revolutionized our understanding of microbial communities [11.56] and currently stand on their own as a valid alternative for bioprospection. These methods are based on the information provided by biomolecules, mainly deoxyribonucleic acid (DNA), bypassing the need of cultivation by extracting these biomolecules directly from the environmental sample. Although they are not exempt from biases [11.57], they are still the best way to gain access to the overwhelming biodiversity of environmental microbes.

Culture-Independent Phylogenetic Approaches

Among culture-independent methods, the approach based on the molecular phylogeny of rRNA (ribosomal ribonucleic acid), particularly the small subunit (16S rRNA for archaea and bacteria), continues to be one of the most widely used. This gene has two properties that have positioned it as a building block for a universal molecular phylogenetic framework: its presence in all forms of life and a domain structure with variable evolutionary rates, which enables phylogenetic reconstruction at various levels. Fingerprinting techniques, polymerase chain reaction (PCR) clone libraries, and microscopy-based techniques like fluorescence in situ hybridization (FISH) have been routinely utilized over the last decades to describe and compare the structure and composition of microbial communities [11.58]. More recently, large-scale sequencing of 16S rRNA gene hypervariable regions has brought new strength to the classical phylogenetic approaches, which suffered a number of limitations associated with low coverage and cloning biases [11.59]. These approaches can be used as a guide for phylogenetically-driven biodiscovery. For example, analysis of community 16S rRNA by sequencing or fingerprinting can be used to select the most diverse sampling sites, thus maximizing novel taxa recovery in culture (Fig. 11.2, [11.23]). This approach is based upon the premise that taxonomic diversity is coupled to chemical diversity due to the role that secondary metabolism plays in speciation [11.23].

Functional Gene-Based Approaches

Approaches based on functional genes, which focus on the potential of the community to perform an activity of interest, can give a complementary view to the phylogenetic approach. Gene coding for key enzymes participating in different environmental processes, such as sulfate reduction [11.60], denitrification [11.61], nitrogen fixation [11.62], ammonia oxidation [11.63], hydrocarbon biodegradation [11.64, 65] among others, have been studied in the marine environment. Targets include not only bacterial but also archaeal populations and subgroups within these, by means of the use of primers with different specificities. Due to its highly focused nature, this approach is very powerful. However, one of its major drawbacks is the relative lack of database sequence information for functional genes, with respect to the 16S RNA gene. Another shortcoming is the lack of accuracy in taxonomic assignment due to lateral gene transfer [11.66].

Functional genes have the potential to be used as biomarkers in assays developed for the environmental biotechnology field, including wastewater treatment [11.67], and environmental remediation (Fig. 11.2, [11.68]). These molecular biological tools have been applied in the marine environment, for example, for the study of hydrocarbon degrading bacterial populations [11.64, 65]. In particular, quantitative polymerase chain reaction (qPCR) is a promising technique due to its quantitative nature, high sensitivity and the possibility of high throughput analysis [11.68]. However, this tool is still in its infancy for field applications in marine environments.

Linking Phylogeny and Function: Labeled Isotopic-Based Approaches

One of the long-standing goals of environmental microbiology is the possibility to link the phylogenetic identity of an uncultured microorganism with its function in

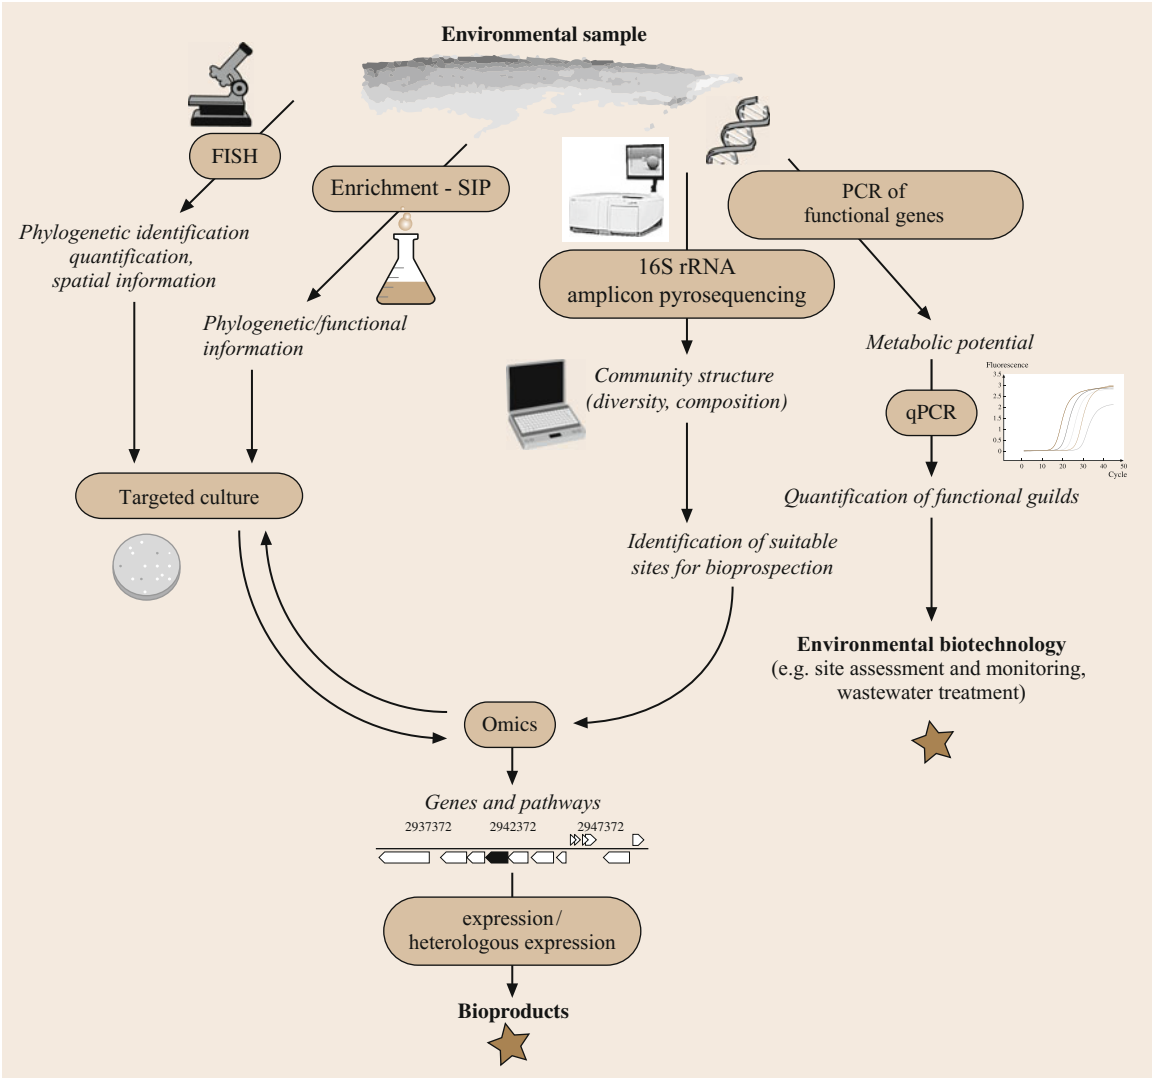

Fig. 11.2 Culture-independent gene-targeted approaches relevant for biotechnology. These approaches can aid in the selection of suitable sites for bioprospection and in inferring possible culturing conditions. They are also relevant in environmental biotechnology

the environment. The achievement of this goal can have far-reaching consequences for our understanding of microbial communities and ecosystems. Furthermore, it can fuel our efforts in the identification of new biotechnologically sound microbes and activities. Advances in isotope labeling have started to contribute over the last years to this goal [11.69]. The basic principle of this approach is that the labeling of substrates with stable or radioactive isotopes allows for the differentiation of metabolically active populations that incorporate the substrate. When this approach is coupled to some form of identification tool, the result is an experimental evidence of both the functional role and the phylogenetic identity of a previously unknown population. Stable isotope probing (SIP) was one of the first methods to be developed [11.70]. Microbial populations utilize the substrates offered labeled with a stable isotope and assimilate the heavier source into cell components, which in turn become labeled. The heavier and lighter molecules are then physically separated and analyzed.

The most widely used method is DNA-SIP, in which DNA is separated in caesium chloride gradients and further purified and analyzed by cloning and sequencing [11.70]. The RNA-based SIP approach maintains the sequence-based phylogenetic resolution of DNA-SIP, but focuses directly on the RNA molecule itself rather than its gene, with the advantage of a high copy number and a turnover that is independent of cell replication [11.71]. Marine environments studied by this method include marine and estuarine sediments [11.72–74] and seawater samples [11.75]. Biotechnological applications of SIP have mainly addressed issues related to environmental biotechnology [11.76].

SIP depends upon the availability of stable isotopes (^{13}C, ^{15}N, ^{18}O) and of substituted substrate compounds [11.69]. However, they have the advantage of generating de novo information about the identity of the populations associated with a certain metabolic process. Interestingly, different incubation times can be used to follow the carbon flow in the different members of the community. The results can then be further tested experimentally, for example, by means of imaging techniques or targeted culture (Fig. 11.2).

Microscopy provides information about spatial arrangement and physical interactions of cells, which is applicable to spatially complex environments such as biofilms, consortia and symbiotic assemblages (Fig. 11.2). The development of fluorescence in-situ hybridization (FISH) enabled the detection and identification of single microbial cells in environmental samples by means of rRNA-targeted gene probes [11.77]. Microscope-based enumeration of cells makes this method an excellent approach for quantitative estimations, which is more accurate than conventional PCR. Furthermore, the technique is suitable for the use of multiple hierarchical probes in the same sample, which reduces the possibility of false positives. This powerful method has been coupled with the microautoradiography technique (FISH-MAR), which offers the possibility to directly observe the incorporation of substrates labeled with a radioactive isotope into single microbial cells [11.78]. As in SIP, the main limitation of this technique is the availability of radiolabeled substrates, with the additional concern of safety issues. In addition, some environmental samples bearing cells with low ribosome content (e.g., marine oligotrophic environments) can have detection problems with FISH. Horseradish peroxidase (HRP)-labeled oligonucleotide probes and tyramide can be used to enhance the signal intensities of hybridized cells. This approach is sometimes called catalyzed reporter deposition FISH (CARD-FISH, [11.79]), which can also be coupled to microautoradiography, further increasing its potential [11.80]. Raman microspectroscopy and nanometer-scale secondary-ion mass spectrometry (nanoSIMS [11.81, 82]), are other techniques that are currently under development and may potentially be useful in the future for bioprospecting.

11.3.3 *Omics* and *Meta-Omics* Approaches

The large-scale study of genes (genomics), transcripts (transcriptomics), proteins (proteomics), metabolites (metabolomics), lipids (lipidomics), and interactions (interactomics) are globally defined as *omics* in the study of individual species and are often referred to as *meta-omics* approaches when microbial communities are analyzed [11.83]. These are rapidly evolving fields, which are highly dependent on the development and improvement of technologies and analysis tools. Besides their critical role for understanding the structure and function of microbial communities, they represent powerful approaches for the bioprospection of biological products and activities with biotechnological potential in marine environments.

Genomics

Since the publication of the genome of the bacterium *Haemophilus influenzae* Rd in 1995 [11.84], the number of sequenced genomes has expanded quickly [11.85]. By the end of 2012, the Genomes Online Database (GOLD, Table 11.2) listed more than 4000 completed genome projects, 90% of them belonging to bacteria. Approximately 60% of these genomes where *finished*, that is, all segments obtained after the assembly were ordered, all gaps were closed, and any ambiguities or discrepancies were resolved after a series of rigorous quality-control steps [11.86, 87]. As the finishing step increases the cost and time required to sequence a genome, often the final goal is to obtain a draft genome, represented by a number of contigs or scaffolds [11.87]. Although there are limitations for the use of draft sequences in some applications [11.88], draft assemblies are a powerful resource for bioprospecting, as the majority of the genes of an organism are usually represented in its draft genome [11.86].

Not only the number of genomes sequenced so far represents a minimal proportion of the microbial diversity present in our planet [11.89], but also some phylogenetic groups of microorganisms (such as members of the Proteobacteria and Firmicutes) are greatly over-represented, while other groups have no represen-

Table 11.2 Websites of initiatives of genomic and metagenomic data generation, repository and/or analysis tools, useful for marine microbial bioprospecting

Initiative/Website	Description
Genomic Encyclopedia of Bacteria and Archaea (GEBA) project www.jgi.doe.gov/programs/GEBA	It aims at systematically filling in the gaps in sequencing along the bacterial and archaeal branches of the tree of life
Marine Microbial Genome Sequencing Project http://camera.calit2.net/microgenome	Its aim is to increase the number of whole genome sequences of ecologically relevant marine microorganisms
Genomes Online Database (GOLD) www.genomesonline.org/cgi-bin/GOLD/index.cgi	Resource for comprehensive access to information regarding genome and metagenome sequencing projects, and their associated metadata
Integrated Microbial Genomes and Metagenomes System (IMG and IMG/M) http://img.jgi.doe.gov	Community resource for analysis and annotation of genome and metagenome datasets in a comprehensive comparative context
National Center for Biotechnology Information (NCBI) Genome and Sequence Read Archive (SRA) www.ncbi.nlm.nih.gov	NCBI Genome organizes information on genomes including sequences, maps, chromosomes, assemblies, and annotations. The NCBI SRA stores raw sequencing data from the next generation of sequencing platforms
Metagenomics Analysis Server (MG-RAST) http://metagenomics.anl.gov	The MG-RAST server is an automated analysis platform for metagenomes providing quantitative insights into microbial populations based on sequence data
Microbial Ecological Genomics DataBase (MegDB) www.megx.net	MegDB is a collection of publicly available georeferenced marine bacterial and archaeal genomes and metagenomes
Earth Microbiome Project (EMP) www.earthmicrobiome.org	Massive multidisciplinary effort to analyze microbial communities across the globe, using metagenomics, metatranscriptomics, and amplicon sequencing
Microme www.microme.eu	Resource for bacterial metabolism, whose aim is to support the large scale inference of metabolic flux directly from genome sequence
Microbial Genome Annotation & Analysis Platform (MicroScope) www.genoscope.cns.fr/agc/microscope/home/index.php	Web-based platform for microbial comparative genome analysis and manual functional annotation
Text Mining for Bacterial Enzymes (TeBactEn) http://tebacten.bioinfo.cnio.es	Tool designed to facilitate the retrieval, extraction and annotation of bacterial enzymatic reactions and pathways from the literature
Characterized Protein Database (CharProtDB) www.jcvi.org/charprotdb/index.cgi/home	Resource of expertly curated, experimentally characterized proteins described in published literature
Natural Product Domain Seeker (NaPDoS) http://napdos.ucsd.edu	Bioinformatic tool for the rapid detection and analysis of secondary metabolite genes
MetaBioME: A Comprehensive Metagenomic BioMining Engine http://metasystems.riken.jp/metabiome	Web resource to find novel homologs for known commercially useful enzymes in metagenomic datasets and completed bacterial genomes

tative sequences [11.85]. This bias has a negative effect on gene discovery and annotation in both genomic and metagenomic data, as microbial genomes provide scaffolds for the interpretation of sequence information. With the aim of systematically filling in these existing gaps, the US Department of Energy's Joint Genome

Institute created the initiative *Genomic Encyclopedia of Bacteria and Archaea* (Table 11.2). Similarly, the Microbial Genome Sequencing Project of the Gordon and Betty Moore Foundation's Marine Microbiology Initiative has sequenced the genome of hundreds of ecologically relevant microorganisms isolated from diverse marine habitats (Table 11.2).

The phenotypic analysis of isolates can severely underestimate its genetic potential, as genes may not be expressed or may be expressed at very low levels under laboratory conditions. For example, it has been proposed that a unique combination of environmental factors may be required for the expression of biosynthetic genes [11.6]. Therefore, the mining for genes or gene clusters in microbial genomes could uncover *hidden treasures* that could be exploited, for example, using heterologous gene expression [11.90]. Moreover, the use of sequence information has assisted in the determination of the chemical structure of new compounds by a combination of bioinformatics and chemistry [11.91]. The potential for biodiscovery of this approach has led to the explosion of interest in genome mining as a tool for bioprospection, which has been aided by the development of new bioinformatic tools for the analysis of the growing volume of DNA sequence data [11.92]. However, as sequencing efforts are rarely followed by the biochemical characterization of the putative gene products, many genes emerging from these studies have unknown functions, and basic local alignment search tool (BLAST)-based protein functional assignments can easily propagate annotation errors [11.93]. Recently, a database of experimentally characterized proteins was created (CharProtDB, Table 11.2), enabling to link experimental characterizations of protein functions with computationally accessible protein sequences [11.94].

The mining of the ever-increasing amount of genomic data from marine microorganisms has led to the bioassay-independent discovery of gene clusters with important biotechnological applications [11.95]. In recently published work, *Wargacki* and collaborators [11.96] used a public database to identify a genome fragment from the *Vibrio splendidus* strain 12B01, containing genes for alginate degradation, transport, and metabolism. This gene cluster was used to construct a microbial platform that enables bioethanol production from macroalgae via a consolidated process [11.96]. In silico mining of genomes combined with molecular biology approaches has resulted in the discovery of novel gene clusters with potential use for the development of peptide-based drug candidates [11.95]. In addition, a search of sequenced bacterial genomes showed that marine cyanobacteria present an extraordinarily efficient strategy for generating many cyclic peptide secondary metabolites [11.97].

Other *Omics* Approaches

Currently, only one-third of an annotated bacterial genome corresponds to information that is well known [11.98]. However, in order to understand how a cell operates and, therefore, for the successful application of its genetic potential, a better knowledge of the two ignored parts is required. Molecular approaches that can be used in combination with genome sequencing to study a marine microbial isolate include, for instance, transcriptomics, proteomics, and metabolomics [11.99]. Concerning transcriptomics, the development first of microarray technology and later of whole transcriptome shotgun sequencing using next-generation sequencing technologies has provided valuable insight into gene function and regulation [11.100]. Importantly, this information also serves as a basis for genome re-annotation. In addition to its function as information carrier, RNA can present various regulatory functions in bacteria [11.101]. Although this information is still in its infancy, it could be highly valuable for the biotechnological application of pure cultures.

Technological advances in the field of mass spectrometry (MS) have enabled us to obtain information regarding a significant proportion of the proteome of microbial isolates [11.102]. Several proteomic studies of cyanobacterial strains have been published, which are microorganisms that have interesting biotechnological applications [11.103]. For example, the analysis of the proteome of *Synechocystis* sp. PCC 6803 rendered evidence of the mechanisms used by this microorganism for gaining resistance against the biofuel hexane [11.104]. In a second study, the complex response of this model microorganism to ethanol was analyzed using a quantitative proteomics approach [11.105]. Ethanol sensitivity of cyanobacteria currently restricts efforts to increase biofuel production levels in metabolic engineered strains for autotrophic ethanol production, and this study provided a list of potential gene targets for engineering ethanol tolerance.

Although highly challenging due to the extremely fast turnover times of the small molecules of the cell, metabolomics is fundamental for the understanding of metabolic reaction networks and their regulation, as well as to link the genotype of an isolate to its phenotype [11.106]. Interactomics, on the other hand, attempts to resolve the whole set of molecular in-

teractions in cells and fluxomics establishes dynamic changes of molecules within a cell over time [11.99]. No single approach is sufficient to characterize the complexity of biological systems [11.99]. In fact, it is only through the integration of multiple layers or dimensions of information (provided by different *omics* approaches) that a proper understanding of the whole cell operation can be obtained [11.98]. The integration of the overwhelming amount of information obtained from multiple datasets can only be accomplished with the use of mathematical modeling and computational tools and results in a dynamic map of all cellular functions and regulatory circuits with spatiotemporal resolution [11.107]. The advances of the field of systems biology are empowering the engineering of industrial microorganisms, allowing the development of more robust strategies and moving the field toward a design-based engineering of biological systems [11.108].

Single-Cell Analyses

The analysis of single cells is an approach with multiple biotechnological applications and presents both unprecedented challenges and opportunities [11.83]. Individual cells can be physically separated from each other and/or from the environmental matrix material before further analysis, through a technique called single-cell isolation [11.109]. In addition, targeted cells can be individually recognized and distinguished from background populations through cell-sorting techniques, although some cell-sorting instrumentation also allows cell isolation [11.109]. The fundamentals, advantages, and drawbacks of the different devices used for cell sorting and cell isolation were recently reviewed in detail [11.107, 109] and therefore they will not be covered in this chapter.

One of the applications of single-cell analysis is the study of cell-to-cell variations within an isogenic cell population, delivering functional biological information beyond the statistical average of a microbial population [11.107]. For example, through the use of total transcript amplification, the heterogeneity of transcript levels among individual cells within a bacterial population can now be studied [11.110]. A second application of single-cell analysis is to individually study yet-to-be cultured microorganisms using *omics* approaches. Single-cell genomics (SCG) involves the isolation of single cells from an environmental sample, the purification of its DNA, followed by whole-genome amplification and sequencing [11.26]. Methodological difficulties of SCG include background contamination during the amplification of single-cell DNA, biases during amplification and sequencing, as well as difficulties in sequence assembly [11.83, 111]. Different strategies have been tested in order to improve SCG, such as reagent decontamination before amplification [11.112], artificially inducing polyploidy in single cells [11.113], improving the efficiency of genome amplification [11.83], as well as using more efficient assembly algorithms [11.111]. In spite of its limitations, it is currently possible to obtain a high percentage of de novo genome sequences from yet-to-be cultured microorganisms.

SCG is considered a powerful complement of both cultivation and metagenomics, as it allows us to link the metabolic potential of an uncultured microorganism with its taxonomic identity, as well as to define possible strategies for the isolation of the microorganism [11.114]. In addition, SCG allows us to study in situ interactions among organisms and is particularly suited for the analysis of symbiotic systems, for example, the biotechnologically-relevant bacterial symbionts of marine sponges [11.115, 116]. In a recent work, *Bayer* et al. [11.117] identified novel enzymes involved in halogenation reactions in marine sponge-associated microbial consortia using a combination of *omics* approaches, including SCG. In another study, *Martinez-Garcia* and collaborators [11.118] sequenced five *Verrucomicrobia* cells, identifying genes encoding a wide spectrum of glycoside hydrolases, sulfatases, peptidases, carbohydrate lyases, and esterases. In addition, the analysis of partially assembled genomes of only ten cells of *Prochlorococcus* increased the pan-genome of this genus by 4.6%, highlighting the potential of this approach for bioprospecting [11.119]. Information concerning which proteins are being expressed in a particular environmental condition, their abundance, as well as post-translational modifications could be obtained through single-cell proteomics. However, further development of MS and micro/nanofluidic based technologies is needed for the analysis of the proteome from single cells. Although still not widely used in biotechnological applications, the combination of single-cell *omics* approaches has the potential to significantly contribute to this field [11.107, 114].

Metagenomic Approaches

Metagenomics, the direct analysis of the genomes contained in a microbial community, nowadays represents a key tool for microbial marine bioprospecting, as it allows access to the genetic potential of a microbial community. Metagenomic analyses typically start with the purification of DNA from an environmental sam-

ple, which is called metagenomic DNA [11.120]. This DNA can be used for the construction of a metagenomic library [11.121] or alternatively, it can be randomly sequenced using next-generation sequencing technologies [11.122]. Due to the uneven distribution and high species richness of most microbial communities, metagenomic analyses are very challenging. Despite the difficulties still affecting metagenomics, in recent years this discipline has been fundamental in increasing our understanding of microbial communities and has become an important tool for mining novel biomolecules or activities with biotechnological potential [11.123, 124]. For instance, the construction and screening of metagenomic libraries have resulted in the identification of many novel biocatalysts, including lipases/esterases, cellulases, chitinases, DNA polymerases, proteases, and antibiotics [11.123, 125]. Marine sediments, microbial communities from marine invertebrates, and cold marine environments are among the most commonly studied habitats, due to their high biotechnological potential [11.126–128].

The cloning of fragments of metagenomic DNA using the appropriate vectors and suitable hosts allows us to store and mine the genetic potential contained in a microbial community [11.121]. The selection of the vector for library construction (plasmids, cosmids, fosmids, or BACs – bacterial artificial chromosomes) depends mainly on the desired insert length. For example, large-insert libraries are required for recovering large gene clusters [11.123]. Other factors to consider are the desired cell copy number, the quality of the metagenomic DNA, the genes that are being targeted, the chosen host, as well as the selected screening strategy [11.121, 123]. In order to reach sufficient coverage of metagenomes of highly diverse microbial communities, such as those from soils or sediments, metagenomic libraries need to contain a large number of clones [11.129]. To increase hit rates, enrichment cultures were used prior to metagenomic DNA extraction, although this approach can result in an overall loss of diversity [11.130]. Another possible strategy is the use of stable-isotope-labeled substrates to enrich the functionally-relevant fraction of the microbial community. In this case, density centrifugation of metagenomic DNA is performed after labeling, before the construction of the metagenomic library [11.121, 131].

Two different strategies can be used for the screening of a metagenomic library: a function-based approach (detection or selection for metabolic activity) or a sequence-based approach (detection of a specific target gene). The first strategy, called functional metagenomics, does not require previous knowledge of sequence information and can, therefore, result in the identification of entirely novel classes of genes [11.123]. It presents the additional advantage that the identified gene or gene cluster is already being functionally expressed in the host. However, functional-based screenings can be problematic due to low-level gene expression, lack of post-translational modifications, the formation of insoluble aggregated folding intermediates, as well as detrimental effects that the products can have on the host cell [11.132, 133]. Currently, the most commonly used vector and host for constructing metagenomic libraries are fosmids and *Escherichia coli* [11.121]. The use of other hosts and the development of vectors able to replicate in various species are particularly useful for expression-based analyses of metagenomic libraries [11.129, 134, 135]. In addition, hosts can be engineered to improve gene expression [11.136].

Different function-driven approaches can be used for the screening of metagenomic libraries. One of them is the detection of the desired phenotype in agar-plate assays, for instance, an enzymatic activity or colony pigmentation [11.124]. Agar-plate based screenings have the advantage of not requiring expensive devices. However, they are usually labor intensive and they tend to have low hit rates due to the generation of weak signals [11.129]. In addition, this strategy depends on the availability of assays able to detect the desired metabolic function, of which there are, unfortunately, very few [11.131]. In order to increase the sensitivity of the assays, the enzymatic activity can be measured in cell lysates [11.124, 129]. This is usually performed using colony picking robots and microplate readers to shorten the processing time. Another strategy, called heterologous complementation, significantly simplifies functional screening by taking advantage of gene targets for which the desired phenotype is required for the survival of the host, such as genes that confer resistance to metals or antibiotics [11.129, 137]. On the other hand, the ability of some substrates to induce gene expression through closely located regulatory elements has been used to engineer vectors containing reporter genes [11.124]. Interestingly, *Uchiyama* and collaborators [11.138, 139] have created specific reporter assays based on fluorescent proteins in order to screen for enzyme-encoding genes in metagenomic libraries.

In contrast to functional metagenomics, molecular screenings involve the use of primers or probes that have been designed based on conserved regions of already-known genes or protein families to mine

a metagenomic library [11.123]. The main advantage of this approach is that the target can be identified even if it is not being expressed by the host [11.128, 140]. Subcloning using the appropriate host and vector can result in the functional expression of the gene or gene cluster of interest, allowing the functional characterization and biotechnological application of the product. A critical drawback of molecular screenings is that they depend on sequence database information, which is currently biased, and as a consequence usually results in the retrieval of variations of previously known genes. In order to maximize the discovery process in molecular screenings, sequences of genes identified in a metagenomic library by a functional approach or gene fragments retrieved by PCR from the same environment can also be used as a source of de novo, unbiased genetic information for primer design [11.141]. An interesting approach to mine for gene clusters involved in the biosynthesis of bioactive molecules is to perform a retrobiosynthetic analysis on the structure of these compounds in order to predict the enzymes involved in the biosynthetic pathway [11.128]. This information is then used to design degenerate primer sets for the retrieval of gene fragments by PCR [11.128].

Besides the construction of metagenomic libraries, DNA isolated from environmental samples can be sequenced directly using next-generation sequencing technologies, resulting in the random generation of sequence information from the genomes contained in the microbial community [11.142]. This approach has been extensively used for the analysis of microbial communities from marine environments, providing unprecedented insights into their genetic potential [11.120]. Continuous improvements in sequencing technologies is resulting in longer read lengths, larger sequence outputs, as well as lower costs, allowing a deeper analysis of the microbial communities. As individual reads are usually assembled, genome fragments containing whole operons, and even draft genomes from uncultured bacteria can be obtained [11.143, 144]. This information is critical in bioprospecting efforts, as it can be used as a basis for the recovery of the genome fragment from the same community, or alternatively, for its synthesis. The term *synthetic metagenomics* has been proposed to define the discovery approach that involves in silico identification of hypothetical target sequences followed by automated chemical DNA synthesis and heterologous expression [11.145]. This approach has recently been used to obtain de novo functional methyl halide transferases using information from the GenBank database, enzymes that are useful for biofuel production [11.145]. This approach allows the exploitation of existing sequence databases, currently underexplored and underexploited [11.146]. Synthetic metagenomics has the additional advantage of allowing codon optimization, which may significantly improve gene expression [11.145]. *Sharma* and collaborators [11.147] have developed a resource called MetaBioME with the goal of facilitating the discovery of novel commercially useful enzymes from metagenome information (Table 11.2).

Other *Meta-Omics*

Next-generation sequencing technologies can also be used to analyze the subset of genes in a microbial assemblage that is being transcribed under a particular environmental condition [11.148, 149]. For this approach, total RNA is extracted from the environmental sample, rRNA is removed in order to enrich for the mRNA fraction, and copy DNA (cDNA) synthesis is performed before sequencing [11.148]. When cDNA yield is insufficient for analysis, however, an amplification step can be included. Metatranscriptome sequencing represents a powerful tool to analyze microbial communities, albeit with considerable challenges. Not only environmental cells present low mRNA contents, but also their half-lives are very short, in the range of a few minutes [11.150]. In addition, mRNA constitutes a very small fraction of the total RNA in bacterial cells and the enrichment of the mRNA fraction in prokaryotes is challenging [11.151]. Limitation in environmental sample quality and quantity, as well as low mRNA integrity and purity can also affect metatranscriptomic analyses [11.149, 151]. Despite these methodological challenges, this approach has been increasingly applied in fundamental research on microbial communities from various marine habitats [11.152–157].

Like shotgun sequencing metagenomics, sequence-based metatranscriptomics presents no significant bias towards known sequences, and is considered highly informative concerning ongoing ecologically relevant processes [11.149, 150]. Other advantages of metatranscriptomics over metagenomics are that only ecologically relevant information is retrieved and fewer resources are required for this analysis [11.148]. However, sequence reads are still too short for bioprospecting efforts. Metatranscriptomics represents a powerful approach for the discovery of metabolically relevant enzymes that are actively involved in particular biochemical pathways [11.148, 158]. Another application is the analysis of community-specific variants of functional genes; this information is highly relevant to the

environmental biotechnology field and may lead to the discovery of genes or processes with biotechnological potential [11.148, 149]. For instance, in a recent study, a combination of *omics* approaches that included metatranscriptomic analysis was able to elucidate which hydrocarbon degradation pathways were actively expressed in the deep sea after an oil spill and to ascribe these pathways to particular taxa [11.154].

Another approach that can be used for the identification of novel enzymes is to directly analyze the proteins of a microbial community using metaproteomics. This approach consists in the extraction of the proteins from an environmental sample, followed by the separation of the proteins (or peptides) by two-dimensional polyacrylamide gel electrophoresis or liquid chromatography, and lastly MS analysis and the identification of the proteins by in silico spectral matching against sequence databases [11.159]. The main challenges of metaproteomics are the large complexity of protein species expressed by the members of the microbial community and the large dynamic range of protein levels [11.159]. However, faster and more sensitive mass spectrometers and advances in *omics* datasets and data handling facilitate the analysis of increasingly complex environments [11.160]. Most marine metaproteomic studies performed so far have focused on the analysis of planktonic microorganisms, providing clues concerning key metabolic processes such as those involved in ocean biogeochemical cycles [11.161–164]. More recently, *Kleiner* and collaborators [11.165] used metaproteomics and metabolomics to investigate metabolic interactions in the association between a gutless marine worm and its bacterial symbionts, revealing highly efficient pathways for the uptake, recycling, and conservation of energy and carbon sources.

Molecular systems biology at the ecosystem level, also known as eco-systems biology, attempts to build models that are able to predict the behavior of a community, through the integration of *omics*, *meta-omics*, and single-cell approaches, as well as the use of mathematical models [11.166–168]. Although still in its infancy, this discipline has the potential to provide a comprehensive understanding of the functioning of microbial communities, and, therefore, to facilitate their management, which is a long-term goal of environmental biotechnology [11.168]. For example, improving the mechanistic understanding of biodegradation processes may facilitate the development of knowledge-based bioremediation strategies and the design of biosensors for the detection of pollutants [11.169].

11.4 Conclusions

Over the last years, the development of a broad array of methodologies for the analysis of environmental microorganisms has profoundly altered bioprospecting efforts, thus significantly increasing our access to the genetic potential contained in microbial communities. However, finding properties of interest in the prospected environments is only the first stage in a series of value-adding steps, which ends in the development of products or services with applications in human health, industry, renewable energy, etc. Importantly, strategies that are able to maximize the biotechnological potential of environmental microorganisms, for example, microbial engineering and synthetic biology, have been matching the evolution of bioprospecting tools.

As microorganisms from marine habitats are increasingly being recognized as particularly promising resources for bioprospecting, both academia and biotechnology industry sectors are increasing their investments in marine biotechnology research and development. This is evidenced by an increment in the number of publications in marine microbial bioprospecting, as well as the development of new products from marine biodiversity. Furthermore, marine biotechnology has been recognized in many parts of the world as having an enormous development potential, and the furthering of this discipline is considered as strategic not only for reaching key societal needs but also for economic growth [11.170].

12. Novel Bioreactors for Culturing Marine Organisms

Debashis Roy

This chapter considers a wide range of novel bioreactor configurations for cultivation of marine organisms for purposes of biomass harvesting/enrichment or synthesis of target metabolites or wastewater treatment. It begins by analyzing biofilm reactors that promote surface-attached growth, including the niche-mimicking types viz. modified roller bottles, air membrane surface bioreactor, and ultralow speed rotating disk bioreactor as well as the small-scale extended surface shaken vessel. Photobioreactors (PBR), used mainly for phototrophic algal growth, are discussed next – these include the tubular, plate/panel and stirred tank types on the one hand and vertical column PBRs on the other, the latter mainly comprising airlift (AL) and bubble column (BC) PBRs. Important AL/BC configurations have been described. Membrane bioreactors (MBR) are then taken up, which include, e.g., the anaerobic MBR, ion-exchange MBR, etc. Immobilized cell bioreactors – primarily packed bed bioreactors (PBBR) and their hybrids (e.g., with PBR, airlift bioreactor (ALBR), MBR etc.), are reviewed next, followed by hollow fiber bioreactors (HFBR) (e.g., HF–submerged MBR, HF–PBR, etc.) which, technically, are also a class of immobilized-cell bioreactors. This is followed by a brief overview of fluidized bed and moving bed bioreactors, used primarily for wastewater treatment. Finally, the different classes of high-pressure and/or high-temperature bioreactors are considered, which are practically wholly devoted to cultivation of extremophiles (barophiles and/or thermophiles) isolated from the deep sea.

12.1 Biofilm Reactors (BFR)

In their natural habitat, most bacteria exist within biofilms that are anchored to surfaces and are inherently different from bacteria existing in a planktonic state. Many bacterial strains upon attaching to a surface reportedly produce exopolysaccharides (EPS) which mediate the attachment of the bacteria to the surface culminating in the formation of a biofilm. Marine microbial communities often occur as biofilms which are high-density surface-attached aggregates embedded in extracellular biopolymer (EPS) matrices. The microbial biofilm is a common adaptation of natural bacteria and other microorganisms. In the fluctuating environment of intertidal systems, biofilms form protective microenvironments and may structure a range

of microbial processes. Surface attachment and biofilm formation possibly also induce metabolic changes resulting in the production of different metabolites under attached growth conditions. Furthermore, many bacteria, including Bacillus species, are known to produce signal molecules that are used by the cells to monitor cell density, a phenomenon termed *quorum sensing*, which also controls cell metabolism. Cells in biofilms usually grow at much higher cell densities (up to 10 000 times higher) than in liquid suspension cultures, and quorum-sensing mechanisms could affect the production of secondary metabolites by these biofilm cells. Biofilm Reactors essentially promote surface-attched growth of biofilms (Table 12.1).

Yan et al. [12.1] examined the possibility whether allowing biofilm forming bacteria to grow under conditions that mimicked their marine ecological niche could elicit the production of antimicrobial compounds that they do not synthesize in the planktonic state, using modified roller bottle cultures (Fig. 12.1). Now, roller bottles provide a (typical) growth environment to cells anchored directly or indirectly to the inner wall of the bottles, allowing the attached cells to form a biofilm periodically in contact with both the gas and the liquid phase, (i. e., culture medium) – conditions similar to the alternating wetting and air exposure experienced by bacteria growing on seaweeds or other surfaces in an intertidal environment. However, the challenge lay in devising a method for anchoring bacterial cells, directly or indirectly, to the inner wall of the roller bottles. During preliminary studies it was noted that the epibiotic marine bacterial strains, EI-34-6 (*Bacillus licheniformis*) and II-111-5 (*Bacillus subtilis*) isolated from the surface of the seaweed *Palmaria palmata*, when cultivated on agar medium remained attached to the agar surface even when mixed or washed with the corresponding liquid broth. Based on this finding, the authors devised a modified roller bottle cultivation method wherein an agar coating on the inner wall of the roller bottles provides the surface necessary for the bacteria to attach and form a biofilm matrix. Subsequently, the effect of surface attachment/biofilm formation on antibiotic production was examined.

To prepare a surface-attached roller bottle culture, an agar coating was deposited on the inside wall of a 500 mL Duran bottle during solidification of the agar (after autoclaving) by rolling on ice, with one part of the coating intentionally thickened. The thickened portion of the agar coating was intended to serve as a baffle and help in enhancing oxygen transfer to the surface-attached culture. The cell inoculum was spread on the surface of the agar coating using a swab. The Duran bottles were incubated under the static condition to initiate an agar surface culture (for biofilm formation), then 50 mL of the corresponding liquid medium was added and the bottles rolled horizontally at 1 rpm; thus allowing the biofilm developing on the agar surface to be periodically exposed to air, and remain submerged in the liquid media.

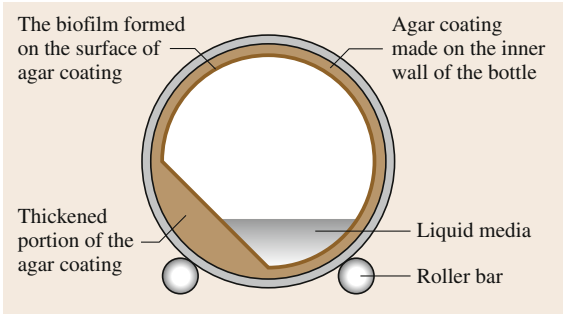

Fig. 12.1 Roller bottle cross section. A layer of agar coating was made on the inner wall of a 500 mL Duran bottle with one fraction thickened. The cell inocula were spread on the surface of the agar coating by a swab and cultivated statically for different times (after *Yan* et al. [12.1])

In suspension cultures, either in a shake flask or in standard roller bottle cultivation, the marine bacteria did not form biofilms on glass surface, which evidently was not conducive for mimicking the ecological niche of the studied strains, i. e., seaweed surface. *B. licheniformis*, strain EI-34-6, characteristically forms colonies that are usually strongly attached to agar surface; thus the agar-coated roller bottle culture makes good use of this phenomenon, facilitating the formation of a strongly bound biofilm. Although the liquid medium provided sufficient nutrients, the cells adhered to the surface of the agar coating, preferring growth in the biofilm even when in the presence of a liquid nutrient source. Furthermore, although the liquid medium provided the same nutrients, cells attached to the agar surface-produced antibacterial compounds that planktonic cells could not. Rolling cultivation for 2 h after the addition of liquid medium showed that antibacterial compounds were produced by surface-attached cells during biofilm growth – in fact detectable antimicrobial activity in the medium was always associated with observed biofilm formation.

Both isolates EI-34-6 and II-111-5 reached very high cell densities (of the order of 10^9 CFU mL^{-1}) even in shaken suspension cultures but without any detectable production of antibiotics, thus pointing to

Table 12.1 Biofilm reactors (BFR)

Sl	Bioreactor	Marine strain and bioprocess	Reference
1	Modified roller bottle cultivation (MRBC)	Antimicrobial compound production by bacterial strains *Bacillus licheniformis* EI-34-6 and *B. subtilis* II-111-5	*Yan* et al. [12.1]
2	Air-membrane surface bioreactor (AMSBR)	Antimicrobial compound production by bacteria *B. licheniformis* EI-34-6	*Yan* et al. [12.2]
3	Ultralow speed rotating disk bioreactor (UL-S-RDBR)	Antimicrobial synthesis by three estuarine/intertidal actinobacteria MS 310, MS 3/20, MS 1/7	*Sarkar* et al. [12.3]
4	ULS-RDBR	Actinomycin-D production by estuarine isolate *Streptomyces* sp. MS 310	*Sarkar* et al. [12.4]
5	ULS-RDBR	Antimicrobial synthesis by estuarine *Streptomyces* sp. MS 1/7	*Sarkar* et al. [12.5]
6	Extended surface shaken vessel (ESSV)	Protease production by intertidal estuarine gamma proteobacterium (DG II)	*Sarkar* et al. [12.6]
7	ESSV	Melanin synthesis by *S. colwelliana* and antibiotic production by *P. rubra* (both bacteria)	*Mitra* et al. [12.7]
8	ESSV	Cellulase and xylanase production by two intertidal filamentous fungi, *C. crispatum* and *G. viride*, respectively	*Mitra* et al. [12.8]

the possibility of either induction mechanisms other than quorum-sensing regulating antibiotic production by the attached cells or mere sensing of the physical attachment by these cells triggering changes in gene expression associated with antibiotic synthesis. The periodic exposure of the growing biofilm to the liquid medium and to air mimics the marine ecological niche of the biofilm-forming microbes on intertidal seaweed, hence the term *niche-mimic bioreactor* for the modified roller bottle cultures.

Yan et al. [12.2], designed a novel bioreactor – the air membrane surface (AMS) bioreactor, that allows the growth of bacteria as biofilms attached/anchored to the surface of a semipermeable membrane disk in contact with air, to investigate the production of antimicrobial compounds by the marine bacterium *B. licheniformis, strain EI-34-6* (used earlier by *Yan* et al. [12.1]) isolated from the surface of a marine seaweed *P. palmata*. The AMS bioreactor (Fig. 12.2) consists of a small, shallow dish filled with sterile liquid medium, with a semipermeable membrane disk placed on top of the dish such that the membrane remains in contact with the medium on one side and with air on the other, is held in place by surface tension. Bacteria were inoculated onto the membrane surface by swabbing, then the inoculated AMS bioreactor was placed in a sterile petri dish during cell growth. *B. licheniformis* produced antimicrobial compounds (the major component identified as bacitracin) when it grew in surface-attached condition as a biofilm at an air–membrane interface in the AMS-BR but not when it was grown planktonically in shake-flask cultures. An unidentified red pigment was also produced by surface-attached cells but not

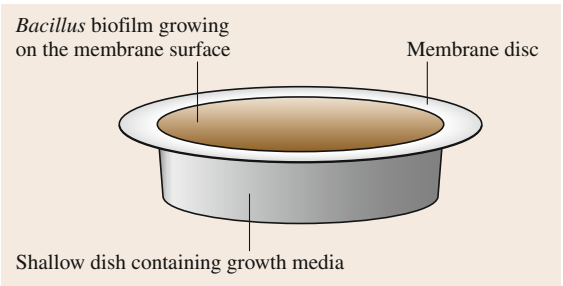

Fig. 12.2 AMS bioreactor. The small chamber beneath the membrane is filled with liquid medium, and the membrane disk is held in place by surface tension. Bacteria were inoculated onto the surface of a semipermeable nylon membrane. The AMS bioreactor was placed in a sterile petri dish during growth to maintain sterility (after *Yan* et al. [12.2])

by suspended cells. Different types of semipermeable membranes with widely varying pore sizes (viz., nylon, cellophane, and flat dialysis membranes) gave similar results, indicating that antibiotic production was not due to the chemical composition of the membrane but rather due to the niche-mimicking environment provided by the AMS bioreactor. Thus, it was established that biofilm formation as well as periodic direct exposure to air are necessary for eliciting production of antimicrobial compounds by the surface-attached cultures of *B. licheniformis*.

Sarkar et al. [12.3], developed an ultralow speed rotating disk biofilm reactor (ULS-RDBR) operated at a rotational speed of one revolution per day at 50% submergence of the rotating discs to mimic the intertidal

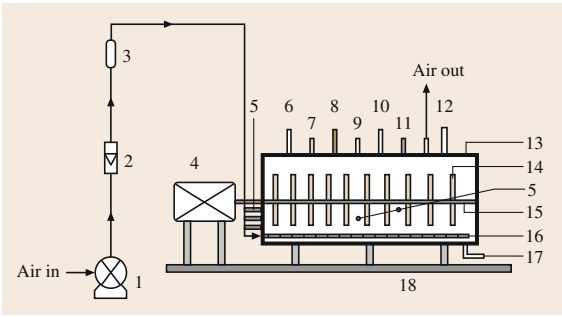

Fig. 12.3 Schematic of the ultralow-speed rotating disk bioreactor (RDBR) (1 – air pump; 2 – rotameter; 3 – air filter; 4 – electrical motor and reducing gear train for speed reduction; 5 – sampling port; 6 – temperature sensor; 7 – antifoam port; 8 – inoculation and medium addition port; 9 – acid port; 10 – pH sensor; 11 – alkali port; 12 – DO sensor; 13 – reactor vessel; 14 – rotating coaxial disks; 15 – shaft; 16 – sparger; 17 – drain; 18 – base plate) (after *Sarkar* et al. [12.4])

estuarine ecological niche of three marine actinobacteria viz. MS 310 (*Streptomyces* sp.), MS 3/20, and MS 1/7. The ULS-RDBR (Fig. 12.3), which facilitates microbial growth in the form of surface-attached biofilms, was designed on the concept of a rotary biological contactor (RBC). The maximum volume of the RDBR is 25 L, and the shaft (on which 10 disks are coaxially mounted) is rotated at an ultralow speed of one revolution per day. When operated with half the volume of the tank filled with liquid medium (i. e., at 50% submergence level), any given point on the disks would remain exposed to air and submerged in the medium alternatively for 12 h; thus mimicking the intertidal conditions of the location from where the microorganism was collected. The ULS-RDBR with its much higher surface-to-volume ratio (compared to a STBR) and niche-mimicking ability, supported good biofilm formation on the extended surface in the reactor (i. e., the rotating disks) and faster attainment of the peak level of antimicrobials metabolized by these isolates. It was also noted that antimicrobial synthesis was growth associated.

The ULS-RDBR (volume 25 L) was employed by *Sarkar* et al. [12.4] for detail investigation of the production of a potentially novel antimicrobial compound by the biofilm-forming marine *Streptomyces* sp. MS 1/7, in particular the effects of pH, aeration rate and disk submergence level (varied at 25, 50 and 75%) on the peak antimicrobial activity (PAMA), peak activity attainment rate (PAAR), and biofilm density (BD). PAMA, PAAR, and BD were all maximized at the intertidal niche-mimic operating condition (1 rev d^{-1}, 50% disk submergence) along with the highest aeration rate provided in the experiment. Furthermore at any aeration rate, PAMA was always highest under the niche-mimic condition – 12 h. alternating cycles of inundation and aerial exposure as in the intertidal conditions characterizing the biofilm-forming microbe's marine ecological niche.

The ULS-RDBR is a horizontal, rectangular parallelepiped shaped vessel (42 cm × 27 cm × 27 cm, volume 25 L), comprising 10 coaxial, equispaced disks (each of 16 cm diameter and 5 mm thickness) mounted on a single rotating shaft. The reactor vessel, the disks as well as the shaft are all made of acrylic (polymethyl methacrylate), which is transparent, corrosion resistant to high salt concentrations, and generally provides a surface conducive to attachment of biofilm. For 50% disk submergence level, i. e., 12.5 L working volume, the ratio of surface area to working volume of the RDBR is 342 $cm^2\,L^{-1}$, considering total surface area of 10 disks only. If, however, submerged wall surface and floor of the tank are also considered together with the disks, then the ratio increases to 552 $cm^2\,L^{-1}$. It was observed (in trial runs) that the roughened acrylic surface allowed substantially more biofilm formation than the smooth surface. Due to this reason, the disk surfaces were roughened using sand paper (Grade 50) to facilitate surface attachment by the biofilm-forming microorganisms. A reducing gear train was designed to reduce the speed of a 7 rpm motor (for driving the rotating shaft) by ca. 10 000 times to the ultralow rotational speed of 1 rev d^{-1}. Air was supplied into the RDBR using an air compressor, passed through a sterilizing air filter, and then uniformly distributed into the fermentation medium using a rectangular sparger (also made of acrylic) having uniformly spaced holes in the downward direction. Ports on the top lid of the RDBR are available for sampling, addition of medium/inoculum/antifoam, pH sensor, DO sensor, temperature sensor, and air exhaust. The fermentation medium was sterilized ex situ and added aseptically to the reactor disinfected both chemically (i. e., by repeated washing with sodium hypochlorite) and by UV radiation.

Sarkar et al. [12.5] found almost similar results in their investigation of actinomycin-D production by the biofilm-forming estuarine isolate MS 310 cultivated in the ULS-RDBR operated at 1 rev d^{-1}. The niche-mimic condition along with maximum permissible aeration was found to be most favorable for antibiotic produc-

tion – peak antibiotic activity (PAA) and peak activity attainment rate (PAAR) simultaneously attaining their highest values at this operating condition – 50% disk submergence. Both PAA and PAAR are observed to increase with increasing aeration at all operating conditions examined. At the niche-mimic condition, a threefold increase in the aeration rate causes PAA to increase by 33%, whereas PAAR increases by 2.5 times, underlining the strong aeration dependence of this actinomycin-D producer. Again, compared to the highest values obtained for antimicrobial production in flask (500 mL) experiments, the corresponding RDBR values were 16% higher for PAA and more than five times higher for PAAR – strong evidence for employing these novel bioreactors for cultivation of antibiotic-producing marine microbes.

It follows from the above discussion that for microorganisms which synthesize metabolites/enzymes at the highest rates only when growing in surface-attached condition, i. e., as biofilms anchored to solid surfaces, special culture conditions are necessary that are conducive to surface attachment and biofilm formation. For this purpose, several typical niche-mimic bioreactors have been developed (e.g., modified roller bottle cultures, AMS-BR, ULS-RDBR, etc.) as described earlier in this section. However, a lack of small-scale shaken vessels with high surface/volume ratio and surface properties favoring attachment of biofilm-forming microbes was noted by *Sarkar* et al. [12.6]. They developed a novel small scale, extended surface shaken vessel (ESSV) in the form of a PMMA acrylic made conico-cylindrical flask (CCF) (volume 500 mL) in which enhanced surface for microbial attachment and biofilm formation was provided by eight equidistantly located vertical rectangular strips radially mounted on the base of the vessel with the base diameter close to that of a 500 mL Erlenmeyer flask (EF) for easy placement in a rotary shaker. The small-scale vessel was designed to allow the use of different internal surface materials – hydrophilic (glass) or hydrophobic (acrylic). Furthermore, protease production by two strains in the ESSV were examined, of which one was marine – an intertidal gamma – Proteobacterium (DG II). Relative to a standard EF with no additional surface, growth and protease synthesis by the marine isolate DG II were 20 and 30% higher, respectively. Again, compared to glass, the use of acrylic surface (hydrophobic) resulted in more than 200% increase in protease production and a dramatic increase (i. e., by 19, 275%) in microbial growth.

Mitra et al. [12.7] cultivated two biofilm-forming marine bacteria in the novel ESSV described above, viz. *Shewanella colwelliana* for melanin production and *Pseudoalteromonas rubra* for antibiotic synthesis. The design allowed comparison of production between (1) CCF with hydrophobic surface (PMMA), (2) ESSV with hydrophilic glass surface, and (3) standard unbaffled EF. Growth and melanin production by *S. colwelliana* were highest in the ESSV with (hydrophilic) acrylic surface, further melanin synthesis increased with increase in surface (for attachment) and increase in biofilm formation and increase in planktonic growth. Growth of *P. rubra* was also highest in the acrylic ESSV but not antibiotic synthesis – it was maximum in the EF without any extended surfaces. Thus antibiotic production was favored by a hydrophilic vessel surface (glass).

Mitra et al. [12.8] examined cellulase and xylanase production in relation to biofilm formation by two intertidal filamentous fungi, viz. *Chaetomium crispatum* and *Gliocladium viride*, respectively, in the novel ESSV (described above) with either hydrophobic (acrylic) or hydrophilic (glass) surface and compared with that in an ordinary EF. Mixed results were obtained with regard to suitability of the EF or the ESSVs for enzyme production by the two filamentous fungi – surface properties as well as surface area of attachment of the cultivation vessel affected biofilm formation and enzyme production.

12.2 Photobioreactors (PBR)–Tubular, Plate/Panel and Stirred Tank Configurations

Photobioreactors, as the name indicates, are specialized bioreactors (Table 12.2) for phototrophic growth of microorganisms – mainly alga but also photosynthetic bacteria; as well as macroorganisms, i. e., macroalgae (*seaweed*). Application of PBRs for microalgal growth has been extensively reviewed [12.19, 20]. PBRs originated as open-air cultivation systems with natural sunlight as the source of illumination that are easy to build and operate – these include natural or artificial ponds/tanks, raceway-shaped culture ponds (which are basically closed-loop recirculation channels) and so-called *inclined surface ponds* driven by paddle wheels. However, open-air PBR systems are prone to evaporative losses and contamination problems and most im-

Table 12.2 Photobioreactors (PBR)-tubular, plate/panel, stirred tank etc.[a]

9	Laboratory-scale and pilot-scale PBRs	Harvesting algal biomass of *Euglena gracilis* as potential animal food source	*Chae* et al. [12.17]
10	Serpentine PBR and hybrid flow through-PBR	Biogas production by anaerobic digestion of microalga *P. tricornutum*	*Zamalloa* et al. [12.18]

[a] Also compares the tabulated reactors with airlift and bubble-column reactors, restated in Table 12.4 with discussion in the Sect. 12.3 ALBR and BCBR

portantly, have significantly lower biomass productivity than closed PBRs. The common design configurations of the latter include plate/panel, tubular, stirred-tank and vertical column (including airlift and bubble – column reactors). Tubular PBRs consist of an array of straight, coiled, or looped transparent tubes through which the culture is circulated by pump or by airlift mechanism – the latter having the advantages of permitting exchange of CO_2 and O_2 between the liquid medium and the aeration gas, minimizing shear damage to the cells caused by mechanical pumping and achieving medium circulation without any moving parts. Increase in tube diameter (above 0.1 m) decreases the surface/volume ratio and as culture density increases with growth, the cells begins to shade one another (*self-shading effect*) which results in decreasing volumetric biomass productivity. Again, excessive increase in tube length causes accumulation of O_2 (produced photosynthetically) which, when in excess of the air saturation value, becomes inhibitory for photosynthesis (oxidative photoinhibition). Some common tubular configurations are horizontal/serpentine, near horizontal, helical, conical, and inclined. In general, tubular PBRs have a large illumination surface area but poor mass transfer characteristics.

Flat-plate-type PBRs probably originated from the laminar morphology of plant leaves which are well-evolved natural solar collectors with high surface/volume ratio. They can be horizontal/vertical and posses the advantage of high illumination surface area, high photosynthetic efficiency, and lower accumulation of dissolved oxygen (than tubular PBRs). A tilted flat-plate PBR (e.g., the flat inclined modular PBR – FIMP) may be angled to ensure maximum exposure of the culture to sunlight and facilitates change of light path as and when required. This flexibility is often crucial as individual photosynthetic microorganisms often have an optimum light path that is a compromise between growth inhibition in innermost layers due to insufficient lighting and self-shading, and photoinhibition of growth in outermost layers due to excessive illumination. Stirred tank PBRs have also been used for algal cultures but they are not as common as flat plate/tubular-PBRs. Vertical column PBRs – mainly AL and bubble column (BC) PBRs are discussed in the following section.

PBRs can be externally or internally illuminated. External illumination may be natural (i. e., direct sunlight) or artificial (e.g., fluorescent lamps), internal illumination is necessarily artificial. Optical fiber-based internally illuminated PBRs have the advantage of heat sterilizability and stability to withstand mechanical agitation stresses; however, low light delivery efficiency ($< 50\%$) is a concern.

Hu et al. [12.9] used a modified flat plate PBR (1.4 L) to investigate CO_2 removal by an ultrahigh-cell-

density culture (i. e., with optimal cell density > 10 g DCW/L) of the marine green alga *Chlorococcum littorale*, which shows extended linear growth under light limiting conditions and grows very vigorously in the presence of extremely high CO_2 levels. The remarkably high CO_2 fixation rate reported with this alga is due to the ultrahigh cell density attained in this PBR which has a narrow light path in which intensive turbulent flow is generated by streaming compressed air through perforated tubing into the culture suspension (that produces vigorous air-bubble mixing). The acrylic-made reactor (Fig. 12.4) (height 50 cm, length 38 cm) consists of an outer chamber (width 6 cm) that serves as a temperature regulator and an inner chamber (with a total illuminated area of about 0.16 m^2) of varying width corresponding to the length of the light path (1, 2, and 4 cm) which was optimized in this study for biomass productivity. An air-bubbling tube is placed along the bottom of the inner chamber, through which compressed CO_2-enriched air is streamed to produce turbulence in the culture suspension. The top opening of the inner chamber is covered by silicone rubber together with a thick acrylic lid with a number of openings/ports for various sensors and for air exhaust. A panel with a bank of white fluorescent lamps was installed on each side of the reactor for illumination.

Microaerobic biohydrogen production by the marine, nonsulfur, photosynthetic bacterium *Rhodovulum* species was examined by *Matsunaga* et al. [12.10] in a *double-phase* flat panel PBR consisting of *light* and *dark* compartments. Hydrogen production under microaerobic conditions was found to be four times higher than in anaerobic conditions, mainly due to the much higher ATP accumulation during respiration under microaerobic conditions – ATP accumulated in the dark compartment was utilized for hydrogen production in the light compartment. Double-phase and conventional flat-panel-type PBRs (2 cm × 10 cm × 30 cm) made from 3 mm polyacryl resin sheets, had an illuminated area of 250 cm^2 and a culture volume of 500 mL. Light and dark compartments in the double-phase PBR were obtained by positioning a flat mirror (18 cm × 10 cm). Six fluorescent lamps were used as the source of illumination in this PBR.

Rodolfi et al. [12.11] used two types of PBRs viz., a flat alveolar panel (FAP) PBR (volume 20 L) and green wall panel (GWP) PBR (volume 110 L) for outdoor mass cultivation of the oil-producing marine eustigmatophyte microalga *Nannochloropsis* species. The study was claimed to be the first report of an increase in both lipid content and areal lipid productivity attained in an outdoor algal culture, through nutrient deprivation.

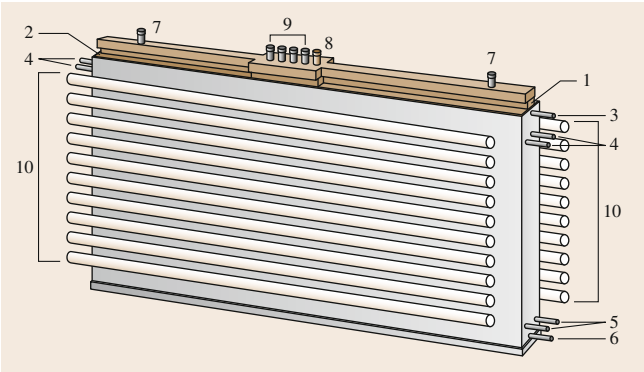

Fig. 12.4 Schematic diagram of the prototype flat-plate photobioreactor. 1 – inner culture chamber; 2 – outer temperature-regulation chamber; 3 – culture overflow; 4 – cooling-water inlets; 5 – cooling-water outlets; 6 – port for compressed-air tubing; 7 – air outlet; 8 – sampling port; 9 – ports for various sensors (pH, temperature, O_2, etc.); 10 – a bank of fluorescent lamps (after *Hu* et al. [12.9])

Merchuk et al. [12.12] studied the effect of light/dark cycles of different frequencies on growth of the red microalga *Porphyridium* sp. in a laboratory-scale tubular loop PBR and compared it with the performances of an AL-PBR and BC-PBR (both of volume 35 L). In the laboratory-scale PBR liquid is circulated by a peristaltic pump at a controlled rate whereas in the column PBRs, which are orders of magnitude larger, liquid movement is pneumatically driven by the injection of gas into the reactors. However, despite basic differences, the light/dark cycles generated, either by the pump of the laboratory-scale tubular bioreactor, or by gas flow in the column PBRs were found to be of the same order. By virtue of the small diameter of the loop and the low concentrations of the biomass used, the performance data from the laboratory-scale tubular loop PBR was free of the effect of self-shading, and therefore, this PBR could be considered as a *thin-film* PBR. The tubular loop PBR (total volume 0.43 L) consisted of a series of glass tubes (I.D. 0.007 m) connected to a small vessel into which 3% CO_2 was bubbled (to provide a carbon source and also to remove O_2) with the loop closed through a peristaltic pump. The cycle time could be varied by manipulating the flow rate in the pump. The ratio of light/dark zones was controlled by darkening different lengths of the tube – the ventilation vessel, being always covered, was part of the dark zone. A bank of fluorescent lamps provided the necessary illumination.

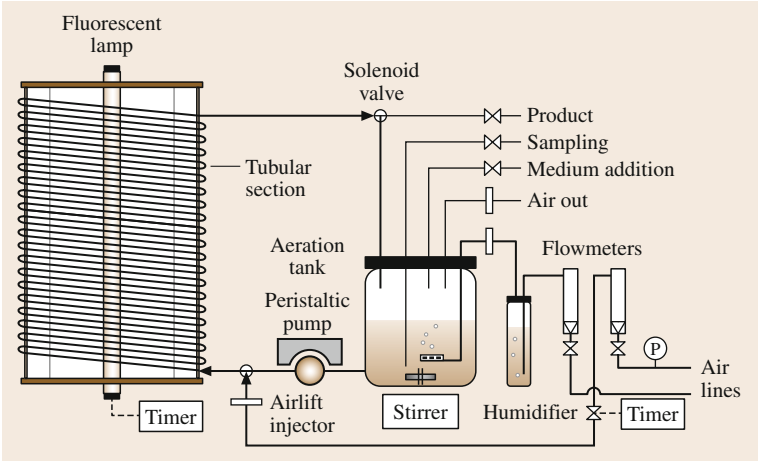

Fig. 12.5 Three-liter tubular photobioreactor, featuring coiled tubular section, aeration tank, and airlift injection system. In batch operation, the product outlet line is closed and the culture continuously recirculates between the aeration tank and the tubular section (after *Rorrer* and *Mullikin* [12.13])

Rorrer and *Mullikin* [12.13] cultivated cell suspension cultures obtained from the marine macrophytic brown alga (*seaweed*) *Laminaria saccharina* in a 3 L tubular recycle PBR (Fig. 12.5) where the culture is recycled between an unaerated coiled tubular section for culture illumination and a nonilluminated aeration tank where absorption of CO_2 (needed for photosynthetic biomass production) and stripping of dissolved O_2 evolved from photosynthesis take place. The tubular recycle PBR could be operated in batch, semicontinuous and continuous-recycle modes. A three-way solenoid valve located at the outlet of the tubular section is used for mode selection. In batch operation, the solenoid valve is closed, and the cell suspension culture leaving the tubular section is recycled back to the aeration tank (total recycle). In semicontinuous or continuous recycle operation, the solenoid valve opens and closes periodically, permitting a portion of the culture to be drawn off as product (while the rest is returned to the reactor), with concurrent feeding of fresh medium.

Rorrer and *Zhi* [12.14] compared the biomass productivities of a semidifferentiated tissue suspension culture of the marine cold-water green macroalga *Acrosiphonia coalita* (a source of oxylipins with potent antimicrobial properties), in two types of PBRs, a stirred tank PBR (ST-PBR) and a BC PBR (BC-PBR). Now, although the parent plant is highly branched and must be anchored to rocky substratum in its marine ecological niche, the tissue culture comprises mainly linear filaments growing in a homogeneous liquid suspension. Toward this end, the inoculum tissue was finely blended to 1–2 mm long filaments but it was observed that only the ST-PBR could provide the agitation necessary for uniform suspension of this tissue culture – in fact, of all the cultivation vessels considered, the highest biomass productivity was obtained in the ST-PBR.

The ST-PBR (Fig. 12.6) (volume 3 L) is actually a jacketed, round-bottomed, glass vessel (I.D. 13 cm, height 24 cm), equipped with a three-blade marine impeller (diameter 4.5 cm, height 6 cm) pitched at an angle of 45°. Ambient air was pumped through a sterile air filter, and then sparged to the culture through an air inlet pipe having seven holes (diameter 1 mm) drilled in a row. Optionally, CO_2 was metered separately and then mixed with the inlet air stream before passing through a sterilizing air filter. Cold water from a low-temperature circulator was pumped through the glass vessel jacket to maintain a constant cultivation temperature. The illumination stage consisted of two light banks positioned on opposite sides of the bioreactor, each comprising three fluorescent tube lamps (each 9 W), mounted horizontally in a parallel array. Each light bank was aligned with the bioreactor vessel so that the length of the lamp coincided with the vessel width, whereas the cumulative height of all the lamps matched the height of the liquid in the reactor vessel. A referencing plate was used to set the distance between the lamp and the vessel surface with high precision so that the desired light intensity (incident on the vessel surface) could be uniformly delivered to the culture. For the ST-PBR, the light sensor was positioned on the inside surface of the vessel to obtain the true incident light intensity to the culture. The light intensity incident on the inner surface of the vessel was fixed at nominally twice the saturation light intensity, to compensate for light attenuation through the culture.

Ogbonna et al. [12.15] studied the production of α-tocopherol by the microalgae *Euglena gracilis* in a con-

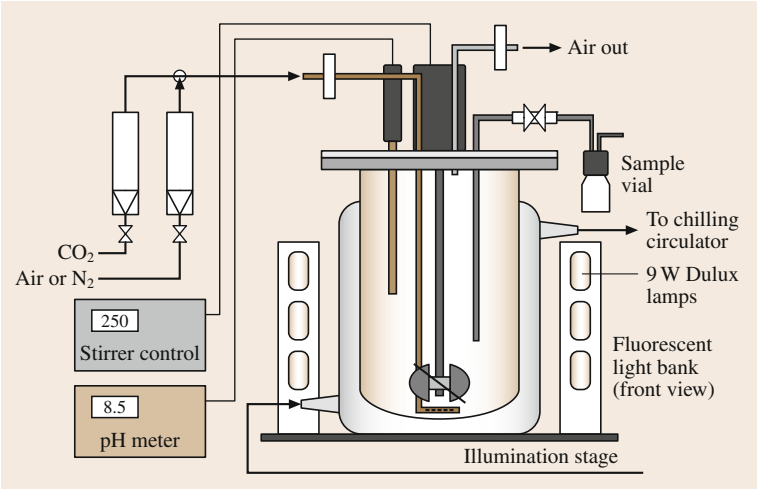

Fig. 12.6 Three-liter stirred-tank photobioreactor, including illumination stage and instrumentation (after *Rorrer* and *Zhi* [12.14])

tinuous sequential heterotrophic–photoautotrophic cultivation system. The cells were continuously cultured heterotrophically in a conventional aerated, stirred mini-jar bioreactor (volume 2.5 L, working vol. 2 L) and the effluent continuously passed through an internally illuminated photobioreactor for the photoautotrophic phase, with α-tocopherol production. The novel sequential continuous process resulted in α-tocopherol productivity (of 100 mg h^{-1}) which is $\approx$ 9.5 and 4.6 times higher than corresponding productivities obtained (individually) in batch photoautotrophic and heterotrophic cultures, respectively.

De Morais and *Costa* [12.16] designed a novel temperature-controlled, three-stage, serial column (i. e., tubular) photobioreactor (volume 2 L, working vol. 1.8 L for each CPBR) to investigate CO_2 biofixation by marine photosynthetic cyanobacteria *Spirulina* species. This study demonstrated the high CO_2 biofixation potential of the cyanobacteria cultivated in the three-reactor cascade CPBR1-CPBR 2-CPBR3. It was also noted that using multiple PBRs in series resulted in much lower CO_2 levels in the final gaseous effluent discharged to the atmosphere. Agitation and aeration were carried out using air from a compressor and a sintered sparger – the effluent air (with or without CO_2) from CPBR1 being fed to the sparger in CPBR2 and the effluent from CPBR2 being fed to CPBR3. The CPBRs were placed in a 30 °C growth chamber under a 12 h dark/light photoperiod with illumination provided by 40 W daylight-type fluorescent lamps during the light period.

Chae et al. [12.17] used two novel PBRs – one laboratory scale (working volume 100 L) (Fig. 12.7) and the other pilot scale (working volume 1000 L) to study single-cell protein production and atmospheric CO_2 biofixation by the microalga *Euglena gracilis*. Besides CO_2 fixation during photosynthesis, algal biomass may be used as a biofertilizer, soil conditioner, and also as feed for terrestrial and aquatic animals. Insofar as the last application is concerned, *E. gracilis* scores highly due to several reasons viz. (1) it has relatively high crude protein content (47% w/w of biomass) and thus higher nutritional quality compared to other microalgae like *Chlorella* and *Spirulina*, (2) its in vitro digestibility is slightly higher than that of casein making it an attractive animal fodder, (3) it grows well under acidic conditions with very little risk of culture contamination. *Euglena gracilis* growth is very sensitive to light intensity. The novel pilot-scale PBR (which uses sunlight as energy source and flue gas from an oil heater as a CO_2 source) minimizes the self-shading effect typical of dense microalgal cultures (that leads to increasing light attenuation with distance from the light source, and thereby to decreasing biomass productivity) and, expectedly, shows much higher biomass yields compared to the laboratory-scale PBR.

The laboratory-scale PBR (90 cm × 20 cm × 70 cm) was provided with a cover and baffles that induced plug flow of the culture medium. Pure CO_2 and air were fed at rates of 0.3 and 2.7 L min^{-1}, respectively, and the mixed gas was passed through a humidifier before entering the reactor. To minimize light attenuation, reactor width was fixed at 20 cm and fluorescent lamps were installed on both sides of the PBR as light sources in parallel. The pilot-scale PBR used sunlight as energy source and flue gas from an industrial oil heater as CO_2

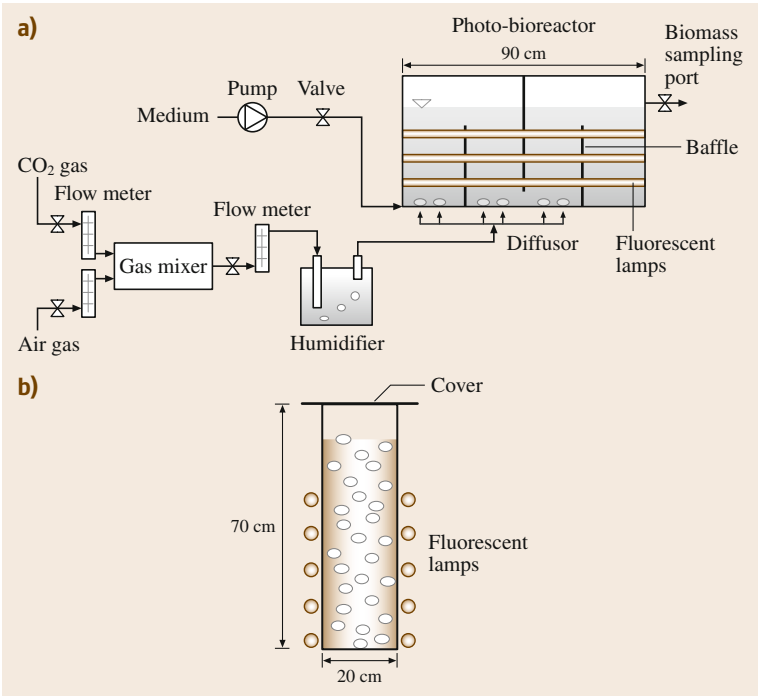

Fig. 12.7a,b Schematic (**a**) and cross-sectional diagrams (**b**) of a laboratory-scale photobioreactor for semicontinuous and continuous culture (after *Chae* et al. [12.17])

source (30 L min^{-1}). The L-shaped PBR (working volume 1000 L) was separated into a dark zone (1.8 m × 0.2 m × 1.4 m) and a light zone (1.8 m × 1.0 m × 0.4 m) of equal working volumes, each 500 L with a cover. To minimize light attenuation, effective height of the light zone was fixed at 20 cm. A scraper was installed for internal circulation of culture medium between dark and light zones.

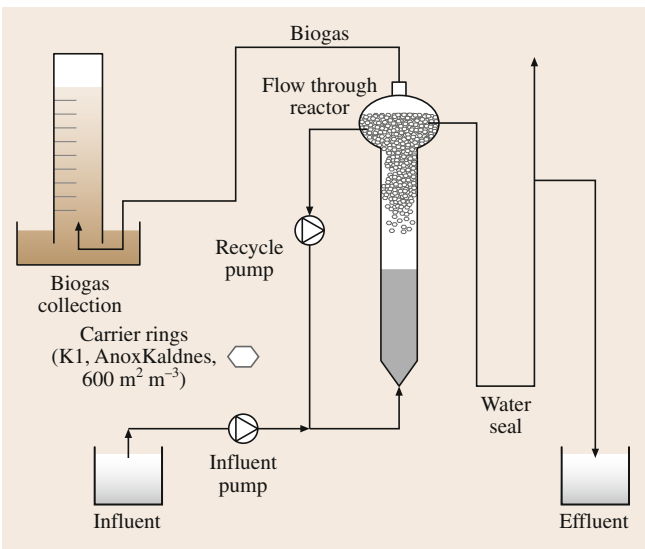

Fig. 12.8 Scheme of the laboratory-scale experimental setup of the hybrid flow-though reactor (after *Zamalloa* et al. [12.18])

Zamalloa et al. [12.18] examined the anaerobic digestibility of the marine microalga *Phaeodactylum tricornutum* for biogas production in a serpentine tubular PBR and a novel, hybrid flow-through anaerobic reactor (HFAR) – the latter essentially a cylindrical tube with a three-phase separator in the upper part (Fig. 12.8). The serpentine PBR comprises of a glass vessel (total volume 80 L, working volume of 65 L) and a transparent tube (diameter 19 mm, length ≈ 80 m). The culture broth was recirculated using a peristaltic pump (10 L min^{-1}). The PBR was installed in a greenhouse at 25 ± 2 °C with illumination provided continuously by fluorescent lamps. Culture pH was controlled (at 8) and regulated by on-demand, automated CO_2 injection. Mixing was achieved by bubbling air through diffusers at an aeration rate of ≈ 0.5 vvm. Each HFAR consisted of a cylindrical tube (diameter 5 cm) having a three-phase separator in the upper part, with a recirculating pump generating an upflow velocity of ≈ 1 m h^{-1}. Biogas production was measured by the liquid displacement method in 10 L airtight calibrated vessels containing water at pH 2 to prevent dissolu-

tion of CO_2. 150 g of plastic carrier rings per reactor were added as carrier material, and an anaerobic filter for increased retention of algal biomass particles, was installed.

12.3 Airlift Bioreactors (ALBR) and Bubble Column Bioreactors (BCBR)

12.3.1 Airlift Bioreactors

Airlift bioreactors (ALBR) (Tables 12.3 and 12.4) are pneumatically agitated gas–liquid or gas–liquid–solid contacting devices characterized by fluid circulation in a defined cyclic pattern through two vertical channels viz. the *riser* for gas–liquid upflow and *downcomer* for downflow) connected at the top (the *gas separator*) and bottom (the *base*). The driving force for recirculation of the fluid is the density difference between the downcomer and the riser which generates the pressure gradient necessary for liquid recirculation [12.21]. Air/gas is usually injected at the bottom of the riser and a portion of the gas disengages in the gas separator. The remaining portion is entrapped by the descending liquid and flows down the downcomer. If the gas residence time in the separator is substantially longer than the time required for disengagement of the gas bubbles, the fraction of gas recirculating through the downcomer would be minimized. In addition to agitation, the gas stream also facilitates exchange of material between the gas phase and the culture medium – oxygen is usually transferred to the liquid and often, metabolic products, from the liquid to the gas phase. ALBRs provide a relatively homogeneous low-shear field for microbial growth. They are further characterized by (a) their total lack of any moving parts and (b) their high aeration efficiency – the latter due to the high rates of oxygen transfer alongside minimal power consumption compared to conventional stirred bioreactor systems. ALBRs may be classified into two basic categories viz. (i) external loop ALBRs, in which fluid circulation occurs through separate and distinct channels, and (ii) internal – loop (baffled) ALBRs – where strategically installed baffles create the channels required for circulation. Configurations of both types may be further modified.

Jiang et al. [12.22] examined simultaneous carbon and nutrient removal from wastewater in a plexiglass bench-scale ALBR (working volume 22 L) by filamen-

tous marine bacteria *Thiothrix* species in a limited filamentous bulking (LFB) state – a repeatable and controllable state that brings about a balance between floc forming and filamentous bacteria. The ALBR with a low height-to-diameter ratio (overall height 1000 mm) consists of a reaction zone (I.D. 160 mm) and an upright settling zone (I.D. 220 mm). Two draft tubes, an upper tube (height 160 mm, dia 130 mm) and a lower tube (height 850 mm, dia 100 mm) were concentrically placed in the ALBR. For sparging gas, 120 holes (dia 0.5 mm) in a perforated pipe were positioned equidistantly around the circle at the middle of the riser. The flow rate of the mixed broth circulating between the annulus and the draft tube could be varied by changing the gas-flow rate. Influent was fed to the reactor through one of the three wastewater inlets located at the bottom and the middle of the riser and the upper part of the annulus, whereas effluent was withdrawn from the liquid in the settling zone. The ALBR and its component tubes were cleaned from time to time to prevent bacterial growth in the lines and on the vessel walls. The authors concluded that under an LFB state in the ALBR, the balance of aerobic and anoxic/anaerobic zones was achieved which is required for enhanced nutrient removal and effluent clarification. Furthermore, the LFB state, which is characterized by low DO levels, causes a reduction in the height-to-diameter ratio of the reactor and thereby in energy requirement for aeration.

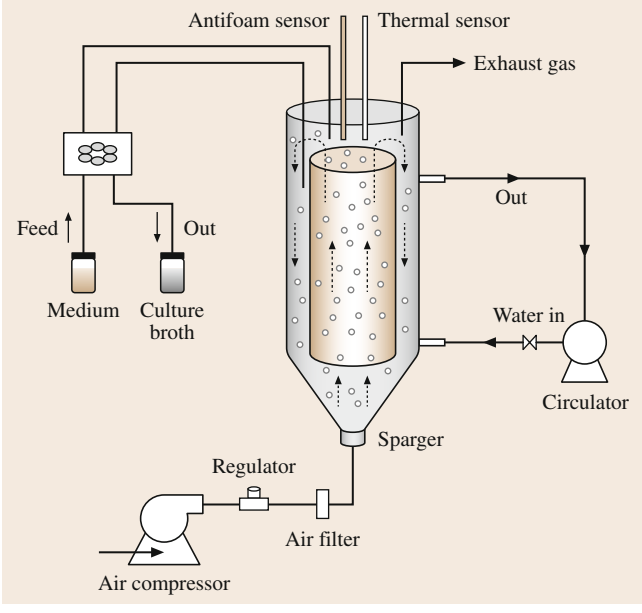

Fig. 12.9 Schematic diagram of an airlift bioreactor (after *Jeong* et al. [12.23])

Jeong et al. [12.23] demonstrated the continuous production of rhamnolipid-type biosurfactants in an ALBR (maximum volume 1.8 L, working volume 1.2 L, diameter 100 mm, height 320 mm) by a marine strain of *Pseudomonas aeruginosa* (isolated from the southern sea of Korea) immobilized, by entrapment in Ca-alginate modified PVA beads (Fig. 12.9). They noted that the medium-to-bead volume ratio is a key parameter for evaluating bioreactor performance and that an optimal value exists considering productivity and economics.

Assadi and *Jahangiri* [12.24] used a split ALBR to obtain a very high level (up to 97%) of decolorization of textile wastewater by a marine strain of *Aspergillus niger* (isolated from Gorgan Bay in the Caspian Sea). The jacketed glass-made ALBR is split by a PTFE strip

(800 mm × 100 mm × 3 mm) and is fitted with a glass condenser to arrest any outgoing moisture. Air is introduced through a chamber (length 100 mm) connecter by a flange to the distributer. 28 holes (1 mm diameter) were drilled (on a square pitch, 6 mm center-to-center) on half of the S.S. sparger that works as a riser. A condenser (area 0.2 m^2) is included to arrest any outgoing moisture.

Munoz et al. [12.25] employed an ALBR fitted with a fiber optic spectrophotometer, for filamentous callus induction and microplantlet culture propagation of the macroalga *Kappaphycus alvarezii* (Doty) which is the largest source of κ-carrageenan in the global phycocolloid industry. Now, ALBRs are usually preferred for macroalgal cell cultivation because they facilitate enhanced gas exchange and light transfer on the one hand and reduced shear damage on the other. Mixing in ALBRs is obtained by pneumatic and/or mechanical agitation in order to maintain a uniform concentration of chemical species in the bulk phase and enhance mass transfer. Since proper mixing is crucial for adequate distribution of cells and nutrients in the liquid phase, a realistic estimation of liquid-phase mixing times is necessary for effective ALBR design. For this purpose, a fiber optic spectrophotometer is used for mixing-time evaluation which has several advantages over other traditional methods viz. faster response without data loss, minimal measurement error, operational flexibility through use of several solutions as tracers, faster in situ measurements and reduced frictional resistance. It is noted that liquid circulation is very sensitive to bioreactor geometry and, on this count, the ALBR described here could provide adequate liquid circulation of the culture media.

The ALBR (effective working volume 1.5 L) externally illuminated with fluorescent lamps, consisted of an acrylic pipe (height 30 cm, I.D. 10 cm) and a draught tube (height 22.5 cm, I.D. 3.8 cm), with inlet air pumped through a flow meter. A fiber optic spectrophotometer was placed 5 cm below the water surface, and a tracer of 1.0 ± 0.3 mL saturated aniline blue aqueous solution was injected over the optical fiber through a Pasteur pipette. Mixing time (defined as the time required to attain a specified mixing intensity at a given scale), was measured from the time at which maximum absorbance was recorded, to the time of minimum absorbance, assuming a completely homogenized medium. It was concluded that filamentous callus production from axenic *K. alvarezii* explants was effectively promoted in the ALBR (with the tested plant growth regulator).

Polzin and *Rorrer* [12.26] used a perfusion airlift photobioreactor, i. e., with continuous liquid medium perfusion, for synthesis of halogenated monoterpenes by regenerated microplantlet suspension cultures of the macrophytic marine red alga (*seaweed*) *Ochtodes secundiramea*, claimed as the *first successful bioreactor production of halogenated monoterpenes from a marine organism*. The bioreactor (Fig. 12.10) is a glass jacketed vessel (working volume 2.1 L, 50 cm high, 7.6 cm I.D.) with the vessel jacket connected to a temperature controlled water circulation bath (maintained at 26 °C). Illumination was provided by four vertically mounted, timer-controlled (14 h on/10 h off) 15 W cool-white fluorescent lamps positioned at 1.0 cm from the vessel to provide a uniform incident light intensity along the reactor surface. CO_2 in the aeration gas served as the sole carbon source for algal growth, supplemental CO_2 (from a CO_2 tank) was mixed with the inlet air which passed successively through a filter (0.2 µm) and a humidifier before entering the reactor through a glass frit (diameter 4 cm, pore size 40–60 µm). Dissolved CO_2 speciates to bicarbonate ion (HCO_3^-) in seawater pH > 7. Fresh medium was continuously pumped into the bottom of the reactor during the 14 h light

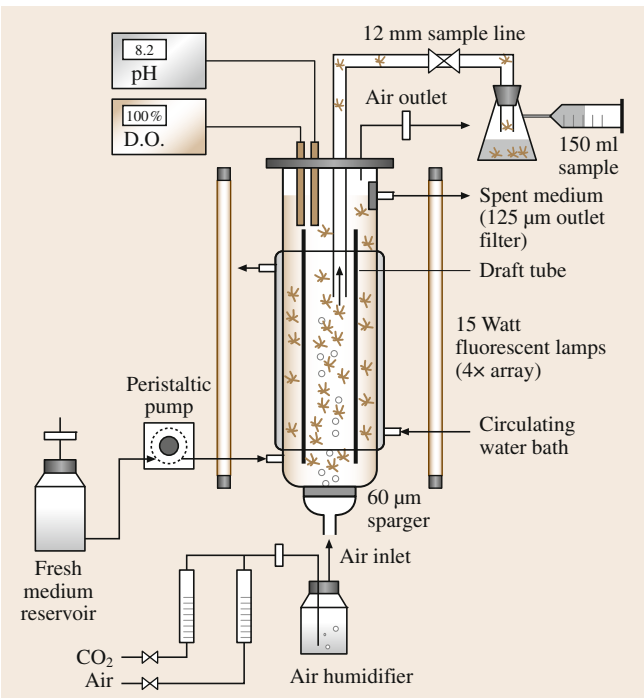

Fig. 12.10 Perfusion airlift photobioreactor (after *Polzin* and *Rorrer* [12.26])

phase. A nylon mesh (125 μm) was affixed on the medium outlet port for biomass retention within the reactor.

Contreras et al. [12.27] employed a plexiglass-made concentric tube airlift PBR (working volume 12 L) for culturing the photosynthetic microalga *P. tricornutum*. The AL-PBR (Fig. 12.11) consisted of a 2 m high outer tube (diameter 0.09 m) within which was installed a 1.5 m high concentric draft tube – the riser, with a cross-sectional area (2.8×10^{-3} m^2) same as that of the downcomer. Continuous illumination was provided by 10 fluorescent lamps, installed around the reactor with an illuminated surface area of 0.471 m^2. Compressed air was passed through an oil separator and a 0.5 mm sterile filter. A cylindrical, sintered glass sparger (diameter 0.02 m, height 0.03 m, pore size 60 mm) located in the riser, was used for aeration. It was noted that the AL-PBR adequately complied with the requirements of microalgal cultivation viz. high mass transfer rates, large surface-to-volume ratio, ease of control, safe sterile operation, and low mechanical shear forces on the cells. The existence of a maximum in μ_{max} of *P. tricornutum* was observed with respect to the gas flow rate as well as the shear rate which is indicative of the presence of a growth limiting or inhibitory effect in the reactor below and above these optimal values.

Vunjak-Novakovic et al. [12.28] designed a novel *triangular-configuration* inclined-tube AL-PBR for CO_2 fixation from flue gas by the marine green algae *Dunaliella* sp. When gas enters from the bottom of an inclined tube, the gas bubble travels along the inner upper surface of the tube – this renews the upper surface liquid layer making surface adherence difficult for the growing algae, thereby preventing fouling. As light penetration into the ALBR usually occurs through the upper surface, this self-cleaning feature substantially reduces the need for tube maintenance. Most of the solar radiation incident on the *triangular-configuration* AL-PBR enters through the hypotenuse (3.3 m long), with a circular cross-sectional area. Thus, the cross section has an *intensive light* region, corresponding to that in the annular region of a concentric-tube ALBR. The liquid flow rate is controlled mainly by the feed flow rate of the gas and can be adjusted to give a wide range (seconds to minutes) of retention times within each of the reactor zones. As the algae circulate through the inclined-tube segment, turbulence caused by two gas spargers creates microtrajectories that carry the suspended cells back and forth between zones with different illumination (i. e., closer to the illuminated surface or deeper into the liquid flow with less illumination). The desired throughput for flue gas purification is obtained simply by increasing the number of ALR *triangles* that are connected in parallel. Preliminary studies were carried out in a small-scale laboratory ALBR (volume 7 L) with no internal temperature control, housed in a wedge-shaped greenhouse (temperature-controlled) with a triangular side view resembling the shape of the reactor. A so-called *second*

[12.29])

pilot-plant unit was also installed that comprised a cascade of 30 ALBRs (volume 30 L each) with a configuration as in Fig. 12.12. These ALBRs were continuously supplied with flue gas from a small power plant to demonstrate CO_2 removal from flue gas by growing algae.

Del Campo et al. [12.29] employed an outdoor airlift-driven tubular photobioreactor (volume 55 L, made of acrylic) for the production of lutein (a valuable carotenoid pigment with a wide range of uses) by *Muriellopsis* species, a chlorophycean microalga. The reactor (Fig. 12.13) has an airlift system to recirculate the cell culture and an external horizontal loop, consisting of tubes (length 90 m, I.D. 2.4 cm, surface area 2.2 m^2) that serve as solar receivers, immersed in a thermostatic pond of water. The airlift consisted of a degasser (in which the pH and temperature probes were inserted) and two 3 m high tubes (i. e., the riser and the downcomer). Compressed air was supplied into the riser to transport the cell suspension through the tubes and create turbulence. The reactor was operated in continuous-flow mode during daylight and in batch mode at night, to prevent culture washout.

12.3.2 Bubble Column Bioreactors (BCBR)

Bubble columns (BC) (Tables 12.3 and 12.4) are also pneumatically agitated vertical column reactors but the main difference with ALRs is in the nature of fluid flow, which depends on the geometry of the reactor. The bubble column is a rather simple vessel into which gas (air) is injected at the bottom and random mixing is produced by the rising bubbles. Now, in contrast to a BC where flow patterns are rather random, the ALR generates a more homogeneous flow pattern that moves suspended cells from the riser to the downcomer. Again cell sedimentation may occur in a BC, but cells remain more uniformly suspended in an ALR.

Guo et al. [12.30] developed an integrated process of CO_2 fixation and biohydrogen photoproduction by the marine green microalga *Platymonas subcordiformis*, grown photoautotrophically in a CO_2 supplemented air BCBR (Fig. 12.14) (volume 600 mL, diameter 50 mm, height 400 mm). CO_2 is required in photosynthesis for algal production of intracellular starch; the latter is then utilized for hydrogen production under anaerobic conditions by mitochondrial respiration to deplete oxygen. In fact, alga with higher starch accumulation shows a substantial increase in rate and duration of hydrogen production. Compressed air and CO_2 were mixed (up to 15 vol. % of CO_2 in air) and

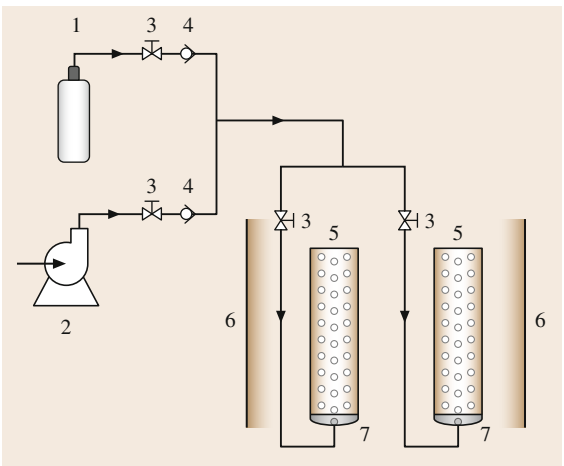

Fig. 12.14 Schematic diagram of the bubble column bioreactor system used for the growth of *P. subcordiformis* cultures under photoautotrophic conditions. 1 – CO_2 bottle, 2 – air compress pump, 3 – manual valve, 4 – gas flowmeter, 5 – bubble column bioreactor, 6 – cool-white fluorescent light, and 7 – porous sieve (after *Guo* et al. [12.30])

metered through calibrated flow meters, and sterilized using membrane filters (pore size 0.22 μm) before entering the reactor (at an aeration rate of 0.2 vvm). The bottom of the bioreactor was filled with a porous quartz sieve (diameter 10 mm), which dispersed the airstream. The cultures were illuminated from two sides with cool white fluorescent lamps under 14 h/10 h light/dark cycle. CO_2 was supplemented in air only during the light phase.

Seven-day-old cell cultures from the BCBR were concentrated by centrifugation and transferred into a 500 mL cylindrical glass bioreactor. They were subjected to the dark anaerobic induction of hydrogenase at 25 °C for 12 h, after continuous flushing for 10 min with N_2 (99.9% purity) through the culture to purge O_2. 15 1M CCCP (carbonylcyanide *m*-chlorophenylhydrazone) was then added, and the culture further incubated in darkness for 20 min, before initiating photobiological H_2 production under continuous illumination. It was demonstrated in this study that the marine green alga *P. subcordiformis* could efficiently convert CO_2 into intracellular starch through photosynthesis and improve H_2 photoproduction through increased accumulation of intracellular starch under CO_2 supplementation in an air bubble column PBR.

Huang and *Rorrer* [12.31] investigated the optimal values of cultivation temperature and diurnal photoperiod for the phototrophic growth of a microplantlet suspension culture derived from the macrophytic marine red alga *Agardhiella subulata* in a BC-PBR. Cultivation temperature and light delivery are two crucial process variables in the design of PBRs for culturing marine microalgae (seaweed). The latter has two components, viz., the light flux intensity and the diurnal photoperiod, i. e., the light/dark (L/D) illumination cycle in 24 h. It was observed in this study that biomass production increased with increasing photoperiod at low fractional photoperiods ($\leq$ 10 : 14 L/D) but at high fractional photoperiods approaching continuous illumination ($\geq$ 20 : 4 L/D) biomass production practically stopped, presumably due to photodamage that inhibits growth). The optimal photoperiod for biomass production was found to be 16 : 8 L/D.

An externally illuminated BC-PBR (same working principle as that used in *Zhi* and *Rorrer* [12.32], cited immediately afterward) (effective cultivation volume 250 mL) consisted of a 12.7 cm straight section (diameter 4.5 cm) and a 15.2 cm conical riser section (inner diameter 1.3 cm at the base). The small vessel diameter minimized light attenuation through the microplantlet suspension. Air was metered, humidified in a bubbler, sterilized through an autoclaved filter (0.2 μm pore size), and then introduced into the base of the riser section through a glass frit (diameter 1.3 cm, pore size 40–60 μm). The liquid suspension culture in the vessel was uniformly agitated and aerated by rising air bubbles (nominal diameter 1.0 mm). Ambient CO_2 in the aeration gas (normally 350 ppm) served as the carbon source for photosynthetic biomass growth. The illumination stage consisted of two 6.0 W cool-white fluorescent lamps vertically mounted on opposing sides of the glass vessel. A referencing plate set the distance between each lamp and vessel wall to deliver the desired incident light flux intensity to the culture and a programmable timer set the photoperiod for each lamp. The PBR was maintained at 24 °C within a temperature-controlled room. Two identical BC-PBRs described above were operated in parallel, each inoculated with microplantets from a common inoculum source.

Zhi and *Rorrer* [12.32] demonstrated the feasibility of the photolithotrophic cultivation of a cell suspension culture derived from the microscopic, filamentous gametophytic life phase of the brown marine macroalga *L. saccharina* in an illuminated BC-PBR, at 13 °C using CO_2 in air as the sole carbon source for growth. Two illuminated glass BCBRs were employed with effective cultivation volumes of 280 and 900 mL, respectively. Each BCBR system, comprising the bioreactor assembly, aeration unit, and illumination arrangement, was housed in a low-temperature incubator fitted with two auxiliary convection fans to maintain uniform temperature, and fresh air was supplied to maintain a constant ambient CO_2 concentration in the incubator gas space (vol. 500 L). Four identical 280 mL bioreactor systems and two 900 mL bioreactor systems were used for batch experiments under different conditions using a common inoculum. The bioreactors of a given volume were all located within the same low temperature incubator.

The 280 mL BCBR (Fig. 12.15) consisted of a 12.70 cm straight section (I.D. 4.45 cm) and a 15.24 cm conical riser section (base I.D. 1.27 cm), and was sealed to the head plate with two G-rings, one above and one below the flange of the glass body. The head plate had two ports, for the sampling assembly and for air outlet, respectively, with the latter connected to a sterilizing filter (0.2 μm). Agitation was provided by rising air bubbles introduced into the reactor base through the sparger assembly. Ambient air from an aquarium pump was metered, filter – sterilized (0.2 μm), and then bubbled through a ster-

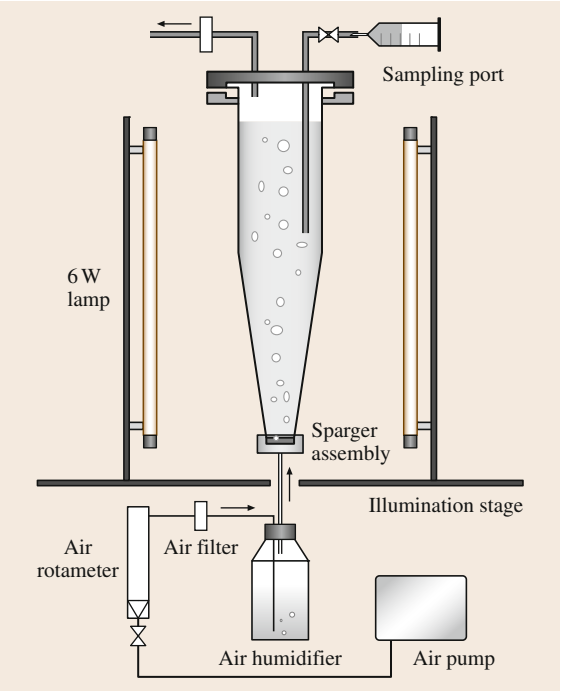

Fig. 12.15 Schematic of 280 mL bubble-column bioreactor (after *Zhi* and *Rorrer* [12.32])

ilized humidifier, before introducing into the culture through the sparger assembly fitted with a removable glass frit (pore size 40–60 µm, diameter 1.27 cm). The sparger generated air bubbles with diameter ranging from 0.2–0.7 mm. The conical riser section improved the fluid circulation provided by the rising air bubbles. CO_2 naturally present in the ambient aeration gas (nominally at 350 ppm) served as the sole carbon source for biomass growth. Illumination was provided by two vertically opposed, timer-controlled 6 W fluorescent lamps mounted on plexiglass plates. A referencing plate set the distance between each lamp and the vessel wall, so that the desired incident light intensity could be applied uniformly to both sides of the reactor. The larger BCBR had the same headplate assembly, sparger assembly, and aeration system as the smaller one but the straight section of the 900 mL glass reactor vessel was 48.26 cm long. Also, the light stage consisted of four 6 W fluorescent lamps mounted vertically, with two per side.

Initial cell density had a profound effect on the final biomass density of the clumped cell suspension, not on the specific growth rate. Increasing the aeration rate somewhat enhanced the specific growth rate and final biomass density, but the culture was not CO_2-transport limited. Initial nitrate concentrations above a certain threshold value had no significant effect on the specific growth rate and final biomass density.

12.3.3 ALBR and BCBR and/or other PBR – Comparative Studies

Nagase et al. [12.33] investigated the removal of NO (present in fossil fuel flue gas) by the marine green algae *Dunaliella tertiolecta* cultured in bubble column and air-lift-type bioreactors. Several alternative means of enhancing NO removal were examined in this study, the first of which was to reduce the bubble size in order to increase the gas–liquid contact surface and thus obtain a higher rate of NO dissolution. For this purpose, S.S. tubes of different gauges, and glass-ball filters (g.b.f.) of varying particle sizes were examined as spargers to give varying bubble diameters – of which the so-called No. 3 g.b.f. generated the smallest bubbles. However on actual use of No. 3 g.b.f in the parallel-flow ALBR, the algal cells became concentrated at the top of the reactor due to froth flotation and could not be cultured further. Secondly, for increasing the NO removal rate, the idea of using a longer column or a modified reactor configuration, viz., the counterflow ALBR, was considered, to increase the gas–liquid contact time. In fact, the counterflow ALBR improved gas liquid contact time by decreasing the rising rate of bubbles (i. e., by increasing gas holdup). With a No. 3 g.b.f. used in the counterflow ALBR, by which a simultaneous increase in gas–liquid contact area and gas holdup was accomplished, a remarkable enhancement in the NO removal rate was observed – there was no growth – inhibition by froth flotation in the reactor and the algal culture remained well mixed. The parallel-flow and counterflow-type ALBRs employed for algal NO removal (shown in Fig. 12.16) were fitted with a draft tube located centrally in the column. The NO containing flue gas was fed outside of the draft tube, where photosynthetic oxygen was produced vigorously. The draft tube was cut near the two parts connected by a fine-mesh stainless steel netting, thereby preventing the mixing of bubbles inside and outside the draft tube and facilitating circulation of the culture medium in the reactor column. The highest NO removal, i. e., 96%, was attained with a counterflow-type ALBR (when 100 ppm NO was aerated with smaller bubbles). The authors concluded that the NO removal ability of a counterflow-type ALBR was threefold higher than a simple BCBR.

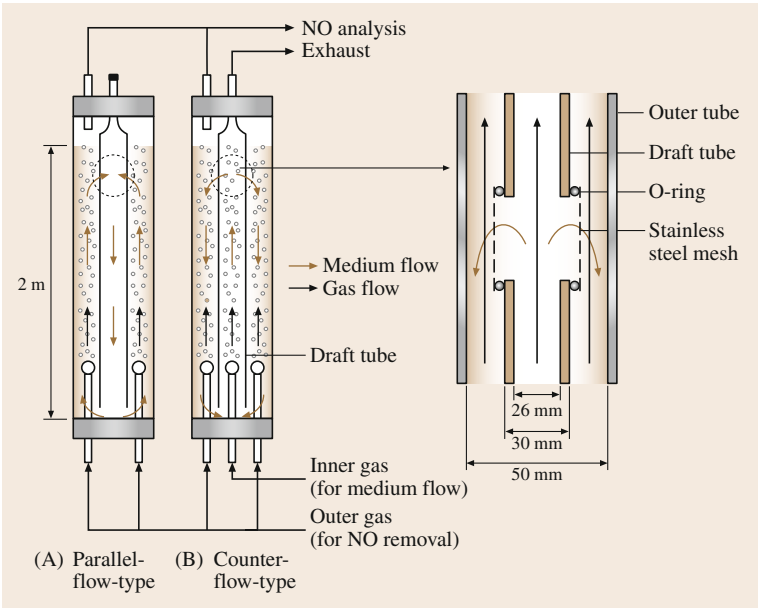

Fig. 12.16 Schematic diagrams of NO removal systems using airlift reactors (after *Nagase* et al. [12.33])

A comparative evaluation of the performance of an AL-PBR and BC-PBR (both 3 L volume, the same column diameter and height) was undertaken by *Monkonsit* et al. [12.34] for the cultivation of the marine diatom *Skeletonema costatum*, which is used as food for shrimp larvae in the first protozoea stage. Maximum cell concentration, specific growth rate, and biomass productivity were higher in the AL-PBR than in the BC-PBR, both having been operated under identical aeration rates and light intensity. The superior performance of the AL-PBR was attributed to its circulatory flow that prevents cell precipitation and improves light utilization efficiency. The optimal reactor operating parameters for cell growth in terms of:

1. Ratio of downcomer-to-riser cross-sectional area (3.27)
2. Superficial gas velocity (1.5 cm s^{-1})
3. Incident light intensity (34 μmol ph m^{-2} s^{-1}) were determined.

The AL-PBR (height 60 cm, column I.D. 9.4 cm) was equipped with a draft tube (height 40 cm) installed centrally in the column. For both reactors, compressed air was passed through a flowmeter and sterilized through a filter (0.45 μm) before entering the reactor bottom. Illumination was provided by 18 W fluorescent lamps installed at the side, along the length of each column (two lamps per column). The reactors were kept in an air-conditioned enclosure with temperature maintained between 25 and 30 °C.

Merchuk et al. [12.12] considered the effect of light/dark cycles of different frequencies on growth and polysaccharide production by the red microalga *Porphyridium* sp. in a laboratory-scale tubular loop PBR (total volume 0.43 L) and compared it with the performance of an AL-PBR and BC-PBR (both of volume 35 L). Whereas the loop device is a small-scale laboratory reactor in which liquid is circulated by a peristaltic pump at a controlled rate, the column reactors (bubble column and air-lift) are orders of magnitude larger, and the liquid movement is driven by the injection of gas into the reactor. However, despite basic differences, the light/dark cycles generated, either by the pump of the laboratory-scale tubular reactor, or by gas flow rate in the much larger BC and ALR, were found to be of the same order.

Under low light intensity and high gas flow rates, the BC and the ALR performed almost identically. However, with high light intensity and low gas flow rates, both growth and polysaccharide production were higher in the ALR. The interactions of photosynthesis and photoinhibition with the fluid dynamics in the bioreactors allowed interpretation of the differences in the performance of the BC-PBR and the AL-PBR. It was posited that the cyclic distribution of dark periods in the AL-PBR facilitates better recovery from the photoinhibition damage suffered by the cells. Due to the

small diameter of the loop and the low biomass concentration involved, the laboratory-scale tubular loop PBR performance data could be considered free of the effect of self-shading, and in this regard, the TL-PBR could be considered a *thin-film* photobioreactor. The larger column reactors were used to examine the effect of mixing under conditions of high optical density, where self-shading and fluid dynamics were responsible for the periodicity of exposure to light.

The tubular loop reactor (volume 0.43 L) consisted of a series of glass tubes (I.D. 0.007 m) connected to a small vessel into which air containing 3% CO_2 was bubbled (to supply a carbon-source and remove O_2); the loop was closed through a peristaltic pump. The ratio of illuminated/dark zones was controlled by darkening different lengths of the tube. The ventilation vessel, which was always covered, formed part of the dark zone. Illumination was provided from a bank of fluorescent lamps.

The column reactors (both 2 m high, column diameter 0.180 m) were also supplied with air containing 3% CO_2 and were housed in a temperature-controlled room at 25 °C. The difference in construction between the AL-PBR and the BC-PBR was that a draft tube (height 1.5 m, diameter 0.09 m) was installed coaxially in the AL-PBR. The draft tube plays a pivotal role in transforming the flow of the liquid, which is approximately random in the bubble column, into more ordered patterns in the ALR. The liquid rises through the central riser due to the difference in hydrostatic pressure, and descends through the annular downcomer, engaging part of the gas. The extent of this gas carryover depends on the operating conditions.

Krichnavaruk et al. [12.35] used a small-scale glass BC-PBR (2.5 L) as well as an AL-PBR and a BC-PBR (both 17 L volume) to investigate the growth of the chlorophyll containing marine diatom *Chaetoceros calcitrans* which is commonly used as feed for shrimp larvae. For the large-scale column reactors, run in batch mode, both maximum specific growth rate and maximum cell concentration were higher in the AL-PBR by about 18 and 16%, respectively. For the AL-PBR operated in semicontinuous mode, maximum specific growth rate increased further by 30%. Experiments to determine the optimal growth conditions of *C. calcitrans* were performed in a small-scale glass bubble column (volume 2.5 L). Compressed air (flowing 3.8 L min^{-1}) entered the bottom of the column. Illumination was provided through 250 W lamps, and incident light intensity was controlled by varying the distance between the lamps and the column. Both large-scale bioreactors were acrylic-made (diameter 15 cm) but the AL-PBR was equipped with a draft tube installed centrally in the column. The ratio between the cross-sectional areas of downcomer and riser was 2.63. Compressed air was supplied at the bottom of the draft tube and a 5 cm gap was left between the bottom of the draft tube and the column to allow liquid circulation. Aeration was controlled by a calibrated rotameter – superficial gas velocity in the riser was controlled in a range of 2–5 cm s^{-1}. Light was supplied through 12 fluorescent lamps placed at the side, along the length of the columns and temperature was controlled ≈ 30 °C (±2 °C).

The superior performance of the ALBR vis-a-vis the BCBR may be attributed to a well-defined flow pattern in the ALBR that allows more effective light utilization by the diatom. In the BCBR, proper recirculation of cells is not possible since aeration only superimposes random motion with no net liquid movement – whereas some cells are exposed to high light intensity in close proximity of the illuminated column walls, those centrally positioned in the column are exposed to much lower light intensity causing ineffective photosynthesis and consequently low biomass growth. However, uneven fluid density in the riser and downcomer sections of the ALBR, induces a well-defined flow pattern – upward liquid movement in the riser and downward in the downcomer. Consequently diatoms in the riser, would, after lapse of a certain time, flow to the downcomer where light is directly incident, implying exposure to more uniform light density than in the BC. Furthermore, liquid movement in the ALR prevents cell accumulation at the bottom of the column (and an uneven cell density along the length of the column arising therefrom) by facilitating cell circulation even at high cell density. Cell accumulation at the bottom of the column may potentially cause starvation, death, and even culture contamination, thereby resulting in an overall reduced growth rate.

Sanchez-Miron et al. [12.36] undertook a comparative evaluation (mainly in terms of hydrodynamics and transport phenomena) of three air-agitated photobioreactors, viz., a bubble column, a split-cylinder or split-column ALR and a concentric draft-tube sparged ALR (Fig. 12.17). Their focus was on fractional gas holdup, liquid circulation velocity, and the overall gas–liquid oxygen mass transfer coefficient and the interdependence of these variables in regimes relevant to microalgal cultures. Comparative evaluation of reactor performance was presented for the culture of the photo-

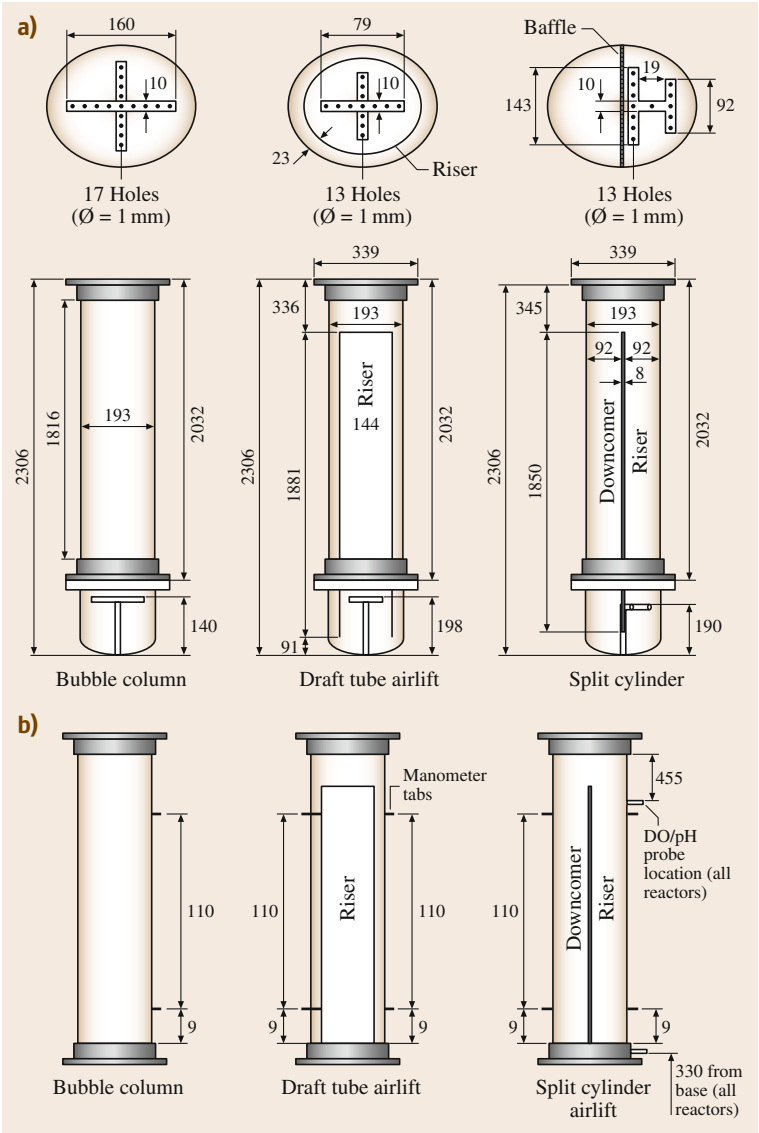

Fig. 12.17a,b Reactors: **(a)** vessel dimensions and air sparger details; **(b)** location of dissolved oxygen (DO) and pH electrodes. All dimensions in mm (after *Sanchez-Miron* et al. [12.36])

synthetic marine microalga *P. tricornutum*, a potential source of certain omega-3 polyunsaturated fatty acids of therapeutic value. Based on the findings of this study, it was noted that the performance of all three reactors were equivalent and that the results did not indicate a clear preference for any reactor – a maximum specific growth rate of 0.022 h^{-1} and a final algal biomass concentration of 4 kg m^{-3} was obtained for all the three reactors.

All the reactor vessels (diameter 0.193 m) were made of acrylic (3.3 mm thick) but for the lower 0.25 m sections, which were made of stainless steel. The ratio of the riser-to-downcomer cross-sectional area for the split cylinder ALBR and draft-tube ALBR were 1.0 and 1.24, respectively. The draft tube (I.D. 0.144 m) and the baffle were located at, respectively 0.091 m, and 0.096 m from the reactor bottom. The gas-free liquid level was about 2 m in all cases.

Merchuk et al. [12.37] considered three types of bench scale, pneumatically agitated photobioreactors for culturing the red microalga *Porphyridium* species – a BCBR, an ALBR, and a modified ALBR fitted with

helical flow promoters (ALBR + HFP). Now, in an earlier study *Merchuk* et al. [12.12] comparing BC and ALR-type photobioreactors for *Porphyridium* growth, it was concluded that the more ordered flow in the ALBR leads to the exposure of the growing cells to light and darkness in more homogenous cycles, resulting in the superior reactor performance.

The HFP is a static device consisting of several fins or baffles that causes fluid flow in a helical path along the downcomer. It effectively modifies the fluid flow path from a rectilinear trajectory along the axis to a helix. Although the HFP may be installed at any point along the riser or the downcomer, a much preferred location is the top of the downcomer – wherefrom a helical flow is generated in the downcomer, which becomes a swirl at the bottom and a corkscrew-like path in the riser. The helical fluid motion causes secondary flow which leads to an enhanced radial mixing, and thus more homogeneous distribution of light among liquid elements and suspended particles. This increases the likelihood of all fluid elements getting the same exposure to light. In this study, the HFPs were positioned at the upper rim of the downcomer. As the ALBRs were illuminated through the external walls, aeration from the bottom of the draft tube was preferred in order to minimize the quantity of bubbles in the downcomer, which would cause loss of efficiency due to light scattering. Installing the HFP at the downcomer inlet maximizes the fluid dynamic effects (i. e., secondary flow) in the photosynthesis zone of the reactor.

The reactors (I.D. 0.13 m, height 1.5 m) were made of flexible polyethylene sleeves with a conical bottom. For operation as an ALBR, an acrylic draft tube (external diameter 0.09 m, height 1.05 m) was inserted. For the ALBR + HFP the same draft tube was used but with the HFP installed. Selection of the draft tube diameter was based on the fluid residence time in the riser as time spent in the dark zone. The HFP comprises three fins at 45° from the axis, placed at the upper 0.05 m of the downcomer, with a width equal to the gap between draft tube and the external wall. Gas entered the reactors through a sparger installed 0.03 m above the bottom. The sparger was a ring of 0.05 m diameter made of a stainless steel tube of 0.005 m diameter, with 15 holes (diameters 0.001 m) equidistantly positioned on its upper face. Now, the gas flow rate to the reactor strongly influences the mixing of medium, the distribution of cells, their nutrient availability, and CO_2 absorption. It was observed for the ALR + HFP that the more ordered flow and the additional secondary circulation due to the HFP provide sufficient mixing and better cell distribution at a lower gas flow rate, without too many cells adhering to the reactor walls. Operability at lower gas flow rates leads to lower consumption of air and CO_2 resulting in lowered costs of air compression and CO_2, thereby improving the efficiency of CO_2 uptake for algal photosynthesis – the basis for superior performance of the ALR + HFP relative to the other reactors considered.

Rorrer and *Cheney* [12.38] have compared four major photobioreactor configurations for microplantlet suspension cultures of photolithotrophic marine macroalgae *A. subulata*, viz., bubble column, airlift (internal draft tube), externally illuminated stirred tank and tubular recycle (helical array) photobioreactors in both batch and medium perfusion modes of macronutrient delivery. Of these four reactors considered, the ST-PBR and tubular recycle PBR have been used earlier by *Rorrer* and *Zhi* [12.14] and *Rorrer* and *Mullikin* [12.13], respectively, and have already been discussed at length in Sect. 12.2. These four PBRs were compared on four major parameters, viz., mixing and biomass suspension, aeration, and gas exchange, light transfer and potential for shear damage. Both BC and ALR-type PBRs have low shear damage potential and very good aeration capabilities, and while mixing and light transfer are rated as adequate for BC, they range from good to very good for ALR. The stirred tank PBR, on the other hand, has high shear damage potential and poor light transfer facilities but with regard to mixing and aeration it is rated as excellent. Finally, for the tubular recycle PBR, while light transfer is excellent and aeration adequate, mixing and shear damage are problem areas. Certain essential common features of these PBR systems are worth noting: the bioreactor control volume being externally illuminated by artificial light source(s), transparency of at least a part of the bioreactor vessel is necessary – this requires the reactor to be made out of glass/polycarbonate for BC/ALR and translucent silicone tubing for tubular PBR; also, the nonfriable nature of the macroalgal cell and tissue precludes continuous culture, because dilution of the culture suspension by continuous addition of fresh medium will dilute out these cell clumps. It may be noted that in microplantlet tissue cultures, since the biomass is compacted into ball-like nonfriable multicellular tissue and not dispersed in the liquid medium as single cells, light attenuation through the culture suspension is low relative to microalgal suspension cultures at the same cell mass density. Again, microplantlets are easily suspended but also easily separated from the culture broth thus facilitating biomass harvesting.

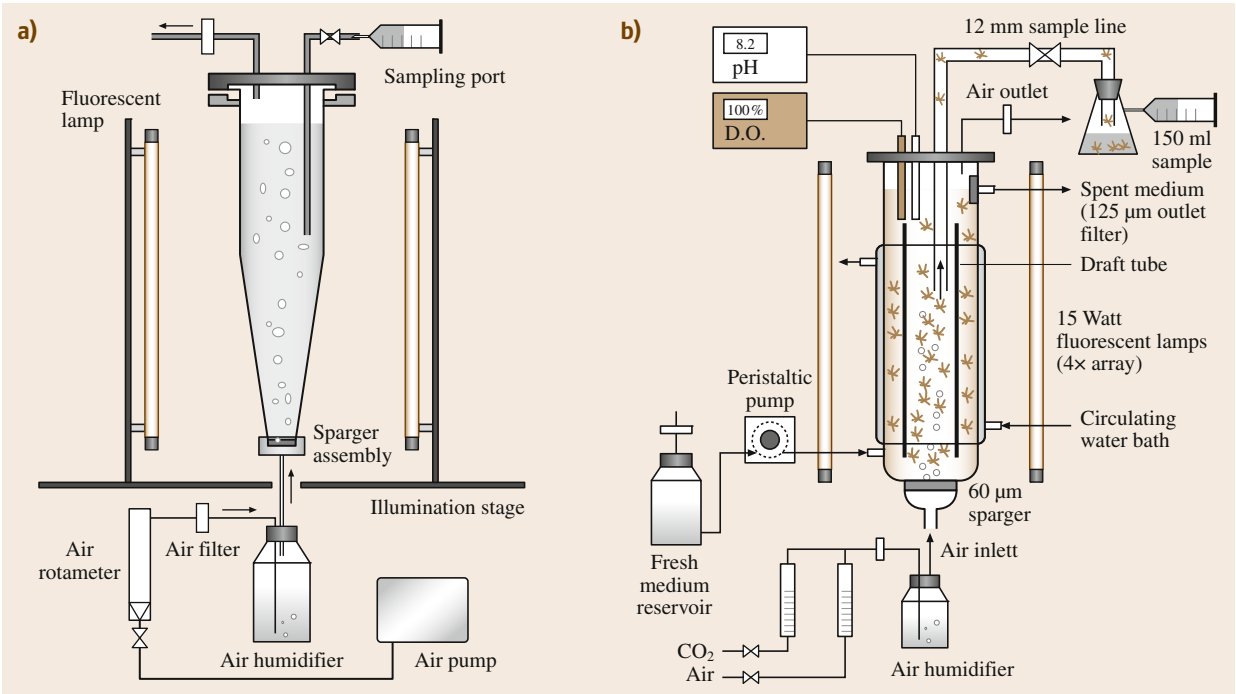

Fig. 12.18a,b Representative bench-scale bubble-column and airlift photobioreactors for macroalgal cell and tissue culture: **(a)** 250 mL bubble-column photobioreactor and **(b)** 3.0 L airlift photobioreactor equipped for continuous medium perfusion (after *Rorrer* and *Chenny* [12.38])

The PBRs discussed (Fig. 12.18), are designed to provide mixing, illumination, gas exchange, and dissolved macronutrients to the macroalgal suspension culture under controlled conditions. In a BCBR, the culture is mixed and suspended by the rising air bubbles, whereas in an ALBR biomass suspension is improved by a *draft tube* (of diameter d_i) which fits within a cylindrical vessel of width d ($d > d_i$). The draft tube provides a defined liquid circulation pattern where the suspension ascends within the draft tube (riser) and descends outside of the draft tube (downcomer). Draft tube ALBRs also provide enhanced light transfer to the culture broth as it moves down the downcomer because the suspension remains in close proximity to the illuminated reactor wall and is confined within a short light path ($d - d_i$). Aerated stirred tank bioreactors improve mixing and biomass suspension. Cell-lift and marine-blade impellers provide axial circulation patterns which help to suspend macroalgal cell clumps and tissues. Moreover, the rotating impeller breaks up and disperses the air bubbles to improve interphase mass transfer for CO_2 delivery. In general, cell cultures derived from terrestrial plants are prone to damage by hydrodynamic shear forces generated by the stirred tank impeller rotation. However, the nonfriable cell and tissue cultures of marine macroalgal plants are not susceptible to shear damage in stirred tank photobioreactors. Light delivery is an important design parameter for PBRs made for macroalgal cell and tissue suspension culture, where growth becomes light saturated at relatively low light intensities compared to microalgae because in the rocky, intertidal, benthic ecological niche microalgae are exposed to much low light intensity. Therefore, as long as the light path through the culture is short and the reactor vessel is transparent, external illumination of the bioreactor with cool-white fluorescent lamps is generally adequate for bench-scale or pilot-scale reactors for macroalgal culture.

For macroalgal culture suspensions that can be pumped, the tubular recycle photobioreactor (TR-PBR) offers excellent light transfer and low light attenuation, because the path length for light transfer is reduced down to the diameter of the coiled tubing, and the light source is placed within the center of the coil. TR-PBR was found to successfully cultivate *L. saccharina* gametophyte cell clump suspensions. It is not suitable for

microplantlet cultures, however since their large tissue size makes it difficult for them to pass through the tubing without settling. Continuous bubbling aeration of the culture with CO_2 in air simultaneously serves four purposes, viz. (1) transfer of CO_2 to the culture; (2) maintenance of the dissolved inorganic carbon level in the culture medium; (3) pH control; and (4) removal of dissolved O_2 produced by photosynthesis.

Although macroalgal suspension cultures grow rather slowly (with specific growth rates less than 0.20 day^{-1}) and k_La values in aerated PBRs are high, it is challenging to supply CO_2 at flow rates that can avoid the CO_2 limited growth rate condition at high cell density unless CO_2 is added to the aeration gas. This requires CO_2 to be present in the aeration gas at 10 times its normal ambient concentration. If the culture suspension is continuously supplied with light and CO_2, then the cumulative biomass production will be limited ultimately by available macronutrients dissolved in the liquid medium, mainly N in the form of nitrate, and P in the form of phosphate. Macronutrient delivery depends on the mode of cultivation. In batch mode, macronutrients are initially provided in the growth medium at culture inoculation. Nitrate and phosphate concentrations in the medium decrease with time until one (or both) becomes zero. At this point, the *limiting nutrient* is exhausted, and cell growth stops even if light and CO_2 are still being continuously supplied. In perfusion cultures, liquid medium containing dissolved macronutrients is continuously supplied to the bioreactor culture suspension. The spent medium leaves the bioreactor but the biomass is retained inside. Under these conditions, cumulative biomass production continues, but its rate is ultimately limited by the rate of CO_2 delivery, or the attenuation of light through the dense culture suspension. The final limit to biomass production is space. If the tissues completely fill up the bioreactor control volume, then biomass production will stop even in the presence of an infinite supply of nutrients (light, CO_2, and macronutrients).

12.4 Membrane Bioreactors (MBR)

An MBR is basically a membrane filtration unit (membranes ranging between microfiltration, and ultrafiltration) coupled or integrated with a suspended phase bioreactor (Table 12.5). Depending on whether the membrane module is located inside or outside the bioreactor, MBRs are categorized as internal (i. e., *submerged*-type) or external (i. e., *cross-flow* type). In a cross-flow MBR medium is recirculated between the membrane module and the BR by pumping it through the membranes. In a submerged MBR, the membrane filtration unit is immersed inside the culture medium in the BR (or sometimes in a separate tank connected to the BR). Some common membrane configurations employed in MBRs are:

i) Hollow fiber
ii) Spirally wound
iii) Plate-and-frame (i. e., flat sheet)
iv) Tubular.

Insofar as wastewater treatment applications are concerned, MBRs provide a host of advantages compared to traditional activated sludge processes that include the total separation of hydraulic retention time (HRT) and solids retention time (SRT), high efficiency of pollutant removal and no requirement of a secondary clarification unit.

Zamalloa et al. [12.39] employed an anaerobic membrane bioreactor (AnMBR) for biomethanation of the marine microalgae *P. tricornutum*. In fact, this report was claimed as the pioneering study to demonstrate the feasibility of an AnMBR for digestion of algal biomass. In conventional, continuously stirred anaerobic digesters, where the SRT is identical to the HRT, a high SRT required for effective destruction of volatile solids necessitates a large, often prohibitively high reactor volume. Now, in an AnMBR, the solids are separated from the sludge suspensions by a membrane so that biomass wasting rates are low – therefore, an AnMBR routinely allows operation at SRTs as high as 50 d or even higher. This facilitates the growth of slow-growing microorganisms, e.g., methanogens, and also increases the fraction of fermented organic matter. The AnMBR employed in this study consists of (a) a reactor (working volume 8 L) made of acrylic panels and (b) a microfiltration membrane module arranged in parallel. Two peristaltic pumps were used to feed influent into the anaerobic reactor and separately withdraw permeate from there. For mixing and membrane scouring to control cake formation, biogas recirculation was carried out using a diaphragm gas pump through a diffuser located just below the membrane module. Biogas production was measured

Table 12.5 Membrane bioreactors (MBR)

Sl	Bioreactor	Marine strain and bioprocess	Reference
1	Anaerobic membrane biorector (AnMBR)	Biomethanation of microalgae *P. tricornutum*	*Zamalloa* et al. [12.39]
2	AnMBR	Biohydrogen production by bacterial consortia	*Oh* et al. [12.40]
3	Ion-exchange MBR (IEMBR)	Nitrate removal from saline water by bacterial consortium	*Matos* et al. [12.41]
4	Submerged-MBR (sMBR)	Harvesting anaerobic methanotrophic archaea (ANME)	*Meulepas* et al. [12.42]

by means of a gas meter. Transmembrane pressure (TMP) was measured with an analogical gauge installed between the membrane module and the permeate pump.

Oh et al. [12.40] studied biohydrogen production by bacterial consortia dominated by marine (viz., *Clostridiaceae*) and nonmarine (viz., *Flexibacteraceae*) bacterial families in an anaerobic MBR (AnMBR) – basically a cross-flow membrane coupled to a chemostat. According to the authors, this was the pioneering study on biohydrogen production in an MBR. The facilities/accessories of the reactor (Fig. 12.19) (volume 2 L, working volume 1 L) include constant stirring, flow level controller, pH controller, three peristaltic pumps (feed, waste, and recirculation – bioreactor side), a centrifugal pump (recirculation – membrane side), a membrane housing, liquid flow meter, three pressure gauges, and a backpulse unit with a control cabinet. The feed tank was pressurized using nitrogen gas. The recycle loop around the membrane module was operated at a flow rate of 378 L h^{-1} producing a membrane cross-flow velocity of 2.8 m s^{-1}. The recycle flow rate from the reactor to the high recycle loop was set at 51 mL min^{-1}. The working volume of the reactor was maintained by a level probe connected to the feed pump. To maintain the SRT, solids were purged from the MBR intermittently using a timer and the peristaltic pump, and medium (without glucose) was simultaneously fed into the reactor at the same rate to maintain a constant liquid level. Three alumina membranes of various pore sizes were used. Pressures were measured at the inlet, outlet, and permeate side of the membrane to determine the TMP. A constant permeate flow was obtained by adjusting the peristaltic pump on the permeate side of the membrane reactor. To limit membrane fouling, intermittent backpulsing (every 10–30 s) was done using a piston that injected nitrogen gas into the permeate side of the membrane module for a very short period of time (0.5–1 s). This backpressure caused a reversal in flow through the membrane thereby removing solids off the membrane surface.

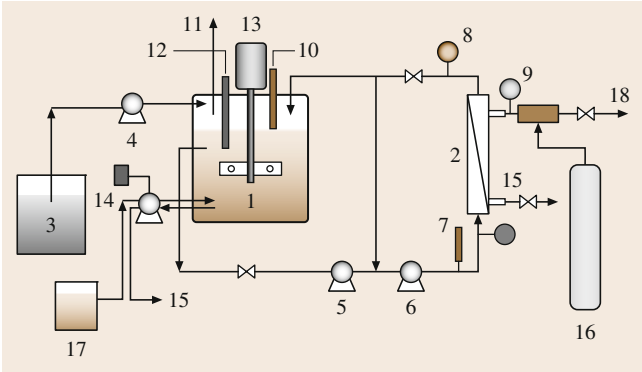

Fig. 12.19 Schematic diagram of the membrane bioreactor for hydrogen production. 1 – anaerobic reactor; 2 – cross-flow membrane; 3 – influent purged with nitrogen; 4 – feed pump; 5 – recirculation pump; 6 – high recirculation pump; 7 – flow meter; 8 – manometer; 9 – backpulsing; 10 – level controller; 11 – gas monitor; 12 – pH-controller; 13 – motor; 14 – timer; 15 – waste; 16 – nitrogen gas; 17 – medium w/o organics; 18 – effluent (after *Oh* et al. [12.40])

A common problem in biohydrogen production is that some of the bacteria in the consortium may consume hydrogen thereby lowering the overall hydrogen productivity, e.g., methanogens that convert H_2 to methane (which has less than half of the specific energy content of H_2). Of the several strategies to control or arrest the growth of methanogens, which are typically slow growing, the one that was deemed most effective was to maintain short residence times in continuous-flow reactors. However, this, in turn, reduces the efficiency of substrate utilization by hydrogen-producing bacteria and thereby that of the overall process.

Matos et al. [12.41] employed the ion exchange membrane bioreactor (IEMBR) for nitrate removal from highly saline water in a closed marine system, viz., a marine aquarium (oceanarium). Ammonia released by catabolism of reduced nitrogen compounds by aquatic animals is converted by nitrifying organisms into nitrate, the latter accumulating in a closed system like an aquarium up to levels potentially toxic for many marine species (which are generally much more sensitive to nitrate than freshwater ones) as well

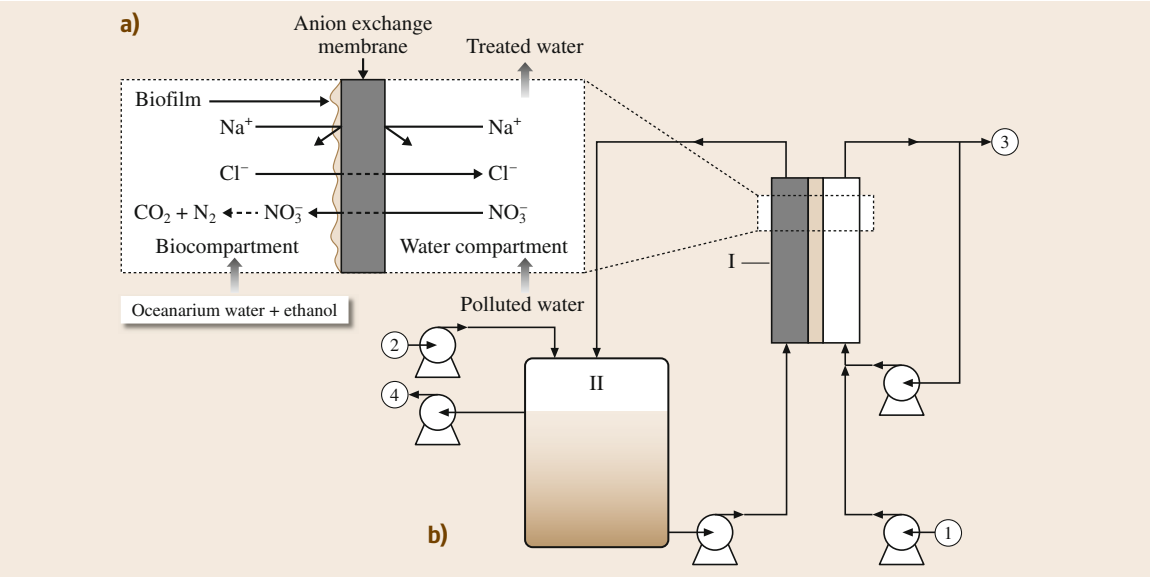

Fig. 12.20 **(a)** Schematic diagram of nitrate transport and bioreduction in the IEMB. **(b)** IEMB setup: 1 – feed water; 2 – biofeed; 3 – treated water; 4 – biocompartment effluent; aI, membrane module with two compartments separated by an anion-exchange membrane; bII – bioreactor vessel (after *Matos* et al. [12.41])

as posing problems related to its discharge into the external environment. The IEMBR concept is based on the integration of membrane separation technology with biological denitrification – nitrate is transported through a dense, nonporous anion-exchange membrane and subsequently converted into molecular nitrogen by a microbial consortium in a separate *biocompartment* isolated from the water stream (by the nonporous membrane *barrier*). This isolation allows for independent adjustment of the HRT in the biocompartment without affecting the production rate of the treated water and prevents the potential risk of secondary contamination of the treated water by excess carbon source (ethanol in this study). The transport across the membrane follows the principles of Donnan dialysis and may be increased by adding a suitable counter-ion (viz., chloride) to the biocompartment. An IEMBR is thus based on biological wastewater treatment avoiding secondary contamination of the treated water by complete isolation of the microbial culture through use of a membrane while preserving the water composition with respect to other ions.

The IEMBR (Fig. 12.20) consists of a membrane module with two identical rectangular channels, separated by a mono-anion permselective membrane (working area 39 cm^2). One channel was connected to an external loop where the aqueous phase was recirculated (at a flowrate of 97.2 $L\,h^{-1}$, $N_{Re} = 3000$). This *water compartment* was continuously fed with oceanarium water containing high levels of nitrate. The other module channel was connected to a stirred vessel through another recirculation loop ($N_{Re} = 3000$). This vessel, inoculated with 100 mL of the enriched microbial culture, was continuously fed (at a flow rate of 0.0048 $L\,h^{-1}$) with nitrate-free saline water from the oceanarium to which ethanol was added as a carbon source. This *biocompartment* was operated at a HRT of 5 d. To lower the volume of effluent produced in the biocompartment, a relatively high HRT was chosen. Lower HRTs could be set without affecting the nitrate reduction rates, which would, however, increase the volume of liquid waste discharged, which is undesirable.

Vis-a-vis other membrane treatment technologies for wastewater, e.g., reverse osmosis (RO), it was noted that the IEMBR provides for conversion of nitrate into harmless N_2 whereas in RO-based processes, the nitrate removed accumulates in a brine stream which usually requires further treatment. Again, in the IEMBR, the ion balance of the treated water is unaffected (other than nitrate) but in RO, demineralized water is obtained and all required salts have to be added to the treated water for it to be reused.

Meulepas et al. [12.42] used a novel, well-mixed, ambient-pressure, submerged-membrane bioreactor

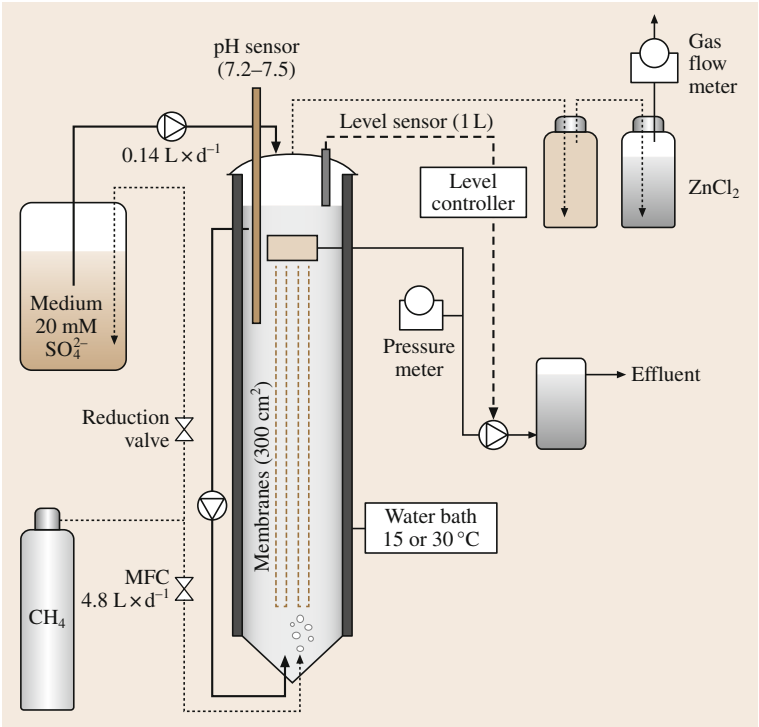

Fig. 12.21 Schematic overview of submerged-membrane bioreactor used for the enrichment experiments (after *Meulepas* et al. [12.42])

(sMBR) for enrichment of anaerobic methanotrophic (ANME) archaea that mediate anaerobic oxidation of methane (AOM) in marine sediments, which is coupled to sulfate reduction (SR) mediated by sulfate-reducing bacteria (SRB) that exist in consortia with the ANME. The sMBR (shown in Fig. 12.21) consists of a cylindrical glass vessel (total volume: 2.0 L; covered with opaque plastic to prevent phototrophic conversions), equipped with sampling ports for the headspace and the culture suspension, and connected to diaphragm metering pumps that continuously feed medium to the reactor. Each reactor was equipped with 4 polysulfone membranes, through which the effluent was extracted by means of a peristaltic pump. The membrane pore size guaranteed complete cell retention. Transmembrane pressure was monitored using a pressure sensor. The effluent pump was controlled by a level switch, which maintained the working liquid volume at 50% of the total volume (1.0 L). Each reactor was equipped with a water-jacket, through which water, cooled or heated in a thermostatic water bath, was recirculated to maintain a constant reactor temperature. CH_4 gas (purity 99.9995%), was supplied through a gas sparger at the reactor bottom to (a) aid the growth of the microorganisms, (b) to promote reactor mixing, (c) to strip off the sulfide, and (d) to prevent membrane fouling. The influent CH_4 flow was measured and controlled by a thermal mass flow controller. The exit gas from the reactor contained hydrogen sulfide (H_2S) and carbon dioxide (CO_2) stripped from the liquid, it was passed through two gas cleaning bottles, the first meant for collecting liquid entrained in the reactor exit gas, whereas the second (filled with a 0.5 M zinc chloride solution), intended to selectively retain H_2S was placed on a magnetic stirrer. The reactor suspension was recirculated from top to bottom to provide additional mixing and to suspend the sediment/biomass. Notably, the reactors in this study were not operated at *niche-mimicking* conditions but rather at conditions that supported high conversion rates. It was found that the AOM rate increased exponentially and a very high enrichment 1.0 mmol (g VSS d)$^{-1}$ was attained – the sMBR could thus be deemed an excellent system for growth of microorganisms mediating AOM-coupled-SR. In contrast to their marine ecological niche, the microorganisms grown in the sMBRs were continuously exposed to high shear forces due to liquid recirculation and gas sparging, and further, were suspended in the liquid phase. However, these factors did not prevent the observed exponential increase in AOM rate.

12.5 Immobilized-Cell Bioreactors

An immobilized cell may be defined as one that, by natural or artificial means is constrained in space such that it cannot independently be in motion relative to cells in its immediate vicinity. The common immobilization techniques are covalent coupling, affinity immobilization, adsorption, confinement in liquid–liquid emulsion, retention by semipermeable membranes and entrapment, of which the last named is the most frequently adopted technique for all immobilization. In immobilization by entrapment, cells are confined in a three-dimensional gel lattice made of either synthetic (e.g., acrylic, polyurethane, polyvinyl etc.) or natural polymer (e.g., collagen, agar, agarose, cellulose, alginate, carrageenan etc.). Substrate/nutrients and products can diffuse through the lattice to/from the cells. The microorganisms are entrapped onto the surfaces of the gel *beads* or *carrier particles* which are normally cross-linked (to obtain a stable immobilization matrix) by polymerization or by other means, e.g., carrageenan droplets are typically cross-linked with K^+.

The most common configuration of an immobilized cell bioreactor (Table 12.6) is the so-called PBBR, where cells immobilized on *carrier particles* or *beads* are *packed* into a matrix or bed that fills the reactor, usually a cylindrical column, and flow of nutrients/gases/products etc. usually occurs longitudinally through the beds. An alternative to cell entrapment is immobilization of cells in semipermeable membranes, which confine and thereby shield the enclosed microorganisms while facilitating transport of soluble matter (nutrients/products) to and from the cells. This technology is employed in HFBR (considered in the following section) where the growing microbial cells are constrained to one side of porous fiber strands and media containing nutrients and products on the other. However, pressure buildup due to excessive accumulation of biomass could lead to membrane rupture/fiber leakage, therefore cell growth in such membranes/fiber immobilized systems must be carefully controlled.

Table 12.6 Immobilized-cell bioreactors

Sl	Bioreactor	Marine strain and bioprocess	Reference

11	Immobilized-cell tubular PBR	Continuous synthesis of the blue-green pigment marennin by the diatom *H. ostrearia* immobilized in an agar gel layer	*Lebeau* et al. [12.53]
12	Free-cell and immobilized cell membrane photobioreactor (M-PBR)	Production of pigments marennin by the diatom *H. ostrearia*	*Rossignol* et al. [12.54]

The nonheterocystous marine cyanobacterium *Phormidium valderianum* (which is known to produce hydrogen under argon atmosphere) was immobilized in combination with two other nonmarine cells (viz., the extreme halophile *Halobacterium halobium* and salt tolerant *Escherichia coli*) for stable, long-term biohydrogen photo-evolution under an alternating light/dark illumination cycle (6 h on/18 h off) in a PBBR by *Patel* and *Madamwar* [12.44], as well as by *Bagai* and *Madamwar* [12.43].

The former workers used Ca-alginate or agar-agar as the immobilization matrix for cell entrapment in a 50 mL working volume PBBR (basically a packed column) continuously fed with N-free growth medium – comparatively better results were obtained with alginate. The problem of cell and enzyme leakage from alginate beads (leading to loss of H_2 production) was overcome by using glutaraldehyde as a cross-linking agent. H_2 photoevolution rate increased with medium feed rate up to a maximum, and then declined markedly. Stable, long-term H_2 production for 11 d was demonstrated.

Using the same combination of microorganisms, in a similar PBBR, but with a different immobilization matrix, viz., PVA cross-linked with glutaraldehyde, *Bagai* and *Madamwar* [12.43] demonstrated continued H_2 production for over 60 d. In both these studies for photohydrogen production, compared with a free-cell system, the immobilized system was much more productive, stable, and long lasting.

Sabu et al. [12.46] and *Kumar* and *Chandrasekaran* [12.45] all reported the production of the therapeutically and industrially important enzyme L-glutaminase by Ca-alginate immobilized marine microorganisms in glass-column PBBRs, but whereas the former employed the fungus *Beauveria bassiana* the latter used the bacterium *Pseudomonas* for that purpose. Although the PBBRs used in these studies differed in dimensions (i. e., column height and diameter) with the one used by *Kumar* and *Chandrasekaran* [12.45] being larger (height 45 cm and internal diameter 3.6 cm), the basic principle of reactor construction was the same – immobilized viable cell beads were aseptically packed into the column with a perforated Teflon disk placed at the top of the packing to prevent bed expansion during operation.

Sabu et al. [12.46] pumped the medium from the bottom of the packed column and collected the effluent from the top. This was, however, reversed by *Kumar* and *Chandrasekaran* [12.45]. The inlet and outlet flow rates were kept equal to maintain a constant liquid level at just above the bed level. Now *B. bassiana* being aerobic with strong aeration dependence, air was introduced through a sparger at the bottom of the packed column after passing through a bacterial filter. Remarkably, *Sabu* et al. [12.46], noted that the maximum enzyme production rate was observed in the absence of forced aeration, and any increase in aeration rate caused a decrease in enzyme productivity. In order to explain this finding, the authors posited that with external aeration, air bubbles fill the void spaces of the packing beads, thus reducing the contact between the cell-laden beads and the liquid medium. They also found that enzyme productivity increased with increasing bed height/decreasing flow rate, leading them to conclude that increase in residence time either with increase in bed height or with decrease in flow rate, in turn increases the contact time between the immobilized beads and the medium, thereby causing an increase in productivity.

Kumar and *Chandrasekaran* [12.45] reported that enzyme production declined with an increase in dilution rate, irrespective of the substrate concentration used. Again, at all dilution rates examined, enzyme yield increased with increase in substrate concentration. It was noted that their continuous-flow PBBR system could be operated for 120 h without any decline in enzyme productivity.

Kumar et al. [12.47] developed a nitrifying PBBR immobilized with an indigenous NBC (nitrifying bacterial consortium) (comprising predominantly marine species, e.g., *Nitrosospira*) for rapid nitrification in brackish water and marine hatchery systems. They examined nitrification performances of the PBBR integrated into a recirculating aquaculture system (RAS) viz., a *Penaeus monodon* (a marine crustacean – shrimp) recirculating maturation system. The RAS (Fig. 12.22) comprises a shrimp maturation tank (MT), an overhead tank (OHT), Six PBBRs (designated as R1 through R6) and a collection tank (CT). Fluid from the MT was pumped into the OHT from where it flowed through the reactors (R1–R6) connected serially by gravitation and finally collected in the CT, from where the treated water was recirculated back to the MT. Pumping was controlled by an automated water level controller installed in the OHT. A regulator valve was connected to the OHT to maintain the flow through the reactors.

All six PBBRs (R1–R6) (working volume 20 L each) were constructed identically, consisting of a fiberglass shell with a perforated Perspex plate carrying nine equidistantly fixed polyvinylchloride (PVC) pipes (air-

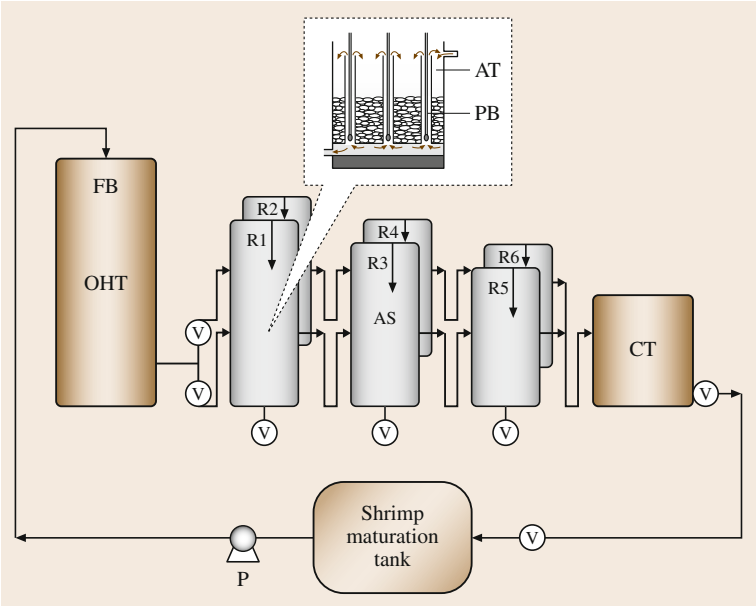

Fig. 12.22 Packed bed bioreactor connected to a shrimp maturation system. AS – aeration supply; AT – aeration tube; CT – collecting tank; FB – filter bags; OHT – overhead tank; PB – polystyrene beads; P – pump; R1–R6 – reactor R1–R6; V – valves (after *Kumar* et al. [12.47])

lift pumps) installed at the base of the reactors. On passing air, the area filled with the support medium surrounding each airlift pump works as an aeration cell. The baseplate is at an elevated location (5 cm) from the bottom, supported by PVC pipes (length 5 cm, diameter 3 cm). An inlet pipe is fixed at a water discharge height of 35 cm from the reactor base. The outflow pipe, on emerging from the base of the reactor, bends upward at a water discharge height of 35 cm from the base to the next reactor. Polystyrene beads (diameter 5 mm, surface area 0.785 cm^2) with spikes on the surface were used as the immobilization matrix – each reactor was packed with 60 000 beads. The reactors were equipped with a valve for periodical backwashing, located at the bottom. A bag filter placed in the OHT was used to filter debris from the incoming water from the MT. Significant nitrification was observed with the immobilized PBBRs integrated into the marine RAS for shrimp (*P. monodon*) maturation, over a wide range of substrate concentrations and flow rates examined. Nitrification was effective even after 70 d of operation as evident from the consistently reducing levels of total ammoniacal nitrogen (TAN).

Kumar et al. [12.48] employed two serially connected activated immobilized-cell PBBRs – one an ammonia oxidizing bioreactor (AOB) activated by ammonia-oxidizing bacterial consortia immobilized on polystyrene (PS) beads and the other a nitrite-oxidizing bioreactor (NOB) activated by nitrite-oxidizing bacteria immobilized on low-density polyethylene (LDPE), for rapid nitrification in a RAS – a brackish water hatchery system for larva production of the marine crustacean *Macrobrachium rosenbergii* (Fig. 12.23). Upon integration of the activated PBBRs with the hatchery system (thereby enabling it to operate in closed recirculating mode), ammonia removal was obtained up to BDL (beyond detectable limit) levels and consequently a substantially higher percentage survival of larvae was

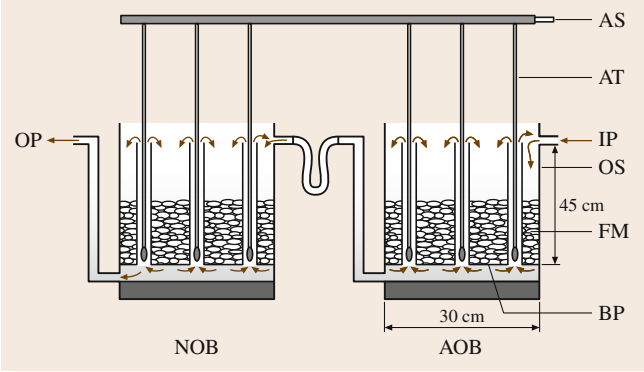

Fig. 12.23 Cross-sectional view of the bioreactors connected serially (AOB – ammonia-oxidizing bioreactor, NOB – nitrite-oxidizing bioreactor, BP – base plate, FM – filter media, OS – outer shell, IP – inlet pipe, OP – outlet pipe, AT – aeration tubes, AS – air supply) (after *Kumar* et al. [12.48])

observed. The PBBR system was energy optimized for continuous operation by limiting energy input to a single stage pumping of water and aeration to the aeration cells.

Both the PBBRs have the same configuration and are identical to the PBBRs used in *Kumar* et al. [12.47], as are the PS beads used for immobilization. The AOB and NOB reactors were connected in series. Water flowed from a large OHT into the AOB and therefrom into the NOB by gravity. The outflow from the NOB flows into a CT and from there into the larval rearing tank (LRT). From the LRT, water is pumped out into the OHT. The major components of the nitrifying bacterial consortia (NBC) were the marine genus, viz., *Nitrosococcus* and *Nitrobacter*. A noteworthy operational flexibility of the PBBRs was that they were interchangeable between prawn (salinity $15\,g\,L^{-1}$) and shrimp (salinity $30\,g\,L^{-1}$) larval rearing systems simply by changing the NBC based on salinity.

Silapakul et al. [12.49] examined a novel packed bed external loop airlift bioreactor (PBEL-ALBR) (volume 60 L) as an integrated system with simultaneous nitrification/denitrification for treatment of marine aquaculture wastewater containing ammonia and nitrate compounds. The PBEL-ALBR consisted of both aeration and nonaeration zones in the same unit, that served as nitrification and denitrification compartments (where ammonia and nitrate were biodegraded, respectively), which were packed with plastic bioballs to increase the surface area for microbial attachment, on the surface of which nitrifying and denitrifying microorganisms were immobilized.

The reactor (Fig. 12.24) consists of one aerated column (riser) interconnected by conduits with two unaerated columns (downcomer) – the cross-sectional area of the downcomers being almost 10 times larger than the riser to ensure adequate retention time for denitrification which is known to require $\approx 5-10$ times longer reaction time than nitrification. The aerated and unaerated columns were packed with 200 and 2000 bioballs (per column), respectively. A porous gas sparger for air dispersion was located at the bottom of the aerated column. The airflow rate was determined as a minimum that could induce liquid circulation between the aerated and unaerated sections. The recirculation of water was driven from the aerated riser where water moved up as aeration was provided and down through the unaerated downcomer. In the riser, nitrifying bacteria fed on wastewater containing high dissolved oxygen, oxidizing ammonia to nitrate. The low dissolved oxygen effluent from the riser flowed through the downcomer where denitrifying bacteria removed the nitrate. The authors noted that no nitrite/nitrate accumulation occurred in any experiment, indicating rapid and effective denitrification. Overall, the reactor performance was satisfactory and comparable with other treatment systems, however, where the PBEL-ALBR stands out is in providing nitrification and denitrification in a single setup without requiring a two-reactors-in-series cascade.

Seo et al. [12.50] examined the nitrification performance of an NBC (comprising mainly *Nitrosomonas* species) immobilized in boric acid treated PVA beads, for a marine RAS, by employing a continuous immobilized-cell ALBR (volume 45 L) for acclimation of the NBC from activated sludge and estimation of ammonia removal rate. In addition, four three-phase, completely mixed, fluidized bed-type bioreactors (FBBR) (volume 2.5 L each) were also employed for acclimation of the immobilized nitrifiers from freshwater to seawater system, with increasing salt concentration. Immobilization in support gel is an effective technique for maintaining high cell density and preventing washout of slow-growing autotrophic nitrifiers (ATN) under a low water temperature or high water flow rates. Although ATNs are sensitive to low temperatures, immobilization (a) improves tolerance to low temperatures and also, (b) provides protection against various toxic agents. In the operational range of values for the HRT, an optimum HRT was found for the marine nitrification process at which the highest ammonia removal rate was reached.

The four reactors were used to determine nitrification activity at four different salt concentrations. Each FBBR consisted of two separate compartments – one for beads settling and the other for airlift of the beads. Air was supplied through acrylic pipes (0.1 vvm). Influent NH_3 concentration was maintained at $10\,mg\,L^{-1}$. Nitrification activity decreased during the immobilization process due to centrifugation, transportation by pump, shear stress arising out of stirring, toxicity from the immobilization support material, and low pH of the boric acid solution. However, nitrification activity gradually recovered with operating time. It was observed that, nitrification activity of recovered nitrifier beads was higher than that of free nitrifiers due to high ammonia loading.

Polysaccharide-based gels and reticulate foams are usually considered as the preferred immobilization matrices for photosynthetic cell systems. Although five major immobilization techniques (viz., entrapment, microencapsulation, covalent coupling, aggregated cells, and adsorption) are in vogue, for growth of photosyn-

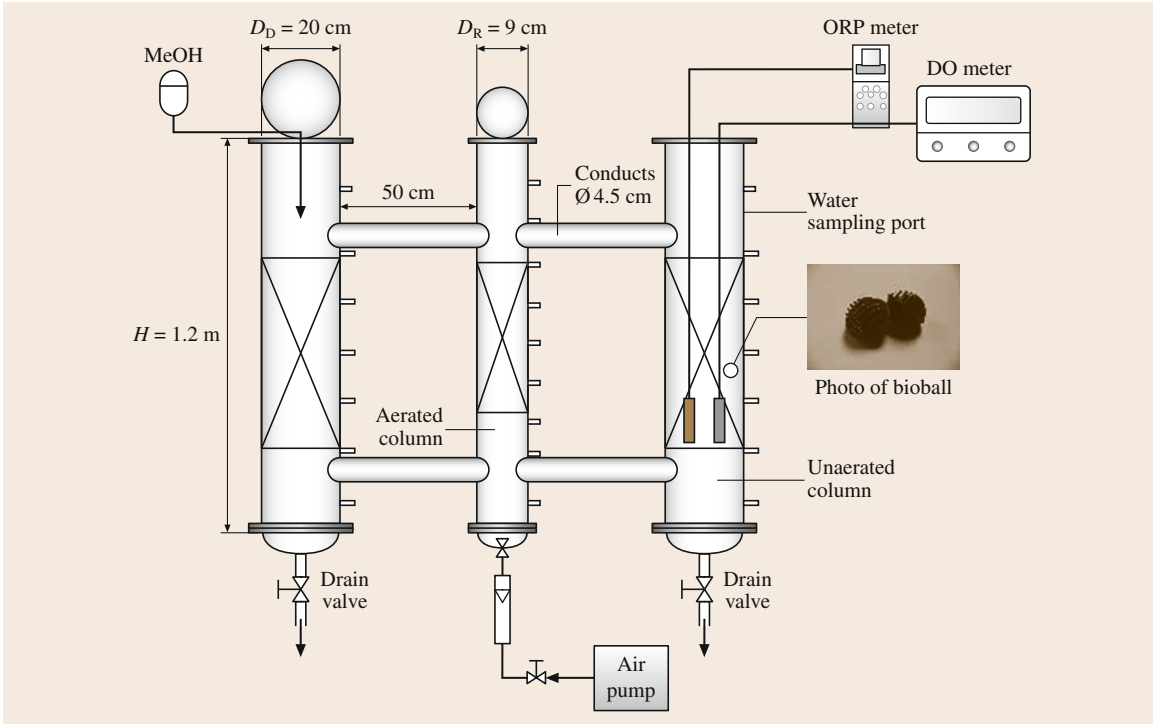

Fig. 12.24 Experimental setup (after *Silapakul* et al. [12.49])

thetic cyanobacteria in foam pieces, immobilization is often carried out by adsorption of cells on the foam surface in addition to entrapment in foam cavities. A continuous-flow packed bed photobioreactor (PB-PBR) was employed by *Garbisu* et al. [12.51] to study nitrate removal from water by cells of the non-N_2-fixing, filamentous, thermophilic cyanobacterium *Phormidium laminosum* immobilized in (a) polyurethane (PU) foams either by (i) absorption, or by (ii) entrapment in the PU prepolymer followed by polymerization, as well as in (b) polyvinyl (PV) foams by adsorption. Although entrapment repeatedly caused toxicity problems leading to rapid cell death, cells could be effectively immobilized by adsorption onto PU/PV foams and maintained their photosynthetic electron transport activities for at least 7 weeks. *P. laminosum* being thermophilic grows at 45 °C, a temperature too high for most other contaminating species, and further, has the ability to utilize either nitrate, nitrite or ammonium as the sole N-source – thus affording great flexibility and efficiency in the water treatment process. It was demonstrated in this study that *P. laminosum* immobilized on polymer foams is of potential value for biological nitrate removal (BNR) from water in a continuous-flow packed bed column PBR.

Urrutia et al. [12.52] obtained almost similar results (similar to *Garbisu* et al. [12.51]) in investigating BNR from water in a continuous packed bed column PBR with immobilized cells, but employing the green, mesophilic, unicellular, chlorophycean microalga *Scenedesmus obliquus*. Cells were immobilized by (a) entrapment, using urethane prepolymer as well as by (b) adsorption in preformed PU/PV foams, the latter deemed more convenient and effective, particularly when cells were subjected to nitrogen starvation, which also caused substantial increase in N uptake rate of immobilized cells. The study established the effectiveness of *S. obliquus* cells immobilized on hydrophilic polymeric foams grown in packed column photobioreactors, in N removal from water. Notably, polymeric foam immobilization has the particular advantage that at any point, after deimmobilizing the cells by simply squeezing the foam, it can be recycled and reused for further cell immobilization almost indefinitely.

Lebeau et al. [12.53] reported the continuous synthesis of the blue-green pigment marennine (with potential anticancer applications) by the marine diatom

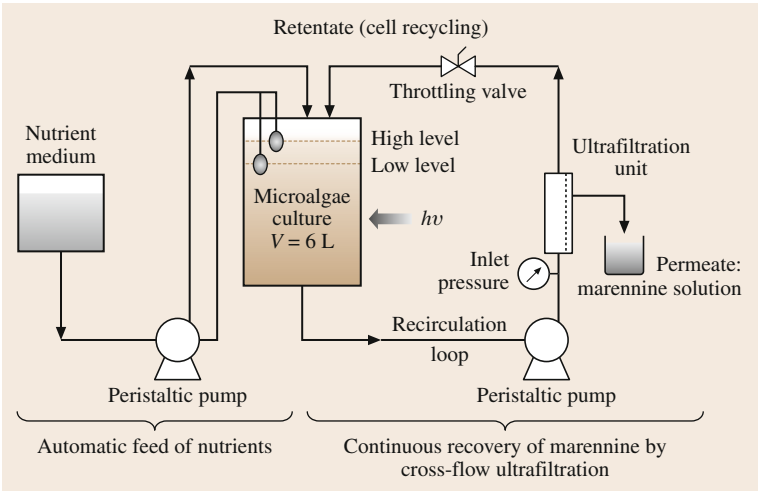

Fig. 12.25 Schematic of the free-cell M-PBR (after *Rossignol* et al. [12.54])

Haslea ostrearia in an immobilized-cell tubular membrane PBR (with internal illumination by optical fiber), described by *Rossignol* et al. [12.54]. Now, in its marine ecological niche, as the diatom migrates from the planktonic to the benthic phase, the number of pigmented cells increase, becoming maximum in the benthic phase where the cells are immobilized in a natural matrix formed from their own exopolysaccharides. Artificial immobilization, as reported in this study, was essentially an attempt to mimic this ecological niche.

The PBR was operated with 10 L of media. Agar immobilized cells were fed continuously (at a dilution rate = $0.025\,d^{-1}$ during the first experiment and at $D = 0.25\,d^{-1}$ during the other two experiments). The PBR was placed in an air-conditioned room with the temperature maintained at 15 °C. The immobilized-cell layer was illuminated by a barrel of optical fibers connected to a 150 W light generator, with a 14 h/10 h light illuminated cycle. The reactor has a large surface/volume ratio and efficient lighting is provided by the evenly distributed optical fibers. The *cold* light source is particularly suitable for *H. ostrearia* whose cultivation temperature is quite low.

Rossignol et al. [12.54] have compared two membrane photobioreactors (MPBRs), with free and immobilized cells, respectively, for the exocellular production of the blue-green, hydrosoluble pigment, marennine by the marine diatom *H. ostrearia*. In the former, cells are free and grown in a recycle PBR with total biomass recycling coupled to a membrane ultrafiltration system (external loop). In the latter, i. e., the immobilized cell tubular membrane PBR, essentially a glass and S.S. cylinder (volume 10 L) cells are immobilized in a tubular agar gel layer (surface area 955 cm^2, volume 550 cm^3) placed in liquid culture medium with an optical-fiber barrel (as a source of artificial illumination) running through the inner annular space of the tubular agar gel and an external microporous membrane forming an outer sheath around the gel layer. Major drawbacks of the free cell continuous recycle system are membrane fouling and hydrodynamic shear stress on the shear-sensitive microalgal cells, which may be somewhat overcome by immobilization that essentially mimics the marine ecological niche of these cells – the number of pigmented cells increase as the algae migrate from the planktonic to the benthic phase becoming maximum as the cells are immobilized in a biofilm matrix formed by their excreted exopolysaccharides. PBRs were housed in a 15 °C air-conditioned room and illumination followed a 14 h/10 h light/dark cycle. The respective reactor setups are shown in Figs. 12.25 and 12.26. The free-cell photobioreactor (FCB) consisted of a glass cylinder integrated with an external flat – membrane module (to perform tangential filtration) comprising a plane polyacrylonitrile (PAN) membrane (MWCO 40 kDa, area 100 cm^2). Although the retentate loop was closed, sampling could be done as scheduled. To maintain a constant volume, sterile nutrient solution was fed into the bioreactor, as the permeate was extracted, using a peristaltic pump. Product (marennine) concentrations and volumetric productivity were found to be much higher for the free-cell system, however specific (i. e., cell number based) productivity was larger for the immobilized cell system due to the decreased cell numbers in the latter at the end of the culture.

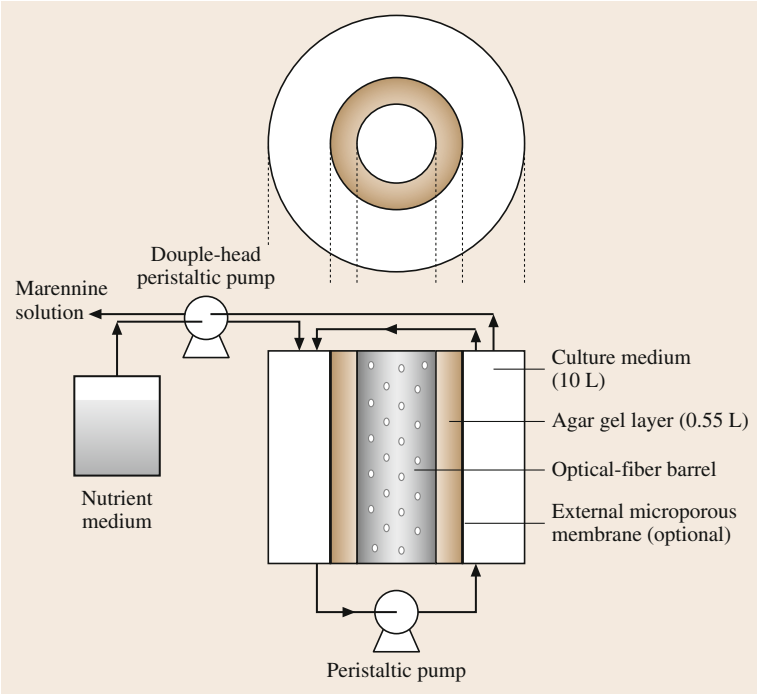

Fig. 12.26 Schematic of the immobilized-cell M-PBR (after *Rossignol* et al. [12.54])

12.6 Hollow Fiber Bioreactors (HFBR)

In an HFBR (Table 12.7), hundreds of thousands of hair-like hollow fibers (which are essentially semipermeable membranes) are bundled together within a tubular/cylindrical casing to form a cartridge. The cartridge is then linked to a perfusion system which circulates nutrient media for cell growth continuously through the fibers. Cells are usually inoculated into the so-called *extra capillary space* or shell-side space external to the fibers within the cartridge, whereas culture media is circulated through the *lumen* of the fibers (i. e., the middle of the fibers), allowing nutrients, dissolved gases and metabolic wastes to diffuse across the fiber walls. HFBRs are characterized by extremely high surface-to-volume ratio (> 150 cm^2) and support surface-attached growth of cells bound to a porous matrix whose MWCO (molecular weight cut-off) may be varied. Hollow-fiber reactors may be operated in direct mode, where growth media is passed through the fiber lumen, or in the transverse mode as done by *Lloyd* et al. [12.55], where growth medium is passed over immobilized cells, and spent medium with products collected after passage of the liquid through the semipermeable membrane of the hollow fibers. Cells are retained in the HFBR unless the hollow fibers rupture or the end-seals fail.

Table 12.7 Hollow fiber bioreactors (HFBR)

Sl	Bioreactor	Marine strain and bioprocess	Reference
1	HF-MBR	Production of recombinant toxoid by bacteria *Vibrio* sp. immobilized on hollow-fiber membrane.	*Lloyd* et al. [12.55]
2	HF-sMBR	Growth of marine rotifer *Brachinus plicatilis* immobilized on Ca-alginate	*Rombaut* et al. [12.56]
3	HF-sMBR	Oily water treatment by bacterial consortium	*Soltani* et al. [12.57]
4	Microfiltration HFBR	Enhancing cell yield of thermoacidophillic archaeon *S. solfataricus*	*Schiraldi* et al. [12.58]
5	HF-PBR	Nitrate and phosphate removal by non-N_2-fixing cyanobacterium *P. laminosum* immobilized on hollow fibers	*Sawayama* et al. [12.59]

An HFBR permits high cell densities to be attained in a practically nonshear environment with mild nutrient perfusion. Bacterial cell densities between 100 and 200 g L^{-1} have been commonly attained in HFBRs. However, the exceptionally high density of 550 g L^{-1} was reported [12.60] for a rifamycin-producing strain of *Nocardia mediterranei* (later renamed *Amycolatopsis rifamycinica*) grown in a dual hollow-fiber bioreactor. It is this ability to establish high cell densities while operating with continuous nutrient supply and product removal, that gives rise to higher product yields. HFBRs have been shown to work well with bioprocesses that result in the synthesis of products from major metabolic pathways, e.g., glycolysis, but, they do not work very well with processes that involve metabolic pathways of apparently less significance to the producer microbe.

Lloyd et al. [12.55] used an HFBR for production of a recombinant toxoid by a marine *Vibrio* species and compared it with recombinant protein synthesis in traditional batch and chemostat cultures. The type of fiber used significantly affected productivity, both with regards to maintenance of reactor integrity and by allowing passage of the toxoid through the selectively permeable membrane. A hollow-fiber-based system was selected for this comparative study because it offers easy immobilization and growth of recombinant cells, in addition to the potential to select fibers with permeability properties that could help improve the purity of the product obtained in the outflow from the reactor, thus maximizing the exploitation of the secretory capabilities of the *Vibrio* species cultured. Fibers were embedded in polyacetal end plugs, but spe-

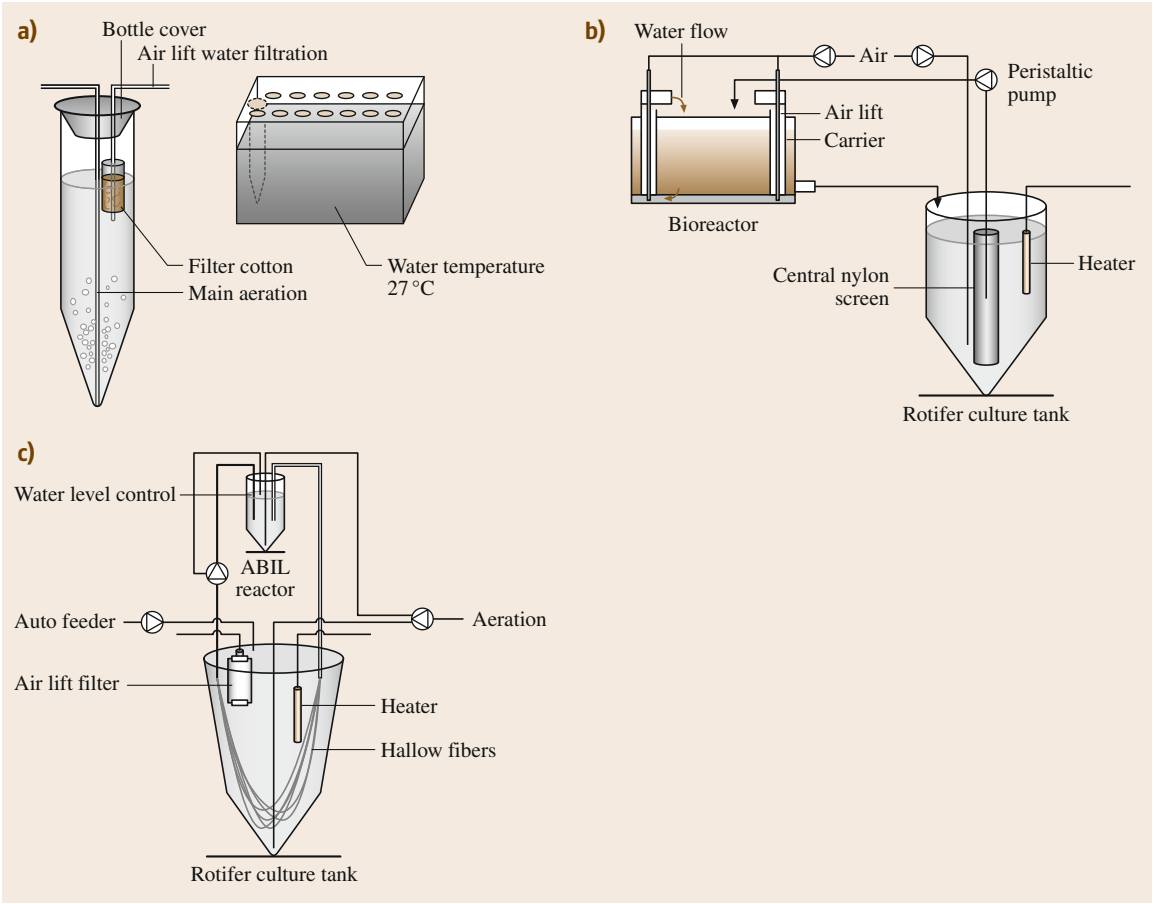

Fig. 12.27a–c Schematic of the experimental setup: **(a)** Batch reactor to test ABIL for rotifers. **(b)** Bioreactor setup with four different carrier materials. **(c)** Integration of an ABIL reactor with hollow fibers to the rotifer culture system (after *Rombaut* et al. [12.56])

cific microfibers were embedded in S.S. tubes (length 2 cm, I.D. 10 mm) using adhesive resin for holding the fibers in place during reactor operation. Medium supply was through the shell-side port. Air was supplied in a transverse mode through the fiber lumen. (It may be noted that air supply may also be done in direct mode through the shell side space.) Growth was evaluated by using a pressure transducer, which monitors the pressure differential between the inside and outside of the fibers and by measuring the protein content of fibers at the end of an incubation.

Rombaut et al. [12.56] used a dense, nitrifying inoculum culture (ABIL) for stimulating growth of the marine rotifer *Brachionus plicatilis* in several bioreactor systems, viz., batch culture, continuous bioreactors packed with carrier materials (a PVC matrix, gravel and $CaCO_3$ were evaluated separately) and a submerged hollow-fiber membrane bioreactor (HF-MBR).

A series of rectangular shaped bioreactors (Fig. 12.27) (total volume of one tank, 10 L) were each filled with 4 dm^3 of carrier material and 4 L of artificial seawater (25 $g\,L^{-1}$ salinity). The bottom of each tank was fitted with a cover (with holes drilled on it) for retaining the carrier material, through which two airlifts were installed for oxygen supply and for recirculation of the aqueous phase. $CaCO_3$ stones (2.0 ± 0.7 mm), gravel (16 ± 2 mm), a mixture of both types of stones, and a PVC-based carrier material (viz., Bionet) were examined as biomass carrier materials, however for the rotifer production periods, only the crushed $CaCO_3$ stones were used. After the start-up period of 11 d, water from the different bioreactors was drained out of the system and replaced by new diluted seawater. Except for the reactor packed with Bionet, the bioreactors were connected to a cylindro-conical culture tank of 10 L, well aerated to ensure good oxygenation and uniform distribution. The culture-rearing tank was filled with artificial seawater and maintained at a constant temperature ($25 \pm 1\,°C$). A central nylon screen (mesh size 33 µm) sieve was installed in the center of each tank to retain the rotifers and also to enable pumping of the culture water (using a peristaltic pump) to the bioreactors. The water returned by gravity to the rotifer culture tanks.

For the experiments with HF-MBR, conical PVC tanks were used for rotifer culture which were filled with 10 L of artificial seawater. Hydrophilic hollow fibers (nominal pore size 0.2 µm; wall thickness 450 µm; inner diameter 1800 µm), adjusted to pieces of 1 m and 10 fibers (total surface area = 0.078 m^2), were installed in each culture tank. The ends of the hollow fibers were connected to the ABIL reactor, inside which filter cotton was placed at the bottom to collect large debris. Water and bacteria from the ABIL reactor were pumped through the hollow fibers (using a peristaltic pump). The rotifer feed was stored at temperatures $< 10\,°C$ and was fed (15 $min\,h^{-1}$) by a peristaltic pump. The rotifer culture tanks were continuously aerated and the temperature was controlled by a heater at 28 °C. Results showed that concentrations of the major nitrogenous waste, viz., TAN in the control batch culture was much higher than that in the HF-MBR recirculating system. Since the principal objective of the bioreactor systems evaluated is the removal of TAN, thereby facilitating vigorous rotifer growth, the improved water quality obtained with the HF-MBR system resulted in much higher rotifier densities compared to the normal batch culture.

Soltani et al. [12.57] demonstrated that a hollow-fiber submerged MBR (HF-sMBR) could be used very effectively for oil removal from oilfield wastewaters using a marine bacterial consortium isolated from sea sediments and adapted to growth environments containing high amounts of salt and oil. The reactor setup (Fig. 12.28) consisted of a hollow fiber membrane module (made from polypropylene with pore size ≈ 0.2 µm) submerged in a feed tank. Permeate was withdrawn by a vacuum pump, its flow rate monitored by a rotameter and adjustable by operating a valve placed before the pump. Oxygen necessary for microbial growth and aeration of the membrane were supplied by two air diffusers, placed below the membrane module. Remarkably, 100% oil removal in the permeate was accomplished. Furthermore, although isolated from a typically saline marine ecological niche, the bacteria didn't lose their oil-degrading ability even in the total absence of salt in the culture medium – leading the authors to classify them as halotolerant.

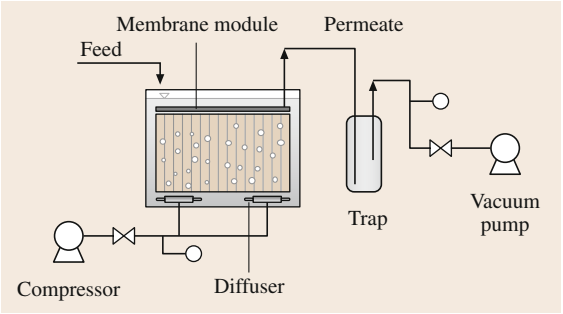

Fig. 12.28 A schematic of the HFBR experimental setup (after *Soltani* et al. [12.57])

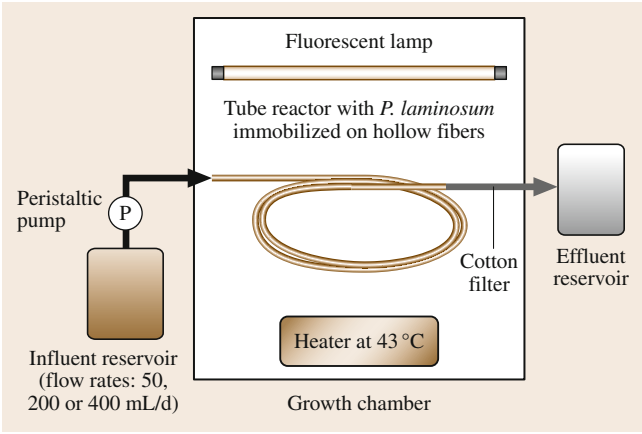

Fig. 12.29 Schematic diagram of the hollow-fiber photobioreactor (after *Sawayama* et al. [12.59])

Schiraldi et al. [12.58] used a hollow fiber microfiltration (MF) bioreactor (HF-MFBR) for high cell density growth of the thermoacidophilic archaeon *Sulfolobus solfataricus* – with the MF-hollow fiber module located inside a traditional fermentation vessel. They obtained biomass yields about 15–20 times higher than in batch culture, and about 6 times that of fed-batch culture. Furthermore, the MF module was found to be highly resistant to the extreme environments typical of thermoacidophile fermentation. Despite the high cell densities attained, transmembrane flux was consistently maintained (with repeated backflushing) at 75% of the maximum which is quite remarkable compared to usual crossflow filtration where flux declines to 20% of the maximum within 30 h of operation. To obtain the same amount of biomass, whereas at least 2000 h of batch time is necessary (ignoring the turnaround time between batches) only about 15% of this time is required with the HF-MFBR.

The polypropylene membrane used consisted of a long capillary (5–10 m) with an inner diameter of 0.2 mm and a cutoff of 0.22 µm. A number of 15 cm-long capillaries were obtained from the original membrane and were assembled together with a silicon adhesive; one side was closed and the other was sealed to a connector. The module was connected to a peristaltic pump equipped with a silicon tube (I.D. 2 mm), which provided the driving force for transmembrane flux. Considering the geometry of the module, the total filtering area measured 1.47×10^{-2} m^2. Before operating the module, the membranes were treated with a 70% ethanol solution for 1 h to make them hydrophilic. The microfiltration module was then placed inside the fermentation vessel and fixed vertically to a baffle in order to expose it (i. e., the module) to high turbulence near the filtering surface for minimizing fouling.

Sawayama et al. [12.59] studied nitrate and phosphate removal from water by the non-N_2-fixing cyanobacterium *P. laminosum* immobilized on cellulose hollow fibers in a tubular photobioreactor at 43 °C, continuously supplying dilute growth medium for 7 d and then secondarily treated sewage (STS) for 12 d. Cyanobacteria can grow much faster than higher plants under appropriate conditions, therefore, cyanobacteria-based inorganic nutrient removal systems are worth exploring. Furthermore, with thermophilic cyanobacteria, contamination can be avoided since it is tolerant of high-temperatures permitting sewage treatment at temperatures (≈ 45 °C), which cannot be tolerated by most other contaminating microbial species. Hollow fiber-immobilized cyanobacterial systems are easy to construct and immobilization is relatively simple. The bioreactor (Fig. 12.29) comprised a transparent PVC tube containing cellulose hollow fibers (used as the immobilization matrix), a peristaltic pump, a heater and two cool, white fluorescent lamps. Cells were immobilized on 600 cellulose hollow fibers (length 0.5 m, internal diameter 0.18 mm, total surface area 0.19 m^2) and placed in a PVC tube (length 0.5 m, I.D. 16 mm) with a total reactor volume of 100 mL. Immobilization was carried out by addition of cell culture (2 mg total chlorophyll) to the reactor using a peristaltic pump. Two days after cell inoculation, diluted medium (at a flow rate of 200 or 400 mL d^{-1}) or STS (at a flow rate of 50 mL d^{-1}) was passed through the HFBR at 43 °C (±1 °C) continuously illuminated with fluorescent light. The quantity of immobilized cyanobacterial chlorophyll in the bioreactor was 1.7–1.9 mg after 24 h of influent flow. *P. laminosum* cultured in the continuous HF-PBR removed nitrate and phosphate ion from water quite efficiently, however nitrate ions present in STS could not be removed satisfactorily. Again, compared to chitosan immobilized cells used earlier, P removal was higher (more than double) in this HF-PBR but N removal was significantly lower (less than half).

12.7 Fluidized Bed and Moving Bed Bioreactors (FBBR and MBBR)

12.7.1 Fluidized Bed Bioreactors (FBBR)

An FBBR (Table 12.8) is a reactor consisting of a *bed* of particles/carriers such that the particles are not in constant contact with each other (i. e., they are in motion resembling that of fluid particles) due to the flow of a fluid through them. If the component particles of the *bed* are indeed in continuous contact with each other, the bed is referred to as a *packed bed*. Often, the term *expanded bed* is used to describe a bed that has expanded just marginally above the corresponding *packed bed* height, i. e., above the *settled height* – the condition when the bed particles have *settled down* and are NOT in motion. The term fluidized bed is usually used for beds that have undergone significant expansion, so that *fluidization* of the bed has occurred – i. e., the bed particles are in continuous motion as in case of a fluid. Fluidization involving liquids and solid particles is commonly particulate characterized by smooth expansion of the bed, as opposed to *aggregative* characterized by violent bubbling and particle motion typical of gas–solid fluidization. FBBRs are essentially immobilized-cell reactors. Individual cells being very small and light and with a settling velocity less than the superficial liquid velocity are washed out, whereas carrier particles with cells immobilized on them have much larger settling velocity and are retained in the bed, which allows operation of FBBRs at dilution rates much higher than the cell specific growth rate. Compared with stirred-tank immobilized reactors, the shear at the particle surface is much lower in an FBBR, which actually poses a problem with bacteria and yeast because they can continue to grow as a biofilm around the particle. Increasing biofilm volumes forces the bed to expand and the steady state, where cell growth equals the rate that cells are washed off by surface shear is attained, only with a very large bed height.

Cytryn et al. [12.61] investigated the diversity of microbial communities correlated to physiochemical parameters in a digestion basin (DB) of a zero-discharge experimental mariculture system that integrated conventional nitrification with a combination of sludge digestion and denitrification. The integrated system comprises an intensively stocked fish basin with two parallel biofiltration loops (Figs. 12.30 and 12.31): (1) a trickling filter, where ammonia is oxidized to nitrate; and (2) a digestion/sedimentation basin connected to an FBBR for organic degradation and denitrification. Surface water from the basin was pumped over the trickling filter in one loop while bottom water was recirculated through a sedimentation basin followed by the FBBR in the other. Ammonia oxidation to nitrate in the trickling filter and organic matter digestion coupled with nitrate reduction in the combined sedimentation basin–FBBR loop, allowed zero-discharge operation of the integrated system. Chemical activity and microbial diversity were higher in the sludge layer than in the overlying aqueous layer of the basin. Chemical parameters in sludge samples close to the basin inlet indicated enhanced microbial activity relative to other sampling areas with evidence of both nitrate and sulfate reduction.

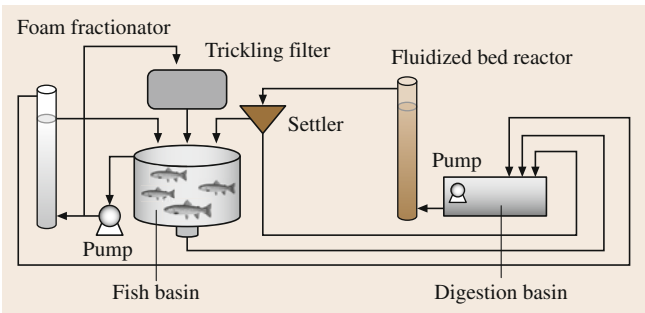

Fig. 12.30 Schematic diagram of the recirculating zero-discharge mariculture system (after *Cytryn* et al. [12.61])

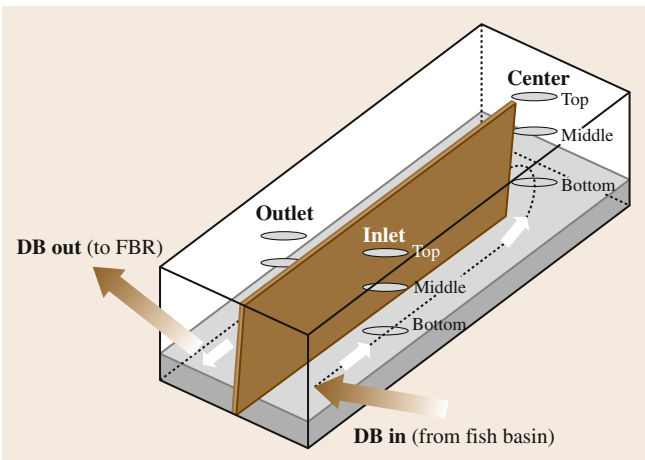

Fig. 12.31 Schematic diagram of the digestion basin. Sampling stations (inlet, center, and outlet) and sampling depths (top, middle, and bottom) are depicted by *ellipses*. *Gray area* indicates the underlying sludge layer of the basin (bottom 5 cm) and the *clear area* indicates the overlaying aqueous phase (top 10 cm). *Arrows* and *dotted lines* indicate the flow direction (after *Cytryn* et al. [12.61])

Cytryn et al. [12.62] integrated microscopic and molecular microbial analyses to characterize rapidly developing white filamentous tufts in an FBBR (used earlier by *Cytryn* et al. [12.61]) for nitrate removal from a marine recirculating aquaculture (fish culture) system – RAS. The dominant constituents of these tufts were identified as filamentous, gram-negative bacteria with densely packed intracellular sulfur granules belonging to the marine *Thiothrix* genus. Water from the upper part of a double-drain fish basin (2.3 m^3), stocked with Gilthead Seabream (fish) to a final density of 20–50 $kg\,m^{-3}$, was recirculated at a rate of 1–2 fish basin volumes per hour over a trickling filter. Simultaneously, water from the bottom center of the fish basin flowed into a digestion basin (DB) (working volume 0.4–0.5 m^3) at a rate of 0.1–0.25 fish basin volumes per hour. Water from the upper layers of the DB outlet was pumped (5–7 $L\,min^{-1}$) into the cylindrical FBBR through a vertical pipe that extended from the top center to ≈ 3 cm above the base of the FBBR. The FBBR (working volume 6.26 L) was filled with sand (average diameter 0.7 mm), as carrier material for growth of microbial biofilm. Upflow from the inlet pipe caused the flocs (biofilm-attached sand grains) to float within the column. Water from the FBBR outlet at the top of the cylinder was drained back to the fish basin after passing through a settler for removal of particulate matter, which was funneled back into the DB.

Schramm et al. [12.63] analyzed the change of activity and abundance of *Nitrosospira* and *Nitrospira* spp. along a bulk water gradient in a nitrifying FBBR, by a combination of microsensor measurements and fluorescence in situ hybridization (FISH), which facilitated a detailed analysis of the in situ structure and function of the nitrifying bioreactor on a microscale. The conical, continuous-upflow FBBR (originally developed by *de Beer* et al. [12.64]) (Fig. 12.32) (volume 360 mL, height 0.8 m, I.D. 1 cm at the bottom, 3 cm at the top) was covered with black paper to prevent phototrophic algal growth. It was fed with mineral medium containing 72 mM NH_4^+ and the liquid phase was recirculated at a rate of 1.8 $mL\,s^{-1}$. The conical shape of the vertical reactor column generates a flow velocity gradient that stabilizes nitirifying bacterial aggregates of different diameters and densities at fixed positions in the column according to their settling velocity. Nitrification occurred in a narrow zone of 100–150 mm on the surface of the aggregates, that contained a very dense community of nitrifying bacteria. The central part of the aggregates was inactive, containing significantly lesser number of nitrifiers. Since conditions in the reactor were ammonium limiting, it was completely oxidized to nitrate within the active layer of the aggregates, the rates decreasing with increasing reactor height. Thus, this study, as well as the one carried out by *de Beer* et al. [12.64] demonstrated the successful operation of a two-phase (liquid–solid) fluidized-bed nitrification reactor with an external aerator, for development of nitrifying bacterial aggregates. Most importantly, the much lower shear forces generated, relative to those in three-phase systems, facilitated development of bacterial aggregates without addition of carrier materials.

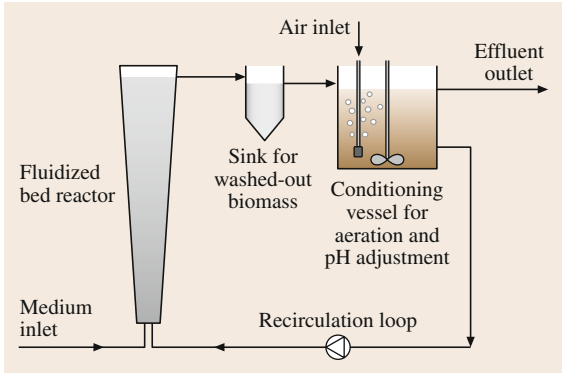

Fig. 12.32 Scheme of the nitrifying reactor setup (after *de Beer* et al. [12.64])

Garbisu et al. [12.65] used free and polyvinyl foam-immobilized cells of the cyanobacteria *P. laminosum* for phosphate removal from water in batch and flow-type FBBRs as well as in continuous flow PBBR. Phosphate uptake by nitrogen starved free-living cyanobacteria showed that N-starvation led to lower uptake rates, but addition of nitrate significantly increased the uptake. Phosphate uptake by free as well as immobilized cyanobacteria was inhibited in the dark and simulated by the presence of calcium ions or bicarbonate. Addition of a chelating agent, such as ethylenediaminetetraacetic acid to the cultures, led to zero phosphate uptake. Although high phosphate uptake was not observed with cyanobacteria immobilized on polymer foams, concurrent removal of nitrate and phosphate from water using nitrogen-starved immobilized cyanobacteria showed sufficient potential for future development.

12.7.2 Moving Bed Bioreactors

Although FBBRs ensure homogeneous environmental conditions for all biofilm surfaces and enhance mass transfer rates, nevertheless, both for upward and down-

ward fluidization, the active volume is low and fluidization performance may deteriorate over time and may not remain at the optimum level, primarily due to the changing density of the carriers with biofilm growth on their surfaces. An effective alternative to an FBBR is an MBBR (Table 12.8), which has carrier particles that are continuously in motion. As the liquid circulates, the carriers move through the liquid between two retention grids at two ends of the reactor and are agitated either mechanically or hydrodynamically by liquid jets. High shear stress from water circulation coupled with interparticle collision prevents uncontrolled proliferation of biofilm on the carrier surface and thereby stabilizes the reactor system.

An MBBR is thus *self-cleaning* and has low head loss. In fact, MBBRs with up to 60% of the working volume occupied by carriers have been used and found to perform satisfactorily.

A pilot scale, submerged MBBR was installed at the Montreal Biodome (a 3.25 million closed-circuit mesocosm) to deal with the constraints of seawater denitrification by an attached-growth process, with an aim to optimize a large-scale MBBR. *Labelle* et al. [12.66], evaluated the seawater treatment performance of the reactors, using methanol as carbon source at different C/N ratios and examined its efficiency in preventing sulfate reduction by limiting biofilm thickness, dead mixing zones and residual substrate in the outflow.

Two well-mixed bioreactors in series (Fig. 12.33) (working volume 110 L each, diameter 43 cm and with conical bottom) were used for deoxygenation and denitrification, respectively. Methanol was fed to both reactors (C-source) and a trace element solution to the second one, the latter intended to maintain iron, manganese, and copper concentrations over 150, 80 and 10 $\mu g\,L^{-1}$, respectively. Indigenous biomass in seawater was used to colonize carriers in the two-stage bioreactor system. The first stage, a pretreatment deoxygenation unit, was actually a packed bed biofilter packed to 80% of its total volume with 63 mm random plastic carriers (specific surface area 180 $m^2\,m^{-3}$, void fraction 91%, specific gravity $\approx$ 0.90). The second stage, a denitrification unit, consisted of a submerged MBBR configured to minimize media fouling and dead

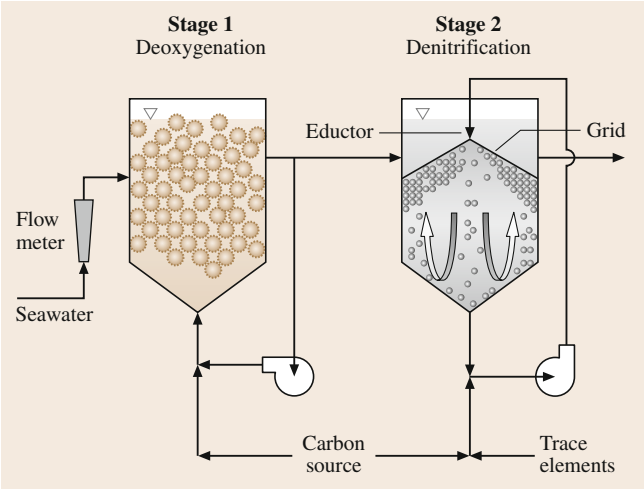

Fig. 12.33 Schematic diagram of experimental setup: Two CFSTR in series for deoxygenation and denitrification, respectively (after *Labelle* et al. [12.66])

mixing zones. The 2.5 cm spherical polyethylene carriers used in the second stage had a fill ratio of 25%, a surface area of 278 $m^2\,m^{-3}$, a void fraction of 90%, and a specific gravity of 0.89. Effective surface area for biofilm attachment was estimated at ≈ 35% of the total surface area (i. e., 97 m^2/m^3) since no growth was observed on the outer parts of the moving carriers. Carriers were kept submerged by a conical welded stainless steel wire mesh (5 mm openings, wire diameter of 0.56 mm) and mixing was ensured by the downflow jet of a 9.5 mm glass-filled polyethylene eductor positioned vertically over the conical grid. The single-jet configuration was designed to generate adequate hydrodynamic shear to prevent carrier fouling and to create a hydraulic movement minimizing the surface diffusion of oxygen in the MBBR. High sulfate concentration in seawater complicates denitrification in attached-growth processes. Natural, anoxic marine environments where sulfate reduction occurs are associated with N_2O production. However, the study demonstrated that a pilot-scale sMBBR could efficiently denitrify seawater/saline water with a high sulfate concentration.

In seawater aquariums, nitrates are produced in the biological aerobic treatment units by nitrification of excreted ammonia, which is toxic in its unionized form. The recommended level of nitrates in an artificial seawater ecosystem is 50 mg NO_3-N L^{-1}, which is low compared to its generation rate in a closed system. *Dupla* et al. [12.67] investigated the hydrodynamic behavior and denitrification capacity of a downflow self-cleaning moving bed bioreactor (MBBR) using floating packed-bed carriers. A deoxygenation unit was installed upstream from the denitrification unit, consisting of an MBBR (Fig. 12.34) (working volume 110 L) packed with plastic carriers placed randomly. The denitrification unit comprised two identical cylindrical reactors made of PVC (height 40 cm, diameter 30.5 cm, height of conical section 15 cm). Each reactor (including pipes) contained 33 L of water and was equipped with a recirculation loop and piping that allowed tangential recirculating water inflow, causing rotational movement of the liquid. Welded stainless-steel grid cones (10°, 45° or 60° inclination) were used to retain the carriers (5 mm grid openings, wire diameter 0.56 mm). Two jet nozzles with outlet diameter of 4.8 mm (small) and 8 mm (large) were installed to generate different water recirculation velocities at the nozzle i. e., 18.5 and 6.6 m s^{-1}, respectively. Eleven types of plastic packed-bed carriers commonly used in biological processes were considered and carrier selection was based on specific surface area, density, and size. The MBBR appeared to control biofilm development and could easily be scaled up to denitrify seawater or freshwater systems. Due to hydrodynamic control by means of the jet nozzle, the carriers did not clog and a thin biofilm was maintained throughout.

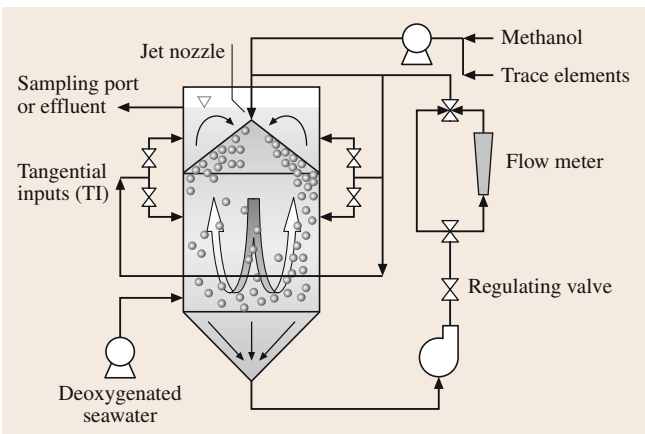

Fig. 12.34 Schematic diagram of the MBBR used in denitrification experiments (*arrows* show water circulation) (after *Dupla* et al. [12.67])

Tal et al. [12.68] examined the microbial communities in the biological filter and waste sludge compartments of a marine RAS to determine the presence and activity of anaerobic ammonium-oxidizing (anammox) bacteria. Fluorescence in situ hybridization (FISH) studies using an anammox-specific probe confirmed the presence of anammox *Planctomycetales* in the microbial biofilm from the denitrifying biofilters, and anammox activity was observed in these biofilters, as detected by the ability to simultaneously consume ammonia and nitrite.

Two tanks (vol. 4.2 m^3 each) containing the fish gilthead seabream (*Sparus aurata*) were operated at a density of 10–50 kg m^{-3} and a feeding rate of 1–1.6% body weight d^{-1}. The tanks were connected to a 2 m^3 nitrifying MBBR filled with 1 m^3 of polyethylene beads (diameter 1 cm, surface to volume ratio 500 $m^2\,m^{-3}$). A flow rate of 16 $m^3\,h^{-1}$ was used to obtain two exchanges of tank water per hour through the nitrifying biofilter. Attached to each tank as a denitrification side loop was a cylindrical up-flow fixed-bed biofilter (volume 0.3 mL) filled with 0.2 m^3 of polyethylene beads. The flow rate for this anaerobic biofiltration compartment was 0.1 $m^3\,h^{-1}$, and the water was supplied by two sources, direct water from the fish tank and water recovered from the sludge tank. Sludge was collected with a drum screen filter using a backwash system in

which tank water was used. Sludge and backwash water were collected in a rectangular tank (volume 0.3 m^3) packed with 0.1 m^3 beads that provided a means for solids removal, as well as a substrate for bacterial colonization. Water from the sludge tank was pumped back into the system through the anaerobic biofilter, and high-density sludge was collected and removed. In view of stricter environmental regulations for effluent discharge from aquaculture facilities there is increasing emphasis on closing the nitrogen cycle in the water treatment system by utilizing the anammox process as a preferred alternative to heterotrophic denitrification, especially in marine recirculating systems in order to reduce effluent volumes as well as nitrogen loads. The results of this study show that anammox bacteria and their activity are associated with the consortia of a denitrifying biofilter, which makes this approach feasible for implementation.

Enhanced biological phosphorus removal (EBPR) in wastewater treatment is based on the fact that phosphorus accumulating organisms (PAOs) can accumulate intracellular phosphorus as polyphosphate (poly-P). In EBPR, the biomass is exposed to cyclically occurring anaerobic and aerobic/anoxic conditions. Under anaerobic conditions, PAOs store rapidly biodegradable substrate in their cells as poly-β-hydoxyalkanoates (PHA) by using intracellular poly-P and glycogen as energy sources. Under aerobic/anoxic conditions, PAOs use PHA as a carbon source to refill poly-P and glycogen stocks. Poly-P synthesis allows bulk phosphate to accumulate in the biomass. The phosphate is then removed with the biomass during aerobic/anoxic conditions. Another group of bacteria, the glycogen accumulating organisms (GAOs), also grow under cyclic alternation of anaerobic and aerobic/anoxic conditions, using only glycogen as energy source and therefore consuming substrate but not removing phosphorus. Thus to optimize EBPR, anaerobic conditions must be strictly controlled, poly-P storage maximized, and GAOs growth minimized. Poly-P storage is maximized by using acetate as a carbon source because it increases the production of poly-P compared to other volatile fatty acids during aerobic periods. Environmental conditions known to favor PAOs over GAOs are temperature $< 25\,^{\circ}C$ and pH > 7.5. Aquariums and fish farms run in closed circuit face major accumulation of phosphate and nitrate which cause, respectively, excessive algal growth and toxicity to aquatic fauna. As an alternative to regularly changing the water that causes highly polluted discharge to the surroundings, denitrifying biological phosphorus removal (DN-BPR) may be applied to this system without producing excessive sludge.

The Montreal Biodome operates a 3250 m^3, closed circuit, cold (10 °C) marine mesocosm named St. Lawrence Mesocosm (SLM) containing very high nitrate and phosphate levels. Earlier workers (e.g., *Labelle* et al. [12.66], *Dupla* et al. [12.67]) have demonstrated the feasibility of denitrifying the SLM water using an MBBR with methanol as the C-source. *Vallet* et al. [12.69] modified the process to implement DN-BPR to promote the anaerobic growth of PAOs in the reactor – and additional C-source was required in view of low concentration of organic matter in the SLM water (2–4 mg C/L). The process developed is based on the alternation of anaerobic and aerobic/anoxic conditions in the MBBR with biofilm growth occurring on the surfaces of plastic carriers. A sequential complete exchange of two waters thus takes place in the MBBR – (1) the influent containing nitrate and phosphate and (2) the anaerobic water stored in a stock tank. Therefore, the environmental conditions in the MBBR selectively favor the growth of PAOs only. An additional advantage is the accumulation of phosphate in a stock tank thereby allowing an easy recovery of P for use as fertilizer.

Two identical reactor setups (used earlier by *Labelle* et al. [12.66]) were operated in parallel under identical conditions. Each setup comprised a well-mixed bioreactor (volume 110 L) filled with 35 L of plastic carriers, and a stock tank (volume 220 L). The packed bed was moved using a circulation pump thereby allowing operation as an MBBR. Water was pumped from the stock tank to the MBBR through a three-way transfer valve, while the MBBR was filled with the pressurized influent through a solenoid valve. A pH probe, a redox-potential probe, an oxygen probe, and a UV nitrate analyzer were installed on the recirculation line. This study demonstrated the inhibition of BPR by seawater presumably due to the high calcium levels in seawater. However, in freshwater, a biofilm was developed with a phosphorus removal efficiency rate of 20% of which 80% was attributed to biological removal and 20% to chemical precipitation.

12.8 High-Temperature and/or High-Pressure Bioreactors (HP-/HTBR)

High-pressure and/or high-temperature bioreactors (Table 12.9) are practically wholly devoted to cultivation of extremophiles (barophiles and/or thermophiles) isolated from the deep sea. Most, though not all, HP/HT bioreactor systems may be expected to fall into one of the following categories:

i) One-phase batch systems without gas enrichment (e.g., *Canganella* et al. [12.70], *Kallmeyer* et al. [12.71]).
ii) Processing of microbial samples without depressurization (e.g., *Parkes* et al. [12.72]).
iii) Two-phase batch systems with gas enrichment from free gas (includes studies by the group of Prof. Douglas Clark at the University of California, Berkeley e.g., *Miller* et al. [12.73], *Miller* et al. [12.74], *Miller* et al. [12.75], *Nelson* et al. [12.76], *Nelson* et al. [12.77], *Hei* and *Clark* [12.78], *Park* and *Clark* [12.79]).
iv) High-pressure fed-batch/continuous incubation (e.g., *Girguis* et al. [12.80], *Houghton* et al. [12.81]).
v) High-pressure fed batch/continuous incubation with gas-enrichment medium without free gas (e.g., *Deusner* et al. [12.82], *Zhang* et al. [12.83]).

Besides the above HP/HT bioreactor systems, *Marteinsson* et al. [12.84, 85] used pressurized gas-

tight syringes for cell cultivation, placed in an HPHT incubation system. Again, *Wright* et al. [12.86] investigated the pressure tolerance of barotolerant (rather than barophilic) strains isolated from surface waters (and not from the deep sea).

Canganella et al. [12.70] investigated the effects of high temperatures and elevated hydrostatic pressures on the physiological behavior and viability of the extremely thermophilic deep-sea archaeon *Thermococcus peptonophilus* (isolated from deep-sea hydrothermal vents in the western Pacific ocean at a depth of 1380 m) in a high-pressure/high-temperature bioreactor (HPHTBR). Growth was fastest at 30 and 45 MPa without any noteworthy increase in cell yields, growth at 60 MPa was slower. The optimal growth temperature shifted from 85 °C at 30 MPa to 90–95 °C at 45 MPa. Cell viability during the stationary phase was also enhanced under high pressure. A trend toward barophily at pressures greater than those encountered in situ at the sea floor was observed at increasing growth temperatures. Relative to that at atmospheric pressure, the viability of cells during starvation, at high temperature (90, 95 °C), as well as at low temperature (10 °C) increased at 30 and 45 MPa. These results established that the extremely thermophilic archaeon *T. peptonophilus* was a barophile. The HPHTBR used in this study was designed to work within a temperature range of 0–300 °C and up to 68 MPa pressure and was suitable for continued sampling without any perturbation of the culture.

Kallmeyer et al. 2003 [12.71] developed a high-pressure thermal gradient system (HPTGS) consisting of a thermal gradient block (TGB) and a high-pressure unit (HPU) for simultaneous incubation of multiple microbial samples over a wide range of temperatures and pressures. To maintain the pressure independent of the thermal expansion of sample vessels, a back-pressure system (BPS) with a constant small leakage was also incorporated into the HPTGS. The HPTGS was used to study the pressure–temperature characteristics of sulfate-reducing bacteria (SRB) isolated from hydrothermal vent sediments (from Guyamas Basin, Gulf of California) and measure bacterial sulfate reduction rates which were found to increase with increasing pressure and showed maximum values at pressures higher than in situ.

The HPTGS consists of two main units: the TGB and the high-pressure unit (HPU). The TGB (Fig. 12.35) consists of an aluminum block (Al Cu Mg Pb F34; 1185 × 150 × 150 mm) with three rows of 15 equidistant holes (140 mm deep × 36 mm diameter) insulated by a 20 cm thick layer of Trolit (proprietary solid material, made from mineral fibers) with very good thermal insulation characteristics, temperature resistant to > 1000 °C, also robust and mechanically stable. The temperature gradient is almost linear, independent of the minimum and maximum temperatures. At incubation temperatures > 200 °C, the outside of the unit is at ≤ 25 °C. For ease of transportation, the whole block is housed in a custom-made case on wheels. The Trolit and the aluminum block are held in place only by the case to allow for thermal expansion of the material and easier dismantling. At one end of the block, a cooling element is attached, milled from a solid piece of aluminum (150 × 150 × 60 mm) with a tortuous internal channel where coolant is circulated. The inlet and outlet are on top of the unit and connected to a cooling unit mechanically fixed to the block with four screws, and

sealed with heat-resistant elastic sealant. The coolant was chosen according to the desired temperature and for very low temperatures, the hoses connecting the cooler and the TGB were thermally insulated to avoid precipitation of moisture and buildup of ice. At the opposite end of the TGB, four electrical heating elements (6.4 mm diameter × 88.9 mm, 200 W) were placed into 6.5 mm diameter holes in the block. The maximum temperature attainable is 220 °C and the steepest thermal gradient is 160 °C, providing ≈ 10 °C temperature difference between each row of containers. Over the length of the block, four thermo-probes (PT 100, −60 to +400 °C) were installed to continuously monitor the temperature, which were connected to an electronic multicontroller for on–off switching of the heating elements.

The HPU (Fig. 12.36) is essentially a back-pressure system with a constant small leakage. Pressure is created by two HPLC pumps that can operate in a higher pressure range (from 400 to 600 bar). The pumps run in constant pressure mode with variable flow rate. In case of any thermal expansion during the warm-up, pressure remains below the specified threshold. The back-pressure system comprises five used HPLC columns (250 × 4.6 mm) in line. At 450 bar pressure, ≈ 0.7–0.8 mL leaks through. During the warm-up period, thermal expansion may cause the pressure to rise faster than the back-pressure system can release it, therefore opening of one of the connections between the HPLC columns smoothly increases the outflow of the system in a controlled manner. After thermal equilibrium is achieved, the connection is fastened again. The outflow of the back-pressure system flows back into the eluant vessel for subsequent reuse.

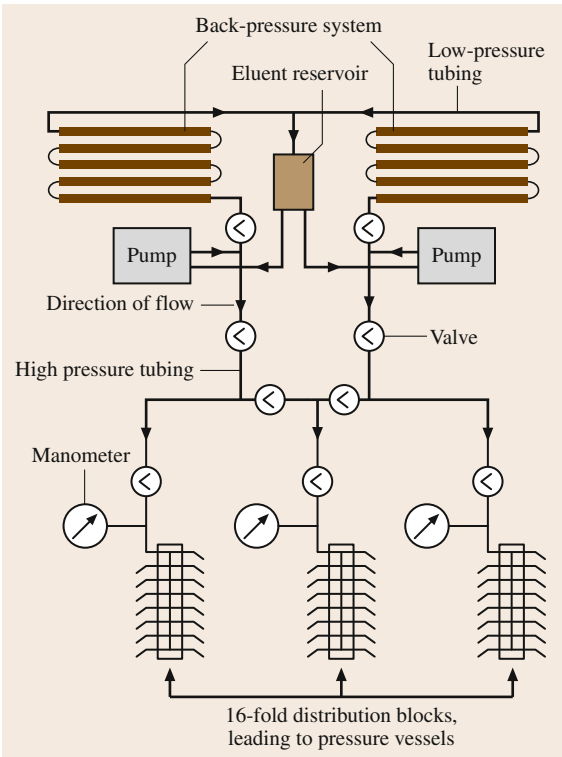

Fig. 12.36 Schematic view of the high-pressure system. The *thin lines* are high-pressure connections; the *bold lines* are low-pressure connections (after *Kallmeyer* et al. [12.71])

The pressure distribution system consists of pumps connected to a manifold of valves which allows connection of each pump to any of the three lines of pressure vessels, or for use of the pumps in parallel. Each line has a Bourdon-type manometer (16 cm diameter) to dampen the pulsation of the pump. A custom-made 16-fold distribution block connects the pressure containers of each line to the valve manifold. Small pockets in the Trolit insulation house the distribution blocks. Pressure vessels consist of large standard S.S. HPLC columns (I.D. 20 mm, 120 mm long), one end having a normal HPLC $\frac{1}{16}$ in fitting, the other end closed with a steel cap. The pressure containers are sealed with copper rings that last for several incubations but must be replaced periodically. Custom-made screw-cap tubes (O.D. 18 mm, 50 mm long) are used as sample vials, two of which fit in each pressure vessel, thereby providing exact duplicates in pressure and temperature.

The pressure vessels are placed in a bucket filled with demineralized water and the sample vials dropped into them. The caps are screwed on the pressure vessel under water to avoid trapping of air bubbles. After all pressure vessels are connected to the distribution block, ≈ 50 bar is applied to check for leaks. When no leak is noted, the vessels are inserted into the TGB and allowed to attain thermal equilibrium. The buildup of pressure is carefully monitored and released if necessary, then, after 1–2 h, the pressure is set to the desired value.

Parkes et al. [12.72] developed the novel DeepIsoBUG system for handling sediments (that contain depressurization sensitive anaerobic, piezophilic prokaryotes) under elevated pressure (up to 25 MPa) for enrichment, growth, and isolation of prokaryotes at pressures up to 100 MPa. When coupled with acquisition of pressurized subsurface cores using the HYACINTH pressure retaining drilling and core storage system and the PRESS core-cutting system, Deep-

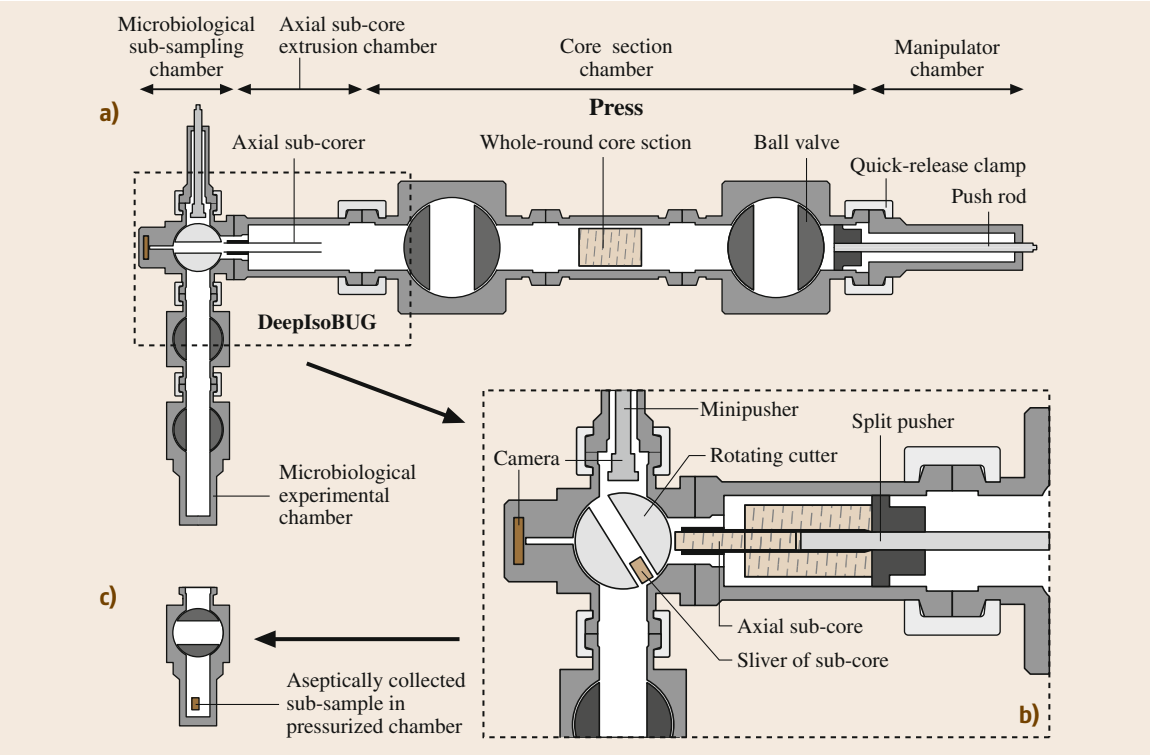

Fig. 12.37a–c Schematic of subcoring and slicing procedure using the coupled PRESS and DeepIsoBUG system to obtain an uncontaminated central core slice for prokaryotic enrichments and other experiments. **(a)** Complete system connected after cutting and transfer of core section. **(b)** Blow-up showing the subcoring and slicing operation. **(c)** Sediment slice isolated in pressure vessel (after *Parkes* et al. [12.72])

IsoBUG enables the recovery and handling of cores at in situ pressures (up to 25 MPa) and subsequent enrichment and isolation of prokaryotes at a range of pressures without depressurization. Using subsurface gas hydrate containing sediments (obtained from the Indian Continental Shelf, the Gulf of Mexico, and the Cascadia Margin), it was examined whether enrichment and isolation of subseafloor anaerobic prokaryotes under elevated pressure, without depressurization, would enable acquisition of different culturable prokaryotes compared with the normal procedure of using depressurized sediments and atmospheric pressure handling and isolation. They found that, in general, highest cell concentrations in enrichments occurred close to in situ pressure (14 MPa) in various growth media, although growth was observed at pressures up to 80 MPa.

The DeepIsoBUG system consists of a subcoring and slicing system (Fig. 12.37), a transfer chamber, an isolation chamber and pressure vessels, described below. The subcoring and slicing system (made of S.S. 316) enables a central subcore (20 mm) to be obtained from a core section and to be sequentially sliced (using a manually rotated blade), with each slice being transferred (using a rotating central section) to a low pressure (up to 25 MPa) vessel (with a large ball valve) containing anaerobic, mineral salts medium, vigorous shaking of which produces a sediment slurry for use as inocula. Two cameras behind sapphire windows allowed viewing of the extrusion process.

Through the transfer chamber, the sediment slurry is transferred from the low-pressure vessel (5 mL slurry aliquots) to a number of high-pressure (up to 100 MPa) culture vessels containing enrichment medium. The chamber also contains a filter ($\approx$ 100 mm) to prevent transfer of large particles that could damage ball valves.

The isolation chamber has 12 agar plates attached to an electric motor-driven chain allowing individual plates to be selected. The chain drive lifts out of the isolation chamber and plates detach so that anaerobic

media can be prepared and the system assembled in an anaerobic chamber and transferred (via an anaerobic bag) to the presterilized and gas-flushed chamber body. The chamber also contains eight detachable cells (up to 15 mL in volume) that allows microbial growth in liquid medium within the chamber and also transfer in and out of the isolation chamber. Enrichments for isolation were transferred into an individual growth cell within the isolation chamber. A motorized robotic arm in the isolation chamber enabled a sterile inoculation loop (electrically heated in situ) to be dipped into the growth cell and its contents to be streaked onto an agar plate. After incubation, individual colonies could then be picked off and transferred to other cells containing sterile media for further growth. Transfer of these purified cultures out of the isolation chamber into high-pressure incubation chambers permitted further subculture and physiological tests to be conducted on isolates. All manipulations in the isolation chamber were viewed through a sapphire window via an endoscope attached to a digital camera and monitor.

Pressure vessels (100 cm^3 total volume, 80 cm^3 medium) made of titanium, used for enrichment and cultivation have a body and a lid, attached together with a screw thread. They are sealed by a male cone in the lid and a complementary female cone in the body, plus O-ring seals. The low-pressure enrichment vessels have a small-bore ball valve (4 mm) on the lid for gas input and liquid transfer, as well as a large-bore ball valve (32 mm) for sediment slice transfer. The high-pressure, incubation vessels have just two small-bore ball valves. Preprepared sterile anaerobic media were transferred into sterile pressure vessels within an anaerobic chamber. For high-pressure liquid transfer between systems, a small pressure differential ($\approx$ 2 MPa) between vessels was maintained. Ball valves were used to prevent shear stresses and possible cell rupture during culture transfer by pressure differential. For routine high-pressure sampling of pressure vessels and subculture into vessels with fresh medium, a bored-out *T*-piece and a series of valves were used, that enabled transfers without depressurization.

The study accomplished the following, viz.:

a) The direct enrichment of subseafloor prokaryotes under elevated pressure.
b) Enrichment of sedimentary, anaerobic prokaryotes without depressurization.
c) High-pressure cultivation from subsurface gas hydrate sediments.

Results showed that many subseafloor prokaryotes from gas hydrate containing sites could grow (anaerobically) up to at least 80 MPa in various media which is a much higher pressure than that previously recorded for subseafloor prokaryotes. As 70% of the ocean is at a pressure of 38 MPa or higher and the average depth of sediments is 500 m, growth at 80 MPa would enable the majority of the subseafloor environment to be populated by prokaryotes. This study was claimed as the first report on the isolation of *Carnobacterium*, *Marinilactobacillus*, *Acetobacterium*, *Clostridium*, and *Bacteroidetes* species from deep, subseafloor, gas hydrate deposits.

Miller et al. [12.73] developed a novel HPHTBR to investigate pressure–temperature relationships (up to 260 °C and 350 bar) in the growth and productivity of the extremely thermophilic methanogenic archaea *Methanococcus jannaschii* isolated from a deep sea hydrothermal vent. The corrosion-resistant reactor system permits direct sampling (of both liquids and gases) from a transparent culture vessel without affecting the internal growth conditions. It was found that increasing the pressure from 7.8 to 100 bar accelerated the production of methane and unicellular protein at 90 °C; raised the maximum temperature for growth from 90 to 92 °C but further increase in pressure did not affect growth. The reactor vessel or pressure cell (internal volume $\approx$ 43 mL) is a transparent synthetic single crystal sapphire tube (I.D. 0.7″, O.D. 1.25″, length 6″) which allows direct visual observation of the growth medium. It may be sealed by two different configurations – one for working at 100 bar consisting of a spring-loaded Teflon gasket held onto the tube ends by flanges which, again, are held in place by six spacer rods. In the other sealing technique, the distance between the flanges is reduced, thus compressing the Teflon rings which, on application of pressure, are further compressed thereby maintaining the seal.

The pressure cell is connected to a magnetic pump to recirculate vapor through the liquid, which serves two purposes, viz. (1) agitation of the liquid and (2) to promote vapor–liquid equilibrium. The pump (I.D. 0.375 in, internal length 2 in) is actuated by a stack of ceramic ring magnets located around the pump body that are oscillated up and down through a motor driven crank and cable. A piston with a plug travels the length of the pump. On the upstroke, gas is pushed out of the pump into the pressure cell, on the down stroke, gas fills the pump for the next stroke. A crank valve at each end of the pump prevents flow in the opposite direction.

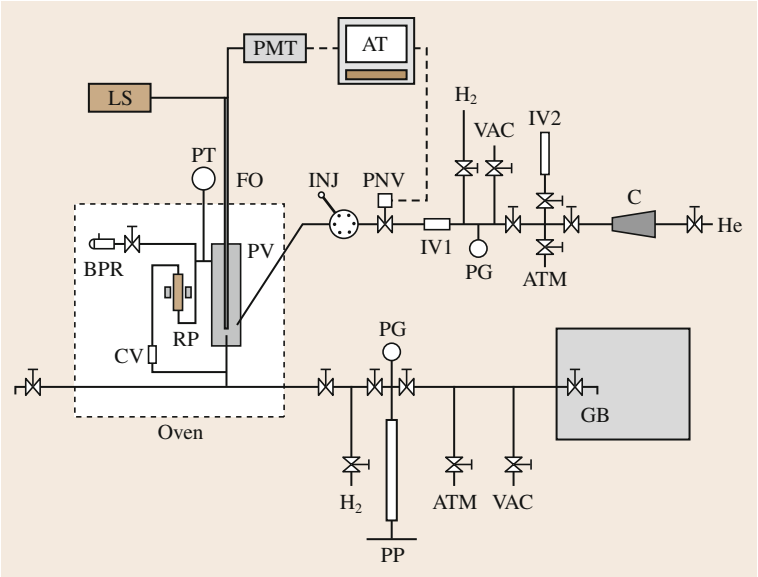

Fig. 12.38 Schematic diagram of the apparatus: PV – stainless steel pressure vessel, RP – magnetically driven vapor recirculation pump, CV – check valve, BPR – back pressure regulator, PT – pressure transducer, FO – fiber optic probe, LS – light source, PMT – photomultiplier tube, water-cooled housing, and photometer, AT – computer, PNV – pneumatic valve, INJ – six-port valve, IV1 – 1 mL injection vessel, HJ – hydrogen supply, PG – pressure gauge, IV2 – 100 mL injection vessel, C – two-stage compressor, He – helium supply, GB – anaerobic glove box, and PP – piston pump. The abbreviations ATM and VAC refer to atmosphere and vacuum, respectively (after *Miller* et al. [12.75])

The pressure cell and magnetic pump are housed in an oven (maximum temp. 260 °C) equipped with a viewing window. The oven temperature is measurable by a thermocouple and a digital thermometer. Pressure is maintained by a triple range strain gauge transducer coupled to a digital voltmeter for display.

All gas entering the high-pressure system is passed through a trap to strictly exclude molecular O_2. For experiments performed at pressures above the cylinder pressure of the gases, a two-stage diaphragm compressor is used to raise the gas pressure. For liquid supply to the reactor vessel, the microbial suspension is drawn (from the anaerobic glove box) into the screw-actuated piston pump, which is operated to raise the pressure on the microbes to the value in the reaction vessel. When the pressure in the pump equals that in the vessel (20 psi initially), the valve is opened for solution inflow to the vessel. In case of methanogenesis, a pressure drop accompanies methane formation – this necessitates use of a pressure regulator for injecting inert gas into the reaction vessel to maintain constant pressure. The regulator also maintains constant pressure when samples are withdrawn. Both the liquid and gas lines are connected to a vacuum system so that lines can be evacuated or purged before material is passed through them into the pressure cell. In this way, molecular oxygen is excluded from the pressure vessel. To prevent corrosion and H_2 embrittlement, all metal parts in contact with high-pressure fluid are made of S.S. 316.

Miller et al. [12.74] cultivated the deep-sea thermophilic archaea *M. jannaschii* in a high-temperature, high-pressure bioreactor (HTHPBR) at high temperatures and hyperbaric pressures of helium. The bioreactor used was similar to a prototypical device described earlier in *Miller* et al. [12.73] modified as follows – the synthetic sapphire pressure vessel (volume 90.63 cm^3) was replaced with a larger S.S. 316 vessel (internal volume, 167 cm^3) capable of withstanding pressures up to 1000 atm; the screw-actuated piston pump was replaced with a higher throughput pneumatic pump to allow rapid addition of fresh medium to the reactor vessel. High hyperbaric pressure of He up to 750 atm was observed to increase the growth rate of *M. jannaschii* at both 86 and 90 °C but did not extend the upper temperature limit for growth. However, increased pressure did extend the maximum temperature for methanogenesis by *M. jannaschii* from < 94 °C at 7.8 atm to 98 °C at 250 atm, indicating a possible pressure-stabilizing effect on enzymes facilitating methane synthesis.

Miller et al. [12.75] designed a HPHTBR for measuring enzyme activity (by UV-visible spectrophotometry/gas chromatography) at temperatures up to 260 °C and pressures up to 667 atm. Initial studies focused on the pressure-enhancement of methyl viologen-reducing hydrogenase activity in crude extracts of *Methanococcus jannaschii*. The oven of this reactor system (Fig. 12.38) contains a S.S. 316 cylindrical

reaction vessel and a magnetically driven pump to recirculate gas through the liquid phase. A fiber optic probe is inserted into the reaction vessel for spectrophotometric measurements (Fig. 12.39). A six-way valve is used to inject substrate or enzyme into the vessel. The rest of the setup is used for transferring fluids and for maintaining constant pressure. The reaction vessel is a custom-built S.S. 316 cylinder (O.D. $3'' \times$ I.D. $\frac{5}{8}'' \times$ length $5\ \frac{1}{2}''$) topped by a high pressure female opening (I.D. $1\ \frac{1}{2}''$, length $\frac{1}{2}''$, threaded 1 in deep, 12 threads in^{-1}) above a $\frac{3}{8}$ in long $60''$ taper. In addition, there is a high-pressure female opening (O.D. $\frac{1}{8}''$) at the bottom of the vessel. Two side arms extend from the vessel: one leads from the injection valve to the liquid phase, and the other from the gas phase to the magnetically driven pump. The pump draws vapor from the headspace and bubbles it up through the liquid. Pressure in the vessel is maintained by a back pressure regulator and measured by a Bourdon tube transducer coupled to a digital voltmeter for display. Temperature is controlled by the oven, which may be operated up to 260 °C.

Nelson et al. [12.76] investigated the effects of hyperbaric helium pressures on the growth and metabolism of the deep-sea hyperthermophilic archaeon, strain designate ES4 (that grows up to 110 °C) in a HPHT bioreactor. Growth studies performed at pressures up to 500 atm in a stainless steel vessel with and without a glass lining indicate that the behavior of ES4, specifically, its ability to grow and its response to elevated hyperbaric pressure, depends overwhelmingly on its environment. ES4 was grown at hyperbaric pressures in an HPHTBR originally developed by *Miller* et al. [12.73] but modified in this study as detailed below. Three pneumatically actuated valves were installed in the gas sampling line for automated sampling. The compressed-air supply to these valves was controlled by electronically actuated solenoid valves, which were in turn controlled by an integrator through a sample/event control module. The integrator was programmed to withdraw samples at any desired interval with less than a 0.75% drop in total system pressure at 500 atm. (The pressure drop was $\approx 2.5\%$ with each sample at 8 atm.) The sample loop had an internal volume of 0.20 cm^3 for pressures up to 10 atm; for higher pressures, its volume was 0.03 cm^3. The larger sample volume at lower pressures was necessary to purge all lines. At each sampling time, two samples were taken: the first to purge the sample lines, and the second for analysis. The lines were evacuated with a vacuum pump between

NPT coupling, E – custom $\frac{7}{8}$ in. high-pressure gland, F – washers, G – $\frac{7}{8}$ in. O.D. $\times \frac{1}{4}$ in. I.D. high-pressure plug with $\frac{1}{4}$ in NPT connector (H) SS316 reaction vessel, (I) $\frac{1}{8}$ in. high-pressure female opening, and J – $\frac{1}{4}$ in. high-pressure collar and gland (after *Miller* et al. [12.75])

all samples. For pressures > 10 atm, a 20 cm^3 reservoir was included between the gas chromatograph and the reactor to allow decompression of the gas sample before it entered the G.C. A back-pressure regulator maintained the gas sample pressure at 120 kPa while the temperature was constant at 100 °C. Helium was used to pressurize the system, and the concentrations of CO_2 and H_2S were measured with a G.C. The final modification was the incorporation of a liquid sampling device that allowed the slow decompression of liquid samples before their removal from the reactor system.

An S.S. 316 high-pressure syringe (internal volume 2.5 mL) was used with a maximum working pressure > 1000 atm. A polycarbonate piston equipped with two

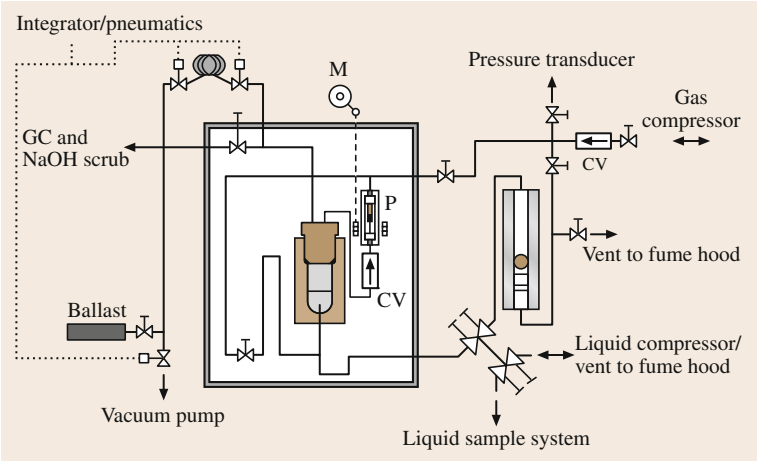

Fig. 12.40 Schematic diagram of modified high-pressure system. CV – check valves; P – gas recirculation pump; M – motor-driven crank; GC – gas chromatograph (after *Nelson* et al. [12.77])

O-rings, separated the culture broth from the hydraulic fluid. A minimum pressure drop of 100 psi across the piston is required for its movement. A second high-pressure syringe (maximum working pressure 250 atm, internal volume 1 mL) was equipped with polycarbonate windows for direct viewing of the sample during decompression.

Nelson et al. [12.77] designed a bioreactor for precise determination of the growth rate as a function of hyperbaric and hydrostatic pressures, simultaneously. The effects of hyperbaric and hydrostatic pressures of up to 500 atm on the growth rate of the deep sea isolate ES4 (*Nelson* et al. [12.76]) were compared at 95, 100, and 105 °C. Results indicate that the microbial growth rate at elevated pressures could have a remarkable dependence on the mode of pressurization.

A previously used high-pressure reactor system (*Nelson* et al. [12.76]) was modified in this study to facilitate studies on hydrostatic pressure concurrently with hyperbaric experiments (Fig. 12.40). A second high-pressure vessel was connected to the gas and liquid lines feeding the hyperbaric system. The temperature and pressure of each vessel were controllable independently, or the pressure could be equilibrated between the two. Temperature was microprocessor-controlled with two types of J thermocouples (one internal and one external) as the input source for the controller. Although He is used as a pressurizing gas, a Teflon piston equipped with O-rings provided a barrier against the direct liquid–gas contact. A ferromagnetic steel ball enabled magnetic mixing of the liquid as required and also marked the location of the piston. The ball could be magnetically lifted to promote mixing prior to sampling, or a stack of ceramic ring magnets could be oscillated up and down by a motor-driven crank and cable if continuous mixing was desired. The hydrostatic vessel (total internal volume 58 mL) has a working volume of 50 mL. The reactor consists of an S.S. 316 tube (length 18″, O.D. 1″, I.D. $\frac{1}{2}$″), with a maximum working pressure of 15 000 psi and a 24 karat gold plated interior surface to reduce corrosion and consequent leaching. The interior of the hyperbaric system was also treated similarly to minimize differences between the two systems. All wetted thermocouples and the steel ball were also gold plated. To minimize erosion of the gold due to piston motion, subsized O-rings (nominal O.D. $\frac{3}{8}$″) were used on the piston, which were stretched to provide a seal. Since the pressure drop across the piston was less than 1 atm when static (up to 10 atm during sampling), little leakage across the piston was detected. It was also possible to use standard $\frac{1}{2}$″. O-rings with deeper-than-standard grooves in the piston to minimize compression of the O-ring. This approach has an advantage of longer O-ring life but could reduce the lifetime of the piston at high pressure. Vertical alignment of the vessel facilitated the removal of trapped gases and containment of sulfur when required.

Hei and *Clark* [12.78] studied the pressure stabilization of enzymes, including a hydrogenase from *M. jannaschii*, an extremely thermophilic deep-sea methanogen, in an anaerobic HTHPBR. *M. igneus, M. jannaschii, M. thermolithotrophicus, and M. maripaludis* (all thermophilic archaea) were grown in artificial seawater medium with a continuous anaerobic gas phase of 20% CO_2 and 80% H_2. The bioreactor (internal volume 10 mL) and all tubings and fittings were constructed of S.S. 316, pressurized with oxygen-

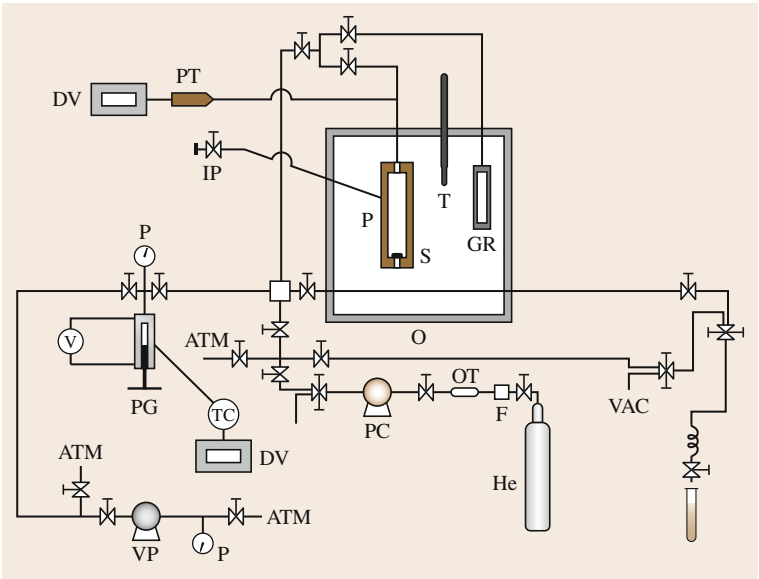

Fig. 12.41 Schematic diagram of the high-pressure reactor used in pressure stability studies. Components shown: P – stainless-steel pressure vessel; GR – gas reservoir; S – water-driven magnetic stirrer; T – ASTM thermometer; O – oven; IP – injection port; PT – pressure transducer; DV – digital voltmeter; P – pressure gauge; PC – pneumatic compressor; F – filter; OT – oxygen trap; PG – pressure generator; TC – thermocouple; V – power supply to heating tape; VP – vacuum pump; ATM – line to atmosphere; VAC – line to vacuum (after *Hei* and *Clark* [12.78])

free helium compressed with a pneumatic compressor and pressure controlled with a manually operated pressure generator (Fig. 12.41). The reactor and the reservoir holding the pressurizing gas were enclosed in a forced-air oven that allowed temperature control to $\pm 0.1\,^{\circ}C$. Agitation of reactor liquid was done by a magnetic stir bar driven by a water-powered magnetic stirrer.

The effect of decompression on the structure of *M. jannaschii*, an extremely thermophilic deep-sea methanogen, was examined in a novel HPHTBR by *Park* and *Clark* [12.79]. The cell envelope of *M. jannaschii* appeared to rupture upon rapid decompression (ca. 1 s) from 260 atm of hyperbaric pressure. However, when decompression from 260 atm was performed slowly over 5 min, the proportion of ruptured cells decreased significantly. In contrast to hyperbaric decompression, decompression from a hydrostatic pressure of 260 atm did not cause cell lysis.

A confined gasket-closure reactor (Fig. 12.42) used as the hyperbaric bioreactor (volume 1.15 L) could be operated up to 200 °C and 590 atm. A thermocouple inserted into an S.S. 316 well extending three-fourths of the way into the bioreactor provided the signal to a PID controller for precise temperature control through a heating belt. A diaphragm compressor was used to supply H_2, CO_2, and He at high pressures. An oxygen trap was installed between the diaphragm compressor and the gas cylinder. The gas atmosphere in the hyperbaric bioreactor was H_2/CO_2 (4 : 1) up to 7.8 atm, and He was used for pressurization > 7.8 atm. For precise pressure control, an air-actuated backpressure regulator was placed in the exit line of the gas loop.

A tubular reactor (volume 65 mL) was used as the hydrostatic bioreactor which was first pressurized with H_2/CO_2 (4 : 1) to 7.8 atm, then pressure was increased to 260 atm hydrostatically by pumping in cells and growth medium. The medium (45 mL) was anaerobically inoculated in a serum bottle with 20 mL of exponentially growing *M. jannaschii* cells, followed by transfer into the hydrostatic reactor through the liquid pump until internal pressure reached 260 atm. Temperature control was achieved by incubating the pressurized hydrostatic bioreactor in an oven. The reactor was reconnected to the system and repressurized to 260 atm every 2 h throughout the incubation period, during which the pressure did not fall by > 10%. After 10 h of cultivation, the hydrostatic bioreactor was depressurized in 1 s and the culture was withdrawn for further analysis.

Girguis et al. [12.80] incubated both marine hydrocarbon seep sediments and marine nonseep (i. e., aerobic) sediments in a continuous-flow anaerobic methane incubation system (AMIS) that simulates the majority of in situ conditions and supports the metabolism and growth of anaerobic methanotrophic archaea. Methane oxidation rates and population growth of MOA (methane oxidizing archaea) were measured over the course of the incubation (24 weeks), thus allowing the evaluation of growth and metabolism of MOA in

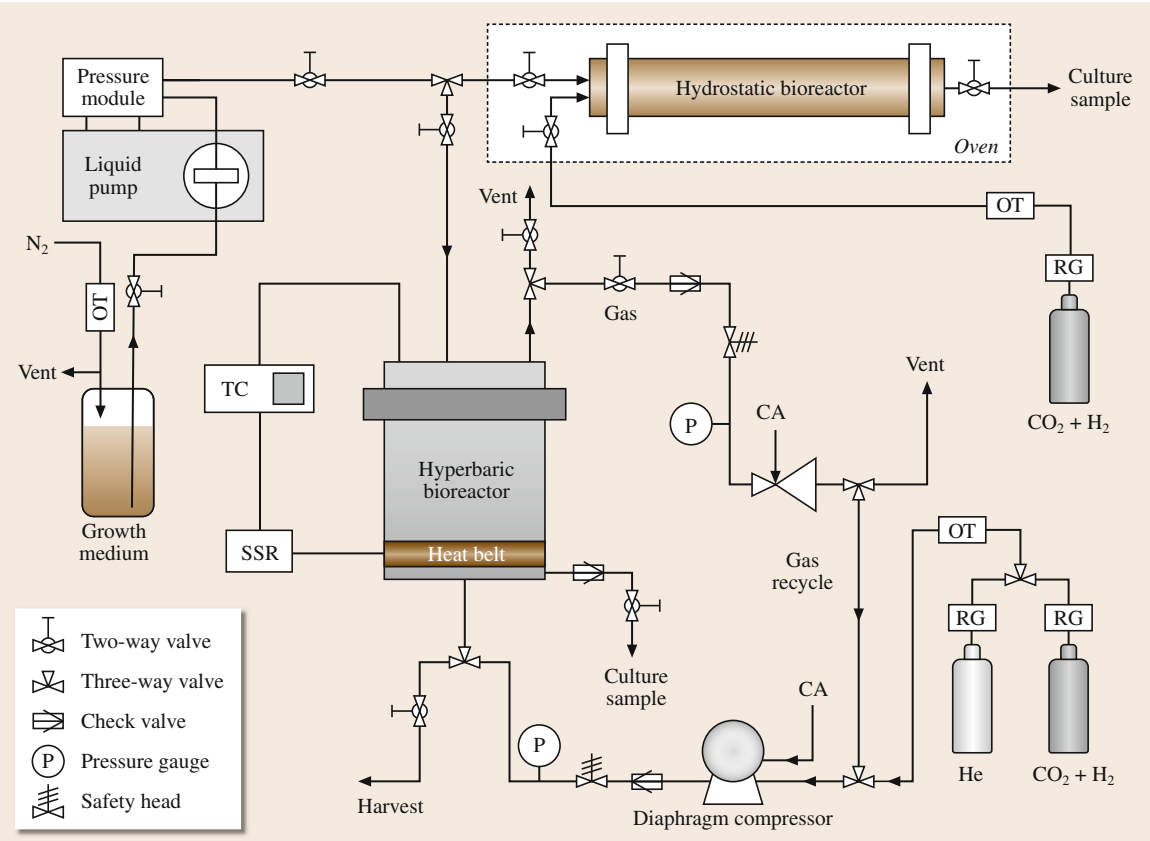

Fig. 12.42 Schematic diagram of a high-pressure, high-temperature bioreactor system. The *dotted lines* signify an oven into which the pressurized hydrostatic bioreactor was placed after being disconnected to control the temperature. SSR – solid-state relay; TC – temperature controller; OT – oxygen trap; CA – compressed air; RG – regulator (after *Park* and *Clark* [12.79])

both seep and nonseep sediments both prior and subsequent to incubation on AMIS.

Conditioned seawater was pumped out of the conditioning column by a diaphragm-metering pump through a capsule filter and rigid polypropylene tubing (I.D. 1.5 cm, O.D. 2.5 cm) into a schedule 80 (PVC) manifold (the *lower* manifold) on which four sediment cores were incubated with a gas- and water-tight seal (using double O-ring seals) maintained on the bottom of each sediment core sleeve. Gas-tight PVC ball valves were installed on both the inlet and the outlet, allowing the manifold to be sealed to maintain anaerobic conditions even during servicing. During operation, the backpressure in the lower PVC manifold was maintained at (200 kPa) by a PVC backpressure valve or by running a length of PVC pipe vertically to create a seawater pressure head at the outlet. After circulating through the manifold, seawater returned to the 25 L reservoir and was recirculated through the conditioning column. The *upper* PVC manifold consisted of PVC tees connected by rigid PVC tubing – here each sediment core sleeve was also sealed to a PVC tee fitting with O-ring seals. The upper PVC manifold was connected to a chilled seawater system (5 °C) and could be sealed at both the inlet and outlet by gas-tight PVC ball valves. During operation, the entire manifold assembly and seawater reservoir were maintained in a cold room at 5 °C. The AMIS system thus successfully stimulated the maintenance and growth of anaerobic methanotrophic archaea, and possibly their syntrophic, sulfate-reducing partners as well.

Houghton et al. [12.81] developed a *PEEK-HPLC column flow-through bioreactor* for continuous enrichment of nitrate and sulfate reducing thermophiles under

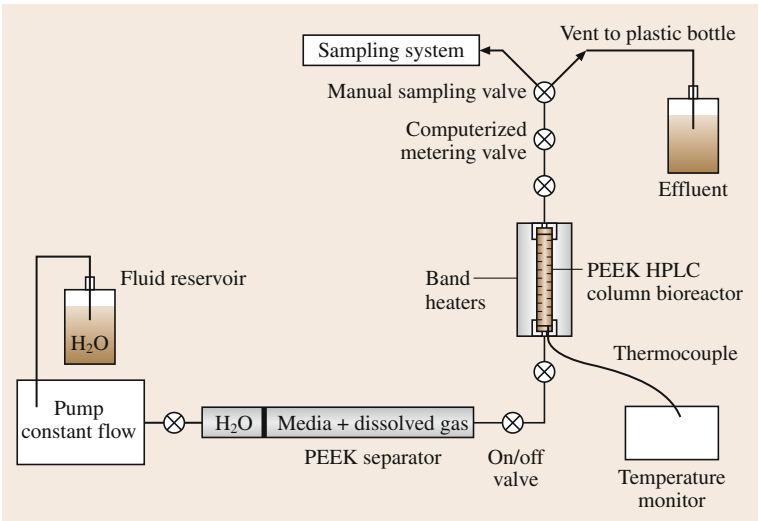

Fig. 12.43 Schematic drawing of the flow-through apparatus designed for this study. All parts were constructed of PEEK plastic, with the exception of the control valves that were composed of stainless steel. The bioreactor in line with the fluid-delivery system contains the sulfide-chimney material used for the experiments. Two thermocouples were attached to the reactor, which in conjunction with a fully automated control system, maintained temperature and pressure within very narrow limits during the 100–180 h experiments (after *Houghton* et al. [12.81])

in situ deep-sea hydrostatic pressures, in order to investigate microbial activity at conditions similar to seafloor hydrothermal vents. The experimental setup (Fig. 12.43) was designed to promote the growth of microbial populations at temperatures $< 100\,°C$ and pressures of ≈ 250 bar while permitting dynamic monitoring of changes in fluid chemistry and microbial diversity.

An HPLC pump and linked *separator* continuously provided fluid reactants and dissolved gases at high pressure to bioreactor columns made of PEEK (I.D. 0.75 cm, length 10 cm, volume 4.41 cm^3), which were maintained at a constant temperature by a series of band heaters external to the reactor and enclosed in an insulated tube furnace. Time proportioning controllers provided temperature control in response to input from a series of thermocouples directly attached to the reactors in the furnace. Except flow control valves, made from S.S. 316, all wetted parts of the fluid delivery and control system were made of PEEK, although buna O-rings were used as pressure seals throughout. Moreover, all tubing, PEEK reactors, and stainless valves were replaced between experiments to minimize contamination effects. Fluid samples could be taken throughout experiments by activating manual and computer-controlled valves, which not only diverted sample fluid into gas-tight containers for processing, but also maintained the system at the desired pressure. The media, mainly artificial seawater was prepared under anaerobic conditions, which were also maintained by bubbling CO_2 and H_2 through the media while filling the separator, which, by piston action, was used to achieve high-pressure conditions. The separator permitted appropriate amounts of gas to be dissolved in the media by filling a headspace with gas before fully pressurizing the system. The media used for all experiments was thus saturated with dissolved CO_2 and contained ≈ 2.2 mM H_2. Water delivered at high pressure to the input side of the piston in the separator ensured complete dissolution of the gas in the media as well as complete pressurization to the operational condition of 250 bar.

The study achieved growth and culture enrichment of thermophiles under conditions of temperature and pressure in a flow-through bioreactor that provided an effective means for investigating hydrothermal systems at temperatures, pressures, and chemical conditions similar to seafloor chimney (vent) deposits and their associated microbial communities.

Deusner et al. [12.82] developed a novel two-stage high-pressure bioreactor system for gas-phase free continuous incubation of enriched, highly active marine microbial consortia (prepared from microbial mats obtained from the Black Sea at a depth of 213 m) performing anaerobic oxidation of methane (AOM). The systems developed, viz., High-pressure continuous incubation system (HP-CI) and high-pressure manifold incubation system (HP-MI) were used to demonstrate the feasibility of investigating bioprocesses in high-pressure fed-batch or continuous incubation systems with gas-enriched medium without free gas in the incubation stage. In continuous operation in the HP-CI system, initial methane-dependent sulfide production increased 10–15 times on increasing methane par-

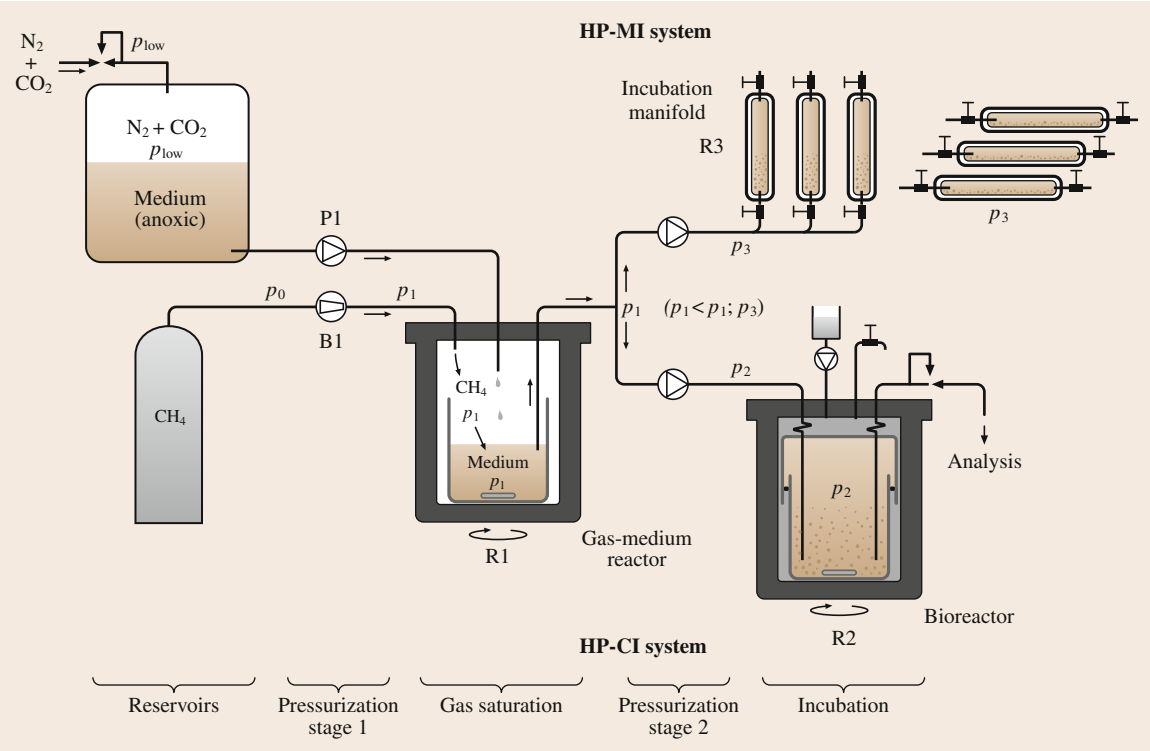

Fig. 12.44 Incubation principle. In two-stage operation, medium is enriched with methane under high-pressure conditions in the continuously stirred gas-medium reactor R1. The gas-enriched medium is further transferred to the bioreactor R2 or R3. Pressure p2 and p3 within R2 and R3, respectively, is increased compared to p1 in R1. In R1, R2, and R3 medium and culture fluid are contained in internal vessels to avoid contact to the metal surfaces. Incubation is carried out without free gas in R2 and R3. To compensate pressure/volume changes in R2 the internal vessel is adjustable in volume. Pressure vessels in R3 can be detached and manipulated separately. Sensors for electronic regulation are not indicated (after *Deusner* et al. [12.82])

tial pressure from near ambient pressure (0.2 MPa) to 10 MPa at a hydrostatic pressure of 16 MPa in the incubation stage. A methane partial pressure of 6 MPa and a hydrostatic pressure of 12 MPa in manifold fed-batch incubation in the HP-MI system gave a sixfold enhancement in the volumetric AOM rate.

The HP-CI system (Fig. 12.44) consists of a two stage high-pressure reactor, viz., a gas-medium reactor (R1) and a bioreactor (R2), along with two high-pressure pumps (P1, P2), and a gas compressor station (B1). Continuous enrichment of medium with methane in R1 occurs at pressures up to 20 MPa. In R1, while gas transfer from the headspace into the medium is expedited by agitation using a magnetic stirrer, liquid remains confined within an internal vessel (made of inert polymeric materials e.g., poly-ether-ether-ketone (PEEK) or poly-oxy-methylene (POM)) that prevents corrosion of the pressure vessel as well as contamination of the biomass. In R1 the fluid flow and the liquid level are automatically adjusted with constant – flow inflow and outflow pumps (P1 and P2) and is also monitored gravimetrically. The pressure P1 is adjusted with the gas compressor unit B1, operated in constant pressure mode, which is linked to R1 through a gas-distribution system comprising of a shut-off valve, a pressure-regulating valve, and a metering valve for fine regulation of gas flow. Pressurized gas can be supplied either batchwise or continuously, which facilitates continuous exchange of the gas phase in R1 and may be utilized for supply of low-concentration gaseous substrates during continuous operation.

Incubation in R2, may be performed up to a hydrostatic pressure of 35 MPa. The gas-enriched medium is transferred to R2 via pump P2 which is set to increase

the hydrostatic pressure relative to the pressure in R1 from P1 to P2 and allows incubation at increased hydrostatic pressure compared to the methane partial pressure in R1. The fluid flow in R2 is also automatically adjusted with pump P2 working in constant flow mode. R2 is also equipped with an internal vessel (made of PEEK or POM) to prevent potential chemical contamination of the biomass. Due to the mode of headspace-free incubation, the internal vessel is designed as a closed vessel. For compensating pressure or volume changes it is has a top and a bottom part and its volume is adjustable. The bottom part is equipped with an O-ring sealing that permits axial movement of the two parts relative to each other. The internal vessel is housed inside the pressure vessel surrounded by a hydraulic fluid that can be pressurized independently. Under standard operating conditions, the free volume for incubation is 420 mL within R2. Medium transport upstream and downstream of R2 is carried out through a tubing that is directly connected to the internal vessel through flexible lead-through systems. The internal vessel can be heat-sterilized and inoculated. The culture broth inside R2 is agitated with a magnetic stirrer. Liquid samples were taken from downstream section of both R1 and R2 at the sampling ports, directly into glass vials closed with butyl stoppers or into glass syringes after opening the shut-off needle valves in the sampling lines.

The HP-MI system (R3), originally developed (*Kallmeyer* et al. [12.71]) for high-pressure/high-temperature (HPHT) batch incubation, was modified and adapted in this study to be operated for manifold fed-batch incubation. Gas enrichment of liquid medium and delivery is attained in a similar method as in the HP-CI system. Each pressure vessel is equipped with shut-off valves at the inlet and outlet, respectively, and can be manipulated independently. Gas-enriched medium is transferred separately to each of the high-pressure vessels and each vessel is filled in upstream mode. Like R2, pressure vessels in R3 are operated without free gas and are equipped with internal vessels (free volume for incubation, 7 mL) (made of PEEK or POM), which are constructed as open vessels that seal against the steel by a polytetrafluoroethylene (PTFE) plate that presses into the cap of the steel vessel. While the medium is delivered into an internal vessel via lead-through tubings (similar to R2 in the HP-CI system), the upper outlet of an internal vessel has a built-in glass filter plate which allows permeation by both gas and liquid medium. Before sampling the biomass was allowed to settle to the bottom of the internal vessel; subsequently, an aliquot of the supernatant was collected through the bottom capillary while the sampled liquid volume was replaced with gaseous methane through the top capillary at the pressure corresponding to the saturation methane partial pressure applied during incubation. On commencing the fed-batch mode of operation, the design of the internal vessels ensured that the gas introduced during sampling was completely removed during filling of the vessels under high-pressure conditions.

This study demonstrated that biomass-specific activity increases substantially as a function of methane partial pressure in both continuous and fed-batch incubation. The systems could be used to control incubation parameters and to simulate environmental conditions with regard to constant substrate supply and product removal in continuous incubation. Stability with respect to sulfide production in continuous operation and reproducibility of results from manifold fed-batch incubation indicate that both the system components and the experimental procedure could be successfully applied for the study and incubation of AOM-performing marine microbial consortia.

Zhang et al. [12.83] developed a novel, continuous high-pressure bioreactor (HPBR) system to mimic a diverse methane-rich deep-sea ecological niche, to stimulate in vitro sulfate reduction (SR)-coupled- anaerobic oxidation of methane (AOM) activity; and to examine the kinetics of the SR-AOM process. The HPBR system (Fig. 12.45) comprises three main parts: (a) the conditioning vessel, (b) the high-pressure pump, and (c) the incubation vessel. The conditioning vessel (volume 1 L) made of S.S. 316 is directly connected to two pipettes – a liquid pipette (to charge liquid medium at high-pressure) and a gas pipette (to charge methane gas at high-pressure) both of which are pressurized by the methane gas bottle. Artificial seawater medium is saturated with methane at a determined pressure (up to 8 MPa) in the conditioning vessel and transferred to the incubation vessel by a high-pressure pump. In the conditioning vessel, built-up gas pressure determines the amount of methane saturated into the medium and available as substrate. A motor-mixer (40 rpm) is used to achieve a homogeneous dissolved methane concentration in the whole vessel. The high-pressure pump is piston based with a separated chamber to rinse the piston while it is moving – this self-flushing mechanism allows feed of saline water without damage to the piston and its seals. The incubation vessel (volume 0.6 L), made of titanium to prevent potential microbial corrosion, is placed inside a thermal regulated incubator (5–55 °C) to control the incubation temperature. The pressure inside this incubation vessel could be in-

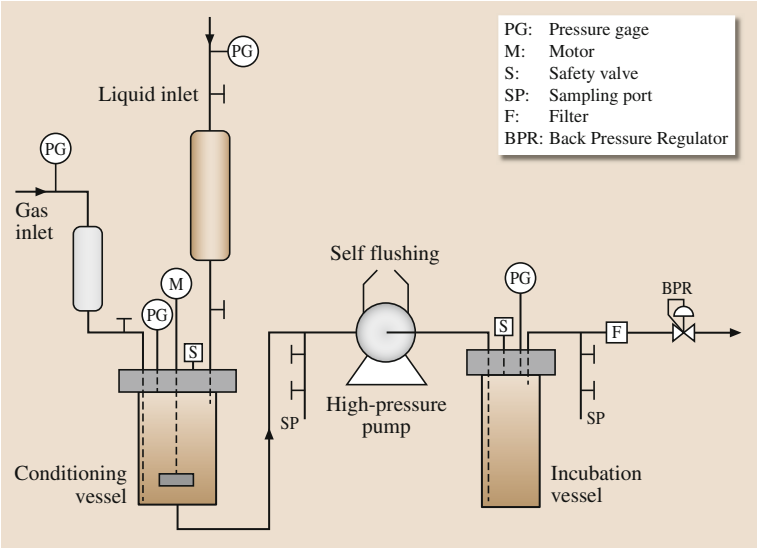

Fig. 12.45 The continuous high-pressure bioreactor system. PG – pressure gage; M – motor; S – safety valve; SP – sampling port; F – filter; BPR: back pressure regulator (after *Zhang* et al. [12.83])

creased to 16 MPa, and is regulated by the pump flow and a backpressure regulator. Two sampling ports were provided – one between the conditioning vessel and the high-pressure pump to take influent samples; the other between the incubation vessel and the backpressure regulator to take effluent samples.

Marteinsson et al. [12.84] examined the growth and survival of the deep-sea hyperthermophilic archaeon *Pyrococcus abyssi* GE5, isolated from hydrothermal vents in the North Fiji Basin at a depth of 2000 m, in sterile gas-tight glass syringes with cut pistons incubated in a high-pressure high-temperature (HPHT) cultivation system (Fig. 12.46) consisting of four S.S. pressure vessel incubators heated in four vertically positioned ovens (300 °C maximum). Pressure was generated with a hydraulic pump (with cold tap water as the hydraulic fluid) and monitored by Bourdon gauges (100 MPa) (maximum working pressure 60 MPa). Thermocouples, one internal and one external, were used for each pressure vessel, independently connected to a microprocessor in a temperature controlling unit, and the vessels could be heated from room temperature to 100 °C in < 30 min. The authors concluded that the effect of growth temperatures and pressure on the deep sea hyperthermophilic archaeon *P. abyssi* was associated with changes in the level of phospholipids more than the level of core lipids or proteins. The resistance shown by *P. abyssi* to lethal temperatures under in situ pressure was considered as the principle reason for its surviving tremendous spatial variability in temperature.

Marteinsson et al. [12.85] studied the effect of pressure, in pressurized syringes, at the temperature range for the growth of *Thermococcus barophilus* sp. nov. (Strain MP^T), a barophilic and hyperthermophilic, anaerobic, sulfur-metabolizing archaeon, isolated under high hydrostatic pressure (40 MPa) and temperature (95 °C) from a deep-sea hydrothermal vent (depth 3550 m). All culturing procedures before the high-pressure experiments were carried out under anaerobic conditions. Samples, stored at 4 °C under 40 MPa hydrostatic pressure, were depressurized and 0–5 mL suspension/fluids were transferred into 10 mL syringes which were sealed (by plunging needles into rubber stoppers), before media/samples were dispensed in them. Finally, the pistons were positioned and the gas phase was purged out before fastening the seal on each syringe. The syringes were then transferred into the HPHT incubation system (*Marteinsson* et al. [12.84]) pressurized to 40 MPa and heated to 95 °C. The archeaon was found to be barophilic at 75, 80, 85, 90, 95 and 98 °C, and was identified as an obligate barophile between 95 and 100 °C. For growth > 95 °C, a pressure of 15.0–17.5 MPa was necessary. It grew at 48–95 °C under atmospheric pressure. The optimal temperature for growth was 85 °C at both high (40 MPa) and low (0.3 MPa) pressures. The growth rate at 85 °C under in situ hydrostatic pressure was double that noted at low pressure.

Wright et al. [12.86] demonstrated the potential of high pressure as a stressing agent for marine bioprocess intensification by evaluating and confirming the

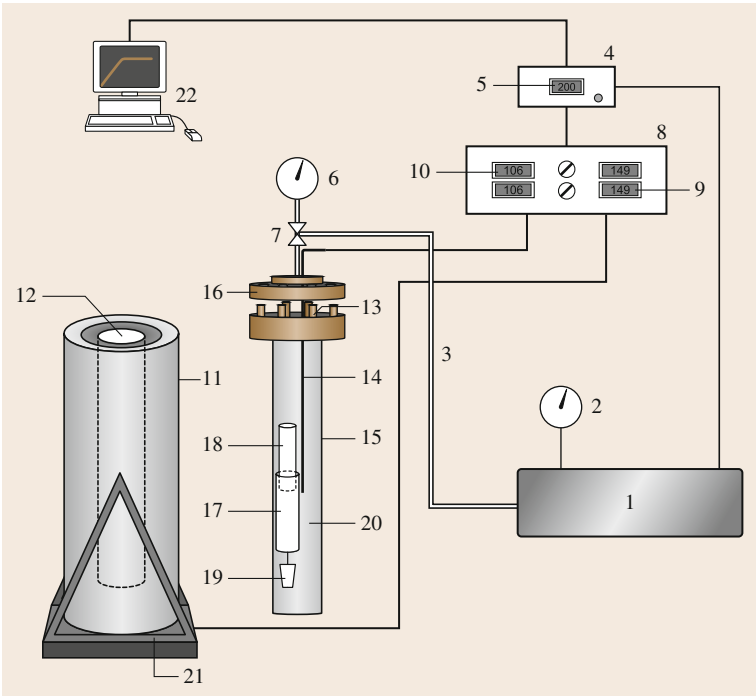

Fig. 12.46 Schematic representation of the high-pressure apparatus *hot bucket* for cultivating microorganisms at high temperature and pressure. One unit of four is shown. Each can be loaded or unloaded separately while the others are kept under constant temperature and pressure conditions. [12.84])

barotolerance (at 12 MPa) of several marine bacteria isolated from shallow surface waters (< 1.5 m depth, pressure < 50 Pa) rather than from the deep sea. For this purpose, they used a high-pressure batch bioreactor (HPBBR) to create a maximum hydrostatic pressure of 120 MPa and to survey the pressure tolerance of the marine isolates. The HPBBR (maximum working volume 3.9 mL) was made of stainless steel and hydrostatic pressure was applied to the culture broth using an electrically driven piston. High-pressure cycling was employed since it is known to lower the tolerance of the microorganisms to high pressure. Interestingly, it was observed that barotolerance was much higher in bacteria obtained from biofilms anchored to the surface of seaweed than those isolated from open waters. It was noted that barotolerant rather than barophilic microorganisms is much more preferable for most bioprocess engineering operations as isolation and culture enrichment of barophiles is technologically more challenging as the barophilic strains must be continuously maintained at the remarkably high-pressure levels (> 50 MPa) for viability.

13. Transgenic Technology in Marine Organisms

Thomas T. Chen, Chun-Mean Lin, Maria J. Chen, Jay H. Lo, Pinwen P. Chiou, Hong-Yi Gong, Jen-Leih Wu, Mark H.-C. Chen, Charles Yarish

Marine organisms into which a foreign gene or non-coding deoxyribonucleic acid (DNA) fragment is artificially introduced and stably integrated in their genomes are termed transgenic marine organisms. Since the first report in 1985, a wide range of transgenic fish and marine bivalve mollusks have been produced by microinjecting or electroporating homologous or heterologous transgenes into newly fertilized or unfertilized eggs and sperm. In the past few years, rapid advances of gene transfer technology has resulted in the production of many genetically modified organisms (GMOs) such as fish, crustaceans, microalgae, macroalgae, and sea urchins. These GMOs are valuable in assisting the advances of basic research as well as biotechnological application. In this chapter, the principle of producing transgenic marine organisms and the application of the technology to produce genetically modified marine organisms in the hope of improving the quality of human life as well as the earth environments will be critically reviewed.

13.1 Synopsis

Marine organisms into which a foreign gene or non-coding DNA fragment is artificially introduced and integrated in their genomes are termed transgenic marine organisms. Since 1985, a wide range of transgenic fish species and marine bivalve mollusks have been produced mainly by microinjecting or electroporating homologous or heterologous transgenes into newly fertilized or unfertilized eggs and sometimes, sperm [13.1–5]. More recently, transgenic *Artemia* [13.6], microalgae [13.7], macroalgae [13.8], and sea urchins [13.9] have also been produced. Among the many transgenic marine organism species developed, transgenic fish species are the most abundant. To produce the desired transgenic marine organisms, several factors should be considered. First, an appropriate marine organism species must be chosen. This decision should depend on the nature of the study and the ability to maintain the organism in a biosafe containment facil-

ity. Second, a specific gene construct must be designed, based on the special requirement of each study. For example, the gene construct may contain an open reading frame encoding, a gene product of interest, and regulatory elements that regulate the expression of the gene in a temporal, spatial, and/or developmental stage-specific manner. Third, the gene construct must be introduced into sperm or embryos in order for the transgene to be stably integrated into the genome of embryonic cells. Fourth, since not all instances of gene transfer are efficient, a screening method must be adopted to identify transgenic individuals.

Since the development of the first transgenic fish in the mid-1980s, techniques to produce transgenic marine organisms have improved tremendously, resulting in the production of many GM marine species. In recent years, transgenic marine organisms have been established as valuable models for different disciplines of biological research, as well as human disease modeling. In addition, the application of transgenic technology to produce fish and other marine organisms with beneficial traits, such as enhanced somatic growth, disease resistance, and production of products for biotechnological applications, is also rising. In this chapter, the principle of producing transgenic marine organisms, especially transgenic fish, as well as the application of the technology to produce GM marine organisms to benefit humans will be critically reviewed.

13.2 Production of Transgenic Marine Organisms

13.2.1 Transgene Constructs

A transgene is a piece of DNA containing a non-self-origin or self-origin gene that is introduced into marine organisms for the production of transgenic marine organisms. Transgenes are usually constructed in plasmids that contain the desired structural genes and appropriate promoter/enhancer elements for proper expression of transgenes in marine organisms. At the beginning of the development of the technology for producing GM marine organisms, a variety of promoters from non-marine species were employed to control the expression of transgenes (Table 13.1). More recently, an increasing number of promoter/enhancer sequences of marine species origin (Table 13.1) have also been used for the purpose of generating *all-marine organism* expression cassettes. Among these all-marine-organism expression cassettes, the carp β-actin promoter from common carp [13.10, 11] has been shown to drive strong expression of transgenes in various fish cell types. Tissue-specific promoters and inducible promoters such as zebrafish *heat shock protein 70* (*hsp70*) have also been used to control the expression of transgenes in the desired tissue(s) under the desired conditions(s). For example, activation of the *hsp70*-controlled transgene can be achieved by heat shock and, intriguingly, by focusing a sublethal laser microbeam onto individual cells carrying the transgene [13.12]. The targeted cells appear normal after treatment.

Depending on the purpose of the gene transfer studies, transgenes can be grouped into three major types: i) *gain-of-function*, ii) *reporter-function*, and iii) *loss-of-function*. The basic feature and the function of these transgenes are discussed below.

Gain-of-function transgenes: transgenes of this type are designed to add new functions to the transgenic individuals or to facilitatey the identification of the transgenic individuals if the genes are expressed prop-

Table 13.1 Examples of representative promoters used in the production of transgenic fish

Origin of species	Promoter
Non-fish origin	
Rat	GAP43[a] ([13.12])
Chicken	β-actin ([13.13])
Xenopus	Elongation factor 1α ([13.14])
Cytomegalovirus	CMV intermediate-early ([13.15])
Moloney murine	MoMLV LTR ([13.16])
Leukemia virus	
Fish origin	
Carp	β-actin ([13.10, 11])
Goldfish	α 1 tubulin[a] ([13.10])
Medaka	Elongation factor 1α ([13.17]), β-actin ([13.18])
Zebrafish	H2A.F/Z ([13.19]), α-actin[a] ([13.20]), heat shock protein 70[b] ([13.21]), VTG[c] ([13.22]), Cyp19a1b[d] ([13.23])

[a] Tissue-specific promoters-GAP43: nervous system, α1 tubulin: nervous system, α-actin: muscle specific, [b] Heat inducible promoters; LTR: long terminal repeat; H2A.F/Z: histone H2A.F/Z, [c] VTG, estrogen inducible vitellogenin promoter, [d] estrogen inducible/tissue specific aromatase gene promoter

erly in the transgenic individuals. The coding region of the transgenes is usually homologous or heterologous genomic, or complementary DNA (cDNA) sequences which encode polypeptide products (Fig. 13.1a). The expression of transgenes is usually driven by promoter/enhancer sequences of homologous or heterologous sources. If transgenes a contain sequence of functional signal peptides, the gene products will be secreted out of cells once they are synthesized. Transgenes containing the structural gene of the mammalian or fish growth hormone (GH) or the respective cDNA fused to a functional promoter/enhancer of chicken or fish β-actin gene, are examples of the gain-of-function transgene constructs. Expression of such transgenes in transgenic individuals has been shown to result in growth enhancement [13.13–16, 24]. Winter flounder antifreeze protein gene or chicken δ-crystalline genes with their respective promoter/enhancer sequences are other commonly used gain-of-function transgenes in various gene transfer studies [13.18, 19].

Reporter-function transgenes: the prototypes of a reporter-function transgene are shown in Fig. 13.1b. Genes such as bacterial chloramphenicol acetyltransferase (CAT), β-galactosidase (β-gal), neomycin phosphotransferase II (*neo*^{R}), luciferase, and green fluorescent protein (GFP) [13.20] are frequently used to produce a gene construct with a reporter-function (Fig. 13.1b). These reporter genes serve as a convenient marker for showing the success of gene transfer into target cells, since the translational products of these genes can be easily monitored. Furthermore, because these gene products can be measured quantitatively, they are also routinely adopted to identify the sequence of an undefined promoter/enhancer or to measure the relative activity of the promoter/enhancer element in question. A less frequently used reporter type is one with target-specificity. One such example is cameleon, a fluorescent calcium sensor, which was originally used to detect calcium transients in culture cells and pharyngeal muscles of *Caenorhabditis elegans*. Recently, cameleon and several other indicator genes have been used to establish transgenic zebrafish to monitor neuronal activity [13.21, 22].

Among the commonly used reporter genes, GFP and its variants identified in jellyfish (*Aequorea victoria*) have become the popular choice of markers for transgenic fish because of the easy and sensitive detection of GFP signals [13.20]. There are numerous GFP variants available, including those producing green, blue, and yellow fluorescent light. Together with red fluorescence protein (RFP), these reporters can be easily detected in the live transgenic fish such as zebrafish and medaka, whose embryos and bodies are transparent without the need to sacrifice the fish [13.20]. Additionally, these reporters can be used to study multiple transgenes simultaneously in the same fish. Since the first GFP transgenic fish produced in 1995 [13.20], GFP-tagged transgenic embryos and fish have become the most convenient and widely used tools in basic biological research, particularly in the regulation of gene expression, morphogenetic movements of cells, and organogenesis during embryonic development [13.17, 21, 23, 25]. More recently, the transgenes of GFP and their variants driven by tissue-specific promoters have also been transferred into medaka, zebrafish, and other

ornamental fish for commercial application [13.26, 27]. Similar applications have also been used with the other reporter genes mentioned above. However, the detection of these reporters is indirect and requires additional steps, such as enzymatic reaction with substrate or immunohistochemical staining with specific antibody to view the reporter gene products.

Lost-of-Function Transgenes: the loss-of-function transgenes are constructed for interfering with the expression of host genes at the transcriptional or translational level. This type of transgene construct is commonly used to inactivate the functions of genes through the mechanism of knocking down the expression of genes or knocking out the gene in various organisms (for a review, see [13.30, 31]). The prototypes of loss-of-function transgenes are shown in Fig. 13.1c. There are at least five types of loss-of-function transgenes. The first type of loss-of-function transgenes may encode antisense RNAs or oligonucleotides that selectively hybridize to an endogenous target messenger RNA (mRNA) of a gene, resulting in degradation of the mRNA by RNase H, or interference with translation of the mRNAs via preventing the binding of ribosomes to mRNA (Fig. 13.1c1, [13.31, 32]). A variation of the antisense RNA approach is to introduce a group of chemically modified oligonucleotides known as morpholino phosphorodiamidate oligonucleotides (MOs) into fish embryos [13.33–37]. In contrast to ordinary antisense molecules, MOs exhibit longer-term stability with less toxicity to living cells and appear to function through translation blockage only. If the MO target site contains bases flanking the intron junction, this MO antisense ribonucleic acid (RNA) can also block the splicing of respective precursor mRNA and thus knock down the gene activity [13.38]. The second type of loss-of-function transgenes express catalytic RNAs (ribozymes) that can cleave specific target mRNAs at a specific site and thereby *knock down* the normal level of gene expression (Fig. 13.1c2, [13.39–41]). The third group of *loss-of-function* transgenes expresses a group of small RNAs known as small (short) interfering RNAs (siRNAs). The prototypes of these genes are shown in Fig. 13.1c3a–c. Since the siRNAs contain sequences homologous to endogenous mRNAs to be regulated, they will guide a ribonuclease known as the RNA-induced silencing complex (RISC) to recognize the respective mRNAs and result in degradation of the mRNAs [13.42–47]. In recent years, several stable transgenic zebrafish lines carrying siRNA or miRNA transgenes have been produced [13.47].

The forth type of loss-of-function transgenes (Fig. 13.2a) is designed to express mRNAs that encode three zinc figure domains linking to the cleavage domain of *Fok*1 restriction endonuclease (ZFN). By introducing transgene expressing specific ZFN mRNA into cells or newly fertilized egg, incision of the gene to be inactivated will occur; and via the error-prone cellular repair enzymes, additional bases will be incorporated into the site of incision and result in creating a gene knockout without using embryonic stem cell lines that are not yet available in fish system [13.48–53]. By varying the number and type of zinc finger peptide (ZFP) in each ZFP-*Fok1* chimera, a cleavage component dimer may be targeted to a user-chosen site of sufficient length (18−36 bp) for a single occurrence in a gene. The ZFN transgene has been used to inactivate genes in zebrafish [13.54–56] and yellow catfish [13.57]. While ZFN is a very powerful technique for gene editing in fish, there exist some complication issues with the designing and application of ZFN. These complications are: i) some ZFNs have been associated with cytotoxicity due to cleavage at the off-target site, and ii) in some cases it is difficult to engineer ZFNs with the desired binding specificity [13.57]. To avoid these problems, scientists have turned to the use of the technique of TALEN (the fifth type of loss-of-function transgenes, Fig. 13.2b) for gene inactivation in zebrafish with greater success [13.58–60]. TALENs are novel

fusion proteins that are engineered by assembling the DNA-binding motif of the transcription activator-like effector (TALE) protein from *Xanthomonas* with *Fok1* nuclease. These molecules function similarly to ZFNs. Since TALEN-binding sites are expected to occur about once in every 35 base pairs on random DNA sequences, they will provide a greater flexibility in the selection of the target sites [13.61]. Very recently, another new method of gene inactivation has emerged from studies conducted on bacteria and archaea. In bacteria and archaea, there exists arrays of clustered, regularly interspersed short palindromic repeat (CRISPR) and CRISPR-associated (CAS) genes that can provide acquired resistance against phages by degrading the phage DNA or RNA [13.28, 62, 63]. From further studies on the structural features of the CRISPR and CAS systems, rational designing of CRISPR RNAs, and the CAS protein have been worked out for direct in vivo cleavage of RNAs or DNAs in zebrafish or other organisms [13.64].

13.2.2 Selection of Marine Organism Species

Gene transfer studies have been conducted in several different aquatic organisms including fish, shrimp, bivalves and algae. Since 1985, transgenic fish have been produced for many fish species such as salmon, rainbow trout, common carp, goldfish, loach, channel catfish, northern pike, seabream, tilapia, walleye, zebrafish, and Japanese medaka [13.1–3]. Depending on the purpose of the transgenic studies, the embryos of some fish species prove to be more suitable than others. In selecting a fish species for gene transfer studies, for instance, a series of parameters should be considered. These parameters are:

i) Life cycle length
ii) Year round supply of eggs and sperm
iii) Culture conditions
iv) Size of the adult at maturity, and
v) Availability of background information on genetics, physiology, and endocrinology of the fish species [13.5].

Japanese medaka (*Oryzias latipes*) and zebrafish (*Danio rerio*) are regarded as ideal fish species for conducting gene transfer studies. Both fish species have short life cycles (3 months from eggs to mature adults), produce hundreds of eggs on a regular basis without exhibiting a seasonal breeding cycle, and can be maintained in the laboratory for 2−3 years. Their eggs are relatively large (1.0−1.5 mm in diameter) and possess very thin and semi-transparent chorions. These features allow easy injection of DNA into the newly fertilized eggs if appropriate glass needles are used. Furthermore, inbred lines and various morphological mutants of both fish species are available. These fish species are ideal candidates for producing transgenic fish for:

i) Studying developmental regulation of gene expression and action
ii) Identifying *cis*-acting elements that regulate the expression of a gene
iii) Measuring the activity of promoters
iv) Producing transgenic models for human diseases and environmental toxicology. While the advantage of using zebrafish or medaka as transgenic model animals is due to the wealth of genetic and genomic databases, a major drawback of these two fish species is their small body size, which makes them less suitable for endocrinological and biochemical studies.

The handicap of using medaka or zebrafish as experimental animals in gene transfer studies can be overcome by the use of fish species such as loach, killifish (*Fundulus*), goldfish, and tilapia. The body sizes of these fish species are big enough to collect sufficient amounts of blood or tissue samples from individual fish for biochemical and endocrinological studies. Another important attribute of these fish species is their shorter maturation time compared to rainbow trout or salmon. In particular, tilapia is a very appropriate medium-sized fish species for gene transfer studies, since it only requires about 4 months to reach reproductive maturation. It is possible to produce almost three generations of transgenic tilapia in 1 year. Unfortunately, the lack of a well-defined genetic background and the asynchronous reproductive behavior of these fish species present some problems for the collection of a sufficient number of newly fertilized eggs to conduct gene transfer, unless a large number of reproductively mature fish is available.

Rainbow trout, salmon, channel catfish, and common carp are commonly used as large body size model fish species for transgenic fish studies. Since an extensive knowledge of the endocrinology, reproductive biology, and physiology of these fish species is available, they are well suited for studies on comparative endocrinology, as well as aquaculture application. However, the maturation time for each of these fish species is relatively long. For example, rainbow trout and salmon require 2–3 years to reach reproductive maturity, and common carp or channel catfish require

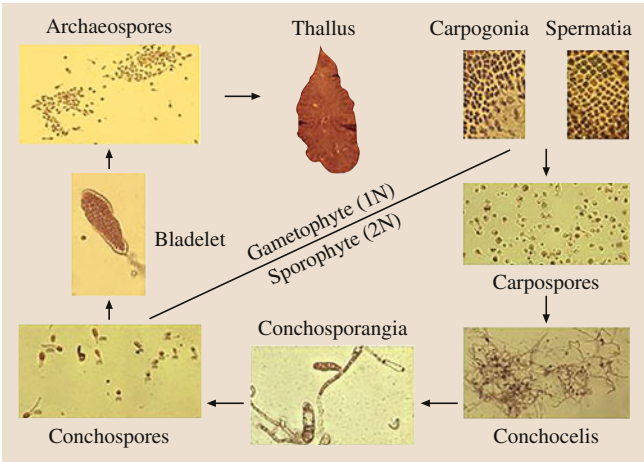

Fig. 13.3 Life cycle of Porphyra

about 1–2 years. Thus it will prolong inheritance studies. In addition, since these fish species have only a single spawning cycle per year, this restricts the number of gene transfer attempt that can be conducted per year.

Marine macroalgae, such as *Porphyra* and *Laminaria*, have a biphasic life cycle that alternates between macroscopic, foliose, gametophytic phase, and microscopic, shell-boring, sporophytic filaments referred to as the sporophytic phase (Fig. 13.3; [13.29, 65]). Since the genetic make-up of the gametophytic phase of *Porphyra* and *Laminaria* are haploid, they are suitable for gene transfer studies for biotechnological applications.

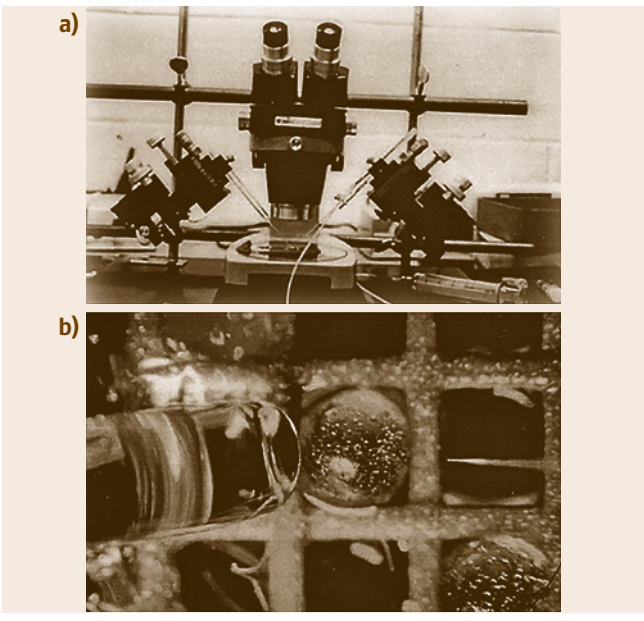

Fig. 13.4 (a) Microinjection setup; (b) microinjection of a medaka egg

13.2.3 Methods of Gene Transfer

Techniques such as calcium phosphate precipitation, direct microinjection, electroporation, retrovirus infection, lipofection, and particle gun bombardment have been widely used to introduce foreign DNA into animal cells, plant cells, and germ-lines of mammals and other vertebrates. Among these methods, direct microinjection and electroporation of DNA into newly fertilized eggs were proven to be the most reliable methods of gene transfer in fish systems in the early days. Methods such as transfection with pantropic retroviral vectors or liposomes have also been used to introduce genes into marine organisms in recent years.

Microinjection

microinjection of foreign DNA into newly fertilized eggs was first developed for the production of transgenic mice in the early 1980s [13.66]. Since then, the technique of microinjection has been adopted to introduce transgenes into Atlantic salmon, common carp, catfish, goldfish, loach, medaka, rainbow trout, tilapia, and zebrafish (for a review, see [13.1–4]). The gene constructs that were used in these studies include human or rat growth hormone (GH) genes, rainbow trout or salmon GH cDNA, the chicken δ-crystalline protein gene, the winter flounder antifreeze protein gene, the *E. coli* β-galactosidase gene, and the *E. coli* hygromycin resistance gene [13.1–4]. Gene transfer in fish by direct microinjection is described below, following the parameters summarized in Table 13.2. Eggs and sperm are collected in separate, dry containers. Fertilization is initiated by mixing sperm and eggs, then adding water, with gentle stirring to enhance fertilization. Eggs are microinjected within the first few hours after fertilization. The injection apparatus as shown in Fig. 13.4 consists of a dissecting stereo microscope and two micromanipulators, one with a micro-glass-needle for injection and the other with a micropipette for holding fish embryos in place. Routinely, about 10^6–10^8 molecules of a linearized transgene or transgene without plasmid DNA are injected into the egg cytoplasm. Following injection, the embryos are incubated in water until they hatch. Since natural spawning in zebrafish, medaka, or tilapia can be induced by ad-

Table 13.2 Parameters of fish transgenesis by microinjection and electroporation

Parameters	Gene transfer method	
	Microinjection	Electroporation
Developmental stage	1–2 cells	1–2 cells
DNA size	< 10 Kb	< 10 Kb
DNA concentration	10^{6-7} molecules/ embryo 100 µg/mL

Pulse shape	N/A[a]	exponential/ square
Pulse duration	N/A[a]	ms[c] to s
Temperature	RT[b]	RT[b]
Medium	PBS/saline	PBS/saline

[a] N/A, not applicable, [b] RT – room temperature (25 °C), [c] ms – millisecond. These parameters were extracted from the following references [13.5, 11, 13, 15]

justing the photo-period and the water temperature, precisely staged newly fertilized eggs can be collected from the aquaria for gene transfer. If medaka eggs are maintained at 4 °C immediately after fertilization, the micropyle on the fertilized eggs will remain visible at least for 2 h. The DNA solution can be delivered into the embryos by injection through the micropyle during this time period.

Depending on the fish species, the survival rate of injected fish embryos ranges from 35 to 80%, while the rate of DNA integration ranges from 10 to 70% in the survivors [13.1, 2]. The tough chorions of the fertilized eggs in some fish species, e.g., rainbow trout and Atlantic salmon, can make insertion of glass needles difficult. This difficulty has been overcome by employing any one of the following methods:

i) Inserting the injection needles through the micropyle
ii) Making an opening on the egg chorions by microsurgery
iii) Removing the chorion by mechanical or enzymatic means
iv) Preventing chorion hardening by initiating fertilization in a solution containing 1 mM glutathione
v) Injecting the unfertilized eggs directly.

Electroporation

Electroporation is a successful method for transferring foreign DNA into bacteria, yeast, plant, and animal cells in culture [13.67–69]. This method has become popular for transferring foreign genes into fish embryos (or sperm) or newly fertilized eggs of dwarf surf clam in the past few years [13.5, 11, 70, 71]. The principle of electroporation is utilizing a series of short electrical pulses to permeate cell membranes, thereby permitting the entry of DNA molecules into embryos or sperm. The patterns of electrical pulses can be emitted in a single pulse of exponential decay form (i. e., exponential decay generator) or high frequency multiple peaks of square waves (i. e., square wave generator). Some commercially available electroporators are depicted in Fig. 13.5. The basic parameters of electroporation are summarized in Table 13.2. Studies conducted in our laboratory [13.11, 70] and those of others have shown that the rate of DNA integration in electroporated embryos is of the order of 20% or higher in the survivors [13.70, 71]. Although the overall rate of DNA integration in transgenic fish produced by electroporation was equal to or slightly lower than that of microinjection, the actual amount of time required for handling a large number of embryos by electroporation is orders of magni-

tude less than that required for microinjection. Several reports have also appeared in the literature that describe successful transfer of transgenes into fish by electroporating sperm instead of embryos [13.11, 70–72]. Fish sperm remain un-activated in the presence of 100% seminal fluid (i. e., dry sperm). Upon dilution of the dry sperm with any aqueous buffer, the sperm will be activated and the window that sperm remain active is very brief (< 30 s). Out of the active window sperm are non-motile and unable to fertilize eggs. Therefore, electroporation of fish sperm needs to be conducted under a buffer condition that sperm remain un-activated. In our laboratory, we found that the dry sperm of rainbow trout can remain un-activated by making a 1 to 4 dilution with a phosphate buffered saline (PBS: 8 g/L NaCl, 0.2 g/L KCl, 1.44 g/L Na_2HPO_4, 0.24 g/L, KH_2PO_4, pH 7.6). With this condition we have successfully transferred foreign genes into rainbow trout via sperm-mediated gene transfer by electroporation.

Like insects, the sperm produced by male shrimp are stored in the spermatophore. Upon copulation, the spermatophore is transferred from the reproductive tracts of males to the reproductive tracts of females to fertilize eggs. By the time that eggs are spawned by reproductively mature females, the embryos are already in multiple cell stage, which is not suitable for conducting gene transfer by electroporation or microinjection. Recently, we found that Harvard Apparatus, Inc. has developed a hand-held electrode (two-needle array handle) for the BTX Medel 532 electroporator (Fig. 13.5c). We have used this hand-held electrode to introduce transgenes into the spermatophore of the American white shrimp, *Lipopenaeus vannamei*, following the protocol depicted in Fig. 13.6 [13.73]. In this procedure, the intact spermatophores were extracted from males, injected with linearized transgenes (20 ng in a final volume of 20 nL) and electroporated in a BTX square Wave Porter attached to a hand-held electrode (two-needle array handle). The conditions of electroporation are: voltage, 800 V; pulse length, 0.1 ms; pulse #, 2; pulse interval, 0.1 s. Following electroporation, the sperm were squeezed out from the electroporated spermatophore with a pair of forceps and transferred to the thylecum of the gravid females (Fig. 13.6). Results of polymerase chain reaction (PCR) analysis of genomic DNA samples isolated from pleopods of 8-month old presumptive transgenic shrimp showed that about 25% of the surviving animals contain the transgene under these electroporation conditions (Table 13.3). J.K. Lu at the National Taiwan Ocean University has also succeeded in producing transgenic tiger shrimp using the same device to electroporate the spermatophore (personal communication). In recent years there have been

Methods of gene transfer	% Transgenic shrimp
In situ electroporation[a]	25
Pantropic viral vector	27
Transfection[b]	
Lipofection[c]	22

[a] In situ electroporation: intact spermatophores were injected with linearized transgene (20 mg in 20 mL) and electroporated in a BTX square Wave Porter attached with a hand-held electrode (two-needle array handle) under the following conditions: voltage, 800 V; pulse length, 0.1 ms; pulse #, 2; pulse interval, 0.1 s. Following electroporation, the sperm were squeezed out from the electroporated spermatophore with a pair of forceps and transferred to the thylecum of the gravid females. [b] Pantropic viral vector transfection: pantropic viral vector (10^7 pfu/50 mL) was injected into each spermatophore, and 10 min after injection, the sperm were squeezed out from the injected spermatophore with a pair of forceps and transferred to the thylecum of the gravid females. [c] Lipofection: Each spermatophore was injected with 50 µl of a mixture containing 2 µg of linearized transgene construct and 3 µg of Lipofectamine (In Vitrogen, CA). The detail procedure of artifical insemination is as described in the text.

increasing numbers of publications appearing in the literature that report transfer of foreign genes into micro and macroalgal species by electroporation with good success [13.7, 74, 75].

By microinjection or electroporation, plasmid-encoded transgenes can be introduced into many fish species to produce transgenic offspring with satisfactory efficiency. However, the resulting P_1 transgenic individuals are almost always mosaics as a result of delayed transgene integration. In addition, neither methods is applicable for transfer of foreign DNA into embryos of life-bearing fish. In order to increase the efficiency of gene transfer by microinjection or electroporation, *Hsiao* et al. [13.76] and *Thermes* et al. [13.77] took the following approaches: i) using the inverted terminal repeat DNA from the *Adeno*-associated virus to increase the stability of transgene integration; and ii) employing *I-SceI* meganuclease to mediate high transportation efficiency of the transgene into the nucleus. While these modifications have resulted in improved efficiency of transgene integration, they are still not applicable for the production of transgenic life-bearing fish species.

Transfection with the Pantropic Retroviral Vector

A replication-defective pantropic retroviral vector containing the long terminal repeat (LTR) sequence of Moloney murine leukemia virus (MoMLV) and transgenes in a viral envelop with the G-protein of vesicular stomatitis virus (VSV) was developed by *Burns* et al. [13.78]. Since entry of VSV into host cells is mediated by interaction of the VSV-G protein with a phospholipid component of the host cell membrane, this pseudotyped retroviral vector has a very broad host range and is able to transfer transgenes into many different cell types. Using the pantropic pseudotyped defective retrovirus as a gene transfer vector, transgenes containing neo^R or β-galactosidase have been transferred into zebrafish [13.79], medaka [13.80, 81], and dwarf surf clams [13.5]. More recently, *Sarmasik* et al. [13.80, 81] and *Chen* et al. (unpublished results) also used a pantropic retroviral vector to transfer genes into the immature gonads of crayfish, desert guppy (Fig. 13.7; [13.81]), and shrimp (Table 13.3), respectively. They found that by using the pantropic retroviral vector as a gene transfer vector, the problem of transgene mosaicism in P_1 transgenic fish is eliminated when transgene-containing pantropic retroviral vectors were introduced into immature male gonads. Very recently, *Core* et al. [13.9] reported that the pantropic retroviral vector has been used as a tool for transducing sea urchin embryos.

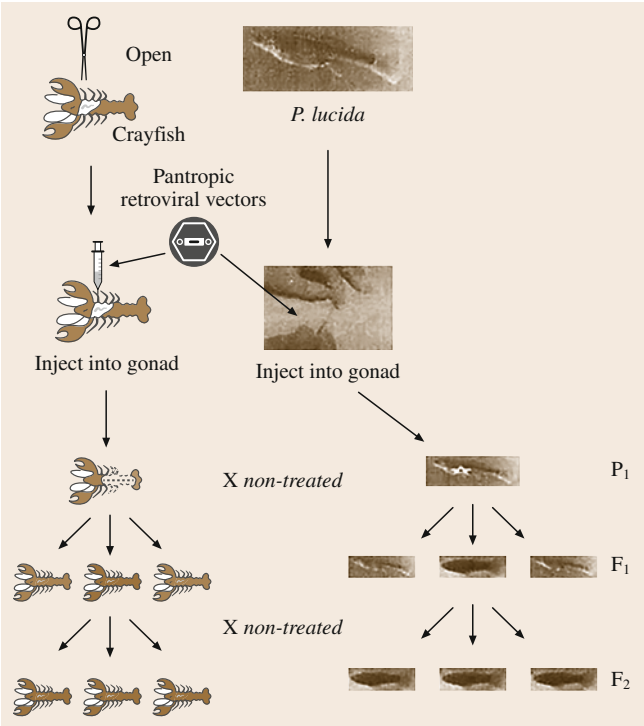

Fig. 13.7 Strategy of producing transgenic crustaceans and live-bearing fish by direct transformation of immature gonads with replicative defective pantropic retroviral vectors (after [13.82])

Transfection with Liposomes (Lipofection)

Cationic liposomes have been shown to be an effective vehicle for delivering DNA, mRNA, antisense oligomers, and proteins into living cells by fusion with cell membranes, since both are made of a phospholipid bilayer [13.83–86]. The efficiency of gene delivery by cationic liposomes has been further enhanced by modifying the compositions of the cationic lipids [13.87]. *Harel-Markowitz* et al. [13.88] have produced transgenic chicken by sperm-liposome mediated gene transfer. *Lu* et al. [13.11] have also succeeded in producing transgenic silver seabream by introducing liposome encapsulated transgenes into gonads of male silver seabream, followed by mating to mature females. In our laboratory, we have also produced transgenic white shrimp by injecting liposome encapsulated transgenes into intact spermatophores, after which we extracted the sperm from the treated spermatophore to inseminate the reproductive females (Table 13.3).

13.3 Characterization of Transgenic Marine Organisms

Once the gene transfer procedure has been conducted, the resulting organisms need to be characterized by i) identifying the presence of the transgene, ii) the expression of the transgene, and iii) the integration of the transgene in the transgenic organisms.

13.3.1 Identification of Transgenic Individuals

Identification of transgenic individuals is the most time-consuming step in the production of transgenic marine organisms. Traditionally, dot blot and Southern blot hybridization techniques were the common methods used to detect the presence of transgenes in presumptive transgenic individuals [13.89]. These methods involve isolation of genomic DNA from tissues of presumptive transgenic individuals, digestion of DNA samples with restriction enzymes, and Southern blot hybridization of the digested DNA products. Although this method is expensive, laborious, and insensitive, it offers a definitive answer as to whether or not a transgene has been integrated into the host genome. Furthermore, it also reveals the pattern of transgene integration if appropriate restriction enzymes are employed in the Southern blot hybridization analysis. In order to handle a large number of samples efficiently and economically, a polymerase chain reaction (PCR)-based assay has been adopted [13.13, 89]. The strategy of the assay is depicted in Fig. 13.8. It involves the isolation of genomic DNA from a very small piece of tissue, PCR amplification of the transgene sequence, and Southern blot analysis of the amplified products. Although this method does not differentiate between whether the transgene is integrated in the host genome or exists as an extrachromosomal unit, it serves as a rapid and sensitive screening method for identifying individuals that contain the transgene at the time of analysis. This method has been used in our laboratory as a routine preliminary screen for the presence of transgenes in thousands of presumptive transgenic fish.

13.3.2 Determination of Transgene Integration

Studies conducted in many fish species have shown that following transfer of linear or circular transgene constructs into fish embryos, the transgenes are maintained as an extrachromosomal unit through many rounds of DNA replication in the early phase of the embryonic development. At a later stage of embryonic development, some of the transgenes are randomly integrated into the host genome, while others are degraded, resulting in the production of mosaic P_1 transgenic fish [13.3]. A founder line of transgenic fish (F_1) should be established by crossing the P_1 transgenic individual with a non-transgenic counterpart. To determine the pattern of transgene integration in F_1 transgenic fish, genomic DNA extracted from PCR positive fish is digested with a series of restriction endonucleases and the resulting products resolved in agarose gels for Southern blot analysis. In many fish species studied to date, it is found that multiple copies of transgenes are integrated in a head-to-head, head-to-tail, or tail-to-tail form, except in transgenic common carp and channel catfish, where a single copy of transgene was integrated at multiple sites on the host chromosomes [13.3, 11, 81].

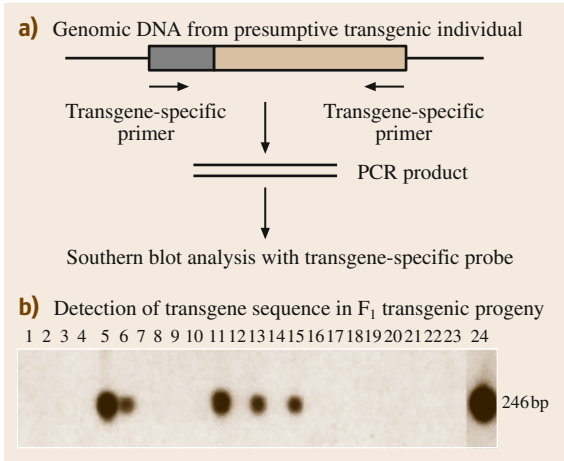

Fig. 13.8a,b Identification of transgene in transgenic individuals by PCR analysis of the genomic DNA. **(a)** Strategy of identifying transgene by PCR analysis of genomic DNA; **(b)** an example of detecting the presence of cecropin transgene in the genomic DNA of transgenic medaka. Genomic DNA samples extracted from the fin tissues of presumptive transgenic individuals were PCR amplified using a pair of transgene specific synthetic oligonucleotides as amplification primers. The PCR-amplified products were analyzed by Southern blot analysis. Lanes 1–22, genomic DNA from presumptive transgenic fish; lane 23, genomic DNA from non-transgenic fish; lane 24, transgene DNA (after [13.15])

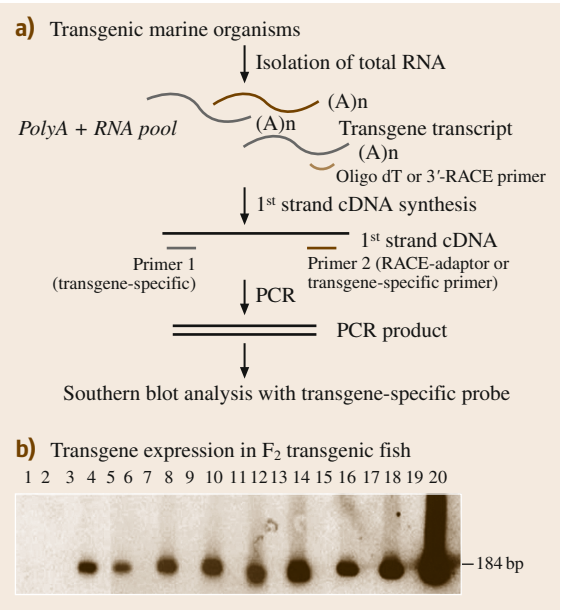

Fig. 13.9a,b Determination of transgene expression by RT-PCR or rapid amplification of cDNA ends-PCR (RACE-PCR). **(a)** Strategy of RT-PCR or RACE-PCR. **(b)** An example of detecting cecropin transgene expression in transgenic fish. Total RNA was isolated from fin tissues of F_2 transgenic medaka and the expression of cecropin transgene was detected by reverse transcribing poly A^+ RNA into cDNA and PCR amplifying the cecropin cDNA using cecropin-specific primers. The amplified product was confirmed by Southern hybridization using a cecropin-specific probe. RT-PCR was conducted with mRNA from transgenic fish without prior reverse transcription (lanes 5, 7, 9, 11, 13, 15, 17, 19) or with first cDNA transcribed from mRNA isolated from the transgenic fish (lanes 4, 6, 8, 10, 12, 14, 16, 18). Lane 1: RT-PCR with no mRNA input; lane 2: RT-PCR with mRNA from negative control fish; lane 3: PCR with mRNA of negative control fish without prior reverse transcription; lane 20: PCR with control plasmid containing cecropin gene (after [13.90])

Stable integration of transgenes is an absolute requirement for continuous vertical transmission to subsequent generations and establishment of a transgenic fish line. To determine whether the transgene is transmitted to subsequent generations, P_1 transgenic individuals are mated to non-transgenic individuals, and the progeny are assayed for the presence of transgenes by the PCR assay method described earlier [13.13, 14, 19, 91]. Although it has been shown that the transgene may persist in the F_1 generation of transgenic zebrafish as extrachromosomal DNA [13.92, 93], a detailed analysis of the rate of transmission of transgenes to F_1 and F_2 generations in many transgenic fish species indicates true and stable incorporation of gene constructs into the host genome [13.1, 3]. If the entire germline of the P_1 transgenic fish is transformed with at least one copy of the transgene per haploid genome, at least 50% of the F_1 transgenic progeny will be expected in a backcross involving a P_1 transgenic with a non-transgenic control. In many of such crosses, only about 20% of the progeny are transgenic [13.13, 19, 81, 89, 91]. When the F_1 transgenic is backcrossed with a non-transgenic control, however, at least 50% of the F_2 progeny are transgenics. These results clearly suggest that the germlines of P_1 transgenic fish are mosaic as a result of delayed transgene integration during embryonic development. For this reason, it is essential to establish a founder line of the transgenic organism by crossing the P_1 transgenic individual with its non-transgenic counterpart before proceeding to characterizing the transgenic organism in details.

13.3.3 Determination of Transgene Expression

An important aspect of gene transfer studies is the detection of transgene expression. Depending on the levels of transgene products in the transgenic individuals, the methods listed in the following are commonly used to detect transgene expression:

a) RNA northern or dot blot hybridization
b) RNase protection assay
c) Reverse transcription-polymerase chain reaction (RT-PCR)
d) Immunoblotting assay
e) Other biochemical assays for determining the presence of the transgene protein products.

Among these assays, RT-PCR is the most sensitive method and it only requires a small amount of sample. The strategy of this assay is summarized in Fig. 13.9. Briefly, the assay involves the isolation of total RNA from a small piece of tissue, synthesis of single-stranded cDNA by reverse transcription, and PCR amplification of the transgene cDNA by employing a pair of oligonucleotides specific to the transgene product as amplification primers. The resulting products are resolved on agarose gels and analyzed by Southern blot hybridization using a radio-labeled transgene as the hybridization probe. Transgene expression can also be quantified by a quantitative RT-PCR

method [13.94] or a quantitative real-time RT-PCR method [13.95].

13.3.4 Breeding Homozygous Transgenic Organisms

Almost all transgenic marine organisms produced by microinjection, electroporation, or transfection with pantropic retroviral vector or lipofection are heterozygous with respect to transgenes. For practical application, the transgenic lines need to be bred to be homozygous to maintain the brood stocks. This purpose can be achieved by self-crossing the heterozygous transgenic individuals and identifying the genotypes of the progeny by performing backcrosses. While this approach may be time consuming, depending on the length of the life cycle, it will obtain homozygous strains. In rainbow trout, since methods of chromosome manipulation are applicable, all male homozygous transgenic strains can be produced by the technique of androgenesis developed by *Parsons* and *Thorgaard* [13.82]. The strategy of this method is depicted in Fig. 13.10 [13.82]. Briefly, eggs from non-transgenic rainbow trout were irradiated with ^{60}Co γ-radiation to inactivate the nuclei and then fertilized with sperm from the heterozygous transgenic fish. Diploidy of the androgenic haploid zygotes was restored by suppression of the first cleavage division with hydrostatic pressure and the hatched fry were reared to adulthood. The YY transgenic males were identified by PCR amplification of the transgene and the Y chromosome specific sequence [13.96].

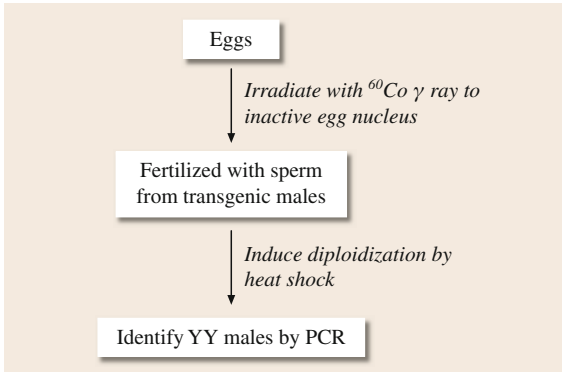

Fig. 13.10 Strategy for producing all male transgenic rainbow trout by androgenesis (after [13.97])

13.4 Biotechnological Application of Transgenic Marine Organisms

As techniques of producing various species of transgenic marine organisms have become mature in the last three decades, there has been a rapid boom in applying transgenic technology to different disciplines of basic research and biotechnological applications. Fish serve as extremely valuable models for basic research in vertebrate biology, as they are functionally similar to mammalian species. In addition, evolutionarily fish species are sufficiently close-distant to mammals; they are well suited for comparative genomics studies. Since transgenic fish can be easily and economically produced and reared in large quantities, this grants them superiority over the transgenic mouse model, especially in studies requiring a large number of animals. In recent years, transgenic fish technology has made major contributions in the areas of the study of vertebrate development, the analysis of promoter/enhancer elements of genes, the dissection of signal transduction pathways, and the development of human disease models. Transgenic fish technology research has also been driven toward biotechnological applications in recent years and it is hoped that it will be of high economic value to humans. Some of the advances in biotechnological applications will be reviewed in the following section.

13.4.1 Enhancement of Disease Resistance

Disease is one of the most severe bottlenecks in aquaculture. For the past few decades, efforts to control infectious diseases in commercially important fish species have primarily focused on the development of suitable vaccines for fish and selection of fish strains with robust resistance to infectious pathogens. Although effective vaccines have been developed for several important fish pathogens, current vaccination practice is expensive, laborious, and time consuming. Genetic selection based on traditional cross-breeding techniques is time consuming, and the outcome is frequently unpredictable, and sometimes disappointing due to a lack of the desired genetic traits. More effective approaches for controlling fish disease in aquaculture are highly desirable.

Transgenic fish technology can facilitate the genetic selection process by directly modifying the undesir-

able genetic traits that confer vulnerability to pathogens or introducing specific genes that are related to disease resistance into fish. The introduced transgenes can be fish-originated or characterized genes from other species. What genetic trait may confer resistance to infection by bacterial or viral pathogens? Upon exposure to invading bacterial, viral, or parasitic pathogens, fish, like higher vertebrates, will produce a family of polypeptides of small molecular weight, called antimicrobial peptides (AMPs), as part of the innate immunity response (Fig. 13.11). This family of peptides exhibits rapid killing of a broad spectrum of targets such as Gram-negative and Gram-positive bacteria, enveloped viruses, parasites, and even tumor cells [13.98–101]. Manipulating the AMP gene in fish may make them resistant to infection by pathogens. We have recently demonstrated the feasibility of introducing the antimicrobial peptide genes, cecropin B and cecropin P1, into fish to enhance disease resistance. Cecropins, first identified in the *Cecropia* moth, are members of the antimicrobial peptide family that are evolutionarily conserved in species from insects to mammals [13.101]. These peptides possess activities against a broad range of microorganisms, including bacteria, yeasts, and even viruses [13.101]. In vitro and in vivo studies conducted by *Sarmasik* et al. [13.90] showed that recombinant cecropin B inhibited the propagation of common fish pathogens such as *Pseudomonas flourescens, Aeromonas hydrophila*, and *Vibrio anguillarum*. Furthermore, *Chiou* et al. [13.102] showed that cecropin P1 and a designed analog, CF-17 peptide, effectively inhibited the replication of fish viruses, such as the infectious hematopoietic necrosis virus (IHNV), the viral hemorrhagic septicemia virus (VHSV), the snakehead rhabdovirus (SHRV), and the infectious pancreatic necrosis virus (IPNV). More recently, our laboratory has shown that synthetic peptide CF-17 is also effective in inhibiting the propagation of insect baculovirus (*Khoo* et al. unpublished result). Additionally, *Jia* et al. [13.97] demonstrated the enhanced resistance to bacterial infection in fish, which were continuously transfused with a cecropin-melittin hybrid peptide (CEME) and pleurocidin amide, a C-terminally amidated form of the natural flounder peptide. These results led to the hypothesis that production of a disease resistant fish strain may be achieved by manipulating AMP genes.

To test this hypothesis, we introduced gene constructs containing prepro-cecropin, procecropin, mature cecropin B, and cecropin P1 into the embryos of medaka by electroporation [13.90]. The F_2 transgenic medaka were subjected to bacterial challenges at an LD_{50} dose with *Pseudomonas fluorescens* and *Vibrio anguillarum*, respectively. The resulting relative percent survival (RPS) of the tested transgenic F_2 fish ranged from 72 to 100% against *P. fluorescens* and 25 to 75% against *V. anguillarum* [13.90]. To confirm the feasi-

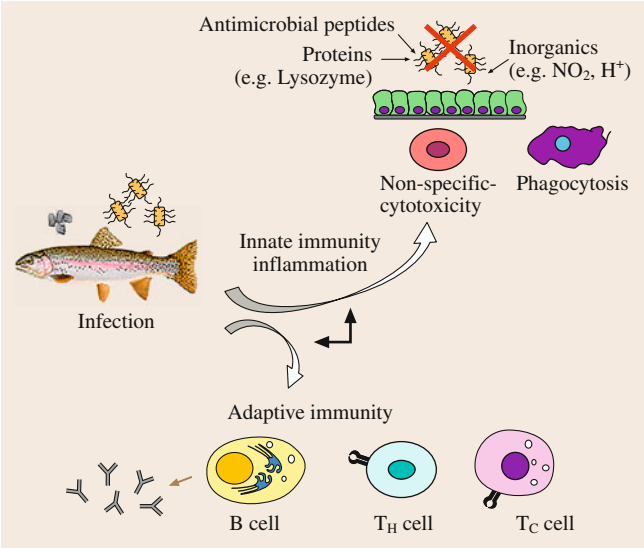

Fig. 13.11 Innate immunity and adaptive immunity exhibited by fish when encountering infection by bacterial and viral pathogenes

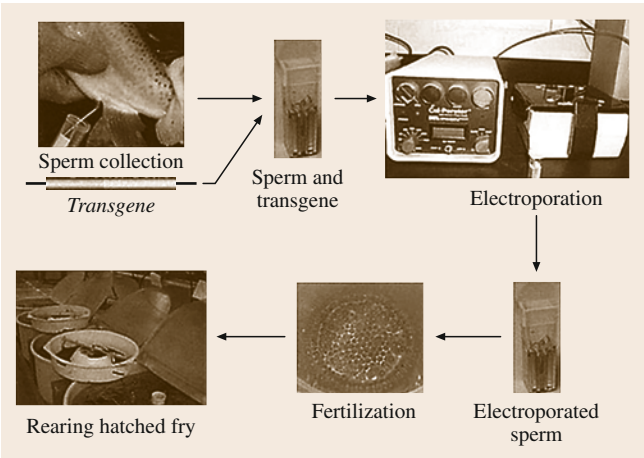

Fig. 13.12 Schematic presentation of the sperm-mediated gene transfer method. Sperm collected in a dry tube, diluted with sperm extender, mixed with insert of transgene DNA to give 10^4 DNA molecules/sperm, and electroporated in a cell porator under the following conditions: capacitance, 110 μF; voltage, 250–300 V; pulse number, 2. The electroporated sperm is used to fertilize rainbow trout and rear the hatched fry to adulthood (after [13.83])

bility of applying this technique to an aquaculture fish species, we transferred transgenes with cecropin P1 and CF-17 into rainbow trout by the sperm-mediated gene transfer method (Fig. 13.12). A total of nine families of cecropin P1 transgenic rainbow trout was established and bred to all male homozygous. Repeated challenge studies revealed that these transgenic trout exhibited resistance to the bacterial pathogen, *Aeromonas salmonicida* and the viral pathogen, infectious hematopoietic necrosis virus (IHNV) [13.103]. Via DNA microarray and quantitative real-time RT-PCR analyses, the expression of many genes in the innate/adaptive immunity pathways in transgenic trout was up or downregulated. This is the first time that a true disease resistant fish is available for detailed analysis of differential expression of genes in the innate/adaptive immunity pathways. All together these results clearly demonstrate the potential application of transgenic fish technology in producing fish with more robust resistance to infectious pathogens for aquaculture.

13.4.2 Enhancement of Somatic Growth

The initial drive of transgenic fish research came from attempts to increase the production of economically important fish for human consumption. The worldwide supply of fishery products has traditionally depended upon commercial harvest of finfish, shellfish, and crustaceans from freshwater and marine water sources. In recent years, while the worldwide commercial catch of fish has experienced a sharp reduction, the worldwide demand for fish products has risen steeply. In order to cope with the demand for fish products, many countries have turned to aquaculture. Although aquaculture has the potential to meet the world demand for fish products, innovative strategies are required to improve its efficiency. What can transgenic fish technology offer in this regard?

There are three aspects of fish growth characteristics that could be improved for aquaculture: i) increasing the initial growth rate of fry for an early head-start, ii) enhancing the somatic growth rate in adults to provide a larger market body size, and iii) improving feed conversion efficiency of fish to achieve effective utilization of feed. Among these three, enhanced somatic growth rates via manipulation of the GH gene show considerable promise. Studies conducted by *Agellon* et al. [13.104] and *Paynter* and *Chen* [13.105] showed that treatment of yearling rainbow trout and oysters with recombinant rainbow trout GH resulted in significant growth enhancement. Similar results of growth enhancement in fish treated with recombinant GH have been reported by many investigators [13.106–108]. These results point to the possibility of improving the somatic growth rate of fish by manipulating fish GH or its gene.

Zhu et al. [13.109] reported the first successful transfer of a human GH gene fused to a mouse metallothionein (MT) gene promoter into goldfish and loach. The F_1 offspring of these transgenic fish grew twice as large as their non-transgenic siblings. Since then, a similar enhanced growth effect has been observed in GH-transgenic fish (carrying the fish origin GH gene or its cDNA) of many other species, such as tilapia [13.110, 111], common carp [13.24, 89], catfish [13.16], sea bream [13.11], and salmon [13.15]. These studies have shown that the expression of a foreign human or fish GH gene could result in significant growth enhancement in P_1, F_1 and F_2 transgenic fish. Additionally, *Dunham* et al. [13.24] have demonstrated that transgenic common carp carrying rainbow trout GH transgene display, consistently in two consecutive generations, a favorable body shape, better dress-out yield, and better fresher quality compared with non-transgenic fish. These studies have demonstrated that GH-transgenic fish may be beneficial to worldwide aquaculture, and hence may help to alleviate starvation in many economically poor countries by providing more efficient, cheaper and yet high-quality protein sources. A strain of fast growing Atlantic salmon (AquAdvantage Salmon), which was initially developed by *Du* et al. [13.15] has been bred by AquaBounty Technologies (Maynard, MA) for approval by the Food and Drug Administration (FDA) of USA for commercialization.

13.4.3 Increase of Body Color Variation in Ornamental Fish

There are two main motives for producing fish with altered body color: i) to generate novel varieties of ornamental fish with rare colors for the purpose of rearing as pets, and ii) to use the change of body color as reporters for detecting environmental changes. The jellyfish green fluorescence protein (GFP) and several GFP variants driven by tissue-specific promoters such as the skin-specific keratin gene (*krt8*) and the muscle-specific gene (*mylz2*) are the genes that are used most for such purposes. Additionally, the melanin-concentrating hormone (MCH) isolated from chum salmon has also been exploited to generate transgenic medaka fish with altered body color [13.112]. So far, researchers have successfully produced several color-

ful transgenic zebrafish displaying whole-body green, red, yellow, or orange fluorescent colors in daylight, dim light. or UV light [13.113, 114]. Some of these fish have been sterilized to avoid contaminating the wild population if they should accidentally be released from aquaria to the environments [13.115]. For research purposes, mutant zebrafish and medaka with less interfering pigmentation for optical observation have also been developed. One such example is a line of *see-through* transgenic medaka that are transparent throughout their entire life, thus allowing clear visualization of GFP that is introduced into the fish as a reporter [13.116].

While studies on enhancing body color variation in ornamental fish were traditionally conducted in medaka and zebrafish, very little has been accomplished in mid-size or larger ornamental fish species. By co-injecting equal volumes of *Tol2* transposase mRNA (50 ng/μL) into one-cell stage angelfish embryos with a *Tol2* transposon-mediated transgene construct containing a muscle-specific zebrafish *CKMb* 2.4 kb promoter/enhancer linked to Acropora coral red fluorescent protein cDNA with SV40 polyA tail, we succeeded in producing strains of pink body color transgenic angelfish expressing the Acropora coral red fluorescent protein (Fig. 13.13). Furthermore, a strain of pink body color transgenic lionhead fish, another strain of mid-size ornamental fish, has also been produced by J.Y. Chen and J.L. Wu in the Institute of Cellular and Organismal Biology, Academia Sinica, Taiwan (personal communication).

Fig. 13.13 Four-month old F_1 transgenic anglefish (*Pterophyllum scalare*) expressing the Acropora coral (*Acroporo millepora*) red fluorescent protein gene. This research project was carried out in a collaboration with H.-Y. Gong and the Jy Lin Company in Taiwan

13.4.4 Models for Studying Human Diseases

In order to provide a general proof of principle or to reproduce specific aspects of human diseases, animal models have long been used to identify disease-associated factors or genes, or to screen new treatments for these diseases [13.117–119]. In addition to primate and murine models, zebrafish have been used to study human diseases for decades, particularly in cancer research and drug discovery [13.120, 121]. In recent years, transgenic zebrafish are emerging as a valuable model for studying human diseases, especially cardiac and neurodegenerative diseases and cancers [13.122–125]. In humans, tau proteins function to stabilize microtubules in neurons of the central nervous system. When tau proteins are defective, they result in dementias such as Alzheimer's disease. However, the early functional consequences of tau protein alterations in living neurons are incompletely understood. The development of transgenic zebrafish expressing mutated human tau in neurons may help to fill in the knowledge gap. By introducing a transgene construct harboring a mutated *tau* gene (FTDP-17 mutant) driven by the promoter of GATA-2 gene into the 1–2-cell stage zebrafish embryos, *Tomasiewicz* et al. [13.126] produced transgenic fish exhibiting characteristics resembled the neurofibrillary tangles (NFT) in human disease. The development of transgenic zebrafish with an approach similar to that described by *Tomasiewicz* et al. [13.126] will have a broad usefulness in the study of functional consequences, as well as in the genetic analyses of the introduction of other molecules involved in the pathogenesis of neurodegenerative diseases in vivo [13.123, 124].

Medaka and zebrafish can be induced to develop tumors in various organ sites that bear a striking resemblance to human malignancies, both histologically and genetically. With the significant advantages of in vivo imagining and well-established transgenic technology of high efficiency, these fish species will serve as powerful model organisms to study cancer biology. Stable lines of transgenic zebrafish expressing a fusion gene of green fluorescence protein and *c-myc* controlled by the *Rag2* promoter have been established [13.127]. Visualization of leukemic cells expressing the chimeric transgene revealed that leukemia arose in the thymus, spread locally into gill arches and retro-orbital soft tissue, and then disseminated into skeletal muscle and abdominal organs in transgenic individuals. The homing of leukemic T cells back to the thymus was also illustrated in irradiated fish transplanted with GFP-tagged leukemic lymphoblasts. This transgenic model provides a platform for drug

screening or for genetic screening aimed at identifying mutations that suppress or enhance *c-myc* induced carcinogenesis.

TP53 is the most frequently mutated tumor suppressor gene in human cancer, with about 50% of all tumors exhibiting a loss-of-function mutation. To elucidate the genetic pathways involving p53 and cancer, *Berghmans* et al. [13.128] developed transgenic zebrafish lines harboring missense mutation in the *tp53* DNA-binding domain. Transgenic zebrafish expressing the *tp53* missense mutation transgene developed malignant nerve sheath tumors. These transgenic lines can provide a unique platform for modifier screenings to identify genetic mutations or small molecules that affect *tp53*-related pathways, including apoptosis, cell cycle delay, and tumor suppression [13.129]. Very recently, a transgenic zebrafish model was established by *Liu* et al. [13.130] to study intrahepatic cholangiocarcinoma (ICC) associated with infection by hepatitis B (HBV) and C (HCV) viruses. These transgenic lines coexpress HBV X and HCV core protein genes in the liver and cause eventual ICC formation in the liver. Results of transcriptome sequencing analysis revealed that gene expression profiles of ICC formation in the transgenic fish are similar to those of human ICC formation. Thus, this in vivo model can serve as an ideal platform for identifying the molecular events leading to fibrosis and ICC caused by HBV and HCV infection. It may also serve as a platform for screening drugs to control hepatic fibrosis and ICC.

13.4.5 Transgenic Fish as Environmental Biomonitors

Fish have long been used as models in environmental toxicology studies. Prompted by concerns of human health, tissues of wild-caught fish have been used as indicators for the presence of dangerous pollutants such as polycyclic hydrocarbons, oxidants, and heavy metals in the waters or fish itself [13.131, 132]. Different assays have been employed to measure the biological parameters impacted by toxic pollutants, including DNA damage, defense enzymes (e.g., glutathione peroxidase and superoxide dismutase), genes inducible by toxic chemicals (e.g., cytochrome P450 1A1 and 1A2), and factors that regulate redox potential (e.g., glutathione and ascorbic acid) [13.131]. Although these assays are very sensitive, they require specialized techniques and equipment, and thus cannot be performed in the field where the samples are collected. In addition, the data obtained from wild-caught fish samples give no indication of the exact time when the fish were exposed to the toxicants.

Transgenic fish can potentially serve as sensitive sentinels for aquatic pollution, with the benefit of avoiding the inconveniences mentioned above. The principle of such fish biomonitoring is to introduce reporter genes that are easy to observe and are under the control of promoter/enhancer elements of pollutant responsive genes. GFP and its variants are thus the best reporters of choice for easy optical observation, whereas luciferase is the most sensitive. So far, researchers have made significant progress in establishing transgenic zebrafish carrying luciferase or GFP reporter genes under the control of aromatic hydrocarbon response elements (AHRE), electrophile response elements (EPRE), or metal response elements (MREs) [13.131]. The specificity of each type of response elements is as follows: AHREs respond to numerous polycyclic hydrocarbons and halogenated coplanar molecules such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and polychlorinated biphenyls; EPREs respond to quinones and numerous other potent electrophilic oxidants; and MREs respond to heavy metal cations such as mercury, copper, nickel, cadmium, and zinc. In the zebrafish cell line, ZEM2S, these three types of elements can drive the expression of luciferase reporters in a dose-dependent, chemical-class-specific manner in response to more than 20 environmental pollutants [13.131].

Many environmental chemical pollutants possess endocrine disrupting activities; these compounds present a significant threat to human health. In recent years, several transgenic zebrafish and medaka lines have been produced for detecting environmental endocrine disruptors [13.132–138]. *Lee* et al. [13.136] developed a transient expression assay for detecting environmental estrogen via introducing a pair of plasmids (pRER_Gal4ff; pUAS_GFP) by microinjection into 1−2-cell stage embryos of zebrafish or medaka. The resulting transgenic embryos expressed GFP in response to exposure to pollutants containing estrogenic activity. This assay system will allow easy testing of environmental oestrogens, as well as detecting the oestrogenic target sites in developing embryos. However, severe drawbacks of the assay are: i) big fluctuations among embryos due to variations of the amount of transgene plasmid in each embryo and ii) cumbersome of microinjection. To overcome these problems, stable lines of transgenic zebrafish or medaka carrying reporter systems can be developed. *Chen* et al. [13.133] and *Brion* et al. [13.134] developed transgenic zebrafish carrying *ere-zvtg1-gfp* and *cyp19a1b-gfp* transgenes,

respectively, for in vivo screening of environmental estrogenic chemicals. Furthermore, by introducing a transgene carrying the *chgH-rfp* reporter system, *Cho* et al. [13.137] developed stable lines of estrogen-responsive transgenic marine medaka for assessing water born estrogenic compounds under a wide range of salinity conditions. Using a similar approach, transgenic zebrafish lines carrying the *gfp* transgene driven by the TH/bZIP promoter (promoter of thyroid hormone responsive genes) were developed by *Terrien* et al. [13.138] for detecting environmental toxicants that may disrupt thyroid function.

13.4.6 Other Biotechnological Applications

Transgenic marine organisms can potentially serve as bioreactors for producing proteins for therapeutic and other applications [13.114]. The advantages of fish as bioreactors include:

i) Relatively low cost as compared to mammals such as cows.
ii) Easy maintenance.
iii) Production of a large quantity of progenies.
iv) Most importantly, no known viruses or prions have been reported to infect both humans and fish.

Successful expression of bioactive human proteins such as coagulation factor VII, IGF-I, and IGF-II in fish embryos [13.139, 140] demonstrate this application of transgenic fish to produce therapeutic chemicals for humans in the future. Another application of transgenic organisms is the production of transgenic microalgae e.g., *Nannochloropsis oculata*) [13.7] and zooplankton (e.g., *Artemina*) [13.6] expressing biologically active fish growth hormones to serve as feed in aquaculture.

Hydrogen metabolism has been extensively studied in green alga, *C. reinhardtii*, resulting in significant advances in both the fundamental understanding of H_2 metabolism in this organism, as well as the improvements of overall H_2 yields. Thus, transgenic manipulation of genes involved in hydrogen production in *Chlamydomonas reinhardtii* would provide a great potential for biofuel production in the future [13.141].

Significant amounts of marine macroalgae (e.g., kelp and *Porphyra*) have been used as food for human consumption, feed for aquaculture of finfish and shellfish, and fine chemicals for industrial and pharmaceutical applications worldwide [13.142]. According to a report from the Food and Agriculture Organization of the United Nations (FAO) in 2005 [13.143], the annual harvests of kelp and *Prophyra* grown on shore and in coastal regions have declined drastically as a consequence of toxicant contamination in the aquatic ecosystem and disease manifestation caused by pathogenic microorganisms [13.144]. These problems may be alleviated by introducing genetic traits that will enable seaweed to remove water-borne toxicants

or confer the seaweed resistant to infection by disease-causing pathogens. Although numerous attempts have been made by scientists in the past to transfer genes into kelp or *Porphyra*, many years, very little success has been achieved in establishing stable transformants. Transient expression of the reporter GUS gene in the protoplasts of *Porphyra* has been reported by several investigators [13.145–148]. Although *Wang* et al. [13.149] reported the expression of the lacZ reporter gene in conchospores transformed through glass bead agitation, there are no data documenting the establishment of stable lines of transgenic *Porphyra*.

Since the genetic make-up of the archaeospore is haploid, it is suitable for conducting gene transfer studies. Our laboratory had initiated a project to establish stable transgenic *Porphyra* by electroporating a transgene carrying blasticidin (BSD) resistance marker driven by the promoter of Cytomegalovirus Mosaic Virus (CMV) early gene into achaeospores by Gene Pulser II with RF module (BioRad Company) or Beckonizer 2000 square wave generator. The conditions of electroporation are listed in Table 13.4. The results of our preliminary studies showed that an antibiotic, blasticidin, at a concentration of 50 μg/mL, is very effective to inhibit the growth of *Prophyra* archaeospores. Thus, it is used as a selection marker for transgenic *Porphyra*. Following electroporation, aschaeospores were incubated in the growth medium without BSD for 24 h to recover, and the transformants were selected by addition of BSD (50 μg/mL) to the growth medium. As is shown in Fig. 13.14, both electroporation conditions were able to deliver pCMV-BSD transgenes into *Prophyra*, and the expression of the BSD transgene was detected (Fig 13.15). Stable integration of pCMV-BSD

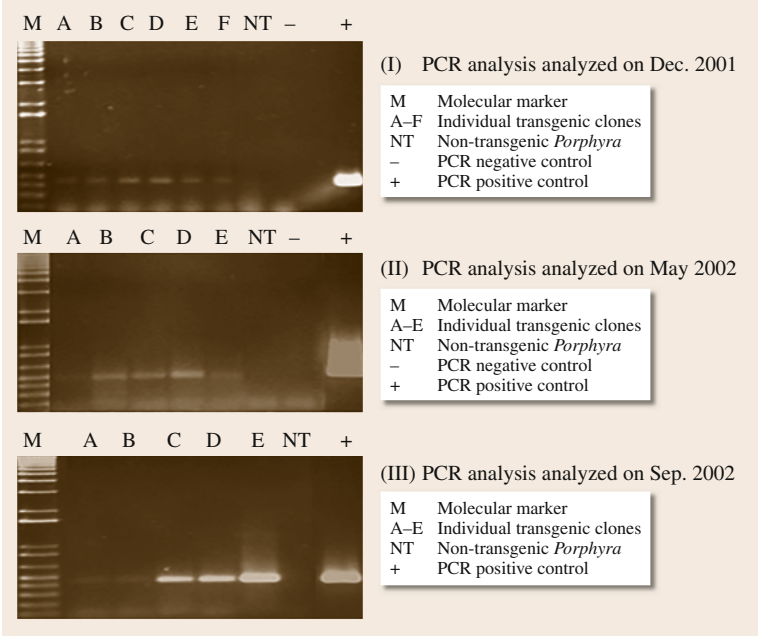

Fig. 13.16 Detection of the pCMV-BSD transgene in transgenic *Porphyra* at different passages. (I) Thallus analyzed in December 2001, (II) thallus analyzed in May 2002, (III) thallus analyzed in September 2002. DNA isolated from the transgenic thallus of different passages, analyzed by PCR amplification. Results show that the BSD transgene was present in the transgenic thallus of different passages, indicating permanent transformation

transgenes was detected in genomic DNA isolated from a *Porphyra* thallus after multiple passages (Fig 13.16). These results confirm the development of a protocol for transferring foreign genes into *Porphyra*.

13.5 Concerns and Future Perspectives

Application of transgenic technology to produce genetically modified (GM) food fish and ornamental fish with beneficial traits such as enhanced somatic growth and resistance to diseases, or diverse body color is on the rise. There have been ground-breaking discoveries made in the past few years based on transgenic fish models, and such applications are expected to continue to thrive in the future. Techniques to produce transgenic fish have improved tremendously in the last two decades; nonetheless, there are still concerns about low efficiency, mosaic expression, non-fish components of the transgenes, and the long generation time for certain fish species. The following advances would thus be essential in developing the next generation of transgenic fish:

i) The development of more efficient mass gene transfer technologies
ii) The development of targeted gene transfer technology such as the embryonic stem cell gene transfer method
iii) Identification of more suitable fish-origin promoters to direct the expression of transgenes at optimal levels and desired time
iv) The development of methods to shorten the time required to generate homozygous offspring.

Despite the promising future of the application of transgenic technology, there are great concerns about the environmental impacts of GM food fish or pets. Based on mathematical modeling, *Howard* et al. [13.150] proposed a *Trojan gene effect* hypothesis using male transgenic medaka expressing the salmon growth hormone gene. They proposed that the release of such fish into the environment could ultimately lead to the extinction of the wild population, owing to their advantage in mating with the wild females. The study provides a sound analysis of the potential impact of the accidental release of transgenic fish into the environment, reminding us of the delicate interaction between a newly introduced species and the native population and environment. However, we would reason that the potential environmental impact by transgenic fish is controllable and even avoidable. First of all, the Trojan gene effect might not necessarily exist for other types of transgenes or in other fish species. In practice, transgenic fish should be maintained in confined areas to avoid their escape into nearby waters. Moreover, as the desirable genetic traits can be introduced into fish, the undesirable behavior traits could be possibly removed from the transgenic population by screening the behavior pattern of each transgenic individual. Ultimately, the establishment of a sterile transgenic population can be applied to avoid the spreading of transgenes into the wild population. Ideally, such sterility should be reversible, otherwise it would mean the loss of the goose that lays the golden egg. Finally, from a historical perspective, the concerns in the early days that arose from the environmental impacts of recombinant DNA technology have not been realized and many lessons can be learned from this experience.

The acceptance of GM fish and other transgenic marine organisms as food by society is a key factor for the development of transgenic marine organisms as a new source of affordable and high-quality food. Largely, the concern is due to the public perception that GM food is unsafe to human health. Safety is the ultimate goal of GM food development and it relies on a thorough characterization of the transgenes used and the safety assessment of the transgenic products, resembling the development of new drugs. Unfortunately, it is a fact that there is always a subpopulation of people who are allergic, to different degrees, to many of the existing natural food sources, such as peanuts and shellfish. Therefore, the challenge to develop GM food with absolutely no adverse effect on every single individual in the human population is great. A thorough evaluation process to fully analyze any health risk of GM food to humans should be established, and the information should be clearly delivered to the public and well marked on the food products. The development of *gene-inactivated* transgenic marine organisms may be more acceptable by people who are concerned about the safety of the *new* genes that are introduced into the marine organisms. Take GM fish, for instance, one candidate GM fish is transgenic fish strains with their myostatin gene being inactivated. Inactivation of

the myostatin gene causes double muscling in animals, resulting in a significant increase in the mass of skeletal muscle. Natural mutation of the myostatin gene has been found in the meaty Belgian Blue and Piedmontese cattle, and the double muscling effect has been observed in mice whose myostatin gene was artificially inactivated [13.151, 152]. Such a *gene-inactivation* approach would be very valuable in producing transgenic fish with more flesh and of a higher food conversion rate, particularly for the economically important aquaculture species.

In summary, the application of transgenic technology in marine organisms has resulted in many valuable discoveries in basic biological science, many of which could lead to the next breakthrough for new cures for human diseases. On the other hand, the potential of transgenic marine organisms as bioreactors or as new renewable energy sources should not be deterred by environmental and safety concerns, but instead requires more research effort in the future to develop new GM species with beneficial traits that are safe to human health and also carry no harm to the environment.

14. Marine Enzymes – Production and Applications

Kai Muffler, Barindra Sana, Joydeep Mukherjee, Roland Ulber

The oceans provide an almost untapped reservoir of novel enzymes which might have a potential as biocatalysts for academic research and for industrial processes. With regard to the broad variety of environmental conditions, interesting enzymes with characteristic traits can be isolated. Especially enzymes from extremophiles, which are classified as thermophilic or psychrophilic, are of particular interest for industrial processes in terms of mass transfer or energy savings. Additionally, enzymes which are adapted towards high salt concentrations may be beneficial for industrial biotechnology applications, because the catalytic reactions can be performed in non-diluted solutions. Up to now only a minor amount of this treasure has found an application in the laboratory and industry. However, regarding the ongoing progress and developments in molecular biology it seems that the portfolio of enzymes that can be applied for the production of bulk and fine chemicals will be broadened in the near future.

In this chapter an exemplary overview about the research work done on the production of enzymes from marine origin, as well as their potential application in industrial processes is given.

14.1 Overview

The oceans provide a broad variety of marine microorganisms whose products such as enzymes and bioactive metabolites are of interest for applications in the food and pharmaceutical industries, as well as for the processing of renewable resources to provide raw material, for example, for the production of biofuels. Considering the size of the marine habitats, which range from tropical to cold polar regions and from coastal to hydrothermal deep-sea zones, they harbor a pool of (micro)organisms that are able to produce enzymes with interesting traits like salt and barotolerance and/or adaptations to high or low temperatures, which are sometimes superior in comparison to their counterparts produced by terrestrial microorganisms.

During its initial phase, research in marine biotechnology was mainly driven by identifying novel bioactive compounds from the micro- and macro-organisms. The screening for novel metabolites was succeeded within the so-called two waves. The first wave began with the identification of novel nucleosides from the sponge *Cryptotethya crypta* by Bergmann more than 60 years ago [14.1] and resulted in the production of artificial nucleosides, e.g., ara-A (vidarabine) or ara-C (cytarabine), which are currently in use in many antiviral formulations. The second wave was initiated in the 1970s by isolation and identification of secondary metabolites featuring antitumoral, antiviral, anti-inflammatory, and/or analgesic activity. The first

drug from the sea was the peptide ziconotide, originally derived from a tropical marine cone snail. The compound was approved in the United States in 2004 under the trade name Prialt for the treatment of chronic pain in spinal cord injury [14.2]. A second drug (ET-743) from sea squirt origin was approved by the European Union in October 2007 for the treatment of soft-tissue sarcoma [14.2]. However, further promising candidates are still in several stages of clinical trials.

Today, natural product research also focuses on the enzyme systems that are responsible for the production of bioactive secondary metabolites, such as, for example, polyketide synthases [14.3, 4], which catalyzes the linkage of acyl-coenzyme A subunits via the generation of cyclic structures (e.g., bryostatin 1). Aside from the natural product research some (novel) marine enzymes, catalyzing a multitude of processes relevant for biocatalytic processes in industrial biotechnology, showing desired properties like high salt tolerance, hyperthermostability, barophilicity and cold adaptivity as mentioned before. Their performance results from the adaptation of their host organisms during the evolutional development to the environmental surroundings. However, the rising demand for environmentally-friendly and beneficial economical manufacturing of bulk and fine chemicals requires the exploitation of these enzymes for the specific and selective production of value-added products like chiral amines, alcohols, halogenated amino acids, as well as the enzymes themselves in the case of, for example, thermostable proteases or polymerases. Thus, marine microorganisms may contribute to expanding the number of (even more) stable and selective biocatalysts for industrial biotransformations. One major concern with establishing these enzymes in industrial-scale applications is their sustainable access. With respect to the difficulties of enzyme expression or cultivation of the natural expression system when transferred from its originally habitat to laboratory conditions, the responsible gene or even the gene cluster must be heterologously expressed. This approach requires identification, isolation, characterization, and cloning of the responsible genes in adequate host organisms (considering the codon usage of marine microorganisms), as well as optimization of enzyme stability and enzyme expression. In addition to microorganisms such as bacteria or fungi, higher organisms such as fish, prawns, crabs, snakes, plants, and algae can also be used for tapping of marine enzymes [14.5]. In particular the latter one represents a mentionable source for a number of halogenating enzymes.

The following chapters give an overview about handling and cultivation of the marine enzymes' hosts as well as expression of the biocatalysts. Moreover, some examples of enzymes from marine origin that are or may be of relevance for biotransformation processes are presented. In the main focus are saccharolytic enzymes such as amylases, cellulases, chitinases, agarases, as well as proteolytic enzymes, DNA polymerases, and halogenating enzymes. Since the supply of the biocatalyst depends on the expression and the applied downstream process, the final section of this review covers current purification techniques for intracellularly and extracellularly expressed proteins.

14.2 Cultivation Techniques of Marine Bacteria

The first step in the supply of an enzyme is the cultivation of the naturally occurring marine producing organism, except for using a metagenome approach, which is not addressed in this overview. Within the marine ecosystem microorganisms such as bacteria or fungi can be found in the free water column, in marine sediments, or in symbiotic associations (endosymbiontic and surface associated) with higher marine organisms even in the light and dark zones of the sea. Phototrophic microorganisms like cyanobacteria and microalgae are, however, primarily found within the zones affected by the sunlight.

The transfer of marine organisms from their natural ecosystems and their reproduction under laboratory conditions often fails, because a potential adaptation of the organism to its natural habitat and its participation in several symbiotic interactions with other organisms is commonly not considered. By establishing as far as possible similar environmental conditions to the marine strain these problems may be overcome in laboratory cultivations. Attention must be paid to the nutrient conditions for cultivation of the desired microorganism. Since bacteria or fungi deriving from the free water column exhibit different nutrient requirements than such organisms deriving from sediments or from the inner tissue of invertebrates, no standard nutrient broth that might be applied to support growth and production of all microorganisms exists.

Seawater contains approximately 10^4–10^6 cells ml^{-1}, whereas on surfaces exposed to seawater much higher cell densities, of six orders of magnitude, can be detected [14.6]. Thus, the applied nutrient media should reflect the nutrient conditions of the natural habitat. However, commonly used nutrient media feature a high carbon content, which is contradictory for the fermentation of marine strains. A special cultivation technique applicable for those strains that are classified as non-reproducible under laboratory conditions is the so-called dilution technique [14.7], whereas the populations in a sample are measured, diluted to a small and known number of cells, inoculated into unamended sterilized seawater, and afterwards examined for a defined period of time.

Another nutrient component which is often available to a less degree in seawater and in artificial nutrient broth is iron; therefore growth may be limited with respect to iron deficiency [14.8, 9]. Because of the limited bioavailability of iron, several organisms have adapted themselves and are able to release particular iron-complexing agents, so-called siderophores, enabling the organism to increase iron uptake [14.10].

Although marine microorganisms have specific nutrient requirements, many complex media have been developed for the cultivation of marine microorganisms under lab-scale conditions. The most prominent is the so-called Marine Broth 2216, which was developed in its primary formulation by *Zobell* in 1941 [14.11]. This complex medium can be regarded as the main reference medium in the field of marine microbiology. To reflect the special nutrient needs of distinct marine microorganisms it is sometimes utilized in diluted concentrations. Moreover, to satisfy the need for iron, it contains a well-accessible iron salt (0.1% iron-citrate).

Besides the cultivation of freely suspended cells, enrichment of organisms deriving from surfaces exposed to seawater or from tissues of higher marine organisms can be a challenging task. The organisms commonly grow as conglomerates of bacteria, fungi, algae, and protozoans and represent a biofilm. Within the biofilm the organisms benefit from the accompanying organisms in the extracellular matrix (commensalism and mutualism). Furthermore, the organisms are sheltered within the matrix thus they are often more tolerant towards unphysiological conditions than their suspended counterparts, e.g., towards high/low pH, pressure, and antibiotics. Microorganisms are exposed to varying conditions in their natural habitats with regard to pH, temperature, osmolality, or nutrients and they have evolved specific adaptation systems. Thus, they are able to respond to such fluctuations by activation or repression of gene expression [14.12]. Apart from these mechanisms alternative stimuli–response regulation patterns can be found in bacterial cell–cell communication by means of small signal molecules, called autoinducers. So far, a multitude of signal molecules and the induced signal cascades have been identified; this form of molecular regulation of signal transduction was defined as quorum sensing (QS). This term was given according to its special mechanism and was inaugurated by *Fuqua* et al. [14.13]. Hence, many interactions within such a microenvironment are mediated via different (chemical) QS communication patterns. During the phase of cell growth a specific autoinducer molecule is produced as a function of increasing cell-population density. The bacteria are able to detect and subsequently respond to the accumulation of these compounds, thus, they are capable of distinguishing between high and low cell population density and control gene expression in variation of cell population. By using such QS circuits a population of microorganisms can control the gene expression of the entire community [14.14]. Such a cell–cell communication was first described by *Hastings* and *Nealson* [14.15, 16], who elucidated the cell-density depending expression of luciferase of *Vibrio fischeri*. The microorganism emits light when growing inside the specialized light organs of the host organism but not when living freely in the ocean. So far, many communication strategies have been discovered, whereas distinct signal compounds have been found, depending on the species. Whereas Gram-positive bacteria commonly utilize amino acids or small peptides for QS [14.17, 18], derivatives of fatty acids (acyl-homoserine lactones) serve as autoinducers for Gram-negative bacteria [14.19]. Alternative communication strategies like hierarchical systems for cross-species communication have been summarized by *Whitehead* et al. and can be found elsewhere [14.19]. The discovery of the QS communication system is also of interest for the cultivation processes of marine microorganisms. For example, *Yan* et al. used a biofilm approach, where two epiphytic isolates were cultivated in a modified roller-bottle bioreactor to produce antimicrobial compounds [14.20]. Due to mimicking of the intertidal environment by application of this type of bioreactor, an enhanced production of antimicrobial compounds was found. When the organisms were cultivated in a planktonic state no antimicrobial activity was observed in the supernatant. Since QS is facilitated in the biofilm, it is assumed that production of the compounds is related to the communi-

cation of microorganisms. Moreover, *Yan* et al. have shown that secondary metabolite production of marine microorganisms can be induced by cross-species interactions [14.21]. They used a novel air-membrane surface bioreactor, allowing the bacteria to grow attached to a surface as a biofilm in contact with air. By exposure of the isolates to *Bacillus* sp. production of antimicrobial substances was induced. It can be assumed that this approach might also be transferable to the production of enzymes by raising the enzyme expression due to QS stimuli. Other reactor types that have shown their potential for cultivation of the biofilm state of marine microorganisms are the rotating disk contactor (rotating disk bioreactor, see Fig. 14.1) and a recently reported CCF (Fig. 14.2) approach. The latter one features an inner arrangement within a conical flask consisting of eight equidistantly spaced rectangular strips mounted radially on a circular disk to provide additional surface area for microbial attachment and ports to allow air supply [14.22]. So far, the CCF has proven its potential for the production of cellulase/xylanase and protease, whereas the biofilm state of the investigated microorganisms results in higher enzyme activities than the planktonic counterparts [14.23, 24]. By application of a novel rotating disk biofilm bioreactor *Sarkar* et al. faithfully mimicked the intertidal estuarine habitat of three marine isolates (salt-tolerant estuarine actinobacteria from the Sundarbans region), and supported biofilm formation, resulting in an increase of secondary metabolite production of the actinomycetes in comparison to stirred-tank cultivation [14.25].

Apart from using biofilms to enable the production of secondary metabolites, manipulating QS circuits by addition of signaling molecules may also be an approach to support the cultivation of bacteria. For instance, *Schink* et al. observed an improved growth of lake water bacteria, if acylated homoserine lactones are used as medium supplements [14.26]. Moreover, *Guan* and *Kamino* reported a three to eightfold increase of colony forming units when cultivation of marine-derived samples is accomplished in the presence of acyl-homoserine lactones and commercial siderophore desferrioxamine [14.27]. In addition to acylated homoserine lactones, other signaling molecules such as cyclic adenosine monophosphate (cAMP) might also influence the growth of marine bacteria. *Bruns* et al. reported a pronounced increase of the number of cultivated bacteria if cAMP, *N*-butyryl homoserine lactone, or N-oxohexanoyl-dl-homoserine lactone are supplemented even at a low concentration of 10 μM to the cultivation medium [14.29]. Interestingly enough, cAMP was identified as the most efficient inducer because the total bacterial counts were increased by 100%.

14.3 Examples of Marine Enzymes

An important factor concerning the application of marine enzymes in industry and academic research is their amenability. Thus, cultivation of the enzyme-producing microorganism as well as identification (by molecular phylogenetic methods) and optimization of the enzymes' expression are crucial factors which must be addressed concerning the supply of the respected enzyme. However, as mentioned before molecular biology in terms of heterologous expression can be beneficial for reproducible (over)expression and production of enzymes on the requested scale. However, the symbiotic nature of the marine strains should be also taken into account, since marine microorganisms are often found in close association with various sponges, corals, and other species). Therefore mixed-cultures such as biofilms can be helpful to produce and identify the desired enzyme or, for example, bioactive secondary metabolites.

In the following sections some enzymes of marine origin, which are applicable in academic and industrial research/production, respectively, are highlighted.

14.3.1 Polysaccharide-Degrading Enzymes

Polysaccharolytic enzymes have well-known applications in the food processing, detergent, paper and textile industries. Furthermore, they have potential applications in the biofuel industry and in waste management. Cellulase, xylanase, and amylase are used in baking, brewing, and the production of natural sweeteners. Xylanases are also useful in the prebleaching of paper pulp and amylases are reported to be components of several laundry detergents. Carrageenolytic enzymes are used for liquefaction of carrageenan for applications in the food, pharmaceutical, and cosmetic industries. In addition to food, pharmaceutical, and cosmetic applications agarases have potential applications in biotechnological research. Cellulolytic and lignolytic enzymes are beneficial in the production of biofuels, since degradation of polysaccharide biomasses is the major challenge in the development of plant-derived biofuels. Plant biomasses often contain complex polysaccharides that need to be converted into simple fermentable sugars for bioethanol production. Cellulose, xylan, and lignocellulose are major groups of polysaccharides that are abundant in nature and they are major components of almost all biowaste and some industrial waste. Degradation of these materials is essential for pollution control. Various polysaccharolytic enzymes may be used for their degradation and conversion to value-added products.

Amylases

Amylase is an enzyme that catalyzes starch hydrolysis and is broadly used for the production of simple sugars. Versatile amylases have been reported from marine organisms. *Legin* et al. reported 70 amylase producing microorganisms while screening 269 thermophilic isolates from deep-sea hydrothermal vents [14.30]. Most thermostable enzymes were produced by several hyperthermophilic archaea belonging to the genus *Thermococcus*. Four of the archaeal strains showed pullulanase and α-glucosidase activity in addition to α-amylase activity. In another screening, several amylase producing psychrophilic bacteria were reported from deep-sea sediments of Antarctica [14.31]. Molecular phylogeny identified the amylase producing strains as members of the genera *Pseudomonas*, *Rhodococcus*, and *Nocardiopsis*. The two most active amylases were purified from two *Pseudomonas* strains and the enzymes were characterized. Both enzymes were optimally produced at low temperatures (15–20 °C), but their optimum activity was reported at a remarkably high temperature (40 °C), which is contradictory to their natural habitat. Both the enzymes retained almost 50% activity at 5 °C. However, the enzymes were unstable at a temperature above 30 °C and retained only half of their maximum activity after 5 min incubation at 60 °C [14.32]. An amylase encoding gene was isolated from a marine metagenomic library and overexpressed in *E. coli* [14.33]. The enzyme exhibited 72% identity of amino acid sequence to a putative glycosidase of the deep-sea bacterium *Photobacterium profundum*, followed by 67% and 53% identity to putative glycosidases of marine *Vibrio splendidus* and *Hahella chejuensis*. It showed about 50% sequence similarity to the putative glycoside hydrolase from the marine fish pathogen *Aeromonas salmonicida*. All these putative glycosidases were identified by genome sequences of marine bacteria and formed a new subfamily of glycoside hydrolase GH13, which is closely related to the bacterial α-amylases. The authors proposed that the subfamily may be an independent clade of ancestral marine bacterial α-amylases. Instead of low similarity of the full length sequence of any known α-amylases this enzyme showed a catalytic domain correlated with the α-amylase superfamily. A similar observation was reported in novel α-amylases isolated from *Thermo-*

toga maririma [14.34]. The putative enzyme had no amino acid sequence similarity to the glycoside hydrolase family (GHF) 13 α-amylases, yet the range of substrate hydrolysis and the product profile suggest the protein to be an α-amylase. A marine *Bacillus* was reported to produce several α-amylases that can degrade various types of plant-based raw starch to produce simple sugars [14.35, 36]. Two statistical analyses were applied to optimize the media composition and fermentation parameters for cold adapted amylase production by the marine isolate *Wangia* sp. C52 in a shake flask culture [14.33]. The study showed starch, tryptone, and initial pH had significant effects on production of this enzyme. The maximum amylase production was optimized at 20 °C and pH 7.18 with a shaking speed of 180 rpm. The experimental yield of the amylase in the optimized media closely matched the yield predicted by the statistical model when the fermentation was performed at theoretically optimized fermentations conditions. Tenfold higher amylase production was observed after this optimization. *Chakraborty* et al. isolated two thermostable alkaliphilic amylases from marine microorganisms that showed excellent stability towards surfactants and commercial detergents – the enzymes, therefore, have potential applications in the detergent industry [14.37, 38].

Cellulases and Lignocellulases

Cellulolytic enzymes were reported from a range of marine microorganisms, including bacteria and fungi. A *Saccharophagus degradans* strain was reported to degrade large numbers of complex polysaccharides from numbers of algae, plant, and invertebrate sources [14.39]. Complete genome sequencing of the bacteria revealed more than 180 open reading frames encoding carbohydrate degrading enzymes. It appears that this bacterium consists of a full array of polysaccharide degrading enzymes for complete degradation of plant cell walls. 13 cellulose depolymerases and seven accessory enzymes including two cellodextrinases, three cellobiases, a cellodextrin phosphorylase, and a cellobiose phosphorylase were predicted by genomic and proteomic analyses. A solvent stable alkaline cellulase was reported from a solvent tolerant marine strain of *Bacillus aquimaris* [14.40]. Enzyme stability increased with the presence of 20 v/v % benzene and it was significantly stable in the same concentration of methanol, acetone, and toluene. The enzyme activity was increased to 150% and 155%, respectively, by pre-incubation in two ionic liquids 1-ethyl-3-methylimidazolium methanesulfonate and 1-ethyl-3-methylimidazolium bromide. Cellulase productions by a group of marine microorganisms were optimized using industrial and agricultural wastes. Rice bran was reported to be a preferential nutrient for optimum production of three cellulases by a *Psychrobacter aquimaris* strain [14.41]. The microbe has optimum growth at 25 °C but maximum production of avicelase, CMCase, and filter paperase was achieved at 30 °C. Aeration was more important than agitation for cell growth and fermentation of all three cellulases. Enzyme production was scaled up to a 100 l pilot plant bioreactor. *El-Sersy* et al. screened six marine strains of actinomycetes for CMCase production and a *Streptomyces ruber* strain showed the best productivity [14.42]. Rice straw was used as the carbon source. The Plackett–Burman design was applied to optimize the media composition and fermentation parameters for maximum enzyme production. Two different cellulases were partially purified and their specific activities were determined as 4239.697 U mg^{-}1 and 846.752 U mg^{-1}, respectively. Three alkaline cellulase producing fungal strains were isolated from mangrove leaves and wood litters [14.43]. The production of β-endoglucanase, β-exoglucanase, and β-glucosidase by these isolates was optimized in submerged fermentation and solid-state fermentation using cheap agricultural and industrial waste as substrates. Maximum enzyme production was achieved by solid-state fermentation at alkaline pH using media containing cotton seed. It is interesting to note that the enzymes produced under alkaline conditions showed higher stability and activity than those produced by the same organisms under non-alkaline conditions. *Pointing* et al. studied 15 marine fungi for cellulolytic and lignolytic activity [14.44]. The lignolytic activity of these microorganisms was dependent on the primary carbon source, pH, and salinity of the medium. In another study, 29 marine fungi were screened for lignocellulose-degrading enzyme activities in agar media [14.45]. The isolates were identified as 27 ascomycetes, one basidiomycete (*Calathella mangrovei*), and a mitosporic fungus (*Cirrenalia tropicalis*). Cellulolytic, xylanolytic, and ligninolytic activities were studied in all 29 isolates. 21 isolates produced three enzymes: endoglucanase, xylanase, and laccase, while 2 isolates showed a lack of xylanase activity and 6 isolates had no laccase activity.

Chitinases

Chitin is a major component of fungal cell walls, the exoskeleton of arthropods including insects and crustaceans (mollusks, crabs, lobsters, and shrimps), and the

internal shell of cephalopods (squids and octopuses). Most of these organisms live in the habitat of the marine ecosystem, and it stands to reason that the chitin hydrolytic enzyme (chitinase) is abundant in the marine environment. Chitinolytic activity was reported in several marine bacteria (pathogens) that attack living arthropods or degrades the chitin-rich biomass derived from their exoskeleton. Chitinase is used for the production of single cell proteins for animal and aquaculture feed, for isolation of fungal protoplasts, and for the preparation of chitooligosaccharides. Chitinases are not widely used at commercial scale due to their high cost but they have interesting potential applications in pest control and preparation of medicines. Chitinase genes can be used to develop chitinase-producing transgenic plants that are resistant to insects and fungi. The cell walls of some human pathogens including fungi, protozoa, and helminths are composed of chitin, which could be hydrolyzed by microbial chitinases and thus, chitinase may be used for the treatment of these microbial infections.

A chitinase C encoding gene from the marine isolate *Salinivibrio costicola* 5SM-1 strain was cloned in the pGEM7Zf(+) vector and overexpressed in *E. coli* [14.46]. The protein was identified as an exochitinase that hydrolyzes colloidal chitin and produces chitobiose as the major hydrolysis product. One catalytic domain and two chitin binding domains were identified by amino acid sequence alignment. The complete loss of chitinase activity by mutation of three conserved amino acid residues at the putative catalytic site confirmed the location of the catalytic domain. Another chitinase C enzyme was reported from the marine *Alteromonas* sp. strain O-7, and the catalytic domain was predicted by a similar approach [14.47]. The same research group also isolated the novel cold-adapted chitinase B from this microorganism [14.48]. *Gohel* et al. used the Plackett–Burman design to optimize media composition for chitinase production by the marine strain of *Pantoea dispersa* [14.49]. In this optimized media chitinase production increases by 4.21 fold in comparison to the basal medium; also a 3.95-fold increase of endochitinase production and a 2.31-fold increase of chitobiase production was reported in this medium. In another study, the impact of process parameters was studied on extracellular chitinase production by a *Beauveria bassiana* strain in solid-state fermentation using wheat bran [14.50]. The chitinolytic marine fungus was isolated from marine sediments from the south coast of India and characterized as a spore-forming alkaliphilic fungus. The initial moisture content significantly affected the microbial growth rate and enzyme production. Maximum chitinase production was achieved after the third day of fermentation using the media containing wheat bran to a seawater ratio of 5 : 3 (w/v). Chitinase production by this fungus was also optimized in solid-state fermentation using chitin-rich prawn waste as nutrient [14.51]. The antifungal activity of chitinase was reported from the marine *Streptomyces* sp. DA11 isolated from a sponge from the South China Sea [14.52]. Amino acid sequence alignment identified the 34 kDa protein as chitinase C. The antifungal activity was confirmed against *Aspergillus niger* and *Candida albicans* with a zone of inhibition of 10.98 ± 0.49 mm and 10.48 ± 0.45 mm, respectively.

Agarases

Agarase is an important enzyme distributed in a wide range of marine organisms. This enzyme has potential application in the food, pharmaceutical, and cosmetics industries. It can also be used in microbiology and molecular biology research. Two β-agarase genes (*agaA* and *agaB*) were isolated from the marine *Pseudoalteromonas* sp.CY24 [14.53, 54]. The *agaB* gene was cloned and overexpressed in *E. coli* and the 50.8 kDa protein was characterized. This enzyme degrades agarose to generate neoagarooctaose and neoagarodecaose as the major products but cannot hydrolyze carrageenan, alginate, or chitosan. The substrate binding site and the mechanism of hydrolysis of this enzyme were predicted by analysis of the enzyme kinetics, the degradation pattern of different oligosaccharides, and ^{1}H-NMR analysis. The enzyme has a large substrate binding cleft and it appears to be structurally and functionally different from other known agarases. It hydrolyzes glycosidic bonds with inversion of anomeric configuration, in contrast to other known agarases that retain the anomeric configuration. On the other hand, the *agaA* gene encodes a 48.4 kDa protein corresponding to a catalytic domain of the glycosyl hydrolase family 16 and a carbohydrate-binding module type 13. It is an endo-type agarase that hydrolyzes β-1,4-linkages of agarose to yield neoagarotetraose and neoagarohexaose as the end products. Another β-agarase producing gene (*agrP*) was isolated from the marine *Pseudoalteromonas* sp. AG4 and was cloned and overexpressed in *E. coli* [14.55]. Sequence similarity suggests that this enzyme is a member of the glycosyl hydrolase family 16. It produces neoagarotetraose and neoagarohexaose from agar and additional neoagarobiose by hydrolysis of agarose. A β-agarase gene from the agarolytic marine bacterium *Agarivorans* sp. HZ105 showed 98.6%

sequence identity with a β-agarase (agaB) from *Vibrio* sp. JT0107 [14.56]. The enzyme was overexpressed in *E. coli* and identified as an endo-type β-agarase. It can hydrolyze neoagarooligosaccharides with a degree of oligomerization above four and produce neoagarotetraose as a dominant end product. Another endo-type β-agarase was reported from marine *Agarivorans* sp. LQ48 [14.57]. This enzyme showed 73% sequence similarity with the β-agarase (AgaB) isolated from the marine *Pseudoalteromonas* sp. CY24. Like AgaB this enzyme also hydrolyzes β-1,4-linkages of agarose and produces neoagarotetraose and neoagarohexaose as the main products. Notably, this agarase retains 95% of its initial activity after 1 h incubation at any pH between 3.0 and 11.0 – such a wide range of pH-stability has rarely been observed in any other agarase.

14.3.2 Proteases

Proteolytic enzymes account for above 60% of the global enzyme market [14.58], and there is no doubt that proteases are one of the most widely studied marine enzymes. They are vastly used in the food processing, detergent,leather, and pharmaceutical industries, and in biotechnological research. They have potential applications in bioremediation and waste management. The increased demand for industrial proteases over its supply from plant and animal sources led to an increased interest in microbial proteases. 70% of industrial proteases come from microbial sources. Alkaline and neutral proteases are obtained mainly from bacterial sources, mostly from different species of *Bacillus*, while fungi are a well-known source of acid proteases. Marine microbial proteases gained attention for their extremophilic properties and stability in the presence of a broad range of chemicals. They possess almost all the characteristics desired for various biotechnological applications of proteases.

A novel alkaline serine protease was reported from the marine fungus *Engyodontium album* BTMFS10 strain isolated from marine sediment from the west coast of India [14.59, 60]. The extracellular enzyme was produced by solid-state fermentation and the process parameters of protease production were optimized. The enzyme was active over a broad range of pH values (6–12) and temperature ranges (15–65 °C) and retained its activity in the presence of hydrocarbons, natural oils, surfactants, and organic solvents. The optimum activity of the purified enzyme at a high temperature (60 °C) and pH value (pH 11) suggest its potential application in detergent industry. *Sana* et al. reported another alkaline serine protease from a marine γ-proteobacterium isolated from the intertidal zone of the Bay of Bengal [14.61]. The enzyme was tolerant to salt, solvent, detergent, and bleaching agents, and showed potential for the detergent industry and dry washing. A protease encoding gene was isolated from *Engyodontium album*, which encodes a protein with 96% sequence similarity to proteinase R of *Tritirarchium album* [14.62]. A homology comparison of the amino acid sequence revealed that this protease belongs to the subtilase family of serine protease. A comparative homology modeling suggested a broad substrate specificity of the enzyme. The enzyme structure was reported to be stabilized by two disulfide bonds and more than two Ca^{2+} binding sites, which are assumed to contribute to the thermostability of the enzyme.

Surface-displaying recombinant alkaline proteases were produced on a *Yarrowia lipolytica* cell surface by overexpressing a marine-derived alkaline protease gene [14.63]. This surface-displaying protease can hydrolyze various proteins for the production of bioactive peptides. The peptides have potential pharmaceutical applications due to their angiotensin-converting enzyme (ACE) inhibitory activity and antioxidant activity. Peptides with high ACE inhibitory activity have well-known potential application in the treatment of hypertension and other bioactive peptides can be used as clinical nutrient supplements.

The production of a thermostable alkaline protease by a marine *Bacillus* was optimized and scaled up in a stirred tank bioreactor using cheap and readily available substrates [14.64]. The authors studied the effects of environmental factors, carbon sources, nitrogen sources, and fermentation parameters on the protease production kinetics. Enzyme production increased with prolonged fermentation time and faster agitation rate. Maximum protease production was achieved after 40h fermentation at 42 °C with an aeration rate of 1.5 vvm and constant agitation at 400 rpm in a soybean–casein medium (pH 9.6). Protease production by the marine bacterium *Teredinobacter turnirae* was optimized for solid-state fermentation as well by immobilization on solid matrixes [14.65–67]. Media composition, initial pH, inoculum concentration, and the effect of different salts and carbon sources were studied to optimize protease production by solid-state fermentation in a soybean-based medium. The maximum protease production was obtained using 1 w/v % soybean concentration, initial pH 7.34, and a 2.5 v/v % inoculum level. The material and particle size of the immobilizing medium, and the method and conditions for

cell immobilization were also optimized for repeated batch fermentation of the alkaline protease by *T. turnirae*. Ceramic support, the different sizes of broken pumice stone, and silicone foam enhanced enzyme production by more than 200%, when compared to free cells. Electron micrograph evident *T. turnirae* colonization in porous support matrices and five repeated batch fermentation was achieved without significant decrease in the enzyme production. When the same strain was immobilized in calcium alginate beads maximum protease activity was achieved at 3 w/v % sodium alginate and 3% $CaCl_2$ concentrations with a 1 : 2 ratio of cell and alginate. Protease production was independent of bead size but decreased significantly when the beads were treated with glutaraldehyde. The immobilized cells were used for 8 cycles, each lasting 72h. Protease production increased with an increased number of fermentation cycles and was maximized at the fourth cycle when the enzyme activity reached about 3.5 times more than that of the first cycle.

14.3.3 Halogenating Enzymes

Halogenated molecules are widely distributed in the environment and their existence is not only related to human industrial processes but also to natural biotic as well as abiotic processes. To date almost 5000 organohalogens are known. Most of them contain chlorine or bromine rather than fluorine or iodine [14.68]. With respect to the relatively high concentration of bromide found in the marine environment, brominated compounds are found quite often and occur in a larger number than in freshwater samples [14.69, 70].

While establishing a halogen–carbon bond, several properties of the compound are changed. The following two effects are the most important: a) the introduction of halogen increases the molecule's thermal and oxidative activity, and b) increases the biological membrane permeability [14.71]. The halogenated compounds currently manufactured by the industry can be discriminated into bulk chemicals and higher value-added pharmaceutical compounds, where it is estimated that 20% of all pharmaceutical small drugs and approximately 30% of all active compounds in agrochemistry are halogenated [14.71]. Considering the problems of chemical halogenation, such as low yield, lack of sensitivity, and the use of harmful/toxic chemicals, there is an increasing demand for less toxic and highly specific halogenation processes. The latter is of particular interest for the production of halogenated pharmaceuticals. However, halogenated compounds are also of interest as intermediates in organic synthesis. Since they can be used as reactant within palladium-catalyzed coupling reactions, novel synthetic routes are accessible for manufacturing of organic fine chemicals.

The formulation of natural halogenated products occurs via abiotic and biotic processes. Particular enzymes are responsible for the biogenous halogenation process. However, halogenation can be accomplished by several types of enzymes featuring distinct substrate specificity. One can roughly distinguish the enzymes as haloperoxidases, flavin-dependent halogenases, non-heme iron halogenases, and the fluorinase/chlorinase system.

Haloperoxidases are versatile enzymes for transformation of many substrates. Most prominent is the chloroperoxidase from *Caldariomyces fumago*. Whereas the enzyme is more or less even unspecific with regard to the substrate, it can be beneficially applied to numerous biotranformations. Reactions such as epoxidations [14.72, 73], enatioselective sulfoxidations [14.74], *N*-oxidation of arylamines [14.75], hydroxylation of side chains of aromatic systems [14.76], oxidation of indole to oxyindole [14.77], or oxidation of primary alcohols to their corresponding aldehydes [14.78] have been reported. Since the expression of the enzyme is accompanied by the production of a black pigment, the efficient supply of the biocatalyst, and thus biotechnological application, is hampered. However, *Yazbik and Ansorge-Schumacher* et al. recently developed a novel purification strategy enabling an efficient supply of the enzyme for technical applications [14.79].

Regioselective halogenation can be accomplished by the application of flavin-dependent halogenases. However, halogenation of positions 4, 5, 6, and 7 of tryptophan-derived rings of natural products, as well as halogenation of tyrosines at the ortho position,and mono and di-chlorination of pyrroles are the preferred reactions catalyzed by such enzymes [14.80, 81]. Interestingly, similarly to haloperoxidases, the flavin-dependent halogenase uses hypochlorite for halogenation. However, unlike haloperoxidases, the generated hypohalous acid cannot leave the active site and can only react with substrates at the active site, resulting in selective halogenation reactions. Halogenation of inactivated carbon atoms can be accomplished by non-heme iron, α-ketoglutarate and O_2-dependent halogenases, which use a radical mechanism [14.82]. Up until now, the application of such enzymes for biocatalytic processes (in vitro) is still hampered due to the restricted substrate spectrum, as well as the required cofactor recycling.

A kinetic study of a *Streptomyces* sp. derived and recombinantly expressed flavin-dependent tryptophan-5-halogenase (including a cofactor regeneration) was also reported by *Muffler* et al. [14.83]. The study was accomplished due to the fact that halogenated tryptophan may serve as a potential serotonin precursor. By application of the FDH/formiate-system for cofactor regeneration, the space–time yield of the halogenation was improved by a factor of 1.6. Furthermore, *Muffler* et al. applied a genetic algorithm approach to optimize the enzyme's performance and the conditions for the biocatalytic process, whereby the yield of the halogenated product improved significantly from 3.5 to 65% [14.84].

Fluorinase and chlorinase have a commonality in that they mediate nucleophilic reactions of their respective halide ions to the C-5′ carbon of S-adenosyl-L-methionine (SAM) [14.85]. Biological fluorination is of tremendous interest, since it might help to overcome the problems associated with chemical fluorination. However, more basic research is needed to characterize the potential of these types of enzymes.

14.4 Molecular Biology

Marine-derived enzymes are inevitable in modern molecular biology research. Polymerase chain reaction (PCR) is a technique for continuous in vitro DNA synthesis by use of DNA polymerases. It is widely used for gene amplification, site directed mutagenesis, DNA sequencing, and diagnostic purposes. The reaction mixture needs to be treated at high temperature, which causes inactivation of the DNA polymerase [14.86]. It is essential to add fresh enzymes at each reaction cycle, and it was not possible to use the technique widely before discovery of the thermostable DNA polymerase. Today, two marine-derived thermostable DNA polymerases are at the center of this technique. Vent polymerase (New England Biolab) from *Thermococcus litoralis* and *Pfu* polymerase (Stratagene) from *Pyrococcus furiosus* are widely used DNA polymerases for this purpose. These enzymes show a better performance than the previously used *Taq* polymerase; they have a lower error rate than the *Taq* polymerase and also have a proofreading ability due to 3′–5′ exonuclease activity [14.87–89]. DNA ligase from *Thermal thermophillus* is another important marine enzyme used in molecular biology research [14.90, 91]. Marine microorganisms are also an important source of restriction endonucleases. *Asp*MD1 is an isoschizomer of *Sau*3AI that was purified from the marine isolate *Alcaligenes* sp. MD1 [14.92]. A novel restriction enzyme *Dma*I was isolated from the marine bacterium *Deleya marina* IAM 14 114 [14.93]. This enzyme is moderately thermostable and recognizes the hexanucleotide sequence 5′-CAGCTG-3′ to produce the blunt-ended digestion product. Several other restriction endonucleases, including *Dpa*I, *Age*I, *Hja*I, *Hac*1, *Hsa*1, and *Hag*1 have been isolated from marine bacteria. All these enzymes are potential tools for double-stranded DNA digestion. DNA topoisomerases play important roles in replication, transcription and gene expression by controlling DNA topology. Several DNA topoisomerases have been isolated from marine bacteria, including *Sulfolobus acidocalcarius*, *Desulfurococcus amylolyticus*, *Thermus acidophilum, Fervidobacterium islandicum*, *Thermus maritima*, and *Methanopyrus kandleri*. [14.94]. Some of these are characterized for their potential application in biotechnological research.

14.5 Downstream Processing of Marine Enzymes

Capturing and purification of a marine enzyme is a very challenging task, which is commonly addressed to a minor extent in comparison to the fermentation process. But both steps are directly linked together, since efficient downstream processing requires a minimum of the target compound otherwise every isolation strategy fails. Furthermore, the fermentation medium should contain only small amounts of supplements which might interfere with the purification strategy of the target enzyme. Thus, optimization of the cultivation process with regard to the yield of the product should be accomplished prior to establishing a downstream technique. This optimization should also focus on a minimization of by-product formation, as these must be separated from the product. Moreover, the production of (unwanted) side products also affects the

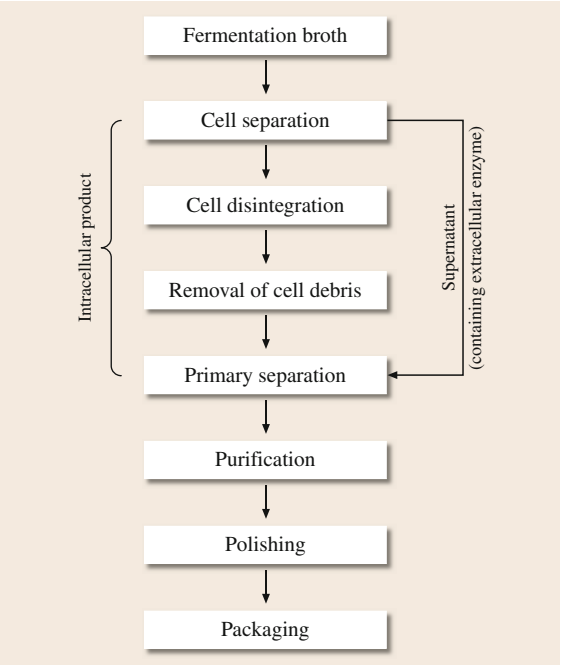

Fig. 14.3 Flow chart of a common downstream process according to *Muffler* and *Ulber* [14.95].

process costs, because the medium is used to a lesser extent for production of the relevant enzyme. In the following section a brief overview about the related steps of downstream processing is given. The interested reader is referred to a review article by *Muffler* and *Ulber* [14.95], which is exclusively dedicated to this topic.

Commonly, a diluted input stream is handled within downstream processing and is subsequently treated by several techniques to obtain a highly concentrated, purified, and storable product (liquid or solid). Initially, the kind of expression determines the first steps of the downstream process. If the enzyme is expressed in an extracellular fashion, it is available among other soluble compounds (e.g., medium components, side products) and insoluble matter (e.g., particles, intact cells). In the case of an intracellular occurrence of the enzyme, the biomass must be disrupted prior to its isolation. In principle, all downstream processes try to remove the insoluble particles and afterwards the product is isolated. A flow chart of the relevant steps of a downstream process is shown in Fig. 14.3.

Fermentation of the enzyme producing strain is followed by separation of the soluble and insoluble components of the fermentation broth. To avoid thermal deactivation of the product the broth is subsequently chilled after termination of the fermentation. The separation of cells can be achieved by application of filters (static filtration or cross-flow filtration), as well as by application of centrifuges or decanters. Selection of the separating unit depends, for example, on the cell concentration, as well as volume and viscosity of the fermentation broth. Extracellular enzymes can subsequently be obtained from the resulting supernatant, whereas disintegration of cells is required for recovery of intracellular enzymes.

Liberation of intracellularly expressed enzymes can be achieved by several procedures; the most frequently applied techniques are mechanical/physical and enzymatic treatment. Since it is difficult to predict the performance of the method of disintegration, some techniques are tested in parallel. The optimal procedure features a maximum of enzyme release and a minimum of structure alteration and deactivation of the target enzyme, respectively. Apparatuses such as homogenizers or bead mills are often applied to arrange mechanical treatment [14.96, 97]. Such techniques are even applicable for (continuous) disruption of biomass within pilot or industrial scale applications. A gentle method allowing cell disruption at lab-scale uses ultrasound. Enzyme release is accomplished via disruption of the cells by shear forces and cavitation. To prevent heat denaturation of the enzyme the cell suspension is cooled during ultrasonic treatment. An approach used to release the intracellular protein under mild conditions utilizes hydrolytic enzymes. Such enzymes are capable of degrading the cell wall of the relevant organism, and disintegration occurs as a result of osmotic pressure; thus the generated protoplasts burst and release the target enzyme into the surrounding medium. An enzyme that is often used for enzymatic degradation of bacterial cell walls is lysozyme, of hens' egg origin. Although lysozyme is most effective for the lysis of Gram-positive bacteria, it also facilitates the lysis of Gram-negative bacteria. However, ethylenediaminetetracetic acid (EDTA) is often added to the enzyme solution if the cell wall of Gram-negative bacteria should be attacked to trigger the hydrolysis via complexation of Ca^{2+} of the outer (protecting) membrane. Lysozyme is commercially available at moderate cost and the process requires only simple equipment. Therefore, enzymatic lysis can be considered as an option for large-scale processes [14.98]. Apart from the hens' egg lysozyme, cell wall degrading enzymes are also available from marine microorganisms, but up until now they have not been provided by commercial suppliers. These marine-derived lysozymes can feature

prospective traits such as high activity even at low temperatures, as well as activity in a broad range of pH values (e.g., [14.99, 100]). Hence the hydrolysis may be performed at low temperatures and thermal enzyme deactivation is minimized. Another approach is the so-called electroextraction, a technique which so far has not been applied for recovery of intracellular enzymes from marine microorganisms, although its potential has been proven, mainly for yeasts (e.g., [14.101]). Electroextraction is based on electro-induced changes in the cell envelope, which result in a release of intracellular proteins without formation of debris.

The diluted enzyme is subsequently concentrated by means of precipitation (e.g., with ammonium sulfate) or ultrafiltration. The unspecific concentration of proteins is followed by chromatographic steps, whereby the enzyme is separated from the impurities according to its charge, size, or hydrophobicity, or due to specific groups of the target enzyme. Analog separation principles are provided by membrane adsorbers. Such devices feature some advantages in comparison to conventional column chromatography. These can be summarized as follows: lower manufacturing costs, no diffusion-controlled exchange kinetics, easier handling, and up-scaling [14.102]. A membrane adsorber is based on a stationary, modified microporous matrix allowing high fluxes and maximization of the mass transfer, thus limiting diffusive transport phenomena as they occur in column chromatography can be minimized. Additionally, the compressibility can be neglected if the module is applied under moderate pressure. Membrane adsorbers are commercially available and can be purchased as ion-exchangers with acidic (e.g., sulfonic acid, or carboxylic acid), basic (e.g., quaternary ammonium or diethylamine), or chelating membranes, which are applicable for immobilized metal affinity chromatography. One example for a successful application of a cation-exchange membrane adsorber for recovery of a marine enzyme was reported by *Muffler* and *Ulber* [14.103]. They established a fed-batch process for optimizing the enzyme expression of the intracellular produced sulfite oxidase by *Sulfitobacter pontiacus*. The supernatant obtained after ultrasonication of the suspended biomass and centrifugation of the cell debris was directly applied to a cation-exchange membrane adsorber. Thus the specific activity within the pooled eluate fraction was increased about a factor of 8 compared to the crude extract. A further increase about a factor of 2.6 of the specific activity was finally achieved by ultrafiltration.

If applicable, affinity chromatography is the method of choice, because this technique relies on the highly specific binding interactions of the target enzyme and the stationary matrix. However, the target enzyme must feature a characteristic subunit or subgroup which can be used for binding to an affinity matrix. A successful application of this technique necessitates that such binding-groups are absent in the co-expressed proteins. Therefore, affinity chromatography is usually applied with recombinant enzymes rather than native enzymes, because the relevant groups, such as, for example, a histidine tag, a chitin binding tag, or maltose binding tag are linked to the native sequence of the protein, thus allowing a subsequent gentle purification of the recombinant protein. For instance, *Kang* et al. expressed an epoxide hydrolase of *Sphingophyxis alaskensis* origin in *E. coli* and purified the heterologously expressed protein by metal affinity chromatography via his-tag [14.104]. Another binding method was applied by *Han* et al., who expressed a chitinase with antifungal activity from marine *Streptomyces* sp.DA11 by *E. coli* and purified the chitinase, showing an antifungal activity by 80% ammonium sulfate, affinity binding to chitin, and diethylaminoethyl-cellulose anion-exchange chromatography [14.52]. However, affinity chromatography had already been successfully used for purification of native marine proteins. *Bertau* et al., for example, reported the purification and characterization of an α-L-fucosidase by application of the glycosidase inhibitor analogue 6-amino-deoxymannojirimycin as ligand for the saccharolytic enzyme [14.105].

14.6 Conclusion

Marine microorganisms can be considered as a powerful resource of enzymes with special traits which are often different from their terrestrial counterparts. In particular, enzymes from extremophiles can be valuable in a broad variety of processes. Enzymes from cryophilic microorganisms are often active at low temperatures and may contribute to, for example, energy savings in laundry processes (cryophilic lipases or proteases). Such enzymes may also contribute to increase the quality of food because processing can be

achieved at low temperatures. Moreover, cryophilic enzymes can simply be deactivated by a small shift in temperature. With respect to mass transfer and viscosity, elevated temperatures for biocatalytic processes can be desirable for several applications, thus thermo- or even hyperthermophilic marine enzymes are of great interest for this type of industrially relevant enzymes.

However, cultivation and expression of natural producing strains often represent a bottleneck for enzyme supply. Therefore, novel cultivation techniques must be introduced at lab scale but also examined and transferred to pilot scale, respectively. The cultivation of (single-species and mixed-species) biofilms is still in its infancy, but the examples presented here give an idea of the potential of this approach. One should bear in mind that up until now only a small fraction of marine bacterial diversity is accessible. Molecular biology and intensification of metagenome approaches may support the identification of many novel genes and enzymes, which will expand the pool of enzymes applicable for industrial processes in the near future.

15. Biofouling Control by Quorum Quenching

Vipin C. Kalia, Prasun Kumar, Shunmughiah K. T. Pandian, Prince Sharma

Bacteria above a threshold cell density regulate the expression of a specific group of their genes in response to small signal molecules called autoinducers. This *twitter* communication phenomenon is called quorum sensing (QS). Among the various genetic expressions mediated by QS, biofilm formation and expression of virulence factors are the most prominent. These phenotypes are a major cause of concern for health departments and a wide range of industries dealing especially with drinking water, waste water reclamation, and desalination. This phenomenon leads to heavy economic losses. Efforts to disrupt biofilms have met with little success. In fact, bacteria within the biofilms are 1000 times more resistant to antibiotics than their planktonic counterparts. Biosensors or reporter strains have been developed to screen QS inhibitors. A potential approach to inhibit the process of biofouling is to interfere with bacterial QS signals. QS inhibiting enzymes and molecules have been isolated from a wide range of organisms such as bacteria, fungi, algae, and marine organisms. Efforts to disrupt biofilm formation have been carried out through designing antifouling agents that primarily reduce surface adhesion of the organisms. These include fouling release coatings such as nanocomposites. In contrast to removing biofilms, there are certain areas where it is desirable to regenerate biofilm for a fresh round of biotransformation.

15.1 Overview

Biofouling (BF) in aquacultures, water treatment, the pulp and paper industry, and marine systems is a major cause of concern for water purification industries, fisheries, merchant and defense naval departments, and manmade structures (monuments/paintings). Worldwide it is a problem of high practical and economic relevance. Micro and macrofoulers can cause severe industrial problems by increasing drag (leading to increased fuel consumption), promoting metal corrosion, and reducing heat transfer efficacy of heat exchangers. A major problem encountered during the production of drinking water, waste water reclamation, and desalination is the biofilm formation on membrane filters. Efforts to control this through the use of antifouling (AF) coating (incorporating biocides such as tributyrin) have imposed environmental burdens, especially since their usage has been banned [15.1–4].

The most evident form of BF is the formation of biofilms, which invariably harbor more than one type of microorganism. Bacterial biofilms play both negative and positive roles. During processing for drinking water, biofilms cause fouling of filtration membranes but act positively as biocatalysts in biologically active filters, riverbank filtration, and membrane biofilm reactors. In the wastewater treatment biofilms also act as biocatalysts in fixed film activated sludge, moving bed biofilm reactors, tertiary filters, and granular sludge, but cause BF of membrane bioreactors. The underlying phenomenon of the occurrence of bacterial communities in this specific niche depends largely on their ability

to communicate among themselves [15.5]. Among the various means of communication, the most widely studied and recognized is that occurring largely under high cell densities and exceptionally at low cell densities, such as in *Vibrio cholerae*. This phenomenon of cell-density-dependent communication is termed quorum-sensing (QS). Here, the release of QS signal molecules is proportional to the cell density and above a threshold level these are retrieved into the cell to trigger the expression of genes responsible for a large number of phenotypic features such as bioluminescence, biofilms, virulence, antibiotic production, and rhizospheric activities, etc. [15.6].

Bacteria have the ability to *sense* and adhere to surfaces to form biofilms. In aquacultures, bacterial pathogens such as *Aeromonas hydrophila, Vibrio anguillarum, V. alginolyticus, V. ichthyoenteri* form biofilms which are mediated by QS signal molecules, such as acyl-homoserine lactones (AHL), furanosyl borate diester, and peptides. Extremophiles – haloalkaliphilic archaeon – *Natronococcus occultus* living in alkaline biotope and acidophilic γ-proteobacterium, *Acidithiobacillus ferroxidans* cause BF through AHL-mediated QS. In water purification systems, *Legionella, Escherichia*, *Pseudomonas*, and *Rhizobium* are responsible for biofilm formation. Biofilms formed on stainless steel surfaces and other metal and alloys are typically dominated by diatoms [15.7–10]. For archaeological departments, the issue of deterioration of buildings and monuments caused by biofilm forming organisms such as *Gloethece*, is a matter of great worry [15.11].

15.2 Bacterial Biosensors

In order to detect the active principle underlying the biofilm formation by bacteria which produce QS signals to communicate among themselves, biosensor bacterial strains have been developed. These biosensors respond to AHLs with distinct acyl chains lengths. One of the most widely exploited bacterial biosensors which responds to C_6HSL is *Chromobacterium violaceum* strain CV026. McClean and his team developed a violacein pigment and AHL-negative double mini Tn5 mutant by transposons inserted into the *cviI* (AHL synthase) gene and in a violacein repressor locus. This biosensor strain produces purple violacein pigment in response to exogenously supplied AHLs. Biosensors for small acyl chains, C_4AHL, have been developed in *Escherichia coli* (pSB536), *E. coli* (pAL101). The plasmid pSB1075-based sensor responds to long acyl chain AHLs such as $3OC_{12}$HSL and pKDT17 responds to C_{12}-HSL and C_{10}-HSL. The biosensor strain *Agrobacterium tumefaciens* (TraI/R) can detect a wide range of AHL signals with acyl chain lengths ranging from C_4 to C_{14} [15.12].

15.3 Quorum Quenching (QQ)

QQ can be inhibited at different stages:

i) Biosynthesis of AHLs by inhibiting enzymes such as the acyl–acyl carrier protein (ACP) and S-adenosyl methionine synthase
ii) Destroying QS signal molecules through the activities of AHL-lactonases and AHL-acylases
iii) The inhibition of AHL efflux proteins
iv) The inhibition of transcriptional activators (LuxR homologs)
v) The use of QS analogs.

15.3.1 Enzymes

Among the various possibilities of down-regulating QS systems, enzymes produced by a range of organisms have been widely studied. These enzymes are of bacterial origin and are categorized as:

1. Lactonases
2. Decarboxylases
3. Acylases
4. Deaminases
5. Oxidoreductases.

Lactonases are produced by *Acinetobacter*, *Agrobacterium*, *Arthrobacter*, *Bosea, Chryseobacterium*, *Geobacillus, Bacillus, Mycobacterium*, *Rhodococcus*, *Klebsiella*, *Ochrobactrum*, *Microbacterium*, *Solibacillus*, *Rhodococcus*, and *Nocardioides, Sphingopyxis*. Acylases having the ability to degrade long-chain AHLs ranging from C_6HSL to C_{12}HSL have been found to

be produced by *Pseudomonas aeruginosa, P. syringae* strain B728a, *Shewanella* sp. strain MIB615, *Streptomyces* sp. strain M64, *Anabaena* sp. PCC7120, and *Ralstonia solanacearum* GM1000. Oxidoreductases from *Bacillus megaterium* CYP102A1, *Burkholderia* sp. strain GG4, and *Rhodococcus erythropolis* W2 act by substituting an oxo group with a hydroxyl group of AHL [15.5, 6, 10, 13–17].

15.3.2 Quorum Sensing Inhibitors (QSIs)

A potential approach for inhibiting the process of BF is to interfere with bacterial QS signals [15.5]. AHL degraders have been isolated from guts of shrimp, *Penaeus vennamei*, European seabass, *Dicentrarchus labrax* L., and Asian seabass, *Lates calcarifer*. Antibiotic malyngolide produced by the cyanobacterium, *Lyngbya majuscula* inhibited QS at concentrations between 3.57–57 μM. Malyngamide C and 8-epi-malyngamide C inhibited luminescence of LuxR-based *E. coli* reporter strains. Malyngamides A and B, which are structurally different from malyngamide C, were effective in inhibiting QS-dependent violacein production by *C. violaceum* CV017.

Bacterial QSIs

The peptide antibiotic – siamycin I, produced by *Streptomyces* sp. strain Y33-1, inhibits the gelatinase and gelatin biosynthesis activating pheromone, which results in disruption of the biofilm formed by *Enterococcus faecalis*. The unique feature of siamycin is the ability to selectively inhibit the growth of Gram-positive bacteria but show no effect on the growth of Gram-negative bacteria. Butyrolactones (2(3H)-furanones) from *Streptomyces* sp. act as analogs of AHL. Naturally occurring intermediates of the butanolide (2(5H)-furanones) biosynthetic pathway in *Hortonia* sp. and *Streptomyces antibioticus* have also been found to be effective. In *Pseudomonas* sp., cyclopeptides and their diketopiperazines act on the QS system. There are few but certain secondary metabolites produced by bacteria: (i) *N*-(2'-phenylethyl)-isobutyramide and 3-methyl-*N*-(2'-phenylethyl)-butyramide produced by *Halobacillus alinus* C42, and (ii) 2-*N*-pentyl-4-quinolinol by *Alteromonas* sp. affect antibiotic (Andrimid) production, bioluminescence (HAI-1 pathway), and prevent surface colonization in different *Vibrio* spp. Based on the molecular size and structure of the inhibitors, phenylethylamides are AHL structural mimics that compete for receptor binding sites.

QSIs from Plants

The traditional of use of plant products for the treatment of BF and ailments has been attributed to the phytochemicals present in them. Plant extracts have been found to act as QSI because of the similarity in their chemical structure to that of QS signals (AHL) and also because of their ability to degrade signal receptors (transcriptional activators, LuxR/LasR). γ-aminobutyric acid produced by plants acts as promoter for the degradation of the AHL signal OHC_8HSL by AttM, lactonase of *A. tumefaciens*, attenuating the QS-dependent infection process. Pyrogallol, extracted from medicinal plants such as *Emblica officinalis* and its analogs exhibit antagonism against AI-2. L-canavanine from seed exudate of *Medicago sativa* affected QS-mediated exopolysaccharide production. *Curcuma longa*, a well-known spice plant produces curcumin, which inhibits the expression of virulence genes of *P. aeruginosa* PA01. QS-regulated activities such as biofilm formation in *P. aeruginosa* and AI-2-mediated QS in different *Vibrio* spp. have been reported to be affected by cinnamaldehyde and its derivatives. Extracts from leaves, flowers, fruit, and bark of *Combretum albiflorum*, *Laurus nobilis*, and *Sonchus oleraceus* were also found to possess anti-QS activities. Flavan-3-ol catechin, a flavonoid from the bark of *C. albiflorum* reduces the production of QS-mediated virulence factors – pyocyanin, elastase, and biofilm formation by *P. aeruginosa* PA01. QSIs have also been reported from garlic. Phenolic plant secondary metabolites such as salicylic acid stimulate AHL-lactonase enzyme expression. Aqueous extracts of edible plants and fruits such *as Ananas comosus, Musa paradiciaca, Manilkara zapota*, and *Ocimum sanctum* have been tested as QSI against violacein production by *C. violaceum* and pyocyanin pigment, staphylolytic protease, elastase production, and biofilm formation abilities of *P. aeruginosa* PA01. The QS system in *Staphylococcus* spp. consists of the AI RNA III activating protein (RAP) and its target molecule (TRAP). Inhibition of RAP by RNA III-inhibiting peptides (RIP) results in attenuation of virulence. Hamamelitanin extracted from the bark of *Hamamelis virginiana* (witch hazel), like RIP, did not affect the growth of *Staphylococcus* spp., but inhibited the QS regulator RNA III, and prevented biofilm formation and cell attachment in vitro. Evidence has also been provided by implantation of grafts soaked in Hamamelitanin into animals, where it decreased the bacterial load in comparison to control.

Extracts of the plants *Moringa oliefera* and *Acacia nilotica*, which contain gallic and ellagic acids,

have anti-QS potential. Epigallocatechin gallate (salt of gallic acid) and ellagic acid inhibited LasR and LuxR-based QS at the concentrations 15–30 μM. Gallic, but not ellagic, acid inhibited QS of *C. violaceum* CVO17 at 64.7 μM. Ellagic acid derivatives from *Terminalia chebula* Retz. fruit downregulate the expression of lasI/R and rhlI/R QS genes and attenuate *P. aeruginosa* PAO1 virulence. They also enhance the sensitivity of its biofilm towards the tobramycin antibiotic. Biomolecules like Hymenialdisine, demethoxyencecalin, microcolins A and B, and kojic acid have been shown to inhibit LuxR-based reporters (*E. coli* pSB401) induced by $3OC_6HSL$ at concentrations ranging from 0.2 μM to 36 μM. The ability to prevent microfouling by kojic acid at 330 μM and 1 mM was observed by a decrease in the cell densities of bacteria and diatoms. Inhibitory concentration of hymenialdisine, demethoxyencecalin, kojic acid, and microcolins A and B were comparable with ones of natural furanones, ellagic acid, malyngolide and manoalide. Other antibiotics such as – azithromycin, ceftazidime, and ciprofloxacin inhibited the QS of LuxR-based reporters based on the QS circuit of *Vibrio fischeri* at sub-lethal concentrations ranging between 0.1–11 μM [15.3, 9]. Even fruit and spices consumed as food in our day to day life have molecules with the ability to inhibit the QS of bacterial pathogens [15.18–21].

Marine Derivatives as QSIs

Extracts of Great Barrier Reef marine invertebrates and cyanobacteria act as QSIs against bacteria. Biochemical defenses against fouling are widely deployed by algae. Metabolites that affect microbial communities have been demonstrated in the red algal family *Bonnesmaisoniae* for *Delisea pulchra, Asparagopsis armata* and *Bonnesmaisonoa hamifera*. The most well-investigated example of this defensive strategy is that of the red alga, *D. pulchra*, which produces halogenated furanones at the surface of the thallus. A high concentration of metabolites at the surface strongly inhibits QS by targeting AHL-dependent signals, and thus the settlement of various fouling propagules, and deters the settlement and growth of both micro and macrofouling agents. Natural chemical defenses are not restricted to the red algal models, as the secondary metabolites from *Dictyota menstraulis* and phlorotannins from *Fucus evanescens* also have AF activity. Ursine triterpenes from *Diospyros dendo* also interfere with QS. Oxidized halogen (HOBr) from *Laminaria digitata*, a brown alga, reacts specifically with 3-oxo-acyl HSLs. Marine bacteria produce QSIs that interfere with the formation of biofilms. For example, the bacterium *Aeromonas veronii* inhibits QS through competition for AHL production. TAGE (*trans*-bromo ageliferin analog) and CAGE (*cis*-bromo ageliferin analog) are two derivatives of the marine natural product bromo ageliferin. Both compounds have been shown to be effective inhibitors of *P. aeruginosa, Staphylococcus aureus, Acinetobacter baumannii*, and *Bordetella bronchiseptica* biofilm formation. There are only a few studies on marine microbes and their metabolites with respect to their antibiofilm activities. This is because the majority (< 95%) of phylogenetic clades of marine bacteria cannot be cultivated in laboratories. AF metabolites from non-cultivable marine microbes can be obtained through a metagenomic approach [15.22].

Biomolecules produced by bacteria associated with sponges have been a very good source of QSIs. Extracts of bacteria such as *Bacillus horikoshi, B. pumilus*, and *Vibrio natrigens*, associated with the coral *Acropora digitifera*, have been found to display efficient activities against biofilm-forming *Streptococcus pyogenes*. Among these bacteria, *B. horikoshi* proved more efficient at a concentration of 50 $\mu g\,mL^{-1}$, in contrast to the other two strains, which were effective at 100 $\mu g\,mL^{-1}$. In a subsequent study, *Bacillus indicus, B. pumilus*, and *Bacillus* sp. SS4 from Palk Bay (Bay of Bengal) were shown to cause significant inhibition of QS-based activities in Gram-negative bacteria such as *P. aeruginosa* PAO1, *Serratia marcescens*, and *Vibrio* species. Marine bacterium *B. pumilus* S6-15 was found to have a wider application in its ability to inhibit biofilm formation in both Gram-positive and Gram-negative bacteria. The active principles were the enzyme acylase and other secondary metabolites like carboxylic acid derivatives (4-phenylbutanoic acid). These QSIs were also found to inhibit the intestinal colonization of *S. aureus* in nematode *Caenorhabditis elegans* and its subsequent killing [15.23–30].

Bacteria in a biofilm can also affect the growth of other bacteria in the same biofilm. The marine bacterium *Alteromonas* sp. produces antibiotic 2-*n*-phenyl-4-quinolinol, which alters the composition of the bacterial community developed on particles. To date, only two classes of marine sponge metabolites house non-bactericidal biofilm modulators, viz. terpenoids and pyrrole-imidazoles. Terpenes are structurally diverse molecules, and this diversity is contributed by their isoprene subunits. The biological activities of terpenes are also diverse, ranging from AF effects to antiproliferative cancer therapeutics [15.31].

Within sponge terpenoids, only ageloxime-D, manoalide, and two manoalide congeners have been reported to have the ability to interfere with bacterial biofilm formation without disrupting cellular growth. Besides terpenoids, marine sponges synthesize pyrrole-imidazole alkaloids (PIA), another class of potent AF molecules that is unique to their phylum only [15.31]. Many families of marine sponges are the source of PIAs, but most of the work has been done on the bromopyrrole derivatives extracted from the *Agelasidae* family [15.31].

Oroidin, sceptrin, and bromo ageliferin are natural PIA products that act as potent toxic AF compounds against microorganisms, as well as higher organisms. *Ageloxime-D*, a diterpenoid metabolite, (−)ageloxime-D 4, from a marine sponge, was shown to inhibit biofilm formation by *Staphylococcus epidermidis* without inhibiting its growth, whereas its parent molecule, (−)agelasine-D 5, showed the opposite effect. *Luffariella variabilis* synthesizes as ester terpenoid–Manoalide – which exhibits both antibiotic and anti-inflammatory activities. There are three additional derivatives of Manoalide, viz. seco-manoalide, (*E*)-neomanoalide, and (*Z*)-neomanoalide [15.31]. These derivative compounds and their parent molecule were tested for antibiotic activity and found to be effective against Gram-positive bacteria only. In 2007, Skindersoe and co-workers found that extracts obtained from *L. variabilis* act as potent QSI agents against both Gram-negative and Gram-positive bacteria. This QSI activity was attributed to the conserved 2(5*H*)-furanone substituent [15.31].

Manoalides work as bactericides against Gram-positive bacteria. Against Gram-negative bacteria, they are not bactericidal but exhibit significant QSI activity. This shows that marine sponges are potential sources for future biofilm modulator molecules, particularly against life-threatening infections caused by Gram-negative pathogens like *P. aeruginosa*, *A. baumannii*, and *Klebsiella pneumoniae* [15.31].

15.3.3 Designing Antifouling Agents

Surface Adhesion

Efforts to modify the surface energy of substrates to reduce adhesion (ca. 25 dynes cm^{-1} as the least hospitable) of organisms could not prevent the adhesion of all fouling organisms. The question arises as to which properties of the surface could be altered to discourage/reduce cellular adhesion. Amphiphilic coating systems having both hydrophobic and hydrophilic domains on the surface show excellent AF properties for both diatoms and macroalgae. Cells adhere more strongly to hydrophobic surfaces, presumably for better survival. Under stressed conditions, the cellular level of nitric oxide (NO)is a good indicator. Levels of NO were fourfold higher in cells on a hydrophilic surface than those on a hydrophobic surface (silicon), indicating that hydrophobic surfaces were less stressful. Incorporation of such molecules that induce stress in fouling organisms can make them potential candidates as AF agents. *Trans*,*trans*-2,4-decadienal (DD), implicated as a chemical defense molecule, inhibits the invertebrate grazing of phytoplankton. Since diatoms can produce DD, it can be exploited to disperse clumping of diatoms [15.4, 8]. Novel antibacterial agents have been developed as NO-releasing silica nanoparticles. With enhanced inhibitory activity and reduced toxicity against *P. aeruginosa* and *E. coli*, the strategy proved better than NO alone in removing biofilms [15.32, 33].

Marine mammal skin is a clean surface, free of all fouling organisms (epibionts). In the pilot whale *Globicephala melas*, such a phenomenon is attributed to nanobridge pores on the surface of the skin. The nanobridge pores ($0.1-1.2\,\mu m^2$) are smaller than most fouling organisms, and it is proposed that they provide few micro niches or contact points for adhesion. These skins thus reduce fouling by the common bacterium *P. aeruginosa* to the extent of 93% in comparison with unprotected surfaces. In the dogfish egg case and sea stars (echinoderms) are a unique group of organisms, whose surface is free of any fouling organisms. Glycoproteins from some species blocked adhesion of bacteria whilst adhesion was enhanced by glycoproteins from other species. Production of free radicals has also been proposed as an AF strategy for marine algae and barnacles. Shark skin is another case that demonstrates that fouling can be controlled based on texture and dimension [15.34].

Nanocomposites

Coatings made of amphiphilic diblock copolymers, consisting of a poly(dimethyl-siloxane) block and a PEGlyated (poly(ethylene glycolated)) fluoroalkyl modified polystyrene block, have proved to possess excellent fouling release properties against the macroalga *Ulva linza*. Enhancement in polymer performance can be achieved through dispersal of nanosized fillers into the polymeric matrix to create a nanocomposite. The use of fluorosilicones, i. e., polymers containing both siloxane and fluorinated moieties in diverse macro-

molecular architectures, e.g., siloxane-fluorinated linear, graft, block, or hyperbranched (co)polymers can add to these AF agents. Coatings incorporating low surface energy fluorinated moieties with hydrophilic poly(ethylene glycol) (PEG) also have strong AF properties against marine organisms. The ability of amphiphilic coatings to lower the adhesion strength of organisms is probably due to certain unique features: (i) the low interfacial tension with water of the hydrophilic PEGylated domains, and (ii) the non-sticky and slippery behavior of the hydrophobic perfluoroalkyl domains [15.35].

Urethane polymers alone have little fouling resistance but provide mechanical strength, whereas siloxanes are not mechanically strong but have fouling-release properties. The AF properties of polysiloxane polymers were also improved by the inclusion of biocides (quaternary ammonium compounds (quats)). Coatings with 18C length quats were effective in inhibiting bacterial biofilm formation. In contrast, 14C quats were effective as growth inhibitors of diatom *Navicula* sp. [15.8].

15.3.4 Fouling – Release Coatings

Commercially available fouling release coatings are based on silicone elastomers, such as polydimethylsiloxane. Here, foulants adhere weakly to the substratum and are released under the hydrodynamic forces. The use of biocides to control BF has not been effective against all microorganisms causing BF. Kojic acid incorporated into a non-toxic paint matrix at a concentration of 0.5% significantly reduced the densities of bacteria and diatoms growing in paint. In addition, it also decreased macrofouling over a period of 30 days. Kojic acid at non-toxic concentration (330 μM) inhibited bacterial density up to 2.5–3.2-fold and diatom density up to 4.7–3.6-fold in biofilms on glass slides. It was suggested that kojic acid reduced the formation of microbial communities by inhibiting non-QS regulatory cascades that affect biofilm formation. Alternative AF coatings employing copper and co-biocides, e.g., Irgarol 1051, zinc pyrithione, and Sea Nine 2011 are the principal replacement for tributyl tin coatings [15.3, 4, 35].

15.4 Applications

Microbes isolated from the gut of marine organisms such as shrimp, European seabass and Asian seabass have helped to improve the survival of larvae of *Macrobrachium rosenbergii*, which can also tolerate a higher concentration of ammonia. Microflora from the intestine of Ayu fish, *Plecoglossus altivel*, especially *Shewanella* sp. strain MIB010, proved to be an AHL degrader. It was effective in dispersing biofilms formed by fish pathogens, *Aeromonas* and *V. anguillarum*. The marine actinomycete, *Streptomyces albus* strain A66, was also effective in disrupting the biofilm. Seabass are inhabited by Gram-positive, *Halobacillus salinus* C42, which release phenethyliamide compounds, especially 2,3-methyl-*N*-(2'-phenylethyl)-butyramide, to inhibit bioluminescence of *Vibrio harveyi*. The marine cyanobacterium *Blennothrix cantharidosmum* exudes a variety of Tumonoic acids with the ability to inhibit bioluminescence, although not very strongly. *D. pulchra* with the ability to produce furanones, inhibits swarming motility in *Proteus mirabilis* and other phenotypes such as inhibition of luminescence and toxin production. *Ahnfeltiopsis flabelliformis*, a macroalgae, produces Floridoside, betonicine, and isethionic acid, which act as QS signal quenchers. *Bryozoa, Flustra foliacea*, isolated from the North sea, reduce a large variety of AHL signals through the action of bioactive molecules such as bromo-tryptamine-based alkaloids. A wide variety of sponges have been found to be very effective as quorum quenchers – *L. variabilis* produces secomanoalide and manoalide to degrade AHL signals. A nanofiltration membrane immobilized with porcine kidney acylase I suppresses exopolysaccharide production and, consequently, inhibits biofilm formation. It has thus proven to be a very good AF agent.

15.4.1 Clinical Settings

Biofilms are made up of proteins, polysaccharides, and DNA These polymers can be targeted by enzymes, e.g., glycosylases [15.36]. Proteases can be very efficient in breaking down the matrix, as has been observed for *Pseudoalteromonas*. Dispersin B (DspB) is a hexosaminidase, produced by a species of *Actinobacilli*, and it attacks polysaccharide intercellular adhesin (PIA)–poly-*N*-acetyl glucosamine polysaccharide (PNAG) [15.37]. Its effectiveness was shown through the prevention of biofilm formation by *S. epidermidis* on implanted devices, precoating plastic and polyurethane surfaces. DspB from the periodontal

pathogen *Aggregatibacter actinomycetemcomitans* is a b-hexosaminidase that exhibits a biofilm detachment ability. A combination of DspB with antiseptics (triclosan or chlorhexidine) has given a synergistic broad-spectrum antibiofilm and shown antimicrobial activity against *S. aureus*, *S. epidermidis*, and *E. coli* [15.38].

15.4.2 The Pulp and Paper Industry

Eight commercial enzymatic preparations were evaluated for biofilm reduction in the paper industry. These preparations contained proteases (pepsin, trypsin, Savinase1, and Alcalase1), glycosidases (dextranase and pectinase), and lipases (from *Candida rugosa* and Lipolase1). Savinase1 was the most efficient protease when used at concentrations of 40.5%. Cellulase is another enzyme that was successful in degrading mature biofilm formed by *P. aeruginosa*. It is possible to use this enzyme in combination with other treatments to increase the effectiveness to attack the mixture of polysaccharides in the EPS [15.39].

15.4.3 Deterrents/Biocides

Naturally produced AF biocide compounds have been divided into two categories: (i) non-polar metabolites which remain on the surface of an organism and may repel larvae exploring its surface, and (ii) polar metabolites, which are liberated into overlying water and may be detected by larval receptors to trigger avoidance behavior. Such AF compounds are classified as deterrents rather than toxins, since their mode of action may or may not be related to toxic effects. Glucose oxidase, hexose oxidase, and haloperoxidase are examples of oxidoreductases that can generate deterrents [15.36]. The oxidases and haloperoxidases catalyze the production of H_2O_2 and hypohalogenic acids, respectively. H_2O_2, like other reactive oxygen species (ROS), can cause oxidative damage in living cells. Hypohalogenic acids, e.g., HOBr or HOCl, being highly reactive, are thus used as oxidants for the treatment of water as disinfecting agents [15.36]. The oxidative damage of cells by H_2O_2 finds many applications. H_2O_2 has been used to reduce macrofouling in marine cooling water systems, particularly as Fenton's reagent when combined with ferrous ions [15.36].

15.4.4 Antifoulants

Hydrolases have been shown to abolish adhesion and biofilm formation by *Pseudoalteromonas* sp. D41 in natural seawater at 20 °C. This antibiofilm effect is due to the hydrolysis of extracellular polysaccharide (EPS), QS molecules, and adhesions as the substrates involved in bacterial adhesion. For example, hydrolysis of mutan and dextran EPS by mutanase and dextranase enzymes inhibits the formation of dental biofilms by *Streptococcus mutans* and *S. sobrinicus*, respectively [15.40]. Proteases, for example, Savinase, are very effective enzymes that prevent adhesion and biofilm formation by marine organisms. Savinase was effective and stable against biofilm formation, even when bacteria were allowed to adhere for 24 h [15.40]. Commercial protease (subtilisin) enzymes like Savinase or Alcalase are very effective when applied during the initial stages of bacterial adhesion. This can be done by conditioning the surface, e.g., by immobilizing the enzyme directly onto the surface or by applying the enzyme through an AF paint [15.40].

Lysostaphin, a *Staphylococcus simulans* metalloendopeptidase, degrades pentaglycine cross links in the cell wall and is effective against *S. aureus*, *S. epidermidis*. This enzyme can also detach biofilms, which suggests a potential contribution of cell wall-associated components to the matrix. Subtilisins, the serine proteases, cleave proteins in which serine serves as the nucleophilic amino acid. Such proteases are easily available as they are produced and secreted in large measures by many *Bacillus* species [15.41]. Subtilisins work on different biofilms, including those produced by industrially significant problematic species such as *Pseudomonas fluorescens* and *Pseudoalteromonas*.

DNA plays an important function in the stability of biofilms. This has been shown by the addition of deoxyribonuclease (DNaseI) leading to the dissolution of biofilms. Addition of bovine DNaseI to established biofilms can disrupt *S. aureus* biofilms formed on glass, plastic, and titanium surfaces. Studies have demonstrated that inducing expression of *S. aureus* endogenous nuclease prevents biofilm formation on abiotic surfaces. The use of DNase as a treatment for staphylococcal biofilm infections has not been attempted, although recombinant human DNase (also called Pulmozyme Dornase alfa) is approved as a treatment to reduce the viscosity of mucous in the lungs of cystic fibrosis (CF) patients. It is postulated that Dornase alfa plays a role in clearing bacterial infections that develop in the CF lung and *P. aeruginosa* is known to form a biofilm in this state. DNaseI also sensitizes biofilm bacteria to killing by various biocides and also to detachment by anionic detergents.

15.4.5 Engineered Bacteriophages

Phages that kill bacteria in a species-specific manner are engineered to express the most effective EPS-degrading enzymes specific to the target biofilm. This strategy permits the development of a diverse library of biofilm-dispersing phages rather than necessitating attempts to isolate such phages from the environment. These recombinant phages not only lyse the bacterial cells rapidly but express and produce the biofilm-degrading enzymes as well. This autocatalytic mechanism leads to efficient removal of bacterial biofilms in a wide range of scenarios, such as industrial, environmental, and clinical settings [15.42]. This strategy also eliminates the need to produce, purify, and deliver large doses of enzymes to target sites of infection that are otherwise difficult to access and would lead to improved and efficient phage therapy for removal of biofilms. For example, the engineered T7 phage expresses the K1-5 endosialidase enzyme, which allows it to replicate in the K1 polysaccharide capsule –producing *E. coli* [15.42].

DspB hydrolyzes adhesions which are important in the biofilm formation by several bacterial species, including clinical strains. Therefore, recombinant phages producing DspB can be applied to a large number of bacterial infections [15.42]. Also, several different biofilm-forming bacterial species, including *E. coli*, produce a group of biofilm promoting factors, required to produce a mature biofilm. These factors are shared among different strains and are, therefore, potential targets for an enzymatically engineered phage [15.42].

In contrast to most works which target only the removal of biofilms and its associated bacteria, a recent approach was aimed at reusing the platform for a fresh round of biofilms in biorefineries. Here, the intention was to reuse the platform for chemical transformations. In the initial step, proteins, global regulator (Hha) and cyclic diguanylate-binding (BdcA), were engineered to disperse biofilms. The dispersal cells were then removed through a chemical switch, isopropyl-β-*D*-thiogalactopyranoside. This technique can be applied to develop biosensors, biocorrosion, BF, and bioremediation [15.43].

Recently, QQ has been applied as a practical solution to control BF of membrane bioreactors (MBR) in water treatment systems. Cells of *Rhodococcus* sp. BH4, a QQ bacterium, were entrapped in alginate beads (cell entrapping beads, CEB), and designed with a porous surface microstructure. When these CEBs were used in MBRs, a transmembrane pressure of 70 kPa was reached in a time period that was ten times longer than MBRs without CEBs. The role of CEBs was dual in controlling the biofilm formation: biological, as quorum quenchers of AHLs produced by BF bacteria, thus inhibiting the synthesis of extracellular polymeric substances involved in biofilm formation, and physical as the source of friction between CEBs colliding with biofilm on the membrane surface. Sloughing off of biofilm was more pronounced with the QQ effect than friction. QQ is thus seen as an efficient and economical alternative to control BF of MBRs [15.44].

We should take inspiration from natural sources, especially skins of marine animals and microbes associated with them to develop the most sustainable marine technologies to control BF [15.9, 10].

16. Detection of Invasive Species

Nathan J. Bott

Marine invasive species incursions can cause significant ongoing damage to marine environments, aquaculture, biodiversity, infrastructure, and social amenity. They represent a significant and ongoing economic burden. Marine pests can be introduced by several vectors, including aquaculture, aquarium trading, commercial shipping, fishing, floating debris, mining activities, and recreational boating. Despite the inherent risks, there is currently relatively little routine surveillance of marine pest species conducted in the majority of countries worldwide. Accurate and rapid identification of marine pest species is central to early detection and management. Traditional techniques (e.g., physical sampling and sorting) have limitations, which has motivated recent progress towards the development of molecular surveillance tools. This chapter highlights the importance of effective sampling and Deoxyribonucleic acid (DNA) extraction strategies and describes developments in polymerase chain reaction (PCR)-based and ecogenomic methods for the detection and surveillance of marine invasive species. Recent advances provide a platform for the development of practical, specific, sensitive, and rapid diagnosis and surveillance tools for marine invasive species for use in effective prevention and control strategies.

16.1 Background

Marine invasive species have the potential to cause significant harm to endemic biodiversity and habitats [16.1, 2]. Marine pests can be translocated and introduced by numerous vectors including ship ballast, hull fouling, floating debris, and man-made structures such as drilling platforms and canals [16.3]. Marine invasive species introductions continue to occur and threaten the marine environment and associated industries [16.4]. With increasing globalization comes faster and more frequent shipping and air transport of live seafood. Propagule pressure is only likely to increase unless effective strategies are employed for early detection, prevention, and control. Central to such strategies is the ability to rapidly identify invasive species from the environment.

In San Francisco Bay there are at least 230 established exotic species that account for 40–100% of the common species at many sites in the estuary [16.5]. Even if suitable eradication technologies were available, in some cases it may be un-economical to them, given the logistical difficulties associated with working in a marine environment. The main economic and social impacts of marine pests are decreases in the economic output of marine-based activities from aqua-

culture, fisheries, and tourism, and negative impacts on human health [16.3]. The total economic cost of a marine pest incursion is difficult to accurately define but in Australia, a major marine pest eradication has been estimated to cost up to AUD$263M [16.6]. The few examples of successful eradication of marine invasive species worldwide have been when the invasion has been detected in its very early stages, and/or it is restricted to an area that can be isolated from the rest of the marine environment (e.g., *Caulerpa taxifolia* eradication in Southern California [16.7]; black-striped mussels, *Mytilopsis sallei*, in Darwin, Australia [16.8, 9]).

Marine invasive species include a wide range of plant and animal taxa. These include macro and microalgae, molluscs, crustaceans, annelids, echinoderms, cnidarians, ascidians, and teleosts. The development and implementation of rapid, sensitive, and accurate diagnostic techniques for the identification and surveillance of marine pests from environmental samples (e.g., sea water, sediments, and ships' ballast), particularly in areas that are currently pest free, is an essential step in early detection and control of marine pests [16.10–12]. In this chapter, we:

i) Briefly describe techniques traditionally used for the identification and/or surveillance of marine pests.
ii) Review DNA technical approaches for the identification of species and definition of genetic markers.
iii) Describe recent PCR-based and ecogenomic methods for the detection of marine invasive species.
iv) Propose some options for the development of improved molecular diagnostic techniques.

16.2 Traditional Techniques

Baseline surveys and repeated monitoring conducted by experienced biologists are the prime requirement for early detection of marine pest species using standard methods. *Campbell* et al. [16.13] reviewed the five survey methods commonly employed for the detection of marine pest species: Hewitt and Martin protocols, rapid assessment surveys, Bishop Museum protocols, Chilean aquaculture surveys, and passive sampling protocols. These methods typically involve physical sampling, sorting, and identification to understand the resident biota and identify marine pests.

Traditional survey methods typically require specialized taxonomic experts, trained in identifying organisms across a range of life-cycle stages. The sorting and identification of plants and animals is time consuming, sometimes taking years before species are accurately identified, but the sampling data provided by surveys of this kind provide an important baseline understanding of biodiversity for future pest surveillance and ecological research. There is a global decline in taxonomic expertise [16.14, 15]. Given the wide range of taxa required to be identified in marine pest surveys and the inherent difficulties in identification, there is a need to develop methods that work in conjunction with, and are complementary to, available taxonomic expertise.

16.3 Sample Collection

The development of sensitive and specific molecular tools is highly important and has been the focus of most recent published studies on the development of marine invasive species surveillance. Without effective environmental sampling strategies and DNA extraction techniques, these molecular tools will prove largely ineffective.

16.3.1 Extraction of Genomic DNA from Environmental Samples

Mackie and *Geller* [16.16] developed a qPCR (quantitative PCR) for the detection of brine shrimp. The principle behind this was to use brine shrimp (*Artemia* spp.) as an additive to plankton samples. *Artemia* spp. inhabit hypersaline environments, so they are perfectly suited to being utilized as a quality control spike in marine plankton samples. Recently, the approach used by [16.16] was modified and used a sample quality control for the marine invasive species monitoring of Port plankton samples in Australia (personal observations). Freeze-dried *Artemia* sp. are added to each individual plankton sample at the time of collection and the *Artemia* qPCR assay is utilized to assess whether samples have been stored and preserved adequately for further analysis for marine invasive species.

Effective routine detection and surveillance of marine pests from environmental samples requires effective sample collection and genomic DNA (gDNA) isolation methodology. *Bott* et al. [16.11] highlighted the need to use samples that will be biologically informative for surveillance purposes. Organisms can be collected from water by filtering known amounts and extracting DNA from the filtrate. Larger sample sizes increase the likelihood of containing invasive species but pose issues surrounding DNA extraction.

Inhibition of PCR due to contaminants in environmental samples can be a limiting factor to accurate detection of invasive species. PCR inhibitors include organic and phenolic compounds, fats, glycogen, Ca^{2+}, humic acids, heavy metals, constituents of bacterial cells, over-abundance of nontarget DNA, and other contaminants [16.17]. There is a need, therefore, to rigorously assess DNA extractions for the presence of PCR inhibitors to reduce the occurrence of false negatives during analysis. Screening DNA extracts with control PCR assays of a known, added indicator organism is a useful approach in samples containing numerous DNA *types*. Correct preparation of environmental samples for DNA extraction can also prove useful in preventing PCR inhibition. For example, anecdotal evidence of freeze-drying marine sediment samples prior to DNA extraction greatly reduces the effects of PCR inhibition [16.11], which may be due to increased DNA extraction efficiency in freeze-dried samples [16.18]. A simple option to limit the effects of PCR inhibition is through the dilution of DNA; provided that a reliable detection limit to detect an organism is known, samples can be diluted to reduce inhibitors to below critical concentrations.

16.4 Molecular Approach to the Identification of Marine Invasive Species

As the use of molecular biological techniques has become more widespread, so too has their use in the identification of marine invasive species. A range of DNA-based techniques have been used (Table 16.1) to discriminate between species because of the ability of these methods to detect subtle genetic differences. DNA is relatively stable and can be readily isolated from fresh, frozen, ethanol-preserved, or commercially available nucleic acid storage buffer (e.g., RNAlater©, Ambion) preserved specimens for subsequent analysis using cloning, hybridization and enzymatic amplification procedures.

PCR [16.58, 59] is a reliable method of enzymatic nucleic acid amplification which has significantly advanced a wide range of scientific areas. The majority of molecular assays for the detection and identification of marine invasive species and their allies involve PCR-based technologies. The key to a reliable and robust molecular method for the identification of a marine pest is the definition of one or more suitable DNA target regions (genetic marker or locus).

Marine invasive species encompass a range of taxonomic groupings and no single marker should be considered universally appropriate to all taxa. Nuclear ribosomal genes and spacers, mitochondrial genes, and chloroplast genes (for plants), have been utilized to identify marine invasive species (Table 16.1). A thorough knowledge of the sequence variation within the marker of choice (both intra and inter-specific variation) must be obtained from previously published data (e.g., GenBank- http://www.ncbi.nlm.nih.gov/Genbank/). DNA sequencing of the marker of choice of both target and related organisms must be carried out in order to design an assay which is specific to the target taxon.

Genes evolve at different rates and a suitable DNA region should vary in sequence sufficiently to allow the identification of an individual to the taxonomic level required. For specific identification, the DNA marker should exhibit little or no genetic variation within a species but differ sufficiently between species so as to allow unequivocal delineation. For the identification of population variants (strains or genotypes), the marker should vary considerably in sequence within a species but still offer enough specificity so as to not cross-react (false-positives) with heterologous species.

In nuclear genes and spacers, there is typically little variation amongst individuals within a population and between other populations [16.43, 45]. Nuclear ribosomal DNA (rDNA) of eukaryotes is repetitive and consists of hundreds of tandem repeats. These tandem repeats are often distributed on different chromosomes [16.60, 61] and like other repetitive DNA elements they show sequence homogeneity as a result of concerted evolution [16.61, 62]. The rDNA array consists of the intergenic nontranscribed spacer (IGS or NTS), the external transcribed spacer (ETS), and the transcription unit comprising three rRNA genes (short subunit (SSU), 5.8 S and long subunit (LSU)), which are separated by the first and second internal transcribed

spacers (ITS-1 and ITS-2). The rDNA genes, ITS, and IGS/NTS regions have been shown to be particularly useful in defining species specific markers for marine pest assay development (Table 16.1).

Genes in the circular mitochondrial genome generally evolve at a quicker rate than nuclear genes; animal cells typically contain hundreds to thousands of mitochondria per cell [16.63]. A high copy number increases detection potential, making mitochondrial markers potentially suitable for sensitive molecular assays. Evolutionary rates of mitochondrial DNA may vary between taxonomic lineages, but are generally believed

to undergo relatively rapid rates of evolution [16.64, 65]. Mitochondria are generally inherited maternally, making them particularly useful as a species-specific marker for the delineation of closely related species e.g., [16.35, 39]. The identification of different strains (i. e., population variants) has important implications for understanding the geographical origin and patterns of spread of marine pest species, potentially providing a better understanding of patterns and means of translocation. Mitochondrial DNA has proven particularly useful in understanding the genetic structure of populations due to their maternal inheritance which provides tracers to patterns of colonization and its smaller effective population size (when compared to the nuclear genome [16.66–68]).

Like mitochondria, chloroplasts have a circular genome that is smaller than the nuclear genome. Typically, chloroplast genomes display lower levels of heterogeneity than mitochondrial genomes; this is in part due to mitochondria having larger genomes which encode for less genes than chloroplasts [16.69, 70]. The ribulose-bisphosphate carboxylase (*rbc*L) gene is of interest for use as a diagnostic marker of algae. *Hanyuda* et al. [16.71] reported that the intron in the *rbc*L gene was highly variable amongst different species and strains of *Caluerpa*, and [16.32] used a *rbc*L PCR-based assay to identify invasive strains of *Caulerpa taxifolia*. *Freshwater* et al. [16.33] also used a *rbc*L gene PCR-based assay to discriminate invasive *Gracilaria* from nearly morphologically identical native species.

16.5 PCR-Based Methods Utilized for Routine Identification and/or Surveillance

A wide range of molecular-based techniques have been employed for the identification of species at adult and/or larval stages of marine invasive species or related species (Table 16.1). The advantages, limitations, and uses of these techniques for marine pest research and detection are summarized in Table 16.2, and the limitations of these approaches are further discussed in the following section. PCR has revolutionized many areas of biological research, including species and strain delineation. PCR can amplify minute amounts of template DNA, and its high specificity makes it highly effective for species and strain identification for a wide range of organisms. PCR with direct sequencing is a gold standard technique; however, it takes several days to obtain results, and a relevant question is whether other PCR-based procedures can be used as reliably in the same amount of time. The relatively low cost of equipment and reagents makes PCR accessible to small laboratories.

16.5.1 PCR-Based Methods

Species Detection Through Design of Specific Primers

PCR utilizing genus or species specific primers for marine pests has been utilized using a wide range of techniques: one-step reactions e.g. [16.23, 24, 30, 35, 38], nested PCR [16.37], and multiplex [16.44] and nested multiplex PCR [16.43, 75].

Random Amplified Polymorphic DNA (RAPD)

RAPD (RAPD) is based on the amplification of random fragments of genomic DNA using single primers of arbitrary sequence. RAPD offers rapid molecular assessment in that it does not require the design of specific primers that bind exclusively to one sequence type. It essentially scans the entire genome without prior knowledge of sequence information. RAPD will produce a specific banding pattern when amplicons are subjected to electrophoresis. It can be particularly useful in discriminating between closely related species or strains and understanding sequence variation between individuals [16.52]. *Zhou* and *Gao* [16.22] utilized RAPD for the identification of mitten crab (*Eriocheir sinensis*) populations, but it has not otherwise been widely utilized for marine pest identification.

Restriction Fragment Length Polymorphism (RFLP)

Restriction (RFLP) endonucleases are used to cut DNA at precise sequences producing specific bands which are visualized via electrophoresis. When RFLP is combined with PCR, a fragment will be amplified via PCR before being digested, using the restriction endonucleases to give a characteristic pattern based on the amplified fragment. RFLP has not been widely used for the identification and/or surveillance of marine pests. *Scholin* and *Anderson* [16.49] used PCR-RFLP to distinguish between

Table 16.2 Molecular diagnostic techniques suitable for different sample types for the identification and detection of marine pest species

Technique	Suitable sample types	Advantages	Limitations	Example references
PCR (end-point one step, nested and multiplex, agarose gel electrophoresis and/or sequencing)	Whole animals, larval and egg/spore stages, environmental samples	Can be highly specific, relatively inexpensive, able to amplify minute amounts of DNA.	Post-PCR handling time consuming, potential exposure to toxic reagents. Nested PCR has potential for PCR contamination. Multiplex PCR can be difficult to develop effectively.	[16.21, 30, 31, 55, 57]
PCR-dot-blot hybridization	Whole animals, larval and egg/spore stages, environmental samples	Can be highly specific, inexpensive, amplify minute amount of DNA, obtain results quickly.	Post-PCR handling time, if hybridization step requires specificity. Slower than qPCR applications.	[16.29]
PCR-RAPD	Whole animals, larval and egg/spore stages	Inexpensive	Not suited to specific amplification, requires post-PCR analysis	[16.52]
PCR-RFLP	Whole animals, larval and egg/spore stages	Inexpensive, can be useful in discriminating closely related species/strains	Not suited to specific amplification, requires post-PCR analysis	[16.22, 49]
PCR-SSCP	Whole animals, larval and egg/spore stages	Cost-effective, a powerful method of distinguishing closely related species/strains	SSCP electrophoresis is time consuming, not suited to widespread testing on environmental samples	[16.45]
Quantitative PCR	Whole animals, larval and egg/spore stages, environmental samples	Highly specific, rapid analysis, allows quantification of amount of target species in a sample, and potential for high-throughput application	Assay development can be expensive and time consuming. Incorrectly developed assays may produce false-positives.	[16.20, 28, 72]
Next generation sequencing	Whole animals, larval and egg/spore stages, environmental samples	Large amounts of data, provide comprehensive analysis. Allows examination for wide variety of species in environmental samples	Expensive per sample, not high-throughput like qPCR. Data processing time consuming	[16.73, 74]

six species of the dinoflagellate genus, *Alexandrium*. *Fernandez-Tajes*, *Medez* [16.76] utilized PCR-RFLP of ITS for the discrimination of razor clams (*Ensis* spp.), and *Yamasaki* et al. [16.77] utilized RFLP of the mitochondrial gene cytochrome oxidase subunit 1 (*cox1*) to identify Japanese mitten crab (*Eriocheir japonica*).

Single Strand Conformation Polymorphism (SSCP)

Single stranded conformation polymorphism (SSCP) is a mutation scanning approach that analyzes amplicons of 100–450 nucleotides by denaturing double-stranded DNA into single-stranded DNA and electrophoretically analyzes the single-stranded conformational profiles (conformers) in a nondenaturing gel matrix. SSCP has been shown to distinguish between sequences that differ by a single base [16.29]. It can be a highly effective cost saving tool. Once sequences (i. e., species or strains) are known for conformational profiles, the extra cost of direct DNA sequencing is eliminated. SSCP generally does not require optimization of different sequences or amplicons [16.29]. *Livi* et al. [16.45] utilized PCR-coupled SSCP of the short subunit (SSU)-rDNA for the discrimination of bivalve larvae.

PCR Coupled Dot-Blot Hybridization

PCR coupled dot-blot hybridization involves firstly PCR amplification and secondly detection of that amplicon using staining or radioassay (e.g., ^{32}P, DIG) of the complementary target bound to a support. The method is useful for differentiating between closely related species when species-specific probes are designed [16.19] and is a quick and relatively inexpensive means of identification and discrimination. *Blomster* et al. [16.19] used an ITS-based dot-blot hybridization to distinguish between species of the Chlorophyte genus, *Enteromorpha*, while [16.78] employed a ^{32}P-labeled probe to identify *Alexandrium* spp.

Quantitative PCR (qPCR)

Quantitative PCR (qPCR) allows the amplification of a target PCR amplicon to be monitored in real-time as amplification occurs. qPCR utilizes two main detection systems: fluorescent intercalating dyes and probes. There are a number of intercalating dyes utilized for qPCR. The original method used ethidium bromide and measured the change in fluorescence after each cycle using a digital camera and a fluorometer [16.79]. Subsequent modifications incorporated intercalating dyes such as SYBR Green I [16.80] LCGreen [16.81], SYTO9 [16.82], and EvaGreen [16.83].

Probe-based detection systems include *Taq*Man probes [16.84], molecular beacons [16.85], fluorescence resonance energy transfer (FRET) [16.86], and minor groove binder (MGB) probes [16.87]. These probes are more expensive than intercalating dyes but ensure specificity of the assay through ensuring exclusive binding to the target sequence [16.82].

qPCR is typically analyzed in two ways. Relative quantification will provide a cycle threshold (C_t) for the specific amplification of the target sequence based on comparison with amplification of a *normalizer* gene from the same DNA template. It should be present with the same copy number of the locus of interest. Absolute quantification is performed by determining the C_t of test samples by amplifying target DNA standards (of known concentrations) at the same time as test samples; the C_t is calculated based on a standard curve generated from the DNA standards.

Quantitative PCR (qPCR) (offers a relatively rapid analysis (> 2 h)); the potential for high-throughput applications, allows linear quantification over a wide dynamic range (> 6 orders of magnitude) and the benefit of not requiring post-PCR handling (*closed-tube* format). It is now routinely used in a wide range of clinical applications for the detection of a wide range of bacterial, fungal, parasitic, and viral diseases of humans [16.28]. Recent advances have seen a number of studies utilizing qPCR-based techniques for the identification of marine pests [16.72, 88].

Melting Curve Analyses. When using intercalating dyes some qPCR thermocyclers can also perform melting analysis or high resolution melting (HRM) analysis mutation scanning techniques. Melting analyses allows for rapid post-PCR analysis of sequence variants or strains/species, or a secondary confirmation of the presence of the target amplicon in the sample based on consistency of the melt curve with the defined DNA standards. This approach has been employed for a number of studies concerned with human and livestock pathogens [16.89, 90]. Intercalating dyes typically bind and allow detection of any double-stranded DNA. This is advantageous but there is also the potential for binding to nonspecific products and primer dimers; careful PCR optimization is required to determine the optimum intercalating dye concentrations. The use of post-PCR applications such as melting analysis can be utilized to distinguish between a nonspecific product/primer dimer and a PCR amplicon.

Potential Issues with PCR-Based Approaches

The issue of PCR inhibition, due to DNA contaminants, potentially causing false negatives needs to be taken into consideration for all PCR-based procedures. Incorrect pipetting techniques or aerosol contamination of DNA and/or PCR products can contribute to false positives in all PCR-based applications. No template controls (NTC) should be used in every experiment to monitor PCR contamination, and laboratories should employ various decontamination procedures to avoid this (e.g., Ultraviolet sterilization, decontamination of bench tops).

16.6 Ecogenomic Techniques

Ecogenomics are methods that allow the examination of genetic material from complex environmental samples containing many different organisms. It provides a step-change approach to environmental surveillance methods through its ability to identify a wider range of taxonomic groupings [16.91]. Ecogenomic methods

have been effectively used for a wide range of taxa, localities, and environs (i. e., sediments and water) such as Sydney Harbour sediments [16.91], marine anoxic water [16.92], ecological characteristics of viruses [16.93], and biotic assemblages of soil DNA [16.94]. The development of molecular tools for ecological monitoring potentially allows for more complete, rapid, and cost effective assessment of biodiversity and ecological shifts to be conducted [16.73]. These methods, once developed and validated, will be applicable to a range of marine habitats that are currently poorly understood. These methods show great potential for the ongoing monitoring and early detection of marine invasive species. Ecogenomic methods can be used to develop baseline information of species assemblages, making subsequent monitoring exercises of ports and harbors more informative, allowing for the loss of endemic biodiversity to be monitored alongside invasive species monitoring.

Recent studies [16.74, 95] have shown the effectiveness of 454 pyrosequencing for marine invasive species detection. *Pochon* et al. [16.74] were able to demonstrate that the detection limit for the Northern Pacific seastar, *Asterias amurensis* is equivalent to qPCR-based detection methods.

Ecogenomic techniques offer the ability to screen environmental samples for a broad range of organisms at once, process large numbers of samples quickly, and offer the ability to screen not only for invasive species (or pathogens) but also for endemic species to provide a broader indication of environmental health [16.91]. Next generation sequencing technology may also facilitate baseline screening of ports and harbors to obtain a rapid understanding of the presence and population densities of all species. This may aid in tailoring more focussed screening for marine invasive species specific to a geographical area and provide valuable data for modeling invasion biology.

16.7 Future Approaches

Commercial shipping can act as a major vector in marine pest translocation [16.95, 96]. Ballast water commonly used to control the trim and draft of a vessel can contain larval and adult stages of marine pest species [16.97]. The potential for these pests to be discharged into a new environment and flourish is high for some species [16.4]. Hull-fouling is also a significant translocation vector, while solid ballast was a dominant vector in previous centuries. As a consequence, ports are the major entry points for the majority of new marine pest incursions. Thus port and ballast water surveys are targeted to areas where effective and efficient detection and management strategies can be implemented to aid in successful prevention and mitigation of marine invasive species invasions.

16.7.1 Routine Monitoring and Surveillance of Marine Invasive Species in Port Waters

Routine monitoring using molecular technologies can alleviate the demand for time-consuming and costly traditional port surveys. Understanding marine invasive species assemblages in ports is a vital tool for managing ballast water in a cost-effective manner as the management requirements are reduced or eliminated for transfers between ports with similar suites of pest species. Robust qPCR, particularly in laboratories with high-throughput capability, can be used to rapidly assess samples for a wide range of marine invasive species at a fraction of the cost of traditional surveys. The vast majority of existing molecular-based assays for marine pests (Table 16.1) are not suited to high-throughput applications, so conversion of tests to formats such as qPCR is important. Continued dedicated research is required to provide reliable, uniform testing procedures (e.g., qPCR) for pest species that display genetic differences across their range. Routine monitoring programs utilizing robust, sensitive, and specific assays for a wide range of marine pest species provide the ability for authorities to monitor and manage marine pest incursions in a cost-effective way.

16.7.2 Testing Ballast Water

Molecular methods could minimize delays and provide data on ballast water safety. There are technical and logistical hurdles to provide suitable testing including timeliness to avoid unnecessary delays. This would be best achieved by streamlining sample collection and DNA extraction.

An effective way to collect ballast water samples is to filter a known amount of water (and ballast sediment)

and collect the filtrate for subsequent DNA extraction and analysis. For this to occur routinely, laboratory facilities may need to be maintained at, or close to ports, and the DNA extraction method must not produce significant PCR inhibition. The use of microfluidic carbon nanotube platforms for the detection of invasive species from substrates such as ballast have been proposed by [16.98], and the use of laser transmission spectroscopy has also been proposed by [16.99]; technology such as this shows potential for on-board or portside applications. Well-defined quantitative testing systems could also be used to test the performance of ballast water treatment systems, particularly the concentrations of indicator microbes and invasive species of high economic importance.

16.7.3 Legal Requirements

It is possible that the result of detection of marine pests through molecular methods would be that legal action (e.g., seizures, quarantine) would be initiated by the relevant jurisdiction. It is, therefore, of utmost importance that positive results are verified through a number of methods: 1. manual discovery and identification of the pest; 2. obtaining DNA sequence data from the sample to further confirm identity; 3. using multiple detection methods (e.g., traditional identification with multiple molecular methods). It is also essential that the laboratory involved follow rigorous protocols and utilize a number of controls (including spikes) to provide quality control and assurance measures.

16.8 Concluding Remarks

This review summarizes studies about the molecular identification and/or detection of marine pest species. For the effective control of marine pest incursions, rapid specific identification is of utmost importance. An understanding and exploration of the genetic diversity of different pest species populations is also required, which will lead to more effective control and a better understanding of pest biology. The development of molecular-based assays for a wide range of marine pests provides a solid foundation for the continued development of robust, sensitive, and specific assays for screening environmental samples. It is important that the opportunity is grasped to develop robust surveillance methods of marine invasive species, as in some situations, detection may prevent release unless appropriate treatment is undertaken. Identification is vital in order for treatment and mitigation program to be implemented in a timely and effective manner.

Provided that they are robustly validated, high-throughput methods such as qPCR currently offers the most cost-effective and rapid means of analysis. The potential of ecogenomic applications is being realized, providing opportunities to not only understand what invasive species are present in a sample but also to analyze endemic species to assess overall environmental health.

An important component in the development of molecular surveillance strategies is an effective DNA isolation and purification technique that works effectively on a range of sample types and locations (e.g., spatial and temporal variation in samples). Methods need to be optimized relevant to the substrate to remove inhibitory substances to enzymatic amplification, and the development of an accepted quality control standard [16.16] for the effective purification of DNA from different sample types is essential.

With the worldwide decline in specialist taxonomic expertise there is an increasing need for accurate and rapid marine invasive species diagnostics. Continued development of marine invasive species molecular diagnostics must occur in conjunction with taxonomic specialists to ensure accuracy of assay development. Studies investigating the systematics and phylogenetic relationships of marine invasive species and related taxa will progress towards the development of robust diagnostics. These studies will help to further identify molecular markers with diagnostic potential and provide baseline genetic information necessary for the design of specific diagnostic assays.

Specific diagnosis is central to: (a) rapidly establishing the prevalence and distribution of marine invasive species in the environment in conjunction with traditional sampling techniques, (b) monitoring changes in marine invasive species distribution spatially and temporally, and (c) conducting targeted eradication and control programs if economics and logistics permit. Developing the capacity for detection and enumeration of marine invasive species seems achievable if appropriate support and funding is provided by relevant stakeholders.

17. Marine Sponge Metagenomics

Valliappan Karuppiah, Zhiyong Li

The sponge is one of the oldest multicellular invertebrates in the world. Because of its special pore canal structure and characteristics of filter feeding, a large amount of microorganisms adhere to it. After hundreds of thousands of years' evolution, they form a kind of symbiosis relationship. A rather large amount of research shows the great diversity of microbes related to sponges using 16S rRNA (ribosomal ribonucleic acid) or 18S rRNA gene-based methods. Just in recent decades, many bioactive compounds have been separated from sponges. However, more and more studies confirm that those bioactive compounds do not derive from the sponges themselves but rather their symbionts. Considering that most of the microbes in sponges are unculturable, the culture-dependent approach is greatly limited. Using metagenomics, it may be possible to produce enzymes of special characteristics and secondary metabolites with biotechnological application from the sponge derived uncultured microbes. What is more, metagenomics can also serve as a way to understand the community structure, as well as the metabolism and function of a complex microbial community. This chapter focuses on techniques and advances in marine bacterial metagenomics, using sponge metagenomics as an example. Several aspects will be considered: The background and problems of sponge research (Sect. 17.1), the principle of metagenomics and related techniques (Sect. 17.2), the application and latest progress in sponge metagenomics (Sect. 17.3), and future perspectives (Sect. 17.4).

17.1 Background and Problems of Sponge Research

Sponges are the simplest form of multicellular animals of the phylum *Porifera*, which literally means *pore-bearing*. Their morphology caused ancient scientists like Aristotle and Pliny to consider them as plants [17.1]. In 1765 John Ellis proved that they are actually animals [17.2]. Marine sponges represent one of the extant metazoans of 700–800 million years. They are classified into three classes according to skeletal type, calcareous sponges – *Calcarea*, demosponges – *Demospongiae*, and glass sponges – *Hexactinellida*. So

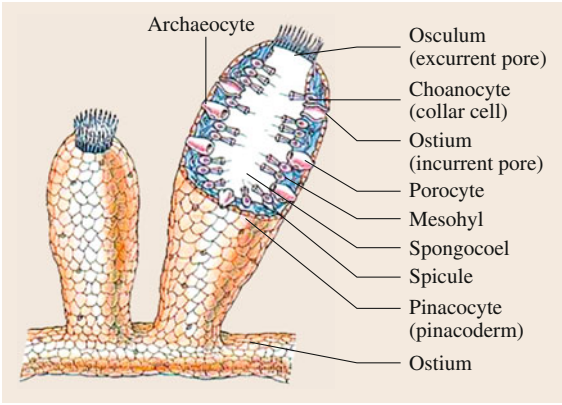

Fig. 17.1 Schematic representation of a sponge (adapted from http://universe-review.ca/R10-33-anatomy.htm)

far, 15 000 species have been described, but the true diversity is probably much higher. Among them, more than 6000 species are found in marine and freshwater systems throughout tropical, temperate, and polar regions [17.3]. An enormous diversity of sponges occurs on coral reefs, where they exhibit a wide range of shapes and colors.

The structure of sponges is different from that of other taxons (Fig. 17.1); the body of sponge is made up of extensive jelly-like material (mesohyl), armored by a network of collagen fibers. Sponges have special collar cells (choanocytes) that are unique in the animal kingdom. They have flagella, whip-like structures that form the external *skin*, breathing pores, and tubes to set up water currents to sieve food particles from the water. The seawater passes through an inhalant pore and leaves the sponge via an exhalant pore. The food particles, including bacteria and microalgae filtered by the choanocytes, are transferred to an extensive layer of connective tissue (mesohyl). In the mesohyl, the special cell archaeocytes will digest the food particles by phagocytosis. Sponges are also unique because nearly all their cells can change function as required (*totipotency*). The mesohyl of marine sponges represents dense communities of microorganisms [17.4].

Sponges are a most important component of benthic fauna and represent the second largest biomass on tropical reefs due to the mechanism of obtaining nutrients. Sponges feed on particles as small as bacteria as well as larger particles in food poor environments. Sponge symbioses were initially documented by electron microscopy. *Webster* et al. [17.5] identified the high density of bacterial cells within the mesohyl region and also choanocyte chambers surrounding the region by fluorescence in situ hybridization (FISH). As filter feeder it pumps large volumes of sea water containing bacteria and effectively removes 60 to 99% of the bacteria [17.6]. Most symbiotic bacteria occupy up to 60% of the sponge volume in the intercellular matrix or mesohyl region. Sometimes, this exceeds the total volume of sponge cells. These bacteria contribute up to 40% of the sponge biomass and play a role in nutrient balance, health, and diseases of sponges. These bacteria are permanently associated with the sponges until disturbed by external factors [17.7]. In addition to fitter feeding, some coral reef sponges also obtain nutrients by photosynthesis. In corals, dinoflagellates (zooxanthellae) perform the photosynthesis. In contrast, sponges contain a wide range of microbial symbionts, unicellular or filamentous cyanobacteria are the photosynthetic symbionts, providing nutrients to the sponges by carbon and nitrogen fixation under normal environmental conditions [17.8–10].

Microbial communities associated with marine sponges include bacteria, archaea, microalgae, and fungi. Initial studies found that bacteria associated with sponges are same as those found in ambient seawater [17.11]. Later, it was concluded that sponge-associated bacteria are exact symbionts and are different from ambient seawater bacteria [17.12, 13]. Radio labeled substrate feeding studies clarified the difference between symbiotic bacteria and ambient seawater bacteria [17.14]. The bacterial count in sponges exceeds by two to three times that in ambient seawater. The relationship between the sponge and microbes could be classified as obligatory mutualism (symbionts have a crucial role in the host metabolism), facultative mutualism (they have a valuable effect on their host, but the host will also exist without the symbiont), or commensalism (they live without providing any valuable effects to their host). In all cases, it is clear that the sponge provides shelter for their symbionts [17.15].

Many diverse studies such as light and electron microscopy, FISH, and cultivation methods have proved the presence of a wide range of microbial associations and their adaptation in a sponge specific host environment. More recently, classical cultivable and uncultivable studies based on the 16S ribosomal RNA gene sequence revealed a high microbial diversity within the sponges; for example, bacterial phyla include *Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, *Chloroflexi*, *Cyanobacteria*, *Deinococcus-Thermus*, *Firmicutes*, *Gemmatimonadetes*, *Nitrospira*, *Planctomycetes*, *Proteobacteria* (*Alpha*, *Beta*,

Delta, and *Gamma Proteobacteria*), *Spirochaetes*, and *Verrucomicrobia*. Furthermore, a new phylum, *Poribacteria*, has also been found in a number of microbially rich sponges. Sequences from the *Chlorobi* (green sulfur bacteria) have not been obtained from sponges, although positive FISH signals were obtained from *Rhopaloeides odorabile*. Two archaea have also been reported from marine sponges, which belong to the members of the phyla *Crenarchaeota* and *Euryarchaeota* [17.4].

Sponges also host eukaryotic microbes such as dinoflagellates and diatoms, with the latter seemingly most prevalent in polar regions. Zoochlorella, an endosymbiotic microalgae, often reported from freshwater sponges. Two previous reports of cryptomonads in sponges were made by Wilkinson [17.16]. Marine sponges' associated fungi are receiving increasing attention due to their biotechnological potential. Fungal strains isolated from marine sponges, representing three phyla of *Ascomycota*, *Zygomycota*, and *Basidiomycota* fungi. In total 22 orders (*Boliniales*, *Botryosphaeriales*, *Capnodiales*, *Chaetosphaeriales*, *Claromycetales*, *Diaporthales*, *Dothideales*, *Eurotiales*, *Helotiales*, *Hypocreales*, *Microascales*, *Mitosporic Agricomycotina*, *Moniliales*, *Mucorales*, *Onygenales*, *Phyllachorales*, *Pleosporales*, *Polyporales*, *Saccharomycetales*, *Sordariales*, *Trichosphaeriales*, and *Xylariales*) within *Ascomycota*, 8 orders (*Agaricales*, *Agaricostilbales*, *Corticiales*, *Malasseziales*, *Polyporales*, *Sporidiobolales*, *Tremellales*, and *Wallemiales*) within *Basidiomycota* and 4 orders (*Rhizopus*, *Mucor*, *Rhizomucor*, and *Syncephalastrum*) within *Zygomycota* have been recorded in sponges [17.17]. Compelling evidence for symbiosis of yeast with sponges of the genus *Chondrilla* was obtained by extensive microscopy studies of both adult sponge tissue and reproductive structures [17.18]. It thus remains unclear in most cases whether such fungi are consistently associated with the source sponge, or even whether they are obligate marine species.

Viruses and virus-like particles (VLP) are abundant in coral reef environments and have been found in the water columns adjacent to sponges in coral reef environments. Virus-like particles have been observed in cell nuclei in *Aplysina* (Verongia) *cavernicola* [17.19]. It was suggested that VLP could be involved in sponge cell pathology. In another study, infection of an *Ircinia strobilina* derived *alphaproteobacterium* by a seawater bacteriophage was also demonstrated in laboratory conditions [17.20], but infection in nature is not known.

It has been assumed that the bacteria associated with the sponge synthesize several bioactive compounds [17.21]. However, cultivation of invertebrates for these bioactive compounds is too expensive and impossible, and hence cultivation of symbiotic microbes may provide an inexpensive supply of the natural compound. Yet, many sponge-associated bacteria have not been cultivable. Thus, metagenomic approaches are intended to isolate the bioactive genes responsible for bioactive compounds and express them in surrogate hosts. Usually, metagenomics begins with the construction and screening of metagenomic libraries for the targeted genes. This approach has resulted in the detection of numerous short biosynthetic pathways and novel bioactive compounds [17.21]. However, to date multidomain modular nonribosomal peptide synthetases (NRPS), type-I polyketide synthases (PKS-I), and type-II polyketide synthases (PKS-II) involved in the biosynthesis of secondary metabolites have been screened based on polymerase chain reaction (PCR) in the sponge metagenome for the novel bioactive compounds.

Marine sponges contain a wide range of microbial communities of significant ecological importance [17.4]. Although the perceptive of sponge microbial diversity is rapidly improving, the role of these microbes are mostly remains unknown [17.4]. Specific microbial mediated processes such as photosynthesis, sulphate reduction, nitrogen fixation, and nitrification have been quantified and identified by isotope enrichments, metagenomics and functional gene analyses [17.22]. These studies have extended our knowledge of the microbial symbiont function in sponges, yet they remain focused on specific processes or particular functional groups of organisms. Further, community wide assessment of microbial symbionts would be useful to elucidate their ecological role and contribution to the host.

Several methods have been developed and applied to evaluate sponge microbial symbiosis and diversity. Early studies in microbial ecology and the biosynthesis of natural products relied heavily on culturing bacteria on laboratory growth media. Unfortunately, most symbiotic microbes cannot be cultivated in laboratory conditions. The presence of abundant unculturable microbes in sponges makes it difficult to understand the functional traits. Therefore, in the last decades, microbial diversity studies have focused on molecular, culture-independent techniques based on the 16S rRNA gene. Cloning and sequencing of 16S rRNA genes are useful to infer phylogenetic relationships of the bacteria in a specific habitat. Cloning and characterization

of the environmental DNA (deoxyribonucleic acid) enables the renovation of metabolic and functional traits. This approach is generally termed *environmental genomics* or *metagenomics*. It has been effectively applied on several environmental samples, including marine sponges.

17.2 The Principle of Metagenomics and Related Techniques

Microbial research radically changed after 1985 due to the pioneering work on rRNA genes by *Carl Woese* [17.23]. This was followed by the work of *Pace* and colleagues, who directly analyzed the 5S and 16S rRNA genes from environmental samples without culturing [17.24]. The next technical step was the development of PCR and primers lead to amplifying the entire gene. This advancement in technology provided a larger microbial diversity that was not distorted by culturing bias.

Each organism in an environment has a unique set of genes in its genome; the combined genomes of all the community members make up the *metagenome*. Metagenome technology (metagenomics) has led to the accumulation of DNA sequences, and these sequences are exploited for novel biotechnological applications [17.25]. Metagenomics and the associated strategies have arrived at the forefront of biology, primarily because of the exploitation of next generation DNA sequencing technologies. This has significantly improved the potential for sequencing large environmental sets. Technological advances have created new opportunities for large-scale sequencing projects that would have been difficult to imagine several years ago. The next key development is an emerging appreciation for the importance of complex microbial communities in the marine environment. Due to the overwhelming majority of unculturable microbes in the marine environment, metagenome searches will always result in the identification of unknown genes and proteins. Currently, single-cell genomics is well suited for symbiosis research including bacterial symbionts of marine sponges. Thus, the probability of uncovering unknown sequences makes this approach more favorable than searches in cultured microbes (Fig. 17.2).

17.2.1 Isolation of Metagenomic DNA

Metagenomics has been confirmed to be a potent tool for studying the diverse environmental microorganism resources. Currently, there are two approaches in research on sponge metagenomics. In the first approach, a massive sequencing facility is employed to decode the metagenomic library with short sequences of fragments for assembly [17.26]. In the second one, scientists focus on the potential of functional expression of metagenomic library clones with large insert DNA [17.27]. In all cases, it starts with isolating DNA from the sponge sample.

Several methods are available for extracting DNA from sponge samples. Commercial kits are also available for extraction and purification of metagenomic DNA, which are easy to use with significant reproducibility. Isolation of metagenomic DNA from sponge samples can be classified into direct, indirect, and enrichment methods. The ultimate methodology should include cell lysis and DNA extraction. The direct method is based on cell lysis within the sample matrix and subsequent separation of DNA from the matrix and cell debris. Indirect DNA isolation is based on the separation of cells from the matrix, followed by cell lysis and DNA extraction. The enrichment method involves the separation of cells from the matrix, followed by cell enrichment, lysis, and DNA extraction [17.28].

17.2.2 Library Construction

Sponge metagenomic DNA is composed of a promising source of novel metabolites. The discovery of these novel metabolites requires the construction of a metagenomic DNA library and its efficient screening. During the construction of the metagenomic library two parameters have been widely considered. The first one is the large size and this should be the mixture of all bacterial genomes colonizing in a given environment. Such diversity improves cloning efficiency, so that the gene libraries provide sufficient functional genes of the entire metagenome. The second parameter is the size and cluster organization of genes involved in the secondary metabolite synthesis. Since the genes encoding the secondary metabolite biosynthesis are normally clustered, clones in the metagenomic libraries should contain larger DNA. Isolation of high molecular weight DNA facilitates the cloning of DNA into bacterial artificial chromosomes (BACs) and allows the characterization

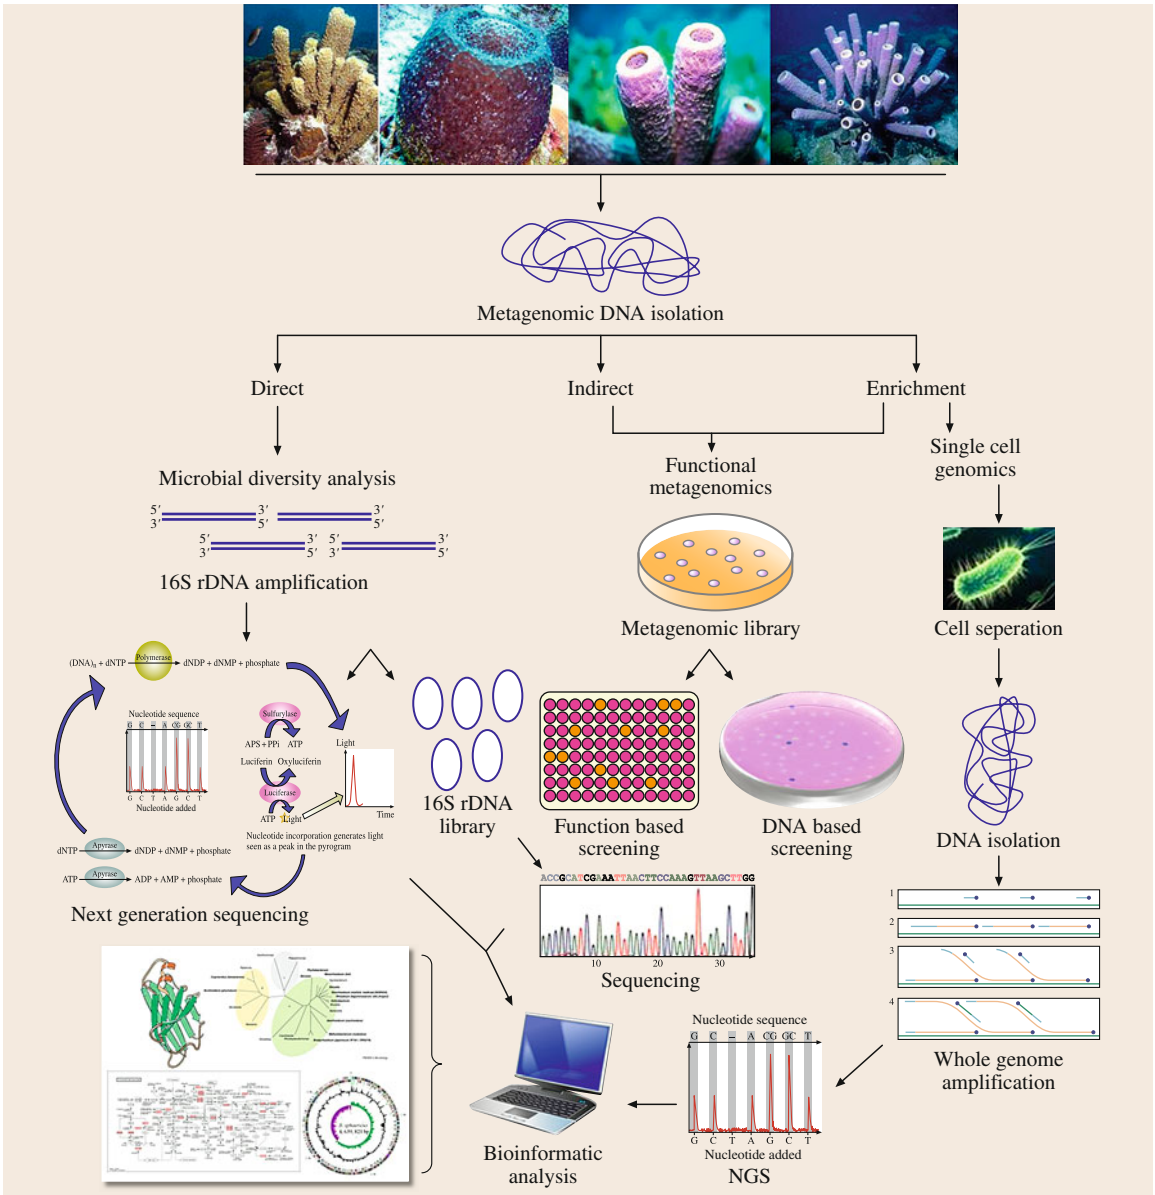

Fig. 17.2 Strategy of sponge metagenomics

of large regions of the genomes [17.28]. In general, the indirect and enrichment methods yield higher molecular weight DNA with high purity than direct methods. However, direct DNA isolation method from sponges is disadvantaged by the difficulty of mechanical shearing that occurs by the physical forces imposed on the sample during isolation. Further, nucleases released during cell lysis may possibly denature the released DNA.

The eukaryotic DNA content is also an important parameter effecting the construction of metagenomic library. Eukaryotic DNA will increase the cloning efficiency, but the expression of eukaryotic genes in bacterial hosts is restricted. In contrast, DNA obtained by the indirect and enrichment methods was suitable for library construction and gene expression due to the separation of bacterial DNA from the eukaryotic genome.

Therefore, it is emphasized that the direct method should be avoided when constructing the metagenomic library for natural product synthesis.

Metagenomic library construction methods have been extensively optimized for cloning in BAC and FOSMID (F1 origin-based cosmid vector); both have been successfully used in sponge metagenomics. Compared with fosmid libraries only capable of screening up to 40 kb inserts, environmental BAC libraries enable the screening of larger DNA inserts up to 200 kb [17.29], which can facilitate the reconstruction and functional analyses of environmental genomes [17.30].

17.2.3 Function-Based Screening of the Metagenomic Library

One of the simplest strategies used to detect antibiotic producing environmental DNA (eDNA) clones is top agar overlay assays. Metagenomic enzymes are usually screened on agar plates supplemented with substrates. Positive clones from the metagenomic library can be identified by visual screening for the appearance of a clear zone or color. Functional screening of a metagenomic library requires no special devices and high throughput can be performed, but the signals are often faint due to low hit rates.

Alternative approaches of cell lysates are applied to improve the sensitivity of agar plate-based screening. By growing the clones of a metagenomic library in 96-well plates, followed by preparing the lysates by either a chemical or a physical procedure, and mixing them with substrates, the sensitivity is improved. This method is frequently applied for screening gene resistance to toxic compounds such as antibiotics and heavy metals. This method can also be applied to screen essential genes using hosts that lack the target genes. A third approach is based on the reporter assay. By linking the target gene with the reporter gene, such as green fluorescent protein, β-galactosidase, and tetracycline resistance genes, screening can be conducted based on the expression of reporter genes [17.31].

17.2.4 Sequence-Based Screening of the Metagenomic Library

Type II PKS Biosynthetic Genes

ThePKSs are responsible for the production of bacterial polyketides, a diverse group of pharmacologically important natural products which include antibiotics, antitumor, immunosuppressive, and cholesterol lowering agents. Bacterial type II PKS biosynthetic gene clusters encode three enzymes, including two ketoacyl synthases, KS a (catalyzes the Claisen type condensation between the growing polyketide and incoming acyl-CoA subunits) and KSb (anchors the growing polyketide chain during chain elongation). The minimal PKS gene cassette is adequate to produce the polyketide in type II PKS systems. Additional enzymes such as ketoreductases (KR), cyclases, and aromatases are required to fold and cyclize the poly b-ketoacyl intermediate into the final structure. The structural diversity of the natural products originates from type II PKS, from divergence within the PKS domains, and their arrangement with assorted modification enzymes. With this knowledge of the functions of all three constituents of the minimal PKS (ketosynthase alpha subunit-ketosyntahase beta subunit-acyl carrier protein, KSa-KSb-ACP), a scheme was designed to determine overall polyketide chain length and structure. Degenerate PCR primers were designed based on conserved regions within KSa and ACP genes in type II PKS were used to amplify KSb sequences directly from metagenomic DNA. The discovery of novel small molecules from metagenomic DNA reveals the enormous genetic diversity encoded within the uncultured bacterial genomes for the discovery of natural products [17.32].

Type I PKS

Type I PKS generally consist of a set of multifunctional modules. Each module is responsible for one cycle of polyketide chain elongation. The module contains ketosynthase (KS), acyltransferase (AT), and acyl carrier protein (ACP) domains that together catalyze a two-carbon extension of the chain. After such an extension, the resulting ketone can either be left as is or converted to a β-hydroxyl, a double bond, or an alkane group by stepwise processing of ketoreductase (KR), dehydratase (DH), and enoyl reductase (ER) domains. The substrate specificities of the ATs, the order and number of the modules, and the composition of catalytic domains within each module provide a *code* for the structure of the synthesized polyketide. Furthermore, the PKS genes for a particular polyketide are usually clustered and colinear with the order of its biosynthesis. Consequently, the structure of the polyketide product of an unknown PKS can be approximated from the sequence of its genes [17.33].

Nonribosomal Peptide Synthetases (NRPS)

NRPS gene clusters encode for a wide range of nonribosomal peptides, ranging from antibiotics, tox-

ins, siderophores, and anti-inflammatorials to immunosuppressants. These pharmacologically relevant bioactivities have motivated extensive searches for novel NRPS genes in microbial isolates and in environmental samples. NRPS are large, multimodular enzymes that are organized in modules containing specific domains that sequentially incorporate amino acid building blocks into a growing peptide chain. A typical NRPS module contains an adenylation (A) domain, a peptidyl carrier protein domain, and a condensation domain [17.32].

17.2.5 Next Generation Sequencing Technologies

Next generation sequencing (NGS) technologies are having a considerable impact on metagenomics. NGS technologies include three commercial platforms, namely the 454 pyrosequencer (Roche Diagnostic Corporation), GAII/HiSeq sequencer (Illumina), and SOLiD instrument (Life Technologies Corporation). The technologies behind each platform were reviewed in detail by *Metzker* [17.34].

Although a huge amount of phylogenetic data has been gathered for microbial identification using Sanger sequencing, new sequencing technologies are having a considerable impact on metagenomics. DNA pyrosequencing was developed to sequence the DNA with a fundamentally different approach in the mid 1990s [17.35]. Sequencing occurs by a DNA polymerase driven production of inorganic pyrophosphate with the formation of ATP and ATP-dependent conversion of luciferin to oxyluciferin (Fig. 17.3). The oxyluciferin generate the emission of light pulses and the amplitude of each signal is directly related to the presence of one or more nucleosides. The main drawback of pyrosequencing is its inability to sequence longer stretches of DNA. Hence, the hypervariable regions within bacterial 16S rRNA genes were amplified by the PCR and subjected to DNA pyrosequencing.

DNA pyrosequencing has been effectively applied in various fields such as genotyping, signle-nucleotide polymorphism, and microbial identification [17.36]. Pyrosequencing has been effectively applied to identify microbes based on the hypervariable regions within the 16S rRNA gene and signature sequence matching [17.37]. After DNA sequencing, sequences should be analyzed carefully to facilitate accurate bacterial identification.

Illumina performs solid surface PCR amplification by immobilizing random DNA fragments on a surface. The resulting cluster DNA fragments are sequenced with reversible terminators by synthesis process. The cluster density is enormous with hundreds of millions sequence reads for each surface channel. In total, 16 channels are run at the same time in the HiSeq2000 instrument. The sequence read length is about 150 bp and it can be sequenced from both ends. By overlapping both sequences, base pair reads can reach up to 300 bp. Approximately 60 Gbp can be expected in a single channel. As compared with 454, Illumina requires only a few nanogram of starting material and provides a superior amount of unassembled sequence reads. The limitation of Illumina is the run time; it takes approximately 10 days but 454 take only 1 day [17.38].

Apart from this, some other sequencing technologies are also available, but they need to prove themselves for metagenomic application. Among them, the Applied Biosystems SOLiD sequencer has been extensively used in genome re-sequencing. SOLiD possibly provides the lowest error rate compared to other NGS sequencing technologies, but the reliable read length is much beyond 50 nucleotides. This will limit its applicability for direct gene annotation of unassembled reads or assembly to large contigs. However, recent research work on the porphyrins from a metagenomic library of the marine sponge *Discodermia calyx* has showed N encouraging outcome [17.39]. Ion Torrent is another emerging technology and is based on the principle that nucleotide incorporation can be detected by proton release during DNA polymerization. This system promises read lengths of more than 100 bp. Most recently, the draft genome sequence of *Gillisia* sp., strain CBA3202 was announced based on the Ion Torrent Personal Genome Machine (PGM) sequencer [17.40].

17.2.6 Metagenomics and Informatics

The challenge for metagenomics is after getting hundreds or thousands of sequences, that is, how to identify the microbes in reasonable time. Existing bioinformatics methods are too slow and not adequate for large-scale projects. Currently, high-throughput metagenomics ribosomal DNA (rDNA) analysis tools are in development. Obviously, enough computational command, distributed computing networks, and robust server technology may ultimately solve the demands of current metagenomics data analysis. Starting with sequence collection and verification, various strategies have been followed to examine the quality of each read [17.41]. Before sequence assembly, the sequences are trimmed by using various algorithms to

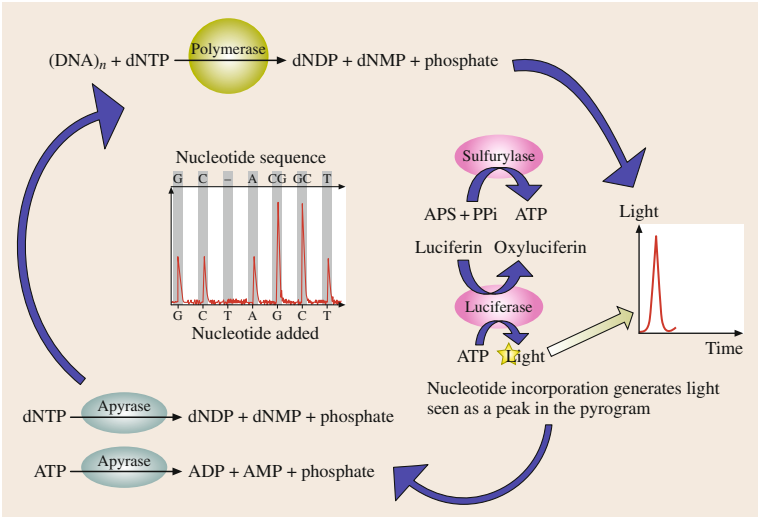

Fig. 17.3 The principle of DNA pyrosequencing [17.36]

remove primer and low quality sequence data. *Huse* et al. analyzed variable regions of 16S rRNA gene sequences generated by 454 sequencing for its error and explained a method for filtering low quality sequence data to produce robust data sets for 16S rDNA analyses [17.41]. Once the primer and low quality sequences have been trimmed, sequences can be aligned using sequence alignment programs such as NAST [17.42] or MUSCLE [17.43]. The next problem is the chimera sequences generated during the amplification process. They can be removed by chimera checking tools such as Greengenes [17.44], Ribosomal Database Project (RDP) [17.45], Bellerophon [17.46], or Pintail [17.47]. After obtaining the high quality sequences, they must be identified accurately in parallel. Sequences can be classified using classifiers such as the Bayesian classifier in the RDP system and can be compared with multiple sequence alignment programs such as RDP, Greengenes, or ARB-SILVA. Aligned sequences may also be classified against databases such asprok MSA (prokaryotic multiple sequence alignment) in Greengenes, and finally phyla may be identified and displayed as relative abundance histograms to compare different bacterial groups.

Novel bioinformatic tools such as CARMA (characterizing short read metagenomes) enable sequences encoding protein segments as small as 27 amino acid residues for microbial identification and comparative metagenomics [17.48]. A high throughput informatics approach, automated simultaneous analysis phylogenetics (ASAP) [17.49], recommend an automated approach for phylogenomics that may facilitate the analysis of large sequence data, especially whole genome-based microbiome explorations. Phylogenetic distance matrices may be constructed in programs such as DNAML (DNA maximum likelihood) [17.50]. Distance matrices may be transferred to DOTUR (Defining Operational Taxonomic Units and Estimating Species Richness) [17.51] for construction of collector's curves, rarefaction curves, calculations of Chao and ACE richness estimates, and computations of Simpson and Shannon indices of diversity.

17.2.7 Single-Cell Genomics

A recent addition to metagenomic research is single-cell genomics. It relies on genomic sequence information of a single culture-independent microbial cell. Comprehensive genomic information of single microbial cells was obtained by using the enzyme Phi29 polymerase. Single-cell genomics is especially well suited for symbiosis research in which the vast majority of symbionts has not been cultivated. Single-cell genomics is especially well suited for symbiosis research, including bacterial symbionts of marine sponges, insects (grasshoppers, termites), and vertebrates (mice, humans). In any case, new insights have been obtained into the repertoire of the bacterial partners; these findings have led to an improved understanding of the related host [17.52].

Single-cell genomics involves the separation of individual microbial cells from environmental samples to access their complete genomic DNA and to generate an adequate quantity of DNA by whole genome amplifi-

cation for sequencing (Fig. 17.2). Cell singularization mainly depends on the characteristics of the sample. If possible, for pure cultures obtained from symbionts, serial dilution is a promising method. Commonly used methods for cell singularization is fluorescence activated cell sorting (FACS). Target cells can be detected by FISH or labeled with a fluorescent dye.

Microfluidic chambers have also proven to be successful for obtaining single amplified genomes (SAG) [17.53]. This method uses reaction volumes of only 60 nl, which reduces the likelihood of contaminating the sample. Microfluidic devices have also been developed recently for FISH and tyramide signal amplification FISH (tsa-FISH) followed by cell sorting via flow cytometry directly on the device [17.54, 55]. This approach holds great promise for 16S rRNA gene-based identification of single cells, while bearing low risks of contamination. Micromanipulation techniques are useful to target morphologically distinct microorganisms. Micromanipulation using microcapillaries has been used successfully in combination with FISH to target the single cell [17.56]. The next step is cell lysis to provide the genomic material for consequent multiple displacement amplification (MDA).

MDA randomly amplifies primed template DNA using the Phi29 polymerase enzyme in an isothermal reaction. DNA synthesized by Phi29 polymerase becomes directly accessible for the next polymerase molecule, thus resulting in continuous DNA amplification. The next step is the whole genome sequencing of MDA products. Various sequencing methods have been employed for whole genome sequencing.

Most studies have relied on shotgun or paired end libraries using 454 pyrosequencing. However, mixture of 454 and Illumina have been also used to enhance the genome coverage. Combinations of 454 and Sanger sequencing have also been used. The first single-cell genome was obtained using Sanger, 454, and Illumina techniques [17.57]. With the evolution of new sequencing techniques, novel approaches such as the PacBio or IonTorrent techniques might facilitate obtaining better genomic data from single cells.

17.3 Application and Latest Progress in Sponge Metagenomics

17.3.1 Diversity of Bacterial Symbionts in Sponges

The use of culture-independent tools has greatly accelerated the understanding of the phylogeny of sponge-associated microbes. Underpinning this development is the application of next generation sequencing technologies. A recent study using 454 amplicon pyrosequencing revealed extraordinary species richness in Australia's Great Barrier Reef sponges (*Ianthella basta*, *Ircina ramose*, and *R. odorabile*) [17.58]. An enormous bacterial diversity was demonstrated in those sponges. This includes the dominant bacterial taxa *Chloroflexi*, *Acidobacteria*, *Actinobacteria*, and *Proteobacteria* (*Alpha, Delta, Gamma*), which are the same phyla that featured in conventional 16S rRNA gene libraries [17.4]. Newly discovered phyla by 454 sequencing (e.g., *Deferribacters, Tenericutes*) were also present, but only in low abundance [17.58].

Next generation 16S rRNA gene tag sequencing suggests that the sponge microbiome may be classified into three main groups (species specific, variable, and core) [17.59, 60]. Species specific microbes comprise 72% of the taxa detected in sponges, whereas only 2% of the detected taxa correspond to the core. The five Mediterranean sponges *Aplysina aerophoba*, *Aplysina cavernicola*, *Ircinia variabilis*, *Petrosia ficiformis*, and *Pseudocorticium jarrei* share a core microbiome, which includes the phyla *Acidobacteria*, *Chloroflexi*, *Nitrospira*, *Poribacteria*, and *Proteobacteria*. The phylum *Chlamydiae* and *Lenthisphaerae* appears to be found only in association with *A. cavernicola* and *I. variabilis*, respectively [17.59]. The core communities are represented as globally distributed microbes that are horizontally acquired from the environment by a sponge, whereas the species specific community could consist of microbes that are vertically acquired from the progenitor [17.60]. Investigation of *Cymbastela concentrica* microbiome helped to further elucidate possible genetic mechanisms involved in the establishment of species specific microbiomes [17.61]. The authors sequenced about 190 623 shotgun sequences and 3545 16S rRNA gene sequences. *C. concentric* contains the vast majority of *Gammaproteobacteria*, *Phyllobacteriaceae*, *Sphingomondales*, *Neisseriales*, and *Nitrospiraceae*. Based on 16S rRNA gene identification (97% identity cutoff), only 34 different OTUs were common between *C. concentrica* and the surrounding seawater, which supported the idea of selection for a specific microbiome, possibly

consisting of several (although nonculturable) bacteria. A recent 16S rRNA gene sequence-based study in the southeastern Atlantic region generated 133 bacterial sequences from the sponges *Hymeniacidon heliophila* and *Polymastia janeirensis* [17.62]. These two sponge species appear to share several bacterial taxa affiliated with *Cyanobacteria* and *Proteobacteria*. An analysis of 254 archaeal 16S rRNA gene partial sequences from the sponges *Hymeniacidon heliophila*, *Polymastia janeirensis*, *Paraleucilla magna*, and *Petromica citrina* suggested that *Crenarchaeota* is well represented in sequence databases [17.63]. *Silva* et al. provided the first large-scale analysis of the taxonomic and metabolic diversity of the microbiome of the sponge *A. brasiliensis*. These results demonstrated that a complex microbiome exists within this sponge, which presents a particular metabolic profile [17.64]. It also indicates the *A. brasiliensis* microbiome is unique, differing from the microbiomes present in the water column surrounding these sponges and those associated with other marine organisms. Within the taxonomic signature of the *A. brasiliensis* microbiome, an enrichment of *Betaproteobacteria* (*Burkholderia*) and *Gammaproteobacteria* (*Pseudomonas* and *Alteromonas*) were detected, which indicates the specificity of the species.

17.3.2 Functional Genes Related to Natural Products of Bacterial Symbionts in Sponges

Natural products isolated from sponges are a key source of new biologically active compounds. However, the development of these compounds into drugs has been held back by the difficulties to achieve a sustainable supply of these, often complex, molecules for preclinical and clinical development. Increasing evidence implicates microbial symbionts as the source of many of these biologically active compounds, but the vast majority of the sponge microbial community remains uncultured [17.65]. Metagenomics offers a biotechnological solution to this problem. Metagenomes of sponge microbial communities have been shown to contain genes and gene clusters typical for the biosynthesis of biologically active natural products. Heterologous expression has also led to the isolation of secondary metabolism gene clusters from uncultured microbial symbionts. Combining a metagenomic approach with heterologous expression holds much promise for the sustainable exploitation of the chemical diversity present in the sponge microbial community.

Polyketides are considered as an important class of bacterial bioactive secondary metabolites. Efforts have been focused on isolating PKS gene clusters from sponge-associated bacterial metagenomic libraries [17.66]. *Piel* et al. [17.67] successfully employed this approach and identified the putative onnamide PKS gene cluster from a marine sponge *T. swinhoei* metagenomic library. Onnamide A (Fig. 17.4(1)), found in marine sponges of the genus *Theonella*, is very similar in structure to pederin (Fig. 17.4(2)) from Paederus beetles. A major difference is the addition of a terminal arginine, potentially added by NRPS domains, in the sponge compounds. The very clear homology between pederin and onnamide genes was used to identify the candidate onnamide gene cluster. The trans-AT feature of this gene cluster was used in the cloning strategy. Interestingly, PCR primers were designed for the PKS genes involved in pederin biosynthesis to identify the closely related onnamide gene cluster.

The dysidenin (Fig. 17.4(3)) group of nonribosomal peptide natural products was isolated from marine sponges of the genera *Dysidea* and *Lamellodysidea*, which harbor photosynthetic symbiotic cyanobacteria of the genus *Oscillatoria*. Synthesis of these nonribosomal peptides was not successfully determined [17.68]. The identification of the barbamide (Fig. 17.4(4)) biosynthetic gene cluster from *L. majuscula* facilitated identification of candidate dysidenin biosynthetic genes within marine sponges [17.69]. This family of compounds contains a very rare chemical motif, a multiply chlorinated leucine residue. The PCR primers were designed for this chemical motif, targeting the halogenase gene. This feature was used to isolate candidate halogenases from marine sponges containing the dysidenin family of compounds.

Fisch et al. [17.70] found that general KS primers amplify too many diverse PKS gene sequences, making it very difficult to identify the correct gene cluster. Hence, they applied a nested PCR strategy to amplify the specific gene cluster. First, the degenerate KS primers were used to amplify the KS region followed by the application of a trans-AT specific PCR primer pair. The primers were designed such that one primer was specific to 84% of all trans-AT KS, while the second primer was specific for certain chemical motifs in the resulting polyketide product. Using this strategy, probable gene clusters were identified for the pederin relatives mycalamide (Fig. 17.4(5)) and psymberin (Fig. 17.4(6)) from marine sponge metagenomes.

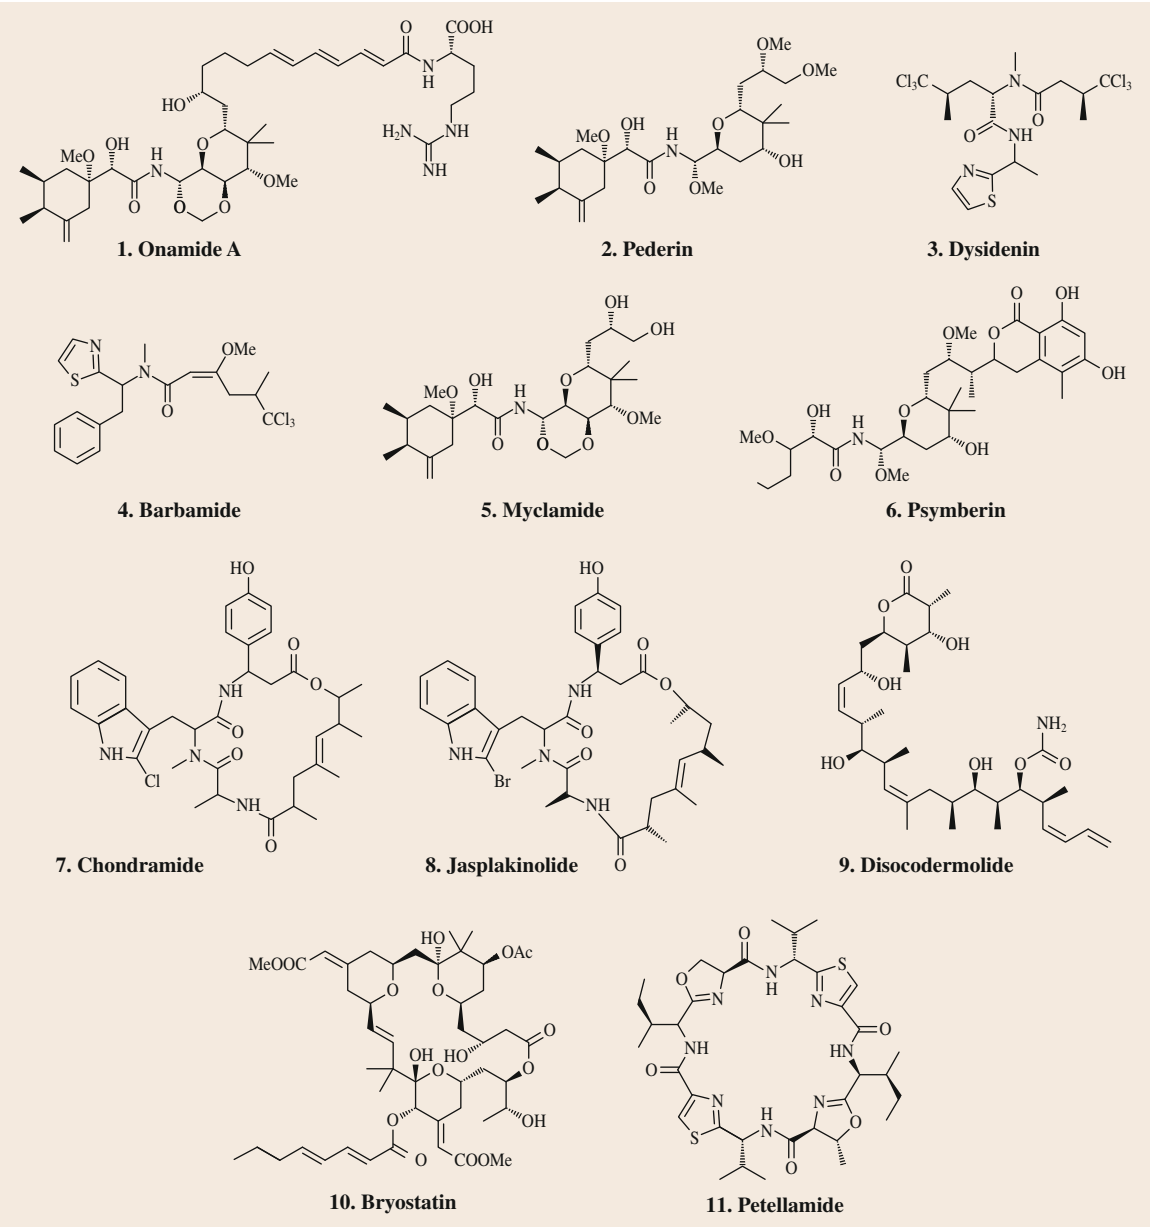

Fig. 17.4 Bioactive metabolites from marine sponges

Similarly, the cloning of the chondramide (Fig. 17.4(7)) biosynthesis cluster from *C. crocatus* [17.71] was used to isolate the biosynthesis genes for the closely related compound, Jasplakinolide (Fig. 17.4(8)) from the sponge *Jaspis* sp. *Kim* and *Fuerst* [17.72] investigated the secondary metabolic potential of the sponge *P. clavata* using PKS probes for isolating the biosynthetic gene cluster of discodermolide (Fig. 17.4(9)). Although this study did not identify the discodermolide gene cluster, it did demonstrate that many PKS genes were present in the sponge metagenome and that it was possible to clone large bacterial PKS gene clusters from the sponge metagenomic DNA.

Later, the investigation of PKS genes in cultivable and uncultivable bacteria proved that some of the PKS genes originating from the sponge metagenome appear to form a sponge specific bacteria and it is phylogenetically distinct from other PKSs. The large number of bacterial PKS genes that has been found using these metagenomic approaches provides compelling evidence in support of the symbiont hypothesis and also demonstrates the complexity of the *bacterio sponge*. Studies with other marine invertebrates have clearly demonstrated that microbial symbionts are the likely producers of the metabolites bryostatin (Fig. 17.4(10)) and patellamide (Fig. 17.4(11)) [17.73–75].

The discovery of bryostatin eventually led to the detection of a huge number of polyketide synthases of biotechnological interest. Metagenomics strategies have led to the identification of the Sup-PKS group, which is dominant in marine sponges and encodes synthases that are present exclusively in these animals. These synthases produce methyl branched fatty acids and they are assumed to be of bacterial origin [17.76].

Sponges exhibit a high level of fatty acid diversity, and it is generally assumed that the methyl branched fatty acids are of microbial origin [17.77]. This finding is supported by the observation that methylated fatty acids in bacterio sponges are more abundant than in bacteria free sponges. Similarly, methyl branched alkanes that are thought to originate from microbial methylated fatty acids are commonly present in fossil sediments and fuels [17.78]. A challenging hypothesis has been put forward that sponges as the most ancient metazoan animals might be extant reservoirs for ancient microbes and their corresponding methylated fatty acid encoding PKS genes.

The biological function of methyl branched fatty acids in sponges is unclear. Interestingly, structurally similar fatty acids are major constituents of the protective lipid cell layer of *Mycobacterium tuberculosis* [17.79]. Deletion mutants lacking intact mycolic acids are significantly attenuated in the mouse model and in macrophages [17.80]. Therefore, it is tempting to speculate the importance of methyl branched fatty acids. Marine sponges are also known to contain large amounts of halogenated organic compounds such as fatty acids and alkaloids and are thus a potential useful source of both the halogenases and the dehalogenases group of biotechnologically important enzymes, which can be used in the production of pharmaceuticals, herbicides, and pesticides [17.32]. A novel halo-tolerant lipase was isolated by following a functional screen of a marine sponge fosmid metagenomic library. The activity and stability profile of the recombinant enzyme over a wide range of salinities, pH, and temperatures, and in the presence of organic solvent and metal ions suggests that there would be a utility for this enzyme in a variety of industrial applications [17.81].

17.3.3 Functions of the Bacterial Community in Sponges

To date, the function of sponge-associated microorganisms lags behind the understanding of taxonomic affiliation. However, recent research on marine sponges has focused on the symbiont function, in particular for nitrogen metabolism. Initially, stable isotope experiments demonstrated denitrification in sponges *Geodia barretti* [17.82], *Dysidea avara*, and *Chondrosia reniformis* [17.83]. Further metagenomic analysis recovered gene encoding cytochrome cd1-type nitrite reductases (nirS) from sponge-associated *Betaproteobacteria* and *Gammaproteobacteria*, which are responsible for denitrification in sponges [17.82]. Gene encoding enzymes such as nitrite reductase and nitric oxide reductase were also identified in the metagenome of *Poribacteria* from the sponge *Aplysina aerophoba* [17.84]. Anammox activity was also demonstrated in the sponge *G. barretti* [17.83]. *Mohamed* et al. [17.85] provided the first molecular evidence for the presence of potential anammox bacteria in sponges. *Liu* et al. [17.86] detected the expression of the ammonia mono-oxygenase membrane bound subunits β and Υ (AmoB and C) and an ammonia transporter (AmtB) in the microbial community of *C. concentric*. The genes encoding AmoB and C were adjacent and orientated in opposite transcriptional directions on a contig of the *C. concentrica* metagenome. The contig also contains a gene for the α-subunit (amoA) and has overall striking synteny with a genomic region of *N. maritimus*.

Sponges are suggested to be capable of differentiating food bacteria from symbionts. *Wilkinson* et al. [17.12] suggest that the chemical composition of the bacterial outer layer may play a role in sponge symbiont recognition. *Wehrl* et al. [17.87] demonstrated that the retention rates of different food bacteria were similar, despite the difference in cell surface properties. However, the question of how sponges discriminate between food and symbionts remains unsolved. Metagenomic analysis of *C. concentrica* has led to the discovery of a number of important genomic factors, including tetratricopeptide repeat domain encoding proteins (TPR) and ankyrin repeat proteins (ARP). The presence of the TPR and ARP proteins in the *C. con-*

centrica metagenome indicate that it interacts with surrounding cells and proteins [17.88]. Ankyrins are especially likely to be of relevance, as they might be involved in the recognition of and protection from host phagocytosis. This theory is further strengthened by the fact that proteins with ankyrin domains are found in other obligate intracellular pathogenic and symbiotic systems, where they interfere with host cell function. Thus, these proteins could represent potential mechanisms that allow the host sponge to discriminate between food and symbiont bacteria [17.88]. Functional analysis performed via shotgun sequencing using the COG (Clusters of Orthologous Group) database suggested that the majority of the detected genes belong to bacteria. The authors also found a large number of sequences identified as transposable insertion elements. The sponge metagenomes contained a greater number of sequences identified as COG0610 (restriction enzymes, type I helicase) and COG1715 (restriction endonuclease) than the surrounding seawater. Both COG groups include specific DNA modification and restriction systems in bacteria, and therefore, the authors hypothesized that this would facilitate horizontal DNA exchange between sponge microorganisms and protect against DNA exchange with planktonic organisms in the surrounding seawater [17.61].

The symbiotic function of the microbial community in the sponge *A. aerophoba* was revealed by whole genome amplification (WGA). The functional data revealed a sponge specific PKS and an NRPS from the *Poribacteria* from the *Chloroflexi* clade, respectively [17.89]. The carbon monoxide dehydrogenase detected in the metagenome of *C. concentrica* [17.88] demonstrated that the *Poribacteria* are mixotrophs that can undertake autotrophic carbon fixation [17.84]. A large number of insertion elements was observed for the first time within the *C. concentrica* metagenome. Large numbers of mobile elements were previously seen within intracellular symbionts in other hosts [17.90] and were proposed to have important roles in the evolution of bacterial genomes for symbiotic relationship with their hosts.

Second, a high frequency of clustered regularly interspaced short palindromic repeats CRISPR and CRISPR-associated proteins (CAS) were observed in the metagenome data set. The elevated abundance of these CRISPRs and CAS were proposed to form a viral specific defense system [17.91]. The defense system may provide proteins that are effective against bacteriolytic viral infection for the sponge symbionts, as sponge bacteria are expected to be exposed to as many as 1000 viral particles on a single day. Therefore, the system would be essential for the survival of high cell density, nonmobile sponge microbial communities and to maintain a barrier against phage-mediated gene transfer from the surrounding planktonic community, where a high phage load could be expected. Third, several shared metabolic interactions between bacteria and host, including vitamin production, nutrient transport and utilization, and redox sensing and response were found. These new previously unrecognized genomic signatures and functions of sponge bacteria provide an insight into the potential metabolic interdependency between host and microorganisms, and into the specific mechanisms used by symbionts to remain in sponge tissue. Also, these novel markers could be used for monitoring the status of the symbiotic relationships between sponge and bacteria by assessing the abundance, diversity, and expression of these functional genes [17.88].

Liu et al. [17.86] unravel some of the interactions between microbial community and the sponge *Cymbastela concentrica* through a combined metagenomic and metaproteomic approach. They provided new data for the first time on specific transport functions for typical sponge metabolites (for example, halogenated aromatics and dipeptides). This study also indicated that there is a requirement for the microbial community to respond to variable environmental conditions and hence express an array of stress protection proteins. Finally, molecular interactions between symbionts and their host might also be mediated by a set of expressed eukaryotic-like proteins and cell-cell mediators, and some sponge-associated bacteria (for example, the *Phyllobacteriaceae* phylotype) may be undergoing evolutionary adaptation process to the sponge environment, as evidenced by active mobile genetic elements.

17.4 Future Perspectives

The application of metagenomics provides access to sponge microbiota as a rich resource for novel enzymes and metabolites, and opens new avenues for the sustainable production of biotechnologically rele-

vant compounds. However, as DNA sequencing and synthesis costs rapidly decrease, eDNA methods are becoming the mainstays of natural product discovery and research. Coupling metagenomics with expression holds much promise for the sustainable exploitation of the chemical diversity present in the sponge microbial community and also enables us to identify the cryptic pathways of natural product biosynthesis in individual microbes. The broadest application of next generation sequencing has enhanced our understanding of sponge microbial diversity and its symbiotic association. Further, the metagenomics has revealed the role of sponge microbes in nitrogen cycling by the analysis of functional genes involved in ammonia oxidization and denitrification. Thus, this method provides a bright future for the discovery of novel pharmaceuticals from marine sponges and for a better understanding of the microbial symbiotic roles in sponges.

However, the standard metagenomic approach of accessing the entire genetic material associated within sponges could not explore the active gene. To overcome this problem, metatranscriptomic-based approaches have been employed to study marine microbial populations, in which only transcriptionally active genes are accessed. Applying this approach to the study of sponges has resulted in the detection of genes known to be involved in key aspects of their metabolism, and in addition many unique transcripts, presumably also of biochemical importance have been detected. Another alternative strategy to accessing the metagenome for proteins within sponges is metaproteomics. This has proven to be useful in providing new physiological data such as the identification of proteins that are essential for sponge symbiosis. It is clear that novel screening tools would discover novel metabolites from sponges.
