Lung Cancer

Eric B. Haura, Susan A. Blackwell, and Jeffrey Crawford

Epidemiology and Risk Factors

In the United States, the leading cause of cancer death in men is lung cancer, with lung cancer continuing to surpass breast cancer as the leading cause of cancer death in women. In men, the overall incidence of lung cancer currently approximates 80 per 100,000 men;¹ this escalates to nearly 600 per 100,000 for men aged 60 to 79 years. In women, the overall incidence of lung cancer is approximately 50 per 100,000 women; lung cancer incidence rates are approximately 400 per 100,000 women aged 60 to 79. The number of older persons who will develop lung cancer is expected to increase as the smoking exposure time effects on birth cohorts become more apparent² (Fig. 35.1).

There is a dose–response relationship for smoking and lung cancer, and the risk for lung cancer increases with smoking duration, number of cigarettes smoked, age at onset of smoking, use of unfiltered cigarettes, tar and nicotine content, and degree of inhalation.¹ The pivotal trial by Doll and Hill in 1956 showed that smoking cessation reduces the risk of lung cancer compared to those who continue to smoke.³ This finding was reproduced by Pathak et al. in 1986 in a case control study of lung cancer in New Mexico, which compared cases and controls less than 65 years of age to those more than 65 years of age⁴ and additionally showed that one decline in lung cancer risk that occurs with smoking cessation in the older person is comparable to that of the young. This same study showed that the number of years of smoking is relatively less important than the number of cigarettes smoked per day in determining the risk for lung cancer in those persons 65 and older.⁵

In a reanalysis of the 1986 Adult Use of Tobacco Survey (AUTS), Orleans et al. found that older smokers smoked cigarettes with a slightly higher nicotine content than younger smokers.⁶ The number of cigarettes smoked per day was similar: 21.3 for smokers aged 21 to 49 and 29.1 for smokers aged 50 to 74. In this reanalysis, it was

estimated that 53% of Americans aged 21 to 49 years were ever smokers, including 31% who were current smokers and 22% former smokers. In the 50- to 74-year-old group, 58% were ever smokers, including 23% current smokers and 35% former smokers. Although the older smokers had smoked for more than twice as many years as the younger group (mean, 39 years versus 16 years), the AUTS survey showed very little difference between the older and younger smokers in either smoking habits or quitting history. Even though the older smokers had smoked longer, they did not report an increased number of quitting attempts. The AUTS did suggest that older smokers underestimate both the risk of smoking and the benefits of stopping smoking (Table 35.1).

A recent American Cancer Society study clarified the risk of lung cancer mortality in smokers and former smokers. Halpern et al. examined and compared absolute and relative lung cancer death risk in former smokers as a function of age at cessation.⁷ In a prospective cohort study with 6 years of follow-up, the absolute risk of lung cancer mortality was compared in individuals who had never smoked and current and former smokers. As expected, there was a lower lung cancer death risk seen for those patients who quit smoking earlier in life, and the risk for those who were former smokers was significantly lower than for those who continued to smoke. However, the influence of age was profound (Fig. 35.2A,B). The lung cancer death risk for persons who stopped smoking between the ages of 30 and 49 rose gradually with age at a rate slightly greater than for those persons who had never smoked. If one quit between the ages of 50 and 64, the lung cancer death risk leveled off at the risk attained at the time of quitting until around age 75, when it increased significantly.

For current smokers at age 75, the annual lung cancer mortality is estimated at 1 per 100 for males and 1 per 200 for females. Table 35.2 demonstrates the relative risk reductions as a function of age of smoking cessation.

FIGURE 35.1. Percent increase in lung cancer mortality by age group, sex, and race. SEER data, 1973–1990. ■, black; □, white.

Former smokers had a relative risk of lung cancer death of approximately 0.45 if they had quit in their early sixties, 0.20 if they had stopped smoking in their early fifties, and 0.10 for those who had stopped smoking in their thirties, compared with nonsmokers who had a relative risk of 0.05 or less. Therefore, in terms of reduced risk of lung cancer mortality, stopping smoking at any age is beneficial, but much more beneficial for those quitting at a younger age. The authors showed that even though the absolute lung cancer risk can plateau following smoking cessation, the lung cancer risk for former smokers is still consistently greater than that of those who have never smoked.

In their model in Figure 35.2, the authors have shown that there is a rise in lung cancer risk seen after age 75, and this is consistent over several cohorts. This biologic difference in the older patient may reflect decline in cellular DNA repair activity with age, or perhaps the cumulative exposure to smoking and other carcinogens combined with decreased repair mechanisms late in life may have a synergistic effect on lung cancer risk. It is, however, also possible that this late rise is a reflection in the differing smoking characteristics of older and younger smokers, as mentioned earlier.

Although this study demonstrated that a greater reduction in lung cancer risk by smoking cessation at a young age, it also confirmed that stopping smoking is beneficial at any age, even in those patients beyond age 60.⁷ Because smokers benefit from quitting smoking and because one in four persons will be age 55 and older by the year 2010, it is important that health care providers counsel all

TABLE 35.1. Perceived benefits and harms of smoking by age among 4835 AUTS smokers 21 to 74 years of age.

Variable	Age 21–49 years (n = 3151)	Age 50–74 years (n = 1234)
Perceived benefits (pros) of smoking		
Smoking reduces tension	65.65	75.91±
Smoking helps me cope	49.18	55.86±
Smoking controls weight	49.12	55.08±
Smoking is less harmful than being 20 lb overweight	28.44	47.0±
Perceived harms (cons) of smoking		
How concerned about personal health effects [% fairly/very (vs. not at all/slightly)]	45.43	35.45±
How much connection is there between smoking and illness? [% very strong (vs. some or none)]	33.48	27.18±
How much more likely are smokers to get these diseases? [% somewhat or much more (vs. no more)]		
Heart disease	79.53	69.64±
Lung cancer	91.19	80.27±
Bladder cancer	33.80	26.87±
Emphysema	91.21	86.83±
Coughs	92.23	86.72±
Larynx cancer	89.81	81.14±
Bronchitis	82.05	72.81±
Belief that smokers get more diseases (mean score)	1.40	1.23±

AUTS, Adult Use of Tobacco Survey.

FIGURE 35.2. (A) Lung cancer death rates by age for men, current, former, and nonsmokers, starting smoking at age 17.5 and smoking 26 cigarettes/day. (B) Estimated lung cancer death rates for women current, former, and never smokers. Starting smoking at age 18.5 smoking 22 cigarettes/day. Plotted are

current smokers (solid lines), never smoked (dotted line), former smokers (dashed lines). Age-at-quit cohorts are distinguished by the following symbols at the age of quitting and also at age 80: Δ , 30–39; \diamond , 40–49; \square , 50–54; \circ , 55–59; ∇ , 60–64. (From Halpern et al.,⁷ with permission.)

patients on stopping smoking. Specifically, older patients are an important target for smoking cessation because they tend to be long-term, heavier smokers and are more likely to have chronic diseases that can be aggravated by smoking.⁸

Pathogenesis

Because of the difference in natural history, survival, and type of treatment, primary bronchogenic carcinomas are commonly divided into two groups, non-small cell lung cancer and small cell lung cancer. Histologically, non-small cell lung cancer can be subdivided into squamous cell carcinoma, large cell carcinoma, and adenocarcinoma, with bronchoalveolar cell being a subtype of adenocarcinoma. Non-small cell lung cancer accounts for approximately 75% to 80% of all lung cancers. Squamous cell carcinoma was once the most common type of non-small cell lung cancer in this country; however, there has been an increase in adenocarcinoma, now accounting for approximately 40% of all lung cancer. Squamous cell carcinoma and small cell carcinoma are highly associated with smoking, although cigarette smoking has been linked with all histologic subtypes. Although there are some differences in the clinical behavior of subtypes of non-small cell lung cancer, they are generally grouped together because of their similar natural history and

response to treatment and because histology and cytology often overlap between these subtypes.¹

Small cell lung cancer can generally be distinguished from non-small cell lung cancer by histology or cytology alone in 95% of cases. Small cell lung cancer also tends

TABLE 35.2. Estimated relative risk (RR) of lung cancer death following smoking cessation: never and former smokers compared with current smokers.

	Relative risk		
	Age 55	Age 65	Age 75
Men:			
Never smokers	0.05	0.03	0.03
Quit 30–39	0.14	0.09	0.07
Quit 40–49	0.36	0.18	0.12
Quit 50–54	—	0.29	0.19
Quit 55–59	—	0.56	0.27
Quit 60–64	—	—	0.45
Current smokers	1.0	1.0	1.0
Women:			
Never smokers	0.07	0.05	0.04

to be detected at a more advanced stage because it grows rapidly and metastasizes early, with very few cases being surgically resectable. Non-small cell lung cancers, in contrast, tend to grow more slowly and are often detected at a stage where surgery may be curative.

The relative proportion of squamous cell cancer increases with increasing age and is particularly prevalent in older males. Squamous cell carcinoma was also found to be the subtype most likely to be detected at an early stage and with the best 5-year survival rate in the National Cancer Institute Early Lung Cancer Detection Program. Large cell carcinoma and adenocarcinoma are intermediate in their growth rate between squamous cell and small cell lung cancer. Adenocarcinoma is particularly prominent in females and is increasing in incidence. Importantly, adenocarcinoma and large cell carcinoma, like squamous cell carcinoma, may also present at a localized stage at which surgery is an option.

Clinical Presentation

Most patients with lung cancer are symptomatic at the time of diagnosis. Unfortunately, their symptoms are often associated with locally advanced or distant disease, which may render them inoperable (Table 35.3).

TABLE 35.3. Lung cancer symptoms and signs.

Asymptomatic
Primary
Cough
Wheeze and stridor
Chest pain
Shortness of breath
Hemoptysis
Fever, chills, or sweats (associated pneumonia)
Systemic
Anorexia
Weight loss
Fatigue
Weakness
Finger clubbing
Paraneoplastic endocrine syndromes
Metastatic
Regional
Hoarseness
Superior vena cava syndrome
Dysphagia
Horner's syndrome
Brachial plexus pain
Chest wall pain
Distant
Bone pain (bone metastases)
Altered mental status (brain metastases)
Palable lymph nodes
Jaundice (liver metastases)
Abdominal pain (liver metastases)

TABLE 35.4. Lung cancer symptoms that may be confused with noncancer symptoms in the elderly.

Lung Cancer Symptom	Cormorbid disease or "aging explanation"
Cough	Chronic bronchitis
Dyspnea	Emphysema, old age
Fever (postobstructive pneumonia)	Cold, flu
Weight loss	Depression, inactivity
Bone pain (bone metastases)	Arthritis, old age
Altered mental status (brain metastases, hypercalcemia)	Dementia, old age

Source: From Crawford et al.,⁵ with permission.

Specific signs and symptoms depend on the location of the tumor, its locoregional spread, and the presence of metastatic disease. In addition, paraneoplastic syndromes occur more frequently in lung cancer than in any other tumor. Also, some patients are totally asymptomatic and for unrelated reasons undergo incidental chest x-ray and are found to have an asymptomatic lesion.¹ Unfortunately, many of the symptoms of lung cancer are non-specific and in the elderly may be attributed to comorbid illness. This may result in a delay in diagnosis, which may have profound effects on the treatment options available for the patient (Table 35.4).

A study by DeMaria and Cohen showed that patients at all ages had a similar prevalence of cough, hoarseness, dysphasia, and weight loss, but patients older than 70 years of age presented more frequently with dyspnea but less frequently with chest pain than did younger patients.⁹

Although mass screening for lung cancer has not been recommended, high-risk patients over age 65 might benefit from screening to detect earlier-stage squamous cell carcinomas with favorable prognosis.⁵ It would seem logical that patients presenting with early-stage lung cancer are far more likely to be cured than those patients with advanced disease. However, over the past 30 years, the percentage of localized disease and resectability rates has remained unchanged at approximately 20%, indicating that screening and early detection programs have been unsuccessful.

Several prospective randomized studies using serial chest x-rays and sputum cytologies to complement each other in early lung cancer diagnosis did not result in detection of lung cancers at a curable stage or demonstrate that intensive screening led to a lower death rate from lung cancer. However, a study conducted by O'Rourke et al. suggested that lung cancer may present at a less advanced stage with increasing age.¹⁰ Information from the centralized cancer patient data system with a total of 22,874 cases showed that the percentage of lung

cancer patients with local stage disease increased from 15.3% for patients aged 54 years or younger to 25.4% of those 75 years or older. An additional 6,332 patients who underwent surgical staging were analyzed and showed a greater likelihood of presenting with local disease with an increase in age. Therefore, in addition to having a higher age-specific incidence, older cancer patients may have a higher likelihood of local stage lung cancer. Thus, the older high-risk patient, smoker or former smoker, should be followed carefully for the development of lung cancer. In the absence of an official recommendation for routine screening, the physician should have a low threshold for obtaining a chest x-ray in these patients as symptoms develop.¹¹

The case for screening for lung cancer has recently resurfaced with the results of the Early Lung Cancer Action Project (ELCAP) group, who examined the usefulness of annual helical low-dose computed tomography (CT) scanning compared to chest x-ray in heavy smokers over the age of 60.¹² Cancers were detected in 2.7% of patients by CT scan compared to 0.7% by chest x-ray; 85% of the CT-detected tumors were stage I and all but one were resectable. The overall rate of detection by CT scanning was six times higher than by chest x-ray. To prevent a large number of questionable biopsies, recommendations were made by the ELCAP investigators to initially biopsy only nodules with nonsmooth edges or noncalcified nodules 10mm or larger. For smaller nodules, documented growth by high-resolution CT was recommended before biopsy. Biopsies were done on 28 of 233 patients with noncalcified lesions, with 27 having malignant disease and 1 having a benign nodule.

Despite these encouraging results, a number of problems still remain. First, the 27 cancers detected by CT scanning represented only one-quarter of all nodules found on CT scans, potentially necessitating a large number of follow-up scans. The need for biopsies, however, was maintained at a reasonable level, possibly because of recommendations offered by the investigators. Issues regarding cost also remain unclear although the investigators claim that the CT scan costs are only slightly higher than that of a chest x-ray and that only 20 s of CT time are required to obtain the images. Finally, the ability of annual screening CT scans to improve overall survival in smokers remains to be determined.

Diagnosis and Differential Diagnosis

Once a patient is suspected of having lung cancer, a diagnosis should be confirmed by obtaining adequate specimens for pathologic analysis. Diagnosis is most commonly made from sputum cytology, bronchoscopy with bronchial washings, and biopsy or transthoracic needle aspiration. It has been shown that elderly patients

FIGURE 35.3. Indicated procedures for diagnosis of lung cancer depending on location of lesion. (From Yancik et al.,² with permission.)

tolerate such diagnostic procedures well, unless they have significant comorbid pulmonary conditions.⁵

Figure 35.3 outlines a strategy based on location of the lung mass. Approximately two-thirds of neoplastic lesions can be seen through the fiber optic bronchoscope. In addition, those lesions that cause extrinsic narrowing of a bronchus can be biopsied transbronchially. The complications of bronchoscopy are minimal in experienced hands. The sensitivity for diagnosis when a lesion is visible is approximately 90%, and the specificity is excellent, with false positives occurring less than 1% of the time.

Bronchoscopy has essentially replaced the once common repeated samples of sputum for cytology because of the greater sensitivity of bronchoscopy. Washing and brushings are routinely obtained during bronchoscopy, and occasionally the cytology is diagnostic although the biopsy specimen is nondiagnostic. For more peripheral lung lesions or when the diagnosis cannot be made by bronchoscopy, transthoracic fine-needle aspiration (TTNA) and biopsy can be performed under fluoroscopic or CT guidance. This procedure, however, carries a much higher complication rate than bronchoscopy, with pneumothorax occurring in approximately 27% of patients and hemoptysis in 2% to 5%. It is, however, an alternative to more invasive procedures. TTNA may also be useful in aspiration of mediastinal structures, with no higher complication rate in the mediastinum than in a peripheral lung lesion. The incidence of false negatives with transthoracic needle aspiration and biopsy ranges from 11% to 69%.¹³ This rate can be improved by the

presence of a pathologist at the time of the procedure to assure that an adequate sample has been obtained, and often a diagnosis can be made immediately in this setting.

The differential diagnosis for patients who present with abnormalities on chest x-ray includes lung cancer, as well as other nonmalignant conditions. These conditions include infectious etiologies such as tuberculosis or bacterial pneumonias, or inflammatory conditions such as sarcoidosis that can result in mediastinal lymphadenopathy and sometimes mimic locally advanced lung cancers. Patients with widely metastatic disease to the lungs are rarely mistaken to have other illnesses, and usually the major problem is confirming the primary source of malignancy.

Prognosis and Course of Illness

Once a tissue diagnosis has been made, staging becomes an important factor in the treatment of patients with lung cancer. Appropriate staging is critical to the prognosis and optional for treatment, as well as to compare results from different clinical treatment series and experimental clinical trials and to develop multimodality treatment regimens.

Mediastinoscopy, mediastinotomy, thoracotomy, and, more recently, video-assisted thoracoscopy (VATS) have been incorporated into the diagnosis and staging of lung cancer. Although video-assisted thoracoscopy remains an investigative tool, prospective studies are currently ongoing. It has proven to be useful in biopsying or excising peripheral nodules and sampling mediastinal nodes and is less invasive than standard thoracotomy (see Fig. 35.3). All these techniques are useful adjuncts in staging lung cancer in appropriate patients. However, many patients present with signs of distant disease, such as distant lymph nodes, skin lesions, liver, adrenal, or bone involvement. Needle-directed biopsies in these patients can often confirm both the cell type and metastatic spread of the cancer and limit further need for evaluation.¹¹

Several studies have suggested that lung cancer presents at a less advanced stage in the elderly patient. Ershler et al., in a review of 157 lung cases in Vermont, showed that the percent of cases with metastatic disease decreased from 80% at age 40 to 40% at age 70.¹⁴ In a review of a centralized cancer patient data system, Crawford et al. analyzed 20,000 lung cancer cases registered between 1977 and 1982. There was an increase in the percent with local stage from 15.3% at age 54 and younger to 25.4% of those 75 or older. In those with distant disease, there was a decrease from 48.7% age 54 or younger to 36.7% age 75 or older.⁵

In 1985, a new international staging system for lung cancer was adopted. The TNM classification groups

patients according to the size and extent of their tumor (T), the lymph node involvement (N), and the presence or absence of metastatic disease (M). A patient's clinical stage is the best estimate of TNM before surgery, with the surgical stage of TNM determined after surgery and with pathologic review of surgical specimens (Table 35.5).

The TNM classifications can then be grouped into four stages of non-small cell lung cancer, with a significant difference in the 5-year survival depending on the stage at which the disease is diagnosed. Stages I and II represent surgically resectable disease, with stage III representing regionally advanced disease and stage IV distant metastatic disease (Table 35.6).

The TNM staging classification can be used in small cell lung cancer, but because of the more advanced stage at

TABLE 35.5. TNM classification of lung cancer.

Primary tumor (T):	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T2	Tumor with any of the following features of size or extent: more than 3 cm in greatest dimension, involves main bronchus, 2 cm or more distal to the carina; invades the visceral pleura; associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T3	Tumor of any size that directly invades any of the following: chest wall (includes superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium, tumor in the main bronchus less than 2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural effusion
Regional lymph nodes (N):	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, including direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Distant metastasis (M):	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

T, primary tumor; N, regional lymph nodes; M, distant metastasis.

Stage IIIB	Any T	N3	M0
	T4	Any N	M0
Stage IV	Any T	Any N	M1

presentation, small cell carcinoma is generally classified as limited or extensive disease, similar to stage III or IV disease. In small cell lung cancer, limited disease is confined to one hemithorax and capable of being encompassed in a single radiation therapy port; this allows for mediastinal or supraclavicular nodal involvement and does not make a distinction between local and regional disease. Extensive disease is defined as metastatic spread beyond the limits of one hemithorax. Extensive disease occurs in two-thirds of small cell lung cancer cases. In small cell lung cancer, the distinction between limited and extensive disease is important in determining combined modality approaches with curative intent versus palliative chemotherapy. In addition, occasional patients present with a peripheral stage I small cell lung cancer and may undergo surgery.⁵

It is important to stage all lung cancer patients before treatment and after therapy. A comprehensive history and physical examination are important to obtain symptoms suggesting regional spread, such as chest pain, hoarseness to suggest recurrent laryngeal nerve palsy, or evidence of obstruction. In addition, symptoms such as bone pain, weight loss, or neurologic symptoms can suggest metastatic disease. Examination of the head and neck for lymphadenopathy may reveal lymphagitic spread.

The chest x-ray remains probably the most valuable tool in diagnosing lung cancer. However, CT plays an important role in staging of lung cancer, often detecting abnormalities that cannot be adequately evaluated on chest x-ray. The mediastinal structures, chest wall, and vertebrae can be evaluated with small pleural nodules or small pleural effusions often not seen on plain films shown on CT scans. In addition, the CT scan can detect metastatic disease to the liver or adrenals. It is important in staging a patient with lung cancer to include the upper abdomen to the level

of the kidneys to evaluate for liver or adrenal gland abnormalities.¹

A CT scan can be helpful in selecting patients who should undergo mediastinoscopy. If the CT reveals mediastinal nodes greater than 1.5cm in diameter, it should not be assumed that this indicates metastatic node involvement with tumor; histologic proof by thoracotomy or mediastinoscopy is indicated. This information is critical for patients with non-small cell lung cancer (NSCLC) being considered for surgery. Developed some 30 years ago to facilitate staging of superior mediastinal lymph nodes, mediastinoscopy remains the most accurate lymph node staging technique to assess superior mediastinal lymph nodes that are frequently involved with disease. In a large study by Luke et al., the mortality rate of mediastinoscopy was zero with major morbidity rate less than 1%.¹⁵ In this study, it was reported that patients who were mediastinoscopy negative but found to have mediastinal lymph node involvement at thoracotomy had better 5-year survivals, compared with patients who were found at mediastinoscopy to have positive lymph nodes, who had much poorer survival.^{1,13}

In patients with small cell lung cancer, staging is important to determine if a patient has limited versus extensive stage disease. In addition to differences in prognosis, those patients with limited disease may also receive chest radiation and possibly prophylactic cranial irradiation. Thus, patients with small cell lung cancer should undergo brain CT or MRI to evaluate the presence or absence of CNS metastases. A CT scan including the upper abdomen to evaluate the liver and the adrenals as well as a bone scan are also important. Pretreatment staging will detect metastatic disease to the bone in approximately 38% of patients, metastases to the liver in 34% of patients, and CNS disease in 14% of patients. If these studies reveal no evidence of metastatic disease, bone marrow aspirate and biopsy should be done because approximately 5% of patients have bone marrow involvement as the only site of metastatic disease.¹

Treatment and Management of Illness

Once the patient has a tissue diagnosis and has been accurately staged, the treatment plan can be determined. The patient's ability to tolerate treatment is of utmost importance, whether the planned therapy is surgery, radiation therapy, chemotherapy, or multimodality therapy. A patient's performance status has consistently been the single most prognostic factor for treatment planning. Patients who are asymptomatic with a Karnofsky performance status of 100% or symptomatic but normally active with a performance status of 80% to 90% generally tolerate therapy better and live longer than patients

TABLE 35.7. Karnofsky performance status.

100%	Normal, no complaints, no evidence of disease
90%	Able to carry on normal activity; minor signs or symptoms of disease
80%	Normal activity with effort; some signs or symptoms of disease
70%	Cares for self, unable to carry on normal activity or do active work
60%	Requires occasional assistance, but is able to care for most personal needs
50%	Requires considerable assistance and frequent medical care
40%	Disabled; requires special care and assistance
30%	Severely disabled; hospitalization is indicated, although death not imminent
20%	Very sick; hospitalization necessary; active support treatment is necessary
10%	Moribund; fatal processes progressing rapidly
0%	Dead

who have decreased performance status (Table 35.7). In addition, weight loss is also an important prognostic variable, with weight loss greater than 5% of body weight being an adverse predictor of survival.

Cancer is no less devastating to an elderly person than to a younger person. Older patients have the same right as younger patients to take part in the decision-making process about their treatment. Quality of life is equally important to older patients, and often they will prefer improved quality over quantity of life, with less interest in a trade-off of months or years of life in exchange for the side effects of treatment. Even though cancer is a disease of the elderly, older patients are often treated less aggressively; this can be explained somewhat by the presence of comorbid conditions that often exist in the elderly.¹⁶

It may be that many physicians are uncertain about subjecting older patients to aggressive chemotherapy. Studies of the psychosocial impact of cancer treatments upon the elderly have shown that older patients are able to cope with the impact of chemotherapy as well if not better than younger patients. Older patients report no greater frequency of toxic side effects and often experience lower levels of emotional distress and life disruption than younger patients.¹⁷

Treatment of Non–Small Cell Lung Cancer

The treatment of non–small cell lung cancer is highly dependent on accurate staging regimens, as already discussed. The following discussion delineates treatment plans based on accurate clinical staging.

Stages I and II

Surgical resection is the treatment of choice for those patients with non–small cell lung cancer presenting with

surgically resectable disease, that is, stages I, II, and possibly IIIa. Five-year survival for stage I is 60% to 80% and for stage II, 40%. In the elderly, extensive preoperative planning is necessary to determine the best surgical procedure for a complete resection of tumor with preservation of as much normal lung tissue as possible. If a pneumonectomy is being considered, the patient's pulmonary status must be adequately evaluated before surgery.

In the past, many physicians have viewed age greater than 70 as an independent risk factor for thoracotomy. However, because surgical resection remains the only potentially curative form for treatment for lung cancer and the life expectancy of patients age 70 is approximately 15 years, surgery should never be denied solely on the basis of a patient's age.

Massard et al.¹⁸ reviewed 1616 patients who underwent thoracotomy for lung cancer from January 1983 to December 1992, with 233 patients aged 70 years or more, at the University Hospital in Strasbourg, France. Of these patients, 29% had no medical history, 26% had a history of cardiovascular disease, and 19% had a previous history of malignancy that was in complete remission; 48% of patients were stage I, 17% stage II, and 30% stage III. Of these, 210 patients were able to undergo resection, with 60 receiving pneumonectomies and 150 lobectomies. A total of 16 patients died postoperatively: 7.2% for the whole series, 10% after pneumonectomy, and 6.6% after lobectomy. The mortality was similar below and above 75 years of age. The 5-year survival for stage I was 45%, 36.3% for stage II, and 13.8% for stage III, with an overall 5-year survival of 39.9%. Survival was not influenced by age.

Patients who have complete resections are sometimes considered for adjuvant therapy with either chemotherapy or radiation therapy. These strategies attempt to reduce the risk of recurrence by treating presumed remaining tumor cells, either still in the chest (radiation) or disseminated to other sites (chemotherapy). Pre- and postoperative radiation therapy has not been shown to benefit survival in two large randomized trials. In addition, a recent meta-analysis also failed to demonstrate improvement in overall survival in completely resected patients who then went on to receive radiation therapy.¹⁹

Despite advances in the treatment of breast and colon carcinomas with adjuvant chemotherapy, there continues to be no strong proof of survival benefit of adjuvant chemotherapy in lung cancer, despite occasional trials that suggest a benefit. However, clinical trials involving newer agents are ongoing in the adjuvant setting and should be considered if available. In one study, patients with stage IB non–small cell lung cancers are being randomized to either observation alone or four cycles of chemotherapy with carboplatin and paclitaxel. Another

large intergroup study is randomizing patients with completely resected stage II or stage III disease to either observation alone or four cycles of cisplatin and vinorelbine chemotherapy. Results from these studies are not expected to be available for a number of years, so until then, no firm recommendation of adjuvant chemotherapy can be given.

Operable Stage III

Surgery alone for stage III disease is associated with 5-year survival of less than 10%. In an attempt to improve long-term outcome of patients with this stage of disease, investigators have added chemotherapy preoperatively before a curative resection is attempted. In one study by Rosell et al., patients with IIIA disease (N₂-ipsilateral node involvement) disease had improved survival after three courses of preoperative chemotherapy with mitomycin, ifosfamide, and cisplatin.²⁰ Another study by Roth et al. demonstrated a 3-year survival of 56% for patients treated with preoperative chemotherapy compared with 15% for patients treated with surgery alone.²¹ Although these studies were not designed specifically for the geriatric population, nonetheless elderly patients were not excluded (in fact, the Rosell study had a patient aged 78 years in the combined treatment arm). The applicability of these studies to elderly patients remains questionable; however, elderly patients with good performance status and absence of other significant comorbidities should be considered for this treatment.

Inoperable Stage III

Radiation therapy has been the most common treatment in inoperable regional non-small cell lung cancer. It has also been considered an alternative treatment for those patients with underlying medical problems who cannot undergo surgery or those patients who decline surgical resection. The median survival for patients undergoing primary radiation therapy for unresectable disease is less than 1 year. Five-year survival data, however, show approximately 6% of patients alive and well with radiation therapy alone. This finding should not be compared with surgical results, because patients who are selected for radiation alone are usually patients with decreased performance status or other less favorable prognostic factors. Radiation therapy can be very useful in the palliation of symptoms resulting from thoracic tumor growth, such as intractable cough, hemoptysis, dyspnea, and chest pain. The major toxicity encountered is esophagitis, which is usually easily managed with patients who received radiation therapy without chemotherapy. Pneumonitis and pulmonary fibrosis are also important toxicities and, although rare, can result in significant morbidity in a patient population that already has preexisting pulmonary compromise.

Lung cancer may be one of the most common tumors treated with primary radiation therapy in the over-65 age group. There are several advantages to radiation therapy. There is no appreciable acute mortality associated with the treatment, and underlying comorbid conditions other than severe pulmonary disease do not often preclude radiation treatments. The normal healthy lung parenchyma can be preserved while relief of endobronchial obstruction is achieved, and the risk of a second malignancy is of less concern than in a younger patient. Relative disadvantages of radiation include the length of time involved in the course of treatment (often 4 to 6 weeks or more) and the side effects associated with radiation treatment, such as fatigue, loss of appetite, nausea and vomiting, dysphagia, and lowered blood counts.²²

Because of the poor survival rates with radiation alone in stage III NSCLC and the frequent development of metastatic disease at distant sites, the role of chemotherapy in combination with radiotherapy has been evaluated. In one study in which vinblastine and cisplatin chemotherapy plus radiation therapy was given, survival rates in years 1 to 7 were 54%, 26%, 24%, 19%, 17%, 13%, and 13%, respectively, in chemotherapy- and radiation-treated patients compared with 40%, 13%, 10%, 7%, 6%, and 6% for patients treated with radiation alone.^{23,24} The benefit of chemotherapy before radiation treatment has been confirmed by other studies as well. Another pivotal trial demonstrated that the concomitant treatment of inoperable NSCLC with cisplatin and radiation leads to improved local control of tumor as well as survival benefit.²⁵ Thus, for good performance status patients with minimal weight loss, the combination of chemotherapy with radiation therapy should be strongly considered. What remains to be determined are the optimal chemotherapy agents used, as well as how they should be combined with radiation therapy.

Stage IV Metastatic Disease

Unlike small cell lung cancer, chemotherapy in advanced (stage IV) non-small cell lung cancer has shown marginal benefit. With the introduction of platinum-based chemotherapy, a modest survival benefit has been seen in patients. However, these benefits are usually brief and have been accompanied by a relatively high incidence of treatment-related toxicity. Best supportive care over chemotherapy remains a frequent choice, although there have been several studies that have shown a statistically significant survival advantage for combination chemotherapy over best supportive care.^{26,27} Much of the debate relates to the lack of quality of life studies in this setting to assess whether the modest improvement in survival is associated with improved quality of life as well.

Recent studies have actually suggested that elderly patients with NSCLC may have a better prognosis with treatment. Albain et al. analyzed 2531 patients with advanced-stage (IIIB/IV) NSCLC in the Southwest Oncology Group from 1974 to 1988 to assess the interactions of host- or tumor-related prognostic factors in therapy to determine whether each independently predicts outcome and define prognostic subsets with different survival potentials.²⁸ It was found that a good performance status, female sex, and age greater than 70 years were significant independent predictors. Giovanazzi-Bannon et al., in an analysis from the Illinois Cancer Center, determined that there were no major differences between patients 65 years of age or more and patients less than 65 years of age when treated on phase II clinical trials.²⁹ It was concluded that elderly patients should not be denied access to cancer clinical trials because of age alone. In this review, the older patients received slightly more courses of therapy with no significant difference between the two groups for treatment interruptions, days of delay, or number of dose reductions. When best response to therapy was analyzed, the elderly patients had more stable disease and less progressive disease than the younger patients. Older patients experienced only slightly more grade III or greater hematologic toxicities with no significant differences in other severe toxicities.

These results support the concept that at least some elderly patients can receive chemotherapy with similar benefit and side effects, if carefully selected based on good performance status and lack of comorbid disease, which are eligibility-applied to most clinical trials. However, application of these regimens to more dependent elderly populations requires further study, and very intensive regimens must be used with caution even in the well elderly. The importance of performance status as a predictor for the ability to tolerate polychemotherapy was most recently demonstrated by the Eastern Cooperative Oncology Group. Patients with performance status two suffered more toxicity and had inferior survival compared with patients with better performance status.³⁰

More recently, the choice of chemotherapy agents useful for the treatment of non-small cell lung cancer has increased; these include the cisplatin analogue carboplatin, the taxanes paclitaxel and docetaxel, the vinca alkaloid vinorelbine, the camptothecin irinotecan, and gemcitabine. In addition to being more effective compared with prior drugs, these compounds are also better tolerated and more easily delivered to patients. Furthermore, formal testing of these agents in elderly patients has now been undertaken.

The Elderly Lung Cancer Vinorelbine Italian Study Group (ELVIS) investigators designed and executed a study to compare best supportive care in elderly patients with good performance status to single-agent chemotherapy with vinorelbine.³¹ Patients aged 70 years or older

who had good performance status (defined as spending no more than 50% of the waking day in bed) were enrolled in the study. All patients had biopsy-proven non-small cell lung carcinoma, either stage IV or stage IIIB (malignant pleural effusions or metastatic disease to the supraclavicular lymph nodes). Treatment consisted of either best supportive care or vinorelbine 30 mg/m² given on days 1 and 8. The chemotherapy was repeated every 3 weeks for a maximum of six cycles. Supportive care treatments were at the discretion of the physicians, and radiotherapy was allowed. No crossover was allowed. The major endpoints of the study included toxicity and response evaluations, a quality of life assessment, and overall survival. Baseline characteristics of the patients were well balanced in both arms. The median age was 74 years, with the majority of patients being men and having stage IV disease. Patients treated with vinorelbine demonstrated a clear survival benefit, with median survival increasing from 21 to 28 weeks; 1-year survival was extended from 14% in the best supportive care arm to 32% in the arm of patients receiving chemotherapy with vinorelbine. The overall response rate (complete and partial responses) was 19.7%. Results of the quality of life assessments were complicated by missing data (resulting from patient death and noncompliance) but nonetheless demonstrated a benefit of chemotherapy. Notable findings include benefits of vinorelbine in dyspnea, pain, and pain medicine consumption. Negative effects of chemotherapy included constipation, nausea and vomiting, hair loss, and peripheral neuropathy. However, only five patients discontinued therapy because of serious side effects, four due to severe constipation and one due to atrial arrhythmia.

This trial is of great importance as it is the first randomized trial of chemotherapy versus best supportive care in the elderly patient population. The results of this trial, as well as others, will make it difficult if not impossible for future trials to include a best supportive care arm. It is important to point out that the survival benefit of chemotherapy was not at the expense of high levels of toxicity and poor quality of life. The safety of this regimen is further suggested by a low level of hematologic toxicities and no treatment-related episodes of neutropenic fever or sepsis.

Vinorelbine has been approved by the Food and Drug Administration (FDA) for treatment of patients with non-small cell lung cancer and was the first of the "modern" chemotherapy drugs approved for lung cancer in the United States in more than 20 years. The combination of vinorelbine with cisplatin has been shown to be superior to single-agent vinorelbine, with single-agent vinorelbine chemotherapy producing a 1-year survival of 30% and a median survival of 31 weeks, whereas the combination led to a 35% 1-year survival rate with median survival time increasing to 40 weeks.³²

The effect and tolerability of monotherapy with gemcitabine has recently been examined in a series of patients over the age of 70 years who had good performance status.³³ Patients received gemcitabine 1000 mg/m² given every week for 3 weeks, followed by a 1-week rest period; the cycle was then repeated every 4 weeks for a maximum of six cycles. Dose reductions and delays were made for hematologic toxicities. Forty-six patients were treated on the study, with the majority of patients being men with stage IV disease. The overall response rate including partial and complete responses was 22.2%. Ten patients who had symptoms demonstrated an improvement in their performance status on therapy. No WHO grade IV toxicities were demonstrated, there were no episodes of neutropenic fever, and no patients died due to complications of therapy. Two patients required discontinuation of therapy due to skin rash. Although this study does not demonstrate a meaningful benefit of single-agent gemcitabine on overall survival, it does suggest that the drug has activity, can improve the performance status of some patients receiving therapy, and has minimal toxicity. Furthermore, gemcitabine may be able to replace cisplatin-based chemotherapy in the elderly, given results of recent trials that demonstrate similar efficacy and better toxicity than the older standard regimen of cisplatin and etoposide.

Preliminary evidence also suggests that paclitaxel given weekly to elderly patients has efficacy and is well tolerated. One study treated patients over 70 years of age with paclitaxel and found a near 30% response rate coupled with symptom relief and minimal or absent side effects.³⁴ Future studies will be needed to determine if a survival benefit exists similar to that seen in the ELVIS trial.

It is hoped that these new agents will lead to more substantial gains in both quality of life and survival for patients with advanced NSCLC.

Treatment of Small Cell Lung Cancer

Surgery is rarely thought to be an option in small cell lung cancer. However, approximately 3% of small cell lung cancer patients present with a solitary peripheral nodule. Surgical resection of the tumor in these patients has been associated with a 5-year survival rate greater than 30%. In those patients presenting with a stage I small cell lung cancer, surgery should be considered as primary treatment with adjuvant chemotherapy, with or without radiation therapy postresection. Chemotherapy is the most important component of small cell lung cancer treatment because of the sensitivity of small cell lung cancer to chemotherapy and the systemic nature of the disease. Patients with limited-stage disease treated with combination chemotherapy have a median survival of approximately 14 to 15 months and 9 months for extensive-stage

disease. There is a 2-year disease-free survival of approximately 13% in patients with limited-stage disease, with only 2% long-term survival in patients with extensive-stage disease. The development of tumor resistance to chemotherapy appears to be a major factor contributing to relapse. Small cell lung cancer cells are quite sensitive to radiation therapy, and therefore radiotherapy is best used early in treatment in combination with chemotherapy in patients with limited-stage disease and good performance status, with the potential to increase the curability of this disease.¹¹ In the elderly, however, the benefits of combined modality therapy must be balanced against the increased toxicities, particularly myelosuppression, pulmonary toxicity, fatigue, and anorexia. Thus, supportive care is critical in the success of combined modality approaches in this population.

The management of limited-stage small cell lung cancer continues to consist of a treatment plan combining chemotherapy and radiation therapy. A meta-analysis of trials comparing chemotherapy with chemotherapy plus radiotherapy demonstrated a small, albeit significant, improvement in overall survival in patients who received a combined approach. However, questions still remain on the best way to combine chemotherapy with radiotherapy, especially given the increased toxicity with the combination. One recent study has suggested that twice-daily radiotherapy improved survival in patients with limited-stage small cell lung cancer.³⁵ Patients with limited-stage small cell lung cancer were treated with four cycles of cisplatin and etoposide chemotherapy given every 21 days. Patients were randomized to receive a standard dose of 45 Gy of concurrent radiation given either twice daily over a 3-week period or once daily over a 5-week period. The median age of the patient population was 62 years, with patients aged over 65 years comprising 31% and 40% of the two arms. At 5 years, 26% of patients receiving twice-daily radiotherapy were alive compared with 16% of patients receiving once-daily radiotherapy. The improvement in survival was at the expense of increased esophageal toxicity in the twice-daily treated group, but no differences in hospitalization or esophageal perforation, and no strictures, were noted. Whether the results of this trial can be generalized to the geriatric population remains to be determined.

One controversial area in the management of small cell lung carcinoma concerns the use of prophylactic cranial irradiation (PCI) for patients with complete responses to chemotherapy. Advances in radiotherapy techniques have reduced the rate of recurrent disease in the chest; however, these patients continue to be at high risk for the development of systemic metastasis, mainly to liver, bone, adrenal glands, and brain. At diagnosis, only 10% to 20% of patients have brain metastasis, while at 2 years post-diagnosis nearly 50% of patients developed brain metastasis. Because of the blood-brain barrier inhibiting

chemotherapy effects, the brain has been believed to be a sanctuary site for subclinical metastasis. Investigators over the years have thought that giving radiotherapy to the whole brain may prevent the development of brain metastasis and positively impact on quality of life and overall survival. Randomized trials have demonstrated a clear reduction in the development of brain metastasis; however, an impact on survival was unclear given the low numbers of patients randomized. Coupled with this enthusiasm, however, came the worry about a deleterious effect on neuropsychologic functioning. Subsequently, studies have demonstrated that a high proportion of patients with limited-stage SCLC had preexisting cognitive dysfunction before receiving PCI, which might have influenced previous studies.^{36,37} To get a better idea of whether PCI can impact patient survival, a meta-analysis was performed on individual data from studies that randomized patients demonstrating a complete response to chemoradiotherapy, to PCI, or to no PCI.³⁸ PCI decreased the cumulative incidence of brain metastasis by nearly 50%, which translated to a 5% increase in the rate of survival at 3 years. The median age of patients in this trial was 59 years, with a range up to 80 years. Again, whether this trial can be generalized to elderly patients remains in question. Subgroup analysis, despite its known limitations, did not demonstrate any difference in benefit as a function of age.

Controversy continues over the benefit of treating elderly patients with chemotherapy, given commonly held views that they are less tolerant compared with younger patients. Elderly patients may be at increased risk of myelosuppression because of less marrow cellularity, as well as impaired renal and hepatic function that alters drug metabolism and excretion. Comorbid disease, often the result of years of smoking, also limits the enthusiasm of oncologists to treat elderly patients. Indeed, in elderly small cell lung carcinoma patients, nearly three-quarters had comorbid disease, including coronary artery disease, chronic obstructive pulmonary disease, and second malignancies. Biases against the treatment of small cell lung cancer in the elderly may not be justified. For example, Shepherd et al. found that elderly patients can tolerate chemotherapy and derive a survival benefit.³⁹ The delivery of chemotherapy was impaired, however, with most patients requiring dose reductions, and less than half of the patients completed six cycles of chemotherapy. These and other studies that have demonstrated similar response rates and overall survival in young and old SCLC patients have made the oncology community reevaluate its view of treating elderly patients with SCLC. Even single-agent chemotherapy, such as with etoposide, can result in high response rates and improvements in survival. Finally, the addition of colony-stimulating factors such as G-CSF and erythropoietin may allow for more aggressive treatment of these

patients. We believe that all elderly patients with small cell lung cancer should receive oncology consultation and those that are medically fit and interested in the palliation and survival benefits offered by chemotherapy should receive treatment.

Supportive Care

Just as elderly patients are often not treated aggressively for lung cancer, the associated side effects of their diseases or treatment may not sufficiently be addressed. Elderly patients with cancer require substantial supportive care. The goal of all supportive therapy should be to maximize the ability of the patient to tolerate both the disease and its treatment.⁴⁰ (Cancer pain is addressed in Chapter 28; also see other Palliative Care chapters in Part IV.)

Patients may present to their physician complaining of unexplained weight loss and loss of appetite and may subsequently be diagnosed with cancer. Cancer cachexia is common in patients with advanced metastatic disease but may also occur in patients with localized disease. Anorexia with abnormalities in taste perception, such as intolerance for sweets, sour, or salty flavors, as well as an aversion for meats, may exist before initiation of treatment and subsequently be exacerbated by the initiation of chemotherapy or radiation therapy.⁴¹ Substantial weight loss, which is progressive, and a malnourished state often prevent a patient from being treated. Treatment should include counseling of the patient and family members as to why the symptoms are present, consultation with a dietician to discuss meal planning and preparation, and often treatment with medications such as megestrol acetate or prednisone that may stimulate the appetite.

Improvements in antiemetics with the use of serotonin antagonists, as well as the use of colony-stimulating factors to ameliorate neutropenia and its complications when appropriate, have had a major impact on the supportive care of the cancer patient receiving chemotherapy. These agents may particularly be useful in the elderly and assist the physician in the decision to use chemotherapy in the elderly lung cancer patient. Recently, the benefit of recombinant erythropoietin on quality of life was described in patients receiving chemotherapy for nonmyeloid malignancies.⁴² In this study, patients were treated with erythropoietin-alpha 10,000 units three times weekly, which could be increased to 20,000 units three times weekly depending on the hematologic response. This therapy was associated with improvements in quality of life scores that were well correlated with levels of hemoglobin. A large number of patients had cancer of the lung and were being treated with modern chemotherapy regimens, including carboplatin/paclitaxel, carbo-

platin/etoposide, paclitaxel, and cisplatin/etoposide. The mean increase in hemoglobin was approximately 2g/dL with nearly two-thirds of patients responding to erythropoietin-alpha. Tumor type, tumor response to chemotherapy, performance status, chemotherapy regimen, baseline hemoglobin, and baseline erythropoietin levels were not found to correlate with quality of life responses. Although not specifically targeting the elderly population, nonetheless the median age of lung cancer patients was 65 years.

Of increasing importance in patients with lung cancer is the coexistence of depression, which can serve as a predictor of quality of life. Recently, the rates of depression were reported in patients with both small and non-small cell lung cancer.⁴³ Depression existed in one-third of patients before the initiation of treatment and persisted in more than 50% of patients. Multivariate analysis revealed that functional impairment was the most important risk factor for the development of depression, along with physical symptom burden and fatigue. Age was not a risk factor for the development of depression; rather, there was a nonsignificant trend toward lower rates of depression in older patients.

Conclusions

The epidemic of lung cancer continues in the United States, and the elderly remain the major target. Despite a decline in smoking by men in the United States, anti-smoking campaigns have not been successful in preventing teenage smoking or in decreasing the percent of women who smoke, so the epidemic will continue.

Despite the high mortality of lung cancer, however, long-term survival is now possible, not only for surgically resected patients but also for some patients with stage III non-small cell lung cancer or limited-stage small cell lung cancer. Even in advanced disease, significant improvement have been made by the use of chemotherapy and supportive care in appropriate patients. Elderly patients with lung cancer deserve careful evaluation of treatment options in a multidisciplinary setting.

Prostate Cancer

Khalid Matin and Donald L. Trump

Prostate cancer is second only to lung cancer as a cause of cancer mortality in men; in 2000, 31,900 deaths were estimated to occur.¹ Among males, no cancer is more prevalent than prostate cancer. Cancer is second only to heart disease as a cause of death in adults; prostate cancer accounts for 20% of the cancer deaths in men over the age of 75. One of every eight men in the 60- to 79-year-old age group will be diagnosed with prostate cancer; by comparison, 1 in 15 women of the same age will be diagnosed with breast cancer. Although many older men who are found to have prostate cancer do not die of prostate cancer, many require treatment of symptoms such as pain, bleeding, and urinary obstruction. Prostate cancer is a major cause of mortality, morbidity, and expenditure of health care resources in older men.

The single greatest risk factor for the development of prostate cancer is age.² As demonstrated in Figure 36.1, the incidence of prostate cancer increases exponentially with age. The underlying biologic cause of this increased incidence is not clear. As the population of the United States ages, the incidence of prostate cancer will likely continue to increase.³

Other risk factors for the development of prostate cancer include family history and race. Men with a first-degree relative (father or brother) with prostate cancer have a twofold increase in the risk of developing the disease, and the risk increases with the number of involved relatives.^{4,5} The risk of prostate cancer is also increased in men with a first-degree female relative with breast or ovarian carcinoma.^{6,7} This latter observation suggests a link between these hormone-related carcinomas. This association is an area of active investigation, and attention is currently focused on the long arm of chromosome 17, also the reported site of the BRCA1 gene. Linkage analysis suggests that alterations at this locus may be associated with prostate, ovarian, and breast cancer in some families.⁸

Considerable work has been done to define a gene or genes associated with prostate cancer. At the broad struc-

tural level the clues are limited. Studies have shown almost 77% of specimens to have a normal karyotype.⁹⁻¹¹ Careful family and detailed linkage studies indicate that familial aggregation of this disease occur in one-quarter of men (two first-degree relatives); however, linkage studies revealing a susceptibility, some inherited with a Mendelian pattern, seem only to account for 9% of hereditary prostate cancer.^{12,13} Genes located on two regions of chromosome 1q, the HPC 1, have been implicated as predisposing to the development to prostate cancer.¹⁴ There is also a report of a second susceptibility gene, Xq (27-28), seen mainly in families of North American and Scandinavian origin.¹⁵ Although other loci including *myc* and *erb B2/neu* proto-oncogenes have been implicated because structural abnormalities or abnormal expression sometimes are seen, data supporting a causative or primary genetic role for these loci are lacking. Alterations in loci on chromosomes 8, 10, and 16 have also been identified as potential markers for the development of prostate cancer.^{16,17}

The racial distribution of prostate cancer also offers the potential for exploring causal relationships. Autopsy studies reveal that blacks, whites, and Asians have essentially the same prevalence of "clinically silent" or latent prostatic carcinoma.¹⁸ Blacks, however, have a higher rate of clinically significant prostate cancer, as compared with whites and Asians.¹⁹ There is evidence that African and Asian immigrants to the United States have increasing risk in successive generations. The risk gradually approaches that seen in African-Americans and whites born in the United States.²⁰⁻²² This finding suggests that environmental factors may play a role in the progression from latent to clinically significant prostate cancer. Several hypotheses for these observations, including quantity and quality of dietary fat intake, vitamin A, and vitamin D metabolism have been suggested.²³⁻²⁵ Androgens are *clearly* important in prostate cancer. Men who are hypogonadal rarely, if ever, develop prostate cancer. There are data indicating that polymorphisms in

FIGURE 36.1. Annual incidence of prostate cancer in the United States. (Data from the Surveillance, Epidemiology, and End Results [SEER] Program Staff.²)

both androgen receptor structure as well as the androgen-metabolizing enzyme, 5-alpha reductase, confer increased risk of prostate cancer. Certain polymorphisms in these moieties can enhance androgen effects on target cells, and this may contribute to enhanced prostate cancer risk.^{26,27}

Although age is a major risk factor for developing prostate cancer, the effect of age on the course of the disease is less clear. Many clinicians have argued that the disease is more indolent in older patients and requires no active therapy. This perception is likely based on the observation that older patients often die of diseases other than prostate cancer. This perception results in less aggressive diagnostic and therapeutic approaches in older patients.²⁸ Data documenting the effect of age on the course of prostate cancer are lacking. Studies that have been carried out provide conflicting data.²⁸⁻³² Multivariate analysis of patients enrolled in a large Scandinavian trial showed that older patients with metastatic disease had a longer time to progression and cause-specific survival.³³ Similar findings were reported for overall survival of patients entered in the National Prostate Cancer Project (NPCP) chemotherapy trials.³⁴ These large studies suggest that if age has any effect, it is a positive one. Decisions about therapy should be based primarily on clearly defined prognostic factors, such as performance status, tumor grade, and extent of disease. Data do suggest that prostate cancers in older men may progress more slowly than in younger men. A critical factor to be taken into consideration in evaluating therapy options is the life expectancy of the patient.

Screening for Prostate Cancer

The basic principles of screening for disease in an elderly population are covered in Chapter 17, Prevention.

However, there are several issues concerning prostate cancer that warrant special mention. Two of the fundamental aspects of a successful screening strategy are the identification of significant cases and the delivery of effective therapy.³⁵ Despite the multiple studies in this area, current diagnosis and therapy of prostate cancer remains controversial in these two aspects. Although measurement of the serum level of prostate-specific antigen (PSA) provides an early indicator of the presence of prostatic disease, this may not necessarily be due to prostate cancer. PSA levels may reflect abnormalities in the prostate that are benign, for example, hypertrophy, infection, or infarction. Until recently, it was unclear whether men who are diagnosed with prostatic malignancy using a PSA-based strategy have clinically significant disease that will result in morbidity and mortality. Data from the Physician's Health Study indicate that an elevated PSA level on a single blood draw is predictive of clinically significant prostate cancer with a low false-positive rate.³⁶ This finding argues strongly that PSA-based screening detects clinically important cancers.

A more difficult problem is that clear proof that the definitive therapies applied to the treatment of prostate cancer improve quality of life or overall survival is lacking. Identifying a patient with prostate cancer may lead to significant diagnostic and therapeutic morbidity and cost for the patient and family because treatment decisions often seem inevitable once the diagnosis is made. Thus, before obtaining a screening serum PSA level, a frank and open discussion about the use of the information and the consequences of the various options is required. For a man with a life expectancy of less than 10 years, even the most ardent therapist is hard pressed to suggest an advantage to diagnosing and subsequently treating prostate cancer.

Diagnosis of Prostate Cancer

Prostate cancer has a long and highly variable natural history. Patients may present with any of several manifestations of the disease, which range from the patient presenting with symptoms of bladder outlet obstruction and a normal PSA in whom cancer is discovered as an incidental finding at transurethral resection of the prostate, to the patient who presents with debilitating bone pain secondary to metastatic disease. In all cases, the diagnosis of prostate cancer should be established by biopsy. A typical scenario in current practice is the patient who presents with an elevated PSA, with or without a palpable abnormality on digital rectal examination. If treatment would be pursued, these patients usually undergo transrectal ultrasound-guided biopsy of the prostate. If treatment is considered, the importance of this biopsy cannot be overstated, particularly because there are benign conditions that can result in a mild to moderate elevation in the serum PSA.³⁷ Furthermore, histologic examination of the biopsy in cases of malignancy yields prognostic information that can have a significant impact on future management. Once the diagnosis of prostate cancer has been established, a limited staging evaluation, typically consisting of a bone scan and routine laboratory studies, is often performed. There are data indicating that a bone scan is unnecessary for asymptomatic patients with PSA less than 20 ng/mL.³⁸ More intensive and invasive staging procedures, such as computed tomography or magnetic resonance imaging, are reserved for special situations and do not impact routinely on clinical decisions.

The clinical stage of prostate cancer is based on extent of disease determined by these data. Histologic description of the biopsy specimen also offers important prognostic information. Although relatively simple staging descriptions have been used for years,^{39,40} the most widely accepted system is that based on the tumor-node-metastasis (TNM) assessment.⁴¹ The TNM system takes into account the patients whose disease is detected by PSA alone without palpable abnormality, reflecting the advances in diagnosis over the past few years (Table 36.1).

Another important prognostic factor is the histologic description of the tumor. This aspect is particularly important in early-stage lesions. The information derived from the histologic evaluation includes the extent of involvement of the resected specimen and the extent of differentiation of the tumor. This latter characteristic is best described in terms of the Gleason grade.⁴² The Gleason grade ranges from 2 to 10 and is derived by the pathologist. Gleason scores (1 through 5) are assigned to the *two* most common histologic patterns seen in the prostate specimen. A well-differentiated tumor is scored as 1 or 2, while a poorly differentiated tumor receives

TABLE 36.1. Comparison of staging systems.

AUA	Entity	TNM
A	Diagnosed incidentally at transurethral resection	T1
A1	≤5% Of tissue involved	T1a
A2	>5% Of tissue involved	T1b
	Diagnosed by needle biopsy, elevated PSA only	T1c
B	Palpable nodule	T2
B1	≤Half of a lobe	T2a
B1	>Half lobe, not both	T2b
B2	Both lobes	T2c
C	Tumor penetrates capsule	T3
	Unilateral	T3a
	Bilateral	T3b
	Seminal vesicle invasion	T3c
	Tumor fixed or invades adjacent structures	T4
	Bladder neck, sphincter, rectum	T4a
	Levator muscles or fixed to pelvic sidewall	T4b
D1	Regional nodes (true pelvis)	N
	One node ≤ 2 cm	N1
	One node > 2 ≤ 5, multiple nodes	N2
	Any node > 5 cm	N3
D2	Metastases	M1
	Nonregional nodes	M1a
	Bone	M1b
	Other	M1c

AUA, American Urologic Association; TNM, tumor-node-metastasis.

a 4 or 5 score. These two scores are added together and expressed as a Gleason score; for example, 4 + 3 = 7. This grade is useful in predicting the biologic aggressiveness of a tumor and correlates with prognosis and extent of disease.^{43–45}

Management of the Patient with Prostate Cancer

Once a histologic diagnosis and clinical stage have been established, patients and their physicians face several major decisions. These decisions are complicated by the variable natural history of this disease and the lack of randomized prospective trials to guide therapeutic decisions. Particularly in the older patient, the primary care physician can and should play a crucial role in this decision making because the past medical history and current condition of the patient will have a significant impact on the options to be considered. The decisions to be made differ widely based on the extent of the disease. In general, patients can be grouped into three categories: (1) those with organ-confined disease; (2) those with regionally advanced disease; and (3) those with metastatic disease.

Organ-Confined Disease

This category is composed of patients with localized prostate cancer (T_{1–2c}, N₀, M₀). There is controversy about

the management of patients in this broad category. These patients range from those with well-differentiated, incidentally detected tumors involving less than 5% of the gland (T_{1a}), to those with palpable tumor diffusely involving both lobes (T_{2c}). These tumors have widely variable natural histories, but the unifying characteristic is that they are potentially curable by definitive therapy. Whether such therapy has an impact on overall survival, particularly for the population of men with T_{1a} or T_{1b} disease, is not known. Thus, there is debate as to how these patients should be managed. This debate is particularly relevant in an elderly population where life expectancy and tolerance of morbidity have considerable impact on treatment decisions.

Consideration of the natural history of prostate cancer is crucial. The overall survival for patients with organ-confined disease who are not treated is numbered in terms of several years.⁴⁶ The two definitive therapeutic modalities that have been utilized to treat this disease are radical prostatectomy and irradiation. There are several techniques for administering irradiation: external beam irradiation administered via an increasing number of techniques that allow increase in dose intensity of irradiation [three-dimensional (3-D), conformal field treatment planning, intensity-modulated radiation therapy (IMRT), brachytherapy using intra prostatic implantation of ^{125}I or palladium-impregnated seeds or high-dose-rate, afterloading techniques]. It is beyond the scope of this chapter to discuss the variety of irradiation techniques. The greatest experience and longest follow-up data for irradiation are derived from a series of patients treated by external beam irradiation.

After surgical treatment for T_1 and T_2 prostate cancer, the cancer-specific survival rate is 90% to 94% at 10 years and 82% to 90% at 15 years.⁴⁷⁻⁴⁹ If the PSA level is considered as an indicator of disease progression, the reported progression rate for the foregoing group is 17% to 31% at 5 years and 23% to 53% at 10 years.^{50,51} Treatment of localized prostate cancer with irradiation yields similar results. In a study of 313 patients with T_1 disease by Hanks et al.⁵² with external beam radiation alone, survival was 77% at 5 years and 51% at 10 years (comparing well with 81% and 62% survival for age-matched normal males). Another study⁵³ of 500 men mostly with T_1 and T_2 disease treated with irradiation revealed 80% survival at 5 years with 72% surviving without clinical evidence of any disease. The rate went down to 51% when the PSA was taken into account as an indicator of recurrence. (*NB:* The surgery data represent cancer-specific mortality and the radiation data overall mortality.) It is critical to realize, when examining outcomes of irradiation and prostatectomy, that surgical series usually include younger men and report results by pathologic stage. By contrast, irradiation series generally are composed of older men and results are reported as the clinical

stage, which notoriously underestimates the local and regional extent of tumor.

Improved results have been obtained in localized prostate cancer using a combination of external beam radiation and goserelin [a gonadotropin-releasing hormone agonist (GnRHa)].⁵⁴ Bolla and colleagues⁵⁴ studied 415 patients with T_1 - T_4 prostate cancer, randomly assigned to irradiation versus radiation and goserelin. The survival in the combined therapy arm was 79% at 5 years versus 62% in the radiation-only group ($p < 0.001$). Eighty-five percent of the surviving patients were free of disease at 5 years. When comparing these data with those for surgery, it should be noted that the Bolla study included patients with T_3 and T_4 prostate cancer, which are not included in the surgery data. The Radiation Therapy Oncology Group (RTOG) has several such ongoing trials in which short-term or long-term therapy with GnRHa + antiandrogen + irradiation is being studied with respect to local control and time to progression in comparison to irradiation alone.

Prostatectomy and irradiation have complications that may have a significant impact on quality of life.⁵⁵ The major complications of these approaches are listed in Table 36.2. Acute radiation proctitis and cystitis are seen often in men receiving external beam radiotherapy; infrequently, chronic cystitis or proctitis may result. Following radical prostatectomy, impotence and incontinence are the complications with the most significant impact on quality of life. In addition, this procedure is associated with 1 to 2 units of blood loss and a 0.1% to 2% risk of perioperative mortality. Reported series from major centers with large experiences note impotence and incontinence rates of 30% to 40% and 5% to 10% respectively. However, a more population-based survey of Medicare patients who had undergone radical prostatectomy revealed that the vast majority were impotent and more than 40% had some problem with continence.⁵⁶ Nearly one-fourth of the patients reported that they required further therapy for recurrent cancer. This survey suggests that the published estimates for the efficacy and complication rates of this procedure may be overly optimistic. There are no satisfactory trials comparing prostatectomy

TABLE 36.2. Complications of prostate cancer treatments.

Treatment	Complications
External beam radiotherapy	Acute cystitis, proctitis: 30%–40% Urinary retention: 3%–5% Chronic proctitis: cystitis 4%–7% Impotence: 40%–60%
Radical prostatectomy	Blood loss: 1–2 units Impotence: 40%–60% Incontinence: 5%–15% Anastomotic stricture: 1%–25% Thromboembolism: 1%–12% Mortality: 0.1%–2%

with radiation that has been completed.⁵⁷ At this time, there is little compelling evidence to support either irradiation or prostatectomy as superior.

The debate regarding radical prostatectomy and radiotherapy takes on particular significance in men with competing morbidities, particularly when there are data suggesting that no treatment at all is an acceptable approach for some men. There are published series that suggest the survival of men with localized prostate cancer who are not treated is comparable to that of men who undergo radical prostatectomy,^{58,59} but methodologic problems, including the lack of statistical power, limit the conclusions to be drawn from these trials. A larger trial designed to address this question is now underway in the Veterans Administration System. There are no randomized trials comparing radiation therapy with observation.

Observation-only is an option for some men with organ-confined prostate cancer, and this is especially true in the elderly population with reduced life expectancy. Several studies have shown that most men with small tumors and well- or moderately differentiated cancer will have long survival without major interventions.⁶⁰⁻⁶⁶ A pooled analysis of more than 800 men with localized disease identified tumor grade as the major factor in predicting disease-specific and metastasis-free survival.⁴⁶ The 10-year, disease-specific survival is 87% for men with histologic grade 1 and 2 tumors (Gleason ≤ 7) and 34% for men with grade 3 (Gleason >7) tumors. This disease-specific survival for men with well- and moderately differentiated tumors compares favorably with the reported survival for both radical prostatectomy and external beam radiotherapy.^{67,68}

A recent development in the therapy of localized prostate cancer is the use of ultrasound-guided cryoablation of the prostate. A preliminary report on this technique showed that 82% of the 55 men who underwent the procedure had no residual disease at 3 months of follow-up.⁶⁹ The procedure is associated with significantly shortened hospital stays and overall morbidity when compared with prostatectomy. However, it has been studied in a relatively small number of men, and short- and long-term efficacy is unknown. Currently, cryoablation for localized prostate cancer is an experimental procedure.

Clinical decision making in older patients with organ-confined disease is largely an issue of how much and which risks patients are willing to tolerate. With observation alone, there is the risk of developing widespread metastatic disease, whereas each of the treatments has risk of side effects. In the older patient, the risk of developing metastatic disease must be weighed against the life expectancy and comorbid conditions that may limit that life expectancy and raise the risk associated with therapy. An open and frank discussion of these risks with each individual is required.

Regionally Advanced Disease

These patients have cancer that is no longer confined to the prostate gland but has not spread to the soft tissue structures or lymph nodes in the pelvis (T_3, N_0 or T_x, N_{1-3}). Patients with clinical T_3 tumors have 5-year survival of 64% to 72% following radical prostatectomy, external beam radiotherapy, or hormonal therapy, and 10-year survival of 29% to 47%.⁷⁰⁻⁷² Recognizing the increased risk for local recurrence and development of progressive disease, most investigators do not believe that patients in this disease category are curable by either radical prostatectomy or external beam radiotherapy alone. In general, however, these patients do appear to have the potential for prolonged survival with median survival greater than 5 years in most studies no matter what therapy is given.

Intuitively, pathologic stage T_3 disease (microscopic penetration of the prostatic capsule or invasion of the seminal vesicles) should have a better prognosis than clinical stage T_3 disease (palpable involvement of the seminal vesicles). Unfortunately, the data to support this assumption are lacking. Patients with T_3 prostate cancer have been treated with radical prostatectomy, with or without additional (adjunctive) irradiation or hormonal therapy,^{70,73} definitive radiotherapy,⁷¹ immediate hormonal therapy,⁷² or observation with hormonal therapy on progression.⁷⁴ Adjuvant radiotherapy has been the primary modality of treatment for patients with extracapsular spread after prostatectomy (pathologic stage C disease).⁷⁵ In most studies, the 5-year survival rates range from 60% to 75% regardless of therapy. Thus, there are no convincing data to specifically recommend any of these approaches.

Patients with regional nodal involvement (N_1) have a much worse prognosis. Median survival is reported to be as low as 39.5 months.⁷⁶ In this small study (44 patients), radical prostatectomy, adjuvant hormonal therapy, and radiotherapy seemed indistinguishable with regard to survival. However, in a large consecutive series of 120 patients with D_1 disease, the 5-year prostate cancer-specific survival was 61% in a group followed with expectant management alone.⁷⁷ The group at the Mayo Clinic has argued that the high risk of recurrence in N_1 patients justifies adjuvant hormonal therapy. This group has reviewed data from 631 patients who underwent pelvic node dissection and were found to have D_1 disease.⁷⁸ Of these patients, 251 went on to radical prostatectomy and orchiectomy, with 97 receiving radiation and orchiectomy and 60 orchiectomy alone. Prostate cancer-specific survival was markedly improved in the prostatectomy patients at 5 and 10 years when compared with the orchiectomy-alone patients (5 year, 90% versus 66%; 10 year, 78% versus 39%). As with many prostate cancer studies, however, these are retrospective data; unknown, unrecognized, or unstated selection bias leading to

treatment decisions prevent firm conclusions from such data.⁷⁷

Adjunctive Androgen Deprivation

Considerable data have emerged in the past 5 years regarding the use of androgen deprivation therapies (ADT) (usually GnRHa \pm antiandrogen) in conjunction with irradiation and surgery for localized disease. Already referred to are the data of Bolla et al.,⁵⁴ which demonstrated a substantial survival advantage for patients with T₃-T₄ primary tumors treated with irradiation + LHRHa compared to irradiation alone. The RTOG is conducting trials of T₃, T₄ and T₁, T₂ tumors evaluating pen-irradiation as well as prolonged androgen deprivation compared to irradiation alone. Freedom from local progression and freedom from PSA progression occur significantly more often when irradiation is accompanied by ADT in RTOG studies. In a multi-institutional randomized trial, Messing et al.⁷⁹ reported an improved survival in men with N+ disease following prostatectomy if ADT was employed. D'Amico⁸⁰ and colleagues note improved survival when irradiation is combined with ADT in a retrospective, case-control study. Taken together, these data suggest that adjunctive ADT improves survival in certain subsets of patients. Although considerably more work is required to clearly define the role of "early" ADT, these observations call into question the long-held dictum that ADT does not affect survival in prostate cancer. No data are available examining the role of ADT as sole therapy for clinically localized prostate cancer. Studies demonstrating superiority of ADT + irradiation versus irradiation alone raise the question of the role of ADT *alone* in men with localized disease, especially, perhaps, men with competing causes of morbidity or mortality.

Metastatic Disease

Approximately 30% of patients diagnosed with prostate cancer have metastatic disease at presentation.⁸¹ An additional 30%, who initially present with organ-confined or regionally advanced disease, manifest evidence of metastasis at some point in the course of their disease. Metastatic prostate cancer is a significant cause of morbidity and mortality in the elderly male population.

Hormonal therapy of patients with metastatic prostate cancer is one of the most effective therapies available for the treatment of disseminated malignancy. Based on the Nobel Prize-winning work of Huggins and Hodges⁸² in the 1940s, ADT had been utilized with great palliative benefit in patients with disseminated prostate cancer. Response rates of 80% to 90% are reported with each of the currently available therapies: estrogens, orchiectomy, and the LHRHa.^{83,84} Diethylstilbestrol (DES) is the

primary estrogen used in the therapy of prostate cancer. This agent is clearly effective in treating metastatic prostate cancer; clinical responses following DES occur as often as with orchiectomy. Unfortunately, even with low-dose regimens, this agent is associated with a significant incidence of cardiovascular side effects, including cardiovascular death.⁸⁵

Orchiectomy is the "gold standard" for ADT, particularly for men at high risk for complications as indicated by extensive bony involvement, obstructive uropathy, or cord compression. Surgical castration results in a rapid, 95% reduction in circulating testosterone and is not associated with the cardiovascular complications of DES.⁸⁶ GnRH analogues require 2 to 3 weeks to produce castrate levels of testosterone.⁸¹ Nonetheless, the GnRHa analogues are effective therapy for prostate cancer. The major limitations to their use are compliance and cost. The currently available analogues require monthly or every 3- or 4-month injections. The cost of these injections is approximately \$400 and \$1400, respectively. A once-yearly implantable form of leuprolide (Viadur) has been developed and is being tested for efficacy and safety.⁸⁷ In a cost comparison analysis with the GnRHa analogues, orchiectomy is clearly more cost effective.⁸⁸ In addition, GnRHa initially induces an increase in circulating levels of testosterone, which may result in tumor flare.^{82,89,90} This surge in testosterone can cause a significant exacerbation of bone pain, increased urinary obstruction, and potentially significant spinal cord compression in some patients. The effects of this flare can be controlled using antiandrogens such as flutamide, bicalutamide, or nilutamide.⁹¹

The antiandrogens are combined with the GnRHa analogues or orchiectomy in a strategy known as total androgen blockade (TAB). This therapeutic approach seeks to improve outcome through "totally" blocking androgen-stimulated growth of prostate cancer by reducing the circulating androgens and blocking receptor binding by any remaining androgens. In uncontrolled studies, response rates as high as 97% with 2-year survival of 89% were reported.⁹² There are currently three antiandrogens in use in this country: flutamide (Eulexin), bicalutamide (Casodex), and nilutamide (Nilandron). Numerous trials have explored TAB with either orchiectomy or GnRHa + antiandrogens compared to orchiectomy or GnRHa alone. Flutamide was studied in a randomized controlled trial in which previously untreated patients with metastatic prostate cancer were randomized to receive the GnRHa analogue leuprolide (Lupron, daily subcutaneous injection) with or without flutamide.⁹³ This trial enrolled more than 600 patients and demonstrated a statistically significant benefit for the combination therapy in terms of both progression-free survival and overall survival. In a subset analysis, these differences seemed particularly prominent in the patients with good

performance status and minimal disease. In contrast, a European study of 571 patients randomized to goserelin with or without flutamide showed no advantage for the combination in terms of response rate, time to progression, or overall survival.⁹⁴ Thus, the efficacy of this combination remains controversial. Metanalyses reveal either no or limited benefit of TAB versus testicular androgen suppression.

An important U.S. trial randomized 1200 men to receive orchiectomy alone or orchiectomy + flutamide. No benefit of TAB was seen in this trial. Benefits of TAB, if any, seem to be limited to TAB employing LHRHa + antiandrogen. This finding may reflect the benefits of antiandrogen antagonism of the initial androgen surge that accompanies initiation of LHRHa or conceivably antiandrogens offsetting a small, but perhaps important, frequency of failure of LHRHa to completely suppress testicular androgen secretion.

Orchiectomy alone can be a highly effective form of androgen suppression. If LHRHa are employed, we routinely initiate antiandrogens simultaneously and continue antiandrogens for at least 6 to 10 months. The major drawbacks to total androgen blockade are the costs and the side effects of antiandrogens. Flutamide is associated with diarrhea (possibly due to the lactose filler in the capsules) and occasional cases of hepatic toxicity.⁹⁵

Preliminary preclinical and limited clinical data suggest that intermittent androgen deprivation (IAD) may have merit in prostate cancer treatment. In androgen-dependent animal tumor models, IAD appears to delay the emergence of androgen-independent tumor growth. In a number of pilot clinical trials IAD appears to be better tolerated than continuous androgen suppression and may be associated with a delay in development of androgen-independent disease progression. A large randomized national trial is underway comparing IAD to continuous androgen deprivation. If IAD is equivalent or superior to continuous therapy in terms of disease control, it will clearly be the preferred approach, because suppressed libido, hot flashes, and loss of bone mineralization should be less frequent with IAD.

The timing of ADT has always been a controversial topic. In a randomized study of 938 patients with either locally advanced (T₂₋₄) or asymptomatic metastatic prostate cancer, done in the United Kingdom, a significant benefit in morbidity and mortality from prostate cancer was seen in the patients who received immediate ADT (orchiectomy or LHRHa) versus the patients who did not receive ADT until clinically indicated.⁹⁶

Despite the success of androgen deprivation therapy as measured by "response," palliation of symptoms, improvement in bone scan, and reduced PSA, the median duration of response for men with metastatic prostate cancer is approximately 18 to 24 months, no matter what therapy they receive. Eventually, in all men, cells emerge that are

able to grow despite androgen deprivation.⁸³ Median survival, once this hormone-"independent" state is established, is approximately 1 year. It is these patients who are destined to die of their prostate cancer. To date, no therapy has been shown to improve overall survival in men with androgen-independent disease. With the increased use of PSA levels to monitor the status of disease in men with prostate cancer, evidence of tumor activity despite androgen deprivation can be ascertained earlier than symptomatic recurrence, radiographic, or physical exam would reveal. By defining survival from the date of increasing PSA, survival in the androgen-independent phase of disease may appear to be increasing; this is an artifact of earlier definition of androgen independence.

Recent studies indicate that the first intervention in patients with androgen-independent prostate cancer should be withdrawal of antiandrogens in those who are taking them. Declines in PSA and decreases in the size of soft tissue masses have been documented following cessation of therapy with flutamide and bicalutamide.⁹⁷⁻⁹⁹ These responses occur primarily in men treated for a prolonged period with total androgen blockade and are usually short lived (6-9 months), but some patients may have extended periods of disease stabilization.

Secondary hormonal therapy has been utilized for many years in the treatment of men with androgen-independent disease.¹⁰⁰ Unfortunately, unlike breast cancer, a prior response to hormonal therapy does not predict for response to secondary hormonal therapy in prostate cancer. Numerous agents have been tested. A partial listing is included in Table 36.3. Objective responses (primarily reduction in PSA) occur in 15% to 20% of patients and are typically of short duration. Appetite stimulation has been demonstrated as a side effect of megestrol acetate.^{100,101} These agents may improve the cachexia seen in these patients but have limited benefit in treating prostate cancer.

TABLE 36.3. Agents used in hormonal therapy.

Reduction in androgen levels
Orchiectomy
Adrenal suppression
Aminoglutethimide
Ketoconazole
Direct cytotoxicity
Ketoconazole
Diethylstilbestrol
Megestrol acetate
Androgen receptor antagonists
Flutamide
Bicalutamide
Nilutamide
Multiple mechanisms
PC-SPES
Megestrol acetate

Two secondary “hormonal approaches” merit special mention.

1. Several randomized trials have employed glucocorticoids alone as the “standard” therapy for androgen independent prostate cancer. These studies consistently reveal a 15% to 20% frequency of 50% or greater decrease in PSA and a similar rate of pain reduction and an improved sense of well-being. These data suggest that relatively low dose glucocorticoids provide real, albeit relatively infrequent, and temporary benefit in men with androgen-independent prostate cancer.

2. The agent PC-SPES is a commercially available, Chinese combination of eight herbs. The active component or components in PC-SPES are unclear, but pre-clinical studies and clinical trials indicate that PC-SPES suppresses the growth of prostate cancer cells in vitro, reduces PSA levels in men with no prior hormonal therapy, and, most intriguingly, results in subjective improvement and a 50% or greater decrease in PSA in approximately 50% of men with androgen-independent prostate cancer. This activity of PC-SPES is dependent, at least in part, on the fact that PC-SPES contains phytoestrogen compounds that suppress testicular androgen synthesis and likely have direct antiproliferative effects against prostate cancer. The toxicity of PC-SPES is the toxicity of estrogen: thromboembolic disease, fluid retention, congestive heart failure. There are no data comparing PC-SPES to other first- or second-line approaches to androgen deprivation.

Cytotoxic chemotherapy has been studied extensively in men with hormone-refractory prostate cancer.¹⁰²⁻¹⁰⁴ Despite numerous studies, there is no evidence that cytotoxic therapy provides survival benefit. This result has led some investigators to question whether any patient with prostate cancer should receive cytotoxic chemotherapy.¹⁰⁵ Two carefully conducted, randomized trials evaluated the role of mitoxantrone and glucocorticoids. Both studies revealed a significant improvement in palliation of bone pain and greater reduction in serum PSA in those who received the combination compared to the arm receiving only glucocorticoids. Mitoxantrone has been approved by the FDA for use in metastatic prostate cancer. Although no impact in survival has been seen with mitoxantrone therapy, these studies do indicate that limited, but real, palliative benefit is achieved with a very safe and well-tolerated cytotoxic therapy.^{106,107}

Several other studies show that taxanes (paclitaxel or docetaxel), with or without estramustine, have anti-tumor effects in men with androgen-independent prostate cancer. Ketoconazole + doxorubicin alternating with vinblastine + estramustine also has clear anti-tumor effects. Although “effective” systemic cytotoxic therapy

for androgen-independent prostate cancer remains to be defined, considerable data suggest that we have entered an era in the care of prostate cancer patients in which the use of cytotoxic therapy will be increasingly employed.¹⁰⁸⁻¹¹²

Supportive Care of the Patient with Prostate Cancer

Prostate cancer is a significant cause of morbidity in elderly men, even in those destined to die of other causes. The primary care physician plays a crucial role in the management of problems with metastatic prostate cancer. The major cause of morbidity in advanced prostate cancer is bone metastasis. These metastases often involve critical structures such as the vertebral bodies and weight-bearing bones, as well as the marrow cavity itself. These patients are at risk for cord compression, major fractures, and bony pain.

Spinal Cord Compression

Spinal cord compression is a true oncologic emergency that occurs in 10% to 15% of patients with prostate cancer.¹¹³ The key to the management of this complication is early recognition. Most patients develop back pain before the onset of neurologic symptoms, and any evidence of neurologic impairment consistent with either nerve root or cord compression is an indication for careful evaluation. Motor abnormalities are usually the initial neurologic manifestation, followed by sensory loss. Once motor or sphincter function is impaired, improvement is relatively uncommon. Approximately 50% of patients who are paraparetic at presentation are able to regain the ability to walk, whereas patients who present with frank paraplegia rarely regain ambulatory function. A high index of suspicion of spinal cord compression must be maintained. High-dose intravenous corticosteroid therapy (dexamethasone 6 mg q 6h) should be instituted in cases of suspected cord compression.¹¹⁴ Contrast-enhanced magnetic resonance imaging or computed tomographic (CT) myelography are the diagnostic tools of choice in assessing this condition. The thoracic spine is the most commonly involved site, and multiple levels of compression are not unusual. Once the diagnosis has been established, therapy is directed at relieving the pressure on the cord exerted by the tumor mass either with external beam radiotherapy or surgery.^{115,116} Currently, there is no evidence that surgery yields superior results when compared with radiotherapy alone in terms of preservation or recovery of neurologic function.

Bone Metastases

Impending Fracture

The management of bony metastases in patients with advanced prostate cancer presents a major challenge. Not only can these metastases result in cord compression as already noted, but they are a significant cause of morbidity and contribute to mortality, particularly when they involve the long bones. Pathologic fracture involving the femurs and hips have an even more ominous prognosis than traumatic fractures do in the healthy elderly. Pathologic fractures are relatively rare in men with prostate cancer, despite the high rate of bone involvement,^{117,118} likely because of the propensity for these metastases to be osteoblastic rather than osteolytic. The development of pain on weightbearing is often the first sign of an impending fracture and should be investigated promptly in patients with known metastatic disease. External beam radiotherapy and prophylactic orthopedic procedures often prevent the development of debilitating fractures and preserve function. Once a pathologic fracture has developed, the outlook for regaining function is markedly decreased, and an aggressive approach to preventing fractures is clearly warranted.¹¹⁹

Pain

Pain due to bone metastases is a common and vexing clinical problem; effective management is often difficult.¹²⁰ Pain may be a major cause of functional limitation and suffering. Several surveys have indicated that patients are extremely fearful of cancer pain and that our current approaches to pain management are marked by an underutilization of appropriate medication.^{121,122} Narcotic analgesics are the mainstay of the management of cancer pain.¹²³ Sustained-release morphine preparations with shorter-acting opioids for breakthrough pain are effective in most patients. Elderly patients are reported to have a higher risk of cognitive impairment with narcotics, but they can be used safely in this population. In the case of bony metastases, narcotics are often supplemented with nonsteroidal anti-inflammatory drugs to good advantage.¹²⁴ These agents were typically associated with side effects including gastric erosions and bleeding and must be used with care in an elderly population.¹²⁵ (Also see Chapter 28, Acute and Chronic Pain.)

External beam radiotherapy should be utilized frequently in the management of painful bone metastases.^{126,127} Irradiation has the advantage of providing rapid and often complete relief of pain. However, it is not unusual for patients to develop multiple areas of involvement with new areas of bony pain occurring during a course of radiotherapy. This complication often results in expansion or addition to previously existing radiotherapy

ports with a resultant exposure of significant amounts of marrow to the toxicity of radiotherapy, which may contribute to the anemia associated with marrow infiltration by prostate cancer, thus having a significant negative impact on quality of life.

Newer approaches to the management of painful bone metastases include the use of bisphosphonates and radiolabeled compounds that are incorporated into bone, including radioisotopes of strontium, samarium, and rhenium.¹²⁸⁻¹³⁰ These agents are preferentially taken up in bone and appear to have significant activity in terms of ameliorating bone pain; up to 70% to 80% of patients report decreased pain. The bisphosphonates may be useful in prostate cancer involving the bone. These agents inhibit osteoclast activity and erosion of bone. Several bisphosphonates have undergone clinical trials to assess their effect on bone pain. Encouraging results have been seen. Bisphosphonates decrease indices of bone resorption that are above normal in 50% to 80% of cancer patients.¹³¹ Recent data indicate that these drugs may also inhibit the adhesion of tumor cells to bone, thereby preventing or delaying the development of new bony, as well as extraosseous, metastases.¹³² The precise role of bisphosphonates in men with prostate cancer is uncertain. In patients with either breast cancer or multiple myeloma, initiation of bisphosphonates early in the evolution of metastatic disease is associated with reduced skeletal morbidity and even improved survival. Some have argued that the primarily osteoblastic nature of bone metastases in patients with prostate cancer means that bisphosphonates will have a limited role. However, osteolysis does accompany even markedly osteoblastic bone metastases. The role of bisphosphonates in men with this disease remains to be determined.

Conclusion

Prostate cancer is a major health problem in the elderly male population, causing significant morbidity, mortality, and expenditure of health care dollars. This problem will only increase as the population ages. Currently, controversy exists in several key areas of prostate cancer management, including screening and treatment of localized, advanced, and androgen-independent disease. These areas are under active investigation, and new approaches to this disease are emerging.

Gynecologic Cancers

Angeles A. Alvarez and Daniel L. Clarke-Pearson

Genital tract cancer afflicts a significant portion of postmenopausal women. These malignancies account for 13% of all cancers in women. Approximately 75,400 new cases were diagnosed and 24,700 deaths resulted from gynecologic malignancies in 1999.¹ Risk of developing a gynecologic cancer increases with age.² Figures 37.1 and 37.2 show the age-related incidence and mortality, respectively, of these malignancies. As with other cancers, early detection provides the best opportunity for successful management. Therapeutic strategies include surgery, chemotherapy, and radiation treatment. Integration of these diverse modalities is best coordinated by a gynecologic oncologist who has the skills necessary to accomplish surgical and medical treatment of these women, as well as the knowledge of appropriate circumstances for the use of radiotherapy.

Endometrial Cancer

Endometrial cancer is the most common invasive gynecologic cancer, representing 5.4% of all malignancies of women, and one of the 10 most frequent cancers.³ The incidence is 72 cases per 100,000 women per year, yielding a lifetime risk of 1 in 45. Approximately 37,400 new cases and 6,470 deaths occurred in 1999.¹ An estimated 39,300 cases will occur in 2002.¹ Seventy-five percent of endometrial cancer patients are postmenopausal, and the average age of onset is 60 years.²

Several risk factors for endometrial cancer have been identified.⁴ Obesity increases the risk threefold for women 21 to 50 pounds overweight; risk is heightened to 10 fold for individuals exceeding ideal body weight by 50 pounds. Risk for nulliparous women is two times higher than primiparas and three times that of multiparous women. Late menopause (age 52 versus age 49) leads to a 2.4-fold increased incidence of endometrial cancer.

Hormones significantly alter the risk of endometrial neoplastic disorders.⁵ "Unopposed" estrogen replace-

ment therapy in postmenopausal patients increases endometrial cancer risk 4- to 15 fold; risk is related to dose and duration of therapy.⁶ On the other hand, cyclic or continuous supplementation with progestins provides protection against endometrial cancer, reducing risk to below that of women without postmenopausal hormonal support.⁵ Tamoxifen, an antiestrogen used in the therapy of breast cancer patients, increases the risk of endometrial cancer two- to threefold. Despite this unwanted side effect of tamoxifen, it is generally accepted that the benefits of tamoxifen therapy outweigh the risks and that therapy should not, in general be halted because of fears of endometrial cancer.⁷ Estrogen-secreting tumors (granulosa cell tumors of the ovary) and polycystic ovarian disease increase the risk of endometrial cancer.⁸ Oral contraceptives decrease the risk of endometrial cancer by approximately 50%, and this effect persists for about 10 years after discontinuation of the pill.⁹ Hypertension has been reported to increase endometrial cancer risk onefold, and diabetes elevates the risk threefold. Ironically, smoking one pack of cigarettes a day decreases risk by about 30%, presumably due to enhanced estrogen metabolism in smokers.¹⁰

Symptoms of endometrial cancer include abnormal uterine bleeding, vaginal discharge, pelvic pressure, and manifestations of metastatic disease. Abnormal uterine bleeding is the most common clinical feature and is present in approximately 80% of women with endometrial cancer. The differential diagnosis of a postmenopausal woman who presents with abnormal vaginal bleeding includes endometrial atrophy, endometrial hyperplasia, endometrial polyps, cervical cancer, and vaginal cancer, in addition to endometrial carcinoma.

Patients with suspicious symptoms should be carefully evaluated with a detailed history, with emphasis on the risk factors already discussed.¹¹ A thorough physical examination should also be performed. The pelvic examination should include a careful assessment of uterine size and an endometrial biopsy.¹² A Pap smear should

FIGURE 37.1. Annual incidence of genital tract cancers by age per 100,000 women in the United States, 1992-1996. (Adapted from Ries et al.¹⁰⁸)

also be done as well; however, Pap smears lack sufficient sensitivity for the diagnosis of endometrial cancer and must not be substituted for biopsy of the endometrial cavity. Transvaginal ultrasound, with measurement of the endometrial stripe thickness, is a useful adjunct. Using a “normal” endometrial stripe measurement of 4 mm or less for women less than 5 years since menopause and 3 mm or less for those 5 years or more since menopause, transvaginal ultrasound demonstrated a 97% sensitivity, 76% specificity, and 99.7% negative predictive value in the detection of endometrial cancer.¹³ For patients receiving tamoxifen, the endometrial stripe may measure up to 10mm and is not a reliable measurement for the detection of endometrial cancer compared to patients not receiving tamoxifen.¹⁴ Dilatation and curettage are recommended if office biopsy cannot be performed or if the clinical suspicion of cancer remains high in the face of a negative biopsy and transvaginal ultrasound. Hysteroscopy may also be performed, allowing visual inspection of the endometrial cavity, and may identify small foci of tumor missed on routine biopsy.

Screening for endometrial cancer has not proven to be of much clinical value. Methods such as routine endometrial biopsy and pelvic sonography have been explored. Given that a high percentage of endometrial cancer patients become symptomatic early in the course of their disease and that endometrial biopsy is readily available, screening does not improve outcome significantly if practitioners keep in mind the risk factors and diligently biopsy the endometrium in suspicious cases.¹⁵

Endometrial cancers are initially treated and staged using a surgicopathologic evaluation to document the extent of spread.¹⁶ Preoperative medical assessment should search for metastases (physical exam and chest x-ray), as well as assure that the patient is medically fit to undergo surgery. Table 37.1 outlines the current staging system. Standard therapy comprises exploratory laparotomy, total abdominal hysterectomy, bilateral salpingo-

FIGURE 37.2. Annual mortality of genital tract cancers by age per 100,000 women in the United States, 1992-1996. (Adapted from Ries et al.¹⁰⁸)

TABLE 37.1. FIGO staging of endometrial cancer.

Stage ^a	Grade	Definition
IA	Grade 1,2,3	Carcinoma confined to the endometrium
IB	Grade 1,2,3	Invasion of less than one-half myometrial thickness
IC	Grade 1,2,3	Invasion of equal to or more than one-half myometrial thickness
IIA	Grade 1,2,3	Spread to endocervical glands
IIB	Grade 1,2,3	Invasion of cervical stroma
IIIA	Grade 1,2,3	Invasion of serosa and/or adnexa and/or positive peritoneal cytology
IIIB	Grade 1,2,3	Vaginal metastases
IIIC	Grade 1,2,3	Pelvic and/or para-aortic lymph node involvement
IVA	Grade 1,2,3	Invasion of bowel and/or bladder mucosa
IVB	Grade 1,2,3	Distant metastases including spread to abdominal viscera or inguinal lymph nodes

FIGO, International Federation of Gynecology and Obstetrics.

^aGrade 1, 5% of less of a nonsquamous or nonmolar solid growth pattern; grade 2, 6%–50% of a nonsquamous or nonmolar solid growth pattern; grade 3, more than 50% of a nonsquamous or nonmolar solid growth pattern.

oophorectomy, washings from the abdomen and pelvis to assess for cytologic evidence of tumor extension, and pelvic and para-aortic lymphadenectomies if poor prognostic or adverse histologic features are present.¹⁷ Clinical staging was employed before 1988 and is still utilized in the fewer than 5% of cases in which the patient is unfit to undergo surgery.¹⁸

Increased risk of recurrence and decreased survival are associated with high-grade histology, cervical extension, deep myometrial invasion, extrauterine extension, and malignant peritoneal cytology.^{16,19} The presence of estrogen and progesterone receptors is associated with a better prognosis and a higher response rate to progestational therapy. Progestational therapy is usually reserved for recurrent disease, salvage therapy, or the medically infirm who are poor surgical candidates.²⁰

Postoperative management of patients with endometrial cancer varies according to the stage and grade of their tumor. Women at low risk for recurrence (stage IA, grade 1 and 2) require no additional therapy. A recent phase III randomized study of surgery versus surgery plus adjunctive radiation therapy in intermediate-risk individuals [stage IB, IC, IIA (occult) and IIB (occult)] demonstrated that the use of adjuvant pelvic radiation therapy decreased the risk of pelvic recurrence but had no significant effect on overall survival. Patients randomized to the radiotherapy group had a higher incidence of adverse effects, including hematologic, gastrointestinal (with and without obstruction), genitourinary, and cutaneous toxicities.²¹ Patients with stage IIB or IIIA should receive tailored treatment, which may include vaginal cuff irradiation, pelvic radiotherapy, or intraperitoneal ³²P.²² Patients at high risk for persistent, recurrent, or progressive disease (stages IIIB, IIIC, IVA, and IVB, all grades) usually receive postoperative radiation treatment to the vaginal cuff, pelvic, or para-aortic regions.^{23,24} Whole abdominal radiation is sometimes employed in cases of intraabdominal tumor spread.²⁵ Currently, a randomized prospective trial comparing whole abdominal radiation versus doxorubicin-cisplatin chemotherapy for patients with advanced disease is under way. Radiation as a primary means of therapy is usually reserved for poor surgical candidates. When utilized, external beam technique followed by uterine intracavitary placement of a radiation source is the usual strategy.²⁶

Hormonal therapy is sometimes used for metastatic or recurrent endometrial cancer.⁸ Progestational agents have proven to be most effective, although responses to tamoxifen have been described.²⁷ Tumors that express progesterone receptor are more sensitive to the growth-suppressive effects of progestins than those lacking receptors (70% versus 16% response rate).²⁸ Cytotoxic chemotherapy may be used for palliation in advanced or recurrent disease.²⁹ Doxorubicin and cisplatin are the best agents available. Response rates of 31% to 81%

have been achieved, but long-term survivors are rare. Paclitaxel combined with platinum-based chemotherapy has demonstrated a partial response rate of 63% in recurrent disease, and this agent is currently being evaluated in phase III trials.³⁰

Prognosis varies according to clinical stage. Five-year survival according to stage is as follows: I, 93%; II, 73%; III, 48%; IV, 25%.³¹ Patients with stage IA endometrial cancer have a 5-year survival of more than 95%. Multivariate analysis has demonstrated that age at diagnosis is an independent prognostic factor; survival decreases from 93% to 71% as age increased from 30 to 70+.^{20,31} Recurrence is most likely in the first 3 years after treatment. About half of recurrences are in the vagina or pelvis. Patients should be seen every 3 to 4 months in follow-up and should be asked about spotting, bleeding, pain, or any other unusual symptoms that may portend relapse. A careful physical examination including Pap smear and pelvic assessment should be performed. Chest x-ray may be valuable for screening for pulmonary metastases. CA 125 is not routinely used to follow these patients but can be useful in isolated cases.³²

Recurrent endometrial cancer is treated on an individual basis. Strategies include radiation therapy (depending on prior treatment), surgery for resection of isolated tumor, pelvic exenteration for recurrence after radiotherapy, or systemic therapy with hormonal or cytotoxic agents. Some patients with recurrent endometrial cancer, especially those localized to the vaginal cuff, can be treated successfully with radiotherapy, surgery, or a combination of the two. Patients who have metastatic recurrent disease generally have a poor survival. Hormonal therapy and chemotherapy may provide palliative benefit.

Although it is labeled as contraindicated by the U.S. Food and Drug Administration (FDA), estrogen replacement given after definitive cancer treatment does not appear to influence survival for patients with early-stage disease. Provision of hormonal support for women with advanced disease must be decided on an individual basis and should be done in close consultation with a gynecologic oncologist.³³

Ovarian Cancer

Ovarian cancer is the leading cause of death among gynecologic malignancies. In 1999, there were 25,200 new ovarian cancers diagnosed and 14,000 deaths from this disease.¹ Women have a 1 in 70 lifetime risk of developing ovarian cancer, and 1 in 100 will die of this disease.³⁴ More than 48% of ovarian cancers occur in women over the age of 65. Age-adjusted incidence rates increase as age advances. For women under 40, the incidence is 1.4 per 100,000 women; the incidence is between 40 and 50 per 100,000 for women over age 60,² and peaks at

FIGURE 37.3. Age distribution of patients with epithelial ovarian cancer, based on data from the International Federation of Gynecology and Obstetrical (FIGO) 1988 Annual Report. (Reprinted with permission from Morley G, Reynolds RK. *Gynecologic, Obstetric, and Related Surgery, 2nd Ed.* Mosby, Boston, 2000.)

57.0 per 100,000 for women 70 to 74 years old³⁵ (Fig. 37.3). Most ovarian cancers are diagnosed at advanced stage, with extensive intraabdominal spread present at the time of initial diagnosis.

Many risk factors have been identified for ovarian cancer.³⁶ The best documented of these is the relationship between the number of lifetime ovulatory cycles and ovarian cancer risk. Events or conditions that suppress ovulation protect women against this malignancy. Thus, multiparity, oral contraceptive use, and a history of breastfeeding are protective. Conversely, women who are nulliparous or who undergo a late menopause are at increased risk. Women who have undergone ovulation induction therapy for infertility may have a higher risk, but this has not yet been firmly established.³⁷ High dietary fat consumption, use of talc in perineal regions, and mumps infections before menarche have also been implicated as factors that elevate ovarian cancer risk.

Genetic influences are also important. About 5% of ovarian cancer patients have a family history of significance.³⁸ Three familial ovarian cancer syndromes have been identified.³⁹ Women who fall into these categories often develop ovarian cancer at a younger age than those who develop sporadic tumors. Site-specific ovarian cancer afflicts families by causing ovarian cancer in the affected kindred. In familial breast/ovarian cancer syndrome, female family members develop early-onset breast or ovarian cancers. Cancer family syndrome (Lynch type II) is characterized by nonpolyposis colon cancer and either breast, ovarian, or endometrial adenocarcinoma. All these syndromes are transmitted in an autosomal dominant pattern with variable degrees of penetrance.

Several pathologic categories of ovarian tumors exist.⁴⁰ Epithelial cancer (adenocarcinoma) accounts for more than 80% of ovarian tumors and has an average age of onset over 40. These malignancies arise from coelomic epithelium; histologic subtypes of epithelial tumors include serous, mucinous, transitional cell, clear cell, and undifferentiated. Epithelial cancers are assigned grades of 1 to 3; the higher the grade, the less well differentiated the tumor. It is important to recognize tumors of low malignant potential (borderline tumors). These tumors are also of epithelial origin and are characteristically indolent and slow growing. They have cellular features of both malignancy and benignity. Because of their torpid nature, low malignant potential tumors have a more favorable prognosis than frankly invasive ovarian cancer. Another malignancy commonly misdiagnosed as ovarian cancer is primary peritoneal serous carcinoma. This cancer, arising from the peritoneum, spreads like ovarian cancer, looks histologically similar, yet minimally involves the ovary.

Sex cord/stromal tumors arise from mesenchymal tissues and account for about 5% of ovarian cancers. These tumors may occur at any age; subtypes consist of granulosa cell, thecoma, fibroma, and Sertoli-Leydig histologies. Germ cell tumors make up another category. They typically afflict children and adolescents and are relatively rare in postmenopausal women. These tumors account for approximately 15% to 20% of ovarian cancers. Ovarian metastases may arise from other primary cancers such as breast, endometrial, lymphoma, colon, and stomach and may present with signs and symptoms similar to de novo ovarian cancer. Because the majority of ovarian cancers in the geriatric population are of epithelial origin, our discussion focuses on this category. Other issues specifically related to the care of elderly ovarian cancer patients are addressed next.

Ovarian cancer often has an insidious onset with non-specific symptoms, which often results in a delay in diagnosis. Gastrointestinal symptoms are common including dyspepsia, nausea, early satiety, altered bowel habits, eructation, abdominal discomfort, pain, and distension. Patients are often initially misdiagnosed with stress, depression, irritable bowel syndrome, or gastritis.⁴¹ The correct diagnosis of ovarian cancer requires a high index of suspicion.

A carefully detailed history and physical examination are essential. Symptoms, family history, and risk factors should be assessed. Physical examination should include meticulous abdominal, pelvic, and lymph node examinations. Omission of the pelvic exam at the first visit is an important factor associated with delay of diagnosis.⁴¹ Examination frequently reveals a significant abdominopelvic mass accompanied by ascites. Radiographic studies are sometimes useful in securing the diagnosis and triaging patients for appropriate treatment. Ultrasound can

help differentiate benign from malignant lesions. Benign tumors often appear as simple cysts under 10 cm in diameter with septations less than 3 mm thick. Malignant lesions often are complex with solid and cystic components or are completely solid. Other malignant features include bilaterality, multiple septations greater than 3 mm, papillations, mural nodules, excrescences, and ascites. Doppler flow studies of malignant tumors show increased vascularity, enhanced blood flow, and decreased blood flow resistance. Computed tomography (CT) scans may be helpful, especially in the evaluation of retroperitoneal structures and the upper abdomen. Magnetic resonance imaging (MRI) is expensive and thus far unproven in the evaluation of the adnexa. Barium enema is useful in cases where gastrointestinal symptoms suggestive of a colonic neoplasia are present. Abdominal plain films are beneficial for demonstrating small bowel obstruction in symptomatic patients. In cases of undiagnosed abdominopelvic masses, radiographic studies cannot replace surgical exploration for definitive diagnosis and treatment.

Standard laboratory studies include complete blood count, electrolyte screen, and BUN–creatinine. Liver function analysis and coagulation panels are not usually informative in the absence of symptoms. The tumor marker CA 125 may be useful in the diagnosis and therapy of ovarian cancer.³² If serum CA 125 is elevated in postmenopausal women with a pelvic mass, cancer should be strongly suspected. However, there are many other causes of elevated CA 125, and this test should not be considered a definitive verification of the presence or absence of cancer. CA 125 is most helpful for monitoring disease status (tumor burden) during therapy.⁴² Paracentesis for analysis of ascitic fluid for diagnosis should be avoided. Risks of this procedure are (1) rupture of a cyst, which could release cancer cells or viscous mucoid material; (2) seeding of the needle tract with tumor; and (3)

false reassurance may be acquired if cytology studies prove to be falsely negative. However, if the patient is experiencing intolerable symptoms, such as dyspnea due to ascites, a therapeutic paracentesis may be indicated.

Spread of ovarian cancer occurs by capsular invasion, peritoneal seeding and lymphatic infiltration.⁴⁰ Peritoneal spread is the most common pattern and includes most peritoneal surfaces with frequent involvement of the omentum and diaphragm. Carcinoma of the uterus and cervix usually disseminate through pelvic lymphatics, whereas ovarian cancer drains to the para-aortic nodal tissue. Distant spread to intrathoracic regions or liver parenchyma may occur when malignant cells are transported via hematogenous routes. Extraovarian spread worsens prognosis. Another prognostic factor is tumor grade, which is usually more important than histologic subtype when forecasting outcome for women with early-stage ovarian epithelial cancers.

Staging of ovarian cancer employs a surgicopathologic system and is outlined in Table 37.2. Surgical staging is best accomplished by a gynecologic oncologist.⁴³ Patients usually undergo preoperative antibiotic and mechanical bowel preparation. Exploratory laparotomy, comprehensive abdominal exploration, hysterectomy, bilateral adnexectomy, omentectomy, and tumor debulking are performed. Peritoneal washings or ascites fluid is obtained for cytology. Random peritoneal or lymph node biopsies are performed in apparent early-stage cases to uncover occult microscopic tumor foci and document their locations. Pelvic and para-aortic lymph node dissections are completed to document extent of tumor spread or to “debulk” the cancer. Bowel surgery is performed in appropriate cases to relieve obstruction or to reduce tumor volume.⁴⁴ Surgical cytoreduction is performed to remove macroscopic tumor deposits because prognosis is directly related to the volume of residual disease before the initiation of adjuvant therapy. Bristow

TABLE 37.2. FIGO staging of ovarian cancer.

Designation	Definition
Stage I	Cancer limited to the ovaries
IA	Growth limited to one ovary, capsule intact, no malignant ascites, no tumor on external surface
IB	Growth limited to both ovaries, capsule intact, no malignant ascites, no tumor on external surface
IC	As for IA or IB but with surface growth, ruptured capsule (before or during surgery), positive washings, or malignant ascites
Stage II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic organs
IIC	As for IIA or IIB but with surface growth, ruptured capsule (before or during surgery), positive washings, or malignant ascites
Stage III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; liver capsule involvement
IIIA	Tumor grossly limited to the true pelvis with negative nodes but microscopic seeding of abdominal peritoneal surfaces
IIIB	Abdominal peritoneal implants, but none exceeding 2 cm; nodes negative
IIIC	Abdominal peritoneal implants larger than 2 cm and/or positive retroperitoneal or inguinal nodes
Stage IV	Tumor involving one or both ovaries with distant metastases; pleural effusions must be demonstrated to harbor malignant cells; liver parenchymal involvement

et al. demonstrated that even patients with stage IV disease benefited from aggressive cytoreduction. Median survival was 50 months for patients in whom both extra- and intrahepatic optimal cytoreduction had been accomplished versus only 7 months for patients who were suboptimally debulked.⁴⁵ The full extent of tumor spread and amount of residual disease is documented so that appropriate therapeutic decisions can be made. Clearly surgical judgement is necessary to achieve optimal surgical and medical outcome, especially in elderly women who may have underlying medical problems.

Patients with stage IA grade 1 epithelial ovarian cancer have such an excellent prognosis that postoperative adjuvant therapy is unnecessary. For those with more advanced cancers, postoperative treatment usually consists of six courses of platinum-based multiagent chemotherapy, usually cisplatin or carboplatin combined with paclitaxel. Paclitaxel and platinum-based therapy has been demonstrated in prospective randomized clinical trials to improve progression-free survival and overall survival for patients with advanced suboptimally debulked ovarian cancer.⁴⁶ Carboplatin is just as efficacious as cisplatin and is associated with an improved adverse effect profile.⁴⁷ Intraperitoneal chemotherapy is also under investigation, and currently clinical trials are evaluating intravenous versus intraperitoneal cisplatin and paclitaxel for patients with optimally debulked stage III ovarian cancer. Novel therapeutic agents (such as antiangiogenic agents and gene therapies) are currently being evaluated in the treatment of ovarian cancer in clinical trials. Herceptin, anti-Her2 neu antibody, is available to patients with recurrent or refractory ovarian cancer who overexpress Her2 neu .

Chemotherapeutic treatment spawns many side effects; elderly women particularly have an elevated risk of complications with some regimens.⁴⁸ Cisplatin causes nausea, irreversible renal damage, and peripheral neuropathy (which is the dose-limiting toxicity). Administration of cisplatin requires extensive hydration and antiemetic therapy but can be safely used in the elderly.⁴⁹ Carboplatin differs from its congener, cisplatin, in that it is much less emetogenic, nephrotoxic, and neurotoxic. Debilitated patients tolerate carboplatin therapy better than cisplatin treatment, owing to different toxicity profiles of these agents.⁵⁰ Carboplatin is better tolerated by the elderly because it does not cause renal injury or nausea. Furthermore, because aggressive hydration is not required, carboplatin administration is less likely to exacerbate congestive heart failure or cause other side effects related to volume overload. The predominant side effects of paclitaxel are neutropenia and alopecia. Age alone is an insufficient criterion to alter the dose of either carboplatin or paclitaxel.⁵¹

Radiation therapy (RT) has a limited role in treatment of ovarian cancer. Intraperitoneal ³²P has sometimes been

used to treat stage IC disease or for patients with persistent microscopic tumor deposits after chemotherapy. However, there are conflicting data regarding the efficacy of ³²P therapy, and one study has even demonstrated that cisplatin significantly prevented relapse in stage IC patients compared to ³²P therapy.⁵²

External beam radiation therapy is sometimes useful for local control of sizable tumor foci, or residual disease, or for treatment of extremely poor surgical candidates. Treatment of the entire peritoneal cavity with teletherapy with curative intent is impractical in most cases. However, lower-dose whole abdominal radiation may be employed in selected cases to control small-volume disease.⁵³

Survival of patients treated for ovarian cancer varies according to the stage of their disease. Five-year survival for women with epithelial ovarian cancer has improved and is as follows: stage I, 93%; stage II, 70%, stage III, 37%; stage IV, 25%.⁵⁴ Survival in ovarian cancer patients is influenced by age.³¹ Multivariate analysis has revealed age to be an independent predictor of outcome. Overall, 5-year survival for elderly women over the age of 75 is only 20%, compared to 70% for women under 45 years of age.³⁵ This trend toward decreasing survival with advancing age holds true for patients with the same stage of ovarian cancer, even when adjustments for life expectancy are included.⁵⁵ Older women are more likely to be diagnosed with advanced-stage disease.³⁵ Older women are also less likely to undergo complete surgical staging, extensive debulking, or receive multimodality therapy because of overriding comorbidities.^{35,55} Bulky residual disease often remains after surgery due to the patient's otherwise poor health or because of limited experience of the surgeon in managing ovarian cancer patients.⁵⁶ More than 40% of women 85 years or older, according to a review of hospital records, did not receive any definitive therapy.⁵⁵ Older women with ovarian cancer, in general, are treated less aggressively than their younger counterparts.⁵⁵ Optimal therapy should not be withheld in elderly patients unless there are overriding medical contraindications.

Analysis of outcomes for patients involved with six randomized Gynecologic Oncology Group (GOG) trials revealed that those over age 69 had poorer survival rates than younger women, even after correcting for stage, residual disease, and performance status.⁵⁷ A retrospective case-control investigation has confirmed this finding.⁵⁸ Other studies have shown that more conservative surgery and less aggressive adjuvant therapy are contributing factors that may lead to decreased survival in elderly patients with epithelial ovarian cancer,⁵⁵ which was demonstrated to be due, in part, to these women receiving their care from obstetrician-gynecologists, general surgeons, and other nononcologists who persuaded them not to seek aggressive treatments. This bias against elderly women has been shown in another report

documenting decreased specialist referral and use of physician influence to dissuade these cancer victims from obtaining optimum therapy.⁵⁹ Thus, although advanced age presages a poorer prognosis, in appropriate candidates maximal surgical debulking and aggressive chemotherapy may partially mollify the effect of age.

Follow-up involves serial physical and pelvic examinations, CA 125 levels, and sometimes CT imaging. Today, "second-look" surgery is infrequently performed after initial chemotherapy to determine the status of the tumor, that is, whether microscopic or grossly evident foci exist.⁶⁰ Although somewhat controversial,⁶¹ and with no evidence that this surgery improves overall survival, this procedure is generally limited to those participating in research protocols to assess the effectiveness of new treatment modalities. About 55% of patients who are clinically free of disease will have a positive (i.e., persistent tumor) second-look operation. Debate regarding second-look operation exists because of its fallibility in predicting survival. There is a 25% to 45% recurrence rate after a negative second-look procedure, and some argue that the information gained does not justify the expense and morbidity of the surgery.⁶²

Recurrence risk is increased with advanced-stage disease, high tumor grade, and large tumor volume.³¹ A number of strategies may be employed to control tumor recurrences, although most are aimed at palliation rather than "cure." Treatment with secondary surgical debulking, multiagent chemotherapy, radiation therapy, biologic response modifiers, or chemotherapy with monoclonal antibody-directed agents, intraperitoneal instillation, or systemic administration with experimental compounds have all been utilized. Therapy must be individualized based upon the site(s) of recurrence, the biology of the tumor, the patient's performance status, her medical comorbidities, and her wishes regarding how aggressively she wants the cancer treated.⁶³

Refractory cancer carries with it a very poor prognosis.⁶⁴ Death usually occurs within 18 to 36 months as the cancer propagates and sprawls out on the splanchnic bed, causing bowel obstruction, nausea, and vomiting. Sepsis often follows bowel or ureteral obstruction. Severe electrolyte abnormalities may result from nutritional deficiencies, renal dysfunction following cisplatin treatment, and accumulation of massive peritoneal or pleural effusions. Decisions regarding management of persistent, progressive disease must be made with care and with the participation of the patient and her family.⁴⁴ Relevant issues include support with total parenteral nutrition (which often can be administered at home by the patient or a family member), medical or surgical relief of bowel obstruction, intravenous hydration or antibiotics, hospice care, and pain management. It is imperative that maintaining quality of life and assuagement of pain be goals of therapy.

Epithelial ovarian cancer is not generally considered an estrogen-dependent neoplasia and, therefore, hormonal replacement therapy is not contraindicated. In fact, estrogen may augment the patient's quality of life and be an important part of her treatment.

Cervical Cancer

Cervical cancer accounts for about 20% of all gynecologic cancers. This cancer is largely preventable through screening and treatment of premalignant lesions. However, there were about 12,800 new cases and 4,200 deaths related to cervical cancer in 1999.¹ More than 50,000 new cases of cervical carcinoma in situ are diagnosed each year. The incidence is 8 to 10 cases per 100,000 women per year. Average age of onset is 45 to 55, but there is a wide variation in the ages of those afflicted.

Several epidemiologic risk factors have been identified.^{2,65-71} Advanced age increases risk twofold. Black, Hispanic, and Native American women have a two- to threefold elevation in risk. A risk about three times that of the general female population is found in women of low socioeconomic status, multiparas, those engaging in sexual activity at a young age or with multiple partners, and chronic smokers. Women with a history of sexually transmitted disease (especially herpes or genital warts) are 2 to 10 times more likely to develop cervical cancer. Lack of regular Pap screening increases risk two- to sixfold. Immunosuppressed patients have a higher risk of cervical carcinoma. Dietary deficiency of ascorbic acid and carotene has been reported to augment the development of cervical neoplasia, although this is less well documented than the other risk factors. Screening is vital for diagnosis and treatment of cervical cancer in its earliest phases.^{72,73} A more detailed discussion of cancer screening may be found in Chapter 32.

Pathogenesis of cervical cancer has received immense scrutiny in recent years. Molecular analysis has demonstrated that the etiology of cervical cancer in older women is similar to younger women.⁷⁴ Human papillomavirus is regarded as the vector that confers susceptibility to neoplastic conversion or that directly incites transmutation to a malignant phenotype in some infected epithelial cells.^{70,75} Neoplastic transformation usually originates at the squamocolumnar junction of the cervix. Varying degrees of cervical intraepithelial neoplasia (CIN) exist; these are graded from 1 to 3 on the basis of increasing severity of the lesion. Carcinoma in situ designates the condition in which all epithelial layers consist of neoplastic cells that are abutting the basement membrane, poised for invasion through this delimitation. It usually takes 10 to 20 years for intraepithelial neoplasia to progress to invasive disease. Most tumors (80%–90%) exhibit squamous histology; adenocarcinoma is the

other predominant category. Other morphologies are rare.

Women with early invasive cervix cancer may have a cervix that appears normal to the naked eye, or they may have a small, ulcerated lesion that may seem to represent a benign inflammatory process. In such cases, cervical smears may be particularly effective in detecting preinvasive or early-stage disease. Most of these women are asymptomatic. On the other hand, patients with advanced cancer often experience symptoms. The most common abnormality is irregular vaginal bleeding. Post-coital spotting has long been considered a warning sign, but metrorrhagia or menorrhagia may occur as well. Some patients have a serosanguinous or yellow vaginal discharge that frequently is malodorous. Another symptom attributable to advanced cervical cancer is pain in the lower abdomen, pelvis, or back. Hematuria or rectal bleeding may occur if bladder or rectal invasion exists.

Invasive cancers display two primary modes of extension: local spread and metastasis via lymphatic and hematogenous routes. Cervical cancer may exhibit an ulcerative or exophytic appearance. Local expansion usually involves extension to the endocervix or vaginal fornices, followed by progressive infiltration of parametrial tissues, uterine corpus, bladder, or rectum. Lymphatic dissemination typically occurs in a stepwise progression. Pelvic nodes become involved before common iliac and para-aortic lymph node chains. Hematogenous spread may give rise to distant implants of cancer in lungs, bones, liver parenchyma, or other tissue. In general, the likelihood of metastasis rises with increasing size and expanse of tumor.⁷⁶ Spread to the pelvic nodes is present in 15%, 30%, or 47%, respectively, for tumors confined to the cervix, in the parametrium, or involving the pelvic side-

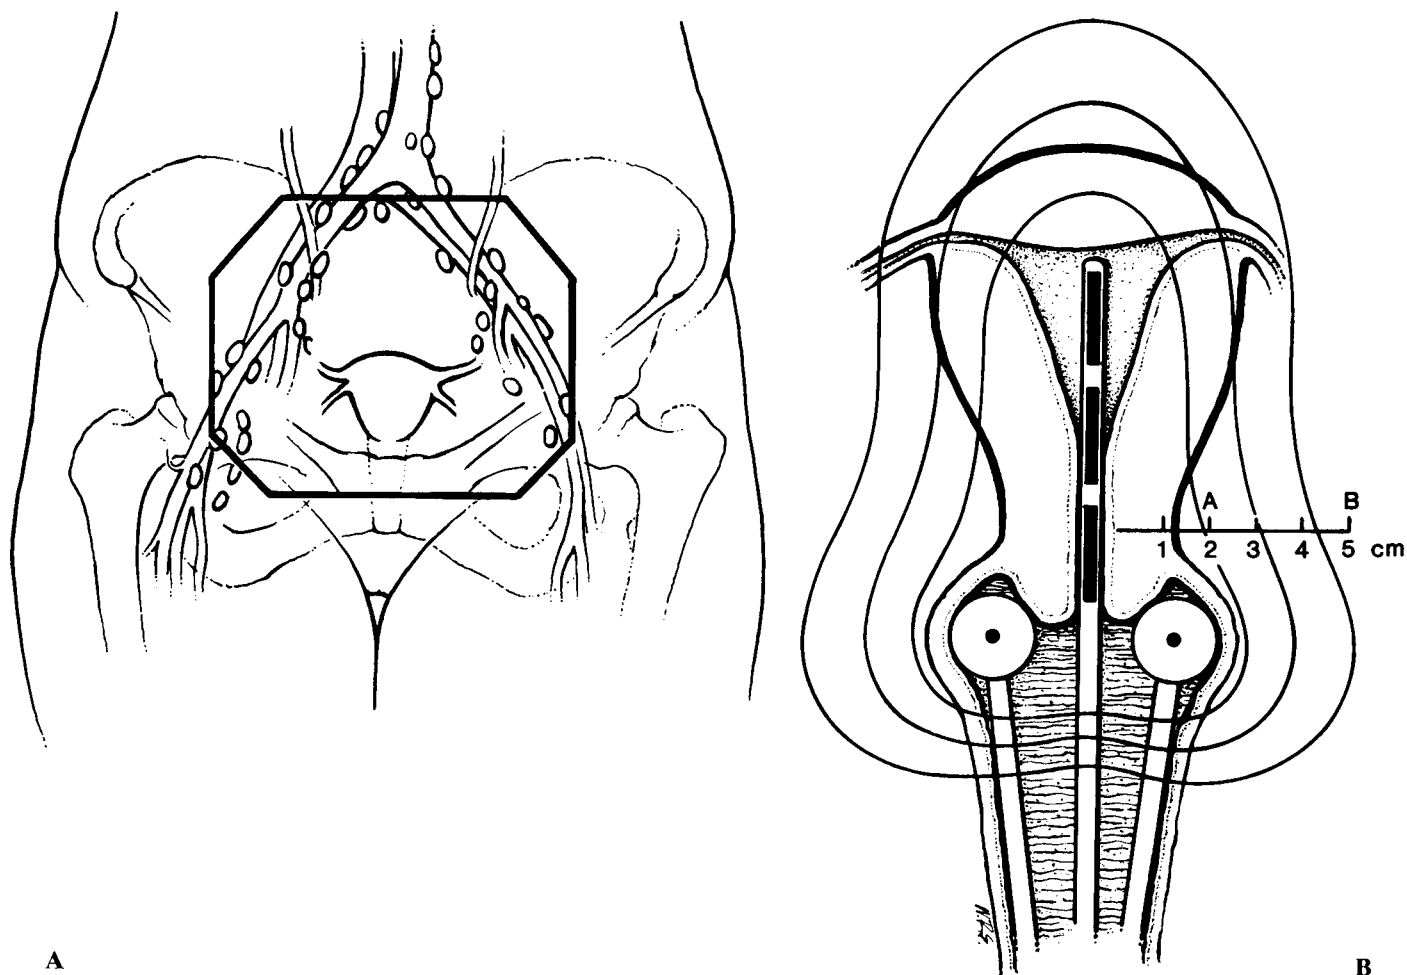

wall. The corresponding para-aortic nodal involvement for these situations is 6%, 16%, or 29%.

Cervical cancer is evaluated using a clinical staging system that is shown in Table 37.3. A pelvic examination should include a thorough evaluation of the cervix, vagina, parametria, and pelvic sidewalls. Extrapelvic regions that should receive extra attention include the abdomen, chest, and supraclavicular lymph nodes. Chest x-ray and intravenous urography are allowable radiographic techniques (under the clinical staging guidelines) for documenting the extent of tumor spread. Cystoscopy and proctoscopy are also permitted. General or conduction anesthesia is often employed to facilitate pelvic examination, procurement of biopsies, and cystoscopic and proctoscopic evaluations. Other studies that are sometimes helpful for diagnosis and treatment planning include lymphangiography, computed tomography (CT) scan, CT-directed lymph node aspiration, magnetic resonance imaging (MRI), positive emission tomography (PET) scan, blood count, serum chemistry profile, and urinalysis.

Treatment for cervical carcinoma may include surgery, radiotherapy and chemotherapy.^{77,78} The most commonly utilized modality is radiotherapy, which ideally employs one or both of two techniques. (1) Teletherapy, or external beam application, is directed to cervical, parametrial, and pelvic nodal regions (Fig. 37.4A). The field may be extended superiorly if there is suspected or documented involvement of the common iliac or para-aortic nodes.⁷⁹ (2) Brachytherapy, or intracavitary treatment, is commonly done with intrauterine placement of cesium over a time period calculated to deliver a standard dose (Fig. 37.4B). The advantage of this technique is that extremely high doses of radiation can be applied to the tumor with less penetration of surrounding normal tissue. Recently, the utility of radiotherapy with concurrent cisplatin-

TABLE 37.3. FIGO staging of cervical cancer.

Designation	Definition
Stage 0	Carcinoma in situ
Stage I	Cancer confined to the cervix (corpus extension is disregarded)
IA	Preclinical cancer, i.e., diagnosed by microscopy only
IA ₁	Measured depth of stromal invasion no greater than 3.0mm
IA ₂	Microscopically measurable lesion with depth of invasion <5mm and horizontal spread <7mm
IB	Clinical lesions confined to the cervix or preclinical lesions greater than stage IA ₂
IB ₁	Clinical lesions no greater than 4.0cm in size
IB ₂	Clinical lesions greater than 4.0cm in size
Stage II	Parametrial extension, but not to the sidewall; involvement of the upper two-thirds of the vagina
IIA	No evidence of parametrial involvement
IIB	Obvious parametrial extension
Stage III	Extension of cancer to the pelvic sidewall or lower one-third of the vagina; hydronephrosis or nonfunctioning kidney secondary to cancer
IIIA	No pelvic sidewall extension
IIIB	Extension to the sidewall and/or hydronephrosis or nonfunctioning kidney
Stage IV	Spread beyond the reproductive tract
IVA	Infiltration of bladder or rectal mucosa
IVB	Metastases to distant organs or disease outside the true pelvis

A

FIGURE 37.4. (A) External beam radiation therapy (teletherapy) is usually delivered to the pelvis through anterior and posterior portals covering the area outlined. Pelvic lymph nodes, parametria, cervix, uterus, and upper vagina are incorporated in this port. (B) Intracavitary Flecher-Suit applicator system. Intracavitary radiation therapy (brachytherapy) is usually given by placing cesium in an intrauterine tandem and contracervical applicators. The cesium sources are placed in a tandem fashion in the uterus, and a single source of cesium is placed in each vaginal applicator. The isodose curve from this application is depicted as three concentric lines. The dose to various pelvic

B

sites is calculated (dosimetry) and depends on the strength of the cesium sources placed, the amount of time the sources remain in place, and the distance from the sources to the tissue in question. Two arbitrary points are usually calculated. *Point A* is found 2 cm cephalad and 2 cm lateral from the external cervical os. This point is where the ureter crosses underneath the uterine artery. *Point B*, which is 3 cm more lateral to point A, represents approximately the pelvic sidewall and pelvic lymph nodes. (Reprinted with permission from Clarke-Pearson D, Dawood Y. *Green's Gynecology, 4th Ed.* Little, Brown, Boston, 1990.)

based chemotherapy has been evaluated in several randomized trials. Patients with locally advanced (stage IIB–IVA) and bulky stage IB₂ cervical cancers who were treated with combined radiation and chemotherapy had significantly improved progression-free and overall survival rates.^{80–82} Of the chemotherapy regimens available, single-agent cisplatin was shown to be just as efficacious as cisplatin/fluorouracil and better than regimens containing hydroxyurea.⁸²

Surgical strategies vary according to the extent of the lesion. Cervical conization or simple hysterectomy (abdominal or vaginal) may effectively treat carcinoma

in situ and microinvasive cervical cancers.⁷⁶ A radical hysterectomy involves removal of the uterus along with parametrial and paravaginal tissues; this is a treatment option for patients with Stage IA₂–IIA disease. The upper portion of the vagina and the pelvic and para-aortic lymph nodes are excised as well (Fig. 37.5). In premenopausal women, ovaries are not removed unless other indications necessitate their removal; however, in the postmenopausal patient a bilateral salpingo-oophorectomy is routinely performed.

The decision of whether to use surgery or RT for early-stage disease turns on several issues. Patients who are

FIGURE 37.5. Radical hysterectomy. This operation is usually performed for the treatment of cervical carcinoma. Therefore, the goals include resection of the parametria and upper vagina to achieve a clear surgical margin around the cancer. Radical hysterectomy does not imply removal of the tubes and ovaries, which may often be preserved in young women. The cardinal ligament and major portions of the uterosacral and vesicouterine ligaments are resected as part of the radical hysterectomy. (Reprinted with permission from Clarke-Pearson D, Dawood Y. *Green's Gynecology, 4th Ed.* Little, Brown, Boston, 1990.)

frail or have serious comorbidities may be poor surgical candidates. Recovery from surgery and most of its potential complications occurs within a narrow time frame, whereas radiation has both acute and chronic effects.^{77,83} Radiation-induced fibrosis is a lifetime process that is set in motion by the endarteritis provoked by RT. Ovarian function is obliterated by RT unless the ovaries have been positioned out of the pelvis. Sexual function is usually better preserved in women who have had surgery, as radiotherapy leads to agglutination of the vaginal tissues.

Advanced age has traditionally been considered a relative contraindication to radical pelvic surgery. The belief that such procedures in the elderly yield unacceptable morbidity has led to treatment of many older cervical cancer patients with radiotherapy rather than radical hysterectomy. Three retrospective studies have shown that, in properly selected older women, application of radical hysterectomy with modern surgical and postoperative care leads to complication rates comparable to those of younger women.^{84,85} Thus, radical hysterectomy should not be withheld as a treatment option for older patients who are otherwise good surgical candidates.

Choice of therapy is based on the clinical stage. Patients with stage IA₁ cervical cancer may be treated by simple hysterectomy or, in selected cases, with conization. Women with stage IA₂ cancer are treated the same as those with stage IB disease if there is more than 3 mm of invasion or lymphocapillary space involvement.⁷⁶ Stage

IB and stage IIA cancer is treated similarly; cure rates are comparable regardless whether radical hysterectomy or RT is employed.⁸⁶ Cervical carcinoma of stages IIB, III, or IVA should be treated with radiation therapy. If ureteral obstruction is present, urinary diversion via nephrostomy or insertion of ureteral stents may be necessary to preserve renal function.⁸⁷ Palliative RT may be used in individuals with stage IVB disease to control pain and bleeding from the pelvic tumor. Chemotherapy with agents such as cisplatin, 5-fluorouracil, bleomycin, vincristine, and ifosfamide is often given in hopes that some therapeutic benefit may be derived in cases of metastatic disease.^{88,89} "Cures," however, are unlikely with currently available chemotherapy.

Exenteration is an ultraradical procedure that is typically used for treatment of central tumor recurrence or persistence after radiotherapy.⁹⁰ This procedure entails removal of pelvic organs, including the bladder and rectosigmoid colon. Exenteration obviously leads to disfigurement and has profound psychologic impact on the patient. Significant potential for morbidity attends this procedure. Therefore, this technique is reserved for patients who are medically fit to undergo an extended procedure and in whom there is a substantial prospect for cure.

Five-year survival figures are given in Table 37.4.³¹ These data highlight the importance of early detection and treatment of this cancer. Influence of age on treatment and survival related to cervical cancer has been

TABLE 37.4. Cervical cancer 5-year survival.

Stage	Survival (%)
0	99+
1A	97
1B	79
IIA	55
IIB	52
IIIA	40
IIIB	27
IVA	14
IVB	2

examined. Five-year survival decreases as age increases; this holds true both for global comparison of age groups and for relationships within stage.³¹ Interestingly, a study from Japan has demonstrated that, when matched with respect to depth of invasion, patients over 60 had a lower incidence of lymph node metastases than their younger counterparts.⁹¹ Despite the lower frequency of lymphatic involvement, the older women still demonstrated a worse prognostic trend. Another study found that overall survival in women 85 years and older was only 23.8%.⁹² The 5-year survival rates for women 85 years and older were 37.5% for stage II and 22.2% for stage III. There were no stage I or stage IV survivors.⁹² Survival is worse in older women, in part because cervical cancer is diagnosed at more advanced stages in this age group.^{76,92}

Interval evaluation of the cervical cancer patient after therapy is imperative. Recurrent cervical cancer detected at its earliest stages might be successfully treated with surgery, radiation, chemotherapy, or a combination of the three. Thirty-five percent of patients with invasive cervical cancer will have persistent or recurrent disease following treatment.⁷⁶ The patient should be seen every 3 months for follow-up for 2 years, then visits should be at the discretion of the practitioner. In addition to focused history and physical examination, a Pap smear should be done. Chest x-rays, intravenous urograms, and CT scans may be ordered if circumstances dictate.

Recurrent cervical cancer carries a poor prognosis.⁷⁶ Seventy-five percent of recurrences occur in the first 2 years after treatment; by the 5-year milestone, 90% of recurrences have developed. Fewer than 15% of patients with recurrent disease survive 1 year, and 5-year survival is less than 5%. Pain control is an extremely important aspect of caring for women with relapses. Therapeutic approaches include RT if the primary treatment was surgical. Cure is sometimes possible for patients with central recurrence following RT if they are candidates for pelvic exenteration. Palliative chemotherapy may be administered.⁸⁸

Death occurs by several mechanisms in cervical cancer patients. Extension of the tumor to the pelvic sidewall may cause ureteral obstruction and uremia. If the patient

has received all available treatment for her cancer, usually no attempt is made at placing ureteral stents or percutaneous nephrostomies because uremic coma is not an unpleasant means of death in these women, who would otherwise often experience severe pain. Hemorrhage from the tumor bed or from erosion into pelvic vessels may lead to exsanguination and death. Hypercoagulability may precipitate pulmonary embolism. Sepsis occurs in many of these women and can be fatal if not promptly recognized. Physical external compression of the rectosigmoid colon may cause large bowel obstruction and the attendant consequences. Radiation enteritis, cystitis, and pelvic fibrosis may all contribute to or directly induce the patient's demise.⁹³

Hormone replacement is not contraindicated in women with cervical cancer. Estrogen therapy may be especially important for maintenance of healthy vaginal tissue following castration or RT. To prevent endometrial hyperplasia or carcinoma, a progestin should be added to the estrogen if the uterus remains intact. Because many women treated for carcinoma of the cervix are relatively young, hormonal therapy affords the same advantages that would otherwise apply if they did not have cancer.

Vulvar Cancer

Vulvar cancer is an uncommon malignancy, responsible for only 5% of all gynecologic neoplasms, but its incidence is on the rise. Although the age of onset of vulvar cancer varies widely, most cases occur in women over age 50. Peak incidence occurs between the ages of 65 to 70.⁸³

Epidemiologic studies have shown associations between vulvar cancer and genital warts, abnormal Pap smears, and smoking.^{76,94} Molecular analysis of vulvar neoplasias has revealed the presence of human papillomavirus (HPV) genomic material.⁹⁵ These findings support an etiologic relationship between papillomavirus and vulvar cancer. Vulvar intraepithelial neoplasia (VIN) predisposes to vulvar cancer. Lichen sclerosis is not generally considered to be a premalignant condition. Squamous cell hyperplasia is often found in regions adjacent to vulvar cancer, but the relationship of this lesion to invasive cancer is unclear.⁴⁰ Advanced age and race (white) have been shown to be independent predictors of poor outcome.³¹

Although it seems intuitive that vulvar cancer would be relatively easy to diagnose because of the accessibility of the vulva to visual inspection, clinical findings may be subtle. Most patients experience a delay in diagnosis; this happens for a variety of reasons. Women may dismiss symptoms as mild or unimportant and delay seeking medical attention. Alternatively, many physicians treat patients on the basis of their symptoms without performing a biopsy of the lesion. About 50% of vulvar

FIGURE 37.6. Modified radical vulvectomy with inguinal lymphadenectomy. Small unilateral (stage I) lesions may be adequately treated by a modified radical vulvectomy. Shown here are the lines of incision. The depth of the excision is carried down to the pelvic floor fascia and pubic ramus, as for a complete radical vulvectomy. The inguinal incisions shown allow inguinal lymphadenectomy through separate portals. (Reprinted with permission from Clarke-Pearson D, Dawood Y. *Green's Gynecology, 4th Ed.* Little, Brown, Boston, 1990.)

cancer patients experience prolonged pruritis or have an ulcerated or palpable mass on their vulva.

Vulvar cancer is easily mistaken for other conditions. There is no absolute consistency in the appearance of vulvar lesions such as VIN, lichen sclerosis, or squamous cell hyperplasia that allows them to be easily distinguished from vulvar cancer. Therefore, it is best to advise that any suspicious areas should be biopsied. Examination of the vulva should include a thorough inspection of the perineal area, including areas around the clitoris and urethra. Palpation of the Bartholin's glands should be performed as well. Biopsies may be guided by use of toluidine blue dye (1%) or dilute acetic acid. Uptake of blue dye is increased in neoplastic cells with enlarged nuclei. This increased nuclear to cytoplasmic ratio is also responsible for the altered appearance of neoplastic cells treated with acetic acid (causing them to appear more white than surrounding tissues). Abnormally pigmented lesions suspicious for melanoma should be biopsied by a gynecologist or gynecologic oncologist familiar with the anatomy of the region because wide excisional margins are required.

More than 85% of vulvar malignancies are of squamous histology. About 5% of vulvar cancers are melanomas.⁷⁶ Squamous cell cancer of the vulva is usually indolent, growing slowly and metastasizing late in its course. Local extension of the tumor occurs first, followed by lymphatic invasion. In general, lymphatic spread occurs in an organized, progressive fashion with superficial inguinal nodes affected before deeper (inguinofemoral and pelvic) nodal chains become involved.

Staging and therapy are primarily surgical, and the extent of resection is related to the stage of the tumor

and the likelihood of nodal metastases. For lesions with less than 1 mm of invasion, radical wide local excision will suffice. Stage I lesions (≤ 2 cm) can be treated effectively with modified radical hemivulvectomy and ipsilateral superficial inguinal node dissection (Fig. 37.6).⁹⁶ Larger tumors usually require radical vulvectomy and inguinal lymphadenectomy (Fig. 37.7). Larger tumors may also be treated primarily with radiotherapy and concurrent chemotherapy followed by surgical resection of residual disease.⁹⁷ Pelvic exenteration is sometimes employed for women with extensive disease or as a salvage strategy for patients with recurrent cancer.⁹⁸ Postoperative morbidity is related to the extent of the surgery. Therefore, the most conservative operation that can effectively treat the patient's condition is performed.⁹⁹ As with the cancers previously discussed here, elderly patients with vulvar cancer should be allowed to receive the full benefit of optimal surgical therapy, as age alone is a poor determinant of surgical risk.¹⁰⁰

Survival is related to clinical stage and the extent of nodal involvement. Five-year survival for stages I and II vulvar cancer treated by standard surgical means is of the order of 90%. Survival (for all stages) still exceeds 70% in the absence of lymph node metastasis. However, lymphatic spread portends a worse outcome. Patients found to have inguinal lymph node metastases are usually treated with inguinal and pelvic radiation therapy post-operatively. Only one-third of patients survive 5 years if nodal metastasis is present. Involvement of the deeper, pelvic nodes results in a 20% 5-year survival rate. Approximately 80% of recurrences occur in the first 2 years after treatment. The majority of recurrences occur near the site of the primary lesion. Seventy-five percent

FIGURE 37.7. Radical vulvectomy with bilateral inguinal lymphadenectomy. The lines of excision of vulvar and inguinal skin are shown by the *heavy outline*. The inner incision allows an adequate surgical margin and usually is made at the introitus. With the resection, the mons, clitoris, and labia are entirely excised to the depth of the pelvic floor fascia and pubic symphysis. (Reprinted with permission from Clarke-Pearson D, Dawood Y. *Green's Gynecology*, 4th Ed. Little, Brown, Boston, 1990.)

of patients with locally recurrent disease (limited to the vulva) can be salvaged with radical wide local excision.¹⁰¹ In contrast, patients who develop a groin recurrence are rarely curable, and palliative surgical resection is associated with a high risk of complications.

The most common complications of treatment are related to wound breakdown and infection and occur in approximately 15% of patients. Other complications that arise in the early postoperative period include urinary tract infection, hematomas, seromas, venous thromboembolic disorders, femoral nerve injury manifestations, and osteitis pubis. Late complications may include lymphangitis, stress urinary incontinence, lymphocyst formation, introital stenosis, vaginal fistula, femoral hernia, and sexual dysfunction, but the most common late complication is intractable leg edema (lymphedema).

Estrogen replacement can usually be given to these patients. Hormonal treatment may help to maintain the health of surrounding perineal and vaginal tissues postoperatively.

Additional Issues for the Geriatric Patient

Since 1990, Medicare coverage for Pap smears has been available.¹⁰² Presently, Medicare pays only the cost of laboratory analysis; the physician visit is covered only if Medicare-eligible services are rendered. Screening interval has been set at every 3 years under the current guidelines. The law permits provisions for more frequent Pap smears in high-risk women. However, no such benefits have been enacted to date.

Given that elderly women are at particularly high risk of developing malignancies, they should be entitled to receive adequate screening for these cancers. Older women are often uninformed about the importance of screening, and physicians are often reluctant to put elderly patients through the discomfort of a pelvic examination if they are asymptomatic.¹⁰³ Geriatric patients usually can safely undergo radical surgery, dose-intense chemotherapy, and radiotherapy after thorough medical evaluation.^{100,104} Decisions to withhold optimum therapy should be made in conjunction with the patient and should be based on intercurrent medical conditions rather than on age alone.^{105,106}

Treatment for gynecologic cancer commonly influences a woman's image of herself and her sexuality. It is imperative that physicians caring for these patients be sensitive to their concerns. Frank discussions about how treatment for cancer will affect appearance and sexuality must be conducted with the patient and her partner before initiation of therapy. Remediable causes of dysfunction should be corrected and referral for counseling considered if problems persist. It is important that sexual apprehensions be taken seriously and that practitioners recognize the importance of sexual issues to older individuals.¹⁰⁷

Summary

As with other malignancies, gynecologic cancers are best managed if they are detected and treated early. Tumor biology varies substantially for each of the cancers reviewed. Stage for stage, elderly patients tend to have

poorer survival rates than their younger cohorts. Appropriate attention to detail during annual or problem-related examinations and diligence in following screening protocols should allow prompt diagnosis. Age does not preclude aggressive management of cancer. Referral to a gynecologic oncologist is important if the patient is to receive the benefit of the most effective therapy and the option of participation in randomized research protocols involving novel treatments. Hormone replacement therapy, sexuality, and other quality of life issues should be considered when caring for individuals with gynecologic cancer.

Hematologic Malignancies

Marc Gautier, Elizabeth M. Bengtson, Edward M. Liebers, and Harvey Jay Cohen

The hematologic malignancies are a diverse group of disorders that are frequently considered together because they consist of clonal expansions of hematopoietic cells. The cell of origin of many of the hematologic malignancies is known. The stage of differentiation of the transformed cell essentially determines the phenotype of the disorder. Before considering the types of hematologic malignancies, we review the normal differentiation pathway of hematopoietic cells.

Figure 38.1 shows a version of the differentiation pathway from the lymphopoietic stem cell to the lymphoid lineages (T and B). There is also a stem cell (not shown) that matures to the myeloid lineages, giving rise to neutrophils, platelets, red cells, monocytes, eosinophils, and basophils. Steps of the differentiation pathway can be blocked, resulting in a clonal expansion of malignant cells. Thus, multiple myeloma represents an accumulation of the terminally differentiated B cell, whereas pre-B acute lymphocytic leukemia (ALL) represents a less differentiated B lymphocyte. Characteristic cell surface markers including the CD antigen system determine the immunophenotype of the malignant cell and assists in the diagnosis; this helps to differentiate morphologically similar entities. Thus, ALL can be differentiated from acute myelocytic leukemia (AML) by the presence of typical lymphoid cell-surface markers, such as CD10 and CD19. In many cases such distinctions have important therapeutic implications.

Hematologic malignancies disproportionately affect elderly patients. The disorders AML, chronic lymphocytic leukemia (CLL), and multiple myeloma all have characteristic patterns of increasing incidence with advancing age, such that the average age of onset of these diseases is 60 years of age or older. Additionally, other than with the acute leukemias, the clinical onset of hematologic malignancies is typically insidious, mimicking many other disease processes and frequently going unrecognized. As the name implies, many of the chronic malignancies can have an indolent or prolonged course.

Elderly patients are frequently compromised from other comorbid diseases and in the past have not always benefited from interventions such as chemotherapy and radiotherapy because of the associated toxicities. More recently, we have made advances in tailoring therapy to the geriatric patient. More importantly, new approaches to treatment, such as immunotherapy and molecular-targeted therapy, have revolutionized our ability to successfully treat the elderly patient while avoiding significant toxicity.

This chapter examines the acute leukemias (AML and ALL). Myelodysplastic syndromes that frequently evolve into leukemia are also considered. We discuss myeloproliferative disorders and lymphoproliferative disorders, including the lymphomas, the chronic leukemias, and the plasma cell dyscrasias. We emphasize new therapy developments that may impact responses and survival while offering less toxic and more tolerable treatment for the elderly patient.

Acute Leukemias

Acute leukemia, now more accurately referred to as acute nonlymphocytic leukemia (ANLL), is the more common form of leukemia in adults. Acute lymphoblastic leukemia is predominantly a disease of children that accounts for approximately 20% of all acute leukemias in adults.¹ ANLL occurs with increasing frequency with advancing age and frequently is preceded by a more chronic hematologic disorder. Multiple myeloma, polycythemia vera, paroxysmal nocturnal hemoglobinuria (PNH), chronic myeloid leukemia (CML), and the myelodysplastic syndromes all have a high propensity to culminate in acute leukemia. When acute leukemia follows these disorders, the prognosis is significantly poorer than de novo leukemia.

Clinical manifestations of the acute leukemias are similar regardless of the cell of origin (lymphocytic or

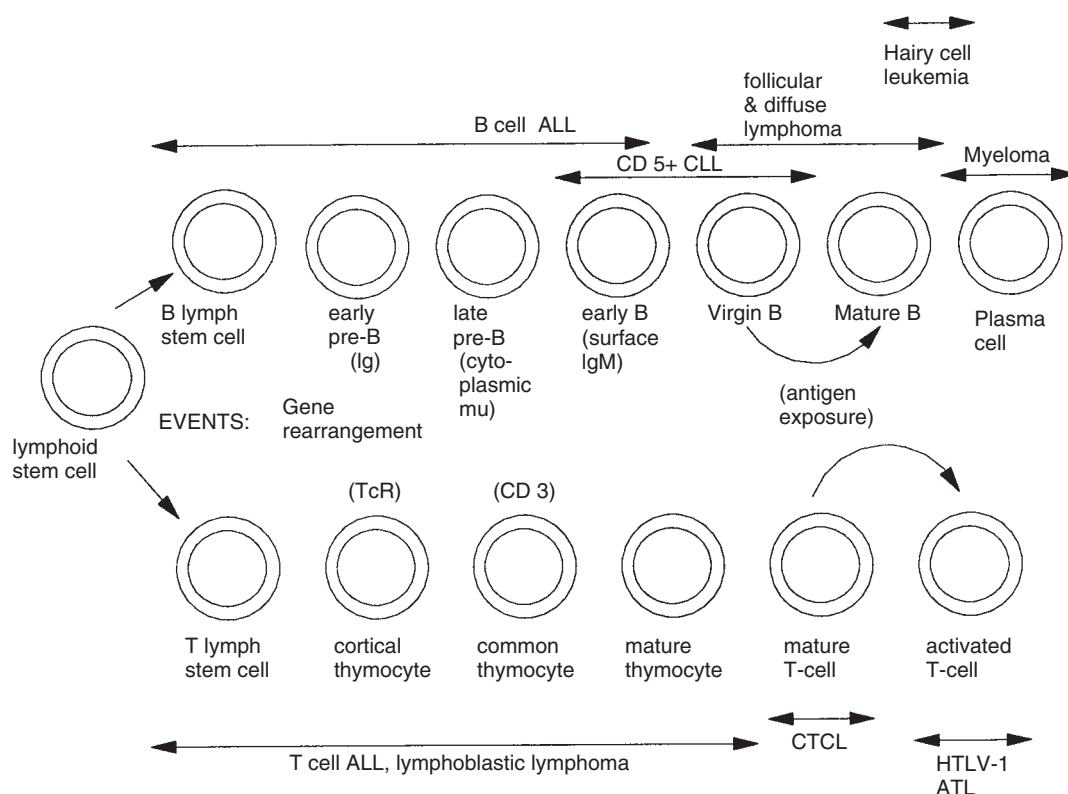

FIGURE 38.1. Diagram of lymphoid differentiation and corresponding disease states. *ALL*, acute lymphocytic leukemia; *CLL*, chronic lymphocytic leukemia; *CTCL*, cutaneous T cell

lymphoma; *HTLV-1*, human T-cell leukemia virus 1; *ATL*, adult T-cell leukemia-lymphoma.

myelogenous). Typically there is an abrupt onset of non-specific complaints, including fatigue, anorexia, weight loss, and weakness. Hematologic abnormalities frequently lead to the presenting symptoms; thus, anemia contributes to fatigue, thrombocytopenia leads to bleeding and bruising, and lack of mature neutrophils can lead to serious infections and concomitant fevers. Those patients who evolve into AML from a preceding hematologic disorder tend to have a more chronic evolution in their symptoms. The presence of anemia, thrombocytopenia, and granulocytopenia with circulating blast cells are the hallmark of acute leukemia. The marrow, when examined, is hypercellular with a lack of differentiation and a predominance of blasts.

The etiology of the acute leukemias is not completely understood but is thought to be the result of multiple genetic aberrations to a clone of hematopoietic cells. Many genetic defects have been associated with both acute myelogenous leukemia and acute lymphocytic leukemia. These genetic defects tend to be chromosomal translocations and frequently when characterized have involved so-called oncogenes.² Many of these abnormalities are thought to be etiologically involved in the evolution of leukemia.

Classification

The acute leukemias are broken down into acute non-lymphocytic leukemia, of which there are seven types, and the acute lymphocytic leukemias, of which there are three types. The lymphocytic leukemias and their subtypes are differentiated from the nonlymphocytic leukemia by the combination of morphology, immunophenotype, and cytogenetics. In some cases, the distinction can be very difficult. Nonetheless, it is important because therapy is directly related to the cell of origin of the leukemia. The most characteristic morphologic features distinguishing acute nonlymphocytic from acute lymphocytic leukemias are the presence of Auer rods and peroxidase stain positivity, which defines the leukemia as acute nonlymphocytic.

Treatment

Acute leukemias have a fulminant course if left untreated, with a median survival of less than 4 months. Death secondary to cytopenias is the rule, with bleeding and infections being very common. The goal of treatment is to induce remission, and currently that requires inten-

sive chemotherapy for both ALL and ANLL. The initial induction chemotherapy is intended to be myeloablative, and thus a prolonged period of cytopenia follows the initiation of therapy.

The chemotherapeutic agents used for remission induction depend on the classification of the leukemia. AML is usually treated with a combination of two drugs, usually cytarabine and an anthracycline such as daunorubicin, given over several days to 1 week. The likelihood of attaining a complete response (CR) with this regimen in patients over 60 is approximately 50% as compared to 70% for younger patients.³ Factors playing a role in the inability of this group of patients to achieve remission is the high incidence of preexisting hematologic disorders, such as myelodysplastic syndrome, chromosomal abnormalities, and chemotherapy resistance. All of these are poor prognostic factors for achieving remission at any age. In addition to difficulty attaining CR, treatment-related mortality associated with induction can be as high as 25% to 50% in patients over 60 years old as compared to 5% to 15% in younger patients.³

The requirements for supportive care through the period of induction are enormous, and in general only hematologists experienced in the care of leukemic patients with adequate blood bank support should treat these patients. Although it has been suggested that a reduced dose of induction therapy is more effective in elderly patients, this remains a controversial area. Several trials have studied the use of hematopoietic growth factor support (G-CSF or GM-CSF) during induction. The growth factors shorten the time of neutropenia but did not impact on early mortality or long-term survival.⁴

Once remission is achieved, additional postremission or consolidation chemotherapy is administered to maximize the odds for a prolonged remission. Several trials support the use of less intense chemotherapy for the elderly during this period without jeopardizing long-term survival.⁵

Much of the effort to have impact on the acute leukemias has been centered on intensification of induction therapy and consolidation therapy with bone marrow transplantation support. This strategy is generally not available to patients over the age of approximately 60 and thus remains of limited value to those patients most commonly affected by these diseases. A more promising approach is the use of molecular targeted therapy. Acute promyelocytic leukemia (APL), a subtype of acute myeloid leukemia, is defined by a t(15:17) chromosomal translocation.⁶ This translocation involves one of the retinoic acid receptor genes. All-*trans* retinoic acid (ATRA) induces differentiation of leukemic blasts and results in a significant remission. With the use of ATRA, induction doses of chemotherapy in APL have been reduced and the prolonged cytopenia following induction has been significantly decreased. In the future,

we may know enough about the pathophysiology of the various forms of leukemia that therapy can be tailored in a much more specific manner, sparing the normal hematopoietic clones.

ALL, which is less common in adults, is treated with multiple drugs. Four drugs are frequently used for induction: vincristine, prednisone, L-asparaginase, and daunorubicin. ALL has rapidly become a curable disease in children, but results in adults are less favorable. Central nervous system treatment is required in all patients. In ALL, once remission is achieved, approximately 2 years of maintenance and consolidation therapy is currently the standard.

Future Directions

As mentioned, most of the progress to date in treating leukemia has centered on optimizing myeloablative approaches. Bone marrow transplantation, which represents the extreme of this approach, was not previously an option in older patients. However, a new approach, the submyeloablative bone marrow transplant, offers a potential cure for some patients over 60 as well. The basis of this approach involves lower doses of chemotherapy with reliance on graft versus leukemia effect to ultimately clear the malignant clone. We need to await results of early trials before we can judge the long-term success of this approach.

Research in immunotherapy is advancing rapidly and offers effective therapy with isolated toxicity. Gemtuzumab ozogamicin (Mylotarg) is an anti-CD33 antibody conjugated with a cytotoxic antitumor antibiotic. CD33 is an antigen found on the surface of myeloblasts. This approach specifically targets the myeloblast and spares other hematologic differentiation pathways. How this cytotoxic antibody will be used in the treatment of acute myeloid leukemia is yet to be determined. Aggressive research and development of molecular-targeted therapy and immunotherapy offers hope for effective treatment options with less toxicity in the future.

Myelodysplasia

The myelodysplastic syndromes (MDS) are a collection of disorders that predominately affect older patients with the median age of 63 at diagnosis. MDS is a heterogenous group of disorders characterized by abnormal growth of the myeloid bone marrow components. This section examines the common mechanism believed to underlie the MDS and then relates that to the propensity of these conditions to evolve into acute leukemia. In addition, we discuss the classification, natural history, and treatment options for MDS.

Pathogenesis

The pathogenesis of MDS is complicated. Current theory holds that MDS results from chromosomal injury that occurs in stepwise progression. Beginning with an initial predisposition to genomic instability, progressive insults result in chromosomal damage that culminates in MDS and can further progress to AML. Common chromosomal alterations involve 5, 7, 8, and 20. The involved chromosome areas are usually rich in hematopoietic genes. In addition to gross chromosome alterations, submicroscopic DNA mutations result in abnormal oncogene expression. Because of secondary DNA damage, exposure to chemicals or prior chemotherapy increases the risk for developing MDS. Although these genes may play a pathologic role in the development of MDS, we still do not understand the critical molecular events that lead to these diseases. The progression of MDS to leukemia is likely the result of additional genetic mutations that provide the evolving clone further growth advantages.

The biology of the disease is further complicated by other abnormalities, including aberrant cytokine production and responsiveness, altered stem cell adhesion, abnormal marrow microenvironment, early cell death secondary to accelerated apoptosis, and immunomediated marrow suppression. With all these contributing factors, MDS is ultimately a clonal hematopoietic stem cell disorder characterized by ineffective hematopoiesis and peripheral cytopenias.

Classification

The WHO classification system was recently proposed to replace the previous FAB classification system.⁷ Some of the subsets are listed here. The distinction among these groups is based on the appearance of the bone marrow. The clinical presentation, however, can be very similar. Low blood counts (cytopenias) are the hallmark, and anemia occurs in the majority of patients. Isolated neutropenia or thrombocytopenia also occurs, but the usual picture is trilineage cytopenias. On examination of the peripheral blood, abnormal morphology is usually apparent. The findings in the marrow are more obvious, with hypercellularity, bizarre nuclear morphology, abnormal iron granules (sideroblasts), and nuclear/cytoplasmic maturation dysynchrony evident. All lines are affected, although frequently one lineage is more markedly dysplastic. An important determinant of overall prognosis is the percentage of blast cells in the bone marrow.

Some of the major types of MDS are (1) refractory anemia (RA); (2) refractory anemia with ringed sideroblasts (RARS); (3) refractory anemia with excess of blasts (RAEB); and (4) chronic myelomonocytic leukemia (CMML). CMML has features of both the dysplastic syndromes and the myeloproliferative disorders

(discussed in the next section). There is usually a significant increase in circulating monocytes, as well as trilineage dysplasia in CMML. This classification system is dependent on the percentage of blast cells in the marrow and also stratifies the risk of progression to leukemia. The risk of leukemia is low (5%–15%) in RA and RARS and higher (20%–40%) in RAEB. Still, up to 50% of patients with MDS die of complications of cytopenias rather than leukemia. The classification system also predicts median survivals, ranging from about 60 months for RA to less than 2 years for RAEB.

The International Prognostic Scoring System (IPSS) has been proposed, which identified significant prognostic indicators;⁸ these include the number of cytopenias, percentage of blasts, and cytogenetic features. This system may be more useful in comparing results of interventions across clinical trials.

Treatment

Treatment of MDS remains problematic. For younger patients with high-grade disease, intensive chemotherapy and bone marrow transplant have been successful. Autologous and submyeloablative allogeneic bone marrow transplants are now being offered to older patients; however, the majority of older patients are still excluded because of either age or comorbid illness. Acute myelocytic leukemia (AML)-type treatment has produced some improvement in patients with severe disease, but this is usually transient and not generally applicable to elderly patients.

Less aggressive treatment options are actively being developed. Most are not of curative intent, but hematologic response and overall survival can be influenced. Use of recombinant growth factors to stimulate an increase in specific lineages has been explored recently. The use of myeloid growth factors has been approached cautiously because of fear of increasing the risk of leukemia. Trials of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) were effective in improving peripheral neutropenia but did not influence leukemic transformation, hemoglobin levels, or overall survival. G-CSF and GM-CSF are not recommended for routine therapy.

Erythropoietin can improve anemia in MDS with an overall response rate of 16%. However, subgroup analysis reports response rates as high as 40% in patients with RA (versus RARS and RAEB) and low serum erythropoietin levels. The addition of G-CSF to erythropoietin can induce erythroid responses in erythropoietin-resistance patients. The mechanism of synergy is unknown. A predictive model for treatment with G-CSF and erythropoietin found the highest response in patients who have low serum erythropoietin levels and low RBC transfusion requirements.

Low-dose chemotherapy has met some success in older patients. Low-dose Ara-C induces a response in 30% of patients. Whether this translates to a survival advantage is unclear. More recently, melphalan has emerged as a well-tolerated oral chemotherapy regimen, with response rates as high as 40% and a significant improvement in survival. Additionally, 5-azacytidine trials report a response rate of 50% to 60% with tolerable toxicity and improved survival.

Future Directions

Research is opening new frontiers in treatment of MDS. Thalidomide, an immunosuppressant and angiogenesis inhibitor, shows promise in preliminary trials. Anti-thymocyte globulin and cyclosporin are being explored as immunosuppressive agents capable of modulating disease. Finally, cytokine inhibition trials with amifostine and pentoxifylline are underway. As we learn more about the pathophysiology of MDS, we will be able to better tailor therapy to effectively treat the disease with less toxicity.

Myeloproliferative Disorders

The myeloproliferative disorders are a group of diseases characterized by excessive proliferation of the myeloid elements secondary to a defect in the hematopoietic stem cell. As discussed earlier, the myeloid elements consist of erythrocytes, platelets, and the granulocytes, and there are disorders associated with the proliferation of each of these lines. These diseases are chronic in nature but tend to culminate in a more acute picture, such as acute leukemia. We consider four clinical expressions of the myeloproliferative disorders:

1. Chronic myelogenous leukemia (CML), with a predominant increase in the granulocytes
2. Polycythemia vera (PV), with a predominant increase in the red cells
3. Essential thrombocythemia (ET), with a predominant increase in the platelets
4. Myeloid metaplasia with myelofibrosis (MMMf), with a progressive fibrosis of the bone marrow with relocation of hematopoietic tissues to extramedullary sites

Chronic Myelogenous Leukemia

CML is a clonal stem cell disorder, characterized by increased proliferative capacity in the myeloid lineage, that is almost universally associated with a typical chromosomal translocation known as the Philadelphia chromosome. This is an acquired disorder, and although no specific etiologic agent has been identified, radiation

exposure does lead to a significant increase in risk. There is an increasing incidence with advancing age, but the average age remains in the fifth and sixth decades of life.

The characteristic Philadelphia chromosome is a result of translocation of genetic material from chromosome 9 to chromosome 22. The gene on chromosome 9 has been identified as the Abelson proto-oncogene (*abl*). The region on chromosome 22 has been defined as the break-point cluster region (*bcr*). The rearrangement creates a *bcr/abl* fusion gene, which is believed to be pathophysiologically involved in the development of leukemia. Depending on the sensitivity of the detection method for the presence of the *bcr/abl* rearrangement, upward of 95% of all cases of CML demonstrate this very typical 9:22 translocation.⁹

The clinical characteristics of CML involve a standard triphasic course of the disease, with an initial chronic phase followed by an accelerated phase and culminating in a blast phase, with the entire course of the disease spanning an average of approximately 3 years. The typical findings at the time of diagnosis include an elevated white blood cell (WBC) count, which may be mild or can exceed 200,000 cells/mL. Anemia or thrombocytopenia may contribute to the presenting symptoms. The most frequent complaints include fatigue, anorexia, abdominal discomfort, and early satiety related to splenomegaly and are generally gradual in onset. Splenomegaly is the most common physical finding, with more than 90% of the cases demonstrating an enlarged spleen. The accelerated phase of CML is heralded by progressive leukocytosis, despite therapy with worsening cytopenia and progressive splenomegaly. Blast crisis has the same clinical presentation as acute leukemia.

The diagnosis of CML is confirmed by the presence of a marked increase in granulocytes with the presence of immature myeloid cells in the peripheral blood. There is usually not a significant peripheral blast count. Eosinophils and basophils in the peripheral blood are common. Leukocyte alkaline phosphatase is typically low or zero in CML. The bone marrow shows hypercellularity with predominantly granulocytic differentiation. The presence of splenomegaly is further evidence for the diagnosis of CML. Chromosomal evidence of the Philadelphia chromosome is confirmatory; however, a rare case of Philadelphia chromosome-negative CML exists.

Treatment

The treatment of CML is beginning to reap the benefit of decades of research into the pathophysiology of the disease. Until recently, there were no curative therapeutic strategies, and the therapeutic goal was to maintain controlled myelopoiesis in the chronic phase and accelerated phase; however, no therapy was known to delay

the conversion to the accelerated phase (or blastic phase) of CML. Standard therapy has consisted of hydroxyurea delivered at 1 to 3 g per day by mouth, with a goal of maintaining the WBC count between 10,000 and 20,000. Direct inhibitors of the *bcr/abl* fusion protein are now able to impact on the disease with minimal toxicity.

Interferon-alpha has been shown to improve the survival of patients with CML compared with treatment with hydroxyurea. Interferon-alpha is generally initiated at 3 to 5 million units subcutaneously per day, and the response is maintained with a 3- to 5-day per week treatment schedule. Flu-like symptoms are common but frequently can be managed with acetaminophen.

Interferon-alpha improved the rate of karyotypic response, as well as the time of progression from chronic phase to accelerated or blastic phase, and was associated with a significant improvement in overall survival (72 months versus 52 months for hydroxyurea).¹⁰ Addition of chemotherapy can improve the percentage of patients achieving a cytogenetic remission. Unfortunately, few older patients have been included in the reported trials.

Bone marrow transplant has been an attractive option for younger patients; in fact, preliminary results suggest early transplant in the chronic phase is associated with the best outcome for those patients who have a human leukocyte antigen- (HLA-) compatible sibling. Unfortunately, two-thirds of the patients diagnosed with CML are either considered too old to undergo this intensive therapy or do not have HLA-compatible siblings.

The development of compounds to directly inhibit the *bcr/abl* fusion product has been a promising area of research. The fusion protein is a unique tyrosine kinase, and the first FDA-approved inhibitor of this kinase has recently been approved for patients with CML who cannot tolerate or have not responded to interferon. Initial results of the oral drug suggest excellent activity with minimal toxicity,¹¹ which may be particularly important to elderly patients who tend to tolerate high doses of interferon poorly. A randomized trial comparing the oral kinase inhibitor (Gleevec) to interferon plus chemotherapy for newly diagnosed patients with CML is ongoing. It is possible that the payoff for years of research will be realized soon.

Polycythemia Vera

Polycythemia vera (PV) is a myeloproliferative disorder with excessive proliferation of red cells, megakaryocytes, and myelocytes. It is usually an insidious disease with gradual onset and can be associated with prolonged survival if the cytosis is controlled. Splenomegaly is common and is frequently one of the presenting features. The clinical course of PV can be quite varied. With uncontrolled proliferation of red cells and platelets, an increase in whole blood viscosity can occur, leading to impairment

of blood flow to critical organs. Central nervous system and cardiovascular symptoms, including confusion, angina, and claudication, can occur as a result of insufficient oxygen delivery. Thrombotic complications are a significant cause of morbidity and mortality, with strokes, myocardial infarctions, arterial occlusions, and thromboembolic complications being common. There is also an increased risk of hemorrhage.

The long-term course of PV can include distinct phases. Initially, an asymptomatic phase may be associated with only mild elevation of the red cell mass and mild splenomegaly; this gives way to an erythrocytic phase associated with pancytosis, with complications such as thrombosis and hemorrhage. An inactive phase may ensue in which no therapy is required to control the proliferative cells, and eventually a postpolycythemic myeloid metaplasia phase can develop with evidence of marrow fibrosis and extramedullary hematopoiesis. A significant percentage of patients with PV will culminate in acute nonlymphocytic leukemia. The ongoing management of patients during the erythrocytic phase affects the risks of developing this devastating outcome.

Although PV increases in incidence with advancing age, there is a wide range of ages, including some childhood cases. There is no known cause, and surprisingly there is no link to radiation exposure. In mice, the friend erythroleukemia virus causes a similar disease, but no viral infection has been found associated with PV in humans.

The diagnosis of PV rests on a combination of clinical and laboratory findings. The polycythemia study group established the diagnostic criteria shown in Table 38.1. The most important step is to confirm that the red cell mass is actually increased using chromium-51 red cell labeling and a plasma volume study. In many patients with apparently elevated hematocrit, the red cell mass is normal and the plasma volume is below normal or reduced, giving a spuriously increased hematocrit without true polycythemia; this effect can be seen in

TABLE 38.1. Criteria for diagnosis of polycythemia vera.^a

Category A
(1) Significantly elevated red cell mass
(2) Arterial blood oxygen saturation $\geq 92\%$
(3) Splenomegaly
Category B
(1) Thrombocytosis $>400,000 \mu\text{L}$
(2) Leukocytosis $>12,000 \mu\text{L}$
(3) Increased leukocyte alkaline phosphatase score in absence of fever or infection
(4) Serum vitamin B ₁₂ level greater than 900 pg/mL or vitamin B ₁₂ -binding capacity greater than 2200 pg/mL

^aDiagnosis of polycythemia vera if A1 + A2 + A3 or A1 + A2 + any two factors from category B.

patients on a diuretic or patients known to have spurious erythrocytosis.

Once the red cell mass is confirmed to be elevated, other primary causes must be evaluated. Hypoxia either from lung disease or as a result of an abnormal hemoglobin variant, as well as erythropoietin-producing renal tumors, needs to be evaluated. The leukocyte alkaline phosphatase score is frequently elevated as opposed to the situation in CML.

Treatment for the patient with PV needs to be individualized. Phlebotomy can reduce the hematocrit quickly. However, in elderly patients, one has to be careful to avoid inducing significant hemodynamic changes that could further compromise the circulation. Very few patients are managed with phlebotomy alone.

The PV study group evaluated three common treatments: phlebotomy, ³²P, and chlorambucil. None of these treatments was without shortcomings.¹² Patients who were managed with phlebotomy alone had a significantly increased risk of thrombotic complications, which appears to be independent of the level of hematocrit or platelet count. Patients treated with ³²P or chlorambucil had a markedly increased risk of developing acute leukemia. Hydroxyurea has emerged as a primary option for many patients. It is well tolerated, and, although not devoid of mutagenic risks, it appears to have significantly less risk than alkylating therapy for the development of acute leukemia.

The goal of therapy should be to maintain the hematocrit in the range of 42% to 45%. There is a direct relationship between the level of hematocrit and the risk of vascular occlusive episodes. Other goals of therapy include control of the frequently associated pruritis with histamine antagonists. Elective surgical procedures should be delayed until counts have been controlled for at least 2 months to reduce the risk of hemorrhage or thrombosis. Aspirin and other antiplatelet agents have not been proven to reduce the risk of thrombotic events and may, in fact, increase the risk of hemorrhage and are not routinely recommended. The prognosis for patients with controlled PV is excellent as compared with the other hematologic malignancies. Long-term survival is common.

Future directions for patients with polycythemia vera include the use of interferon-alpha. In early studies, it appears to be active in reducing the red cell mass and platelet counts.¹³ Although side effects of interferon continue to limit its use in older patients, it can be useful in patients with extreme thrombocytosis.

Essential Thrombocythemia

Essential thrombocythemia (ET) is a myeloproliferative disorder defined as a persistent isolated platelet count above 600,000/mL. It is frequently accompanied by a

marked increase in megakaryocytes in the bone marrow, and on physical examination splenomegaly is common. Patients frequently develop complications with both thrombosis and hemorrhage.

The exact incidence of ET is unknown, although it is not a rare disorder. There is no known etiology. The major clinical manifestations are related to the elevated platelet count, resulting in either hemorrhagic or thrombotic episodes. Elderly patients can be particularly prone to these additional thrombohemorrhagic complications because of other comorbid conditions. The platelets in patients with ET are qualitatively abnormal, and this may explain why the frequency of thrombohemorrhagic complications is not directly related to the absolute number of circulating platelets.

The diagnosis is made on the basis of a sustained and unexplained increase in the platelet count. It is important to distinguish primary thrombocythemia from reactive thrombocytosis, as well as to consider the possibility of another myeloproliferative disorder associated with an elevated platelet count. Some of the important causes of secondary thrombocytosis that should be considered in a differential diagnosis include iron deficiency anemia, occult carcinoma, chronic inflammatory conditions such as rheumatoid arthritis and inflammatory bowel disease, and acute or chronic infections. Treatment for patients who have reactive thrombocytosis should be directed at the underlying etiology regardless of the platelet count because these patients rarely develop thrombohemorrhagic complications despite markedly elevated platelet counts.

Treatment

The treatment of ET is usually with hydroxyurea, and the goal is to control the platelet count to around 500,000/mL. The important point is that many patients can be observed without therapy until the platelet count approaches 1 million. Older patients may need to be treated somewhat earlier because of their otherwise increased risk for thrombohemorrhagic complications. Previous studies using busulfan and ³²P have demonstrated increased toxicities, and these therapies are no longer standard for ET. The prognosis is similar to that of PV, with prolonged survival possible. Hemorrhage or thrombotic complications frequently contribute to morbidity and mortality. Some patients will evolve to myelofibrosis or acute leukemia.

Future Directions

The new antiplatelet agent anagrelide can inhibit platelet aggregation and platelet production. Interferon-alpha has some activity in this disorder. Combinations of these agents, with or without hydroxyurea, may represent an improvement in the management of patients with ET.

Carefully controlled trials are needed to assess these issues.

Myeloid Metaplasia with Myelofibrosis (MMMMF)

MMMMF is an unusual clonal disorder sometimes also known as idiopathic myelofibrosis. Gradual fibrosis of the marrow space with extramedullary hematopoiesis is the typical course. Splenomegaly is common. An examination of the peripheral blood film shows the presence of nucleated red blood cells and teardrop forms that are the characteristic leukoerythroblastic findings. The incidence of MMMF is unknown, but it tends to be a disease of the elderly, with an average age of approximately 60 years.

The malignant transformation appears to occur at the level of the stem cells, with a dense collagen fibrosis developing in the marrow space. There is no known etiology. The clinical manifestations relate to either the presence of splenomegaly or the consequences of anemia or other cytopenia. Rarely, sites of extramedullary hematopoiesis appearing in the pulmonary, gastrointestinal, central nervous, or genitourinary systems have been the presenting finding for occult MMMF.

As noted, the peripheral blood smear typically shows teardrop poikilocytes, confirming the leukoerythroblastic blood picture. Nucleated red blood cells and immature myeloid elements are also frequently seen. There are variable effects on circulating white cells and platelets. The diagnosis is made on the basis of the characteristic clinical findings and the presence of fibrotic marrow, which can be more accurately assessed histologically with the aid of a reticulin stain. Many conditions can lead to secondary fibrosis of the marrow, including lymphoma, carcinoma, and chronic diseases such as TB and histoplasmosis, as well as some of the other myeloproliferative syndromes as previously mentioned, and these need to be ruled out before a primary diagnosis is made.

Therapy for MMMF is unsatisfactory. In general, a conservative management strategy is adopted, although some authors have suggested that chemotherapy early in the course of disease can be beneficial. Symptomatic patients generally require symptom-directed therapy. Thus, anemia is treated with transfusion, as well as complete evaluation for other coexistent disorders such as nutrient deficiencies. Androgen stimulation is also frequently used.

Symptoms of splenomegaly, such as early satiety, are treated with measures to induce reduction in splenic size. Chemotherapy with hydroxyurea, ³²P, and other agents has been used with some, at least short-term, success. Interferon has been used successfully to shrink splenomegaly but has frequently resulted in worsened cytopenias. Splenic radiation has also been used, but

usually a short duration of response is seen. Splenectomy is a controversial issue.¹⁴ It is indicated for patients with severe thrombocytopenia, uncontrolled hemolysis, or painful splenomegaly that is refractory to other methods of control. However, there is a significant perioperative mortality rate. The prognosis for MMMF is worse than that for essential thrombocythemia and polycythemia vera. Average survival is approximately 5 years.

Lymphoproliferative Disorders

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is the most common form of leukemia in the United States. This prevalence is due to two factors. First, the incidence of CLL rises with advancing age with the median age in the sixties. As noted previously, the population over the age of 60 continues to grow. Second, patients with CLL can experience a long survival, with median survival approaching 6 years. Thus, the prevalence of the disease is quite high.

CLL is generally a neoplasm of activated B lymphocytes. The leukemic cell morphologically resembles mature small lymphocytes normally seen in the peripheral blood. A sustained blood lymphocyte count that is greater than $10 \times 10^3/\text{mL}$ has been required to diagnose CLL. Additionally, 30% of nucleated cells in the bone marrow should be lymphocytes, and the peripheral blood lymphocytes should be positive for B-cell markers. In some clinical situations, CLL can be diagnosed with fewer total lymphocytes if surface markers confirms a monoclonal population of typical lymphocytes.

The exact cell of origin in CLL is unknown. Although 95% of patients have a B-cell phenotype, T-cell CLL can rarely occur. The typical B-cell CLL does stain positive with antibody to CD5, which is normally a T-cell antigen, and this has been taken to imply that the malignant cell is arrested at an intermediate stage of B-cell differentiation. Other diseases, such as hairy cell leukemia, to be considered later, are thought to result from the malignant transformation of a lymphocyte at a different stage of development.

The etiology of CLL is also unknown. Retroviruses and ionizing radiation, which lead to other forms of leukemia, apparently do not increase the risk for CLL. Interestingly, the incidence of CLL is far less in Japan than in Western populations. In addition, there is an increased risk of a variety of autoimmune disorders in relatives of patients with CLL, implying a genetic predisposition to the development of lymphocytic disorders.¹⁵

The lymphocytes in CLL usually express a specific surface immunoglobulin, although at low intensity. Normal control of antibody production in patients with

TABLE 38.2. Staging systems for chronic lymphocytic leukemia (CLL).

	Rai	Binet	Expected median survival (years)
Lymphocytosis	O	A	8–10
Lymphadenopathy	I	BI ^a	5–6
Hepatomegaly/splenomegaly	II	BII	5–6
Anemia	III	C	2.5
Thrombocytopenia	IV	C	2.5

^aThree or more groups of lymph nodes must be positive.

CLL is disrupted. There is a marked reduction in normal antibody production manifested as a diffuse hypogammaglobulinemia, resulting in a high incidence of infections. On the other hand, there is a paradoxical increase in autoimmune complications, including hemolytic anemias. This dysregulation is an exaggeration of the phenomena seen in normal aging.

The diagnosis and staging of CLL has produced two excellent classification systems, one by Binet and one by Rai. Recently, these two staging systems have been combined and are represented in Table 38.2, along with the expected median survivals. There are a few points worth making regarding the stage of CLL at the time of diagnosis.

Approximately 25% of patients present with only a lymphocytosis in the peripheral blood and the marrow but no evidence of lymphadenopathy, organomegaly, or other cytopenias. These patients have an exceedingly good prognosis and in general should not undergo any therapy unless their disease progresses. The development of multiple enlarged lymph nodes, hepatomegaly, or splenomegaly mark progression to stage B disease. The development of either anemia or thrombocytopenia on the basis of marrow compromise portends a significantly worse prognosis.

The treatment of CLL has, in general, been aimed at controlling the disease rather than curing it. Therapy is withheld until significant cytopenias or symptomatic lymphadenopathy or organomegaly develops. In general, treatment is initiated with an alkylating agent. Most frequently chlorambucil is used, in either low daily doses or pulses from 2 to 4 weeks. Fludarabine is an active agent for the treatment of CLL. It produces a higher rate of complete remissions and a longer duration of response than chlorambucil.¹⁶ This agent has response rates of 50% to 80% in both previously untreated as well as treated patients. Overall survival is not improved, and because fludarabine is associated with increased toxicity, especially for older patients with renal impairment, many clinicians use it only after failure of chlorambucil. Other alkylating agents such as cyclophosphamide are also effective. Prednisone is usually given with the alkylating

agent and sometimes alone for patients with manifestations of autoimmune phenomena.

Unfortunately, the course of CLL is progressive despite initiation of therapy. Several attempts have been made to predict the course of patients with CLL more accurately than the current staging system. At least two criteria appear to suggest rapid progression of disease. The rate of increase of blood lymphocytes has long been recognized to be a useful indicator of prognosis. Most authors recommend a period of observation before initiating cytotoxic therapy in an effort to evaluate the pace of the disease. A doubling of lymphocytes in the peripheral blood in less than 1 year is associated with a worse prognosis. Investigators have also reported that the pattern of bone marrow infiltration with lymphocytes is prognostic. Patients with a diffuse lymphocytic infiltration have more rapid progression of their disease than patients with nodular involvement of the bone marrow.

Future Direction

Recently, there has been renewed interest in immunotherapy of CLL. Recombinant monoclonal antibodies have demonstrated activity against this disease. Campath 1-H is approved for patients with CLL who have failed fludarabine. This modified antibody recognizes the CD-52 antigen on the surface of CLL lymphocytes and can initiate antibody-dependent cell-mediated cytotoxicity (ADCC), as well as activate the complement cascade causing death of CLL cells.¹⁷ There is a considerable infusion-related reaction with the drug, and patients can be immunosuppressed because of the resultant lymphopenia resulting in reactivation of latent CMV. Nonetheless, this new avenue of attack may prove quite beneficial to elderly patients.

Supportive therapy is very important for patients with CLL because of the many associated clinical phenomena. Autoimmune phenomena, such as anemia or thrombocytopenia, can be treated with a steroid alone without cytotoxic therapy. Pure red cell aplasia, which occasionally occurs, may respond to either cyclosporin or antithymocyte globulin (ATG). Recurrent infections with encapsulated organisms frequently result from the hypogammaglobulinemia that occurs in these patients. The mainstay of therapy is prompt initiation of appropriate antibiotics. However, intermittent intravenous gamma globulin can be effective in reducing the frequency of infections, especially in those patients with very low levels of serum immunoglobulin G (IgG).¹⁸

Hairy Cell Leukemia

Hairy cell leukemia is another chronic lymphoproliferative disorder that is now known to be a clinical entity distinct from CLL. Similar to CLL, it is a proliferation of

neoplastic B lymphocytes. Hairy cell leukemia cells also expresses the receptor for interleukin 2 known as CD-25; this suggests that the arrest in differentiation for these lymphocytes occurs later than that for CLL but earlier than that of the lymphocytes in myeloma.

Most patients with hairy cell leukemia present with pancytopenia. Circulating hairy cells are seen in approximately 90% of the cases. The typical hairy cell is a large lymphocyte with an eccentric nucleus, and the cytoplasm typically has fine irregular projections. The tartaric acid-resistant acid phosphatase (TRAP) stain, although not specific, is usually positive because of increased levels of an isoenzyme in these cells. The majority of patients present with complications of cytopenia, and 80% will have splenomegaly.

Treatment

Therapy for hairy cell leukemia has undergone a rapid change over the last few years. In fact, the hematologist is now confronted with choosing from more than one highly effective therapy. Historically, initial therapy was splenectomy. This intervention usually improved the cytopenias but only provided transient benefits. Subsequently, interferon-alpha demonstrated significant activity with a response rate of close to 80%.¹⁹ Some patients (about 10%) achieved complete responses. Once interferon was stopped, relapses were common, but frequently patients would respond to another course of treatment with interferon.

Most recently, deoxycoformycin and chlorodeoxyadenosine (2-CDA) have demonstrated remarkable activity.²⁰ Deoxycoformycin appears to be active even in those patients who fail interferon, whereas 2-CDA has an extremely high complete response rate and, in fact, may be curative after a single course of therapy.

With such impressive therapy, the indications for initiation of therapy have been reevaluated. In general, up to 20% of patients with hairy cell leukemia have a very indolent form of the disease and may never require therapy. It is important to spare these patients the potential morbidity of treatment. The indications to consider therapy include significant cytopenias, repeated infections, massive or painful splenomegaly or lymphadenopathy, or vasculitis. Close observation for those patients without these indications is warranted.

Plasma Cell Dyscrasias

The lymphoproliferative disorders are malignant transformations of lymphocytes. The clinical syndromes corresponding to each diagnostic category result from the characteristic behavior of the transformed cell. The end stage of B-lymphocyte development is the plasma cell producing large amounts of immunoglobulin. The malig-

nant transformation of cells with this degree of differentiation represents a group of diseases termed the plasma cell dyscrasias or plasma cell proliferative disorders.

A spectrum of clinical conditions exists from monoclonal gammopathy of uncertain significance to multiple myeloma, Waldenstrom's macroglobulinemia, and amyloidosis. However, it is the production of immunoglobulin by a plasma cell that ties these diseases together.

Normal B-cell development involves production of one of the five classes of immunoglobulins. The earliest event in B-cell development involves rearrangement of the germline immunoglobulin genes to produce a unique immunoglobulin. Ultimately, a specific immunoglobulin of the IgM class is made. Subsequently, the cell is able to alter the class of immunoglobulin (IgG, -A, -D, -E) while retaining the unique antigenic recognition sites. Each clone of cells produces only one immunoglobulin with one heavy chain (G, A, M, E, D) and one light chain (kappa, lambda). Protein electrophoresis and immunoelectrophoresis can detect the production and secretion of these immunoglobulins or their components (a light chain or heavy chain). The abnormal accumulation of monoclonal immunoglobulin in the serum is frequently called an M spike and is usually one of the early clues to the diagnosis of plasma cell dyscrasias.

Monoclonal Gammopathy of Uncertain Significance

Monoclonal gammopathy of uncertain significance (MGUS) is a relatively common condition that increases in older patients. The definition of monoclonal gammopathy of uncertain significance is somewhat problematic. In essence, it represents the presence of an M spike without an underlying diagnosis of multiple myeloma, Waldenstrom's macroglobulinemia, or amyloidosis. Formerly known as benign monoclonal gammopathy, it is no longer called this because a significant proportion of patients ultimately will develop one of the aforementioned diseases. In this way, it can be considered one step in the multistep pathway to oncogenesis.

MGUS is defined as having an M spike of IgG less than 3.5 g/dL or IgA less than 2 g/dL or the presence of a small amount of urinary light chain in the urine in 24h. The plasma cells in the marrow cannot exceed 10%, and there can be no lytic bone lesion or other symptoms related to a lymphoproliferative disorder. Finally, a stable level of monoclonal protein characterizes MGUS. MGUS is common and, like myeloma, shows an increasing incidence with advancing age. As many as 10% to 14% of those over the age of 70 may have a detectable M spike.²¹

The course of monoclonal gammopathy has been well characterized by the Mayo Clinic Group. They followed 241 patients for a median of 19 years and found that only

24% of them had a stable or "benign" monoclonal gammopathy; 22% of them developed myeloma, macroglobulinemia, or amyloidosis, and 51% died of unrelated causes. Only 3% of the patients had a progressive rise of their M protein without the development of an underlying disorder.²²

The evaluation of a patient who has been found to have an M spike should be aimed at discovering a potential underlying lymphoproliferative disorder. In a report of more than 800 cases of monoclonal protein seen at a referral center during 1988, 64% were related to MGUS, with myeloma, amyloid, lymphoma, Waldenstrom's macroglobulinemia, and CLL accounting for the remainder.²³ However, it should be remembered that the incidence of MGUS far exceeds the incidence of myeloma in the general population. This referral population is markedly enriched for patients with documented lymphoproliferative disorders.

A complete history and physical examination, routine CBC, electrolytes, and renal function with a serum calcium and uric acid should be obtained. Quantitative immunoglobulin, a 24-h urine for electrophoresis, and total skeletal x-rays may be required to evaluate the significance of a monoclonal gammopathy. A bone marrow aspirate and biopsy or a biopsy of a single soft tissue mass or lytic bone lesion may also be required.

In the absence of identifying an underlying lymphoproliferative disorder, the patient should be diagnosed with MGUS. Follow-up electrophoresis in 3 to 6 months and then yearly should be adequate for those patients who show no progression in their M spike. Patients who have an M protein in the urine should be followed more closely.

Multiple Myeloma

Multiple myeloma is a common malignancy with about 12,000 cases each year in the United States and 9000 deaths. The incidence of the disease increases dramatically with advancing age. The incidence is approximately 2 per 100,000 under the age of 50, but 20 to 25 per 100,000 of those in the seventies. The mean age of diagnosis is in the upper sixties. Given the increase in the geriatric population in the United States, we should continue to see an increasing incidence of multiple myeloma.

The etiology of myeloma is unknown, but there are genetic as well as environmental factors. Controversy exists regarding the role of viral factors in the development of myeloma. Specifically, human herpesvirus 8 (HHV-8) has been associated with some patients with myeloma. The disease occurs more frequently in blacks than whites and more frequently in males than in females. Radiation exposure, as well as occupational exposure to asbestos and petroleum products, is associated with increased risk for the development of myeloma. Multiple

myeloma can evolve from a monoclonal gammopathy of uncertain significance (MGUS).

The cell of origin in multiple myeloma remains unknown. Plasma cells themselves have little proliferative potential. It is likely that clonogenic pre-B cells account for the majority of proliferation in multiple myeloma. Thus, it is at the level of the pre-B cell or earlier that the transformation to malignancy occurs.

Karyotypic alteration is frequently seen in myeloma, with 30% to 50% of patients having abnormalities of their chromosomes. Oncogenes and tumor suppressor gene abnormalities, such as *ras*, *myc*, *bcl-1/PRAD-1/cyclin D-1*, *bcl-2*, *Rb*, and *P53*, have recently been implicated in the development of myeloma. The low proliferative potential of plasma cells has hampered the elucidation of genetic events in this disease.

Clinically, the manifestations of the disease are usually caused by one or a combination of the following factors: (1) proliferation of the malignant clone causing replacement of normal structures; (2) elaboration of cytokines by the malignant plasma cells; and (3) accumulation of the M component in plasma and in tissue.

The most common findings include fatigue, anemia, renal failure, hypercalcemia, hypogammaglobulinemia, and infections. Rarely, hyperviscosity or complications of amyloid infiltration of tissues can occur. The diagnosis of multiple myeloma requires a significant M spike (3.5 g/dL of IgG or 2.0 g/dL of IgA), plasmacytosis greater than 30% in the marrow, or plasmacytoma on tissue biopsy. Additionally, the presence of lytic bone lesions or low residual immunoglobulins can provide supportive evidence in the diagnosis of myeloma.

Pathophysiology

We now understand the pathophysiology of many of the characteristic clinical manifestations of multiple myeloma. Skeletal complications occur quite commonly. Because the lesions are typically osteoclastic with minimal osteoclastic activity, bone scans are typically negative. Plain x-ray and magnetic resonance imaging (MRI) of the bone are more sensitive than a bone scan.

The excessive bone resorption that occurs has been the subject of much research. The plasma cells in the marrow secrete tumor necrosis factor (TNF) and interleukin 1 (IL-1), among other cytokines. These cytokines contain most of the activity previously referred to as osteoclast-activating factor (OAF). Further, the TNF and IL-1 secreted by the plasma cells stimulate secretion of IL-6 by marrow stromal cells. IL-6 not only adds to the osteoclastic activity but also is one of the major growth factors for the myeloma cell clone. A cascade of bone resorption and myeloma cell growth with continued secretion of cytokines can quickly result in clinical hypercalcemia.

The hypercalcemia associated with multiple myeloma usually is multifactorial, with increased bone turnover, dehydration commonly found in the elderly, and renal insufficiency all playing a role. Inactivity secondary to debilitation or bone pain also adds to the progression of hypercalcemia.

The anemia of multiple myeloma is also a multifactorial process. The major influence, however, remains the proliferation of the myeloma cell clone within the bone marrow. Renal insufficiency, chemotherapy, and shortened red cell survival also play a role. Renal insufficiency in the setting of myeloma is a bad prognostic indicator. Monoclonal light chains (known as Bence–Jones proteinuria) accounts for more than 90% of the renal dysfunction. However, amyloid, infection, Fanconi's syndrome, and hyperuricemia can be other mechanisms for renal insufficiency.

Hypogammaglobulinemia is common and frequently results in recurrent infection by encapsulated organisms. Amyloid may develop in the setting of myeloma, with light chain deposition in susceptible organs. Hyperviscosity typically occurs in the setting of IgM production but can occur with very high levels of IgG or IgA. Transfusion in the setting of subclinical hyperviscosity can precipitate symptomatic hyperviscosity because the increased hematocrit after transfusion can adversely affect the whole blood viscosity.

Staging

The Durie and Salmon staging system combines easily obtainable clinical parameters and divides patients into three groups with significantly different expected survival (Table 38.3). More recently, additional prognostic factors have been evaluated. Of these, beta-2-microglobulin and plasma cell labeling index appear to be useful individual parameters. Overall, the median survival is 2 to 3 years with treatment.

Treatment

Treatment for myeloma has shown marked improvements over the last several years, but cure remains elusive. In the 1960s, melphalan and prednisone were first used and improved survival from about 7 months to the current level of about 3 years.

Multiple regimens combining alkylating agents, nitrosourea, doxorubicin, vincristine, and prednisone, as well as interferon, have been studied over the last 15 years. An overview analysis comparing melphalan/prednisone versus several other combination chemotherapy (CCT) regimens demonstrated there was no improvement in overall survival for those patients who received the CCT regimen.²⁴

Although melphalan/prednisone remains an option, particularly for the majority of patients who are over the

TABLE 38.3. Durie and Salmon staging system for multiple myeloma.

Stage	Criteria	Survival (months)
I	All the following: 1. Hemoglobin >10 g/dL 2. Serum calcium <12 mg/dL 3. Normal bones or single plasmacytoma 4. Low M component: a. IgG <5 g/dL b. IgA <3 g/dL c. Urinary M component: <4 g/24 h	46
II	Neither stage I nor III	32
III	At least one of following: 1. Hemoglobin <8.5 g/dL 2. Serum calcium >12 g/dL 3. Advanced bone disease 4. High M component: a. IgG >7 g/dL b. IgA >5 g/dL c. Urinary M component: >12 g/24 h	23

age of 65, high-dose therapy with bone marrow transplantation has been explored for younger patients as well as older patients with good performance status. A randomized study confirmed a survival advantage for those patients who underwent bone marrow transplant compared to those patients who received multiagent chemotherapy.²⁵ Many of the patients who were over the age of 60 were unable to proceed on to their planned high-dose chemotherapy program. Nonetheless, a significant improvement in survival was noted with a dose-intense strategy.

The group in Arkansas has further explored the value of a high-dose strategy in older patients. In a separate report, among 49 patients over the age of 65 who underwent autotransplant for multiple myeloma, outcomes were identical to a matched-pair group of younger patients receiving the same therapy.²⁶ This finding suggests that age alone is not sufficient to deny a high-dose strategy to the patient with multiple myeloma. The group further explored the value of an intermediate dose of melphalan (100 mg) in patients over the age of 60 compared to an historic control group of matched patients who received melphalan and prednisone. Overall survival was 56 months for the Mel 100 versus 48 months for MP. These studies suggest that every patient needs to be evaluated for a high-dose strategy regardless of the age of the patient.

Although high-dose strategies can improve duration of survival, they do not appear to induce a high rate of long-term control. Thus, relapses continue to be a problem both for the patients treated with standard dose

chemotherapy as well as for those who have been through a high-dose program. For patients who either develop resistance or are refractory to melphalan/prednisone, there are a variety of therapeutic choices. However, response rates are on the order of 25% to 30%. Pulse high-dose steroids appear to be as effective as more toxic combination regimens.

Recently, enthusiasm has been generated for the use of thalidomide in patients with myeloma. The initial reports suggested that as many as 30% of patients who had failed high-dose chemotherapy programs would have a significant response to the use of oral thalidomide.²⁷ Multiple reports have confirmed significant activity of this compound. Continued clinical trials are evaluating the optimal role of thalidomide with consideration for both upfront therapy as well as therapy of relapsed disease. Combinations of thalidomide with dexamethasone appear to be particularly active even in patients who had failed dexamethasone regimens previously.²⁸

Resistance to chemotherapy that frequently develops in the setting of myeloma is caused by multiple mechanisms. One important mechanism is expression of the multidrug resistance (MDR) gene product. The MDR acts as an energy-dependent pump that can remove cytotoxic agents from the cytoplasm. This pump also transports other substances, such as cyclosporin. Trials have aimed at providing a molecule that will be transported by the pump and allow increased concentrations of cytotoxic agents to accumulate in the cell. Attempts at reversing the MDR phenotype have been promising in patients previously resistant to therapy.²⁹ Overcoming resistance to treatment may be a valuable therapeutic tool in the future.

The typical response to therapy is the achievement of a plateau phase where the level of tumor, as reflected by the M spike, remains stable. Further therapy during this period has been termed maintenance, and many studies have attempted to evaluate the role of maintenance therapy. The most promising agent for maintenance therapy has been interferon. Studies have produced mixed results, but, for some patients who have a significant reduction in the M spike level, interferon given three times per week may prolong a stable plateau phase. The side effects of interferon include a flu-like syndrome, and this can be very bothersome for elderly patients. Newly available pegylated interferon may generate more enthusiasm for maintenance because this formulation is more convenient and has fewer side effects.

Future Direction

Thalidomide has been the most encouraging new drug to become available for the treatment of patients with myeloma. Optimal use of this drug continues to be explored. Unfortunately, it does not seem to induce a

high rate of complete remission or to induce cures. Likewise, high-dose therapy with bone marrow transplant support has not been able to induce elimination of the malignant clone in most patients and has only been applied to older patients with excellent performance status.

Increased understanding of the biology of the disease, highlighted by the important role played by IL-6, has prompted studies aimed at interrupting the IL-6 cytokine loop with a variety of strategies. Although the initial reports were promising, this therapy has not produced a significant impact. Immunotherapy continues to be attractive. Several reports have demonstrated the feasibility of idiotype vaccine development in patients with myeloma. While the studies are early in development, they may prove particularly useful for older patients.

Supportive care measures have improved for patients with multiple myeloma. The anemia associated with multiple myeloma, although multifactorial, frequently responds to erythropoietin.³⁰ The skeletal complications, including hypercalcemia, can be impacted on with bisphosphonates. These agents act as analogues of pyrophosphatases and are incorporated into the hydroxyapatite, subsequently inhibiting osteoclastic bone resorption. These compounds may exert some outright antimyeloma activity. Newer, more potent, and more convenient formulations of bisphosphonates will be available soon. Last, bacterial infection is a major cause of morbidity and mortality. Prompt recognition and initiation of appropriate antibiotics are required. Intravenous gamma globulin may be helpful, although expensive.

Waldenstrom's Macroglobulinemia

This disorder also involves a proliferation of neoplastic B cells, which produce an M protein of the IgM class. The disease is similar to other lymphocytic malignancies, with a median age of approximately 63 years. It is an uncommon disease, with an incidence of approximately one-tenth that of myeloma.

Clinically, the manifestations of the disease are frequently the result of the very high viscosity resulting from an increased level of IgM in the plasma. Visual changes, neurologic symptoms, congestive heart failure, and recurrent infections frequently occur. Bone pain and lytic lesions are rare in macroglobulinemia. Hepatosplenomegaly and lymphadenopathy are common. Retinal hemorrhaging and vascular segmentation (sausage links) are characteristic. A chronic demyelinating polyneuropathy can be seen in 10% of the patients.

The serum protein electrophoresis demonstrates a protein peak of gamma mobility (IgM), and frequently a monoclonal light chain is present in the urine. The bone marrow demonstrates extensive infiltration with so-

called plasmacytoid lymphocytes. In one series, the measured serum viscosity related well with development of symptoms; six of eight patients with a serum viscosity higher than 5 cp (normal is 1.8 or lower) had symptoms, whereas no patients had symptoms if viscosity was below 3 cp.³¹

The prognosis for patients with Waldenstrom's macroglobulinemia can be quite variable. About one-third of patients will die of unrelated causes and one-third will die of infectious complications. The remainder will die of complications of their illness including the conversion to a higher-grade lymphoma, conversion to AML, renal failure, or other complications.

Treatment

Treatment for complications of the M protein, including hyperviscosity, cryoglobulin, or peripheral neuropathy, should be a course of plasmapheresis. The emergent treatment of symptomatic hyperviscosity is effected with plasmapheresis. It is recommended that daily plasma exchanges of 3 to 4 L occur until the patient is asymptomatic.

Reducing further M protein excretion by the lymphocytic clone requires cytotoxic chemotherapy. Chlorambucil is the most frequently used alkylating agent for Waldenstrom's macroglobulinemia. However, regimens similar to those used for myeloma are also successful. Recently, nucleoside analogues 2-CDA and fludarabine have produced a significant number of responses for untreated patients (80% response rate), as well as those patients refractory to standard alkylating agent therapy.

Amyloidosis

Amyloidosis is a group of disorders of varying etiology. The consistent pathologic event is the deposition of a characteristic insoluble protein in tissues and structures causing organ impairment. The most susceptible organs are the kidney, gastrointestinal tract, myocardium, and peripheral nerve. Amyloid is detectable by tissue biopsies where the characteristic apple-green fluorescence using the Congo red stain is seen. Rectal biopsies or subcutaneous fat biopsies have 80% to 90% sensitivity in confirming the presence of amyloid.

Primary amyloid is generally considered among the plasma cell dyscrasias, although an extremely low order of plasma cell proliferation is noted. Primary amyloid, or so-called AL amyloid, results from the deposition of immunoglobulin light chain in the susceptible organs. Secondary amyloid, also known as the AA type, is derived from "serum amyloid precursor protein" and is not associated with immunoglobulins. Secondary amyloid is associated with chronic conditions such as rheumatoid arthritis or chronic infections such as tuberculosis (TB).

Therapy for primary AL amyloid is generally directed at the presumed underlying lymphoproliferative cellular elements. Thus, melphalan and prednisone have been used most frequently. Unfortunately, response to therapy is difficult to follow because the total body burden of amyloid is unmeasurable.

In several studies from the Mayo Clinic, there appears to be an improvement in survival for those patients who take melphalan/prednisone versus placebo or colchicine.³² However, the studies have been complicated by design flaws and small numbers of patients. Most responses have been seen in patients with predominately renal, splenic, or hepatic involvement. The management of organ dysfunction remains important. Once patients develop symptomatic congestive heart failure, survival is poor. Those patients who have only a peripheral neuropathy have a median survival of more than 5 years.

Based on the success of high-dose strategies with the treatment of myeloma, high-dose strategies are also being applied to patients with amyloidosis. The initial results suggest that in selected patients there may be substantial benefit to this strategy.

Malignant Lymphomas

The malignant lymphomas are a group of lymphoproliferative disorders that are usually divided into Hodgkin's disease and the non-Hodgkin's lymphomas. These two disease entities have markedly different clinical characteristics. For instance, Hodgkin's lymphomas commonly occur as localized areas of lymph node enlargement. They tend to spread to contiguous lymph node groups and do not commonly involve extranodal sites of disease. Further, they are cured in more than 75% of the cases. Non-Hodgkin's lymphomas tend to be disseminated at presentation, will spread in a discontinuous fashion, and frequently involve extranodal areas. Further, the cure rates remain in the 30% to 40% range. The cell of origin in the non-Hodgkin's lymphomas is usually a B cell but occasionally a T cell. The cell of origin in Hodgkin's disease remains unknown.

An experienced hematopathologist is required to distinguish some forms of non-Hodgkin's lymphoma from Hodgkin's disease. However, the importance of the subclassification of the non-Hodgkin's lymphomas is critical, as is detailed later.

Non-Hodgkin's Lymphomas

The non-Hodgkin's lymphomas occur commonly. There are more than 40,000 new cases of non-Hodgkin's lymphoma each year in the United States. Recently, it has become clear that there is an increasing incidence of the non-Hodgkin's lymphomas. There are several compo-

nents to this increasing incidence. First, non-Hodgkin's lymphomas occur more frequently in the elderly, and as the elderly population has increased in the United States, so has the incidence of NHL. However, the rates of non-Hodgkin's lymphomas seem to be going up for all age groups, with the largest increase occurring in the elderly. HIV infections account for a proportion of the increase but in general has added only to the incidence in young single males. The possibility of environmental exposures such as chemicals, pesticides, solvents, and infectious etiologies adding to the increased incidence of lymphoma needs to be considered.³³

There is no clear etiology of the non-Hodgkin's lymphomas. However, there are several known factors that increase the risk. Chief among these are immunodeficient states, either acquired, iatrogenic, or genetic. Concomitant Epstein-Barr virus (EBV) infection appears to markedly increase the risk of non-Hodgkin's lymphoma in immunosuppressed populations. Environmental factors as noted may be involved, and several viruses are closely associated with development of non-Hodgkin's lymphoma. EBV is strongly associated with the development of Burkitt lymphomas in Africa (but not in the United States). The human T-cell leukemia virus 1 (HTLV-1) has been associated with adult T-cell leukemia-lymphoma. The hepatitis C virus has been linked to a variety of B-cell malignancies, including indolent lymphomas and cryoglobulinemia. Bacterial infections seem to play a role in some non-Hodgkin's lymphomas. For example, not only is the *Helicobacter pylori* infection associated with the development of gastric mucosal-associated lymphoid tissue (MALT) lymphoma, but its eradication through antibiotic therapy leads to tumor regression in a majority of cases.

A host of genetic alterations have been reported in the non-Hodgkin's lymphomas.³⁴ One example of a translocation seen frequently in follicular lymphomas is the t(14:18) translocation. When this occurs, the gene for *bcl-2* is juxtaposed to the immunoglobulin heavy chain locus with subsequent overexpression of *bcl-2*, which is normally involved in control of programmed cell death or apoptosis. The process of planned death of a cell, known as apoptosis, is an important mechanism for maintaining homeostasis in all organisms. Prevention of apoptosis provides a survival advantage to the clone of cells. The increased levels of *bcl-2* prevent the programmed death of the cell from occurring. This translocation appears to be present in at least 85% of follicular lymphomas.

Classification

The classification of the non-Hodgkin's lymphomas can be confusing and has been controversial. Multiple classification systems have been introduced and used over the past 40 to 50 years. The various classification schemes

differ in their primary guiding principles of classification from cell morphology, to cell lineage and differentiation, to clinical response to treatment and survival. Over time, as advances in immunophenotyping and molecular genetics have been made, classification based primarily on a single guiding principle has proven inadequate, failing to recognize many distinct, clinically relevant disease entities. This realization led to the introduction of the Revised European-American Classification of Lymphoid Neoplasms (REAL) by the International Lymphoma Study Group in 1994. This classification scheme attempts to include immunophenotype, genetic information, morphology, and clinical features in defining a specific disease entity. Nonetheless, for the purposes of treatment and development of new therapies for the non-Hodgkin's lymphomas, many clinicians find it useful to distinguish those diseases with a more indolent natural history from those with a more aggressive course.

The indolent lymphomas frequently present with few symptoms but disseminated disease. Survival is quite long, but there is no known curative therapy. Aggressive lymphomas frequently present with more localized disease and can be cured with multiagent chemotherapy, even in advanced stages.

Clinical Manifestations and Treatment

The indolent lymphomas, which make up 20% to 40% of all the non-Hodgkin's lymphomas, tend to occur with advancing age. The median age is approximately 50 to 60 years. The majority of patients have advanced-stage disease, and bone marrow involvement is common. The t(14:18) translocation is seen in most patients with follicular lymphomas. Fevers, sweats, and weight loss (B symptoms) are uncommon.

The staging evaluation of indolent lymphomas is not as critical as in the aggressive lymphomas or in Hodgkin's disease. Typically, physical examination, routine laboratory tests, chest x-ray, computed tomography (CT) scans, and bone marrow biopsy provide sufficient information to evaluate prognosis and plan of treatment.

Physicians treating indolent lymphomas must recognize that although these diseases are slow to progress and frequently respond to chemotherapy, they are as yet incurable. The median survival approaches 7 to 8 years. However, ultimately the disease progresses and frequently transforms to a more aggressive lymphoma.

The goals of therapy are generally palliative. Rarely, a patient with localized disease can obtain long-term remission with involved field radiation. For the majority of patients who present with advanced-stage disease, there is a wide range of treatment options. Most studies have shown no survival benefit for early treatment, and, in fact, a watch-and-wait approach may be optimal for many patients. However, in these circumstances patients should

be monitored closely to prevent complications such as renal failure secondary to ureteral obstruction. In reported series when watchful waiting is applied to a cohort of patients, overall survival is equivalent to those treated at presentation. The median time to instituting therapy is 2 to 3 years.³⁵ This strategy may be particularly appropriate for older individuals with significant comorbidities that might further adversely affect therapy.

Other treatment strategies, including immediate chemotherapy or aggressive chemotherapy, have also been attempted. Cyclophosphamide and chlorambucil have been used alone, with response rates in the 50% to 80% range. Cyclophosphamide, vincristine, and prednisone frequently have been combined, showing higher response rates. Nonetheless, a continuous relapse pattern is observed. When more aggressive chemotherapy is used, such as the CHOP regimen containing cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), and prednisone, a higher percentage of responses and complete responses is seen. However, it does not appear to change the rate of recurrence. The purine analogues such as fludarabine have shown activity in indolent lymphomas alone and in combination. Fludarabine, when combined with mitoxantrone, has demonstrated significant response rates.

As an alternative to chemotherapy, the option of monoclonal antibody therapy for indolent, B-cell non-Hodgkin's lymphoma has become available. The human-mouse chimeric anti-CD20 monoclonal antibody, rituximab, was initially shown to be effective in the setting of recurrent indolent lymphoma, with a response rate of 48% and a favorable toxicity profile.³⁶ The median time to progression for those responding was approximately 1 year. More recently, rituximab has been studied as initial therapy for indolent lymphoma and has shown high levels of activity, mild toxicity, and excellent progression-free survival.³⁷ Rituximab's activity as a single agent, in addition to its favorable toxicity profile and specifically the lack of significant hematologic toxicity, has led to the investigation of its use in combination with conventional chemotherapy. Czuczman et al. have reported an overall response rate of 95% and a complete response rate of 55% in patients with indolent B-cell lymphomas treated with a combination of CHOP and rituximab.³⁸ The study suggests additive activity with the combination without a significant increase in toxicity, which may be particularly pertinent for some elderly patients who have a limited ability to tolerate more toxic therapies. Interestingly, the *bcl-2* t(14:18) translocation could not be detected in the follicular lymphoma patients who demonstrated a complete response.

The indolent lymphomas tend to be radiosensitive, and frequently symptomatic areas of adenopathy can be treated with palliative radiotherapy. This sensitivity to radiation has also been utilized through radiolabeled

monoclonal antibodies. Anti-CD20 monoclonal antibodies radiolabeled with yttrium-90 or iodine-131 have shown superior CR and overall response rates to those of rituximab alone in trials looking at recurrent or refractory indolent lymphomas. Toxicity is greater when compared with rituximab, with the primary toxicity being myelosuppression.

The aggressive lymphomas tend to present with diffuse adenopathy but rarely involve the bone marrow. When the bone marrow is involved, there is a high correlation with involvement of the central nervous system, and this portends a bad prognosis. Extranodal sites such as the gastrointestinal tract are frequent areas of origin of the intermediate-grade lymphomas. They are predominantly B-cell, although as many as 20% of them may be T-cell immunophenotype, which has identical behavior.

The prognosis for patients with aggressive lymphoma has improved markedly with the advent of multiagent chemotherapy, as is detailed here. Nonetheless, many patients do not either obtain or maintain a complete remission (CR). The prognostic factors that predict the likelihood of response have recently been more fully characterized.³⁹

Age remains an important prognostic factor. Patients under the age of 60 have a significantly better prognosis than those patients over the age of 60. Serum levels of lactate dehydrogenase (LDH), performance status, and stage of disease, as well as the number of extranodal sites, are also important prognostic factors, as detailed in the international index recently reported.³⁹ Other important parameters of prognosis include the rapidity of response, usually measured as the time to achieve a CR. Those patients who achieve a CR quickly (fewer than three to four cycles of therapy) have an improved long-term survival compared with those patients who have not achieved a CR by this time. There appears to be a significant dose-response relationship in the treatment of these lymphomas. Patients who receive dose-reduced therapy appear to achieve CR less frequently and relapse from CR more frequently than those who receive full-dose therapy.

The dose intensity of therapy has been studied specifically in the elderly. The Southwest Oncology group studied CHOP chemotherapy in elderly patients.⁴⁰ There were several interesting results of this study. The rate of complete response was 65% in those under 40 years of age and 37% in those 65 years and older. The median survival for the younger group was 101 months but only 16 months in the older group. This protocol called for initial dose reduction for patients 60 years of age and older; however, some patients received full doses of chemotherapy in violation of the protocol. When these patients were examined separately, the rates of CR and survival were markedly better than those receiving reduced doses of chemotherapy. This finding suggests that full doses of

chemotherapy are important in elderly patients as well as in younger patients. Toxicity, however, remains a major problem.

Other investigators have sought to develop regimens specifically for the elderly. In one prospective, randomized, phase III trial, CHOP was compared to CNOP (cyclophosphamide, mitoxantrone, vincristine, and prednisone) in patients 60 years of age and older with aggressive lymphomas. CHOP was found to be superior in achieving complete responses in 49% versus 31% in the CNOP group. Three-year survival was also superior in the CHOP group, and toxicity was comparable.⁴¹

Rituximab therapy in elderly patients with aggressive lymphomas has been studied with some promising results. In a recent report, previously untreated patients aged 60 to 80, with aggressive B-cell lymphomas, were treated with a combination of CHOP plus rituximab versus CHOP therapy alone. At 1 year, the combination of CHOP plus rituximab was found to demonstrate superior overall survival and event-free survival as compared with CHOP alone, with comparable toxicity.⁴²

In general, it would appear that, for elderly patients with aggressive lymphoma who have good performance status and normal organ function, attempting full-dose chemotherapy with a curative intent seems reasonable. Patients with poor performance status or impaired cardiopulmonary or renal reserves are unlikely to tolerate these aggressive therapies without significant morbidity. There may also be a role for hematopoietic growth factors in mitigating hematologic toxicity for elderly patients. The physician needs to balance the risks and benefits of these aggressive regimens.

For patients who do not achieve a CR or who relapse from CR, the overall prognosis is poor. Several aggressive regimens are available for the treatment of relapsed and refractory lymphoma, and high-dose therapy with bone marrow transplant support has also been used. In general, elderly patients are unlikely to significantly benefit from these aggressive interventions. Continued effort to define optimal initial treatment regimens that may be curative for elderly patients seems warranted.

Hodgkin's Disease

As noted previously, Hodgkin's disease is a group of disorders with a characteristic clinical course. The early studies by Henry Kaplan defined the typical pattern of spread of Hodgkin's disease. As opposed to the non-Hodgkin's lymphomas, Hodgkin's disease tends to spread to contiguous lymph node groups. Thus, intricate staging at the time of diagnosis is critical for developing a plan of treatment. The incidence of Hodgkin's disease demonstrates a bimodal age-specific pattern. There is an early peak between the ages of 20 and 30. Some have suggested that there is an infectious etiology for this form of

Hodgkin's disease as there is increasing risk for Hodgkin's disease with higher socioeconomic status. The later peak, occurring about age 50, is not related to socioeconomic status. There are many reasons to think that the etiology of the early peak of Hodgkin's diseases is different from the etiology of the cases that occur in elderly individuals.

Classification and Clinical Presentation

All forms of Hodgkin's disease have demonstrable Reed–Sternberg cells, which are large binucleated cells with prominent nucleoli, and although not pathognomic for Hodgkin's disease these are typical. The debate regarding the origin of this cell continues. There are four subtypes of Hodgkin's disease. In decreasing frequency, they are nodular sclerosing, mixed cellularity, lymphocyte predominant, and lymphocyte depleted.

Most patients present with an enlarged lymph node; however, there is some difference in the clinical presentation from older to younger patients. Older patients are more likely to have systemic symptoms and abdominal disease, especially bulky abdominal disease. The most common histologic pattern in all age groups is nodular sclerosing, but it appears from a multitude of studies that with advancing age there is decreasing nodular sclerosis and increasing mixed cellularity.

The clinical presentation of Hodgkin's disease as noted is typically with adenopathy, with more than 70% of people presenting with palpable lymph node enlargement. Rarely, the lymph nodes become painful after consumption of alcoholic beverages. As many as a third of patients will develop so-called B symptoms with fevers, night sweats, and weight loss of more than 10% of body weight. Other symptoms such as fatigue, weakness, and pruritus occur commonly but are not officially considered B symptoms. Presence of true B symptoms has adverse prognostic implications.

Staging

An important point to differentiate between the Hodgkin's lymphomas and the non-Hodgkin's lymphomas is the relative importance of histologic classification and staging. The treatment plan for Hodgkin's disease is critically dependent on accurate staging, whereas the histologic subtype is less important. Conversely, in the non-Hodgkin's lymphomas, the histologic subtype is the critically important determinant of therapy, and, while staging is important, it is not as critically important as in Hodgkin's disease.

The Ann Arbor classification is the most commonly used staging system for Hodgkin's disease (Table 38.4). The suffix E represents the presence of extralymphatic involvement with disease, and the suffix A or B denotes

TABLE 38.4. Ann Arbor staging system for Hodgkin's disease.

Stage	Involved lymph nodes	Extralymphatic organ
I	One region (I)	Or localized involvement of single site (Ie)
II	Two or more regions on same side of diaphragm (II)	With localized involvement of one site (IIe)
III	Regions on both sides of diaphragm (III)	With localized involvement of one site (IIIe) or spleen (IIIs)
IV		Diffuse or disseminated involvement of one or more organs (liver, bone marrow)

Subdesignations: A, asymptomatic; B, fever, sweats, weight loss; CS, clinical staging; PS, pathologic staging (usually laparotomy).

presence or absence of B symptoms, as noted in the previous section.

The optimal staging procedures for Hodgkin's disease continue to be an area of debate. Given that therapy is dependent on stage, accurate staging is essential. CT scans of the chest, abdomen, and pelvis can accurately search for enlarged lymph nodes. Bone marrow biopsy should also be obtained. Routine laboratory studies, including liver and renal function, uric acid level, and the erythrocyte sedimentation rate (ESR), are useful. Specialized staging studies for patients with otherwise localized disease are important. A lymphangiogram to evaluate periaortic and iliac abnormalities is better than CT scans at detecting normal-size lymph nodes that are involved with Hodgkin's disease.⁴³ Staging laparotomy and splenectomy at one time were a standard intervention for all patients with stage I, II, or III Hodgkin's disease. However, this continues to be evaluated, and clearly those patients who will be receiving chemotherapy for other indications should be spared laparotomy and splenectomy. Gallium scan is useful both at the initial diagnosis and in follow-up of patients. It is recommended that it be obtained before initiating therapy to determine if the lymphoma is gallium uptake positive because treatment with chemotherapy can produce false-negative results in the gallium scan.

Treatment

Hodgkin's disease is a curable malignancy, and treatment should be initiated with curative intent. Both radiotherapy and combination chemotherapy can cure Hodgkin's disease. The choice of therapy modality is dependent on the stage of disease. Localized disease (stage IA, IIA, IB, and IIB) is typically treated with radiotherapy. Abbreviated courses of chemotherapy before radiation treatment may improve outcome in early-stage Hodgkin's disease.

The principles of radiation treatment were established by Henry Kaplan. Although doses less than 4000 centigray (cGy) were effective in inducing responses, 4000 centigray was required for curative therapy. Because of the typical contiguous pattern of spread of Hodgkin's disease, radiation treatment ports could be devised to cover all known involved regions of disease plus one additional nodal group. Using current radio-

therapy, patients with localized disease (stage IA and IIA) have a cure rate greater than 80%. B symptoms reduce the cure rate to approximately 70%.

More advanced disease requires combination chemotherapy. DeVita developed the regime MOPP [nitrogen mustard, Oncovin (vincristine), procarbazine, and prednisone] and for the first time demonstrated long-term disease-free survival for patients with advanced-stage Hodgkin's disease. Over the past 20 years, attempts at refining MOPP therapy have concentrated on improving the response rates, as well as limiting toxicity. Most recently, ABVD (adriamycin, bleomycin, velban, and dexamethasone) has been shown to be more effective than MOPP, with less toxicity.⁴⁴ Hybrid regimens combining MOPP and ABVD are also an improvement over MOPP alone. Toxicity from chemotherapy includes acute side effects such as bone marrow suppression and a high incidence of sterility. Secondary malignancies, including leukemia and solid tumors, have been recognized as a late toxicity from these therapies.

Using both chemotherapy and radiotherapy together has been referred to as combined modality therapy. The rationale for combined modality therapy in advanced-stage Hodgkin's disease rests with documentation that recurrence frequently occurs in the site of previous bulk adenopathy. Thus, in retrospective studies, radiotherapy to areas of previous bulk disease once chemotherapy has been completed has been associated with improved survival rates. Nonetheless, no randomized trial has demonstrated superior results with combined modality therapy. There is concern regarding increased toxicity when combining chemotherapy and radiotherapy. Despite the controversy, patients with bulky mediastinal adenopathy are routinely treated with combined modality therapy because they fare less well with single modality therapy. As mentioned earlier, there is support for combined treatment for early-stage disease as well.

Salvage

Patients who relapse with Hodgkin's disease need to be accurately restaged. The prognosis for those who never achieved a CR or relapse within 12 months of obtaining a CR is significantly worse than for those who remain in complete remission for a significant duration of time. Patients

who relapse after curative radiotherapy should be treated with chemotherapy and have a high likelihood of response and long-term disease-free survival. Patients who relapse with localized disease after chemotherapy can be treated with salvage radiotherapy. For those patients relapsing in less than 12 months, a salvage regimen that is noncross-resistant with their induction regimen should be considered. High-dose therapy with autologous or allogenic bone marrow support can also be considered for younger patients. There is little evidence that older patients can undergo these aggressive regimens.

Prognosis and Survival

Many studies have evaluated the prognostic factors associated with surviving Hodgkin's disease. Increasing age is a poor prognostic factor. Different investigators have used different age cutoffs, but typically survival worsens for patients over the age of about 40 to 50. In the recent study reported by Canellos et al., 5-year survival for patients under the age of 40 was 80%; for those 40 to 60, it was 63%; and for those over 60 survival was 31%.⁴⁵

It has been suggested that the inability to tolerate chemotherapy has been a factor in the poor prognosis for elderly patients. Although this may be true, other factors may also play a role in the worse outcome for elderly patients. Given the different epidemiologic phenomena and the response to therapy for this age group, patients over the age of 60 with Hodgkin's disease probably have a different disease from younger patients.⁴⁵ Other prognostic factors, including bulky disease, high LDH, and extranodal site involvement, may be as important as age.

Summary

The hematologic malignancies are a diverse group of disorders that vary in clinical severity and response to treatment. Some are compatible with a long life expectancy, and others can produce a fulminant course rapidly leading to death. Treatment strategies generally result in significant morbidity, and for elderly patients with comorbid conditions, a careful analysis of options, including no treatment, is appropriate. Supportive care is improving, and elderly patients should benefit from improved understanding of the biology of many of these diseases. Molecularly targeted and immunologically targeted treatment may improve the ratio of benefit to toxicity for older patients.

Cardiovascular Disease

Nanette Kass Wenger

Thirteen percent of the U.S. population is currently 65 years or older, and about half of these 25 million people have cardiovascular disease. By the year 2030, 1 in 5 Americans will be older than 65 years, with the subset older than 85 years increasing most prominently in size. Data are limited regarding cardiovascular disease in the octogenarian and beyond, compromising optimal clinical care for such patients.¹

Cardiovascular disease increases dramatically with aging and is the major cause of mortality and disability in elderly persons; 83% of all cardiovascular deaths in the United States occur in patients older than 65 years of age.² Cardiovascular disease is also a major contributor to the need for hospital, ambulatory, and custodial care. In 1987, two-thirds of the U.S. health care expenditures for cardiac disease (totaling \$22.3 billion) was for patients older than age 65.³ Elderly patients are intensive users of emergency medical services⁴ and of medical services in general. However, because most elderly cardiovascular patients entering hospitals are discharged, the majority of elderly patients appear to benefit from active treatment rather than using the hospital for custodial care. The aim of ongoing care should be to return elderly patients to independent living in their home setting for so long as is reasonable. Coronary heart disease is the most prevalent cardiac problem, followed by hypertensive cardiovascular disease,⁵ with valvular and pulmonary heart disease other important etiologies. Despite these statistics, the scarcity of scientific studies involving very elderly patients is striking. Age-based exclusions from most clinical trials limit the generalizability of data to the characteristically high-risk geriatric population. Review of databases can provide added information about efficacy and safety of interventions and identify priority areas for future study.⁶ Cardiovascular disease at elderly age is additionally complicated by its frequent association with multiple other comorbid illnesses. Moreover, data from the Cardiovascular Health Study define a substantial decline in functional status between persons aged 75 to

84 years and those 85 years and older.⁷ Physical disability independently predicted coronary mortality in the established populations for epidemiologic studies of the elderly (EPESE) cohort.⁸

Recent data suggest that the management and outcomes for most patients aged 65 to 75 years are comparable to their younger counterparts, but that cardiovascular diagnosis and therapy must be highly individualized beyond this age.

Cardiovascular Changes of Aging

The presentation of cardiovascular disease in elderly patients is complicated by its superimposition on the physiologic and structural cardiovascular changes of aging. These variables influence the response of elderly patients both to specific cardiac illnesses and to their therapies. Both the physiologic and the structural changes that occur in the cardiovascular system with aging decrease cardiac functional reserve capacity, limit the performance of physical activity, and lessen the ability to tolerate a variety of stresses, including cardiovascular disease.⁹

Maximal heart rate and maximal aerobic capacity decrease progressively with age,¹⁰ independent of habitual physical activity status, owing in part to decreased catecholamine responsiveness. Although maximal oxygen uptake decreases with aging, the decline is less prominent than previously described when corrected for the decreased lean body mass of aging. Nonetheless, the maximal oxygen uptake of sedentary elderly individuals is 10% to 20% less than that of their physically active counterparts, with maximal work capacity comparably decreased. Peak exercise cardiac output and peak exercise ejection fraction also decrease at elderly age. Cardiac dilation, enabling an increase in stroke volume, compensates for the diminished heart rate response to maintain the increase in cardiac output required for exercise.

Aortic and large artery thickness and vascular stiffness increase with aging, with a resultant increase in arterial systolic pressure and impedance to left ventricular ejection. This increased afterload of aging is likely the stimulus for left ventricular hypertrophy, even in normotensive elderly persons. Both systolic blood pressure and mean blood pressure increase with aging with widening of the pulse pressure.

Aging changes in the heart also include the following features:¹¹ an altered geometric contour; a decrease in ventricular compliance with substantial reduction in the early diastolic filling rate, the diastolic dysfunction of aging, with increased dependence on the contribution of atrial contraction to late left ventricular filling to maintain cardiac output; a prolonged duration of myocardial contraction and relaxation times; and lessened chronotropic and inotropic responses to sympathetic (catecholamine) stimulation. Cardiac filling pressures at rest vary little with increasing age, but end-diastolic pressure with exercise is prominently greater as an adjustment to the decreased left ventricular distensibility. Combined with the increase in left ventricular mass, this places the aged heart at a mechanical disadvantage. Cardiac dilation with exercise (using the Frank–Starling mechanism) enables the ventricles to increase stroke volume and cardiac output; this differs from the exercise response at younger age, when an increase in heart rate effects the increase in exercise cardiac output.

Baroreceptor responsiveness decreases with aging, due in part to loss of vascular distensibility. Although consequences of postural hypotension, particularly falls, have been attributed to the sluggish baroreceptor reflex of aging, recent studies in community-dwelling elderly individuals show that they have preserved baroreceptor responsiveness.¹² Nevertheless, more than 18% of community-dwelling elderly individuals in the Cardiovascular Health Study¹³ had orthostatic hypotension, with the prevalence increasing with increasing age.

The number of pacemaker cells in the sinoatrial (SA) node and number of bundle branch fibers decrease with age, with loss of SA pacemaker cells more pronounced.¹⁴ The sick sinus syndrome is caused by loss of sinus node pacemaker cells and fatty infiltration around the sinoatrial node with aging. Atrioventricular block, intraventricular conduction delay, and bundle branch blocks may be caused by fibrosis and calcium deposition in the cardiac skeleton. These problems may be accentuated by drugs used to treat hypertension and coronary disease, such as beta-blockers and calcium antagonist drugs. The combination of atrial dilation and atrial fibrosis may underlie the increased prevalence of atrial arrhythmias.

Thickening of the aortic and mitral valve leaflets and the circumference of all four cardiac valves increase at elderly age. Collagen degeneration and secondary calcium deposition are common at elderly age; one-third

of patients aged 70 and older have calcium deposition in either the aortic or mitral valve.¹⁵ Calcific degeneration is the major cause of aortic valve disease in elderly patients. Mitral annular calcification, appearing initially in the submitral position, also increases in frequency with age. Mean pulmonary artery pressures and pulmonary vascular resistance are also increased at elderly age.

These myriad changes require that the cardiovascular manifestations of aging be differentiated from those of disease.

Limitations of the History and Physical Examination in the Diagnosis of Cardiovascular Disease in Elderly Patients

Limitations in obtaining information from the clinical history include the potential altered mental acuity with aging; cognitive disturbances related to illness, medications, or effects of depression; or a combination of these features. The coexistence of multiple diseases also hinders the accurate evaluation of symptoms. Because these variables may obscure or complicate the patient's clinical history, confirmatory data often must be obtained from family members or medical records. Habitual activity levels differ substantially but often decrease with progressive aging, so that many symptoms do not retain their activity-precipitated characteristics.

Because orthostatic hypotension is common in elderly persons, it is essential to document the effect of postural change when measuring blood pressure. Disease and medications, rather than aging per se, account for the preponderance of postural hypotension. However, in frail elderly nursing home residents, orthostatic hypotension is often encountered postprandially and when first arising in the morning.¹⁶ Reduced heart rate variability, a measure of cardiac autonomic function, predicted an increased mortality risk among the elderly cohort of the Framingham Heart Study.¹⁷

The increased vascular stiffness of aging causes the upstroke of the arterial pulse to appear more brisk than usual, potentially masking the slowly rising carotid pulse of aortic stenosis. Frequent findings in elderly individuals include the early-peaking basal systolic murmur of aortic sclerosis, typically accompanied by a fourth heart sound at the cardiac apex as evidence of reduced ventricular compliance. Aortic sclerosis, potentially as a marker for atherosclerosis, is associated with an approximate 50% increase in cardiovascular mortality risk and risk of myocardial infarction (MI).¹⁸ Dilation of the ascending aorta as well as decreased aortic compliance may also produce basal systolic murmurs. Neither the S₄ nor the increased ventricular filling pressure reflect ventricular

systolic dysfunction, whose counterpart is an S_3 . S_2 may be single at elderly age or the inspiratory splitting may be less prominent. A combination of dorsal kyphosis, emphysema, or chest wall alterations may limit palpation of the apical impulse, even when left ventricular hypertrophy is present. Data from the Cardiovascular Health Study suggest the importance of the ankle–arm index, a noninvasive assessment for peripheral arterial disease; a normal value is inversely related to the risk of cardiovascular disease.¹⁷

Importance of Noninvasive Diagnostic Tests and Their Limitations

Because of difficulties in obtaining a clinical history and in interpreting findings at physical examination, diagnostic tests assume greater importance. Noninvasive methods should initially be selected in that elderly patients are at increased risk for complications of most diagnostic procedures. However, many noninvasive tests have limitations unique to an elderly population.

Resting Electrocardiogram

About 50% of elderly individuals have abnormalities of the resting electrocardiogram (ECG). Aging changes in the cardiac conduction system and the age-related increase in left ventricular mass underlie the ECG changes, most commonly PR and QT interval prolongation, intraventricular conduction abnormalities, reduction in QRS complex and T-wave voltage, nonspecific ST-segment and T-wave changes, and a leftward shift of the frontal plane QRS axis. QT prolongation is more common in elderly women than elderly men.¹⁹ QTc dispersion in the Rotterdam Study predicted cardiac mortality at an elderly age.²⁰ Both lung hyperinflation and dorsal kyphosis accentuate the diminution in QRS voltage, despite the increase in left ventricular mass. ECG criteria are unreliable for the detection of left ventricular hypertrophy at an elderly age.²¹ These changes occur in addition to the arrhythmias described next. Elderly men more frequently have major electrocardiographic abnormalities than elderly women, and the prevalence of these abnormalities increases with older elderly age. Electrocardiographic evidence of myocardial infarction occurs far more frequently than reported in the clinical history.²²

Long-Term (24-h) Ambulatory Electrocardiogram

The 24-h ambulatory electrocardiogram or use of an event recorder is the most useful diagnostic technique

TABLE 39.1. Ambulatory ECG findings in elderly subjects with no clinical heart disease.

Variable	Finding
Heart rate, beats/min	34–180
Longest sinus pauses, s	1.8–2
Supraventricular premature complexes (>20/h), %	66
Paroxysmal supraventricular tachycardia, %	13–28
Ventricular premature complexes (>10/h), %	32
Ventricular couplets, %	8–11
Ventricular tachycardia, %	2–4

to identify symptomatic arrhythmias, particularly when diary evidence is available to correlate symptoms with these spontaneously occurring arrhythmias. The test is indicated to identify cardiac rhythm disturbances as etiologic of otherwise unexplained lightheadedness, dizziness, giddiness, falls, frank syncope, or uncomfortable palpitations. The limitation of utility of this study is the high prevalence of both supraventricular and ventricular arrhythmias in the absence of cardiac disease or cardiac symptoms, even arrhythmias as potentially serious as nonsustained ventricular tachycardia²³ (Table 39.1). Most asymptomatic arrhythmias in the absence of cardiac disease do not warrant therapy. Importantly, syncope may result from orthostatic hypotension, significant aortic stenosis, carotid sinus hypersensitivity, and age- and disease-related impairments of cerebral blood flow, as well as arrhythmias. Specific arrhythmia identification is needed to guide pharmacologic or pacemaker therapy.

The increase in both supraventricular and ventricular ectopic beats with aging is more likely a consequence of aging changes in the aorta and ventricles than of intrinsic abnormalities of the conduction system.

Echocardiogram

The echocardiogram is far more accurate than the chest roentgenogram in the assessment of cardiac chamber size because the kyphoscoliotic chest deformity and sternal depression common in elderly persons may cause a factitious increase in heart size on the chest roentgenogram. The echocardiogram is also more accurate for the determination of left ventricular hypertrophy, a powerful marker for coronary risk, than is the electrocardiogram; in addition to identifying left ventricular wall thickness and mass, cardiac chamber size, and valvular abnormalities, wall motion abnormalities and ventricular ejection fraction can be determined, as can pericardial effusion. However, a technically adequate echocardiogram cannot be recorded in some elderly patients because of their chest configuration.

Doppler echocardiography is reliable for determining the aortic valve area and estimating the pressure gradient in elderly patients with significant aortic stenosis; there is a good correlation of the calculated echocardiographic valve area with cardiac catheterization data.²⁴

Dobutamine stress echocardiography to detect myocardial ischemia has not been systematically assessed in an elderly population.

Exercise Tests and Exercise Radionuclide Studies

Exercise testing can be undertaken with comparable safety and efficacy in elderly patients as in younger patients, that is, among elderly patients able to perform an adequate exercise test. Treadmill exercise testing in elderly individuals provided prognostic information incremental to clinical data.²⁵ A normal response to exercise testing has the same favorable prognosis as in a younger population, and an abnormal response to exercise imparts comparable risk as in younger individuals; the high predictive accuracy of an abnormal exercise test at elderly age reflects the high prevalence and severity of coronary heart disease in this population.²⁶ Few data are available regarding exercise testing in patients older than 75 years of age. Careful explanation of the test procedure, a practice session on the bicycle or treadmill before the actual test, meticulous skin preparation and electrode placement, and selection of an appropriately low-intensity exercise protocol increase the likelihood of a satisfactory exercise test. The Naughton protocol or a modification of the standard Bruce protocol is preferable for treadmill exercise testing of elderly patients with limited exercise capability. Arm ergometry can be considered for elderly patients who are unable to perform treadmill or bicycle exercise because of arthritis, claudication, or cerebrovascular or musculoskeletal disorders. The exercise test can help determine if the chest discomfort represents myocardial ischemia, can characterize risk status in the patient with angina pectoris or following myocardial infarction, can guide recommendations for a physical activity regimen, and can assess the suitability for return to work when appropriate.

Exercise thallium scintigraphy is helpful when conduction abnormalities or repolarization changes on the resting ECG limit the interpretation of the exercise ECG. The presence and extent of exercise-induced reversible thallium-201 or technetium-99m scintigraphic abnormalities permit effective risk stratification in elderly patients.^{27,28} Exercise-induced evidence of cardiac dilation and abnormal radioisotope lung uptake indicate a high-risk status. Myocardial perfusion scintigraphy after intravenous administration of dipyridamole (Persantine) is well tolerated by aged patients and may help identify myocardial ischemia in elderly patients who are unable

to exercise. The sensitivity, specificity, and safety appear comparable in populations older and younger than 70 years of age.²⁹

Ventricular function can be assessed by radionuclide ventriculography; although it is more expensive than echocardiography, it is applicable to elderly patients in whom adequate echocardiographic images cannot be obtained. Contrast-enhanced computed tomography (CT), positron emission tomography (PET) scanning, and magnetic resonance imaging (MRI) require systematic study in elderly populations.

Because of the progressive nonuniformity of lung function with aging, perfusion defects may occur in the absence of pulmonary embolism, rendering this test somewhat less reliable in an elderly population. Spiral CT imaging appears valuable to identify pulmonary embolism.

Invasive Diagnostic Tests

Transesophageal echocardiography, used to evaluate for aortic dissection, infective endocarditis, and valvular heart disease, among others, appears well tolerated at elderly age.

Cardiovascular catheterization and coronary arteriography are also well tolerated in elderly patients. Precise diagnosis may enable more successful medical and surgical therapies. Procedure-related morbidity and mortality, although relatively infrequent, are increased two- to threefold at elderly age.^{30,31} The number of coronary arteriograms performed annually on patients older than age 65 continues to escalate in the United States; arterial tortuosity increases the difficulty of the procedure.

Manifestations of Cardiovascular Disease

Heart Failure

Most of the 5 million patients with heart failure in the United States³² are elderly, and heart failure is the most frequent hospital discharge diagnosis for patients older than 65 years of age.³³ Seventy-five percent of heart failure hospitalizations occur in individuals older than 65 years and 50% in patients 75 years and older. Heart failure is more common in men than in women until about age 80; an eightfold increase in heart failure among men in the seventh decade of life compared with the fifth decade was noted in the Framingham population.³⁴ In a Medicare cohort, one-third of patients died within 1 year of initial hospitalization for heart failure.³⁵ During the past two decades, heart failure deaths have almost doubled in the over-75 population. Most of the 400,000 new cases of heart failure diagnosed annually in the

United States are in the geriatric population. With the continuing dramatic increases in the size of the elderly population, comparable dramatic increases in heart failure incidence and prevalence can be anticipated. The prevalence of heart failure increases with increasing age and is estimated to involve 5% of the population aged 65 to 74 years and 10% of those older than 75 years.

Heart failure tends to be both underdiagnosed and overdiagnosed in elderly patients. Many elderly patients fail to report progressive easy fatigability, dyspnea, cough, and ankle edema, considering these a consequence of aging. Early manifestations of heart failure may be masked by the sedentary lifestyle of many elderly patients, whereas exertional dyspnea may reflect another common problem, chronic pulmonary disease, rather than cardiac failure. Deconditioning may also cause breathlessness. Pulmonary changes associated with aging may decrease exercise tolerance, even in the absence of heart failure. Basal lung rales and relatively large heart volumes, normal in an older population, may be mistakenly ascribed to heart failure. Owing to activity limitations, profound fatigue rather than exertional dyspnea may be the presenting feature. However, comparable fatigue, as well as exhaustion, confusion, and altered mentation, may result from excessive diuresis. Ankle edema may reflect venous stasis, decreased tissue turgor, or be a consequence of treatment with vasodilator drugs, rather than evidence for heart failure. On occasion, only anorexia, insomnia, nocturnal cough, or frequent nocturnal urination may herald heart failure. Many elderly patients with heart failure may have disordered mental function and behavior consequent to diminished cerebral blood flow.

Coronary atherosclerotic heart disease, hypertensive cardiovascular disease, and hemodynamically significant calcific aortic stenosis are the most prevalent causes. Mitral regurgitation is also contributory. Pooled data from hypertension trials in elderly patients showed a 52% reduction in incident heart failure with antihypertensive therapy.³⁶ Because of its high prevalence, occult coronary disease must be considered with otherwise unexplained systolic heart failure.³² Cardiac amyloidosis increases in prevalence with aging; the initial diastolic dysfunction is often accompanied by arrhythmias and conduction disturbances. Heart failure is more frequently precipitated or exacerbated by associated medical problems than in younger patients. These problems include atrial fibrillation and other arrhythmias, acute myocardial infarction, uncontrolled hypertension, intercurrent infections and fever, fluid overload,³⁷ acute blood loss, pulmonary embolism, anemia, occult thyrotoxicosis, renal insufficiency, acute lower urinary tract obstruction in men, and major dietary indiscretions. Drugs causing myocardial depression (β -blocking drugs, calcium-blocking drugs, and a number of antiarrhythmic agents) and/or poor compliance with the medical regimen are

also contributory. Frequent use of nonsteroidal inflammatory agents by elderly patients, often as nonprescription drugs, can precipitate heart failure by a combination of sodium and water retention and the induction of renal dysfunction. Iatrogenic heart disease, often related to inappropriate pharmacotherapy, in hospitalized frail elderly patients portends a poor prognosis.³⁷ Given the limited cardiac reserve and the frequent multifactorial etiology of heart failure in an elderly patient, remediable factors should be carefully identified and corrected. The occurrence of heart failure adversely affects the prognosis of most cardiovascular disorders and is an important contributor to the excessive mortality among elderly patients in the early months after myocardial infarction.

Echocardiography has substantially improved the recognition of heart failure in elderly patients and is the most useful noninvasive test to differentiate systolic and diastolic ventricular dysfunction.³⁸ Echocardiography is also useful in defining an otherwise inapparent cause of the heart failure; it can assess the characteristics of the heart valves, the size and function of the cardiac chambers, the presence of pericardial effusion, and focal wall motion abnormalities.

Although ventricular systolic dysfunction with cardiac enlargement is a frequent finding in elderly patients with heart failure, diastolic dysfunction is a prominent cause of heart failure in this population; this is the case in more than half of octogenarians with heart failure.³⁹ Among octogenarians, the predominant presentation of heart failure is in women with systolic hypertension and diastolic dysfunction with preserved ventricular systolic function. Clues to diastolic dysfunction as the mechanism for heart failure include a normal or near-normal heart size and a cause for left ventricular hypertrophy such as hypertension or hypertrophic cardiomyopathy. The characteristics of the aging heart and associated diabetes mellitus may impair ventricular diastolic distensibility. Ventricular diastolic dysfunction may be present in as many as half of all elderly patients with clinical manifestations of heart failure and has a more favorable prognosis than systolic dysfunction when correctly treated.⁴⁰ The earlier descriptions of adverse outcomes of diastolic heart failure may reflect suboptimal or inappropriate therapies.⁴¹ About 40% of patients hospitalized with a diagnosis of heart failure have preserved ventricular systolic function, and this percentage increases dramatically at elderly age.

The decreased ventricular compliance of aging is an important contributor to age-related exertional dyspnea, even with exercise of low to moderate intensity. Decreased ventricular compliance results in elevated left atrial and pulmonary capillary pressures and may produce pulmonary congestion, pulmonary edema, and other classic manifestations of heart failure. Differentiation from predominant systolic dysfunction is important in that therapies differ markedly. Diuretic and venodilator drugs alone

may reduce ventricular filling volume and potentiate diastolic dysfunction; in one study, withdrawal of furosemide improved postprandial hypotension in elderly patients with heart failure and intact ventricular systolic function.⁴² The positive inotropic effect of digitalis may also be deleterious in diastolic dysfunction. Alleviation of heart failure symptoms in patients with ventricular diastolic dysfunction occurs with treatment with calcium channel-blocking drugs, beta-blocking drug, and angiotensin-converting enzyme (ACE) inhibitors.^{43,44} With verapamil, diltiazem, and beta-blocking drugs, surveillance is needed for adverse effects, including slowing of atrioventricular conduction and serious bradyarrhythmias.

Patients with left ventricular systolic decompensation present with cardiac enlargement, tachycardia, gallop sounds, lung rales or pulmonary edema; dependent edema, jugular venous distension, hepatomegaly, and ascites occur when right-sided heart failure supervenes. Weight gain may be evident. The skin, particularly of the extremities, may be cool as a result of peripheral vasoconstriction. Restlessness and agitation are due, in part, to increased sympathetic activity; control of heart failure more effectively limits these symptoms than does sedation. Pulsus alternans and Cheyne–Stokes respiration are evidence for severe cardiac decompensation.

As in younger patients, the major components of therapy for ventricular systolic dysfunction include restriction of dietary sodium, activity limitation until compensation is achieved, digitalis, diuretic drugs, vasodilator drugs, beta-blocking drugs, and spironolactone. These agents improve cardiac function by decreasing the cardiac workload, limiting sodium and water retention, and enhancing myocardial contractility.

Vasodilator therapy, beta blockade, and spironolactone have improved the outlook for elderly patients with ventricular systolic dysfunction. Vasodilator drugs—ACE inhibitors, angiotensin receptor-blocking drugs, and hydralazine plus nitrates^{45–48}—favorably alter the loading conditions of the heart, improve symptoms of reduced cardiac output, improve functional status, retard the spontaneous worsening of heart failure, and improve survival.

Some controlled clinical trials documenting the benefits of vasodilator therapy have included elderly patients.^{45,49,50} In the Veterans Administration Cooperative Study of hydralazine and nitrates that randomized patients as old as 75 years,⁵¹ comparable benefit occurred in patients older and younger than 60 years. ACE inhibitor benefit has also been demonstrated at very old age.⁵² ACE inhibitors are superior to hydralazine plus nitrates,⁴⁷ which can be used for patients intolerant to ACE inhibitors. Although a pilot study⁵³ suggested superior survival benefit with angiotensin II receptor blockade with losartan compared with ACE inhibition with captopril at elderly age, this was not subsequently substantiated.⁵⁴ Comparable benefit of ACE inhibitor

therapy in improving exercise tolerance and left ventricular ejection fraction occurred in patients older and younger than 65 years. As in younger patients, ventricular ejection fraction correlates poorly with symptoms and with exercise tolerance in the elderly. Although experience with beta-blocking drugs in elderly patients is less extensive than at younger age, with trials excluding patients over age 75 to 80 years, both carvedilol and metoprolol given to patients with class II and III heart failure improved ventricular systolic function, exercise tolerance, and survival.^{55–57} Spironolactone in patients up to age 80 with severe heart failure improved symptoms and prognosis.⁵⁸ These data suggest that newer therapies for heart failure should be applied to elderly patients, with careful attention to dose titration. However, these pharmacologic agents are currently underutilized in elderly patients hospitalized for heart failure.⁵⁹

Digitalis improves myocardial contractility and remains an important component of management of ventricular systolic dysfunction, even when sinus rhythm is present;⁶⁰ digitalis may limit the ventricular response to supraventricular tachyarrhythmias. In the DIG Trial,⁶¹ although survival was not altered, the combined endpoint of heart failure death or hospitalization was reduced in patients treated with digitalis. Lower doses are appropriate for elderly patients, such as 0.125 mg digoxin daily; because of the reduced glomerular filtration rate at elderly age that lessens drug excretion and because of the decrease in lean body mass, the volume in which digitalis is distributed, which causes an increase in plasma concentration. Dosage should be further reduced if quinidine, verapamil, or amiodarone are given concomitantly or if renal function is compromised. Digitalis overdose should be suspected when confusion, bizarre behavior, altered mental status, fatigue, or anorexia occur, in addition to the usual nausea and vomiting. Digitalis given for heart failure precipitated by an acute problem that has resolved can be safely discontinued.

Common complications of excessive diuretic therapy include dehydration and electrolyte abnormalities that often are manifest as altered mental status, increased likelihood of digitalis toxicity, and orthostatic hypotension that may result in orthopedic complications. The expected reflex tachycardia response to hypotension and hypovolemia is delayed and decreased at elderly age because of attenuation of baroreceptor reflexes.

Sodium restriction improves diuresis and limits the resultant hypokalemia; however, major dietary alterations require assistance and encouragement in elderly patients. Difficulties with food purchasing and preparation, lack of interest in meals when eating alone, dental problems that impair chewing, and financial constraints often hamper dietary alterations. Preprocessed “convenience foods,” which have high sodium content, are often a sizeable component of the diet of elderly individuals.

Although physical activity limitation is advisable when heart failure is decompensated, protracted immobilization predisposes to deep vein thrombosis and pulmonary embolism. When activity levels are increased after initial control of heart failure, the patient should be carefully observed for fatigue, breathlessness, edema, and weight gain as evidence of recurrent decompensation.

Deconditioning of skeletal muscles and impaired skeletal muscle vasodilator response to exercise result in a greater impairment of functional capacity in elderly than in younger patients with systolic heart failure. Resumption of a regular physical activity regimen is recommended once compensation is achieved;³⁸ functional capacity improves without apparent deterioration of ventricular function,⁶² predominantly due to adaptations of the intact skeletal musculature. Improvement in functional capacity can decrease dependency and disability.⁶³ Functional capacity, as gauged by a 6-min walk test, is an independent marker of prognosis.⁶⁴

Elderly patients with severe systolic dysfunction, particularly in association with atrial fibrillation, are candidates for oral anticoagulant therapy to limit thromboembolic complications.

Reversion of atrial fibrillation or atrial flutter to sinus rhythm can substantially augment the cardiac output and improve heart failure because of the importance of the atrial contribution to ventricular filling in the poorly compliant aged ventricle.

Because of the significant morbidity and mortality from cardiac failure at elderly age, patients require frequent and meticulous surveillance. An intensive multidisciplinary treatment strategy for heart failure involving specialized education, assessment, and management in a randomized clinical trial decreased readmissions and improved medication compliance. This approach has proved cost-effective in elderly populations by limiting rehospitalizations.^{65,66} Intensive home care surveillance resulted in improved functional status.⁶⁷ Absence of emotional support was a strong independent predictor of fatal and nonfatal cardiovascular events after hospitalization in older women.⁶⁸

Cardiac transplantation is uncommon in elderly patients but has been accomplished using older donor hearts. Rejection is less frequent, but the risk of infection and malignancy is higher in older than younger transplant patients.⁶⁹

Arrhythmias and Conduction Abnormalities

Both arrhythmias and conduction abnormalities increase in prevalence with increasing age.⁷⁰⁻⁷² Reflecting age-related changes in specialized conducting tissue and in atrial and ventricular myocardium.¹⁴

Although arrhythmias may present as syncope or altered consciousness, many elderly patients have significant arrhythmias in the absence of these symptoms or of palpitations. Syncope may result from either tachyarrhythmias or bradyarrhythmias. Because of the age- and disease-related decreases in cerebral blood flow, a lesser severity of bradyarrhythmia or tachyarrhythmia than required in younger patients may cause an alteration of consciousness or true syncope at elderly age. Because syncope of cardiovascular origin entails an enormous 1-year mortality rate, 24%, identification of its mechanism is urgent to enable appropriate therapy; elderly patients with syncope of a noncardiac cause have a more favorable outlook, with their annual mortality approximating 3%.^{73,74}

The prevalence of single supraventricular premature beats increases with aging. These beats are present in virtually all individuals older than 80 years of age, even in the absence of heart disease, are typically asymptomatic, and do not require treatment. There was no gender difference in the Cardiovascular Health Study.⁷⁵

Atrial fibrillation also increases in prevalence with increasing age, being present in almost 10% of the population older than 80 years;⁷⁶ it is a major contributor to stroke in elderly patients, even in the absence of valvular disease.⁷⁷ Atrial fibrillation was present in 5% to 6% of patients in the Cardiovascular Health Study,⁷⁸ predominantly in association with cardiovascular disease. In this study,⁷⁸ a history of heart failure, valvular heart disease, or stroke; left atrial enlargement on echocardiogram; abnormal mitral or aortic valve function; treated hypertension, and advanced age all were independently associated with an increased prevalence of atrial fibrillation in community-dwelling elderly men and women. In the Framingham Heart Study,⁷⁹ atrial fibrillation was associated with an increased risk of mortality, more so for women than for men (odds ratio of 1.5 and 1.9, respectively). The major issues relate to rate control, cardioversion, and stroke prevention. Success of cardioversion, in a prospective study, was comparable for patients older and younger than age 65.⁸⁰

Chronic atrial fibrillation is associated with an increased incidence of stroke that accelerates with age. Anticoagulation⁸¹ can reduce stroke risk by almost 70%. Warfarin anticoagulation appears particularly warranted when atrial fibrillation is associated with heart failure.⁸² Reduction in stroke and stroke mortality has been documented with warfarin treatment, even in patients older than 75 years so treated. However, elderly patients remain undertreated with warfarin based on clinical practice guidelines for atrial fibrillation.⁸³ Antiplatelet agents have not been effective in preventing stroke in elderly patients with nonvalvular atrial fibrillation.

Ambulatory electrocardiography in elderly persons who are presumably free of cardiac disease shows that

ventricular arrhythmias are pervasive (see Table 39.1), including frequent multiform ventricular ectopic complexes (PVCs)⁸⁴ and nonsustained ventricular tachycardia (VT).⁷² Asymptomatic ventricular arrhythmias do not impart excess risk in healthy elderly patients and rarely require treatment in the absence of significant myocardial ischemia or ventricular dysfunction. Ventricular arrhythmias on 24-h ambulatory ECG were more common in elderly men than elderly women in the Cardiovascular Health Study.⁷⁵ Nonsustained VT on 24-h ambulatory ECG in the Bronx Longitudinal Aging Study⁸⁴ independently predicted death and MI. Very frequent ventricular premature beats, in excess of 1000 per 2h, signify a poor prognosis in very old people with coronary heart disease.²³

Older age independently predicted increased ventricular arrhythmia following MI in the cardiac arrhythmia suppression trial (CAST) Registry.⁸⁵ Hourly PVCs increased from 0.4 in patients younger than 50 to 4.0 at 75 to 80 years, with VT prevalence increasing from 7.3% to 15.3% respectively. Electrophysiologic testing or signal-averaged ECGs offer little benefit in identifying high risk status in asymptomatic elderly patients with ventricular arrhythmias.⁸⁶

Adverse antiarrhythmic drug reactions are more common in elderly patients due to their altered metabolic function and drug elimination, as well as to the frequent polypharmacy; antiarrhythmic drugs also are more likely to potentiate conduction abnormalities and ventricular dysfunction in an elderly population. In one study of antiarrhythmic drug therapy for asymptomatic complex ventricular arrhythmias in a geriatric population, the high incidence of adverse drug effects necessitated frequent discontinuation of therapy, and therapy did not improve survival, with or without ventricular systolic dysfunction.⁸⁷ Elderly patients with symptomatic, refractory life-threatening ventricular tachyarrhythmias tolerate electrophysiologic testing well; this procedure can identify patients who require drug therapy or surgical intervention including Coronary Artery Bypass Graft (CABG) surgery, endocardial resection, aneurysmectomy, or cardioverter-defibrillator implantation.⁸⁸ The pharmacologic management of supraventricular and ventricular arrhythmias is comparable in elderly and younger patients, except that lower doses of medication are usually indicated. Radiofrequency catheter ablation therapy is effective and safe to treat tachyarrhythmias at elderly age.^{89,90}

Bradycardias, both the sick sinus syndrome and complete atrioventricular block, occur frequently in an elderly population; symptomatic bradycardias are the major indications for pacemaker implantation. Sick sinus syndrome does not generally require treatment in the absence of symptoms or extreme bradycardia. Digitalis and calcium- and β -blocking drugs, used to treat coronary disease and hypertension, may accentuate the

bradycardia of the sick sinus syndrome; in elderly patients with the bradycardia-tachycardia subset of the sick sinus syndrome, pacemaker implantation may be required to permit pharmacologic treatment of the tachyarrhythmias with digitalis, β -blocking drugs, or calcium-blocking drugs.

Pacemaker implantation is appropriate at all ages, because pacemakers can improve symptoms and both the length and quality of life.⁹¹ Currently the median patient age of pacemaker recipients in the United States is approximately 70 years, rendering the geriatric population the major beneficiary of this therapy. Before permanent pacing, more than half of all patients with complete atrioventricular block died within 2 years. Pacemaker implantation, even at an elderly age, entails minimal morbidity and mortality. Even in octogenarians and nonagenarians, normal relative survival occurred in those without other heart disease.⁹² Coexisting heart disease and, in particular, preexisting heart failure adversely affect long-term survival.⁹²

Although ventricular demand pacemakers remain the most common units in use, rate-responsive dual-chambered pacemakers have advantages in alert and active elderly patients with underlying sinus rhythm in that atrial contraction contributes importantly to ventricular function when ventricular compliance is abnormal, and that the cardiac rate is proportional to the activity need.⁹³ Disadvantages of these complex pacemakers are their higher cost and the increased skill of the physician needed for implantation and surveillance. However, dual-chamber pacemaker use in the Medicare national hospital database was associated with increased survival,⁹⁴ even after controlling for potentially confounding patient characteristics.

Pacing mode should be determined not by patient age but by the etiologic electrophysiologic problem. Sinus bradycardia is a common rhythm in elderly patients; when asymptomatic, it is not an indication for pacemaker implantation or other intervention. Similarly, asymptomatic complete atrioventricular block does not warrant pacing. A consensus guideline for indications for pacemaker implantation prepared by the American College of Cardiology/American Heart Association is equally appropriate for older and younger patients.⁹⁵ In elderly patients with limited mobility, transtelephonic pacemaker surveillance may be helpful.

Limited data are available about use of implantable cardioverter-defibrillators in elderly patients. Although these devices can be placed with minimal risk and are equally effective in preventing sudden death in older as in younger patients, nonsudden cardiac death was increased three times in one series of patients older than 75 years.⁹⁶

A review of the success of cardiopulmonary resuscitation in elderly patients shows it to be less effective than

in younger individuals. Characteristics associated with a favorable outcome include ventricular tachycardia or fibrillation as etiologic versus asystole or electromechanical dissociation and the symptom of chest pain versus that of dyspnea. Survival after cardiopulmonary resuscitation among elderly nursing home residents is extremely low.⁹⁷

Atherosclerotic Coronary Heart Disease

Atherosclerotic coronary heart disease (CHD) is the most prevalent cardiac disease at elderly age, involving an estimated 3.6 million patients.⁹⁸ Coronary disease is responsible for more than two-thirds of all cardiac deaths among the elderly U.S. population, and morbidity and mortality from CHD increase progressively with age. In the United States, most patients with CHD, with new episodes of acute myocardial infarction, and with chronic heart failure secondary to CHD are older than 65 years of age.⁹⁹ About 60% of patients hospitalized in the United States for acute myocardial infarction are older than 65 years,¹⁰⁰ and the incidence of MI increases prominently with increasing older age.¹⁰¹ Not only is coronary disease highly lethal at elderly age, but disability is prominent; 50% of men and 20% of women aged 55 to 64 years with CHD have activity limitation, versus 85% and 55%, respectively, at 75 years and older. Nevertheless, there is a wide variation in the severity of coronary illness and in the functional status of elderly coronary patients. The male preponderance among younger coronary patients lessens at elderly age and gender difference in MI incidence virtually disappears by the eighth decade; clinical evidence of CHD is present in about 20% of both men and women by age 80. Although coronary atherosclerosis is almost uniformly present at autopsy examination of elderly patients, many have never had clinical manifestations of myocardial ischemia.

Angina Pectoris

A recent study of nonhospitalized patients with angina pectoris¹⁰² revealed a mean age of 69 years, with 75% of the population women; although 90% described effort angina, 47% had rest angina, and 35% had angina precipitated by mental stress.

The presentation of angina pectoris, both as an isolated event and following myocardial infarction, is more likely to be atypical, owing to a combination of a habitually decreased activity level, associated diseases, and possibly an altered sensitivity to pain in elderly persons. Angina is less likely to be activity induced in that arthritis, claudication, or musculoskeletal problems limit activity for many elderly patients before angina occurs. This angina

may be misinterpreted as unstable because it occurs at rest in predominantly inactive patients. Furthermore, angina is more likely to be precipitated by a concurrent medical or surgical problem such as infection, blood loss, hypertension or hypotension, thyrotoxicosis, or arrhythmia. Dyspnea and fatigue may be the prominent manifestations of myocardial ischemia, and eating may precipitate angina. Additionally, patients with memory loss may not remember transient chest pain and those with chronic brain syndromes may not appreciate, describe, or express the occurrence of chest discomfort. Silent ischemia is highly prevalent at elderly age,¹⁰³ with the risks greatest in the early morning hours or on awakening; standard anti-ischemic therapy is appropriate. Despite this high prevalence of silent ischemia, exertional chest pain independently predicts coronary death at elderly age,¹⁰⁴ with comparable prognostic significance for men and women, although anginal severity does not define risk status.

Therapy is as for younger patients, but attention must be directed to identification and remediation of precipitating or exacerbating factors. Elderly patients with stable angina, without evidence of early ischemia at exercise testing, who have a satisfactory symptomatic response to medical management are best suited for this approach. Elderly age is associated with increased fatal and nonfatal coronary events in patients with both stable and unstable angina; suboptimal pharmacologic and revascularization therapies likely contribute to the less favorable outcome.¹⁰⁵

Severe unstable angina is common in elderly persons. When unresponsive or poorly responsive to intravenous nitroglycerin, oral aspirin, heparin, β - and calcium-blocking drugs as tolerated, and IIb/IIIa glycoprotein inhibitor therapy, urgent coronary arteriography is indicated to evaluate suitability for myocardial revascularization.

Myocardial Infarction

Elderly patients have a significantly different presentation, clinical course, and prognosis of MI than is the case at younger ages.⁹⁹ There is a marked increase in morbidity and mortality,¹⁰⁶ with 80% of all MI deaths occurring after age 65. Mortality from acute MI is increased 6-fold at ages 75 to 84 years and 15-fold after 85 years, compared with that at ages 55 to 64 years.¹⁰⁷ Functional disability before MI importantly predicts MI severity and postinfarction survival.¹⁰⁸ Although age adversely affects MI survival in part because prior MI, hypertension, and heart failure all increase with increasing age,¹⁰⁹ the contribution of less aggressive therapies requires study.¹¹⁰ In the Myocardial Infarction Triage and Intervention (MITI) project, MI mortality was increased 10-fold in elderly patients (17.8% at 75 years

or more versus 2% at less than 55 years).¹¹¹ The prognosis was worse for elderly women than elderly men,¹¹² although data from the U.S. National Registry of Myocardial Infarction-2 suggest otherwise.¹¹³

Chest pain as the presenting manifestation of acute MI is less frequent in elderly individuals.^{114,115} Classic chest pain is reported by only one-third of patients older than 85 years of age. Elderly patients have an increased prevalence of comorbid illness associated with painless infarction such as diabetes and hypertension. Additionally, there may be lesser or altered sensitivity to pain with aging. Although the myocardial infarction may be painless, the clinical presentation is often not asymptomatic and may include acute dyspnea, exacerbation of heart failure, or pulmonary edema; and syncope, cerebrovascular accident, vertigo, palpitations, peripheral arterial embolism, nausea and vomiting, or acute renal failure; more subtle changes involve altered mentation, including acute confusion or agitation, profound weakness or fatigue, and changes in eating pattern or in other usual behaviors. The onset of symptoms of MI is more likely to occur at rest or during sleep in elderly patients, likely reflecting their more sedentary lifestyle. Unrecognized MI has as serious a prognosis as identified episodes of MI.¹¹⁴ Based on Framingham data, unrecognized MI is more common in elderly women than in elderly men. Twenty-three percent and 38% of elderly men and women, respectively, with ECG evidence of MI in the Cardiovascular Health Study⁶ did not report a history of MI. In the Goteborg Study, 60% of patients with ECG evidence of MI gave no history of an acute episode.¹¹⁶

Asymptomatic or atypical presentations of MI commonly exclude elderly patients from the potential benefits of thrombolytic therapy or acute coronary angioplasty. Acute MI in elderly patients is often a non-Q-wave MI and, as is the case with angina pectoris, is more often precipitated by an intercurrent medical or surgical problem associated with hypovolemia, blood loss, infection, hypotension, and the like (Table 39.2). Atypical symptoms may partly explain the delayed hospital presentation at elderly age.¹¹⁷ Acute myocardial infarction, because of its atypical presentation, is more often unrecognized in aged patients, despite the fact that infarction in elderly persons characteristically is of increased severity, has a greater occurrence of complications, entails a longer hospital stay, and results in a higher mortality than in a younger age group. Elderly patients are more likely to be female; to have associated hypertension, diabetes mellitus, and cerebrovascular accident; and to have a history of prior infarction and of heart failure.

In addition to the atypical presentation, the diagnosis of MI may be further obscured in that the electrocardiographic diagnosis is limited by the increased occurrence of non-Q-wave infarction,¹¹⁸ and elevated myocardial

TABLE 39.2. Atypical manifestations: acute myocardial infarction (MI) in elderly patients.

Presentation
Painless infarction more common
Acute symptoms

Hypotension

band (MB) fractions of creatine kinase (CK) are common in the presence of a normal total CK level because of decreased lean body mass with aging.¹¹⁹

Pooled data from large randomized placebo-controlled trials of thrombolytic therapy for acute MI, involving more than 58,600 patients, have shown comparable benefit at young and older ages up to age 75 years, with comparable efficacy of all thrombolytic drugs tested in elderly patients.¹²⁰⁻¹²² Advanced age alone (up to age 75) should not exclude patients from treatment with thrombolytic therapy.¹²³ The ACC/AHA clinical practice guidelines for acute MI cite a class I recommendation for this treatment for patients up to age 75 and a class IIa for those 75 and older.¹²⁴ Statistically significant reduction in mortality was more prominent at older than at younger age, despite the increased risk of bleeding, and in particular intracerebral bleeding, in the elderly.¹²⁵⁻¹²⁸

Improvement in ventricular function occurred at all ages studied. Because the absolute risk of MI mortality is greater at 65 to 75 years than for younger patients, the absolute benefit of successful coronary thrombolysis is also greater.¹²⁹ However, even with successful thrombolysis, patients older than 75 years in GUSTO-I had more left ventricular (LV) dysfunction and greater mortality than those younger than age 75.¹³⁰ Lesser use of thrombolytic therapy at advanced age is due, in part, to the later arrival at hospital of elderly patients.^{111,131,132} Even in elderly patients known to have CHD, delay in accessing medical care was substantially greater than at younger age.¹³³ Elderly female patients and those with

diabetes were treated later in the GUSTO-I trial, adding to their already substantial risk.¹³⁴ Since 1990, however, data suggest increased use of thrombolytic therapy for elderly patients, particularly elderly women.¹³⁵ Robust data are lacking for patients older than 75 years of age¹³⁶ because these patients typically have been excluded from earlier studies of these interventions.

Caution is warranted regarding coronary thrombolysis beyond age 75. An observational study derived from the Medicare database suggested significant survival disadvantage, without benefit in any clinical subgroup.¹³⁷ Clearly randomized trial data are needed, given the limitations of observational studies.¹³⁸ In particular, the contribution of higher-dose, nonweight-based heparin therapy to bleeding risk at elderly age was not ascertained. In GUSTO V, thrombolysis with half-dose reteplase plus abciximab (a IIb/IIIa platelet glycoprotein inhibitor) was associated with increased intracranial bleeding beyond age 75.¹³⁹

In the Cooperative Cardiovascular Project, primary percutaneous transthoracic coronary angioplasty (PTCA) was associated with modestly lower short- and long-term mortality rates than coronary thrombolysis,¹⁴⁰ there was a 16% reduction in 30-day mortality risk. Among the 80 patients older than age 80 in GUSTO-IIB,¹⁴¹ there was no 30-day mortality difference between coronary thrombolysis and acute angioplasty, with high mortality rates in both groups. Acute coronary angioplasty (PTCA) should also be considered for elderly patients for whom coronary thrombolysis is contraindicated; up to a 90% procedural success rate was described for patients age 70 years and older,¹⁴² with favorable outcomes also described in octogenarians.¹⁴³ Risk of cerebral hemorrhage is dramatically less with acute PTCA than with coronary thrombolysis in elderly patients.

In-hospital mortality is greater in patients older than 70 years of age; the 30% to 40% mortality is about twice that of younger patients. Complications including hypotension and cardiogenic shock, atrioventricular block, atrial arrhythmias, heart failure, pulmonary edema, and cardiac rupture occur with increased frequency in elderly patients. In the SHOCK trial, emergency revascularization did not benefit patients with MI and cardiogenic shock older than age 75.¹⁴⁴ Cardiac rupture during the first week after MI occurs, particularly in elderly women with hypertension. In one series, MI mortality was doubled with the occurrence of atrial fibrillation. Right ventricular infarction substantially increases hospital mortality.¹⁴⁵ Severe mitral regurgitation due to papillary muscle infarction and cardiac rupture of either the ventricular septum or a papillary muscle usually are heralded by recurrent chest pain, pulmonary edema, and/or cardiogenic shock. Use of intraaortic balloon counterpulsation enables survival until cardiac catheterization and surgical repair can be performed. In patients

with these surgically correctable lesions, favorable responses to surgical intervention have been described.¹⁴⁶ Despite the high operative mortality, survivors have a satisfactory long-term outcome. Not surprisingly, elderly patients often have a more protracted hospital stay for MI.

Although survival of elderly patients improved substantially from 1987 to 1990, particularly for those younger than 85 years, the decline in CHD mortality has been less prominent in elderly than in younger patients. Concomitant changes included the increased use of acute pharmacologic and invasive interventions to limit infarct size and revascularize myocardium.^{147,148} In one study,¹⁴⁹ hospital complications and 30-day and 1-year mortality rates declined approximately 30% in patients aged 75 and older, with the most marked benefit in reperfused patients. Major differences still persist in the application of beneficial therapies to patients older than 75 versus younger than 55: 5% versus 39% thrombolytic therapy, 7% versus 29% PTCA, 5% versus 11% CABG, and 57% versus 82% aspirin use.^{111,150,151} Early beta-blocker therapy was not used for 51% of elderly patients hospitalized for acute MI in the Cooperative Cardiovascular Project,¹⁵² although this therapy was associated with a 19% reduction in mortality risk across all age groups in the Medicare cohort. Posthospital mortality is also increased following MI, due to the increased severity of infarction, often superimposed on prior infarction; this also accounts for the increased residual invalidism and increase in late deaths at elderly age.

In the early years of acute coronary care, elderly patients were arbitrarily excluded from coronary or intensive care facilities on the basis of age alone. However, elderly patients benefit equally from intensive coronary care, ECG monitoring, and arrhythmia prevention and reversion. In particular, they have an equally favorable response to defibrillation as younger patients. The increased occurrence of heart failure at elderly age and other complications of infarction and frequent complicating illnesses warrant meticulous surveillance. Elderly patients with heart failure more often require monitoring of cardiac output and intracardiac pressures through a pulmonary artery catheter to guide therapy. Other problems encountered more frequently in the elderly patient with MI include difficulty with urination, particularly in men with prostatic enlargement who receive diuretic therapy; constipation and a variety of nonspecific gastrointestinal symptoms; and the precipitation of glaucoma, urinary retention, or confusion when atropine is used to reverse sinus bradycardia. The early mortality of elderly patients after MI has been reduced from an estimated 43% to 79% to as low as 25% to 27% with coronary care unit management; this difference probably is related to increased intensity of coronary care unit therapy.¹⁵³

Drug management of acute MI is comparable with that of a younger population. There is an increased propensity to adverse effects from narcotic analgesic medications; half the dosage usual for younger individuals is recommended. In general, adverse responses to drug therapy are more likely to occur and can be exacerbated by coexisting medical illnesses and related multiple-drug therapy. All drugs should be introduced at lower doses than in younger patients, with gradual dosage increases as tolerated. Intravenous administration of beta-blocking drugs in acute MI improved survival only in older patients,¹⁵⁴⁻¹⁵⁸ although data are not available for patients older than 75 years. Long-term oral beta-blocking drugs provide equal or greater long-term survival benefit and reduction of reinfarction after MI in elderly as in younger patients,¹⁵⁹ particularly for patients with anterior MI, with data available to age 75 years.^{155,160,161} Contemporary data suggest underutilization of beta-blocking drugs in elderly patients after acute MI,¹⁶² with only 21% of eligible patients receiving this therapy¹⁶³ in one study and 50% in another.¹⁶⁴ Beta-blocker use was associated with a 43% decreased mortality rate and 22% decreased rehospitalizations in a Medicare cohort, with benefit also evident in patients older than age 75.

Diltiazem and verapamil appear to provide comparable benefits in younger and older patients with non-Q-wave MI and preserved ventricular function, although calcium channel-blocking drugs have not improved survival and may worsen outcome in patients with ventricular dysfunction.¹⁶⁵ However, most studies of calcium channel-blocking drugs in patients with non-Q-wave MI did not provide aged-based analysis, despite inclusion of elderly patients.

Comparable reduction in mortality occurred in patients with MI older and younger than 70 years treated with aspirin during acute MI in the international study of infarct survival (ISIS-2) trial.¹⁶⁶ Virtually no patients older than 75 years were enrolled in other clinical trials of aspirin use. Of concern is that about one-third of elderly patients with acute MI without contraindications to aspirin use failed to receive aspirin during the first 2 days of MI hospitalization.¹⁶⁷ Aspirin use was associated with a 22% decrease in 30-day mortality risk in this Medicare population. Aspirin was not prescribed at discharge to 24% of eligible elderly patients in the Cooperative Cardiovascular Project.¹⁶⁸

Angiotensin-converting enzyme (ACE) inhibitors likely provide comparable benefit in elderly and younger patients, particularly those with large infarctions and ventricular dysfunction. ACE inhibitor therapy in patients with a decreased ejection fraction following MI decreased fatal and nonfatal cardiovascular events, including the development of heart failure and recurrent infarction; relative risk reduction was greater for the 35% of patients older than 65 years.⁴⁹ Elderly patients in the

GISSI-3 trial also had decreased mortality and severe ventricular dysfunction associated with ACE inhibitor therapy.¹⁶⁹

Long-term warfarin anticoagulation after acute MI reduced reinfarction in elderly patients in the Sixty-Plus Reinfarction Trial, without significant deleterious bleeding risk. The Warfarin Re-Infarction Study¹⁷⁰ showed survival, reinfarction, and cerebrovascular benefits in patients up to age 75 randomized to warfarin, although a post hoc analysis showed attenuated benefit with increasing age.¹⁷¹

Data from the Cardiac Arrhythmia Suppression Trial (CAST) discourage use of antiarrhythmic drugs for MI survivors of all ages without symptomatic arrhythmia, even those with complex ventricular arrhythmia, owing to increased mortality risk from drug proarrhythmic effects.¹⁷² In CAST, ambulatory ECG data showed that age was an important independent predictor of ventricular ectopy in postinfarction patients.¹⁷³

Nitrate drug use requires attention to orthostatic hypotension because of diminished baroreceptor responsiveness; elderly patients must be cautioned to sit when taking sublingual nitroglycerin for relief of angina.

Among eligible patients recently hospitalized for MI, lipid-lowering drugs were used by only one-third. Age greater than 74 years was independently related to lack of lipid-lowering drug use.¹⁷⁴

A substantial number of elderly patients have an essentially uncomplicated MI with an excellent prognosis for recovery and rehabilitation. They are ideal candidates for early ambulation to prevent the deleterious effects of prolonged immobilization. Education and counseling are important components of care. At discharge, there should be a careful review of medications, with written recommendations for diet, activity, and coronary risk reduction.

Predischarge exercise testing appears safe for appropriately selected elderly patients who remain asymptomatic and offers prognostic data comparable to that reported for younger patients.¹⁷⁵ Inability to undergo exercise testing 1 month after MI is a marker of unfavorable prognosis.¹⁷⁶ As is the case in younger patients, the lower the exercise intensity at which ischemic ST segment abnormalities appear, the greater their severity, and the longer their persistence after cessation of exercise, the greater the risk. Failure of SBP to increase with exercise or exercise-induced hypotension also indicates a high-risk status. Evidence of residual ischemia at exercise testing, with and without radionuclide studies, or with dipyridamole-thallium imaging in elderly patients with non-Q-wave MI is associated with an increased risk of mortality and warrants consideration for invasive intervention.^{177,178} Elderly patients with non-Q-wave MI have greater mortality risk in the year after hospital discharge than do patients with Q-wave MI; aggressive diagnostic

and therapeutic interventions may be of particular benefit in these patients.¹⁷⁹ (See p. 530 for coronary risk reduction.)

Lack of emotional support independently predicts mortality risk after MI.¹⁸⁰ Although many male coronary patients 80 years and older have a spouse for social support and to assist as a caregiver, women with CHD of comparable age often have no such companion and may forfeit their independent lifestyle.

Exercise test data can be used to recommend the intensity of physical activity that can be performed with safety following discharge from the hospital. Many elderly patients can exercise safely without supervision; pre-discharge exercise testing can identify the high-risk subset of patients for whom initially supervised exercise is appropriate. Exercise test results can also guide recommendations for return to preinfarction physical activities, including resumption of remunerative work when appropriate. Many physicians underestimate the habitual physical activity level of their older cardiac patients and inappropriately recommend restriction of physical activity.¹⁸¹ Excessive immobilization is associated with detrimental physical and psychologic consequences. In contrast, many elderly individuals decrease their activity levels because any submaximal task is perceived as requiring increased work; this is because of the increase in relative energy cost caused by the lessened aerobic capacity that occurs with aging. Even with usual daily activities, there is a greater increase in heart rate in elderly people. Additionally, combinations of musculoskeletal instability, emotional problems (particularly depression), and often inappropriate admonitions from family members and friends further decrease activity levels.

Rehabilitative exercise training can limit the high risk of disability of elderly patients after a coronary event¹⁸¹ and encourage coronary risk reduction.¹⁸² The goal of rehabilitation is restoration, maintenance, and extension of a reasonably independent and active lifestyle. Although an increasing percentage of elderly patients after MI or myocardial revascularization procedures are currently enrolled in supervised exercise rehabilitation programs or prescribed an independent exercise regimen by their physicians, elderly patients (particularly elderly women) are less likely to be referred than younger patients.⁶³ Comparable improvements in physical work capacity and in endurance occur in elderly as in younger men and women, and appropriate exercise entails no greater risk.^{63,183,184} Walking is an ideal exercise regimen after discharge from the hospital, with gradual increases in the pace and distance of walking. Because the energy expenditure of walking often entails a significant proportion of the aerobic capacity of elderly patients, walking even as slowly as 3.5 miles per hour is an excellent physical conditioning stimulus. The major physio-

logic effect is a decrease in the heart rate response to submaximal work. Additional benefits of exercise training include improved neuromuscular coordination, joint mobility, coordination, and flexibility, and the potential to limit bone demineralization. Exercise testing for exercise prescription is recommended before embarking on a more intensive physical activity regimen. High-impact aerobic activities are inappropriate at elderly age as they are associated with an increase in musculoskeletal complications.¹⁸⁵

Myocardial Revascularization

Elderly patients with chronic angina unresponsive or poorly responsive to medical management, or those with persisting chest pain following MI, are candidates for coronary arteriography to assess their suitability for myocardial revascularization. Older patients with evidence of myocardial ischemia at low work loads at exercise testing also constitute a high-risk group for early recurrent coronary events and should be evaluated for myocardial revascularization. Because a high percentage of posthospital deaths in very elderly patients are either sudden or due to recurrent MI, risk stratification testing should routinely be considered for patients older than 75 years as at ages 65 to 75¹⁵⁰ to identify the subset for whom myocardial revascularization is appropriate.

Elderly patients are more likely to have multivessel coronary disease and left main coronary stenosis, and coronary lesions are more likely to be diffuse and calcified. It is thus not surprising that elderly patients undergoing CABG are more likely to have unstable angina, prior MI, and New York Heart Association class IV heart disease than younger patients. Elderly patients are also characterized by a higher percentage of women and a greater likelihood of comorbid conditions including diabetes, hypertension, heart failure, renal insufficiency, and PVD.

Older age patients now constitute more than half the population undergoing cardiac catheterization, PTCA, and CABG surgery.¹⁰⁰ CABG surgery in patients 80 years and older increased 67% between 1987 and 1990,¹⁸⁶ providing a Medicare database of almost 25,000 such patients; in recent years, mortality rates for elderly patients undergoing revascularization procedures decreased in this Medicare database. In nonrandomized but comparable elderly patients older than 70 years undergoing myocardial revascularization procedures, there was substantially less hospital mortality, stroke, and MI with PTCA than with CABG; in the ensuing 5 years, however, PTCA patients required more repeat procedures, but 5-year mortality was comparable for PTCA and CABG patients, about 30%.¹⁸⁷ Elderly patients (≥ 70 years) with unstable angina at high risk for CABG who

were treated successfully with PTCA had long-term mortality comparable to that of age-matched subjects without diagnosed CHD.¹⁸⁸

Recent series have described outcomes of CABG surgery in selected octogenarians and nonagenarians, usually with highly symptomatic and unstable coronary disease, who were unresponsive or poorly responsive to medical management.¹⁸⁹⁻¹⁹² In addition to the more likely left main and triple-vessel coronary disease, often with ventricular dysfunction, and substantial comorbidity in elderly patients, older age is an independent risk factor for morbidity and mortality from CABG, with elderly women at highest risk.¹⁹³ A recent report describes a 10% hospital mortality rate in octogenarians, with diabetes and ventricular dysfunction adversely affecting outcome.¹⁸⁹ Despite the initial high risk and significant hospital expenses, survivors were pain-free, often with restored performance status, and with 5-year survival rates comparable to that of the general octogenarian population in the United States.¹⁸⁶ Evaluation of elderly patients with diabetes in the CASS Registry¹⁹⁴ showed surgical benefits comparable to those in nondiabetic elderly patients, a 44% reduction in mortality compared with medical therapy. As in younger populations, use of at least one internal mammary artery graft improved symptoms and event-free survival in patients 70 years and older.¹⁹⁵ The symptomatic improvement and favorable late sustained improvement and quality of life among elderly survivors of CABG suggest that an optimistic approach to the management of symptomatic elderly patients with advanced obstructive CHD is reasonable,¹⁹⁶ even for selected octogenarians and nonagenarians.^{190,191}

Patients older than 70 years of age sustain a higher operative mortality from elective CABG than do younger individuals, as well as higher rates of postoperative cardiac and noncardiac complications, which occur in as many as 30% to 50%. These complications include greater need for prolonged ventilatory support for respiratory failure; for implanted pacemakers; for inotropic support and use of the intra-aortic balloon pump; greater reoperation for bleeding; stroke; delirium; renal failure; perioperative infarction; and sepsis. Complications are most frequent in elderly women.¹⁹⁷ Atherosclerotic emboli from aortic atheromatous disease contribute importantly to complications; intraoperative transesophageal echocardiography can identify protruding atheromas that require modification of aortic manipulation.¹⁹⁸ Increased age predisposes to impaired cognition after cardiac surgery unrelated to changes in cerebral blood flow autoregulation.¹⁹⁹ Elderly patients can be anticipated to have a longer hospital stay following CABG, with more time spent in an intensive care setting.¹⁸⁹ Emergency CABG in elderly patients entails a substantially increased mortality risk, 14.9% versus 3.6% for elective surgery in one series.²⁰⁰

In elderly patients with preserved ventricular function and without major associated medical problems, 5-year survival following successful CABG approximates 90%. In the CASS, 81% of elderly patients were free of recurrent angina, MI, requirement for repeat CABG surgery, or death at 1 year, and 40% were free of such events at 5 years. These results were comparable to those in patients younger than age 65. High-risk patients older than age 65 years in the CASS²⁰¹ had better survival and freedom from chest pain with surgical management than with medical management. Nevertheless, operative morbidity and mortality is greater, hospitalization is more protracted, and overall survival is less than that for younger patients.²⁰² However, because elective CABG in patients older than 75 years resulted in an operative mortality of 3.6% in one series versus 14.9% mortality for urgent or emergency CABG surgery,²⁰⁰ early evaluation and referral for elective revascularization of symptomatic elderly patients may avert the excess mortality of emergency revascularization. In a study comparing CABG in patients older and younger than 75 years, actuarial 5-year cardiac event-free survival rates were comparable.²⁰³ As myocardial revascularization procedures are increasingly undertaken in highly symptomatic octogenarians and nonagenarians, the outcomes appropriate for assessment include restoration of comfort, self-sufficiency, and improved functional status, that is, meaningful long-term survival.²⁰⁴ Early ambulation and gradually progressive physical activity after CABG can help limit complications and improve the functional status at discharge from the hospital.

Although direct comparison of the results of PTCA with those of CABG is not available, because of the increased risk of CABG at elderly age and because catheter-based interventions often are better tolerated than surgery, there has been increased application of PTCA to elderly patients. There is an equal or greater increase in PTCA application among elderly women than elderly men. However, often the coronary anatomy is unsuitable for transcatheter revascularization. The incidence of left main coronary artery disease has been estimated to be 13% to 35% in different series. Recent reports of PTCA at elderly age documented angiographic success rates of 80% to 90%, even with multivessel PICA, without excess occurrence of procedural complications and with functional improvement and patency rates comparable to those at younger age.²⁰⁵⁻²⁰⁷

If complete revascularization is achieved, freedom from recurrent angina and cardiac death is comparable to that in younger patients.²⁰⁸ Incomplete revascularization is associated with poorer long-term survival.²⁰⁹ In the Mayo Clinic experience, despite improved technical success and decreased short-term PTCA complication rates, event-free survival rates continued to be influenced by baseline characteristics.²¹⁰ Restenosis rates, even

among octogenarians, are comparable to those in younger patients.²¹¹

Age remains an important predictor for procedural mortality and late survival in PTCA, particularly for patients older than 80 years.^{206,212} However, almost three-fourths of elderly survivors of PTCA do not require CABG surgery and remain free of MI at 4 to 5 years. Compared with patients 65 to 74 years, patients older than 75 years were more symptomatic, more likely to have heart failure, and more likely to require multivessel PICA.²¹³ The increased incidence of vascular site complications reflects the high prevalence of PVD. Despite a high rate of procedural success, PTCA in patients older than 90 years involved a high rate of in-hospital complications and limited clinical benefit.²¹⁴

Limited data from elderly patients with high-risk lesion morphology at coronary arteriography suggest that coronary angioplasty using new devices and stenting may be a therapeutic alternative.²¹⁵ Substantial changes in both surgical and transcatheter revascularization techniques mandate comparison of these contemporary approaches in the elderly population.

Systemic Arterial Hypertension and Cardiovascular Risk

Hypertension is highly prevalent at elderly age, occurring in more than half of the U.S. population older than 65 years.²¹⁶ Hypertension and its consequences comprise the major reason for which patients in the United States consult their physicians. In most populations, systolic blood pressure (SBP) increases into the eighth and ninth decades, whereas diastolic blood pressure (DBP) levels off in the fifties and sixties; thus, isolated systolic hypertension (ISH) is prominent in geriatric populations.²¹⁷ Both reduced arterial compliance and increased cardiac output appear to contribute to ISH at elderly age.²¹⁸ Pulse pressure widens in old age as a result of a continued increase in SBP and a decrease in DBP. Low DBP, particularly in association with a wide pulse pressure, appears to reflect widespread atherosclerosis at elderly age.²¹⁹ The age-related increase in SBP is not invariable and is infrequent in most nonindustrialized societies. Lower rates of hypertension are described in physically active elderly women, with blood pressure progressively lower at higher levels of activity.²²⁰ The World Health Organization (WHO) definition of hypertension is a blood pressure in excess of 160/95 mmHg. Isolated systolic hypertension is defined as a SBP in excess of 150 mmHg with a DBP below 90 mmHg, and accounts for approximately two-thirds of hypertension in persons older than 65 years. In the United States, approximately one-third of elderly women and one-fifth of elderly men have ISH. Either ISH or combined sys-

tolic and diastolic hypertension occurs in 63% of whites and more than 75% of blacks older than 65 years.²¹⁶ Major elevation in DBP in excess of 110 mmHg is three times as common in elderly black patients as in elderly white patients. Hypertension remains a powerful predictor of cardiovascular mortality at all ages; even borderline systolic or diastolic hypertension doubles the risk of cardiovascular events at elderly age. Although the increase in risk is related to the severity of hypertension, systolic hypertension is more closely correlated with cardiovascular and cerebrovascular morbidity and mortality at elderly age than is diastolic hypertension.^{221,222} Systolic blood pressure, determined by ambulatory blood pressure monitoring, significantly predicted cardiovascular risk over and above conventional blood pressure monitoring in the Systolic Hypertension in Europe trial.²²³ Development of left ventricular hypertrophy (LVH), a potent independent risk factor for cardiovascular mortality, is highly correlated with systolic hypertension. In the Framingham Heart Study, even borderline ISH at elderly age was associated with increased LV wall thickness and impaired diastolic filling.²²⁴ Antihypertensive agents that can effect regression of LVH may contribute to decreasing cardiovascular complications. Elevated SBP, which increases ventricular afterload and myocardial oxygen demand, may depress cardiac function, particularly with coincident CHD. Blood pressure should be measured annually even in previously normotensive elderly persons. Because blood pressure measurements are highly variable at elderly age, two or three baseline readings on separate occasions are recommended before treatment is initiated.²²⁵

Hypertension contributes importantly to accelerated CHD, heart failure, cerebrovascular accident, renal failure, aortic dissection, and aortic aneurysm rupture in the elderly, as well as in younger populations. Although only 20% of patients in the Veterans Administration Cooperative Study on Antihypertensive Agents were older than 60 years, half of all morbidity, heart failure, and stroke occurred in this age group.²²⁶ Control of hypertension decreases the risk of complications: cardiovascular death, fatal MI, heart failure, and stroke in elderly patients.^{216,227} Control of isolated systolic hypertension in the Systolic Hypertension in the Elderly Program (SHEP)²²⁸ using low-dose chorthalidone as initial therapy, with low-dose beta blockade added as needed, reduced stroke by 36% and fatal and nonfatal cardiovascular events by 32%, the latter largely due to decreased fatal MI. Occurrence of heart failure was reduced approximately 50%, particularly among patients with prior MI,²²⁹ with comparable benefits in patients with and without baseline ECG abnormalities and with or without noninsulin-treated diabetes.²³⁰ In the SHEP cohort, depression was associated with a significant substantial increase in risk of death and stroke or MI.²³¹ In the

Swedish Trial in Old Patients with Hypertension-2 (STOP-2) study,²³² outcomes were comparable with conventional drugs (beta blockers and diuretics) and the newer ACE inhibitors and calcium channel-blocking drugs. However, elderly patients receiving ACE inhibitor compared with calcium channel-blocking drugs had fewer MIs and less heart failure.

Particularly in elderly patients with mild hypertension, nonpharmacologic approaches including reduction of sodium intake, weight reduction, moderation of alcohol consumption, and regular modest-intensity physical activity²²⁵ should be initially considered. In the randomized Trial of Nonpharmacologic Intervention in the Elderly (TONE), the best results were associated with combined sodium restriction and weight loss.²³³ Elderly patients should be cautioned that nonsteroidal anti-inflammatory drugs can decrease the efficacy of anti-hypertensive drug treatment.²³⁴

Based on results of major randomized clinical trials that enrolled elderly patients,^{217,235} comparable or greater benefit of pharmacotherapy to that at younger age was documented, at least to age 80 years. The European Working Party on Hypertension in the Elderly (EWPHE) trial,²²² in which 70% of patients were women, showed a favorable effect of antihypertensive therapy on cardiac mortality, fatal MI, heart failure, and overall cardiovascular mortality. In these clinical trials, there were no increased rates of therapy discontinuation resulting from adverse effects in elderly patients, and study medication adherence was comparable to younger patients. In one study, calcium antagonist drugs, compared with beta-blockers, increased the risk of gastrointestinal hemorrhage in hypertensive patients over age 67.²³⁶ Meta-analysis of antihypertensive therapy trials involving more than 15,000 patients older than 60 years showed comparable reduction in stroke risk and cardiac morbidity as in younger patients.²³⁷

Goal blood pressure should be 140/90mmHg, with avoidance of postural hypotension and maintenance of renal function; this should be accomplished without adverse symptomatic side effects and at reasonable cost. Goal blood pressure of less than 130/85 is a cost-effective intervention in elderly diabetic hypertensive patients.²³⁸ Initiation of drug therapy should involve half the usual adult dose, with gradual increments in drug dosage. However, few elderly patients achieve goal blood pressure levels with monotherapy; low doses of two drugs are often necessary. Because of impaired baroreflex control of blood pressure at elderly ages, blood pressure should be checked in the sitting and standing positions when therapy is instituted. The drugs chosen, in addition to lowering blood pressure, should be those that effect regression of left ventricular hypertrophy. Hypertension and its therapy are discussed in more detail in Chapter 40.

Valvular Heart Disease, Congenital Heart Disease, Infective Endocarditis, and Nonvalvular Cardiovascular Infections

Aortic Stenosis

Hemodynamically significant symptomatic calcific aortic stenosis is the most frequent valvular heart disease that requires surgical correction in elderly patients.²³⁹ One in four patients who undergo aortic valve replacement are 70 years or older. Although more common in men in younger age groups, calcific aortic stenosis predominates in women after age 80. Frequent underdiagnosis of hemodynamically significant aortic stenosis is of concern because correct diagnosis and valve replacement surgery are associated with a favorable long-term prognosis, that is, improved symptoms and survival.

Aortic stenosis in elderly patients is typically caused by calcification of a tricuspid aortic valve; 90% of aortic valves in elderly patients with calcific aortic stenosis are tricuspid.

Symptomatic hemodynamically important aortic valvular stenosis is characterized by the same presentations in the elderly as in a younger population: angina pectoris, exertional dizziness or syncope, and dyspnea or heart failure; however, these symptoms are often misinterpreted as being caused by other cardiac problems, such as CHD, or by neurologic disease when the presentation is with syncope.²⁴⁰ Significant aortic stenosis is one of the most common anatomic causes of syncope at elderly age. Symptoms are less often activity precipitated than in younger patients because a relatively sedentary lifestyle more frequently occurs with aging. Progression of the severity and symptoms of aortic stenosis at elderly age is characteristic and often rapid. Aortic valve replacement is indicated, in that fewer than 50% of patients with hemodynamically significant symptomatic calcific aortic stenosis survive for more than 5 years after symptom onset; sudden death is common.²⁴¹ Differentiation is required from the benign, but pervasive, short early-peaking basal systolic murmur of aortic sclerosis, present in one-half to one-third of elderly patients.

The classic slow-rising small-volume carotid pulse of a younger patient with aortic stenosis, occasionally associated with a thrill, may be masked by sclerosis and decreased elasticity of the carotid vessels in an elderly patient; these may also mask the usual narrow pulse pressure. The carotid bruit may be erroneously attributed to primary vascular disease. Systemic arterial hypertension, rarely seen in younger individuals with severe aortic stenosis, is not uncommon in elderly persons because of vascular stiffening. The late-peaking, harsh basal systolic murmur that radiates into the neck often has high-

frequency components that are heard along the lower left sternal border and toward the cardiac apex throughout most of systole, mimicking the murmur of mitral regurgitation. The apical systolic murmur of associated mitral annular calcification may further complicate recognition. Hyperexpansion of the lungs and dorsal kyphosis may limit the palpatory evidence of the forceful sustained apex impulse of left ventricular hypertrophy and, at times, the basal systolic thrill; the harsh basal systolic murmur may become softer and the thrill no longer palpable as the cardiac output lessens. Lack of commissural fusion of the calcified aortic valve in elderly persons further mutes the harsh characteristics of the murmur and also explains the absence of an ejection sound. S_2 is soft with occasional reversal of splitting, and an S_4 is prominent when sinus rhythm is present. Atrial fibrillation rarely occurs in younger patients with aortic stenosis, but often precipitates heart failure in elderly patients, due to a loss of the atrial contribution to ventricular filling in a poorly compliant ventricle in combination with the lessened ventricular filling resulting from the rapid heart rate. Atrial fibrillation may be present in as many as one-fourth of elderly patients with severe aortic valvular stenosis. There is frequently a coexisting basal early diastolic decrescendo murmur of aortic regurgitation, but aortic regurgitation of hemodynamic significance is unusual.

The ECG has characteristic changes of left ventricular hypertrophy, although concomitant emphysema may mask the increased voltage. The heart size on chest radiograph is usually normal; aortic valvular calcification may be evident and can be confirmed by echocardiography. Critical aortic stenosis virtually never occurs in the absence of echocardiographically detectable calcium deposition. An increased left ventricular wall thickness is evident in most patients.

Echocardiography with Doppler studies can noninvasively assess the severity of aortic valvular obstruction. The aortic valvular pressure gradient at Doppler echocardiography correlates reasonably with the aortic valve area at cardiac catheterization. Hemodynamically severe aortic stenosis as evaluated by Doppler echocardiography in the Helsinki Aging Study²⁴² markedly increased 4-year mortality risk. Cardiac catheterization and coronary arteriography are warranted, nonetheless, because coexistent coronary disease is frequent²⁴³ and concomitant myocardial revascularization may be required if aortic valve replacement is undertaken.²⁴⁴ Exercise testing is hazardous if critical aortic stenosis is suspected because syncope and sudden death have been precipitated.

Aortic valve replacement for symptomatic critical aortic stenosis is indicated at virtually all ages in otherwise functional elderly patients²⁴⁴ because of their excessive mortality after the onset of angina pectoris, heart failure, or syncope. Asymptomatic elderly patients with

reasonable exercise tolerance with severe aortic stenosis do not warrant surgery; sudden death is very rare without antecedent symptoms.²⁴⁵ Symptomatic geriatric patients with severe aortic stenosis have mortality rates as high as 50% in the first year.²⁴⁶ Although angina and heart failure symptoms may respond to medical management, clinical deterioration is frequent, leading to urgent surgery with its increased operative mortality. Aortic valve replacement can be performed at an acceptable risk, even in octogenarians and in patients with class III and class IV disease,²⁴⁷ because left ventricular function is often well preserved even after the onset of heart failure. CHD, prior MI, heart failure, and atrial fibrillation all increase surgical risk.²⁴⁸ Aortic valve replacement dramatically improves survival, hemodynamic status, and the patient's quality of life. However, neurologic complications are more common than at younger age. In one series, actuarial survival at 1, 3, and 5 years was 90.8%, 84.2%, and 76.0%, respectively, although concomitant surgical procedures increased the operative risk.²⁴⁹ In another series, perioperative mortality was 2.5% in patients below 70 years, 7.3% in those beyond 70 years, and 12.5% in those older than 80 years; among patients older than age 70, 1-year survival was 83%, and 5-year survival 52%.²⁵⁰ There was a favorable 10-year postoperative survival with maintenance of functional status. About 10% of patients will require permanent pacemaker implantation for perioperative heart block.

Comparison of valve replacement for aortic stenosis in another series among patients older and younger than 75 years showed a surgical mortality of 12.4% versus 6.6% in the two groups.²⁵¹ In another report of aortic valve replacement in octogenarians where half had concomitant CABG surgery, operative mortality was 9.8%.²⁵² In a more recent series,²⁵³ isolated aortic valve replacement beyond age 70 entailed a perioperative mortality of 4.3%, which increased to 10% with concomitant CABG surgery. Of equal importance to survival is the resultant functional status and life quality. Among an octogenarian group with 69% of patients class III or IV preoperatively, 81% were class I or II at follow-up.²⁵⁴ Formal quality of life assessment in patients 70 to 89 years after aortic valve replacement showed comparable scores to age-matched population norms in most domains.²⁵⁵ Bioprosthetic rather than mechanical valves are often chosen for very elderly patients to avoid problems of anticoagulation and because these valves deteriorate more slowly in elderly patients.²⁵⁶ Concurrent CABG surgery decreased early mortality in elderly patients with significant associated CHD.²⁴⁴

Aortic balloon valvotomy is rarely undertaken because of the high rates of restenosis and of posthospital mortality, but it may offer limited palliation for highly symptomatic elderly patients who are not candidates for valve replacement.²⁵⁷⁻²⁵⁹ Despite modest decreases in

peak pressure gradient and increases in valve area, hospital mortality was 4% to 9%, one-fourth of patients had died by 6 months, and their event-free 1-year survival was 43%.²⁵⁸ Balloon valvotomy may be used to improve the status of elderly patients with severe aortic stenosis and heart failure, increasing the likelihood of subsequent successful valve replacement.²⁶⁰

Aortic Regurgitation

Aortic regurgitation, caused by myxomatous or other valvular degeneration, congenital bicuspid aortic valve, rheumatic heart disease, infective endocarditis, rheumatoid disease, aortic dissection, trauma, syphilis, systemic arterial hypertension, and a number of other disorders, is the most common cause of a diastolic murmur at old age and can usually be diagnosed by clinical examination. Echocardiography and Doppler studies can help to assess the hemodynamic severity.

Aortic regurgitation is typically managed medically with dietary sodium restriction, diuretics, vasodilator drugs, and digitalis to control cardiac failure. Nifedipine therapy in asymptomatic patients with severe aortic regurgitation and normal left ventricular function may avert or delay the need for valve replacement.²⁶¹ Exercise tolerance, as in younger patients, is often preserved even with advanced disease. Decrease in left ventricular contractility (ejection fraction below 50%–55%) or progressive increase in ventricular volumes (end-systolic volume greater than 55%) warrant valve replacement; surgical mortality is excessive once clinical heart failure supervenes.²⁴⁵ The results of aortic valve replacement for aortic regurgitation are less satisfactory than for aortic stenosis, at least in part because of the frequently severe ventricular dysfunction.

Acute aortic regurgitation, as may occur with trauma or infective endocarditis, typically presents with acute pulmonary edema and requires urgent valve replacement. Patients may be misdiagnosed as having MI. The diagnosis is often overlooked because of the lack of the characteristic wide pulse pressure and cardiac enlargement and the brief or inaudible murmur due to overwhelming cardiac failure. Diagnosis is often made by echocardiography.

Mitral Regurgitation

Mitral regurgitation is more common than mitral stenosis at elderly age. Common causes of mitral regurgitation in elderly patients include rheumatic heart disease, myxomatous mitral leaflet degeneration, mitral valve prolapse, mitral annular calcification, and papillary muscle dysfunction or chordal rupture, secondary to CHD. Mitral annular calcification is more frequent in women than men and can often be diagnosed by the character-

istic C-shaped roentgenographic calcification or at echocardiography. Myxomatous degeneration of the mitral valve may cause mitral valve prolapse. Many elderly patients with chronic mitral regurgitation and sinus rhythm are asymptomatic, with the onset of atrial fibrillation precipitating hemodynamic decompensation. The diagnosis of mitral regurgitation usually can be made by clinical examination, but echocardiographic examination often suggests the cause. Medical therapy is usually appropriate unless mitral regurgitation is of major hemodynamic importance; Doppler echocardiography may help to quantify the severity of the mitral regurgitation. Assessment of exercise capacity and noninvasive documentation of left ventricular systolic function can identify symptomatic patients for whom cardiac catheterization is appropriate to assess suitability for operative intervention. Outcomes are improved with operation before deterioration of ventricular function.²⁶²

The prevalence of mitral valve prolapse in elderly patients is not well established. Mitral valve prolapse may be asymptomatic in some elderly patients and be diagnosed only by the classic auscultatory findings. In others, however, disabling chest pain occurs.²⁶³ Because of the frequently associated nonspecific repolarization abnormalities on the electrocardiogram, an erroneous diagnosis of angina pectoris may be made. Palpitations should suggest an associated arrhythmia. In contrast to younger patients, mitral valve prolapse in elderly patients, particularly elderly men, may result in severe mitral regurgitation and symptomatic heart failure. There may be complicating infective endocarditis or ruptured chordae tendineae; again, in contrast to the female predominance in the younger population, heart failure secondary to mitral valve prolapse predominates in elderly men.

Mitral valve replacement in elderly patients is less satisfactory than aortic valve replacement,²⁶⁴ with a surgical mortality rate of 10% to 14%. This difference is due in part to urgent or emergency surgery as with MI-related severe acute mitral regurgitation, prior limited attention to papillary muscle preservation, and almost uniform associated left ventricular dysfunction. Papillary muscle integrity seems especially important in elderly patients to prevent progressive ventricular failure.

Mitral regurgitation secondary to myocardial ischemia is also more frequent in elderly patients. The mortality rate of combined mitral valve replacement and CABG surgery may average 30% for patients in the eighth and ninth decades, and residual cardiac dysfunction and symptoms are more likely to be present than after aortic valve replacement. Mitral valve repair entails both lower mortality and fewer thromboembolic complications, but data are limited on mitral valve reconstruction in elderly patients.^{197,202,265} Extensive mitral annular calcification may complicate surgery. Requirement for anticoagulation must be considered with decision for mechanical

valve implantation. Although bioprosthetic valves may enable freedom from anticoagulation in patients in sinus rhythm, bioprosthetic valve degeneration may necessitate reoperation at even older age.

Education of elderly patients, attention to drug interactions, and contemporary lower-dose regimens can minimize bleeding complications of ambulatory anticoagulation. Antibiotic prophylaxis against infective endocarditis is needed for the frequent invasive diagnostic or surgical procedures performed in hospitalized elderly patients; recommendations apply comparably to older and younger patients.²⁶⁶

Acute massive mitral regurgitation, as occurs with chordal rupture or flail mitral leaflet associated with infective endocarditis or papillary muscle rupture in the setting of acute MI, typically presents with acute pulmonary edema with hypotension or cardiogenic shock and requires emergency valve replacement. Transesophageal echocardiography is valuable for clinical decision making.²⁶⁷ Intraaortic balloon counterpulsation support may be needed to enable cardiac catheterization and induction of anesthesia.

Mitral Stenosis

Mitral stenosis, usually rheumatic in origin, rarely becomes newly symptomatic in elderly patients, except at the development of atrial fibrillation. Control of the ventricular response rate typically restores compensation. Rarely, mitral stenosis is caused by progressive mitral annular calcification. Mitral balloon commissurotomy is increasingly used for symptomatic elderly patients because of its long-term beneficial effects on symptoms, functional status, hemodynamic measurements, and exercise capacity.^{257,268,269} However, calcification of the mitral valve and valve apparatus limits the suitability for balloon valvuloplasty.

Congenital Heart Disease

Congenital cardiac lesions rarely cause de novo hemodynamic problems in the elderly population. Most congenital cardiac lesions of hemodynamic significance have been corrected in childhood or young adulthood.²⁷⁰ Too few patients with corrected congenital heart disease have yet reached a very old age for determination to be made regarding their risk of arrhythmia, ventricular dysfunction, and other abnormalities.

Uncorrected secundum atrial septal defect is the most frequent congenital cardiac lesion in elderly patients; these patients are characteristically asymptomatic in the absence of complicating pulmonary hypertension or supraventricular tachyarrhythmias. In patients symptomatic with dyspnea and fatigue who do not have elevated pulmonary vascular resistance, shunt closure improves

symptoms and entails only a modestly greater risk than in a younger age group. Surgical correction is not indicated for a small calcified persistent ductus arteriosus because of the unacceptably high surgical risk without defined benefit.

Infective Endocarditis and Nonvalvular Cardiovascular Infections

Although one-third of all cases of infective endocarditis occur in elderly patients, its recognition is often delayed or missed in this age group because of fewer and atypical symptoms²⁷¹ and an absent or minimal febrile response. A cardiac murmur may not be prominent; the major presentations may be anemia, renal failure, hemiplegia, or unexplained coma. A high index of suspicion for endocarditis is warranted in elderly patients with otherwise unexplained fever, weight loss, embolic episodes, or confusion. Earlier recognition associated with the high diagnostic sensitivity of transesophageal echocardiography is credited in a recent report with improving clinical outcomes at elderly age, making them comparable to those for younger patients.²⁷¹ Elderly individuals constitute an increasing percentage of patients with infective endocarditis, and the problem is likely to increase further in prevalence as more elderly patients are hospitalized and undergo complex invasive diagnostic and therapeutic procedures. Endocarditis is associated with a higher mortality than in younger patients,²⁷² in part because of the delay in diagnosis and in the initiation of appropriate therapy. Invasive vascular procedures are the most common sources of infection; almost one-fourth of all episodes are nosocomially acquired. In addition to the organisms usually encountered in a younger population, enterococci, *Streptococcus bovis*, and coagulase-negative staphylococci occur with excess frequency in elderly patients.²⁷² Coagulase-negative staphylococci are typically traceable to invasive vascular or skin sources. *Streptococcus bovis* appears due to gastrointestinal problems, and enterococcal endocarditis appears related to the increase in genitourinary procedures performed in elderly men.

Aortic valve endocarditis is most common, with mitral regurgitation the second most frequent predisposing valvular lesion. Infective endocarditis often occurs in elderly patients with intracardiac prosthetic devices.²⁷³

Dosages of antibiotics may require reduction due to abnormalities of renal function and comorbid illness. Valve replacement must be addressed with hemodynamically significant abnormalities. Use of prophylactic antibiotics for appropriate invasive procedures can limit the occurrence of infective endocarditis in susceptible elderly patients.²⁶⁶

Nonvalvular cardiovascular infections are also more common in elderly patients, reflecting frequent use of implantable devices and prosthetic materials in a geri-

atric population. The subtle presentations warrant a high index of suspicion to initiate diagnostic measures.²⁷⁴

Cardiomyopathy

Hypertrophic cardiomyopathy occurs relatively frequently and is commonly underdiagnosed in elderly patients;²⁷⁵ it may be incorrectly labeled as aortic valvular stenosis, mitral regurgitation, or the papillary muscle dysfunction of CHD. Incorrect diagnosis, with resultant inappropriate drug therapy (e.g., digitalis and other positive inotropic drugs, diuretics, nitroglycerin, and vasodilator drugs), may exacerbate the outflow obstruction and result in serious complications. Although about one-third of individuals with hypertrophic cardiomyopathy are older than age 60, little is known about the natural history of hypertrophic cardiomyopathy in elderly patients. In some series, women predominate among elderly patients with hypertrophic cardiomyopathy. The prognosis appears to be better than in a younger population, as serious arrhythmias or sudden cardiac death are unusual.²⁷⁶ This prognosis may represent survival of a low-risk population, decreased physical activity with aging that limits risk, or this may be a different disease; disproportionate septal thickening and alteration in ventricular configuration occur with aging.²⁷⁷ It remains uncertain whether hypertension is etiologic;²⁷⁸ anterior displacement of the mitral valve due to mitral annular calcification may also be contributory. Left ventricular hypertrophy is described as more modest in elderly patients, involving predominantly the ventricular septum, with outflow obstruction caused by a combination of systolic anterior motion of the anterior mitral leaflet and posterior motion of the ventricular septum.²⁷⁹

Elderly patients characteristically have onset of symptoms late in life.²⁷⁹ Clinical symptoms include dizziness, palpitations, syncope, chest pain, fatigue, and dyspnea, with the latter often the prominent complaint. Severe dyspnea portends an unfavorable prognosis.²⁷⁶ It is uncertain whether symptoms differ from those of younger patients. Onset of atrial fibrillation may produce rapid hemodynamic deterioration, owing to dependence of the poorly compliant hypertrophied ventricle on the atrial contribution to ventricular filling to maintain stroke volume.

Physical examination may pose diagnostic problems in that brisk carotid pulsations are erroneously ascribed to decreased vascular elasticity, and an S₄ and nonspecific systolic murmurs are common in elderly patients. A bisferiens carotid pulse or a double cardiac apex impulse may be the clue to perform appropriate maneuvers. The left sternal border systolic murmur increases with a Valsalva maneuver and decreases on squatting. An aortic regurgitant murmur may be caused by coexisting calcific aortic valve disease.

The electrocardiogram is that of left ventricular hypertrophy; Q waves of septal hypertrophy may mimic MI. Echocardiography can confirm the diagnosis. Free wall myocardial hypertrophy may equal that of the ventricular septum.

Prophylaxis against infective endocarditis is appropriate. The majority of symptomatic elderly patients benefit from medical therapy. Calcium- or beta-blocking drug therapy can alleviate symptoms of angina and dyspnea. Hypovolemia increases risk and should be avoided. Occasionally, severely symptomatic elderly patients with a significant ventricular outflow gradient and an unsatisfactory response to medical management warrant surgical correction.²⁸⁰

Dilated cardiomyopathy is infrequent in an elderly population, as the majority of patients with this problem do not survive to an elderly age. Hypertension and lower educational levels are associated with dilated cardiomyopathy at elderly age.²⁸¹ The management is as for ventricular systolic dysfunction and includes digitalis, diuretics, angiotensin-converting enzyme (ACE) inhibitors, and other vasodilator drugs; anticoagulation is recommended, particularly when there is associated atrial fibrillation, to prevent embolic events.²⁸²

Restrictive cardiomyopathy is unusual in elderly patients. Although senile cardiac amyloidosis has a high prevalence among the oldest old patients, atrial fibrillation, rather than restrictive cardiomyopathy, seems to be the more frequent manifestation. ECG voltage is low in patients with cardiac amyloidosis, and echocardiography may demonstrate a "sparkling" appearance to the myocardium. Hemochromatosis is another, although uncommon, cause of restrictive cardiomyopathy. Restrictive cardiomyopathy is increasingly encountered as a consequence of CABG surgery and postoperative pericarditis, as well as of radiation therapy to the chest.

Cardiac Disease Secondary to Pulmonary Disease

Pulmonary embolism is a frequent and often unrecognized complication of many systemic illnesses in elderly patients.²⁸³ The combination of prolonged bed rest, a sedentary lifestyle, cardiopulmonary diseases, heart failure, and frequent surgical procedures are the major predisposing factors, as is atrial fibrillation. It is often misdiagnosed as pneumonia or heart failure. An estimated 107,000 hospitalizations annually in the Medicare population result from deep vein thrombosis and pulmonary embolism.²⁸⁴

The clinical presentation varies from an acute cardiovascular emergency characterized by dyspnea, orthopnea, chest discomfort, syncope, or shock, or at times may be manifest only as increased cough, mild chest discom-

fort, transient dyspnea, or a worsening of heart failure. Sudden unexplained dyspnea should be considered to be caused by pulmonary embolism until proved otherwise. A high index of suspicion is warranted to search for evidence of deep vein thrombosis of the leg and evidence of acute cor pulmonale. Pulmonary ventilation-perfusion scanning is the initial screening procedure. However, isotopic perfusion lung scanning abnormalities may occur in the absence of pulmonary embolism because of the nonuniform perfusion of the aged lung. Spiral CT scanning appears to provide comparable diagnostic accuracy and greater safety. Pulmonary angiography, if needed, does not entail substantially greater risk than at younger age, save for the more frequent complicating renal failure.²⁸³

Clinical findings include tachypnea, tachycardia, often a low-grade fever, an accentuated pulmonic component of S_2 with wide splitting, a prominent parasternal impulse, an accentuated *a* wave in the jugular venous pulse, and at times evidence of right ventricular decompensation. Deep vein thrombosis of the leg also may be evident.

In a Medicare population, the 30-day case-fatality rates increased with increasing age. The risk of fatality was very high (25%–40%) when pulmonary embolism complicated cardiac problems, including heart failure, stroke, MI, and chronic pulmonary disease, and after CABG surgery or hip or knee replacement. These data highlight the need for deep vein thrombosis prophylaxis in these populations.²⁸⁵

Anticoagulation, initially with heparin and subsequently with warfarin, is the treatment of choice. Thrombolytic therapy may be indicated for massive pulmonary embolism with hemodynamic instability; the risk of bleeding is increased at elderly age. Vena caval obstruction with a transvenously inserted filter device is appropriate when anticoagulation is contraindicated.

Pulmonary heart disease in elderly patients is superimposed on the decreased elastic properties of the aged lung, as well as the loss of pulmonary vascular reserve and the decrease in ventilatory function and pulmonary diffusing capacity of aging. The most common form of chronic pulmonary heart disease that causes cor pulmonale and right ventricular failure at elderly age is chronic obstructive pulmonary disease due to chronic bronchitis and emphysema. The mortality from this problem among elderly patients is related, at least in part, to their coexisting cardiovascular disease, predominantly CHD and hypertensive cardiovascular disease. Recurrent pulmonary embolism is an important etiology, especially with prolonged immobilization at bed rest. Primary pulmonary hypertension has also been described in old age.²⁸⁶ Smoking is a chronic contributor to the increased severity of cardiac decompensation; environmental pollutants and respiratory infections cause intermittent exacerbations.

An accentuated pulmonic component of S_2 , often with wide splitting; jugular venous distension with prominent *a* and *v* waves; a parasternal cardiac impulse; a right-sided S_3 ; the holosystolic murmur of tricuspid regurgitation that increases with inspiration; hepatomegaly and peripheral edema; and right axis deviation of the frontal plane QRS axis and evidence of right ventricular hypertrophy and right atrial abnormality on the ECG are the clinical findings of pulmonary hypertension and right ventricular decompensation.

Echocardiography or radioisotope angiography may help differentiate pulmonary hypertension due to pulmonary vascular obstruction with right-sided heart failure from left-sided heart disease, pulmonary hypertension, and right-sided heart failure.

Therapy includes smoking cessation, bronchodilator drugs, liquefaction of sputum, and treatment of respiratory infections. Sodium restriction and diuretic therapy may lessen heart failure. Digitalis use is controversial except for control of the ventricular response rate to supraventricular tachyarrhythmias. Digitalis toxicity is common in elderly patients with chronic lung disease.

Compensation of the pulmonary status best controls supraventricular arrhythmia. There is no evidence that any pulmonary vasodilator drugs have a beneficial effect on a long-term basis, despite the demonstration of acute hemodynamic improvement. Similarly, phlebotomy to reduce blood viscosity in patients with moderate erythrocytosis remains controversial in that the oxygen-carrying capacity of the blood is reduced and little hemodynamic benefit is attained. Low- to moderate-intensity regular aerobic exercise can improve functional status in patients with a compensated pulmonary status.

Therapeutic problems are accentuated with concomitant cardiac and pulmonary disease, in that the nonselective beta-blocking drugs used to treat CHD or hypertension may induce bronchospasm and worsen chronic lung disease; conversely, theophylline and beta-agonist drugs used as bronchodilators to manage chronic obstructive pulmonary disease may worsen angina and hypertension and induce arrhythmias. Corticosteroid therapy for chronic obstructive pulmonary disease may exacerbate hypertension and heart failure. When significant hypoxemia is present, elderly patients have a favorable response, comparable with that of younger patients, to continuous low-flow oxygen therapy, if respiratory depression does not occur.

Noncardiac Surgery in Elderly Patients with Cardiovascular Disease

The increasing numbers of elderly persons and the success of surgical procedures at geriatric age have increased the number of surgical interventions in this

population. More than one-fifth of all noncardiac surgical procedures currently involves elderly patients. Cardiac complications are the major contributors to perioperative morbidity and mortality. Emergency surgery entails the highest cardiovascular risk, as cardiac problems cannot be optimally managed preoperatively or cardiac risk status is unknown.

There is more heterogeneity in an elderly population than within any other age group; chronologic age poorly predicts either a patient's physiologic age or functional capabilities. Negative stereotypes of elderly persons as being seriously ill and disabled often inappropriately bias recommendations and decisions about medical care and particularly surgical interventions for elderly cardiac patients. Age alone should not constitute a contraindication to surgical therapy; the increased complications in elderly patients relate predominantly to their associated diseases; these should prominently influence clinical decisions. Mental status, cognitive ability, and expectations from medical care are other attributes to be considered. Both overt and occult cardiovascular disease, but particularly CHD, contribute to the increased risk of perioperative cardiovascular complications. In addition to cardiac disease, noncardiovascular surgery in elderly patients is often complicated by cerebrovascular and peripheral vascular disease, atherosclerosis of the aorta and great vessels, impaired renal function, prostatic obstruction, pulmonary disease, and malnutrition. In addition to cardiac status, cardiac risk for anesthesia and surgery encompasses the baseline physiologic changes of aging and the comorbid illnesses. As with cardiac surgery, overall recovery from noncardiac surgery at elderly age is protracted, with increased needs for nursing care and more time spent in an intensive care setting.

Perioperative MI is the major cause of postoperative mortality at elderly age owing to the high prevalence of known and unrecognized CHD.²⁸⁷ The highest risk for noncardiac surgery is within 6 months of MI; only emergency or urgent surgery should be undertaken in this period. Unstable angina, residual myocardial ischemia, uncontrolled hypertension, and decompensated heart failure also entail an adverse prognosis. Because of the high prevalence of significant CHD in asymptomatic or minimally symptomatic elderly patients, preoperative exercise or pharmacologic thallium scintigraphy or echocardiography helps evaluate CHD status, assessing the extent of myocardial ischemia and consequent risk status, suggesting the need for further evaluation.²⁸⁸ A normal study identifies low risk status, abnormalities in one vascular territory intermediate risk status, and reversible defects in more than one vascular territory (suggesting multivessel CHD) high risk status. Determination of anaerobic threshold at exercise testing is described to precisely assess cardiovascular reserve and surgical risk at elderly age.²⁸⁹ Coronary arteriography can

define the need and suitability for myocardial revascularization before noncardiac surgery. High-risk patients with a varied age range who had CABG surgery before noncardiac surgery had a mortality risk comparable to that of patients without significant CHD.²⁹⁰ Risk stratification is particularly indicated before elective peripheral vascular surgery because of the substantial concordance of known and unrecognized but correctable CHD with peripheral arterial disease.^{291,292}

Intraoperative and postoperative surveillance should highlight adequate oxygenation, electrolyte balance, and control of cardiac failure and arrhythmia. Pulmonary artery catheter monitoring is warranted for severe heart failure or suspected myocardial ischemia. Prophylactic digitalis administration and prophylactic pacemaker insertion are not indicated. Most patients with known suspected CHD should have continuous intraoperative ECG monitoring. Evaluation for an acute event by cardiac enzymes and ECG daily for at least 3 days postoperatively shows the highest occurrence of acute coronary events on postoperative days 2 and 3.

Preventive and Rehabilitative Approaches to Care

As increased numbers of reasonably healthy and active individuals enter old age, more precise assessment of their functional capabilities will be required to determine suitable vocational, as well as recreational and leisure, activities. Remunerative work, continuing into the eighth decade, may soon be usual. This elderly population can be anticipated to have greater interest in and requirements for both primary and secondary preventive cardiovascular care. At the same time, an overriding concern among elderly persons is maintenance of a self-sufficient and independent lifestyle, to which loss or deterioration of functional capability is viewed as a threat.

Preventive strategies are increasingly applied to the elderly population, as modifiable coronary risk factors are highly prevalent in elderly patients²⁹³ and continue to predict the occurrence and recurrence of coronary events and mortality in old age²⁹⁴ (Table 39.3). Elderly persons are health conscious, as shown by their disproportionate representation in most health screening programs. Given the estimated U.S. life expectancy of 16.9 years at age 65 and 10.7 years at age 75, coronary risk reduction strategies are appropriate. However, data from a Canadian study²⁹⁵ show that even among hospitalized patients at high risk for cardiovascular events, risk factor assessment and modification was suboptimal, particularly for women and elderly patients. Because of continued progression of coronary atherosclerotic lesions even in old age, risk intervention may arrest the progression or induce regression of atherosclerosis. Because preventive data are less

TABLE 39.3. Impact of risk factors on cardiovascular disease incidence by age in men and women at 30-year follow-up: Framingham Study.

Risk factor	Multivariate logistic regression coefficients ^a at age:			
	35–64 years ^b		Age, 65–94 years ^b

robust than for younger patients, interventions should entail few risks, involve few adverse effects, and have reasonable cost. Preventive approaches include control of hypertension, weight reduction or control, dietary sodium and fat restriction, regular modest-intensity physical activity, and emphasis on smoking cessation. Although the relative importance of coronary risk factors decreases somewhat with age, the absolute or attributable risk is greater due to the excess coronary morbidity and mortality in elderly patients. In the Honolulu Heart Study smoking, hypertension, diabetes, and hypercholesterolemia conferred a comparable relative risk for CHD at middle and old age.²⁹⁶

In the Cardiovascular Health Study (CHS),²⁹⁷ noninvasively detected subclinical disease was associated with a very high risk of clinical disease, with systolic hypertension and diabetes the most powerful traditional risk factors.¹⁰¹ Noninvasively detected subclinical disease, that is, abnormal echocardiographic ejection fraction, increased internal carotid intima-medial thickness, and low ankle–arm index, also was an independent predictor for 5-year mortality.²⁹⁸ Aggressive preventive interventions appear warranted for elderly persons with subclinical disease.

Higher levels of fibrinogen and factor VIII²⁹⁹ were associated with an increased risk for cardiovascular events and mortality in CHS, and C-reactive protein was associated with incident cardiovascular events, especially in elderly individuals with subclinical disease.³⁰⁰

The lesser risk relationship of cholesterol levels to coronary disease in older adults is offset by the greater occurrence of CHD in elderly persons.³⁰¹ Elevated total

cholesterol levels increase risk of coronary death at elderly age; risk for coronary death decreased as cholesterol levels decreased.³⁰² In the Zutphen Elderly Study,³⁰³ both total and HDL cholesterol were important predictors of CHD in elderly men. Vegetarians, who have lower cholesterol levels than nonvegetarians, also show lower CHD rates even in the 75- to 84-year-old age group.³⁰⁴ Women constitute a greater proportion of the elderly population, where the occurrence of MI is comparable in elderly men and women, so that detection and management of CHD must intensively involve elderly women. Although mean blood cholesterol levels are higher in men before the fifth decade, women subsequently have higher mean total cholesterol levels, which continue to increase at least to age 80, due to progressive increases in low-density (LDL) cholesterol, which exceeds that for men at elderly age.

Recommendations for recognition and management of hyperlipidemia are comparable in younger and elderly populations, as hypercholesterolemia continues to confer increased coronary risk at elderly age. The Adult Treatment Panel of the National Cholesterol Education Program (NCEP) recommends that all adults with total blood cholesterol values above 200 mg/dL be evaluated and that those with elevated LDL cholesterol levels be treated.³⁰⁵ About one-third of elderly men and one-half of elderly women have elevated cholesterol levels warranting intervention, based on NCEP guidelines.³⁰⁶ Recommendations for cholesterol lowering in the elderly population are based predominantly on extrapolation of data derived from younger populations, although one study of postinfarction patients that included a sizeable

elderly cohort³⁰⁷ described a 28% reduction in total mortality in patients treated with lipid-lowering agents. Nevertheless, few elderly patients were enrolled in most secondary prevention studies, and virtually none older than 75 years. Although intervention outcome data are limited for geriatric populations, statin drugs appear to have similar efficacy and safety in nonelderly and elderly populations.³⁰⁸⁻³¹¹ Dietary therapy is recommended for the aged adult; this consists of a diet restricted in saturated fat and cholesterol and high in fruits, vegetables, and grains; additional dietary components include lean meats, fish, and low-fat dairy products. A trained nutritionist or dietitian can often help elderly individuals initiate appropriate dietary management, while assuring adequate nutrition. This diet may confer other health benefits as well.

Cigarette smoking continues to be associated with an increased risk of sudden cardiac death and fatal reinfarction,³¹² and smoking cessation decreases cardiovascular risk to that of nonsmoking individuals, independent of the age at smoking cessation.³¹³ Smoking cessation decreased the risk of mortality or MI in older men and women with angiographically documented coronary disease in the Coronary Artery Surgery Study (CASS) Registry.³¹⁴

Because deconditioning from inactivity occurs more rapidly at elderly age, a physically active lifestyle should be encouraged for elderly patients, incorporating a planned regimen of modest-intensity physical activity, designed to improve functional status and minimize or delay subsequent disability and dependency. A physical activity regimen, even in previously sedentary elderly patients, can enhance endurance and functional capacity. Resistance training improved walking endurance in healthy elderly individuals.³¹⁵ Although the effect of exercise on coronary risk has not been examined systematically in elderly populations, high-level physical activity (>2000 Kcal weekly) in persons 65 to 79 years was associated with improved survival compared with individuals with lower physical activity levels.³¹⁶ Moderate- and high-intensity walking lowered blood pressure in normotensive elderly subjects;³¹⁷ lower rates of hypertension are described in physically active elderly women.²²⁰

Both the physiologic characteristics of aging and the superimposed limitations due to cardiovascular disease must be addressed in formulating physical activity recommendations. Exercise recommendations must be individualized, avoiding excessive fatigue or exhaustion and limiting musculoskeletal injuries by restriction of running, jumping, and other high-impact activities.¹⁸⁵ Brisk walking is generally recommended. Both physical activity³¹⁸ and correct nutrition, including weight control, contribute importantly to the maintenance of cardiovascular function at elderly age. High-intensity resistance exercise can effectively counteract muscle weakness and physical frailty in very elderly people.³¹⁹

Hypertension, elevation of both the systolic and the diastolic blood pressures, is the dominant cardiovascular risk factor in the elderly population, with its incidence increasing with advancing age; it continues to impart risk in elderly persons. Control of blood pressure limits cerebrovascular complications and facilitates the management of angina and of heart failure. Dietary sodium restriction is important in blood pressure control. Electrocardiographic evidence of left ventricular hypertrophy, intraventricular conduction disturbances, and nonspecific repolarization abnormalities all independently predict future cardiovascular events.

Control of obesity, in addition to decreasing cardiac work and cardiovascular risk, favorably affects glucose tolerance, blood pressure, and serum lipid levels. Diabetes mellitus or glucose intolerance remains an independent predictor of cardiovascular risk in old age. Postmenopausal estrogen use by women in the Cardiovascular Health Study³²⁰ was associated with a more favorable cardiovascular risk profile well into the eighth decade. Whether this improvement reflects hormone effect or the baseline characteristics of women who continue hormone therapy or both is unknown. The role of dietary and pharmacologic antioxidants remains uncertain.³²¹ The decline in coronary mortality in the United States from 1963 to 1981 affected all ages, but was less prominent in the elderly population; because most cardiovascular risk factors can be modified in elderly persons, attention to this aspect seems to be appropriate. Based on Framingham data,⁹⁹ the 10% of individuals aged 65 to 74 years with the highest multivariate coronary risk scores had a twofold greater occurrence of coronary events among men and fourfold greater occurrence among women. In the elderly Framingham cohort, elevated risk levels for cardiovascular disease were associated with increased Medicare costs.³²² Benefits of risk reduction, however, must be extrapolated from intervention trials in younger-aged patients; however, conventional risk modification may favorably affect other health aspects as well.

Risk status can be ascertained by standard clinical examinations and simple laboratory tests. Most preventive measures that are appropriate for older individuals constitute reasonable and relatively simple modifications of existing habits; unfavorable lifestyle behaviors can be modified to favorably affect cardiovascular risk.

Conclusion

In planning for health care in the twenty-first century, the increased proportion of elderly patients, who often will have cardiovascular disease and often will require advanced technology diagnostic and therapeutic interventions, must be addressed.³²³ Comparison must be

made of the resources required for and outcomes of palliative care if sophisticated techniques are not undertaken. The use of health care resources will increase not only with increasing age but with the improved expectations of older persons about their health status.

At the same time, it will be necessary to avoid overzealous and redundant diagnostic and therapeutic measures. Data are needed to define interventions at old and very old age that favorably affect morbidity and mortality, functional status, and other meaningful quality of life attributes. Preventive aspects will increasingly become important components of care for elderly cardiac patients, and require the development of cost-effective preventive strategies, although it remains uncertain how much extension of years of health and decrease in disability can be anticipated in later life. The decline in premature cardiovascular mortality in recent decades appears an important component in the longevity of the elderly population; however, it is not certain whether the effect of preventive efforts in limiting or delaying cardiovascular disease will ultimately decrease overall health care costs.

Acknowledgments. With appreciation to Julia Wright and Jeanette Zahler for assistance in the preparation of the manuscript.

Hypertension

Mark A. Supiano

Classification and Epidemiology

Results from cross-sectional studies have shown that blood pressure, particularly systolic blood pressure (SBP), increases with increasing age.¹ No age adjustment is made in setting the threshold value that defines high blood pressure. The classification of blood pressure outlined by the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VI), shown in Table 40.1, is the same for all adults irrespective of age.² There were several minor modifications made in the JNC-VI revision of blood pressure classification that have major significance with respect to geriatric hypertension. The former category of isolated systolic hypertension [i.e., SBP > 160 mmHg and diastolic blood pressure (DBP) < 90 mmHg] was removed. In addition, the conjunction linking the systolic and diastolic blood pressure columns that define each stage was changed from “and” to “or.” As a consequence of this new approach to classification and because isolated diastolic hypertension is so uncommon in older individuals, the correct categorization of blood pressure among those above age 60 may be made by using the level of SBP alone in 99% of cases.³ Thus, the SBP level matters for the purposes of classification. Finally, as is discussed, treatment recommendations are stratified, based in large part on the classification strategy shown in Table 40.1.

Contrary to a former point of view that held that high blood pressure is an expected normal aspect of aging, it is now evident that hypertension in older individuals defined according to these blood pressure levels should be viewed as a disease state that is associated with an increased risk for adverse outcomes [e.g., coronary heart disease, congestive heart failure (CHF), stroke, peripheral vascular disease, and renal disease) and mortality. Therefore, although common, high blood pressure in older individuals is not benign. It is also important to note that, for any level of diastolic blood pressure, the risk for

these adverse events is progressively greater at higher levels of systolic blood pressure.^{4,5} Thus, systolic blood pressure matters as a risk factor for cardiovascular disease. In addition, it is increasingly being recognized that a major predictor of cardiovascular risk is the pulse pressure—the difference between systolic and diastolic blood pressure.⁶ An analysis of data from the Systolic Hypertension in the Elderly Program (SHEP) identified that pulse pressure was a significant predictor of stroke and total mortality independent of the influence of mean arterial blood pressure.⁷ Therefore, the age-associated increases in systolic blood pressure and in pulse pressure are important contributors to the morbidity and mortality associated with hypertension in older individuals.

Epidemiologic studies such as the National Health and Nutrition Examination Surveys have shown that the overall prevalence of hypertension in noninstitutionalized individuals above the age of 65 is between 50% and 70%. The prevalence is highest among African-Americans relative to whites and Mexican-Americans. Unlike the younger hypertensive population in which there is a male predominance, there is no marked gender difference in the overall prevalence of hypertension in the elderly. Moreover, the age-associated increase in the prevalence of isolated systolic hypertension appears to be greater for women than for men.⁸

Pathophysiology

Many age-related changes in physiology contribute to the increase in blood pressure. Lifestyle factors, such as diet, obesity, and physical activity, and the presence of comorbidities are also important contributors. A multitude of pathophysiologic mechanisms interact in the dynamic and complex regulation of arterial blood pressure. The maintenance of blood pressure homeostasis and the provision of adequate cerebral perfusion in the response to such hypotensive stimuli as volume depletion, upright

TABLE 40.1. Classification of blood pressure.

Category	Systolic (mmHg)		Diastolic (mmHg)
Normal	<130	and	<85
High normal	130–139	and	85–89
Hypertension			
Stage 1	140–159	or	90–99
Stage 2	160–179	or	100–109
Stage 3	≥180	or	≥110–119

posture, vasodilating medications, or a meal is an important physiologic challenge facing the aging individual. As is the case in younger individuals, the etiology of essential hypertension in older humans is not known. An increase in peripheral vascular resistance is one pathophysiologic feature of hypertension in the elderly. Several mechanisms contribute to the increase in peripheral vascular resistance. Table 40.2 summarizes those mechanisms that appear to be associated with aging and are discussed in detail here. A rational approach to therapy of hypertension in older individuals requires an understanding of this pathophysiologic context. Although not all the following mechanisms have been convincingly proven to be primary age-associated changes (i.e., independent of the effects of disease or lifestyle factors), they may be important contributors to hypertension in the elderly. It is also quite possible that the age-associated increase in blood pressure is secondary to age-related disease or lifestyle factors, because in some populations the increase in blood pressure with aging is either absent or less marked.⁹

An age-associated increase in arterial vascular stiffness has been demonstrated, particularly in the larger arteries.^{10,11} Several alterations in vessel structure contribute to the decrease in distensibility, such as an increase in smooth muscle cell size and number, an increase in medial collagen deposition, and a decrease in elastin content.⁹ Arterial compliance and stroke volume are the major determinants of pulse pressure. Because stroke volume does not vary significantly with age, the decline in arterial compliance produces an increase in pulse pressure, which contributes to a disproportionate increase in systolic pressure. This finding may account for the age-associated increase in the prevalence of isolated systolic hypertension, as well as an increase in pulse pressure. Another consequence of the decrease in arterial compliance with aging is an increase in arterial pulse wave velocity.¹² The increase in arterial pulse wave velocity has been shown to lead to an early return of wave reflection, which alters the aortic pressure wave contour, increasing the pressure in late systole.¹³ The wave reflection further accentuates the increase in pulse pressure between central and peripheral arteries.

In addition to changes in vascular structure, the dynamic regulation of vascular tone by the autonomic nervous system, as well as by the vascular endothelium, is an important determinant of peripheral vascular resistance. A decrease in baroreceptor sensitivity with age has been described,^{14,15} perhaps as a manifestation of the decrease in arterial distensibility already discussed. The decline in baroreceptor sensitivity alters the central nervous system (CNS) control of sympathetic nervous system (SNS) outflow, resulting in two important manifestations. First, having an insensitive baroreceptor means that a larger change in blood pressure is needed to activate the baroreceptor and produce the appropriate compensatory response. Attenuated baroreceptor sensitivity is believed to contribute to the greater blood pressure variability in older individuals.¹⁶ Second, attenuated baroreceptor sensitivity results in enhanced SNS activity for a given level of arterial blood pressure.^{17,18} Many studies have demonstrated an age-associated increase in the activity of the SNS measured by an increase in plasma norepinephrine levels,^{19,20} rates of norepinephrine release determined from tracer kinetics studies,^{18,21,22} and muscle sympathetic nerve activity.²³ The increase in the rate of norepinephrine release would be expected to result in increased cardiovascular adrenergic responses if it were not for the corresponding down-regulation of adrenergic receptor function. Indeed, there is evidence to suggest an age-associated decrease in adrenergic responsiveness for β -adrenergic receptor chronotropic,²⁴ inotropic,²⁵ and vascular²⁶ responses, as well as for α -adrenergic vasoconstrictor responses.^{22,27} As a result of the decrease in arterial α -adrenergic receptor response, it appears that overall arterial α -adrenergic tone is similar in older normotensive compared with younger normotensive subjects²² and that an increase in peripheral vascular resistance cannot be accounted for solely by age-associated changes in SNS function. Hypertensive older individuals, however, have been characterized by having greater arterial α -adrenergic receptor responsiveness relative to their level of SNS activity in comparison to older normotensive subjects.²⁸

Another important modulator of vascular tone is the vascular endothelium, which synthesizes a number

TABLE 40.2. Pathophysiologic alterations that may contribute to or are associated with elevated blood pressure in aging.

Increased arterial stiffness
Decreased baroreceptor sensitivity
Increased sympathetic nervous system activity
Decreased α - and β -adrenergic responsiveness
Decreased endothelial cell-derived relaxing factor function
Sodium sensitivity
Low plasma renin activity
Insulin resistance

of vasoactive substances. Endothelial-derived relaxing factor (EDRF) is a potent vasodilator that has been extensively investigated since being identified as nitric oxide.^{29,30} Several studies have demonstrated that there is an age-associated decrease in EDRF-mediated vasodilation,^{11,31} and there may also be endothelial dysfunction with hypertension.³² Impaired function of this important regulator of vasodilator tone could lead to an increase in peripheral vascular resistance if not met by appropriate compensatory alterations in other vasoactive systems. The extent to which impaired endothelial function contributes to an increase in blood pressure in aging remains to be defined.

Several age-associated changes in renal function (e.g., decreased renal blood flow and glomerular filtration rate) combine to result in an age-associated inability to rapidly excrete a sodium load.³³ The net result of these alterations is a tendency for sodium retention by the aging kidney and an increase in total body sodium.³⁴ It has been observed that a greater proportion of older hypertensives demonstrate an increase in mean arterial blood pressure in response to challenge with a sodium load or demonstrate sodium sensitivity.^{35,36} These renal changes in sodium balance may contribute to the increased prevalence for sodium sensitivity among older individuals.

The renin-angiotensin system represents another blood pressure regulatory system that may be altered with advancing age. The evidence in this instance is for an age-associated decline in plasma renin activity.³³ There is a corresponding low prevalence of older hypertensives with high renin levels.³⁷ The decrease in plasma renin activity may be related to a decrease in the number of glomeruli, as well as an increased delivery of sodium to the macula densa.³⁷

Several studies have identified an age-associated impairment in glucose tolerance.^{38,39} Decreased sensitivity to the peripheral effects of insulin on carbohydrate metabolism, or insulin resistance, with aging may contribute to the decline in glucose tolerance.⁴⁰⁻⁴² Insulin resistance and an associated increase in fasting insulin levels have been shown to be a characteristic of some hypertensive groups,^{43,44} including older hypertensives.⁴⁵ Although a mechanistic causal link between insulin resistance and hypertension has not yet been identified, if such a mechanism exists, an age-associated decline in insulin sensitivity could contribute to hypertension. However, based on the results of a study performed to determine predictors of insulin sensitivity, it appears that age is not an independent predictor of insulin sensitivity after accounting for the confounding effects of higher body mass index and blood pressure.⁴⁶ Thus, although there is a clear association between blood pressure and insulin resistance and many older hypertensives are insulin resistant, there are no data to indicate that an age-

associated decline in insulin sensitivity independently contributes to hypertension in older adults.

Diagnosis and Evaluation

Measurement Issues

In light of the greater variability in blood pressure among older individuals (due, in part, to the decrease in baroreceptor sensitivity), it is critically important to make an accurate diagnosis of hypertension in this population. To do so requires careful attention to correct measurement of blood pressure with respect to utilizing the proper cuff size, measuring the blood pressure in both arms, having the patient appropriately positioned (sitting comfortably following 5 min of quiet rest with the arm supported at heart level), palpating the systolic blood pressure level at the radial artery to avoid the auscultatory gap, and taking two blood pressure measurements separated by at least 2 min (more if there is greater than 5 mmHg difference between the first two readings) at each of three visits. The average of these measurements is used to define an individual's blood pressure, which determines the presence or absence of hypertension according to the classification scheme given in Table 40.1. The statement that "hypertension should not be diagnosed on the basis of a single measurement"⁴² is especially relevant to the older patient. It has been observed that, when antihypertensive medication is withdrawn from some older individuals, a significant number do not manifest a blood pressure high enough to be classified as hypertensive, suggesting that some older individuals are at risk for overtreatment of their blood pressure.⁴⁷ Careful adherence to these measurement techniques will minimize the likelihood that older individuals are misdiagnosed as hypertensive and inappropriately placed on an antihypertensive medication.

Given the age-associated increase in arterial vascular stiffness, there have been concerns that indirect (cuff) blood pressure measurement may not accurately reflect actual intra-arterial blood pressure in older individuals. This overestimation of true blood pressure by the indirect method secondary to the incompressibility of the brachial artery is referred to as pseudohypertension. Despite these concerns, it has been demonstrated that indirect blood pressure measurement is as accurate among older (at least up to age 80 years) as it is in younger individuals; the indirect measurement tends to underestimate systolic and overestimate diastolic blood pressure to similar degrees in both age groups.⁴⁸ Similar findings have been observed in a group of 26 subjects from age 50 to 80 years who had isolated systolic hypertension.⁴⁹ There remains some uncertainty as to the true frequency of pseudohypertension in the elderly population;

prevalence estimates vary from 2% to 70% among the published descriptions.⁵⁰ Some investigators have suggested that the presence of a positive Osler's sign, the ability to palpate the radial artery when the radial pulse is obliterated by inflating an arm cuff to above the systolic blood pressure, increases the likelihood of pseudohypertension.⁵¹ The utility of identifying a positive Osler's sign has been questioned, however, due to its poor reproducibility⁵² and low positive predictive value.⁵³ The possibility of pseudohypertension should be entertained in the presence of a discrepancy between the severity of the blood pressure and evidence of target organ damage, a wide pulse pressure, or perhaps a positive Osler's sign. In these situations, other measurement techniques, such as oscillometric or plethysmography of the digital blood pressure (Finapres) methods, or in some cases direct intra-arterial blood pressure monitoring, may be utilized to make the definitive diagnosis.

Another clinical situation in which overestimation of blood pressure may occur is office or "white coat" hypertension. Ambulatory home blood pressure monitoring or patient self-monitoring may provide additional information needed to evaluate the patient's blood pressure when concern for white coat hypertension arises, in borderline situations where there is uncertainty about the diagnosis of hypertension, or when there is extreme variability in blood pressure readings. In a substudy reported from the Systolic Hypertension in Europe Trial, results from 24-h ambulatory blood pressure readings provided a better predictor of subsequent cardiovascular events than did the standard blood pressure readings, suggesting another potential benefit of ambulatory blood pressure monitoring.⁵⁴

Although not directly pertinent to the diagnosis of hypertension, another critically important aspect of blood pressure measurement in the older hypertensive patient is obtaining baseline postural or orthostatic blood pressure measurements. Orthostatic hypotension is usually defined as a decline in blood pressure from the supine baseline of greater than 20mmHg systolic and/or 10mmHg diastolic after 1 to 2 min of standing. This definition is supported by a careful study of the postural blood pressure response of normal individuals that determined that this extent of decline exceeded the 95% confidence limits for the postural change in blood pressure.⁵⁵ Aging per se is not associated with an increased prevalence of orthostatic hypotension.^{56,57} The supine systolic blood pressure has been identified as the best predictor of the postural decrease in systolic blood pressure.^{58,59} Accordingly, the presence of supine hypertension is an important risk factor for orthostatic hypotension.⁵⁷ Baseline orthostatic blood pressure readings are therefore required in every patient to avoid adverse events related to further declines in postural blood pressure that may result from antihypertensive therapy.

Secondary Causes

The approach to the evaluation for secondary and potentially reversible factors that may account for the increase in blood pressure in older individuals is similar to that recommended for younger hypertensive patients. Thus, a standard clinical evaluation consisting of a complete history and physical exam, chemistry profile (to assess electrolytes, renal function, and glucose), ECG, and chest x-ray is recommended to identify these factors. Further evaluation is normally not needed unless there are abnormal symptoms or signs elicited from this evaluation that would be consistent with renal disease (elevated serum creatinine or abnormal urinalysis), renovascular disease (e.g., presence of abdominal bruit), hyperaldosteronism (hypokalemia), hypercortisolism (hyperglycemia, cushingoid appearance), hyperparathyroidism (hypercalcemia), or pheochromocytoma (symptoms of headache, palpitations, diaphoresis, and paroxysmal elevations of blood pressure). A careful review of medications is warranted to determine if medication-related increases in blood pressure (e.g., due to corticosteroids or nonsteroidal anti-inflammatory drugs) could be contributing to the elevated blood pressure. Other clinical situations that might lead to an evaluation for secondary hypertension in the older patient include malignant hypertension, the abrupt development of diastolic hypertension (which is unusual in light of the general decrease in diastolic blood pressure with age above the age of 60 years), worsening of blood pressure control, or blood pressure that remains uncontrolled on a regimen of three antihypertensive medications.

As is the case in younger hypertensive populations, the overwhelming majority (greater than 90%) of older hypertensive patients have essential or primary hypertension. Secondary forms of hypertension may be even more rare in the older population. Renal disease and renovascular hypertension are the most frequent cause of secondary hypertension in the elderly; endocrinologic causes are generally less common. The only possible exception to this is a suggestion that the incidence rate for pheochromocytoma, although still exceedingly rare (incidence less than 1% among patients with hypertension), may increase progressively with age.⁶⁰

Target Organ Damage and Risk Factor Assessment

Once the diagnosis of hypertension has been appropriately made and secondary causes considered, the remainder of the evaluation should be directed toward the identification of target organ damage, an assessment of other cardiovascular risk factors, and identification of comorbid conditions that may influence the therapeutic decision-making process. In the older hypertensive

patient, it may be more difficult to detect the manifestations of target organ damage that are directly attributable to elevated blood pressure because of concurrent age- or disease-associated changes in organ function. With this proviso, it is useful to determine if there is any previous history consistent with coronary artery disease, cardiac failure, cerebrovascular disease (transient ischemic attack or stroke), or peripheral vascular disease. The patient should be assessed for any physical signs consistent with these conditions, as well as for evidence of hypertensive retinopathy or left ventricular hypertrophy. In addition to identifying the presence of hyperlipidemia or diabetes mellitus, information concerning smoking history, dietary intake of salt and fat, alcohol intake, and level of physical activity should be obtained to aid in a determination of overall cardiovascular risk. This information will affect the patient's risk stratum assignment and the approach to his or her treatment and is also needed to advise the patient about lifestyle modifications that may be recommended as nonpharmacological approaches to blood pressure control. Finally, knowledge of comorbid conditions is necessary to identify special clinical situations where a given class of antihypertensive medication would be either recommended or contraindicated (see Table 40.2).

Treatment

Results from Clinical Trials

There is now no question that a significant reduction in cardiovascular and cerebrovascular morbidity and mortality results from treatment to reduce blood pressure in older hypertensive patients. Several randomized clinical trials of antihypertensive therapy in older populations have provided compelling evidence that treatment is effective in reducing cardiovascular (e.g., chronic congestive heart failure) and cerebrovascular (e.g., stroke) morbidity and mortality. A meta-analysis of outcome trials in systolic hypertension demonstrated that treatment was associated with significant reductions in overall mortality, cardiovascular events, and stroke.⁶¹ The treatment effect was largest in men, in those over the age of 70 years, and in those who had larger pulse pressures. Similarly, another meta-analysis of nine treatment trials⁶²⁻⁷⁰ confirmed that treatment of hypertension in the older population is associated with significant benefits: the treatment group had significant reductions in all-cause mortality [odds ratio, 0.88; 95% confidence interval (CI), 0.80-0.97], stroke mortality (0.64; CI, 0.49-0.82), and morbidity (0.65; CI, 0.55-0.76), as well as cardiac mortality (0.75; CI, 0.64-0.88) and morbidity (0.85; 0.73-0.99).⁷¹ Based in part on these data, an analysis of the effectiveness of antihypertensive therapy utilizing data derived

from the NHANES I survey suggested that the number needed to treat (assuming a 12 mmHg reduction in SBP for 10 years) to prevent cardiovascular events and deaths or all-cause mortality decreased as a function of the initial blood pressure reading and of increasing risk strata (derived from JNC-VI definitions); the prevention of 1 all-cause death required that 81 patients in the lowest risk grouping be treated compared to 9 patients in the highest risk group.⁷²

In addition to the demonstrated efficacy of antihypertensive therapy with respect to cardiovascular and stroke outcomes, it is worth noting that there may be other benefits. An analysis of data from the SHEP study identified that the relative risk of developing congestive heart failure among the treatment group was approximately one-half that of the control group.⁷³ Other studies have focused on a possible relationship between hypertension and the risk of developing cognitive impairment. Results from a vascular dementia project designed as part of the Syst-Eur trial suggest that the rate of the development of dementia was significantly lower (approximately one-half) in the active treatment compared with the control group.⁷⁴ It should be noted, however, that the dementia incidence was small (7.7 and 3.8 cases per 1000 patient-years in control and treated groups, respectively), and this observation has not yet been replicated.

Although the results from these randomized clinical trials have provided convincing support for the beneficial effects of treatment of hypertension in older patients, there nevertheless are several unanswered questions. The majority of these trials focused on those with simple hypertension and, for example, excluded those with significant comorbidities such as diabetes or a history of prior stroke or heart disease. The extent to which these results are applicable to frail older patients with multiple coexisting diseases is not known. Another issue is whether these beneficial results extend to the old-old, individuals over the age of 85 years. One report has identified an inverse association between blood pressure and mortality in a group of individuals over the age of 85 years.⁷⁵ This study reported the entry blood pressure measurements (separately grouped by systolic and diastolic) and 5-year survival rates of a group of 561 individuals over the age of 85 years who resided in the community, as well as in nursing homes and hospitals, in Tampere, Finland. The lowest survival rate was in the lowest systolic and lowest diastolic groups. Because 80% of individuals in these groups resided in either hospital or nursing home settings, it is not certain whether other confounding disease-related factors might have accounted for their decreased survival. However, a subsequent report whose study population was restricted to community-dwelling elderly aged 84 to 88 years demonstrated increased mortality in those with either very low or very high blood pressure.⁷⁶ Another report utilizing

data obtained from the Established Populations for Epidemiological Studies of the Elderly (EPESE) determined the mortality risk associated with blood pressure in community-dwelling older people.⁷⁷ This study found an increasing risk of death with increasing systolic blood pressure in men and women between age 65 and 84 years, but in men above the age of 85 years, an inverse relationship between systolic blood pressure and mortality risk was observed.

Very limited numbers of subjects over the age of 80 years have been included in the controlled clinical trials of hypertension treatment. Results from the European Working Party on High Blood Pressure in the Elderly (EWPHE) Trial suggested that no significant benefits of drug treatment occurred in those 80 years and older (group size, $n = 155$).⁶³ A similar trend for a reduction in treatment benefit with age was noted in the meta-analysis of the nine studies already cited (including the EWPHE); however, this difference was not statistically significant.⁷¹ For isolated systolic hypertension, comparable treatment benefits were observed in the 649 subjects 80 years and older who were enrolled in the SHEP study.⁶² Finally, a meta-analysis of data from subjects older than 80 years enrolled in randomized controlled studies suggests that significant reductions in the development of stroke (34%), cardiovascular events (24%), and congestive heart failure (42%) occurred in the treatment compared to the control group.⁷⁸ However, in this analysis a slight, although statistically nonsignificant, 6% increase in all-cause mortality was identified in the treatment group. Ultimately, results from the Hypertension in the Very Elderly trial should help to resolve this matter.

Another still unanswered question is a concern that reduction in blood pressure below a certain level may be associated with increased rather than decreased mortality, or a J-shaped curve. This relationship has been most often identified between the level of diastolic blood pressure and cardiovascular mortality. The knowledge that blood flow to the myocardium occurs primarily during diastole provides a potential physiologic mechanism to account for a relationship between low diastolic blood pressure and cardiovascular mortality. The J-shaped curve has been raised as a concern in some treatment studies in which reduction in cerebrovascular but not cardiovascular mortality has been identified. Results from several longitudinal studies have identified an increased risk for stroke and overall mortality in individuals in the lowest systolic and, particularly, diastolic blood pressure levels. The relationship between the diastolic blood pressure achieved in subjects enrolled in the Systolic Hypertension in the Elderly Program with respect to their relative risk for developing cardiovascular disease has been shown to be inverse; namely, the relative risk increased as diastolic blood pressure decreased below

70 mmHg.⁷⁹ Thus, until additional prospective data are available to provide guidance in this therapeutic dilemma, it is prudent to use caution in lowering blood pressure in older individuals with hypertension. Excessive reductions in blood pressure (e.g., diastolic levels below 70 mmHg) and the development of treatment-induced postural hypotension should be avoided.

General Approach to Therapy and Monitoring

As is the case in the approach to treatment of other chronic diseases in an older patient, it is important to define goals of antihypertensive therapy that are individualized to a given patient. In this context, the benefits as well as the potential risks of any therapeutic intervention need to be balanced to achieve, on the one hand, an overall goal of preventing the morbidity and mortality associated with high blood pressure without adversely affecting the patient's functional performance or quality of life on the other. A therapeutic approach directed toward reduction of systolic blood pressure to below 135 to 140 mmHg and diastolic blood pressure to less than 85 to 90 mmHg should be developed utilizing treatments least likely to produce adverse effects. For individuals with markedly elevated systolic blood pressure, an intermediate target, such as 160 mmHg, may be appropriate. The major focus of treatment should be on the systolic blood pressure and pulse pressure because, among older hypertensive individuals, these are stronger predictors of adverse outcomes than is the diastolic blood pressure. In view of the concerns about the J-shaped curve, it is important not to overtreat with an intervention that produces an excessive reduction in diastolic blood pressure. With the exception of hypertensive urgencies and emergencies (discussed next), it is unnecessary and perhaps deleterious to attempt rapid reductions in blood pressure to achieve this target level of control. In light of the age-associated pathophysiologic changes that result in impaired blood pressure homeostasis, too rapid a reduction in blood pressure may be associated with the development of symptomatic hypotension in some situations (e.g., postural or postprandial hypotension). Likewise, it is advisable to not make dosage adjustments or additions of other therapies too rapidly to avoid overtreatment. Once the patient's blood pressure has been controlled to an optimal level, it is appropriate to reevaluate the need for continued therapy. A reduction in dose or in some cases a trial period without antihypertensive medication (with close monitoring of the patient's home and office blood pressure) will help to minimize the possibility of overtreatment of blood pressure.

Another general approach to therapy is to continuously assess not only the response to therapy, but also the development of adverse effects of treatment. The development of orthostatic hypotension is an adverse effect

that may occur with any antihypertensive medication, although central-acting agents and vasodilators are more commonly implicated in this regard. The symptoms of orthostatic hypotension may be atypical; rather than providing a history of postural unsteadiness, the older patient may cite generalized weakness or fatigue. Because orthostatic hypotension is common in hypertensive patients (its frequency increasing in parallel with the supine systolic blood pressure level^{58,59}), and given the often occult nature of its presenting symptoms, it is essential to determine supine and upright blood pressure measurements as part of routine monitoring of all older hypertensive patients.

Nonpharmacologic Treatment Modalities

There are several reasons to review the role of nonpharmacological treatment modalities in treating geriatric hypertension. The older hypertensive population may in general be characterized as overweight, sedentary, and salt sensitive. Lifestyle modifications targeted toward these characteristics may therefore be of particular benefit in older hypertensive patients. Nonpharmacological therapies may be effective initial therapy; individuals with stage 1 hypertension (systolic blood pressure less than 160mmHg) who do not have diabetes should complete a 6-month trial of nonpharmacologic therapy before adding an antihypertensive medication if the target blood pressure is not achieved. In addition, these therapies may be adjunctive in combination with pharmacologic treatments, they may result in concurrent improvements in other cardiovascular risk factors, and there are minimal associated risks (as well the benefit of possibly avoiding adverse side effects associated with antihypertensive medications). A number of lifestyle modifications may be recommended: weight reduction; an aerobic exercise program; dietary alterations to decrease sodium, saturated fat, and cholesterol while maintaining adequate intake of potassium, calcium, and magnesium; smoking cessation; and moderation of alcohol intake.

A randomized trial of nonpharmacologic interventions in older hypertensive subjects that evaluated the effects of dietary sodium restriction and weight loss (the TONE study) demonstrated that relatively modest reductions in dietary sodium intake (~40mmol/day) and in body weight (~4kg) were accompanied by a 30% decrease in the need to reinstitute pharmacologic treatment.⁸⁰ A meta-analysis of randomized trials assessing the effects of dietary sodium restriction demonstrated that there is a significant reduction in systolic (a mean decrease of 3.7mmHg for each 100mmol/day decrease in sodium intake) but not in diastolic blood pressure.⁸¹ Consistent with these results, a follow-up study to the dietary approaches to stop hypertension (DASH) trial⁸² that

added a sodium restriction component identified that the DASH diet in combination with sodium restriction (~65mmol/day intake) resulted in a decrease in SBP of 11.5mmHg in hypertensive patients in comparison to the control, high-sodium diet.⁸³ Although diastolic blood pressure was also lower, the magnitude of the effect was less than that for systolic BP. The differential reduction in systolic pressure in response to dietary sodium restriction observed in these studies is particularly well suited for the older hypertensive patient.

There is a high prevalence of obesity in the older population: 26% of black and white men, 36% of white women, and 60% of black women between the ages of 65 and 74 years were characterized as overweight (defined by body mass index $\geq 27.8\text{kg/m}^2$ for men and $\geq 27.3\text{kg/m}^2$ for women) in the National Health and Nutrition Examination Survey.⁸⁴ There is increasing evidence that the distribution of body weight is an important determinant of cardiovascular risk. In particular, central adiposity has been shown to be associated with hypertension, hyperlipidemia, and insulin resistance.⁸⁵ Weight reduction is recommended for hypertensive individuals who are more than 10% above their ideal body weight, and weight loss of the order of 5kg has been shown to result in small (generally less than 5mmHg), but significant, decreases in blood pressure.⁸⁶⁻⁸⁸ There are likely additive antihypertensive effects of lower extremity aerobic exercise programs.⁸⁹ Although there are special considerations in an older hypertensive patient with regard to screening for the presence of underlying cardiovascular disease and attention to the prevention of injuries, the safety and efficacy of aerobic exercise has been identified in studies of older hypertensive individuals.⁹⁰

Overview of Pharmacologic Treatments

The general approach to pharmacologic treatment of hypertension is outlined in JNC-VI.² Treatment is stratified as a function of blood pressure stage (high normal: 130-139/85-89; stage 1: 140-159/90-99; and stage 2 and 3: $\geq 160/\geq 100\text{mmHg}$) and three levels of risk. Because age greater than 60 years is considered as one component of cardiovascular risk, all older hypertensive patients fall into the middle risk group (risk group B) at a minimum. For those with high-normal and stage 1 hypertension with no additional cardiovascular risk factors, 6-month trial of nonpharmacologic therapy is warranted. If a 6-month trial of nonpharmacologic treatment fails to produce the desired reduction in blood pressure, pharmacologic therapy should be initiated while nonpharmacologic treatments are continued. Older patients who initially present with more severe hypertension (stage 2 or 3), as well as those with diabetes or additional cardiovascular risk factors or evidence of target organ damage (risk

group C), should receive pharmacologic therapy initiated concurrently with nonpharmacologic methods.

The choice of initial antihypertensive drug class should be based on an individualized patient assessment. One should consider whether the patient has simple hypertension or if their hypertension is complicated by the coexistence of other conditions (e.g., diabetes, coronary artery disease, heart failure, or prostatism) that may influence drug selection. Each of the antihypertensive drug classes have been shown to be effective in reducing blood pressure in the older patient population. For those with simple hypertension, the initial drug selection based on the evidence available to date is either a thiazide diuretic or a long-acting dihydropyridine calcium channel antagonist.² Beyond this general recommendation, selection of a particular antihypertensive drug needs to be an individualized decision for each patient, taking into account the drug's potential advantages and disadvantages (see Table 40.2), together with the patient's comorbidities. Irrespective of the initial agent that is selected, in general, the starting dose should be reduced and dose titration done more gradually in an older hypertensive patient. If the target blood pressure goal is not obtained at a maximal dose of the initial agent following several months of treatment, therapy may either be switched to an alternate class or a second drug from another class may be added. A brief overview of the major classes of antihypertensive drugs that are currently recommended for initial therapy follows, focusing on their potential benefits and side effect profiles.

Diuretics

Therapy with low-dose thiazide diuretics (e.g., hydrochlorothiazide dose <50 mg daily, or equivalent) has demonstrated significant benefits in mortality, stroke, and coronary events in randomized clinical trials in older hypertensive patient populations. These beneficial effects combined with their relative safety, favorable side effect profile (their adverse metabolic effects—hypokalemia, hyperuricemia, and glucose intolerance—are attenuated at lower doses), once-daily dosing, and low cost have led to the recommendation that thiazide diuretics are preferred for initial therapy.⁹¹ Another advantage is that diuretic therapy leads to a disproportionate reduction in systolic relative to diastolic blood pressure and is better at achieving a reduction in systolic blood pressure compared to other agents.^{91,92} Thiazide diuretics are also well suited for use in combination therapies because of synergistic effects with other antihypertensive drug classes. It is worth noting that, despite these recommendations, only 23% of the subjects who were on monotherapy at the time of their entry into the TONE study were treated with diuretics,^{80,93} suggesting that this class of therapy is being underutilized.⁹⁴

Calcium Channel Antagonists

Each of the three chemical classes of calcium channel antagonists, that is, phenylalkylamines, dihydropyridines, and benzothiazepines, has been shown to be effective in treating hypertension in older patient populations.⁹⁵⁻⁹⁷ There are significant age-associated alterations in the pharmacokinetics of each of the three classes of calcium channel antagonists (a decrease in clearance and an increase in plasma levels) such that lower doses of these agents should be used in older patients.^{98,99} Based on their mechanism of action, which leads to a reduction in peripheral vascular resistance and their lack of significant CNS or metabolic effects, the calcium channel antagonist family of medications is well matched to the pathophysiology of the older hypertensive patient. The dihydropyridine class (e.g., nifedipine) has more potent direct vasodilator effects and may be more likely to produce peripheral edema and reflex tachycardia. Members of the phenylalkylamine (e.g., verapamil) and benzothiazepine (e.g., diltiazem) classes have more potent effects on suppressing atrioventricular (AV) conduction and may produce heart block, and also these appear to be more commonly associated with the development of constipation.

Several randomized controlled trials of the efficacy of long-acting dihydropyridine calcium channel antagonists (nicardipine or amlodipine) in the treatment of older hypertensive patient populations have been reported. The Systolic Hypertension in Europe (Syst-Eur) trial identified that active treatment was associated with a significant decrease in cardiovascular complications, including a 44% reduction in nonfatal stroke.¹⁰⁰ No significant benefits were observed in all-cause mortality. The conclusions were similar in a subsequent per protocol analysis of these data.¹⁰¹ The benefits of treatment on total and cardiovascular mortality were less in those older than 80 years. From the per protocol analysis, it was estimated that treating 1000 patients for 5 years would prevent 24 deaths, 54 major cardiac events, and 29 strokes.¹⁰¹ To address concerns that calcium antagonist therapy may be deleterious in those with diabetes, a subgroup analysis of the Syst-Eur population found similar beneficial effects in the diabetic population as had been noted in nondiabetics.¹⁰² Finally, a Japanese Intervention Cooperative Study followed older hypertensive patients randomized to the dihydropyridine calcium channel antagonist nicardipine or a thiazide diuretic and reported similar benefits in decreasing the risk of cardiovascular events between groups.¹⁰³

β -Adrenergic Antagonists

Beta-receptor antagonists are recommended in the JNC-VI report as another option for initial drug therapy for uncomplicated hypertension.² The primary mechanism of action of β -adrenergic antagonists is a reduction in

TABLE 40.3. Potential advantages, disadvantages, and special clinical considerations in the older hypertensive related to the major antihypertensive classes recommended for initial treatment.

Antihypertensive class	Potential advantages	Potential disadvantages	Clinical situations to recommend use	Clinical situations to recommend against use, or that require monitoring
Diuretics	Benefit documented in clinical trials Produce greater reduction in SBP than DBP Inexpensive	Metabolic abnormalities Urinary incontinence	Systolic hypertension	Glucose intolerance, gout, hyperlipidemia
Calcium antagonists	Benefit documented in clinical trials Absence of CNS or metabolic effects	Peripheral edema, constipation, heart block	Systolic hypertension Coronary artery disease	Left ventricular dysfunction
β -Antagonists	Benefit documented in clinical trials	May increase peripheral vascular resistance Metabolic abnormalities CNS effects	Coronary artery disease and postmyocardial infarction	COPD, peripheral vascular disease, heart block, glucose intolerance, type 2 DM, hyperlipidemia, depression
ACE inhibitors	Absence of CNS or metabolic effects	Hyperkalemia, renal insufficiency, cough	Congestive heart failure, type 2 DM	Renal insufficiency or renal artery stenosis

SBP, systolic blood pressure; DBP, diastolic blood pressure; ACE, angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; DM, diabetes mellitus; CNS, central nervous system.

cardiac output without significant reduction in peripheral vascular resistance (and less reduction in systolic blood pressure compared to other agents). Based on the physiologic characteristics of the older hypertensive (Table 40.3), there are several reasons to question whether β -adrenergic antagonists would be the appropriate choice for the older hypertensive patient. Indeed, one report that analyzed evidence from recent randomized controlled trials has questioned whether β -adrenergic antagonists are effective therapy for older hypertensive individuals.¹⁰⁴ This report analyzed results from 10 randomized controlled trials that evaluated morbidity and mortality outcomes in hypertensive patients above the age of 60 years following β -adrenergic antagonist therapy. These results suggested that β -receptor antagonist therapy is less effective as monotherapy with respect to blood pressure reduction and in the prevention of cardiovascular events and death in comparison with low-dose thiazide diuretics. In addition, there was a higher discontinuation rate due to adverse side effects. This report concluded with a recommendation that β -receptor antagonists not be considered as first-line monotherapy for simple hypertension in older patients. Because of their effectiveness in the management of symptomatic coronary artery disease, in secondary prevention following myocardial infarction, and in certain congestive heart failure settings, β -receptor antagonists should be considered in older patients whose hypertension is complicated by these comorbid conditions. Glucose and lipid profile monitoring should be done in patients who are treated

with β -receptor antagonists. In addition, depression and lethargy may develop during β -receptor antagonist therapy, particularly with those who are more lipophilic.

Angiotensin-Converting Enzyme (ACE) Inhibitors

Because older hypertensive individuals are in general characterized as having low renin levels (see Table 40.3), one might predict that ACE inhibitors would not be effective therapeutic agents in this population. Nevertheless, this antihypertensive class has been shown to be effective in treating the older hypertensive.^{96,97} ACE inhibitors are generally well tolerated by older patients (with the exception of cough), and their lack of CNS and metabolic (glucose, electrolyte, and lipid) effects may be a particular advantage. Although postural hypotension is not common, an exaggerated hypotensive effect may develop in volume-depleted patients receiving concurrent therapy with diuretics; particular attention to this possibility is required with the initiation of ACE inhibitor therapy. There are compelling indications to use ACE inhibitor therapy in patients with coexisting left ventricular systolic dysfunction as well as in diabetic patients who have microalbuminuria.

The major limitations to the use of ACE inhibitors in older hypertensive patients are the development of hyperkalemia (especially in those with renal insufficiency) and the potential for development of renal failure in the setting of bilateral renal artery stenosis. Fortu-

nately, ACE inhibitor-mediated renal failure is not a common occurrence and is generally reversible. The use of ACE inhibitors with short duration of action and frequent monitoring of renal function will aid in the detection and prevention of this adverse outcome. Although it may seem paradoxical, despite these potential adverse effects on renal function, there appears to be a role for ACE inhibitors in treating hypertensive patients with chronic renal insufficiency.¹⁰⁵ Close monitoring of potassium levels and renal function is necessary when ACE inhibitors are utilized in these patient groups. Other potential adverse effects of ACE inhibitors are the development of a nonproductive cough (occurring in up to 10% of patients), rash, or angioneurotic edema.

α₁-Adrenergic Receptor Antagonists

Although the reduction in peripheral vascular resistance that occurs with α-receptor antagonist therapy is particularly appropriate for the pathophysiologic profile of geriatric hypertension, and although these agents are effective in blood pressure reduction,^{106,107} the development of postural hypotension has limited the widespread use of this class of antihypertensive in the geriatric population. Further, a preliminary report from the currently ongoing Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) identified that subjects randomized to therapy with the α-receptor antagonist doxazosin had similar outcomes to those receiving a diuretic but had a twofold greater likelihood to be hospitalized for CHF. Consequently, this arm of the ALLHAT study was closed. Until additional information is available from the ALLHAT and other ongoing trials, monotherapy with α-adrenergic receptor antagonists to treat simple hypertension is not advised. One clinical situation in which α-receptor antagonist therapy may be considered is in older hypertensive men with prostatism, because these drugs have been shown to be efficacious in improving obstructive urinary symptoms.⁹⁹

Patient Adherence and Resistant Hypertension

Effective management of hypertension in an older individual requires an approach that promotes the patient's adherence to its long-term treatment. The role of patient education cannot be overlooked with regard to explaining the goals of a therapeutic program and the importance of adherence to this program. There are several specific methods to enhance adherence to the long-term medical therapy of this condition. Written information describing the specific treatment and an agreed-upon blood pressure goal should be given to the patient. In general, a simpler regimen promotes patient adherence. The use of calendar or pillbox systems may be recom-

mended to further assist patient adherence. Blood pressure self-monitoring by the patient is another approach to involve the patient in the management of their hypertension and perhaps enhance adherence to therapy. Patient education regarding the significant benefits to be gained from adequate blood pressure control is of particular importance because hypertension is usually asymptomatic. The interdisciplinary geriatric team is well suited to promoting this approach. To this end, it may be useful to involve nurses to provide reinforcement and feedback on the degree of blood pressure control during visits for blood pressure monitoring, dietitians to review dietary information and adherence, pharmacists to promote adherence to the medical regimen, and social workers to solicit the assistance of family members, if needed, and to review the financial burden associated with the cost of medical therapy.

The frequency of follow-up visits should be adjusted to reflect the patient's degree of blood pressure elevation at presentation with closer follow-up indicated for those with stage 3 hypertension (i.e., a systolic blood pressure greater than 180mmHg). With the exception of hypertensive urgencies (discussed next), attempts to reduce the patient's blood pressure to target levels too rapidly are unnecessary and likely deleterious. For most patients, an interval of 1 to 2 months is appropriate between visits to determine the need for dose titration. Given the age-related changes in systems that regulate blood pressure and impaired blood pressure homeostasis, overtreatment of hypertension may result in situational (postural or postprandial) hypotension. At all follow-up visits, it is imperative to determine the supine and standing blood pressure. It is good practice to titrate antihypertensive drug doses to achieve the target (seated) blood pressure only with the knowledge of whether this increase in dose could exacerbate preexisting postural hypotension. It is also prudent to assess the patient's adherence to his or her antihypertensive medication before recommending an increase in its dosage or considering switching to an alternative medication. For some patients, it will be important to obtain additional information derived from home or nonoffice setting blood pressure measurements.

Patients who fail to achieve adequate control of their blood pressure (failure to reach a target of 140/90) despite the use of three antihypertensive medications at maximal doses should be evaluated for causes of resistant hypertension. This evaluation should include an assessment of their adherence to the medical therapy, a review focused on potential drug interactions (e.g., nonsteroidal anti-inflammatory agents, corticosteroids, sympathomimetics, and alcohol), and an assessment for volume overload. Other potential explanations for resistant hypertension are the presence of a secondary cause (renovascular hypertension in particular) or

pseudohypertension, which should be evaluated as already outlined.

Special Clinical Situations

Hypertensive Urgencies and Emergencies

Hypertensive urgencies and emergencies are defined by the necessity to reduce blood pressure quickly to prevent target organ damage, not by an absolute blood pressure level. Elevated blood pressure in and of itself without symptoms or signs of target organ damage does not usually require aggressive therapy. Aggressive blood pressure reduction in a patient who presents with incidentally noted elevated blood pressure is inappropriate in the absence of a true urgency or emergency. It is of particular importance to obtain an accurate blood pressure measurement to avoid overdiagnosis of a hypertensive emergency when none is present (e.g., to consider the possibility of pseudohypertension as just discussed). It is possible to produce complications such as orthostatic hypotension or coronary or cerebral hypoperfusion syndromes resulting from treating an elderly patient with elevated blood pressure too aggressively.

Hypertensive urgencies are more common than true hypertensive emergencies.¹⁰⁸ These are defined as situations in which blood pressure should be lowered within 24 h to prevent the risk of target organ damage, such as accelerated or malignant hypertension without symptoms or evidence of ongoing target organ damage.¹⁰⁹ The majority of these situations may be managed as with oral administration of antihypertensive medications but generally necessitate a hospitalized setting for frequent blood pressure monitoring. The medications recommended for this situation include nifedipine, clonidine, labetalol, and captopril. Because no additional benefit has been noted with the use of sublingual administration of any of these agents and the more rapid onset of action may unpredictably produce a deleterious reduction in blood pressure, the oral dosage forms, which are effective within 15 to 30 min, are recommended.¹¹⁰ It should be noted that the blood pressure need not be reduced to normal levels within 24 h; indeed, an attempt to do so carries with it the risks of complications from coronary or cerebral hypoperfusion.

Examples of true hypertensive emergencies in older patients include hypertensive encephalopathy, intracranial hemorrhage, acute heart failure with pulmonary edema, dissecting aortic aneurysm, and unstable angina. These situations present with symptoms and signs of vascular compromise of the affected organs: brain (symptoms of severe headache, altered vision, altered mental status, and severe hypertensive retinopathy including papilledema, or focal neurologic signs), heart (symptoms

and signs of left ventricular failure or angina), or kidney (presenting as acute renal failure). The goal of treatment in these emergent clinical situations is immediate reduction in blood pressure, although again not necessarily to a normal level. The management of these conditions usually requires an acute hospital setting to permit the parenteral administration of an antihypertensive agent and continuous blood pressure monitoring by either arterial line, automatic cuff, or oscillometric (Finapres) devices. Intravenous nitroprusside has been the most widely utilized of these medications. Its onset of action is essentially immediate, it has a very short duration of action, and its rate of infusion may be titrated to result in a carefully controlled reduction in blood pressure over a 30- to 60-min period. Prolonged nitroprusside administration is limited by the accumulation of a thiocyanate metabolite and the risk of cyanide toxicity. Intravenous nitroglycerine is an alternative for longer duration of therapy. Additional parenteral alternatives include labetalol, enalaprilat, and hydralazine. In addition, for patients with evidence for fluid overload, parenteral loop diuretics may aid in achieving blood pressure control. Once the hypertensive emergency or urgency has been managed, the next steps are an evaluation to attempt to determine an explanation for the increase in blood pressure (i.e., a workup for secondary causes paying particular attention to the possibility of renovascular hypertension, assessment of adherence with the antihypertensive regimen, and evaluation of resistant hypertension) and developing a plan to achieve effective blood pressure control with appropriate close patient follow-up and monitoring.

Hypertension in Long-Term Care Center Residents

Information concerning the prevalence and management of hypertension in residents of long-term care (LTC) facilities is beginning to emerge.^{111,112} The prevalence of hypertension in this population ranges from approximately one-third to two-thirds. Special considerations are warranted in LTC residents with respect to making the correct diagnosis and defining the goals of therapy and its effects on quality of life. Blood pressure measurements in LTC settings may not be accurate.¹¹³ Inaccuracies result from measurement errors and from the temporal variability in blood pressure, particularly in relation to meals. Blood pressure appears to be highest in the morning before breakfast.¹¹¹ Postprandial hypotension is common among LTC residents, affecting about one-third of this population.^{114,115} The presence of postprandial hypotension has been associated with otherwise unexplained syncope and has been found to be a significant independent risk factor for falls, syncope, stroke, and overall mortality.

There are several factors to consider in the management of hypertension in the LTC population. First, the advanced average age and multiple comorbidities in this population raises several questions surrounding the beneficial effects of antihypertensive therapy. The beneficial effects of treatment must be carefully balanced against the potential adverse effects of therapy, and the goals of therapy must be defined within the context of the patient's overall clinical situation. Even an intervention as seemingly innocuous as a sodium-restricted diet needs to be evaluated in the context of the high prevalence of protein-energy malnutrition among nursing home residents. Second, the medication list of the average LTC resident includes seven medications, and most have three or more comorbid conditions. The addition of an antihypertensive medication increases the possibility of an adverse drug event in this frail, at-risk group. Third, several studies have identified antihypertensive medications, particularly vasodilators, as a risk factor for falls in this high-risk population who experience an average of two falls each year.¹¹⁶⁻¹¹⁸ Consequently, it is appropriate to assess both postural and prandial blood pressure in this population. Randomized controlled trials have not yet been conducted in the LTC population to provide clear risk-benefit evidence to support an approach to antihypertensive management. The available data suggest that diuretic therapy is effective in controlling systolic blood pressure elevations and that blood pressure reduction with diuretics lowered the prevalence of postural hypotension.¹¹¹

Peripheral Arterial Disease

William R. Hiatt and Mark R. Nehler

Peripheral arterial disease (PAD) involves the atherosclerotic occlusion of the arterial circulation to the lower extremities. The disease may be asymptomatic (identified only by a reduced blood pressure in the ankle), or it may manifest symptoms of intermittent claudication or severe chronic leg ischemia. The typical patient with PAD presents a decade later than the patient with coronary artery disease and experiences a profound limitation in exercise capacity and quality of life. In addition to affecting the limbs, PAD is a manifestation of systemic atherosclerosis affecting other major circulations involving the cerebral and coronary circulations. Thus, all patients with PAD are at an increased risk of cardiovascular morbidity and mortality. The treatment goals are directed at providing symptom relief and at reducing the risk of systemic cardiovascular morbidity and mortality.

Epidemiology

In the Framingham study, subjects were assessed for PAD using a history of claudication as a marker of the disease. Men and women had a similar incidence of intermittent claudication, which increased with age.¹ However, symptoms underestimate the true incidence and prevalence of the disease. Using the ankle-brachial index (ABI; described later), the prevalence of PAD is quite high, affecting 12% of the adult population and 20% of individuals over the age of 70.² These figures extrapolate to approximately 8 million persons affected with PAD in the United States.

The natural history of PAD has been evaluated in several studies.³⁻⁷ These studies have shown that elderly control subjects had an all-cause mortality rate of 1.6% per year. This rate was increased to 4.8% per year in patients with PAD, a 2.5-fold increased risk. Cardiovascular mortality rates are similarly affected, with 3- to 4-fold increased risk for patients with PAD. Importantly,

women are at approximately the same risk as men, and even asymptomatic individuals, who are identified solely based on an abnormal ankle-brachial index (ABI), have a markedly increased risk of cardiovascular events. The mortality risk in patients with PAD is maintained after adjustment for other cardiovascular risk factors and even in patients with known coronary artery disease.⁸

Risk Factors

The risk factors for PAD are those that are expected for any patient population with atherosclerosis. The most potent risk factors for PAD are age, diabetes mellitus, and cigarette smoking. In addition, hyperlipidemia, hypertension, and elevations in plasma homocysteine levels play an important role in promoting peripheral atherosclerosis.

Age

All forms of cardiovascular disease become more prevalent with age, and PAD is particularly prevalent in the elderly. In several studies, the risk of PAD increased approximately twofold for every 10-year increase in age.^{2,9}

Diabetes Mellitus

Diabetes is a major risk factor for PAD; persons with diabetes were four to five times more likely to develop claudication than nondiabetics.² The major risk for PAD due to diabetes appears to be the association of smoking, hypertension, and hyperlipidemia with diabetes, and not the degree of glycemic control per se.¹⁰ Thus, diabetes is a critical risk factor in the development of PAD, particularly in conjunction with other risk factors.

Cigarette Smoking

Cigarette smoking is associated with an approximate three- to fourfold increase in risk for peripheral atherosclerosis.¹¹ In addition, current cigarette smoking also significantly affects PAD outcomes. For example, progression from intermittent claudication to ischemic rest pain with risk of amputation occurs significantly more frequently in patients who continue to smoke than those who are abstinent.^{12,13}

Hyperlipidemia

Independent risk factors for PAD include a reduced HDL cholesterol level, and elevations of total cholesterol, LDL cholesterol, triglycerides, and lipoprotein(a).^{2,11} For every 10mg/dL increase in total cholesterol concentration, the risk of PAD increases approximately 10%.²

Hypertension

The presence of hypertension increases risk of PAD approximately two- to threefold.^{2,11}

Homocysteine

Alterations in homocysteine metabolism are a recognized independent risk factor for PAD.^{14,15} Homocysteine promotes the formation of oxidized LDL cholesterol, endothelial dysfunction, and the proliferation of vascular smooth muscle cells.¹⁶ Perhaps the most common cause of elevations in homocysteine levels are nutritional deficiencies of B vitamins, particularly folic acid and vitamins B₆ and B₁₂.

Additional Risk Factors

An elevated fibrinogen level is an independent predictor of PAD and also for the severity of claudication.¹⁷ Hypercoagulable states have not been extensively evaluated as risk factors in PAD. The lupus anticoagulant has been associated with peripheral atherosclerosis, as have markers of platelet activation such as increases in beta thromboglobulin levels.^{18,19} However, the frequency of these abnormalities is low and not fully substantiated and therefore does not warrant screening.

Pathogenesis

The underlying disease process in PAD is the result of atherosclerosis in the arterial circulation of the lower extremity, caused by similar pathogenic mechanisms as for coronary and cerebral atherosclerosis. Arterial occlu-

sive disease results in reduced blood flow, particularly to the calf muscles during exercise in patients with claudication, but with critical leg ischemia, blood flow is inadequate to meet the resting metabolic demands of the limb. Importantly, altered hemodynamics do not completely explain the pathophysiology of claudication. Work from several laboratories has demonstrated secondary changes in the skeletal muscle of patients with PAD that are consistent with motor nerve injury and loss of type II muscle fibers leading to muscle weakness.^{20,21} In addition, these patients acquire a metabolic myopathy characterized by the presence of somatic mutations in the mitochondrial genome, alteration in the expression of mitochondrial enzymes, and the accumulation of metabolic intermediates that have functional significance.^{22–24} These abnormalities are associated with specific defects in the activity of complex I and complex III of the electron transport chain that provide further evidence of a chronic, ischemia-induced myopathy in PAD.²⁵

Clinical Presentation and Diagnosis

Clinical Assessment

PAD is associated with two very characteristic types of limb symptoms, intermittent claudication and ischemic rest pain. Claudication is derived from the Latin word meaning to limp, which is the type of gait observed when a patient with PAD develops symptoms of claudication. The discomfort most commonly involves the calf or buttocks during walking exercise and is resolved within 10 min of rest. These patients commonly can walk no more than two to three blocks (200–300m) before they must stop to relieve the claudication pain. Peak exercise capacity is reduced 50% compared to healthy elderly subjects, and there is a profound limitation in daily activities.²⁶

Patients with chronic critical limb ischemia often present with rest pain in the distal foot that occurs at night and is relieved with dependency. Patients with more severe disease develop ischemic ulcers that are usually found at the distal points of the foot (toes, etc.) and are painful. In general, any patient with an open foot wound needs to have adequate arterial circulation confirmed by vascular studies.

The differential diagnosis in patients with leg symptoms includes PAD, diabetic sensory neuropathy, reflex sympathetic dystrophy, vasculitis, spinal stenosis, and arthritis. Patients with diabetic neuropathy may present with normal pedal pulses, but symptoms consistent with ischemic pain, and nonhealing neuropathic ulcers (these ulcers are usually on the plantar surface of the foot at pressure points—metatarsal heads). Reflex sympathetic dystrophy may present after surgical or other forms of trauma and leads to a painful, discolored, swollen extrem-

ity. Although this disorder is most likely caused by an autonomic neuropathy, arterial perfusion is typically normal. Patients with vasculitis may present with Buerger's disease (thromboangitis obliterans) and a strong smoking history. Claudication-like symptoms may also arise from spinal stenosis, which is due to osteophytic narrowing of the lumbar neurospinal canal. These symptoms include numbness and weakness in the lower extremity that is produced by standing or increasing lumbar lordosis rather than just ambulation. The symptoms are relieved not simply by rest, but also by sitting down or leaning forward to straighten out the lumbar spine. Patients with arthritis of the knee or hip may also have not only pain in the joint with ambulation, but also pain at rest or with weightbearing.

Hemodynamic Assessment

An ankle-brachial index (ABI) should be performed in patients suspected of having PAD, which would include persons at risk who are over the age of 70 years or younger patients between the age of 50 to 69 years who smoke or have diabetes. The estimated prevalence of PAD in this population at risk is more than 25%.²⁷ In addition, patients with exertional leg symptoms should also be evaluated with an ABI. The ABI test can be performed in the office setting using a routine sphygmomanometer and a handheld, continuous-wave Doppler to determine the systolic blood pressure in the arms and posterior tibial and dorsalis pedis arteries of each ankle. The ABI calculation is based on the higher of the two arm pressures and the higher pressure of the two vessels in each ankle. There is not a single cutoff value to define an abnormal ABI, but a ratio of 0.90 or less should be considered diagnostic for PAD.²⁸ ABI values of 0.40 or less are consistent with critical leg ischemia. In addition to obtaining the ABI, occlusive lesions can be further localized by taking pressure measurements in the upper and lower thigh and calf (segmental limb pressures). In patients with iliac occlusive disease, the thigh pressures are reduced, whereas patients with disease more distal in the leg may have a normal thigh pressure but reduced calf and ankle pressures.

Functional Assessment

Patients with claudication have a severe limitation in exercise performance and walking ability. Thus, determining functional status is an important aspect of the overall evaluation of the patient with PAD. In patients with claudication, treadmill testing can be used to define the distance at which claudication pain begins (initial claudication distance) and the maximal walking distance. Claudication therapies typically increase both the initial and maximal walking distances.²⁹

In addition to treadmill testing, several questionnaire measures of functional status have been developed and validated in this patient population. The walking impairment questionnaire (WIQ) is a disease-specific instrument that asks a series of questions regarding the patient's claudication severity and ability to walk defined distances, speeds, and stairs.²⁹ This questionnaire is simple to administer and has been shown to predict the response to claudication therapies.³⁰ The Medical Outcomes Short Form-36 instrument is a nondisease-specific questionnaire that assesses a variety of functional status domains. This questionnaire has also been sensitive in detecting treatment effect, particularly in the physical functioning realm.

Figure 41.1 provides an approach to the diagnosis of PAD in elderly populations.

Medical Therapy

The primary initial goals of medical therapy in patients with PAD are to treat the systemic atherosclerosis by risk modification and antiplatelet drugs in an attempt to reduce cardiovascular morbidity and mortality. Once that has been accomplished, the physician can then address the relief of symptoms and limb preservation.

Smoking Cessation

Several studies have suggested that smoking cessation will decrease the risk of critical leg ischemia and even reduce mortality in patients with PAD.^{12,13} All patients with PAD should be referred to a smoking cessation program and prescribed nicotine replacement and antidepressants.³² Nicotine replacement therapies, in addition to behavior modification, are slightly more effective than behavior modification alone. A recent meta-analysis of several placebo-controlled trials revealed cessation rates of 23% to 27% over 6 to 12 months using a nicotine patch as compared to placebo, where the quit rates ranged from 13% to 18%.³³ Also, in patients with medical diseases, transdermal nicotine patches have been shown to be safe even in high-risk populations. Thus, this is a strategy that should be considered for patients with PAD.

Diabetes

Patients with diabetes should first undergo intensive blood glucose control to target a hemoglobin A₁C less than 7.0%. Obtaining this goal may have favorable effects on the risk of cardiovascular events in both type 1 and type 2 diabetes.^{34,35} However, intensive glycemic control had no effect on the risk of amputation from PAD.³⁵ In addition to intensive blood sugar control, patients with atherosclerosis and diabetes also need

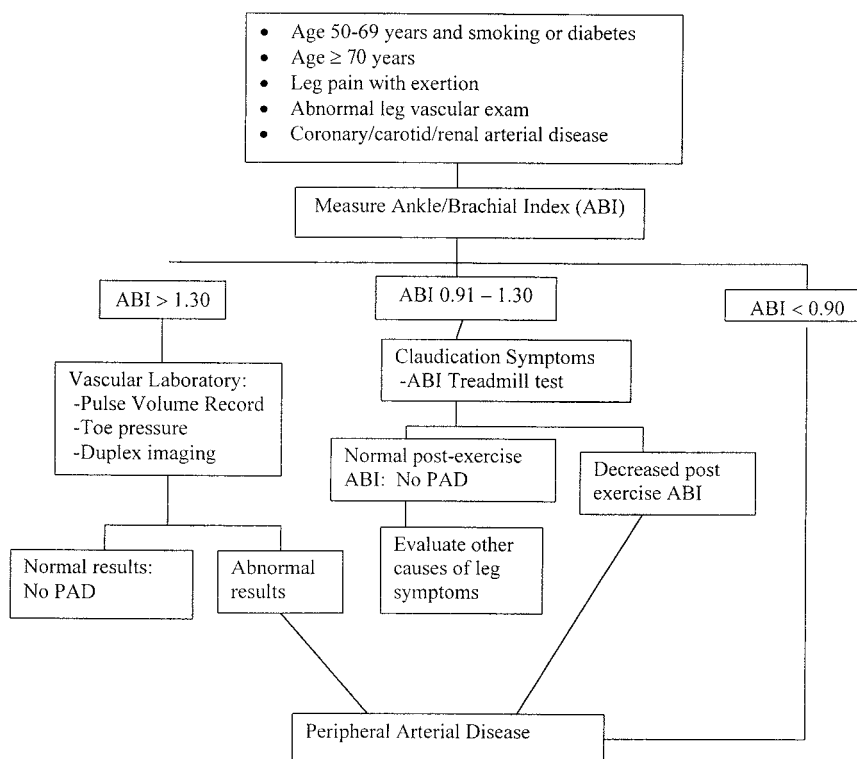

FIGURE 41.1. Evaluation of patients suspected to have peripheral arterial disease (PAD). Patients should be evaluated for peripheral arterial disease if they are at increased risk because of their age or presence of atherosclerotic risk factors, have leg symptoms on exertion, or have distal limb ulceration for which history and examination do not provide an obvious explanation. Additional vascular studies can be obtained in patients with an ankle-brachial index (ABI) above 1.30, including pulse volume recordings (PVR), and pressure in the first toe,

or by duplex imaging of the peripheral vessels to determine if peripheral arterial disease is present. Patients with leg symptoms on exertion who have an ankle-brachial index of 0.91 to 1.30 should be considered for an exercise test. An ankle-brachial index that is above 0.90 at rest but decreases by 20% after exercise is diagnostic of peripheral arterial disease.⁹⁶ If the initial ankle-brachial index is 0.90 or less at rest, then the patient likely has peripheral arterial disease and no additional tests are necessary.

aggressive risk factor modification; this may be particularly true in the treatment of hypertension when an angiotensin-converting enzyme (ACE) inhibitor may be a preferable agent.³⁶ Given the lack of specific trials, drug therapy for patients with diabetes and PAD should follow general published recommendations.³⁷

Hyperlipidemia

Several effective therapies have been developed to treat patients with hyperlipidemia. Dietary restriction of cholesterol and saturated fats has only a modest effect on LDL cholesterol levels, but a more substantial decrease in triglyceride levels, important in the management of PAD. The statin drugs have become a well-established means of reducing LDL cholesterol levels. In addition to statin drugs, gemfibrozil has been shown to lower LDL cholesterol concentration, with the added benefit of increase in HDL cholesterol concentrations. Additional means to modify HDL cholesterol concentration is the

use of niacin, which in a recent study was found to be safe in patients with PAD and diabetes.³⁸

In patients with PAD, a meta-analysis of randomized trials of lipid-lowering therapies showed a nonsignificant reduction in reducing mortality (odds ratio, 0.21; 95% CI, 0.03–1.17). This analysis also concluded that lipid reduction therapies favorably altered angiographic disease progression and symptoms of claudication.³⁹ Limitations of the analysis were a relatively small sample size and the fact that there have been no clinical trials in PAD of lipid therapy to prevent ischemic events.

Patients with PAD are at high risk for systemic ischemic events but at less risk for progression of their leg arterial disease. Based on evidence from the lipid trials in coronary artery disease, the National Cholesterol Education Program guidelines include PAD as a patient population at the highest risk for future coronary heart disease events and therefore in need of aggressive secondary prevention therapies.⁴⁰ The current recommendation for lipid therapy in the PAD population is to achieve

an LDL cholesterol level less than 100mg/dL and a triglyceride level less than 150mg/dL.⁴¹ The LDL cholesterol goals often require the use of HMG-coenzyme A reductase inhibitors, and achieving the HDL cholesterol goals often requires the use of niacin.

Hypertension

All patients with PAD and hypertension should undergo aggressive lowering of their blood pressure according to the Joint National Committee VI guidelines.⁴² All classes of antihypertensive agents can be used in patients with PAD, including beta-adrenergic blockers, which are safe in patients with claudication.^{43,44} In addition, beta-adrenergic blockers are routinely used in the perioperative setting to decrease the risks of vascular surgery.⁴⁵ Another class of drugs, the ACE inhibitors, may be protective against cardiovascular events in PAD patients. In the Heart Outcomes Prevention Evaluation Study, 44% of the population had evidence of PAD.⁴⁶ The study demonstrated that ramipril was associated with a reduced risk for vascular death, nonfatal myocardial infarction, or stroke in patients with PAD. This study suggests that ACE inhibitors may be important agents in reducing the risk of ischemic events in the PAD population.

Additional Approaches to Risk Modification

Elevated homocysteine levels can be reduced by supplementing the diet with B vitamins and folate.⁴⁷ Despite the ease of therapy with vitamin supplements, there are no clinical trials that demonstrate a clinical benefit in reducing homocysteine levels.

Estrogen therapy in postmenopausal women may also favorably influence several cardiovascular risk factors.⁴⁸ However, the Heart and Estrogen/Progestin Replacement Study showed no overall benefit of hormone therapy for reduction of cardiovascular events or peripheral arterial endpoints.⁴⁹ Thus, at the present time, there are no recommendations for this therapy in PAD patients.

Antioxidant vitamins such as vitamin E have been advocated to prevent ischemic events. However, the HOPE trial showed no benefit of vitamin E on prevention of cardiovascular events.⁴⁶ Thus the use of antioxidant vitamins in patients with PAD may not result in any clinical benefits.

Antiplatelet Therapy

In addition to risk factor modification, other therapies have been targeted to slow the progression of peripheral atherosclerosis, as well as to decrease the risk of cardiovascular morbidity and mortality. The role of platelets in thrombus formation has led to many studies in the effec-

tiveness of various antiplatelet agents, particularly aspirin, in the prevention of ischemic events. The meta-analysis by the Antiplatelet Trialists' Collaboration concluded that, in patients with a history of myocardial infarction or stroke, antiplatelet therapy reduced the risk of ischemic events by approximately 25%.^{50,51} In patients with PAD treated with bypass surgery, the Antiplatelet Trialists' Collaboration also found that antiplatelet therapy significantly promoted graft patency following vascular surgery.⁵² Thus, it would seem prudent to treat patients with PAD with low-dose aspirin.

In patients with PAD, ticlopidine has been shown to be more effective than placebo at reducing the risk of fatal and nonfatal myocardial infarction and stroke.^{53,54} This observation has led to the development of other drugs including clopidogrel, which lacks many of the side effects of ticlopidine. The clopidogrel versus aspirin for the prevention of ischemic events (CAPRIE) trial demonstrated that PAD patients showed a 24% risk reduction on clopidogrel as compared to aspirin in terms of reducing risk for ischemic events.⁵⁵

In summary, patients with PAD frequently have a history of coronary artery disease and stroke, and even in the absence of this history, PAD remains an independent predictor of cardiovascular morbidity and mortality. Aspirin should be considered as the primary antiplatelet agent for preventing ischemic events in PAD. Aspirin is also effective in maintaining vascular graft patency and may prevent thrombotic complications of PAD. Clopidogrel has FDA approval for the prevention of ischemic events in PAD, and, although based on a subgroup analysis, clopidogrel may be more effective than aspirin in PAD patients.

Claudication Medical Therapy

Exercise Training

The use of a formal exercise program to treat claudication has been studied over the past 30 years. Exercise therapy for claudication had demonstrated efficacy in terms of improving exercise performance, quality of life, and functional capacity.⁵⁶ Numerous types of exercise programs have been devised, but the most successful employ a supervised exercise setting. Patients should also undergo an exercise test to maximal claudication pain. A typical supervised exercise program is 60 min in duration and is monitored by a skilled nurse or technician. Patients should be encouraged to walk primarily on a treadmill because this most closely reproduces walking in the community setting. The initial workload of the treadmill is set to a speed and grade that brings on claudication pain within 3 to 5 min. Patients walk at this work rate until they achieve claudication of moderate severity. They then

rest until the claudication abates and then resume exercise. This repeated on-and-off form of exercise is continued throughout the supervised rehabilitation setting. On a weekly basis, patients should be reassessed as they are able to walk farther and farther at their chosen workload; this then will necessitate an increase in speed or grade or both to allow patients to successfully work at harder and harder workloads. This scenario then induces a training benefit. The duration of an exercise program is 3 to 6 months. The typical benefits include a 100% to 200% improvement in peak exercise performance on the treadmill and significant improvements in functional status.³⁰

Drug Therapy for Claudication

Vasodilators were an early class of agents used to treat claudication but have not been shown to have clinical efficacy.⁵⁷ In 1984, pentoxifylline was approved for the treatment of claudication. In early controlled trials, the drug produced a 12% improvement in the maximal treadmill walking distance.⁵⁸ However, in a recent study, pentoxifylline was no more effective than placebo on improving treadmill walking distance or functional status assessed by questionnaires.⁵⁹ A meta-analysis concluded that the drug produced modest increases in treadmill walking distance over placebo, but the overall clinical benefits were questionable.⁶⁰

Cilostazol is currently the most effective drug for claudication. Approved in 1999, the primary action of cilostazol is to inhibit phosphodiesterase type 3, which results in vasodilation and inhibition of platelet aggregation, arterial thromboses, and vascular smooth muscle proliferation.⁶¹⁻⁶³ In four trials of 1534 patients, cilostazol 100mg twice daily improved both pain-free and maximal walking distance as compared with placebo.^{59,64-66} In one trial, cilostazol 100mg twice daily was superior to both placebo and pentoxifylline.⁵⁹ In three of the trials, cilostazol also improved several aspects of physical functioning and quality of life as assessed by questionnaires.⁶⁴⁻⁶⁶ The most common side effects of cilostazol are headache, transient diarrhea, palpitations, and dizziness. Cilostazol should not be given to patients with claudication who also have heart failure.

Additional drugs are in clinical trials for treating claudication. Propionyl-L-carnitine is a metabolic agent that has been shown to improve treadmill performance and quality of life in patients with claudication.⁶⁷⁻⁶⁹ Prostaglandins have been extensively studied in patients with PAD, but with mixed results. In a recent study, beraprost, an oral prostaglandin, had positive effects on treadmill walking distance and quality of life.⁷⁰ However, these drugs are still under study and their utility needs further evaluation. Very few studies have addressed the issue of combined drug plus exercise therapy for claudi-

cation. However, the available data suggest at least an additive effect of exercise training plus a drug for claudication.^{71,72}

Interventional Therapy for PAD

Claudication

In patients with claudication, the natural history of the limb disease is relatively benign in that the risk of progression to critical limb ischemia and limb loss is quite small.^{73,74} Therefore, the decision to proceed with interventional therapy in patients with claudication is typically based on lack of response to medical therapy and a suitable lesion for angioplasty or surgery.

Angioplasty with or without stenting has been evaluated in both the iliac and femoral arteries. Although the initial technical success is high (>90% for both), the durability of angioplasty with stenting is far greater in the iliac vessels.⁷⁵ The Trans-Atlantic Inter-Society Consensus (TASC) document provides summary recommendation for lesions that are appropriately treated with angioplasty.⁷⁶ In the iliac arteries, a single stenosis of 10cm or less, two stenoses less than 5cm, and unilateral common iliac occlusion are best treated initially with angioplasty. In the femoral arteries, a single stenosis of 10cm or less and multiple lesions each less than 3cm may also be approached with angioplasty, typically without a stent.

Surgery for claudication generally involves two operations, the aortofemoral bypass and the femoral above-knee popliteal bypass. Aortofemoral bypass has good patency in older patients (80% patent at 10 years).⁷⁷ However, these procedures have a 3% to 5% mortality risk and a 1% incidence of graft infection.⁷⁸ Aortic surgery is a morbid operation from which an older patient frequently requires months to recover completely. Femoral popliteal bypass is less durable, with patencies of 50% to 60% at 5 years.^{79,80} Operative mortality rates up to 3% are typical when operating for claudication.⁸¹ In addition, femoral popliteal bypass is more likely to lead to limb threat following graft failure. The TASC recommendations for aortoiliac surgery are for more diffuse disease,⁷⁶ which would include bilateral stenoses of 5-10cm, diffuse, multiple unilateral stenoses greater than 10cm, bilateral occlusions, and diffuse disease involving the aorta and iliac arteries. In the femoral vessels, similar criteria apply for surgery, including multiple stenoses or occlusions, each 3 to 5cm, and complete common or superficial artery occlusions.

Critical Leg Ischemia

The initial management of patients with critical leg ischemia involves pain relief including narcotics. Patients

with more severe disease including ischemic ulceration or gangrene also need wound care to control infection and prevention of further trauma to the extremity. Specific medical treatments for critical leg ischemia have been limited. Numerous trials have been performed in Europe using prostaglandin drugs. These trials have met with marginal success using a variety of agents. Antiplatelet therapy is critical to maintain graft patency, whereas the use of anticoagulation to maintain graft patency is empiric and done only in selected cases.

Definitive evaluation and management requires arteriography and revascularization, or primary amputation. Revascularization operations for critical limb ischemia use the patient's own veins (greater saphenous, lesser saphenous, and arm veins) as the optimal bypass conduit. Current 5-year patency rates for below-knee popliteal (distal anastomosis to a modest-sized artery just below the knee) and tibial (distal anastomosis to smaller arteries at the calf level or below) bypass of 60% to 70% and 50% to 60%, respectively, have been reported by multiple centers.⁸⁰ Limb salvage (prevention of amputation) rates of 80% or better for the same time interval are also the rule,⁸⁰ which is due to success in second bypass surgeries when the first operation eventually fails. Operative mortality is 5% in most series but may reach 10% in patients over 80 years of age.⁸² Hospital stays of 10 or more days are common due to slow healing and frequent complications and comorbidities. About one-quarter to one-third of patients need to go to some sort of rehabilitation facility on discharge, although the majority will stay for only a few weeks.⁸² The decision to use surgery or angioplasty as the initial treatment option follows the TASC guidelines described earlier.

Despite these impressive patency data, 23% of bypasses will need some sort of operative revision (usually within the first year) to repair a stenotic area that develops in the vein graft.⁸³ Twenty percent of patients will require at least one readmission for wound care issues, usually associated with an operative incision.⁸⁴ The majority of patients develop significant lymphedema in the operated leg. Constant graft ultrasound surveillance to locate the asymptomatic stenoses before graft occlusion and limb threat (every 3 months for the first year and every 6 months for life) and potential revision needs lead to a substantial amount of patient anxiety.

In patients who progress to amputation, below-knee amputations are performed in patients with ambulatory potential. However, despite many different techniques, there is no guaranteed method to assure healing of below-knee amputations. Issues that complicate healing include poor circulation, chronic edema, and skin changes consistent with chronic venous disease. This difficulty is reflected in a reamputation rate to attempt below-knee salvage from 4% to 30%.⁸⁵⁻⁸⁷ Importantly, half of all below-knee amputees who fail primary healing ulti-

mately require above-knee amputation.⁸⁸ Primary above-knee amputation is considered the best option for patients without any ambulatory potential (dementia, stroke, obesity, etc).

More below-knee amputees achieve ambulation than above-knee amputees,⁸⁹⁻⁹¹ although overall the number of major amputees who achieve meaningful independent ambulation is small. Initial rehabilitation can require 9 months or longer. By 2 years, 30% of amputees who were walking are no longer using their prostheses.⁸⁹ Advanced age and female gender bode poorly for ambulation.⁹² Fifteen percent of amputees require contralateral amputation, and another 20% to 30% have died by 2 years.^{89,93,94}

An overall approach to the treatment of PAD is presented in Figure 41.2.

Conclusions

Peripheral arterial disease is a prevalent manifestation of atherosclerosis that is associated with significant risk of morbidity and mortality and also a marked reduction in ambulatory capacity and quality of life. Unfortunately, PAD is undertreated with regard to risk factor modification, use of antiplatelet therapies, and management of symptoms.⁹⁵ The data to support intensive risk modification in PAD patients have not been as extensively established as is the case for patients with coronary artery disease. Clinical trials specifically in the PAD population are needed to address the benefits of the treatment of hyperlipidemia (including not only LDL cholesterol reduction, but also modification of other lipid fractions), diabetes, elevated homocysteine levels, and other prevalent risk factors in PAD. Despite these limitations, patients with PAD should be considered candidates for secondary disease prevention strategies. Target goals for the management of atherosclerotic risk factors should be achieved in all PAD patients. The use of ACE inhibitors may confer additional benefits in terms of a reduction in the risk of fatal and nonfatal ischemic events. The data are better in support of the use of antiplatelet therapies to prevent ischemic events in PAD. Aspirin should be considered in all PAD patients, with clopidogrel an alternate (and potentially more effective) agent. Studies evaluating the combination of clopidogrel with aspirin or aspirin with other antiplatelet agents are needed.

Medical therapies to treat the symptoms of claudication and limited mobility are now well established. A supervised walking exercise program should first be considered in all patients, given the low risk and marked improvements seen in functional capacity. Pharmacologic therapies are also available that offer meaningful improvements in functional status. Pentoxifylline has limited utility, but cilostazol has been shown to improve both

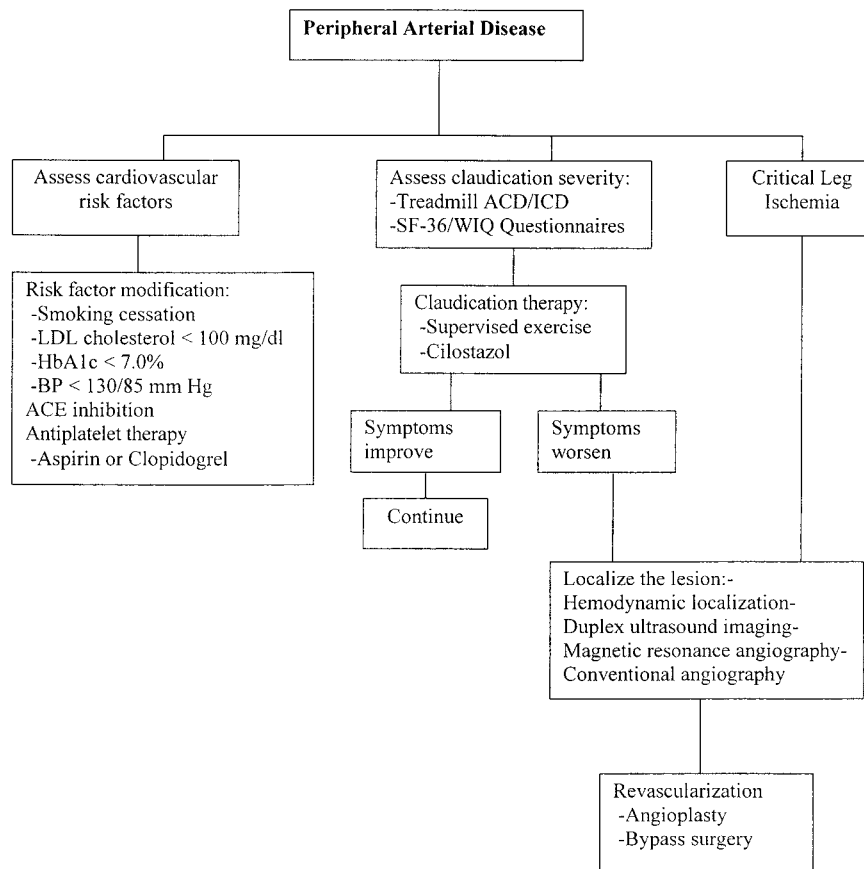

FIGURE 41.2. Evaluation and treatment of patients with proven peripheral arterial disease. All patients with peripheral arterial disease, regardless of symptom severity, should undergo risk factor modification to achieve the listed treatment goals and receive antiplatelet drug therapy with aspirin, but clopidogrel is an acceptable alternative drug. Angiotensin-converting enzyme inhibitors should be considered because of the potential for prevention of ischemic events that is independent of blood pressure lowering. A treadmill test to define the absolute claudication distance (ACD) and the initial claudication distance (ICD) can provide an objective assessment of the severity of claudication and response to therapy. The functional limitations of claudication and response to therapy can also be quantified by the physical function scales of the nondisease-specific Medical Outcomes Short Form 36 questionnaire (SF-36) and the disease-specific Walking Impairment Questionnaire (WIQ).

treadmill walking capacity and quality of life. A number of other compounds such as propionyl-L-carnitine, prostaglandins, L-arginine, lipid-lowering drugs, and angiogenic growth factors are under investigation for both claudication and critical leg ischemia. Future studies may confirm the benefits of combining treatments for claudication, including exercise following angioplasty or exercise plus a medication.

Patients who do not respond to medical therapies for their claudication symptoms should be considered for

Treatment of claudication should begin with exercise therapy or drugs such as cilostazol. Patients who do not improve and remain disabled, or who have worsening symptoms, should have additional localization of the occlusive lesions to plan endovascular or surgical intervention. Noninvasive disease localization can be done with hemodynamic tests such as segmental limb pressures or pulse volume recordings. In addition, duplex ultrasound and magnetic resonance angiography (MRA) both have a high sensitivity and specificity for localization of lesions (with MRA having the highest sensitivity), but conventional angiography is still required in most patients before a surgical or angioplasty procedure. Patients with critical leg ischemia typically have an ankle-brachial index less than 0.40 and should initially be considered for localization of their occlusive disease in anticipation of the need for revascularization.

angioplasty if they have a lesion amenable to the procedure. Patients with critical leg ischemia should be initially considered for vascular surgery and/or angioplasty.

Rheumatologic Diseases

Daniel J. Brauner, Leif B. Sorensen, and Michael H. Ellman

Old age superbly rising! O welcome, ineffable grace of dying days.

—Walt Whitman, *Song of Myself*

Part of the ineffable grace of growing older involves living with and overcoming the travails of rheumatic diseases, especially osteoarthritis (OA), which becomes increasingly common with age. The projected growth of people aged 65 years and older in the United States has focused attention on preserving and improving their quality of life; important among the factors determining this are the prevention and treatment of musculoskeletal conditions. Arthritis and other rheumatic conditions, and chronic back conditions, are the leading causes of disability in the United States, affecting approximately 43 million people.¹ Given current population projections, arthritis will affect nearly 60 million people in the year 2020 and will limit the major activities of nearly 11.6 million. Arthritis has a sizable economic impact, as it is the source of at least 44 million visits to a health care provider, 744,000 hospitalizations, and 4 million days of hospital care per year. In 1992, the estimated medical care cost for persons with arthritis was \$15 billion, and total cost (medical care plus lost productivity) was \$65 billion, the latter amount being equal to 1.1% of the gross domestic product.² Arthritis is a leading health problem among all demographic groups, but it is especially important in the elderly; the prevalence of common types of arthritis increases with age, with as many as 50% of people aged 65 years and older affected by some type of arthritis.³

The older patient with rheumatologic disease presents a unique opportunity for the astute clinician to untangle diagnostic puzzles and offer treatments that can improve function and relieve pain and suffering in very meaningful ways, but diagnosis of rheumatic disease in the elderly can be especially challenging for several reasons (Table

42.1). Besides presenting important diagnostic and therapeutic demands because of its almost ubiquitous presence in the older patient, osteoarthritis, the most common rheumatic disease, also provides the substrate on which other rheumatic diseases are superimposed in this group, complicating their diagnosis.

The presentation of other rheumatic diseases in the older patient is further altered by immune, endocrine, and vascular changes associated with aging, modulating their expression and making their diagnosis more difficult. The well-described higher rate of false-positive serology in older patients is among the changes that complicate the diagnosis of rheumatic disease in this group. The commonly held misconception that “other” rheumatic diseases are rare or nonexistent in this age group is another factor that often delays or precludes the diagnosis of rheumatic diseases in the older patient. As we show here, incidence rates of diseases such as rheumatoid arthritis and systemic lupus in older patients are high enough to warrant more consideration than they are presently given. Some, such as temporal arteritis and polymyalgia rheumatica, occur almost exclusively in the older patient. Because unifying diagnoses to explain multiple symptoms are less common in the older patient, multisystem rheumatic diseases such as systemic lupus and temporal arteritis are less often considered in this group and are often diagnosed late or possibly not at all.

Inflammatory conditions, such as rheumatoid arthritis, can “burn out” in older patients who may still have pain and decreased function from osteoarthritis, which is more common in previously damaged joints. There may even be some inflammation in these joints from crystal-induced arthritis that is also common in this group, further complicating the diagnosis. We begin this chapter with an in-depth review of osteoarthritis, the most important rheumatic disease in the older patient, and then go on to cover the other rheumatic diseases, with special emphasis on their altered manifestations in this group.

TABLE 42.1. Factors complicating diagnosis of rheumatic diseases in the elderly.

1. High prevalence of underlying osteoarthritis
2. Immune, endocrine, and vascular changes
3. Higher rates of false-positive serology
4. Misconceptions about incidences of rheumatic diseases
5. Lower incidence of “unifying” diagnoses
6. Inflammatory conditions may “burn out”

Osteoarthritis

Osteoarthritis (OA), once the poor stepchild of the more esoteric and “interesting” rheumatic diseases, with patients often systematically “weeded out” of standard rheumatology clinics, is finally getting the attention it deserves as one of the most prevalent conditions of humankind and the one that causes the most disability. The commonly held notions that OA is an inevitable consequence of aging because of the normal “wear and tear” of the joint is much too simplistic. Cartilage does not simply wear out like the soles of one’s shoes. Rather, the changes seen in OA involve the complex interaction of genetic susceptibility, joint mechanics and injury, chondrocytes that live a robust metabolic existence, biochemical alterations, and the complex interplay of mediators, as well as structures that surround the joint.

Perhaps more than any other condition, the changes associated with OA are most strongly associated with images of aging, as in the gnarled hands and antalgic or painful, noisy gait of the old person with arthritis. But although OA is common in older people, it is not universal or inevitable. Teasing out the normal changes of aging from those associated with OA and their interplay has been a major area of inquiry and is discussed in detail later. Definitions of OA are problematic because they are so dependent on what tools, modalities, or scales one chooses to consider: clinical symptoms, functional impairment, findings on physical examination, x-ray changes, gross or microscopic structural changes, biochemical alterations including cytokines and enzymes, and cellular alterations. One useful way of understanding OA is as a final common pathway, a clinical and pathologic outcome of a range of disorders resulting in similar alterations in articular anatomy and function.⁵ OA occurs when the dynamic equilibrium between the breakdown and repair of joint tissues is overwhelmed. Factors that have been implicated include occupation, body weight, trauma, recreational activities, developmental abnormalities, collagen gene mutations, muscle weakness, alterations in proprioception, denervation of joints, and inherited and acquired errors of metabolism.

Epidemiologic studies have shown that the prevalence of OA increases progressively with age. Autopsy surveys have shown that, by age 40, 90% of all persons have histologic evidence of OA, while in the tenth decade the process has become universal. In a survey of roentgenograms of hands and feet, 37% of all adults in the United States had some evidence of OA. The prevalence rose from 4 per 100 among persons 18 to 24 years of age to 85 per 100 at age 75 to 79. In the Framingham study,⁶ radiographic evidence of knee OA increased with age, from 27% in subjects younger than age 70 to 44% in subjects aged 80 and older. Anatomic and radiologic examinations define disease earlier than do clinical studies based on symptoms and signs. In two studies, the prevalence of symptomatic knee OA was only 29%⁷ and 43%⁸ of radiologically defined disease. Until middle age, OA occurs with the same frequency in men and women, but after age 50, symptomatic osteoarthritis is more common in women, and this difference in prevalence widens with increasing age. Women are also more likely to have multiple joint involvement.

Presentation of the Older Patient with Osteoarthritis

When presented with an older patient with mobility problems or pain that appears to be musculoskeletal in origin, the geriatrician should take a broad perspective that includes evaluation of the involved joints and the surrounding tendons, bursae, bones, and, importantly, muscles. Very often, by the time the patient comes to the physician’s attention several of these structures have been affected. The clinician needs to consider the “functional unit” composed of articulating bones, cartilage, ligaments, capsule, the muscles that affect movement and the nerves that control movement, and sense position and movement, that is, proprioception. Pain is the classic symptom that brings the patient to see a physician. However, aches and pains of joints and muscles, especially with prolonged or increased use, are so common among older people and often expected as a part of aging that many patients do not seek medical care or complain of pain unless specifically probed. This pattern, of course, varies with patients and is dependent on psychologic factors, the presence of other medical problems often deemed more serious, access to health care, pain threshold, and impact on function.

The most common pain described with OA is an aching type associated with use of the particular joint. Occasionally, the pain is described as sharp and fleeting, especially in the knees, where it can be associated with certain movements during weightbearing. When osteoarthritis involves the lower back or hips, the pain is often poorly localized. The pain is typically related to activity, but rest

pain is present in approximately 50% and night pain in about 30%. The origin of the pain experienced in OA is a complex phenomenon, as the primary tissue that is involved, cartilage, contains no nerve input. Other structures in and around the joint have been implicated. The impact of psychosocial factors is poorly understood but may help explain difficulties correlating pain with other measures of disease such as radiologic findings. In one study, women with knee pain who did not have radiographic evidence of knee OA had higher anxiety scores than those without pain.⁹

Stiffness is another commonly described symptom of OA. The stiffness associated with OA may be described as difficulty initiating movement in a joint or decreased or painful movement in a joint. Morning stiffness, commonly seen in the more inflammatory types of arthritis such as rheumatoid arthritis, may be present but is usually of shorter duration (less than 30 min) and limited to fewer joints. More commonly, patients describe a gelling phenomenon in which particular joints, most commonly the knees and hands, become stiff after periods of inactivity. This discomfort is usually quite short lived, lasting minutes, and improves after the joint is “worked out.”

As opposed to the younger patient with OA who commonly presents with one affected joint, frequently associated with a history of trauma, the older patient is more likely to have involvement of multiple joints in characteristic patterns. Even though trauma may have initiated problems in a joint in an older patient, OA is such an insidious condition that the trauma is usually not reported or remembered, as it may have occurred 20 to 30 years previously. Even if the mind can forget an insult, however, the body is tenacious when it comes to remembering old traumas.

An attractive explanation of the patterns of joint involvement in OA and one that helps track the joints commonly involved in older patients comes from an evolutionary theory first elaborated by Hutton. Our human ancestors have only been walking upright for about 3 million years, starting with *Australopithecus aferensus*. The bulk of the evolution of our joints, therefore, probably occurred while our ancestors were brachiating (swinging through the trees by their arms) and knuckle-walking. According to this theory, certain joints that are more prone to OA may be underdesigned for the stresses of modern life, with little functional reserve. Underdesigned joints include those required for pincer grip, such as the distal interphalangeal and proximal interphalangeal joints, as well as those stressed by upright walking such as the knees and lower back. Overdesigned joints, the shoulders (for brachiating) and metacarpophalangeal joints (for knuckle-walking), are rarely involved in primary OA.¹⁰

The joints most commonly involved in osteoarthritis are the distal and proximal interphalangeal joints of the

hands, the first carpometacarpal joint, the first metatarsophalangeal joint, the knee, the hip, and the spine. As the clinical manifestations of OA are dependent on which joints are involved, they are discussed individually.

Heberden's nodes, characterized by bony enlargement of the dorsolateral and dorsomedial aspects of the distal interphalangeal (DIP) joints of the fingers, are extremely common in older patients. Flexor and lateral deviation of the distal phalanx are common. They may be single, but they usually are multiple. In most patients, they develop slowly over months or years, usually around the time of the menopause, giving rise to little or no pain. In a few patients, they evolve rapidly with redness and tenderness. Small gelatinous cysts sometimes appear over the dorsal aspects of the joint. These cysts, which morphologically resemble ganglia, may disappear spontaneously or persist indefinitely. Similar nodes at the proximal interphalangeal (PIP) joints are known as *Bouchard's nodes*. Involvement of the *first carpometacarpal (CMC) joint* is common and is frequently symptomatic. Marked osteophytosis at this site leads to a characteristic squaring appearance of the hands. The radiographic patterns of hand OA assessed in the older Framingham subcohort found women with a much higher incidence than men. However, the relative frequency of joint involvement was similar in both sexes: DIPs, followed by the first CMC, PIPs, and rarely metacarpophalangeal joints (MCPs). Isolated involvement of any one or two MCP joints can occur as a result of trauma or in association with crystal disease. Once established, OA of the hands is usually not very painful, but a weaker grip and some functional impairment involving fine motor skills with increasing clinical severity of hand OA are common complaints.

Erosive inflammatory osteoarthritis is a variant of OA of the hands. This entity, which most often affects postmenopausal women, involves the distal and proximal interphalangeal joints and less often the metacarpophalangeal joints. Painful inflammatory episodes eventually lead to joint deformities and sometimes to ankylosis. After years of intermittent acute flares, the joints become quiescent. The clinical picture may be confused with rheumatoid arthritis. Radiographic findings include loss of joint cartilage, spur formation, subchondral sclerosis, and bony erosions, usually in the central portion of the joints. Rheumatoid factor tests are negative, and the sedimentation rate is normal or only slightly elevated. The presence of immune complexes in the synovium and a frequent association with the sicca syndrome suggest that immune mechanisms may be at work in this subset of OA.

Osteoarthritis of the knee, although not the most common site, probably has the greatest impact in terms of disability. Knee pain severity is the strongest risk factor for self-reported difficulty in performing tasks of upper and lower extremity function.¹¹ The knee joint is com-

posed of three compartments, the medial and lateral tibiofemoral and the patellofemoral. The medial compartment bears the greatest load during walking and is most commonly involved, followed by the patellofemoral and last, the lateral compartment. Persons affected with knee OA commonly complain of pain on walking, stiffness of the joint, and difficulty with ascending steps. Involvement of the medial compartment will eventually lead to varus deformity secondary to loss of joint space (cartilage) from this compartment. Bony deformities are further compounded by osteophyte production at the medial and lateral joint margins. Crepitations caused by cartilage irregularities, eburnated or exposed subchondral bone, or thickened joint capsule or tendons are frequently felt and occasionally heard with flexing and extending the joint. Not uncommonly, joint effusions can be appreciated either by a positive bulge sign in which fluid is milked from the medial compartment and then seen to flow back when pressure is placed on the lateral compartment, or when more fluid is present by ballotment of the patella. When testing for ballotment, care needs to be taken to milk the fluid out of the suprapatellar joint compartment by gentle pressure applied above the patella, as this pushes the fluid, if present, under the patella. Otherwise, fluid will simply flow upward and produce a falsely negative test. Assessment for quadriceps atrophy and strength is important with consideration that obese patients may have proportionally decreased strength and still appear fairly strong.¹²

A common complaint associated with knee OA is a feeling that the knee is about to "give out." A thorough assessment for ligament stability should be performed. Laxity of the collateral ligaments is documented by increased varus-valgus movement. However, on examination, many of these patients do not have grossly unstable knees, and it is thought that the perceived instability is more related to muscle weakness and fatigue. The neighboring joints should be carefully examined, as they often exhibit decreased range of motion despite not being primarily involved with OA. The physical examination should include observation of the gait, checking for an antalgic gait that is characterized by a short stance phase on the affected side, but when subtle, more easily recognized by a fast swing phase on the opposite side. Patients with cognitive impairment may not complain of pain but may instead present with antalgic gait, falls, or decreased mobility, causing them to spend more time in bed.

Spontaneous osteonecrosis of the knee must be considered in the differential diagnosis of an acutely painful knee in the elderly. In a study of 68 patients with spontaneous osteonecrosis of the knee, the mean age of onset was 68 years and the majority were female.¹³ The structural changes alter biomechanics of the joint and may lead to the rapid development of severe osteoarthritis.

Osteoarthritis of the *hip* is less common but primarily confined to older individuals. It may be unilateral or bilateral. Hip joint pain is usually localized to the groin or along the inner aspect of the thigh. It may be referred to the buttock or along the obturator nerve to the knee. At times, the pain in the knee dominates the clinical presentation, and the diagnosis may be missed. Conversely, in the evaluation of pain in the hip area, other causes must be considered. Disorders of the lumbar spine at the L2–L3 level may refer pain into the groin, and at the L5–S1 level into the buttock. Trochanteric bursitis also may be confused with intra-articular hip disease. Physical examination shows loss of internal rotation and abduction early in the disease process. Flexion contracture may be determined by using the Thomas test, in which the knee of the uninvolved leg is drawn to the chest to flatten the lumbar lordosis. If a flexion contracture exists, the involved leg will flex off the examining table. On gait examination, the patient may demonstrate an antalgic gait limp or a gluteus medius lurch, in which the torso leans over the involved weightbearing hip. This move reflects an unconscious attempt to place the center of gravity over the painful hip, thereby decreasing the forces across that joint. In advanced disease, the leg is often held in external rotation, with the hip flexed and adducted. Functional shortening of the leg may result in a short-limb limp.

Osteoarthritis involving the back is a complex and poorly understood syndrome. Back pain or discomfort is an extremely common symptom in older people. As part of the Framingham Study, Felson et al. studied back symptoms in their elderly cohort aged 68 to 100 years.¹⁴ In their study group, 22.3% reported back symptoms on most days. Lower back pain was more common than mid- or upper back complaints. Age did not affect the prevalence of back symptoms within this elderly cohort. Symptoms were more common in women than men. Older people confined mostly to their homes had an especially high prevalence of back symptoms.

Degenerative joint disease of the spine results from involvement of the intervertebral disks, vertebral bodies, and/or the posterior apophyseal articulations. Narrowing of the disks may cause subluxation of the posterior apophyseal joints. The term *spinal osteoarthritis* describes the changes in the apophyseal joints, whereas *degenerative disk disease* applies to the changes in the intervertebral synchondrosis.

Impingement on the nerve roots by spurs that compromise the intervertebral foramina is particularly common in the neck because of the small size of foraminal spaces in this location. In patients with involvement of the lower cervical spine, pain in the neck radiates to the shoulder and sometimes to the arm and hand. Paresthesias and reflex changes are common in the distribution of the involved nerve root.

Osteophytes in the uncovertebral (Luschka) joints may compress the neighboring vertebral arteries as they traverse the transverse processes of the cervical spine, leading to signs and symptoms of basilar artery insufficiency. Narrowing of the vascular lumen is most marked during rotation of the head. Symptoms that frequently present in an intermittent pattern include vertigo, headache, blurring of vision, diplopia, and defects in visual field. Other symptoms include sudden loss of strength in an extremity, as well as nystagmus and ataxia, which may be seen on examination. Angiographic studies serve to confirm the diagnosis.

Large spurs arising anteriorly from the vertebral bodies are prevalent. They rarely give rise to symptoms, but dysphagia due to external compression of the esophagus and respiratory symptoms in the form of coughing and hoarseness have been reported. Large posterior spurs protruding into the spinal canal may compress the spinal cord, leading to upper motor neuron and other long tract signs. Compression of the anterior spinal artery may produce a central cord syndrome.

Nerve root compression in the dorsal spine causing radicular pain around the chest wall is less common. Involvement of the nerve roots in the lumbosacral area is associated with low back pain and neurologic signs and symptoms in the distribution of the involved roots. Neurologic symptoms that are secondary to spinal OA must be differentiated from those that result from primary neurologic disorders. Neurologic complications of osteoarthritis of the cervical spine may be confused with amyotrophic lateral sclerosis, spinal cord tumors, and basilar artery disease. The differential diagnosis is also complicated by the high prevalence of asymptomatic x-ray evidence of OA in the elderly.

Acquired spinal stenosis is an important cause of low back symptoms in the older patient rarely seen in those under 50 years. Symptoms consist of back, buttock, or leg pain that usually worsens with ambulation, occasionally in combination with lower limb sensory and motor deficits and rarely with problems with bowel and bladder control. Classically, pseudoclaudication is present, with pain and discomfort worsened with walking and relieved with stopping, sitting, or lying down and with symptoms eased in positions of flexion (bending forward, e.g., on a grocery cart) and exacerbated by positions of lumbar extension (walking uphill). The volume of the lumbar canal tends to decrease with age with most individuals having at least an anatomic lumbar stenosis by age 80 relative to the volume of a younger population. With the development and progression of OA involving the lower back, the facet joints and ligamentum flavum hypertrophy, diminishing the spinal cord volume and purportedly reducing the blood supply to the nerve roots, thus causing symptoms.

A variant form of spinal osteophytosis seen in the elderly is the *ankylosing hyperostosis of Forestier*. This condition is characterized by large spurs or marginal proliferations that fuse to form flowing ossifications along the anterolateral aspects of vertebral bodies. The process extends to the connective tissue surrounding the spine, including the anterior longitudinal ligament. The distal thoracic spine is the site of predilection, but other levels of the spine may be affected. Radiographic criteria include the presence of flowing calcifications and ossifications along the anterolateral aspects of at least four contiguous vertebral bodies, relative preservation of the intervertebral disk height, and absence of ankylosis of the sacroiliac and apophyseal joints. It is estimated that 5% to 10% of persons over 65 years meet the radiologic criteria for establishing a diagnosis of Forestier's disease. Despite extensive anatomic abnormalities, the patients are either free of symptoms or they complain of modest pain and stiffness and mild restriction of motion.

The term *diffuse idiopathic skeletal hyperostosis* is applied when the vertebral condition is accompanied by extraspinal manifestations. Those changes include irregular new bone formation or "whiskering" commonly seen in the paraacetabular, tarsal, and metatarsal areas, large bone spurs on the olecranon process, calcaneus, and patella, and ligamentous calcification and ossification, particularly of the sacrotuberous and ileolumbar ligaments. Heel pain may be a prominent symptom. Dysphagia related to cervical osteophytosis has been reported.

Commonly Associated Conditions: Bursitis and Tendinitis

Part of the assessment of a painful joint in the older patient should include evaluation of periarticular bursae and tendons, irritation of which can mimic joint involvement. Inflammation of the anserine bursa, which is situated just inferior to the knee joint on the medial aspect of the tibia, can produce fairly significant juxta-articular pain that is difficult to distinguish from primary knee OA. Tenderness over the bursa that reproduces the pain the patient experiences may indicate that the anserine bursa is the culprit. Injection of a crystalline corticosteroid preparation into the bursa may relieve the discomfort. When evaluating the painful hip, one should always check for tenderness over the greater trochanter. Trochanteric bursitis causes pain, often aggravated by stair climbing, over the lateral aspect of the hip whereas hip joint pain is usually experienced more in the groin.¹⁵

Fibromyalgia

Fibromyalgia is a poorly characterized, poorly understood clinical syndrome whose main characteristic is pain

in various locations without any clear underlying pathology. The American College of Rheumatology guidelines for fibromyalgia is the presence of 11 or more tender points and widespread pain.¹⁶ Associated symptoms include fatigue, sleep disturbance, anxiety, and depression. Geriatricians need to have a good understanding of this syndrome because the prevalence increases with age, with the highest prevalence attained between 60 and 79 years (>7.0% in women).¹⁷ Fibromyalgia may be a primary or secondary disorder related to other rheumatic diseases. In the older patient, it is most commonly seen as secondary problem related to OA.

Besides presenting a treatment dilemma, it appears that the presence of fibromyalgia may have important implications on how patients will experience and report other medical problems. Data suggest that patients with fibromyalgia appraise medical symptoms and their importance differently from patients with other rheumatic conditions. Wolfe et al. found patients with fibromyalgia reported more conditions (4.5 versus 3.1) than those with RA or OA, and in 20 of the 23 conditions, the importance attached to the conditions by patients with fibromyalgia exceeded that of the importance attributed by RA and OA patients without fibromyalgia.¹⁸ Although fibromyalgia is a recognizable clinical entity, there seems to be no rationale for treating fibromyalgia as a discrete disorder, and it would seem appropriate to consider the entire range of tenderness and distress with the tender point count potentially functioning as a "sedimentation rate" for distress.¹⁹

Laboratory and Radiographic Findings

Although the diagnosis of OA can be made without x-ray, the plain x-ray is still the most important imaging tool for investigating OA. The classic x-ray findings of OA include osteophytosis, joint space narrowing, subchondral sclerosis, and cysts. Cysts, varying in size from a few millimeters to several centimeters, are seen as translucent areas in juxta-articular bone. Small age-related marginal osteophytes associated with some squaring of the joint margin should be differentiated from OA, in which the osteophytes are larger and have a more abnormal shape.²⁰ X-rays are useful for confirming the diagnosis, assessing progression of disease, and timing for joint replacement. It is important to remember that x-rays often do not correlate well with symptoms. However, when joint space narrowing, sometimes with "bone-on-bone" appearance, large osteophytes, and subchondral sclerosis, are present on a knee x-ray, there is little doubt that such changes represent severe OA. Proper positioning is important. In the case of the knee, loading the joint by standing is necessary to adequately assess the extent of cartilage wear.

Radiographic changes of OA of the spine are common in the older patient and are notorious for their lack of correlation with actual symptoms. Abnormal findings include decreased intervertebral space, endplate sclerosis, osteophyte formation, and spondylolithesis, which is a slipping of one vertebra forward on the one below. The sclerotic bony changes associated with OA of the spine can give falsely elevated readings of bone mineral density.²¹

As mentioned, there are large discrepancies between radiologic incidence of OA and clinical complaints. In the Framingham Study²² of elderly subjects, the prevalence of radiographic changes of OA in the knee was 34% in women and 31% in men. Yet, only 11% of all women and 7% of all men had symptomatic disease. The discordance between symptoms and radiographic findings of OA in the lumbar spine is striking. At age 50, 87% of adults have radiographic evidence of lumbar spondylosis, and almost 70% of asymptomatic persons have degenerative disk disease on spine films.²³ Because of the high frequency of osteoarthritic changes on radiologic examination of the lower spine, the main utility of plain x-rays in older patients is to rule out other processes such as infection, fracture, or malignancy.

Tailored magnetic resonance imaging (MRI) producing high spatial or contrast resolution images is proving to be an important tool in the early detection and surveillance of OA progression, as well as assessment of surrounding soft tissues. MRI, with its unique ability to noninvasively image and characterize soft tissue, has shown promise in assessment of cartilage integrity. MRI imaging of knee cartilage correlates well with arthroscopy for quantification of chondropathy.²⁴ Conventional radiographs are unreliable for evaluating articular cartilage loss in patients with early OA. Interestingly, initial joint space narrowing by conventional knee radiographs has been shown by MRI to be caused mostly by meniscal extrusion rather than thinning of articular cartilage.²⁵ Meniscal subluxation seen on MRI is highly associated with symptomatic knee OA, and increasing meniscal subluxation on MRI correlates with the severity of joint space narrowing.²⁶ This finding has important implications for evaluating therapies that may have a disease-modifying effect, because actual narrowing may not reflect cartilage damage but movement of menisci.

The need for better evaluation of OA and its progression, from a clinical perspective as well as for assessing possible disease-modifying osteoarthritis drugs (DMOADs), has prompted substantial effort to develop markers that accurately evaluate the progression of joint damage; this is especially important in evaluating early disease, as standard radiographs and even MRI detect relatively advanced disease. Earlier excitement was generated when serum levels of cartilage-derived keratin

sulfate appeared to reflect the magnitude of articular cartilage breakdown in OA, but subsequent studies found the correlation to be weak. Serum concentrations of cartilage oligomeric protein is considered the current main contender for a serum marker of OA, but some argue that no serum marker can adequately reflect what is going on in specific joints.²⁷ The C-reactive protein level, but not the erythrocyte sedimentation rate, was found to be associated with clinical severity in patients with OA of the knee, probably reflecting an inflammatory component to the disease.²⁸ Interest has shifted to searching for possible synovial fluid markers. A “daunting” number of matrix proteins, enzymes, cytokines, and other macromolecules are detectable in OA synovial fluid. Altered concentrations of chondroitin sulfate and keratan sulfate can be detected in OA with characteristics that differ from those seen in RA.²⁹ One problem with this approach relates to the changing clearance kinetics with progression of disease that can lead to misleading levels. As yet, there is no synovial fluid marker that has been shown to reflect disease activity accurately and consistently.³⁰

Risk Factors

Knowledge of risk factors is important in understanding OA to help identify those with higher likelihood of getting the disease, as well as for developing preventive strategies, both primary and secondary, and for therapeutic interventions. Factors that place increased stress on joints appear to be important risk factors for the later development of OA. This stress can take the form of repetitive stress and trauma as occurs in certain occupations. Probably the oldest evidence of occupation-related OA was reported in a 7000-year-old skeleton of a prehistoric man with bilateral scapholunate advanced collapse, the most common form of OA of the wrist.³¹ Ligamentous rotary subluxation of the scaphoid is the most common cause of scapholunate advanced collapse. Bilateral ligamentous distension caused by repeated microtrauma, possibly from the manufacture of stone tools, was suspected to have been responsible for these lesions. Many classic studies have implicated various occupations such as coal miners, pneumatic drillers, cotton operatives, iron workers, and elite athletes.

Large longitudinal health studies have identified several important risk factors associated with OA. Heavy physical activity in general has been implicated in the development of OA, and it appears that modulating factors such as type of activity, presence of obesity, and at what point in the life cycle the activity took place are all important. In a subcohort analysis of the Framingham Heart Study, heavy physical activity was found to be a risk factor for incident knee OA in a dose-dependent fashion in both men and women.³² Although activities

such as moderate running appear to be well tolerated in younger people, a stronger association of knee OA with physical activity has been found in women over the age of 50, compared with younger women. Increasing age is an important factor in determining the development of OA after a joint injury such as to the anterior cruciate ligament.³³

There is a well-described association between obesity and OA, established mostly from cross-sectional studies, but the question of whether obesity is a true causative factor or whether OA predisposed individuals to obesity because of decreased activity was until recently uncertain. Longitudinal studies have since found obesity to be a predictor for the development of OA. This association has been found to be the strongest for knee OA, less so for OA of the hands, and inconsistent for OA of the hip. The risk appears to be much stronger in women, although it also is present in men with severe obesity (highest quintile).^{34,35} Even mild obesity (BMI > 25) has been found to put women at increased risk for the development of OA of the knee.³⁶ Obesity appears to provide an additive risk when combined with heavy physical activity. As yet unknown metabolic factors, possibly related to estrogen, are theorized to explain the differences in risk associated with sex, as well as the increased risk for hand OA with obesity. Because of the markedly increased prevalence of OA in women, as well as the appearance of generalized OA around the time of the menopause, several studies have addressed a possible protective role of estrogen replacement on OA. One cross-sectional study showed an association between postmenopausal estrogen replacement therapy and a reduced risk of radiographic evidence of OA of the hip, with greatest reduction among those who had taken estrogen for 10 or more years.³⁷ The first prospective cohort study to address this question was performed on a subcohort from the Framingham Study.³⁸ Only a modest and not statistically significant protective effect of estrogen replacement therapy on OA of the knee was observed in this particular study.

Ever since orthopedic surgeons began noticing that patients undergoing surgery for hip fractures seemed to have a lower than expected prevalence of OA, the possibility of an inverse relationship between OA and osteoporosis has been suspected. The theoretical underpinning for this relationship is that subchondral bone acts as a shock absorber for overlying cartilage and that osteoporotic or softer bone may be acting as a better shock absorber and thus protect against the development of OA.³⁹ This observation has been strengthened in epidemiologic studies, which have verified an inverse correlation between OA and osteoporosis. Women with radiographically defined knee OA had greater bone mineral density (BMD), as measured by dual-energy x-ray absorptiometry at the femoral neck, than did women

without knee OA.⁴⁰ An inverse relationship between OA and osteoporosis of the spine was found when comparing normal subjects with those with OA or osteoporosis of the spine.⁴¹ Radiographic hip OA was associated with increased BMD in the femoral neck compared with control subjects in a large prospective study in a cohort from the Study of Osteoporotic Fractures.⁴² Interestingly, the increase in BMD was not associated with a decreased risk of hip fractures, possibly related to the numbers and types of falls sustained by subjects with OA. This relationship seemingly pertains to OA involving the hand joints as well.⁴³ Osteoarthritis was associated not only with increased BMD but with an increased rate of bone loss as well, suggesting an increased turnover.⁴⁴

Crystals that are known to cause acute arthritis and peri-arthritis also play an important role in mediating the expression of OA. The class of crystals most commonly found in osteoarthritic joints is the calcium-containing crystals, of which calcium pyrophosphate and basic calcium phosphate are the best studied.⁴⁵ Osteoarthritis is both more common and more severe in joints in which chondrocalcinosis or crystals have been demonstrated. The distribution of joints is altered in those with crystal-associated OA. Involvement of the carpus, elbow, and shoulder is significantly more common in crystal-associated OA than in primary OA. The presence of multiple knee compartment involvement is also more common in crystal-associated OA than in the absence of crystal deposition. In the only prospective study to systematically evaluate knee synovial fluid for the presence of calcium pyrophosphate crystals, the presence of crystals was found to be associated with progressive cystic changes, progressive bone attrition, and poor symptomatic and functional outcome.⁴⁶ However, chondrocalcinosis was not found to be a risk factor for the development of knee OA in a subanalysis of the Framingham Study.³⁴ Importantly, the true prevalence of crystals is probably underestimated by both x-ray and routine synovial fluid analysis as more sensitive methods have demonstrated one or both crystal types in the majority of cases of severe OA of the knee.⁴⁵

The Role of Joint Instability in the Pathogenesis of OA

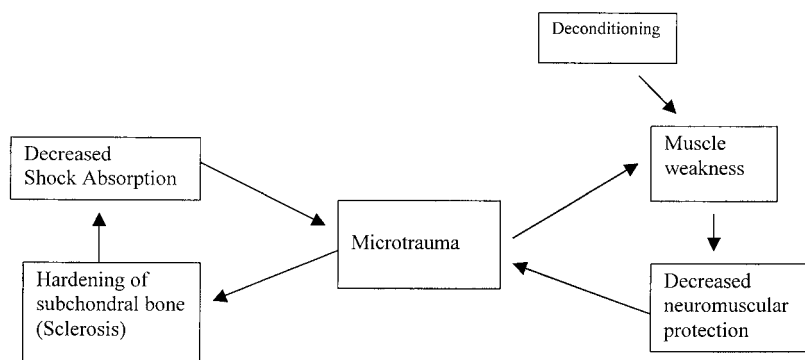

OA is not merely a disease of cartilage but of all the tissues of the diarthrodial joint, as well as surrounding structures. There is now increasing interest in the changes that take place in the periarticular skeletal muscles, as well as other factors involved in maintaining joint stability and proprioception. Ligaments, essential components of joint stability, become more compliant with increasing age, but whether this is clinically important and related to the increasing prevalence of OA with age is not known. Ligamentous laxity is a cause of OA in animal models but

has been less well studied in humans, although the hypermobility syndromes are known to be a risk factor for OA. Increased ligamentous laxity, as evidenced by increased varus-valgus movement, has been found to be correlated with the degree of radiologic OA of the knee.⁴⁷ In patients with unilateral OA of the knee, the uninvolved knee had greater varus-valgus laxity compared with control knees. This finding supports the concept that ligamentous laxity may predate the disease and may increase the risk of knee OA, as well as contributing to its progression.

The role of periarticular muscle weakness in the pathogenesis and progression of OA has sparked recent interest. Reduced quadriceps strength relative to body weight is found in women with OA of the knee compared to those without OA.⁴⁸ Although it had been previously assumed that decreased quadriceps strength in OA of the knee was related to decreased use of the painful joint, recent studies point to a possible pathogenic role of quadriceps weakness. Comparing a community-based cohort of older persons (average age, 71 years), researchers found quadriceps weakness was greater in participants with radiographic knee OA compared with those without it, even in the absence of joint pain. This finding suggests that knee extensor weakness may be a risk factor for the initiation and progression of knee OA.⁴⁹ Complaints referable to quadriceps weakness are one of the most common and early symptoms reported by patients with OA and are a better determinant of pain than radiographic changes.⁵⁰ Muscle weakness may play a large role in the age-related increase in incidence of OA, as aging is also frequently associated with generalized weakness related to deconditioning. The phenomenon of arthrogenous muscle dysfunction (AMD) describes the decreased strength of voluntary contraction of muscle acting across a joint with OA and may, in part, explain knee extensor weakness in OA.⁵¹

The relationship between muscle weakness and OA is receiving increasing interest. Skeletal muscles are essential components of the neuromuscular protective mechanisms that provide shock absorption for the joint. Coordinated joint movement and muscle activity control joint loading so that loads applied across joints are dissipated. A well-described example of this occurs with normal gait when the knee is loaded during heel strike. Eccentric quadriceps contraction, which involves muscle lengthening but maintaining tension, cushions the impact. Weak muscles are fatigued more readily, and their voluntary and reflex motor control is slower than those of well-conditioned muscles; this compromises the neuromuscular protective mechanisms of the muscle and leads to excessive joint movement and instability that stresses innervated tissues, elicits pain, and gives rise to rapid jarring loading of the joint. This rapid loading results in microtrauma to articular cartilage and subchondral bone.

FIGURE 42.1. The relationship between muscle weakness, subchondral bone, and osteoarthritis.

Subchondral bone becomes harder and less able to act as a shock absorber, which then creates an amplification loop in which mild trauma can result in severe joint destruction (Fig. 42.1).

Problems with proprioception, the conscious and unconscious perception of limb position and movement in space, have been implicated as a risk factor for OA. In a canine model of anterior cruciate ligament (ACL) transection, OA was more severe and developed earlier when performed in combination with either a dorsal root ganglionectomy or articular neurectomy than with ACL transection alone.⁵² In humans, this question has been studied most extensively in the knee where proprioception derives from integration of afferents from receptors in muscles, tendons, joint capsule, ligaments, meniscal attachments, and skin. The hypermobility syndrome, a well-known risk factor for precocious OA, is associated with impaired proprioception, especially near full extension, and may result in mechanically unsound joint positions that could predispose to OA.⁵³ Cross-sectional studies show that knee proprioception is worse in patients with knee OA than in controls. Proprioception was found to be worse in older subjects and even worse in the elderly subjects with knee OA.⁵⁴

Theoretically, proprioceptive inaccuracy may contribute to gait characteristics associated with increased stress across joints that predispose toward OA. However, it is not clear whether the proprioceptive problems predispose to OA or if changes associated with OA themselves contribute to worsening in proprioception. Proprioception in older patients with unilateral knee OA was found to be worse in both the involved knee as well as the uninvolved knee compared with older control subjects.⁵⁵ This finding implies that impaired proprioception is not exclusively a result of local disease in knee OA, but the relative importance of impaired proprioception in the development and progression of knee OA requires longitudinal study.

Inactivity is an important risk factor for OA that has been incompletely explored in humans, although there are excellent animal models that demonstrate immobi-

lization leading to OA. Prolonged bed rest with lack of joint loading is a theoretical risk for the development of OA that should be included on the long list of adverse consequences of bed rest.

Acetabular dysplasia, a very important risk factor for hip OA in younger people, is responsible for only a very small percentage of incident hip OA in the elderly.⁵⁶

Genetics of OA

Since the familial occurrence of Heberden's nodes was documented 60 years ago, there has been an appreciation that genetic factors play a major role in OA. Because of the complex nature of this role and the multifactorial nature of OA, the genetics of OA is poorly understood. Primary generalized OA is the most common form of OA that is clearly associated with genetic influences. About 20% of those patients describe a positive family history. Multiple studies suggest that the inheritance is probably polygenic. Family aggregation of OA among siblings involving the DIP, PIP, and first CMC joints in a cohort from the Baltimore Longitudinal Study on Aging contributes to evidence of inheritability.⁵⁷ Study of hand and knee radiographs of families from the Framingham Study cohort and Framingham Offspring Study suggests a mixed model in a Mendelian mode with a major recessive gene and a residual multifactorial component in generalized OA.⁵⁸ Mutations of the genes that code for type II collagen are probably responsible for small groups of families with precocious OA. The Arg519-Cys mutation in type II collagen results in severe, precocious familial OA in 100% of carriers within the first three decades of life.⁵⁹ Another area of possible genetic influence is in control of mediators such as IGF-1 that may be important in cartilage formation during development stages and remodeling of adult cartilage.⁶⁰

Pathophysiology of OA

Knowledge of the physiology of cartilage and the pathophysiology of OA is becoming increasingly important to

appreciate risk factors and institute preventive measures, as well as to understand new treatment modalities.

Cartilage

Hyaline articular cartilage, the main tissue of interest in OA, is composed mainly of a protein matrix and chondrocytes, which live scattered in normal cartilage in isolation. The “effete” chondrocyte comprises less than 5% by volume of the cartilage but is extremely metabolically active and responsible for maintaining the extracellular matrix (ECM). The two major components of the ECM are proteoglycans and collagen fibers. The collagen fibers (90% type II collagen) provide the tensile strength and structural integrity of the cartilage, and the proteoglycans, extremely complex glycoconjugates, are responsible for its ability to undergo reversible deformation or elasticity. The predominant proteoglycan of articular cartilage is aggrecan, which is composed largely of glycosaminoglycans. Glycosaminoglycans are long-chained, repeating, sulfated, disaccharide units (the most common ones being keratan sulfate and chondroitin sulfate) that are attached to a core protein. Aggrecan molecules are synthesized and secreted into the ECM by the chondrocyte, where they form aggregates of up to 200 aggrecans attached to a hyaluronic acid core, a linear,

high molecular weight glycosaminoglycan, via a link protein. Aggrecans are highly concentrated in the ECM and compressed to approximately 20% of their extended volume by the collagen fibers that form a three-dimensional network, preventing further expansion of the proteoglycans. The proteoglycans carry a high concentration of negatively charged anions at physiologic conditions and thus are highly hydrophilic, providing a swelling pressure that is restrained by the stiffness and tensile strength of the collagen fibers so that only a fraction of their hydrodynamic domain is exposed.

When cartilage is loaded, it is deformed by the expulsion of fluid, which tends to move toward the load into the synovial cavity, carrying the waste products of the cells with it. As water is released from the aggrecans, negative charges are exposed. As aggrecan molecules are forced closer together by the load, increases in the density of negative charges and in the repulsive forces tend to resist further deformation. Ultimately equilibrium is reached, in which the external loading force is balanced by internal forces. When the load is removed, water, along with nutrients, is forced back into the ECM and the cartilage regains its original shape⁶¹ (Fig. 42.2).

The fact that cartilage is both avascular and aneural has important clinical ramifications. Nutrients diffuse into the cartilage via the synovial fluid, but this requires

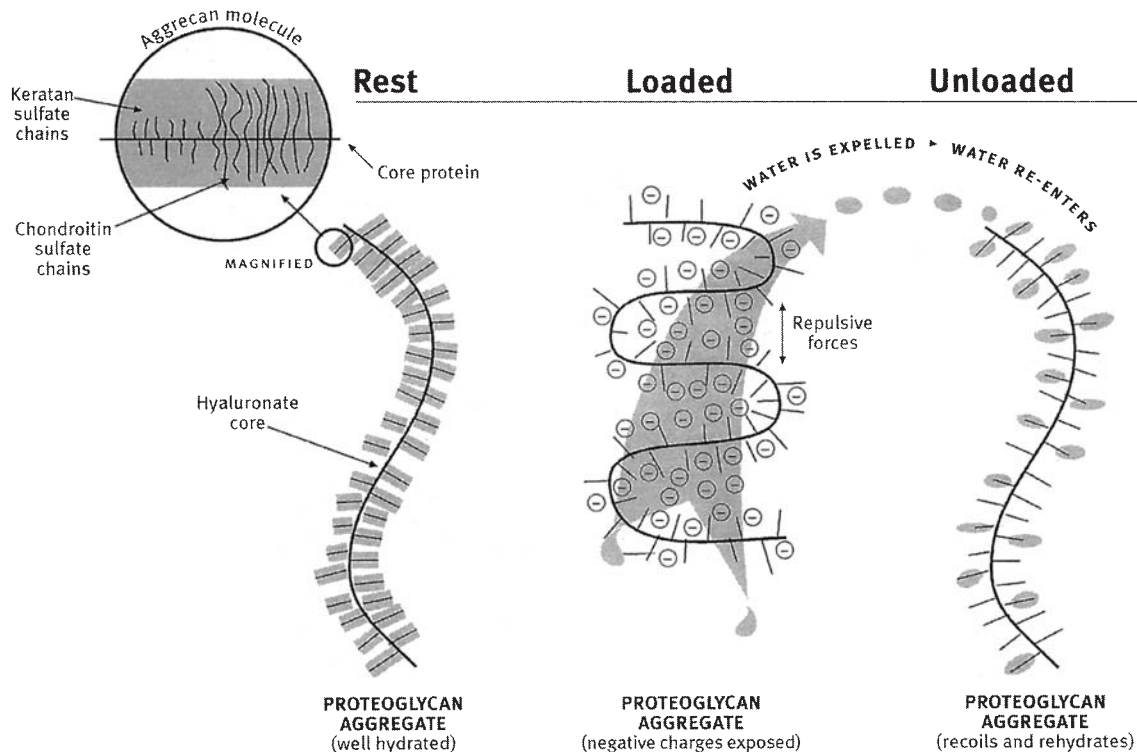

FIGURE 42.2. Schematic of structure and properties of proteoglycans in cartilage.

TABLE 42.2. Changes in cartilage proteoglycans with aging.

1. Progressive decrease in the average length of the core protein of the aggrecan molecule
2. Decreased hydrodynamic size of the aggrecan molecule via decreased length of chondroitin sulfate chains and increase in number of keratan sulfate chains
3. Decreased proportion of aggrecans able to form aggregates with hyaluronic acid
4. Decreased size of aggregates from reduction of length of the hyaluronic acid molecule and smaller size of the aggrecan molecules

joint loading, as already described. A well-described model for inducing OA in animals involves unloading limb joints by casting for several weeks, thus disrupting the flow of nutrients to the chondrocyte. When the cast is removed and the joint is reloaded, premature cartilage damage and OA quickly ensue. Importantly, because of the lack of neural input when damage is isolated to the cartilage, there will be no associated sensation or warning.

Many changes have been found to occur in cartilage with aging. The changes in cartilage proteoglycans are summarized in Table 42.2. These changes lead to a decrease in the hydration of the articular cartilage with aging, which causes a thinning and increased stiffness of the articular cartilage. Articular cartilage show a marked age-related enrichment in a different type of cross-linking product produced by nonenzymatic means (browning) that tends to stabilize it and retain its properties. Collagen has an extremely long half-life, of the order of 100 years; thus, tensile integrity should remain despite aging.

Changes in Matrix in OA

Under normal physiologic conditions, chondrocytes regulate a dynamic metabolic steady state in which anabolism is balanced by catabolism. The earliest change of OA observed from animal models and ex vivo analysis of human cartilage involves increased hydration of the cartilaginous matrix; this is in distinction to the normal changes of aging, which involve a decrease in the water content of cartilage, as just described. This increase in hydration is thought to be associated with clipping of collagen fibers and consequent release of the physical restraint to the hydrophilic proteoglycans that swell with water. Early on in the process there is an increase in the rate of proteoglycan synthesis by the chondrocyte, which may be an attempt to compensate for an increase in catabolism of the matrix, causing an early hypertrophic phase preceding the later degenerative phase. The subsequent degenerative phase is associated with extensive depletion of matrix proteoglycans via digestion of their

core proteins by proteases released from chondrocytes. In later stages, chondrocytes synthesize less matrix than normal. Matrix synthesis varies by regions, being strongly suppressed in the superficial layers of cartilage but less so in the deeper layers.⁶²

Because chondrocytes lack cell-to-cell contact, communication between them must occur across the ECM via cytokines. Elucidating the complex interactions and effects of these cytokines in OA has been an important area of recent investigation. A number of mediators that influence chondrocyte metabolism have been elucidated, including interleukin-1-alpha and -beta (IL-1), tumor necrosis factor (TNF), and nitric oxide (NO). The cytokine IL-1 is the prototypic inducer of cartilage catabolism. IL-1 inhibits collagen production and causes collagen degradation through the induction of matrix metalloproteinases, a variety of which have been described.⁶³

Chondrocytes are probably the major site of production of mediators of inflammation in OA showing high expression of IL-1, TNF, and NO.⁶⁴ IL-1-alpha and -beta have been demonstrated in chondrocytes at the articular surface, as well as distributed throughout cartilage demonstrating OA changes.⁶⁵ Cartilage exhibiting the early changes of OA had the highest intensity of staining and the highest frequency of positive cells, suggesting a role in pathogenesis.

The free radical nitric oxide also appears to occupy an important mediator role. In the joint, chondrocytes are the major cell source of NO. One of the major functions of NO in cartilage is its role in the suppression of matrix synthesis. NO is at least partly responsible for IL-1-induced suppression of glycosaminoglycan and collagen synthesis. Interestingly, production of NO by normal cartilage in response to IL-1 decreases with advancing age. NO may also be involved as a mediator of IL-1-induced expression of matrix metalloproteinase mRNA and protein and may contribute as an activator of the latent forms of the enzymes. NO also regulates chondrocyte metabolism in response to mechanical loading.⁶⁶ NO may also to have some protective effects in cartilage; it is probably involved in antimicrobial defense and may have anabolic effects stimulating proteoglycan production under certain conditions, as well as participating in wound healing and stimulating collagen production.

Another response of the chondrocyte to cartilage damage is the production of matrix molecules such as type X collagen, not found in normal articular cartilage but found in developing growth plate cartilage. Although this is interpreted as a repair response, it results in the production of a mixture of fibrocartilage-like and hyalin cartilage-like matrix, in addition to matrix calcification.

Besides alterations in chondrocyte metabolism, there are also changes in their growth characteristics. In normal mature human articular cartilage, there are no detectable

levels of chondrocyte proliferation, although very low levels of proliferation are probably needed to maintain cartilage cellularity. With increasing age, there is a decline in cellularity. In osteoarthritis, once the continuity of the surface of cartilage is disrupted, the cells can divide, forming clusters of chondrocytes, the so-called brood capsules. Another response of chondrocytes found in OA cartilage is to undergo morphologic changes characteristic of apoptosis, possibly as a result of NO production.

Fibrillation is the earliest gross change of cartilage in OA seen in association with increased hydration and depletion of proteoglycan. As fibrillated cartilage is abraded, focal erosions and vertical clefts are formed. These erosions coalesce with progressive denudation of underlying sclerotic bone. Proliferation of bone occurs at the joint margins to form osteophytes and in subchondral bone, especially in areas denuded of cartilage. The term eburnation applies to the glistening appearance of the polished sclerotic bone surface.

The classic morphologic changes of subchondral sclerosis in OA are thought by some to have a role in the pathogenesis of the condition. Although many authorities believe that the earliest events in OA occur in cartilage, an alternate view suggests that changes in subchondral bone precede measurable changes in the cartilage. It is postulated that the earliest lesions are trabecular fractures in cancellous bone. The healing of these fatigue fractures results in thickening of the trabeculae, leading to an increase in the density of bone with a consequent reduction in its ability to absorb energy. With loss of this functional role of bone, energy absorption is shifted toward the overlying cartilage whose collagen fibers sustain fatigue fractures, eventually leading to deterioration of cartilage. Cyst formation is commonly seen in the juxta-articular bone, probably a result of tissue breakdown related to focal areas of microfracture in the ischemic subchondral bone. Although several studies have shown evidence of increased subchondral bone turnover in early OA, there is still disagreement about whether these changes are concurrent with, primary to, or secondary to cartilage deterioration.⁶⁷

Focal, chronic synovitis, characterized by lymphocyte and mononuclear cell infiltration, is frequently seen in OA; this is probably due to secretion of inflammatory mediators initiated by the release of hydroxyapatite or calcium pyrophosphate crystals or by cartilage breakdown components, or the presence of immune complexes in the surface of the cartilage.

Prevention

As with other chronic diseases for which there is no cure, priority needs to be given to measures that can prevent the condition. Although OA is commonly thought of as a disease of older people, consideration needs to be given

to events that occurred earlier in life. Studies have shown associations between recreational physical activity performed years ago and radiographic OA.⁶⁸ The level of activity appears to correlate with risk; however, it is also well known that some loading, as well as maintenance of muscle strength, is also important in preventing OA. The ideal level of activity to minimize OA development has not been established and probably is quite variable between individuals. In a 9-year longitudinal study of recreational runners compared with nonrunners (average age, 66 at the end of the study), Lane et al. found no increase in the rate of development of hip or knee OA.⁶⁹ Much more attention should be paid to the activities, especially sports, in which even very young children are participating, and the potential risks they pose for later development of OA. Well-designed long-term studies of programs to determine if prophylactic exercises can prevent OA or diminish its severity are needed to answer these questions.

Although obesity is an important risk factor, from a prevention perspective, early intervention is important because it appears that cumulative exposure is important, with increased body mass index (BMI) in young men 20 to 29 being more predictive of subsequent knee OA than at ages 30 to 39 or 40 to 49.⁷⁰ Observational data from the Framingham OA Study suggest that weight loss of approximately 5 kg will reduce a person's risk for the development of knee OA over the subsequent 10 years by 50%.⁷¹ The role of micronutrients in prevention is a frequently asked question. An analysis of the Framingham data found no significant association of incident radiographic knee OA with any micronutrient.⁷² However, a threefold reduction in risk for progression of radiographic OA was noted for those in the middle and upper thirds of vitamin C intake; those in the upper third for vitamin C intake also had a reduced risk of developing knee pain during the course of the study. The theoretical explanation for the possible effects of vitamin C on OA comes from its involvement in collagen metabolism. Vitamin C acts as an electron donor in the synthesis of type II collagen and is involved in the hydroxylation of proline to form hydroxyproline. It also plays a role in glycosaminoglycan synthesis through its role as a carrier of sulfate groups. Its role as an antioxidant may also have some effect.⁷³ Interest in vitamin D increased when investigators reported that a relative deficit of vitamin D intake predisposes to progression of preexisting OA.⁷⁴ Both lower intake of vitamin D and decreased serum levels have been well documented in older people.

Treatment

The goals of therapy for OA are to reduce pain, slow progression, and improve function and quality of life. As for many other chronic diseases, lifestyle modifications

play an important part of the therapeutic approach of OA. Nonpharmacologic approaches are by far the most important therapies for OA. An important goal of therapy is to reduce stress on joints by weight reduction if indicated, strengthening of the muscles around involved joints, improving flexibility and proprioception, and joint protection strategies, including improving joint mechanics and the use of assistive devices and orthotics. In managing osteoarthritis, it is important to establish and communicate realistic objectives for each patient. It is critical to focus the patient's attention on enhancement and preservation of functional ability, such as walking, dressing, and living independently. Many patients who present with hand involvement need only reassurance that the disease process is not likely to become generalized or crippling.

Exercise in the Treatment of OA

“Exercise may be the most effective, malleable, and inexpensive modality available to achieve optimal outcomes for people with OA.”⁷⁵

There is a growing recognition that health and fitness are achievable with less intense regimens than previously thought and that these regimens are feasible for people with a variety of chronic and disabling conditions. For more information on this subject, the interested reader is referred to the American College of Sports Medicine Guide to Exercise Testing and Prescription for People with Chronic Diseases and Disabilities.⁷⁶

Rehabilitation that increases muscle strength has been shown to be associated with decreased joint pain and disability without exacerbation of knee OA pain. Reeducation of neuromuscular skills can decrease reaction times and improve functional joint stability and proprioception, which are important in restoring shock absorption function of muscle and protecting against further joint damage.

OA changes found in one joint frequently affect other joints with range of motion and strength deficits generally found in adjacent joints and bilaterally. A poorly appreciated but consistent finding in people with unilateral knee OA is not only decreased range of motion of the involved knee, but of the hip and ankle as well, and significant limitation of motion of all three joints of the uninvolved contralateral limb. Older people with knee OA have been found to decrease range of motion in all the major joints of the lower extremities.⁷⁷ Decreased range of motion of the hip and knee increases the risk for injury and falls, in part because it becomes much more difficult to recover balance from a stumble. To prevent a fall after a stumble, one must produce rapid changes in hip and knee flexion angles while weightbearing.⁷⁸ Maintaining or improving the compliance of periarticular soft tissue is also thought to protect joints from damaging

peak forces as part of the neuromuscular protective system. Stretching and flexibility exercises are therefore key elements in exercise programs for people with OA. In the first large multicenter controlled study of its kind, investigators sought to answer several important questions about the potential benefits of exercise for people with OA. They found that both aerobic and resistance exercise programs over an 18-month period resulted in modest but consistent improvement in self-reported pain and disability and better scores on performance measures of function compared with controls participating in a health education program. Importantly, they found that the subgroup of older participants, those over 70, experienced the same beneficial effects. They also showed that moderate exercise did not worsen the disease in terms of either pain or x-ray scores.⁷⁹

Improved proprioceptive accuracy has also been demonstrated following muscle training. Knee orthoses have been shown to improve knee proprioception. Use of an elastic knee bandage improves proprioception, probably because the bandage stimulates superficial skin receptors, free nerve endings, and hair end organs that would react strongly to bandage movement on skin.⁸⁰ This increase in proprioception may, in part, explain the improvement, especially the sense of safety patients report with elastic bandages, which do not provide significant mechanical support. A modality intimately linked with exercise but also found to be an important adjunct in itself for the treatment of OA is education. Self-care education for OA resulted in notable preservation of function and control of resting knee pain in one large study.⁸¹ The cost of such a program was shown to be defrayed by a drop in the number of clinic visits but had no significant effects on the utilization and cost of pharmaceutical, laboratory, or radiology services.⁸²

Biomechanical Approaches to Therapy

Simple interventions directed toward reducing the load in affected joints include the use of walking aids, wedged insoles that change the angle of the legs, shock-absorbing footwear that reduces impact, and a heel lift if one leg is shorter than the other. Viscoelastic inserts may be effective in relieving pain and disease progression or even prevention, as they have been found to reduce the amplitude of the shock waves at heel strike with walking by 42%.⁸³ If hip or knee involvement is unilateral, a cane held in the contralateral hand is helpful. If involvement is bilateral, crutches or a walker are more desirable. Biomechanical principles provide a rationale for prescribing adaptive devices such as an elevated toilet seat and high chairs. Knee cages around the knee may provide some stability when ligamentous laxity is pronounced. Pillows should never be placed under the knees at night because of the risk of developing flexion contracture.

Flexion contracture of the hip may be prevented and mild contractures may be corrected by having the patient lie prone for 30 min twice daily. Occupational therapy to modify activities of daily living can reduce unnecessary overloading of the joints of the upper and lower extremities. Other nonpharmacologic approaches include thermal modalities, transcutaneous electrical nerve stimulation (TENS), exercise programs, weight loss programs, patellar taping, tidal irrigation, and programs to improve coping skills and social support.

Sexual function is often affected in persons with arthritis. It is important for the physician to evaluate problems in this area and to advise the patient of measures aimed at overcoming handicaps. Patients with osteoarthritis of the hips, knees, or spine frequently have problems with sexual intercourse due to pain or mechanical problems. Despite these limitations, sexual activity can be undertaken with the use of analgesics beforehand. Patients should be encouraged to try a variety of positions that allow the successful, pain-free performance of intercourse. The Arthritis Foundation's pamphlet "Living and Loving with Arthritis" describes a variety of sexual problems and suggested solutions.

Drug Therapy

Although the future holds promise for the development of disease-modifying modalities for the treatment of OA, the current pharmacologic approach to treating OA is palliative rather than curative. The primary objective of drug therapy is to reduce pain. Pain is generally undertreated in older patients, and the pain of OA is no exception. On the other hand, pain may be an important signal to prevent certain types of use that might result in further damage to the joint. Analgesic arthropathy, in which the relief of pain causes accelerated joint damage because of increased joint loading, needs to be kept in mind with any successful therapy.

Guidelines for management of OA suggest a stepwise approach, starting with simple analgesic medication, which is usually acetaminophen. Despite its lack of anti-inflammatory properties, acetaminophen has been shown to perform well in double-blind placebo-controlled trials against the nonsteroidal anti-inflammatory drug, ibuprofen.⁸⁴ These data suggest that pure analgesics should be considered as first-line drugs in OA much more frequently than is the case today. For patients without liver disease, doses of 1 g acetaminophen up to four times daily are recommended. For the management of moderately severe pain, viz., acute radicular pain of spinal osteoarthritis, tramadol HCl (Ultram) has comparable efficacy to acetaminophen with codeine #3. Ultram is a centrally acting agent with low potential for addiction. For pain associated with acute or chronic conditions, the dose is one or two 50-mg tablets every 4 to 6 h, as needed,

to a maximum of 400 mg/day. For patients over 75 years of age, the maximum dose should not exceed 300 mg/day. Individualization of dose is necessary for patients who have renal or hepatic impairment. Propoxyphene is no better than acetaminophen and should be avoided in older patients.

For patients not receiving adequate relief, the addition or switch to a nonsteroidal anti-inflammatory drug (NSAID) is the next step. NSAIDs are among the most widely used therapeutic agents today, with nearly \$2 billion spent in the United States yearly on prescription NSAIDs alone.⁸⁵ These agents provide analgesia and suppress inflammation by inhibiting the cyclooxygenase enzymes that catalyze the formation of prostaglandins from arachidonic acid. Cyclooxygenase (COX) exists in two distinct isoforms, which display important differences in their patterns of distribution as well as their regulation. COX-1 is constitutively expressed in virtually all tissues. COX-1-mediated prostaglandins regulate renal and platelet function, protect the gastric mucosa, and promote hemostasis. COX-2-mediated prostaglandins play a role in pain, inflammation, and fever, and in the regulation of cell growth, apoptosis, and angiogenesis. COX-2 is constitutively found in small amounts in such dissimilar tissues as the brain, endometrium, and the kidneys, as well as in certain neoplasms. A characteristic feature of the COX-2 enzyme is its presence in an inducible form and its upregulation at sites of inflammation and in some tumors. Stimulation by inflammatory cytokines, endotoxin, or growth factor leads to a 10- to 80-fold increase in COX-2 levels in such cells as macrophages, fibroblasts, chondrocytes, synovial cells, and endothelial cells.

It is a widely held view that the anti-inflammatory properties of NSAIDs are mediated through COX-2 inhibition, whereas most of their adverse effects occur as a result of the inhibiting effects on COX-1. Conventional or traditional NSAIDs, such as ibuprofen and naproxen, suppress both COX-1- and COX-2-mediated prostaglandins. More recently, a new class of NSAIDs, termed coxibs, has been added to the therapeutic armamentarium. The actions of coxibs are more specific to COX-2. The traditional NSAIDs include the time-honored aspirin and other salicylates, and a large number of NSAIDs that have been developed over the past 30 years in the hope of enhancing efficacy and reducing side effects. These drugs have in common analgesic effects at a lower dosage and anti-inflammatory effects at a higher dosage. At therapeutically equivalent dosages, most traditional NSAIDs have not proven to be much safer than aspirin. No significant differences in efficacy or side effects are apparent among the different classes of traditional NSAIDs. The choice between the various traditional NSAIDs becomes largely empirical, and it is often necessary to go through a sequential trial of several

different NSAIDs to arrive at the one that best suits the patient. Intermittent rather than continuous use of NSAIDs is preferable. In the elderly, compounds with a short biological half-life, such as ibuprofen and ketoprofen, are preferable to those with prolonged half-lives. Concomitant administration of two NSAIDs is not generally recommended because of the potential for added adverse effects. If the decision has been made to prescribe a traditional NSAID to an older patient, it is important to keep in mind that the starting dose should be lower than that recommended for younger adults, and stepwise adjustments should be made until an optimal therapeutic response is obtained. Patients with OA generally obtain effective analgesia at about half the daily dose given to patients with rheumatoid arthritis.

There is a vast body of literature on the evils of NSAIDs for older patients who are more prone to their side effects, especially gastrointestinal toxicity and renal dysfunction. Serious gastrointestinal toxicity such as bleeding, ulceration, and perforation can occur at any time, with or without warning symptoms, in patients treated chronically with conventional NSAIDs. Gastrointestinal ulcers can be demonstrated by endoscopy in 10% to 20% of patients who take NSAIDs on a regular basis, and the annual incidence of clinically important GI complications approaches 2%.⁸⁶ It has been conservatively estimated that 16,500 NSAID-related deaths occur among patients with rheumatoid arthritis and osteoarthritis every year in the United States. If deaths from gastrointestinal toxic effects of NSAIDs were tabulated separately in the National Vital Statistics reports, these effects would constitute the fifteenth most common cause of death in the United States. Advanced age has been consistently found to be a primary risk factor for adverse gastrointestinal (GI) events. The risk increases linearly with age.⁸⁷ The very essence of this debate, especially as regards GI side effects, has been altered by the recent release of the new class of NSAIDs, the selective COX inhibitors.

At the time of this writing, two specific COX-2 inhibitors are available, rofecoxib and celecoxib. Additional coxibs are currently undergoing clinical trials. The recommended daily dose of rofecoxib is 12.5 to 25 mg and that of celecoxib 100 to 200 mg. Several investigators have concluded that rofecoxib 12.5 mg qd is equipotent to celecoxib 200 mg qd. Although rofecoxib is the more selective of the two, both agents appear to be as effective as traditional NSAIDs in suppressing inflammation and providing analgesia, while reducing the incidence of endoscopic ulcers to levels similar to those seen with placebo.⁸⁶ In a double-blind, placebo-controlled study, specific inhibition of COX-2 by rofecoxib, administered once daily, resulted in clinically meaningful improvements in patients with OA, confirming that COX-2-derived prostanoids are important mediators of pain and

other symptoms of knee OA and that inhibition of COX-1 is not required for clinical benefit.⁸⁸ Celecoxib has similarly been shown to be associated with a lower incidence of upper GI ulcer complications in a recent randomized controlled study.⁸⁹ Another important benefit of the coxibs is that, in contrast to the nonselective NSAIDs, they do not inhibit thromboxane B2 levels or the antiplatelet effects of low-dose acetylsalicylic acid (ASA), nor do they increase bleeding time.⁹⁰

Although coxibs do reduce the risk of ulcers, a cost-benefit analysis is useful for putting the benefits into perspective. Peterson and Cryer considered patients at higher risk for ulcer complications, such as those aged 75 years or older with a prior history of ulcer and gastrointestinal tract bleeding, who have about a 5% risk of developing a complicated ulcer while taking a traditional NSAID. Assuming that COX-1-sparing agents reduce the risk by approximately 50% (i.e., to 2.5%), 40 patients would need to be treated with a COX-1-sparing NSAID instead of a nonselective NSAID to prevent one ulcer complication. The yearly incremental cost of this approach to preventing one complicated ulcer would be about \$30,000, a cost that was thought to justify switching such patients to COX-1-sparing NSAIDs. This approach also would be less costly than prescribing cotherapy for a generic NSAID with misoprostol or a proton pump inhibitor, although the occurrence rate of complicated ulcers with these two strategies has not been compared in a head-to-head study.⁸⁵

Because COX-2 is expressed in both a constitutive and inducible fashion in the kidney, it is not surprising that renal adverse effects may result from treatment with coxibs as they do with nonselective NSAIDs. In general, renal adverse effects of NSAIDs include reductions in glomerular filtration rate (GFR) and renal blood flow, sodium retention, and increases in serum potassium. These effects can lead to fluid retention, edema, mild elevations of the blood pressure, and hyperkalemia. Obviously, these effects are more likely seen in frail patients, such as the elderly and those with chronic illnesses. Supportive of this notion is a study in elderly subjects demonstrating that COX-2 inhibition resulted in renal effects similar to those observed with nonselective NSAIDs.⁹¹

Systemic adrenal corticosteroid analogues are not usually recommended in the management of osteoarthritis. Clinical results with these drugs are equivocal and are outweighed by their potential side effects. However, in the patient with severe debilitating pain in whom other therapies have not helped sufficiently, a brief course of low-dose prednisone (5 mg a.m.) may give remarkable palliation.

Topical application of creams containing a NSAID or capsaicin appears to have analgesic effects. Local application of capsaicin, which depletes substance P from

sensory nerve endings, caused a 30% reduction in pain in OA of the knee.⁹²

If pain relief is still not adequate, then Tylenol with codeine or oxycodone, which has been shown to be effective in OA, should be tried in carefully selected patients. Controlled-release oxycodone or in fixed combination with acetaminophen added to NSAIDs have been compared in patients with OA with similar significant effectiveness in reducing pain and improving sleep found over placebo. The controlled-release preparation was found to produce fewer side effects with significantly less nausea and dry mouth.⁹³

Nutraceuticals as Therapeutic Agents in OA

Two compounds that are receiving increasing attention are the nutraceuticals glucosamine and chondroitin sulfate. These compounds have been used in various forms for OA in continental Europe for more than a decade and have recently acquired substantial popularity in this country because of several lay publications. The medical community in the United Kingdom and the United States, on the other hand, has paid little attention to the potential benefits of these compounds, largely due to concerns about the validity of clinical trials.

The theoretical considerations for the possible effectiveness of glucosamine in OA stems from its status as a principal component of glycosaminoglycan (GAG), a key constituent of the matrix of all connective tissues. It is formed by the addition of an amino group to glucose that is then acetylated to acetyl-glucosamine. More than 50% of the glucosamine is nonionized at a pH of the small intestine, thus allowing significant and rapid absorption. Glucosamine has a special tropism for cartilage and is incorporated by the chondrocyte into proteoglycans, which are secreted into the extracellular matrix. In rats, ¹⁴C-labeled glucosamine appears in rat cartilage 4h after ingestion. When glucosamine is added to cultured human chondrocytes from osteoarthritic cartilage, a dose-dependent increase in proteoglycan synthesis occurs.⁹⁴

Most clinical studies have been conducted on glucosamine. In some preparations glucosamine is combined with chondroitin sulfate. Glucosamine and chondroitin are prepared by extraction from animal products, including bovine and calf cartilage. More than 90% of ingested glucosamine is absorbed, while less than 10% of chondroitin sulfate is absorbed. In short-term studies, glucosamine and chondroitin preparations have proven to be safe, but long-term toxicity studies remain to be done. The concern about the quality of clinical trials led McAlindron et al. to perform a meta-analysis combined with systematic quality assessment of 15 double-blind, placebo-controlled clinical trials of these preparations in knee and/or hip OA.⁹⁵ In summing up the results, the

authors found that the clinical trials of glucosamine and chondroitin preparations for OA symptoms demonstrate moderate to large effects but exhibit methodologic problems that have been associated with exaggerated estimates of benefit. The overall impression was that the compounds did show some benefit in treating OA symptoms. Given their excellent safety profile, glucosamine and chondroitin are likely to be useful in the treatment of OA even though they may be only modestly effective. Glucosamine and chondroitin are available in pharmacies and health food stores. The amounts generally administered are glucosamine 1500mg/day and chondroitin sulfate 1200mg/day, with an average cost of about \$30 to \$45 per month.

Joint and Bursa Injections

Aspiration and joint injections with corticosteroids have been one of the mainstays for the palliative therapy of painful joints. When effusions are large, especially in the knee, relief of symptoms often occurs with simple aspiration of the joint fluid. However, the fluid will quickly reaccumulate unless corticosteroids are also injected. A single intra-articular injection of triamcinolone hexacetonide in knee OA provides short-term pain relief compared with placebo, with best results seen in those with clinical evidence of joint effusion and successful aspiration of synovial fluid at the time of injection.⁹⁶ The mechanism for alleviating pain besides decreasing inflammation, which is usually minimal in OA, is unclear. Because of earlier experience with frequent injections of corticosteroids leading to an accelerated rate of joint damage, it is recommended to limit the frequency of joint injections to once every 3 months and not to exceed three injections in a given joint per year. The joint damage seen with multiple corticosteroid injections over shorter periods of time has been attributed to a direct effect of steroids on chondrocyte metabolism, possibly combined with a component of analgesic arthropathy. In weightbearing joints, decreased loading should be recommended for at least 2 days. Response to steroid injections is highly variable, and repeat injections should be limited to those who have a significant response that lasts several months.

Steroid injections are also useful adjuncts in the treatment of inflamed bursae. Observational studies have demonstrated both short- and long-term response to steroid injection, with a majority of patients showing improvement when assessed 26 weeks after injection.⁹⁷

Viscosupplementation

In recent years, viscosupplementation has begun to emerge as an alternative or supplement to analgesics and NSAIDs in the management of patients with OA of the knee. Viscosupplementation for the management of OA

was first used and tested on race horses in the early 1970s and shortly thereafter in people with OA of the knee. The rationale for this therapy stems from the unique properties of hyaluronic acid (HA).

The synovial lining of the diarthrodial joint is composed of one to two layers of cells that produce a highly viscous lubricating fluid, which contains high molecular weight substances, such as HA and lubricin. These substances coat the surface of the articular cartilage, providing lubrication as the articular cartilage surfaces move across each other during movement. The highly viscous nature of the synovial fluid is important for normal joint function, providing a nearly frictionless surface for joint movement.

Arthritis is associated with elaboration of enzymes and free radicals that degrade both HA and lubricin. Breakdown of HA leads to a decrease in the viscosity of the synovial fluid with loss of smooth movement of the articular surfaces, leading to further joint deterioration. It has been known for many years that synovial fluid from OA joints is lower in elasticity and viscosity than that from normal joint joints. This decrease in rheologic properties of the synovial fluid is due to reductions in the molecular size and concentration of hyaluronan and results not only from increased degradation but also from decreased synthesis and an inferior quality of synthesized hyaluronan.

In early clinical studies with hyaluronan products (1–2 million in molecular weight), viscosupplementation was shown to be a safe treatment in osteoarthritis. However, 6 to 10 injections were often required to show any efficacy because the elastoviscous properties of the early hyaluronan preparations were inadequate and the injected hyaluronan was eliminated too quickly. Because of this limitation, hylans were developed to produce a more highly elastoviscous fluid with rheologic properties similar to those of synovial fluid in the knee joint of healthy young persons.⁹⁸ Hylans are cross-linked forms of purified hyaluronan to form polymers of high molecular weight (6 million). Hylan preparations have a longer residence time in the joint space, and because of cross-links, they become more resistant to free radical degradation. A treatment regimen consisting of three injections of hylan given 1 week apart has been shown to provide optimal pain relief in people with OA of the knee. In one study comparing hylan G-F 20 with a lower molecular weight hyaluronon, hylan was found to yield significantly better results at 12 weeks in all the primary outcome measure, which included weightbearing pain and overall treatment response.⁹⁹ Systemic adverse events have been reported rarely with viscosupplementation and have not occurred with repeat injection, but mild to moderate transient local pain and swelling occur in 2% to 3% of intra-articular injections of hylan G-F 20.

There is some speculation that hylan may act as a DMOAD, but no studies are yet available to confirm this. Theoretically, the introduction of replacement HA preparations of sufficiently high molecular weight might delay, if not halt, the progression of OA. More studies are needed to assess long-term effects of this therapy. Some skepticism is warranted in view of recent findings in a canine model of OA. In this study, a series of intra-articular injections of HA did not alter the development of osteophytosis or fibrillation, and, in addition, prostaglandin concentration in the cartilage of treated knees was significantly reduced, suggesting that HA therapy may adversely affect cartilage.¹⁰⁰

Joint Replacement

Surgical intervention, mostly in the form of total knee and hip arthroplasty, is recommended for patients in whom pain and disability cannot be controlled by other means. Many recent studies have established the effectiveness and safety of total joint arthroplasty. However, these studies have tended to include mostly younger patients. Brander et al. looked specifically at subjects 80 years of age and older who were undergoing either hip or knee arthroplasty and compared their outcome with a younger, otherwise matched control group. They found that the older group had similar dramatic improvements in pain and function, as well as similar complication rates and length of stay in acute care facilities, compared with the younger group. The most dramatic postoperative functional gains were seen in the most disabled people.¹⁰¹ The decision to perform a total hip arthroplasty (THA) for patients with OA is based largely on patient reports of pain and disability and not on the radiographic findings of OA. Fox et al. reviewed the x-rays of elderly patients who had undergone unilateral THA and found that this group tended to have the contralateral THA performed with less severe x-ray findings.¹⁰² This finding suggests that if patients had a better understanding of the procedure and its benefits, they would opt for earlier surgical intervention. Besides alleviating pain and improving function, elective THA has consistently resulted in improved health-related quality of life, which was often dramatic and was most likely to occur within the first 3 to 6 months after THA.¹⁰³

Loosening remains a major complication following total joint replacement. Infection needs to be ruled out whenever loosening occurs. However, the rate of prosthetic joint infection has decreased to less than 1% with improvements in the operating room environment and the use of prophylactic antibiotics. Recent studies suggest inflammatory reactions directed against the implanted materials may contribute to aseptic loosening. Elevated

immune cell proliferation responses to both acrylic and cobalt/chromium were observed in patients with aseptically loosened prostheses.¹⁰⁴ Like many other procedures, the outcome of elective hip replacement bears a relationship to the volume of procedures performed by surgeons and hospitals, with low-volume providers tending to have higher rates of adverse events and serious complications.¹⁰⁵

Treatment of Low Back Pain

Besides the usual therapies already discussed, therapy for low back pain may include a course of physical therapy, with special attention to body mechanics, and epidural injections in selected cases. Osteopathic manual therapy (i.e., spinal manipulation) is a frequently used method of treatment for patients with chronic and subchronic back pain that has only recently been systematically studied. A randomized controlled trial comparing standard allopathic therapies with osteopathic manual therapy, albeit in subjects between 20 and 59 years of age with low back pain that had lasted at least 3 weeks but less than 6 months, found that both groups improved similarly during the 12-week follow-up. The allopathic treatment included analgesics, anti-inflammatory medication, active physical therapy, or therapies such as ultrasonography, diathermy, hot or cold packs (or both), use of a corset, or TENS. The osteopathic group required significantly less medication and used less physical therapy.¹⁰⁶

Surgical and Nonsurgical Treatment of Spinal Stenosis

Conservative treatment of lumbar spinal stenosis consisting of exercise programs and pain medication is recommended for those with tolerable symptoms or in whom surgery is too risky or not desired. Caudal epidural blocks are a reasonable therapeutic option in some patients with lumbar stenosis, especially those who are poor surgical risks or have refused surgery. For those with progressive neurologic impairment, decompressive lumbar laminectomy with or without posterior spinal fusion may be indicated. A prospective cohort study assessed 4-year outcomes for patients with lumbar stenosis treated surgically or nonsurgically.¹⁰⁷ For the patients with severe lumbar spinal stenosis, surgical treatment was associated with greater improvement in patient-reported outcomes than nonsurgical treatment at 4-year evaluation, even after adjustment for differences in baseline characteristics among treatment groups. The relative benefit of surgery declined over time but remained superior to nonsurgical treatment. Outcomes for the nonsurgically treated patients improved modestly and remained stable over 4 years. In a study with a longer evaluation

period, Amundsen et al. followed a cohort of 100 patients with symptomatic stenosis for 10 years who received either surgical or conservative treatment.¹⁰⁸ Those patients selected for surgery had better outcomes than those treated conservatively. Importantly, Amundsen et al. found that many improved with conservative therapy and, in those who did not, that a delay in surgery of from 3 to 27 months did not appreciably alter their outcomes compared with those who had surgery initially, suggesting that an initial conservative approach is prudent. There has been limited systematic study of surgical outcomes in older patients; however, two recent studies evaluated the efficacy of surgical treatment in patients who were older than 70 and 75 years of age, respectively.^{109,110} These studies found that with appropriate preoperative selection and evaluation, the surgical treatment of elderly patients with lumbar spinal stenosis can produce significant improvement with acceptable levels of morbidity. Katz et al. found that the most powerful predictors for positive outcomes after surgery for degenerative lumbar stenosis was the patient's report of good or excellent health before surgery.¹¹¹

Role of Acupuncture

Acupuncture appears to be a safe and effective adjunctive therapy for short-term relief of symptoms of OA involving the knee. The benefit of treatment shows some decline at 4 weeks after cessation.¹¹² The response to acupuncture appears to be quite variable among patients. Efforts to relate differences in response to psychosocial factors have not been rewarding in predicting response.

Experimental Therapies

The recent appreciation of the active metabolic life of the chondrocyte has led to an interest in biologically based therapies for OA. The potential use of doxycycline in the treatment of OA is based on its inhibition of protease activity against collagen *in vitro* at concentrations achieved in serum after oral dosing.¹¹³ Oral administration of doxycycline significantly inhibited collagenase and gelatinase activity in human OA cartilage that was removed for THA.¹¹⁴ Much more work is needed before therapy with doxycycline can be recommended for OA. Other potential biologic agents include inhibitors of IL-1 and NO, which are known to suppress synthesis of cartilage matrix. The administration of NO synthase inhibitors in experimentally induced arthritis have resulted in reduction of both synovial inflammation and destruction of cartilage and bone. Another avenue of future potential treatment is gene therapy, specifically manipulation of those genes whose products stimulate chondrogenesis or inhibit breakdown of cartilaginous matrix.¹¹⁵

Crystal Deposition Disease

Deposition of crystals in and around joints may be associated with acute or chronic arthritis. Crystals implicated in arthritis include monosodium urate monohydrate (MSU), calcium pyrophosphate dihydrate (CPPD), and HA and other basic calcium phosphates. The prevalence of crystal deposition diseases increases with age. Deposits of calcium pyrophosphate and hydroxyapatite are often seen in association with OA. Articular manifestations of this group of diseases are extremely common in the geriatric population, presenting a wide range of clinical responses.

Deposition of Crystals: Relationship to Aging and Osteoarthritis

The precise mechanisms by which crystals are deposited are imperfectly understood, but increased concentrations of metastable calcium salts and sodium urate, the unmasking of activators of crystal nucleation and crystal growth, or a decrease in concentration of inhibitors of crystal nucleation may act singly or together to promote crystal formation. In idiopathic or sporadic CPPD deposition disease seen in the elderly, isolated elevation of pyrophosphate in synovial fluid is due to local abnormalities. Increased pyrophosphate production has been demonstrated in osteoarthritic cartilage and probably results from enhanced breakdown of nucleotides mediated by the chondrocytic ectoenzymes, 5'-nucleotidase and nucleoside triphosphate pyrophosphohydrolase. The increased activity of these metabolic processes is an attempt by chondrocytes to repair damaged cartilage. Ultrastructural studies have demonstrated deposits of CPPD in chondrocyte lacunae in areas of damaged matrix and activated chondrocytes. Aggregated proteoglycans are potent inhibitors of crystal formation. Deaggregation of proteoglycans in aged and osteoarthritic cartilage would lead to a loss of natural calcium crystal inhibitor.

It would appear that deposits of CPPD and MSU can form in the absence of osteoarthritis. The familial cases of chondrocalcinosis and gout in younger persons are examples of deposition of crystals in seemingly normal cartilage. On the other hand, biochemical changes in osteoarthritic cartilage may predispose to crystal deposition, which in turn may contribute to further joint deterioration. In this latter setting, crystal deposition is a secondary, opportunistic process in damaged cartilage. Aging alone appears to be the major factor leading to formation of CPPD in fibrocartilaginous structures. The simultaneous finding of mixtures of crystal deposits in the same joints of elderly patients is further evidence of their susceptibility to intraarticular and periarticular

crystal deposition. A positive association exists between gout and CPPD deposition disease and between CPPD and hydroxyapatite formation.

Crystal-Induced Synovitis

It is generally believed that preformed microcrystals are shed from cartilage or synovium. Crystals that are associated with arthritis possess a negative surface charge and avidly bind proteins, including immunoglobulins, albumin, lysosomal enzymes, complement, and lipoproteins. Urate crystals have a strong affinity for IgG. The molecular orientation of IgG on the crystal surface leaves the Fc portion exposed and free to interact with Fc cell membrane receptors on leukocytes, monocytes, synoviocytes, and platelets. The interaction between cells and crystals causes the cells to become activated with release of a host of inflammatory mediators. Coating of the crystal surface with IgG greatly enhances phagocytosis and complement activation. Monocytes and polymorphonuclear leukocytes release a potent chemotactic factor that causes rapid accumulation of polymorphonuclear leukocytes. Phagocytosis induces release of oxygen radicals and lysosomal enzymes. MSU crystals induce release of interleukin-1 from monocytes, an observation that may explain the fever of acute gouty arthritis.

Some crystals, for example, MSU, are membranolytic. After digestion of their protein coating in the phagolysosome, the uncoated crystal causes rupture of the phagolysosome with release of its enzymes into the cytoplasm, resulting in cellular autolysis, increased permeability of the cell wall, and release of intracellular enzymes into the surrounding medium. Coating of the crystals with hyaluronic acid and certain proteins, such as albumin or lipoprotein, may inhibit or prevent crystal-induced inflammation, which may explain the occurrence of crystals in joint fluid after the inflammatory reaction has subsided or even in the absence of any detectable inflammation.

Study of synovial fluid by polarized light microscopy provides clinicians with a precise method of identifying MSU and CPPD when the crystals are more than 1 μm in size. Using a first-order red plate compensator allows one to determine the sign of birefringence and further differentiate between crystal types. Nonbirefringent apatite and other basic calcium phosphate crystals are so minute that they cannot be identified by ordinary light microscopy; they tend to aggregate into nonbirefringent microspherules that are difficult to distinguish from cell detritus and fat droplets. Definitive identification of apatite and other basic calcium phosphates requires sophisticated techniques.

Plain radiographs identify macroscopic deposits of radiopaque calcium containing salts. Hydroxyapatite deposits are frequently seen in periarticular and capsular

distribution, whereas CPPD deposition disease is associated with characteristic punctate and linear calcifications in fibrocartilaginous and hyaline cartilage.

Gout

New onset of gouty arthritis is common among the elderly. Most of these patients have hyperuricemia on the basis of decreased urinary excretion of uric acid, related to the effects of diuretic therapy, mild renal failure, hypertension, or hypertriglyceridemia. It has been estimated that about half of all patients who present with their initial attack of acute gouty arthritis are taking a diuretic. With the widespread use of these drugs in the elderly population, it is hardly a surprise that diuretic use is a major cause of gout in this age group. Less commonly, gout is secondary to overproduction of uric acid due to increased turnover of cells, as in myeloproliferative disorders.

The presentation of gout in the elderly differs from the more classic picture in younger men. The pattern is frequently polyarticular, subacute or chronic, and men and women appear to be affected with the same frequency. In women, the first manifestations of gout may be acute arthritis in finger joints, sometimes presenting as inflamed Heberden's or Bouchard's nodes. Elderly women are particularly prone to develop diuretic-induced polyarticular gout. Many have underlying osteoarthritis, and concomitant tophi and osteoarthritic changes in the same joint have been described. The appearance of asymptomatic tophi in Heberden's and Bouchard's nodes in elderly women as the initial manifestation of gout has been highlighted in several recent reports.^{116,117}

Chronic polyarticular gout with tophi can be misdiagnosed as rheumatoid arthritis with rheumatoid nodules, resulting in improper treatment and otherwise preventable disability. To add to the confusion, rheumatoid factor tests are positive in about 30% of patients with tophaceous gout, a finding that relates to the coating of urate crystals by IgG.

The diagnosis of gout can be readily established by studying synovial fluid or tophaceous material by polarized light microscopy. Needle-shaped negatively birefringent crystals of MSU are seen in 95% of patients with acute gouty arthritis and are a *sine qua non* for establishing a definitive diagnosis. Hyperuricemia, common in the elderly, is less reliable as a diagnostic test. Furthermore, serum urate levels are within normal limits at the time of the acute attack in 7% of the cases. Calcium pyrophosphate dihydrate crystals can coexist with urate crystals, and isolated cases of bacterial arthritis superimposed on gouty arthritis have been reported. If the clinical picture is suspicious of a septic joint, synovial fluid must be cultured.

The management of gout in the elderly is guided by the same principles that apply to a younger age group. The acute attack is treated with colchicine or one of the NSAIDs. The cautious use of NSAIDs has been discussed under osteoarthritis. A patient with decreased renal function, whose gout is precipitated by administration of a diuretic, is at risk of developing renal insufficiency if a NSAID is used to treat acute gouty arthritis. Colchicine has a low therapeutic margin and should be administered with caution. It is given in hourly doses of 0.6 mg, for a total of four to eight doses with decreases in dosage for hepatic or renal disease. The drug must be stopped promptly at the first sign of loose stools to avoid the consequences of dehydration and potassium loss. Renal, hepatic, and myocardial impairment, and the presence of cardiac arrhythmias, enhance the risk for colchicine toxicity. Chronic usage in patients with renal insufficiency has been associated with myoneuropathy syndrome. Colchicine may be administered slowly into a large vein in a dose of 2 mg. Great caution must be exercised to avoid extravasation, which may result in tissue necrosis and sloughing of the skin. Intra-articular injection of corticosteroid is helpful when gout involves an accessible joint. Oral administration of corticosteroids is also useful in older patients, but because of a tendency of gouty arthritis to rebound, concomitant administration of a maintenance dose of colchicine or a NSAID is necessary.

Drugs to lower serum urate should be initiated once the acute attack has subsided. Because acute gouty arthritis may occur during the initial treatment with a hypouricemic drug, it is advisable to use colchicine prophylactically in a dose of 0.6 mg twice daily for several weeks. Uricosuric drugs are effective so long as the creatinine clearance exceeds 50 mL/min. Probenecid and sulfapyrazone are the principal uricosuric drugs. Diflunisal in a dose of 500 mg two times daily is weakly uricosuric and may be worth trying in a patient who also requires an analgesic drug for symptomatic OA. Aspirin abolishes the effect of uricosuric drugs and should not be given concomitantly. Allopurinol is the drug of choice for patients with overproduction of uric acid or with significant reduction in renal function or those who require continuous treatment with aspirin, diuretics, or other drugs that interfere with the tubular secretion of urate. The dose of allopurinol in elderly patients with diminished uric acid excretion is smaller than in overproducers of uric acid. The goal is to prescribe the lowest dose of allopurinol that will maintain serum urate between 5 and 6 mg/dL. Frequently, 100 or 200 mg allopurinol given in a single morning dose will suffice. Serious toxicity includes agranulocytosis, granulomatous hepatitis, and exfoliative dermatitis. Many cases of prolonged hypersensitivity reactions characterized by an erythematous maculopapular rash, eosinophilia, fever, liver function

abnormalities, and progressive renal failure have been recorded. Another concern in using allopurinol is the observation of an increased incidence of severe hypersensitivity reactions from coadministered drugs, for example, penicillin and ampicillin. Asymptomatic hyperuricemia is not an indication for long-term urate-lowering therapy; the risks of drug toxicity outweigh any benefit.

Calcium Pyrophosphate Dihydrate Deposition Disease

Calcium pyrophosphate dihydrate (CPPD) causes the most common crystal-associated arthritis in the elderly. In 1962, McCarty reported an acute arthritis mimicking gout, and therefore termed pseudogout, in elderly patients with chondrocalcinosis.¹¹⁸ He further identified the crystals in synovial fluid and cartilage as calcium pyrophosphate dihydrate ($\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$). CPPD crystal deposition disease is a heterogeneous disorder. Familial or hereditary cases have been reported from several countries. A small fraction are associated with underlying metabolic disorders, including hyperparathyroidism, hypothyroidism, hypophosphatasia, hypomagnesemia, hemochromatosis, ochronosis, gout, Wilson's disease, and senile amyloidosis. CPPD crystal deposition disease associated with genetic disorders has an early onset. In the elderly, the idiopathic or sporadic form is by far the most common type of CPPD deposition disease. The prevalence increases in stepwise fashion with age. It is rare before age 50 and increases from 10% to 15% in those aged 65 to 75 to 30% to 60% in those over 85 years. Ellman et al. studied the prevalence of knee chondrocalcinosis in hospital and clinic patients older than 50 years and found an overall prevalence of 9.6%.¹¹⁹ In a representative sample of 79-year-olds in Gothenburg, radiographic evidence of chondrocalcinosis in knees or hands was present in 16%.¹²⁰

The majority of patients with chondrocalcinosis are free of symptoms. Radiopaque densities are noted in fibrocartilage (especially menisci, radiocarpal joint, symphysis pubis, shoulders, and hips and in the midzonal layer of hyaline cartilage), giving rise to punctate or linear calcification. Acute synovitis, or pseudogout, is the most dramatic clinical manifestation. It presents as an acute monoarthritis, most often located to the knee, but also commonly seen in the wrist, shoulder or ankle. As in gout, surgery, trauma or serious medical illness may trigger an acute attack. About 10% of patients have oligoarticular involvement or a migratory pattern involving several joints successively, sometimes over a course of many weeks or months. About half of symptomatic patients present with clinical and radiographic features that are reminiscent of low-grade osteoarthritis, except that joint

involvement is that of pseudogout rather than generalized OA. The patients complain of chronic pain, stiffness and restricted movement of knees, wrists, shoulders, elbows, metacarpophalangeal joints, hips, and ankles. Minor acute attacks may be superimposed on chronic symptoms. Acute and chronic tenosynovitis may be present. Wrist involvement may produce a carpal tunnel syndrome. The chronic polyarticular arthropathy seen in 5% of the patients may be confused with rheumatoid arthritis. A number of reports have described a severe destructive arthropathy similar to a Charcot joint and affecting almost exclusively elderly women in association with calcium pyrophosphate deposition, involving the shoulder, elbow, or wrist, in addition to knees or hips.¹²¹ In addition to the typical x-ray findings of calcifications in articular cartilage already described, calcifications may be seen in the joint capsule, synovium, and bursae and in tendons, especially the Achilles, triceps, quadriceps, and supraspinatus tendons.

The diagnosis is confirmed by presence of weakly positively birefringent calcium pyrophosphate crystals in synovial fluid and characteristic radiologic findings. In acute arthritis, polymorphonuclear leukocytes predominate. Total synovial fluid WBC counts range from 4000 to 50,000/mm³. Triclinic (crystals with three axes, all unequal and none at right angles), rhomboid crystals are found within leukocytes and extracellularly. In chronic arthritis, the leukocyte count is lower and mononuclear cells are more numerous. CPPD synovitis is a prevalent disease, and one should always keep in mind the possible coexistence of another joint disease. The screening for rare metabolic disorders is unrewarding in the elderly, but measurement of serum calcium, iron, and iron-binding capacity should be obtained, and screening for hypothyroidism in a geriatric population is always worthwhile.

Treatment of acute synovitis is with nonsteroidal anti-inflammatory drugs, aspiration of joint fluid, and intra-articular injection of corticosteroid. The effect of colchicine is less reliable than in acute gouty arthritis. Chronic CPPD arthritis is managed in much the same way as osteoarthritis. The principles and potential hazards of using NSAIDs have been discussed in the section on OA.

Hydroxyapatite Deposition Disease

Hydroxyapatite (HA) and other basic calcium phosphates, which comprise the mineral phase of bone and teeth, make up the majority of ectopic or extraskeletal calcifications. Ectopic calcifications can be divided into dystrophic types, which occur in tissue that has been injured, and metastatic calcifications, which are related to increased calcium and phosphate concentration. Examples of dystrophic lesions are calcifications, which may

occur in scleroderma, dermatomyositis, ochronosis, and tophi and following local injections of corticosteroids. Metastatic calcifications may be seen in hyperparathyroidism, sarcoidosis, and end-stage renal disease managed with chronic hemodialysis.

Idiopathic periarticular HA deposition occurs commonly in bursae and tendons. More recently, HA crystals have been found in synovial fluid in a high percentage of patients with osteoarthritis, and less often in patients with other types of arthritis. Because of their minute size (75–250 Å in diameter), individual HA crystals cannot be identified by ordinary or polarized light microscopy. Their precise identification requires electron microscopic techniques or microprobe or x-ray diffraction analysis.

HA crystals can cause acute inflammation of tendons and bursae. The common rotator tendon is one typical site. The etiology of calcific tendinitis is unknown; presumably trauma leads to tissue damage with calcium deposition in the form of HA occurring at the site of tissue injury. In calcific periarthritis, the skin is often warm and red over the affected joints and the tissues are boggy and tender, but effusion is absent. Periarthritic calcification is visible on radiographs.

HA crystals, detected by electron microscopy, were present in synovial fluid from more than half of patients with OA of the knee.¹²² The crystals were associated with more severe disease but did not correlate with the concentrations of putative markers of cartilage such as keratan sulfate. HA crystals have been shown to have phlogistic properties and have been implicated as a cause of the flares of synovitis seen in osteoarthritis, in which cases there is a tendency to higher synovial fluid cell count and a more severe course.

HA-associated destructive arthritis is an unusual form of rapidly progressive destructive OA of the large joints in elderly patients that is associated with HA crystals in the synovial fluid. Although the shoulder is a typical site (so-called Milwaukee shoulder),¹²³ it is well recognized that similar destructive changes can occur in other larger joints such as the knee, hip, and ankle and even in small joints. The overwhelming majority of patients with HA-associated destructive arthritis have been elderly women. Rapid joint destruction leading to instability and large, noninflammatory, often hemorrhagic effusions, containing large amounts of HA particles and joint detritus, are cardinal clinical features. Radiographs show characteristic changes, such as marked attrition of bone and cartilage on both sides of the joint, scalloping pressure defects, and periarticular calcifications. Osteophytosis, subchondral sclerosis, and cyst formation are either absent or are minor findings. The pathogenesis of this destructive arthropathy has not been fully delineated, but activated collagenase and neutral protease play a major role in accelerating chondrolysis and joint destruction.

Other Crystals and Particles

A variety of other birefringent materials may occasionally cause synovitis. Calcium oxalate crystal deposition can be seen in elderly patients with end-stage renal disease who are receiving chronic hemodialysis. Positively birefringent bipyramidal and polymorphic calcium oxalate crystals have been demonstrated in cartilage, synovium, and synovial fluid. Radiographically, deposits in cartilage cannot be distinguished from calcium pyrophosphate deposition. Involvement of metacarpophalangeal and proximal interphalangeal joints is common. Joint disease in chronic renal failure may be associated with either HA or calcium oxalate deposition.

Cryoglobulins found in essential cryoglobulinemia and multiple myeloma can precipitate in crystalline form in a variety of tissues, including the synovium. Rare cases of cryoglobulin crystal-associated arthritis have been reported. Cholesterol crystals are mainly seen in chronic inflammatory effusions. Crystalline depot corticosteroid preparations may occasionally induce a transient inflammation hours after intra-articular injection (postinjection flare). Corticosteroid crystals can appear as positively or negatively birefringent rods, similar in size to urate or CPPD, as granules, or as irregular debris. Finally, particles of wearing surgical articular implants can be associated with a chronic detritic synovitis in elderly patients who have undergone partial or total joint replacement.

Polymyalgia Rheumatica and Giant Cell Arteritis

Temporal arteritis and polymyalgia rheumatica are closely related diseases that primarily affect the elderly, frequently occur in the same individual, and usually are associated with constitutional symptoms in the form of malaise, fatigue, weight loss, anemia, and elevated levels of acute-phase reactants. Furthermore, in both syndromes, a rapid response to glucocorticoids is seen regularly. Temporal arteritis and polymyalgia rheumatica are nosologic terms used to define typical clinical syndromes, whereas giant cell arteritis denotes a specific pathologic process. The question of the relationship between temporal arteritis and polymyalgia rheumatica is still a valid one. Some consider the two to be syndromes at either end of the spectrum of one disease, with temporal arteritis the more severe and polymyalgia rheumatica the less severe expression of an underlying giant cell arteritis. Others believe that a common etiologic agent produces either a proximal synovitis leading to symptoms of polymyalgia rheumatica, or a giant cell arteritis leading to symptoms of vasculitis and occlusion of elastic arteries originating from the aortic arch.

The association of polymyalgia rheumatica with giant cell arteritis is striking. Most series have shown that 40% to 60% of patients with giant cell arteritis have symptoms of polymyalgia rheumatica, which may be the initial presentation in one-third of patients. Conversely, biopsy of the temporal artery has demonstrated giant cell arteritis in 15% to 30% of patients with polymyalgia rheumatica who had no symptoms or signs of arteritis.

The term *polymyalgia rheumatica* was coined by Barber in 1957 to describe a syndrome characterized by myalgias and stiffness of the shoulder and pelvic girdles, neck, or torso for a duration of 1 month or more, accompanied by constitutional symptoms and an elevated erythrocyte sedimentation rate in patients who have no underlying disease to explain the symptoms. The syndrome is extremely rare in people under the age of 50 years. Despite widespread awareness of the condition in the United States, the first report in the American literature did not appear until 1963.

Giant cell arteritis, clinically also known as temporal arteritis or cranial arteritis, is a form of granulomatous vasculitis, typically containing giant cells, that most often causes occlusion of the branches of the external and internal carotids but may involve many medium- and large-sized arteries throughout the body, including the aorta.

Epidemiology

Polymyalgia rheumatica and giant cell arteritis are relatively common diseases in the elderly. The incidence rate has been shown to be highest in northern Europe and in populations of the same ethnic background in the northern United States. Epidemiologic studies of these entities have been conducted in Olmstead County, Minnesota, which comprises an urban population in Rochester and a surrounding rural population.^{124,125} The mean annual incidence of polymyalgia rheumatica over a 10-year span (1970–1979) was 53.7 per 100,000 population 50 years of age and older; this may be compared to an incidence of rheumatoid arthritis of 77 per 100,000 in the same age group. The prevalence of polymyalgia rheumatica was estimated at 550 per 100,000 aged 50 and older. The average annual incidence of giant cell arteritis in the period between 1950 and 1983 was 16 per 100,000 population 50 years and over, with a slightly higher figure of 21.7 for the period between 1975 and 1983. The age-specific incidence rate rose, from 1.4 per 100,000 population aged 50 to 59 years, to a maximum of 44.7 per 100,000 population older than 80 years. In 1984, the prevalence of persons with a history of temporal arteritis was 234 per 100,000 population aged 50 and older. Two prospective studies from Denmark and Norway found incidence rates that were higher than those reported in prior retrospec-

tive studies,^{126,127} the annual incidence of giant cell arteritis, which was the term used to encompass temporal arteritis and polymyalgia rheumatica, occurring either together or alone, was 76.6 and 141.7 per 100,000 population aged 50 years or more, respectively. The annual incidence of biopsy-proven giant cell arteritis in persons 50 years and older was 23.3 and 29.0 per 100,000, respectively. All studies have found the incidence rates of polyalgia and giant cell arteritis to be significantly higher for women than for men. Autopsy studies suggest that giant cell arteritis may be even more prevalent. In a prospective study, Östberg examined sections of the temporal arteries and two transverse sections of the aorta and found giant cell arteritis in 1.6% of 889 consecutive postmortem cases.¹²⁸

Etiology and Pathogenesis

The causes of polymyalgia rheumatica and giant cell arteritis is not known, nor has its striking prevalence in older people been elucidated. However, during the past few years, remarkable progress has been achieved in the understanding of the pathogenic mechanisms that lead to inflammation and damage of the vessel wall in giant cell arteritis.^{129,130} The cellular infiltrate is dominated by macrophages, a heterogeneous population of CD-4+ T lymphocytes, a smaller number of CD-8+ T cells, and nucleated giant cells. B lymphocytes are usually absent. The CD-4+ T lymphocytes accumulate preferentially in the adventitia of the artery in close proximity to TGF- β_1 - and IL-1-producing macrophages. A small population of CD-4+ T cells takes on the phenotype of an activated T-cell blast and undergoes clonal expansion with associated production of interferon- γ . These findings suggest recognition of an antigen that resides in the adventitia. This location is apart from the internal elastic membrane and adjoining tissue that bears the brunt of injury and which is characterized by infiltration by a population of macrophages that have undergone functional differentiation to produce collagenase and inducible nitric oxidase synthase. The nature of the antigen in giant cell arteritis has not been identified. The fragmentation of the elastic lamina observed in pathologic specimens has long led to speculation that elastic fibers represent a target antigen. Support for this view has come from a recent report suggesting release of elastase-derived elastin peptides that serve as the putative autoimmune targets in this disease.¹³¹ On the other hand, the sudden onset of giant cell arteritis in some patients and the finding that the peaks of incidence of giant cell arteritis correlate with peaks of incidence of respiratory diseases have raised questions of an infectious agent triggering the autoimmune process. A viral etiology has been suspected but never proven.

Two recent studies have suggested that a virus may play a role in the pathogenesis of giant cell arteritis. The Mayo group found a statistically significant association between histologic evidence of giant cell arteritis and the presence of parvovirus B19 DNA in temporal artery biopsies.¹³² A strong association of IgM directed against parainfluenza virus type 1 and biopsy-verified temporal arteritis, with a significant rise in positivity rate between the onset of symptoms and diagnosis, was found in a multicenter, prospective study.¹³³ This finding suggested that reinfection with parainfluenza virus type 1 is linked to the onset of giant cell arteritis in a subset of patients. Although vasculitic lesions are absent in polymyalgia rheumatica, it may nevertheless represent a forme fruste of arteritis. Analysis of tissue cytokines by molecular techniques has demonstrated the presence of proinflammatory cytokines such as TGF- β_1 , IL-1, and IL-6 in temporal artery specimens from patients with polymyalgia rheumatica who had no obvious findings for arteritis on histologic examination.¹³⁴

Epidemiologic evidence supports a genetic role in the pathophysiology of the disease. Although no association with class I HLA antigens has been detected, susceptibility and disease severity appear to be linked to certain class II antigens. Studies of northern European populations have shown an association with the HLA-DR4 haplotype, but not as strong as that observed in rheumatoid arthritis. The incidence of HLA-DR4 in patients with giant cell arteritis seen at the Mayo Clinic was 60% compared with 24% for a normal control group. An analysis of the functionally most important locus of the HLA class II complex, the HLA-DRB1 locus, in patients with biopsy-proven giant cell arteritis revealed an overrepresentation of three allelic variants of the HLA-DRB1 *04 family.¹³⁵ In this particular study, the clinical findings were similar in DR4+ and DR4- patients. Relapses occurred in both subsets, and associated polymyalgia rheumatica was observed with similar frequency. The frequency of molecularly defined HLA alleles varies greatly among different ethnic groups. The lower incidence of polymyalgia rheumatica and giant cell arteritis among blacks and in southern Europe can be explained, at least in part, by the lower prevalence of the HLA-DR4 haplotype in these populations. In addition, recent studies from Spain and Italy show that susceptibility and severity of these diseases are more closely associated with other, non-DR4, HLA class II alleles.

Pathology

The pathologic diagnosis of giant cell arteritis is based on the presence of typical histology changes in each arterial layer. The changes tend to affect the arteries in a patchy fashion with abnormal segments of the artery interspersed with normal segments. A distinctive fibromyxoid

intimal proliferation causing variable degrees of luminal compromise with or without thrombus formation is seen in almost all patients. Giant cells are often closely associated with elastic lamina fragmentation. The media shows patchy degeneration, dropout of smooth muscle cells, and granulomas containing lymphocytes, histiocytes, epithelioid cells, and multinucleated giant cells. Giant cells are not seen in all sections, and their presence is not required to make the diagnosis if other histologic findings are characteristic.

Giant cell arteritis has a predilection for elastic arteries that originate from the arch of the aorta, but involvement of almost every medium- and large-sized artery has been reported. The intracranial arteries are involved less often. It has been suggested that the relative sparing of the intracranial arteries is related to the small amount of internal elastic lamina in this vascular bed.

In polymyalgia rheumatica, muscle biopsies have been normal or at most have shown nonspecific type II muscle atrophy, but a number of ultrastructural abnormalities have been observed. Arthroscopy and biopsy of shoulder and knee joint have demonstrated synovitis, characterized histologically by mild inflammation with lymphocytes and a few polymorphonuclear leukocytes, but without vasculitis. Granulomatous myocarditis and hepatitis have also been reported.

Clinical Picture

The mean age of onset of both giant cell arteritis and polymyalgia rheumatica is about 70 years. Both diseases occur twice as often in women as they do in men. In terms of diagnosis and treatment, it is useful to recognize four patient groups: (1) patients with polymyalgia rheumatica; (2) patients with temporal arteritis; (3) patients with symptoms of both polymyalgia rheumatica and temporal arteritis; and (4) patients without local symptoms of arteritis or muscular symptoms but with systemic symptoms such as fever, malaise, and weight loss.

The onset of polymyalgia rheumatica usually is insidious but can be abrupt. The most common symptoms are aches and stiffness involving the proximal muscle girdles and the neck. The discomfort usually extends to the proximal portion of the arms and thighs and to the axial musculature. The stiffness is prominent in the morning and after prolonged inactivity. Pain is accentuated by movements of the joints. Pain and stiffness may be so incapacitating that the patient cannot get out of bed in the morning without the assistance of another person. Generalized systemic complaints may include low-grade fever, night sweats, anorexia, weight loss, and depression. Peripheral musculoskeletal symptoms occur in approximately half the cases of polymyalgia rheumatica; these include a mild, usually asymmetric arthritis that predominantly involves wrists and knees, and inflammatory

involvement of distal tenosynovial structures that may cause a carpal tunnel syndrome or swelling of the distal extremities, with and without pitting edema. In the absence of peripheral manifestations, physical signs are conspicuously few. Muscular strength is not impaired. Tenderness, when present, is felt mostly around the shoulders. Active range of motion may be limited due to elicitation of pain, but passive motion is normal.

Giant cell arteritis is also often insidious in onset and is associated with symptoms and signs that are dictated by the anatomic involvement. Most of the clinical features can be related to vasculitis and occlusion of the cranial branches of arteries originating from the aortic arch. The most common symptom is a headache, which is usually boring or lancinating in nature. Scalp tenderness along the course of the superficial temporal, posterior auricular, or occipital arteries is a telltale sign. The temporal artery may be swollen and pulseless. Tender nodules are sometimes felt. Rarely, occlusion leads to areas of gangrene of the scalp. Jaw claudication is often considered pathognomonic but occurs in less than half of patients. Giant cell arteritis may present with unusual manifestations, and the diagnosis should be considered in elderly patients who complain of pain with deglutination, throat or tongue pain, hoarseness, cough, ear pain, or sudden loss of hearing when no obvious cause for these symptoms can be found.

A well-recognized and serious complication of giant cell arteritis is ocular involvement, leading to partial or complete visual loss in 15% to 20% of the patients. An even lower incidence rate of permanent loss of vision (8%) was found in the Mayo Clinic series of 166 patients with biopsy-proven giant cell arteritis.¹³⁶ This incidence is lower than the incidence found in older studies and may reflect earlier recognition and treatment of the disease. Even though the dramatic manifestations of ocular involvement may appear abruptly, most patients have various complaints relating to the eyes for some time before loss of vision occurs, that is, transient blurring, amaurosis fugax, and diplopia, ptosis, or other manifestations of ophthalmoplegia. Both eyes can be affected, but loss of vision in one eye usually precedes loss of vision in the other by 1 to 12 days. Impaired visual acuity is caused by ischemic optic neuritis that is secondary to involvement of the ophthalmic or the posterior ciliary arteries that supply the optic nerve. Occlusion of the central retinal artery is rarely a cause of blindness in temporal arteritis. Ophthalmoplegia is a common ocular manifestation, and, as mentioned, it may precede more classical symptoms of giant cell arteritis. Occasionally, patients may complain of diplopia in the absence of detectable ophthalmoplegia. Other ophthalmologic complications of giant cell arteritis include episcleritis and scleritis.

Clinical evidence of involvement of large arteries occurs in 15% of cases. Arteritic lesions of the aorta

may lead to aortic valve incompetence or a dissection aneurysm and rupture of the aorta. Several reports have called attention to the increased incidence of aortic aneurysm and dissection in patients with giant cell arteritis. A population-based study from Olmsted County, Minnesota, revealed aneurysm of the thoracic aorta in 11.5% of their cases, a 17-fold higher rate than observed in the general population.¹³⁷ Aortic aneurysm rupture was the cause of death in 8% of their patients. Upper extremity claudication, Raynaud's phenomenon, paresthesias, bruits over the large proximal arteries, and decreased or absent pulses and blood pressure are common manifestations of vasculitis of the large arteries to the upper extremities. Lower extremity involvement, when it occurs, presents as leg claudication. Rare cases of involvement of the vasculature of the foot, leading to pedal gangrene, have been reported. Visceral manifestations include myocardial infarction, abdominal angina, and neurologic symptoms due to vertebral arteritis. Fever and high erythrocyte sedimentation rate in patients with myocardial infarction, cerebrovascular accident, or aortic aneurysm may signal giant cell arteritis. Acute neurologic problems were observed in 51 of 166 patients with biopsy-proven giant cell arteritis.¹³⁶ This group excluded patients with ophthalmologic problems and large artery abnormalities on physical examination. Of these 51 patients, 23 had peripheral neuropathies and 12 had transient ischemic attacks or strokes related to carotid or vertebral artery involvement. A multitude of neurologic manifestations can be seen when the vertebrobasilar artery system is involved, including ataxia, lateral medullary syndrome, hemianopsia, hearing loss, and dementia.

Instead of the classic symptoms of arteritis, patients may present with prominent constitutional symptoms, such as fever, weight loss, malaise, and depression. In a retrospective study of 100 patients with biopsy-proven temporal arteritis, 15 fulfilled the criteria for fever of unknown origin.¹³⁸ In 11 of the 15 patients, manifestations suggesting giant cell arteritis were eventually recognized, but in 4 patients the giant cell arteritis was discovered only after a random temporal artery biopsy. Therefore, temporal artery biopsy must be considered strongly in an elderly patient who presents with fever or unexplained anemia.

The prognosis for giant cell arteritis is generally favorable once the condition has been recognized and treatment is under way. In most studies, the survival rate for patients with giant cell arteritis was found to be the same as for the general population of the same age. A recent follow-up study of the more than 200 patients in the 1990 American College of Rheumatology giant cell arteritis classification criteria cohort found survivorship to be virtually identical to that of the general population.¹³⁹ However, large artery involvement resulting in a fatal

outcome does occur,¹⁴⁰ and a study from Sweden showed an increase in mortality during the first 4 months after diagnosis in 284 patients with biopsy-proven giant cell arteritis.¹⁴¹ Thereafter, the death rate was equal to that of the general population. Fatal outcome was usually seen in patients who were insufficiently treated with corticosteroids. It is important that all patients with giant cell arteritis be examined carefully for large artery lesions, because early recognition and treatment may prevent arterial occlusion, rupture, and death.

Diagnostic Studies

Polymyalgia rheumatica and giant cell arteritis characteristically are associated with a very high erythrocyte sedimentation rate and elevation of other acute-phase reactants, such as C-reactive protein, fibrinogen, platelet count, and complement level. Westergren's sedimentation rate in giant cell arteritis is frequently more than 100mm in 1h. It should be appreciated that a normal sedimentation rate does not completely rule out a diagnosis of polymyalgia rheumatica. A subgroup of polymyalgia rheumatica with low sedimentation rate (<40mm/h) at the initial presentation has been recognized over the past 15 years. The frequency of a normal sedimentation rate has varied between 7% and 20% in several retrospective studies. It is not clear whether patients in this subgroup have a more benign disease. The levels of C-reactive protein (CRP) increase and decrease more rapidly than does the erythrocyte sedimentation rate, and diagnostic specificity is enhanced by the use of CRP in conjunction with the sedimentation rate. The Mayo group has used IL-6 serum levels as a measure of disease activity in polymyalgia rheumatica and giant cell arteritis. A moderate normochromic, normocytic anemia is a characteristic finding. The leukocyte count is generally normal. Abnormal liver function tests, especially elevation of alkaline phosphatase, are present in one-third of the cases. Rates of positive rheumatoid factor and antinuclear antibody tests do not differ from those in control populations of elderly patients. Antithyroid antibodies are found in about 10% of the patients. The synovial fluid is mildly inflammatory, with a cell count between 1000 and 8000/mm³, of which 40% to 50% are polymorphonuclear leukocytes. Synovial fluid complement level is normal. In patients with polymyalgia rheumatica, technetium-99m diphosphonate scintigrams show increased uptake in central joints, such as shoulders and hips.

The diagnosis of giant cell arteritis may be confirmed by superficial temporal artery biopsy, but because this condition is segmental and often has skip areas, it is necessary to remove a 2- to 3-cm segment of the artery and perform serial sections. If the first biopsy is normal, and suspicion of giant cell arteritis remains strong, a contralateral biopsy should be carried out. The posterior

auricular or the occipital arteries may be chosen for biopsy when tenderness is marked along their distribution. Miniarteriography and Doppler flow studies have been used to locate a suitable area of the temporal artery for biopsy, but these methods are nonspecific and inconsistent and are not advocated for routine use. In patients with aortic arch syndrome, angiographic studies should be performed because temporal artery biopsy is not always diagnostic of giant cell arteritis. Angiographic features of arteritis include segments of smooth-walled constrictions, alternating with areas of normal caliber or aneurysmal dilatation, smooth-tapered occlusions of affected large arteries, and absence of irregular plaques and ulcerations. These lesions are characteristically found in the subclavian, axillary, and brachial arteries.

The need for temporal artery biopsy in all cases of polymyalgia is debatable. An acceptable course of action would be to follow carefully, without biopsy, those patients who show a rapid response to corticosteroid treatment in terms of symptomatic relief and normalization of the sedimentation rate. On the other hand, biopsy should be performed in cases where clinical evidence for giant cell arteritis is present. It is well recognized that symptoms of giant cell arteritis may occur suddenly in a patient who was originally thought to have pure polymyalgia and who is being treated with small doses of prednisone sufficient to control all symptoms of polymyalgia and to normalize the sedimentation rate.

Differential Diagnosis

When the typical clinical features of polymyalgia rheumatica occur in an elderly person, the diagnosis is usually easy. The clinical picture may at times be obscured by musculoskeletal symptoms related to underlying degenerative joint disease and neurologic conditions that are prevalent among the elderly. The differential diagnosis includes other inflammatory and noninflammatory rheumatic diseases, malignancy, and occult infections. About a quarter of patients with elderly-onset rheumatoid arthritis present with synovitis involving shoulder and hip, absence of rheumatoid nodules, an erythrocyte sedimentation rate greater than 50mm/h, and a negative test for rheumatoid factor. This presentation resembles that of polymyalgia rheumatica, and it may not be until later in the course that a clear differentiation between the two can be made. Conversely, the occurrence of peripheral arthritis or carpal tunnel syndrome may pose diagnostic difficulties between polymyalgia rheumatica and elderly-onset seronegative rheumatoid arthritis. Associated peripheral manifestations of polymyalgia rheumatica respond dramatically to corticosteroid treatment. Any evidence of erosive arthropathy suggests an alternative diagnosis.

Polymyositis can be distinguished from polymyalgia rheumatica by its characteristic muscular weakness, elevated muscle enzymes, and abnormal electromyogram. Prolonged viremia or chronic bacterial infection, such as subacute bacterial endocarditis, may present with polymyalgia-like symptoms. The elevated sedimentation rate in polymyalgia rheumatica is helpful in differentiating noninflammatory rheumatic diseases, such as fibromyositis, tendonitis, and capsulitis. Patients with hyperparathyroidism or hypothyroidism may present with musculoskeletal symptoms that may be mistaken for polymyalgia rheumatica. One study found a higher prevalence of hypothyroidism (4.9%) and antithyroid antibodies (37 of 367 patients) in polymyalgia rheumatica and giant cell arteritis than in the general population.¹⁴² Occult cancer may be associated symptoms similar to polymyalgia rheumatica. Search for malignancy should be considered if patients fail to improve clinically with corticosteroid treatment. These are several case report of polymyalgia rheumatica associated with malignancies, but compared with age- and sex-matched controls, the incidence of neoplasia does not appear to be increased.

The diagnosis of giant cell arteritis is not difficult in the presence of classic symptoms. It is important to keep this diagnosis in mind when an elderly patient presents with fever and marked constitutional symptoms. Likewise, it is important to recognize cases of giant cell arteritis with typical clinical features of the disease, but with a normal erythrocyte sedimentation rate, to prevent vascular catastrophes of untreated vasculitis. Patients with giant cell arteritis and a low sedimentation rate are more likely to have a history of polymyalgia rheumatica or to have received prior corticosteroid treatment.

Treatment

Pure polymyalgia rheumatica is best treated with 10 to 15 mg prednisone given in the morning. Usually, the patient obtains dramatic, symptomatic relief within a few days. A prompt response to corticosteroids can be regarded as additional confirmation of the diagnosis. In contrast, polymyalgia-like symptoms of a paraneoplastic syndrome respond poorly to corticosteroid treatment. Prednisone dosage should be slowly tapered in parallel with symptomatic relief and the decrease in the erythrocyte sedimentation rate or serum C-reactive protein. When the daily dose level has reached 10 mg, we recommend that further reduction be done in 1-mg decrements. Relapses accompanied by new elevation of the sedimentation rate are usually caused by too rapid reduction of corticosteroid dosage. In such a situation, prednisone dosage will have to be increased temporarily, and subsequent reductions may have to be made in smaller decrements at longer intervals. Polymyalgia rheumatica shows considerable variability in

its course. Several studies have noted that patients differ in their initial response to prednisone as well as in their long-term steroid requirements,^{143,144} a finding that suggests the existence of patient subsets differing in disease course and prognosis. In one study, patients treated with a defined schedule of prednisone could be subdivided into three groups on basis of clinical response and laboratory parameters.¹⁴⁴ An earlier study found two populations of patients, one with a self-limited illness requiring prednisone for 1 to 2 years, and another with a more persistent process requiring long-term therapy;¹⁴³ 40% of the patients in the latter group required treatment for more than 4 years.

A debate is ongoing in regard to the ideal initial dosage and the optimal tapering schedule. Mild cases of polymyalgia rheumatica have been treated with aspirin or nonsteroidal anti-inflammatory drugs, but the response has been less dramatic, and many patients initially treated in this way have had to be switched to prednisone. The risk of diabetes mellitus, vertebral fractures, and femoral neck fractures was found to be two to five times greater among patients with polymyalgia rheumatica compared with age- and sex-matched individuals. Other drugs such as methotrexate and azathioprine have been tried as corticosteroid-sparing agents, but the results have not been convincing. These drugs should be reserved for patients with severe comorbid conditions, such as uncontrolled diabetes mellitus or severe osteoporosis.

The manifestations of giant cell arteritis respond favorably to high-dose corticosteroid. Treatment should begin with 60 to 80 mg prednisone in divided daily doses. Constitutional symptoms resolve within 24 to 48 h after initiation of treatment. Localized symptoms of arteritis usually improve after 2 to 4 weeks. However, visual loss, once it occurs, is rarely reversible. In patients with threatening vascular complications, corticosteroid therapy should be initiated while awaiting arterial biopsy. Changes of inflammation of the arterial wall can be recognized for at least a week after corticosteroid treatment has been started. Once reversible symptoms have subsided and laboratory tests have reverted to normal, the dose of prednisone may be tapered slowly to a maintenance dose of 7.5 to 10 mg daily, with careful attention to readjustment of dosage if symptoms recur. Stepwise reduction of the corticosteroid dose should be done in decrements of 10%. Treatment should be continued for at least 2 years. In general, the prognosis is quite good with optimal corticosteroid treatment. Most patients achieve complete remission that is often maintained after withdrawal of treatment.

Patients should be made aware that adverse effects of corticosteroid treatment, including cushingoid appearance, symptomatic vertebral compression fractures, proximal muscle weakness, subcapsular cataracts, and, in

patients with diabetes mellitus, increased insulin resistance, occur in one-third of the patients. Corticosteroids continue to be first-line therapy for giant cell arteritis. The addition of methotrexate with gradual tapering of corticosteroids is a reasonable alternative to reduce the potential adverse events seen with chronic administration of glucocorticoids. A recent study found methotrexate to be effective in the treatment of giant cell arteritis.¹⁴⁵ In this 2-year clinical trial to determine safety and efficacy of combined therapy with prednisone plus methotrexate versus prednisone alone, the group who was treated with combined therapy had fewer relapses (45%) compared with the group who received prednisone alone (84%).

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the most common inflammatory arthritis and second only to osteoarthritis as the most common type of arthritis. The disease affects about 1% of the adult population with a peak incidence between the 35th and 45th year; however, new onset of disease is not uncommon in older people. Several surveys have shown that the incidence of rheumatoid arthritis in the 60 or older age group amounts to 10% to 20% of the total population with RA. As a result of new cases being added to those carrying residua from prior onset, the prevalence of RA rises with age. The prevalence among 537 79-year-olds in Gothenburg, Sweden, was 10%.¹⁴⁶ Other surveys have found the prevalence to be even higher. In all age groups, women have the disease more often than men do. At any age, the disease needs to be diagnosed promptly and treatment started early as joint damage occurs early in the course of the disease, although in some patients there is continuous progression of joint damage.¹⁴⁷

The disease is characterized by synovial thickening in the involved joints, and this soft tissue swelling can be readily palpated allowing diagnosis and separation from OA. Normal synovium is only one or two cell layers thick and cannot normally be appreciated on examination. In OA, bony overgrowth rather than soft tissue swelling causes the joint enlargement. The pattern of joint involvement in RA is quite different than in OA. There is usually sparing of the distal interphalangeal joints, and the axial skeleton, and wrist, elbow, and shoulder involvement is common in RA and uncommon in OA. However, it is very common to encounter OA in the older patient with RA because of the high prevalence of OA in this group as well as the increased prevalence of OA in previously damaged joints. In patients with earlier onset of RA, the articular disease may "burn out" in old age, but others have argued that once established the disease will likely require treatment for that patient's life-

time.¹⁴⁸ The disease can shorten the patient's life span and is a major cause of disability. Even disease that begins very late in life (median age, 73 years) is associated with marked increased morbidity and mortality compared to an age-matched general population.¹⁴⁹ It reduces the quality of life in almost all patients. On an optimistic note, there has been an explosion in successful treatment options in the past several years that has created an excitement among rheumatologists that has probably not been experienced since the disease was first named by Alfred Baring Garrod in 1876.

Epidemiology

Rheumatoid arthritis is present worldwide, but the incidence varies widely in different populations. Women are two- to threefold more likely than men to develop RA. The explanation for this has not been fully elucidated. Estrogen and pregnancy mitigates against the development of RA, and pregnancy improves the symptoms of RA in about 75% of patients. Postpartum flares of RA are common. Prolactin has a likely role in rheumatoid inflammation stimulating T-cell activity and promoting inflammation, with new evidence suggesting a paracrine effect of prolactin because of its production by T lymphocytes infiltrating synovium.¹⁵⁰ However, no consistent association between postmenopausal estrogen therapy and disease activity in RA has been demonstrated.¹⁵¹ The phenotype of rheumatoid arthritis may be different in men and women. Erosive arthritis is more common in men, but structural consequences requiring joint surgery was more common in women. In one study, arthroplasties and arthrodesis of hand and foot joints were performed 34 times in women and once in men (the study had 110 women and 55 men with RA).¹⁵² Nodules and rheumatoid lung disease were more common in men, and the sicca syndrome was more common in women.

There is a strong genetic basis for the development of rheumatoid arthritis. In most but not all populations, there is an association between the MHC class II HLA-DR1 and -DR4 genes and seropositive (rheumatoid factor-positive) RA. This HLA association influences the severity and persistence of the disease more than the absolute predisposition to the development of RA. A 5-amino-acid sequence is present in position 70 to 74 in the third hypervariable region of DR-beta-1 molecules that is present in the haplotypes associated with RA. HLA-DR molecules encode nonpolymorphic alpha (A) chains and polymorphic beta (B) chains. The subtypes of the beta chains of HLA-DR1 and -4 are now designated B1*0101, B1*0401, etc. Patients expressing two DR haplotypes carrying the shared epitope in position 70 to 74 have the highest risk of developing severe disease.

Etiology

Joints have unique qualities that may predispose them to damage in the presence of immune inflammation. The cartilage is avascular and has limited ability for repair. Chondrocytes are able to produce proinflammatory cytokines and toxic oxygen species when appropriately stimulated, leading to cell death and irreversible cartilage damage. Antigens that penetrate into the joint may be able to persist on cartilage for prolonged periods of time while inducing an inflammatory reaction that may be difficult to extinguish. There is a sense that once inflammation starts in the confines of the joint with release of self-antigens and persistence of the inciting antigen, it becomes self-sustaining. Once joint damage ensues, the joint may become unstable, leading to further joint deterioration.

The inflamed synovial membrane becomes infiltrated with activated lymphocytes and macrophages. Most investigations have focused on activated T lymphocytes, suggesting that presentation of antigen to effector T cells is involved in the pathogenesis of RA. However, B lymphocytes, mast cells, and especially macrophages are enriched in rheumatoid synovium and contribute to the soup of activated cells, chemokines, cytokines, lytic enzymes, etc., that makes up the pannus and synovial fluid.

Rheumatoid factors are autoantibodies, classically IgM but of any isotype, reacting to epitopes in the Fc portion of IgG. These autoantibodies may be present in the sera of patients with a variety of inflammatory diseases, and they are present in putatively normal subjects, especially those over the age of 60 years. However, in one recent study, the prevalence of rheumatoid factor was only increased in older subjects with chronic illnesses and not in healthy elderly subjects.¹⁵³ This finding raises the possibility that the presence of rheumatoid factor is related more to global health status than to the effects of aging. Rheumatoid factor, although not specific for RA, is nevertheless an important serologic test supporting a diagnosis of RA. Seropositivity is associated with more aggressive joint destruction, the presence of nodules, and extra-articular manifestations. Rheumatoid factors are prominent constituents of immune complexes, enhancing complement activation and influencing the processing of the complexes. Rheumatoid factor can interfere with phagocytosis of IgG complexes and directly activate natural killer cells.

Clinical Features

The clinical course and prognosis of RA in adults varies widely, ranging from a mild pauciarticular disease to a progressive destructive symmetric polyarthritis associated with systemic vasculitis. The pattern is influenced by

sex, rapidity of onset, presence of rheumatoid factor, and genetic and endocrine factors. In general, patients whose sera contain high titers of rheumatoid factor fare less well. Insidious onset and slow progression are usual but sudden onset of RA occurs and the latter is generally associated with a better prognosis. Age is of significance, and when onset occurs before the age of 16 years, the difference in clinical presentation is recognized by its separate classification of juvenile rheumatoid arthritis. Changes in the pattern of disease in old age are less well recognized. Nevertheless, the few studies that have addressed onset of RA after age 60 have noted a greater frequency of acute onset, systemic symptoms, and large joint involvement, as well as less rheumatoid factor seropositivity, than in younger patients, and a better prognosis for seronegative elderly-onset rheumatoid arthritis.

Most elderly patients with RA have lived with their disease since youth or middle years. In many cases, the disease is no longer active, and the patient presents with functional deficits from deformities or with symptoms and signs of superimposed osteoarthritis. However, some patients continue to show evidence of active synovitis, or they develop serious extra-articular and systemic complications such as vasculitis presenting as skin ulcers or mononeuritis multiplex.

When rheumatoid arthritis has its onset after the age of 60 years, the clinical picture conforms more often than not to the pattern seen in younger patients. Constitutional symptoms such as fatigue, weight loss, and generalized stiffness may precede or accompany the insidious onset of arthritis in the small joints of hands and feet, wrists, and knees. Symmetric swelling of the second and third metacarpophalangeal joints (MCP), fusiform swelling of the fingers, and prolonged morning stiffness of the inflamed joints are characteristic. Later, arthritis may spread to involve more central joints. As the disease progresses, erosions of bone of the MCP and PIP joints, the wrists, and the metatarsophalangeal (MTP) joints become visible on radiographic examination. Progressive joint damage leads to the development of characteristic deformities. This presentation is usually associated with rheumatoid factor positivity, and rheumatoid nodules are seen in approximately 25% of the patients. Unlike early-onset RA, vasculitis is uncommon in RA that has its onset in later years. A retrospective review of the natural history and clinical features of RA in 129 patients with onset after age 60 years had some disquieting findings.¹⁵⁴ Forty-eight patients had abrupt onset, with illness occurring in less than 2 months; 69 had indolent onset, with illness occurring from 2 to 6 months; and 12 had a polymyalgia rheumatica-like syndrome. Of the 129 patients, 91% were rheumatoid factor positive, and 83% had erosive disease. Secondary Sjögren's syndrome was present in 63% of the patients. Most of the patients

had progressive erosive joint disease. Over the 6-year follow-up period, there were eight deaths, three directly attributable to active RA.

Several medical reports indicate that about a quarter of patients with elderly-onset RA (EORA) exhibit a clinical picture that is less often seen in younger age groups. This subgroup is characterized by the acute and florid onset of arthritis, early and more severe involvement of large joints, especially the shoulder joint, prominent constitutional symptoms, very high sedimentation rates, and a near equal sex distribution.¹⁵⁴ Three small studies that included a younger onset rheumatoid arthritis (YORA) group for direct comparison¹⁵⁵⁻¹⁵⁷ found abrupt onset arthritis occurred nearly twice as often in the EORA group.¹⁵⁷ Younger patients were twice as likely to have small joint disease, whereas elderly patients tended to have more arthritis in hips and shoulders. Patients with EORA had a higher initial sedimentation rate and were more likely to be negative for rheumatoid factor. A polymyalgia rheumatica-like presentation was observed in 23% of the EORA group, compared with only 5% of the YORA group. Both groups received nearly identical treatment. Patients with EORA had significantly better outcomes than younger patients after a disease duration of 2.5 years and at the end of the study, some 5 years after disease onset. These outcome differences persisted when patients with polymyalgia-like presentations were excluded from the analysis.

Although RA is often associated with systemic features and extra-articular organ involvement, it is first and foremost an arthritis, characterized by synovial thickening and inflammation. Some patients, especially those with rheumatoid factor and those with more severe disease, have nodules that are prominent over pressure sites such as the forearm. These patients more often experience extra-articular inflammation such as rheumatoid lung disease. Morning stiffness that represents pain with joint motion may last for hours and often makes morning activities of daily living very difficult to perform. Hand involvement is the bellwether of the disease. Foot involvement usually mirrors the hand arthritis. Flexion contractures can develop early, although in the wrist it is the loss of extension that may occur rapidly and contribute to hand weakness. The subtalar joint, the joint that provides inversion and eversion of the foot, is often involved with inflammation early in the disease, and limited motion commences quickly. Fatigue is common.

Atlantoaxial subluxation happens frequently in patients with chronic RA. The odontoid process is normally surrounded by synovium, and as this synovium proliferates, it can rupture the transverse ligament that normally keeps the odontoid process snug to the posterior portion of C1. Over time, the odontoid shifts becomes more posterior in position as C1 slips forward on C2, with the odontoid compressing the cervical cord.

Pyramidal tract findings may be detected on examination. Deep tendon reflexes usually decrease with age, but with high cord compression, the reflexes may be hyperactive and Hoffman's sign may be positive and the toes upgoing with the Babinski maneuver. Remembering the possibility of atlantoaxial subluxation is important if neck manipulation is planned, for instance, when inducing general anesthesia or with physical therapy or chiropractic treatment. It is also important to remember that older patients with "burnt-out" RA can harbor asymptomatic atlantoaxial subluxation that may become symptomatic with manipulation. Plain cervical spine radiographs in flexion and extension usually detect the cervical instability and atlantoaxial subluxation, although MRI best demonstrates the cervical cord compression.

The joint fluid is always inflammatory in RA and has a predominance of neutrophils on examination. Anemia is common, and the acute-phase reactant proteins are usually elevated. Renal and liver involvement are uncommon, although the medications used to treat RA can induce abnormalities in those organs. Pulmonary involvement occurs more frequently than renal or liver involvement and can have a variety of manifestations that include interstitial fibrosis and pleural inflammation. Cardiovascular disease may be more common in RA and is a cause of 40% of the increased mortality seen in the disease.^{158,159} Male sex, rheumatoid factor positivity, and late age of RA onset predicted premature death due to cardiovascular disease.¹⁶⁰

Differential Diagnosis

Rheumatoid arthritis is usually easy to diagnose at the bedside, but symmetric small joint synovitis may be seen in other diseases. Systemic lupus erythematosus with predominantly joint involvement and polymyalgia rheumatica may be difficult to differentiate from early RA. Even sarcoid and certain viral infections can mimic early RA. However, once RA is established, the disease is quite unique having exuberant pannus formation, nodules, and characteristic hand changes including prominent ulnar deviation of the fingers.

The clinical overlap between RA, especially seronegative disease, and polymyalgia rheumatica can be quite striking.¹⁶¹ When a patient presents with constitutional symptoms, marked shoulder synovitis, and a high erythrocyte sedimentation rate (ESR), it is often difficult to differentiate polymyalgia rheumatica (PMR) from EORA. The two diseases have many manifestations in common. PMR is usually an axial synovitis, primarily of hips and shoulders, but peripheral synovitis is seen in a third of the patients, most frequently involving knees, wrists, carpal tunnels, and metacarpophalangeal joints. It is not unusual to diagnose polymyalgia rheumatica and find the disease "progressing" to RA as the arthritis per-

sists.¹⁶² The difficulty in separating these two diseases poses a challenge to geriatricians and rheumatologists.

Amyloid arthropathy may be mistaken for RA. Primary amyloid and that which occurs in association with multiple myeloma may infiltrate the synovium of joints and periarticular structures, causing joint swelling and sometimes carpal tunnel syndrome. Prolonged morning stiffness is not a feature of amyloid arthritis. Other conditions that need to be excluded include erosive osteoarthritis of the hands, polyarticular gout and other crystal diseases, and cancer-related syndromes, including pulmonary osteoarthropathy.

Treatment

The treatment of a chronic disease of unknown etiology can be difficult. However, a standardized approach to the treatment of RA has become generally accepted although there is wide latitude about the timing and type of medication use. Early diagnosis is extremely important because significant joint damage occurs early in RA. The treatment of RA arising *de novo* in the elderly follows the same guidelines as in younger patients. The main objectives are to reduce or suppress inflammation, relieve pain, and preserve muscle and joint function. Appropriate drug treatment in concert with systemic and local rest, good nutrition, physical and occupational therapy, use of appropriate appliances and special equipment, and orthopedic evaluation and corrective surgery are the mainstays of the management program. Every patient with RA should have a physical exercise program tailored for optimum activity and rest. Patients must learn that both excessive rest and excessive exercise can lead to increased joint stress. Prescribed individual exercises alternating with specific rest periods are required to maintain good muscle tone and avoid fatigue.

Treatment is needed at every stage of the disease. Patient education and effective communication between the medical and nursing personnel and the patient and family are crucial. Physical and occupational therapies are needed in most patients.

Drug Treatment

Three major classes of drugs are available in the treatment of rheumatoid arthritis: nonsteroidal anti-inflammatory drugs, corticosteroids, and disease-modifying drugs. Until recently, it was customary to start a patient with newly diagnosed rheumatoid arthritis on aspirin or one of the newer NSAIDs. These drugs are quick in their action, provide symptomatic relief, and often reduce joint swelling, but they do not prevent progression of rheumatoid arthritis. Because there is only a narrow window between disease onset and the beginning of irreversible joint destruction, a more vigorous

approach to treatment is essential. In recent years, several new disease-modifying drugs with proven and prompt efficacy in the majority of patients have been added to the treatment armamentarium. These drugs have not been studied extensively in the elderly, and their interactions with other medications and concurrent illnesses have also not been well studied.

The cautious use of NSAIDs and the new selective cyclooxygenase inhibitors has been discussed under osteoarthritis. A key difference in treating RA is that to obtain the anti-inflammatory effect of NSAIDs they must be administered in a higher dosage than is required for relief of pain. The principles guiding the use of these drugs in the older patient with inflammatory arthritis dictate that the starting dose should be low, that adjustments are made stepwise until optimal therapeutic response is obtained, and that the maximum tolerated dose may well be lower than that for younger individuals. Physiologic changes that occur with aging may profoundly alter patient response to therapy. Most NSAIDs are bound to plasma proteins. In elderly patients with low serum albumin concentration and in patients who are treated with other drugs that bind to plasma proteins, concomitant treatment with an NSAID may require a reduction in its dose. Drug interactions are more likely in the elderly, who frequently take multiple medications. Potential drug interactions of NSAIDs with some of the most commonly used drugs in the elderly (anticoagulants, hypoglycemic drugs, digoxin, antihypertensives, and diuretics) should be kept in mind.

Most patients who develop joint erosions do so within 2 years of onset of joint symptoms. It is important to identify these patients early on in the course of RA. The indications for commencing second-line or disease-modifying antirheumatic drugs (DMARDs) are not different in elderly patients. Experience to date suggests that second-line drugs are as effective in the older age groups as in younger patients but that the elderly are at increased risk of developing adverse effects, in part as a consequence of altered pharmacokinetics and reduced functional reserve of organ systems. In the study of late-onset RA, 77% of the patients required continued use of disease-modifying drugs to maintain disease control.¹⁵⁴ Overall, methotrexate was the most efficacious second-line drug in EORA, with clinical improvement being noted in 33 of 37 cases.

Methotrexate

Methotrexate has become the drug treatment of choice of rheumatoid arthritis in patients with progressive disease and disease that is or likely will be destructive. It is administered in pulse fashion, usually orally once weekly in divided doses, with 7.5 mg being the current standard starting dose. In the elderly, starting at lower

doses may reduce the incidence of stomatitis and gastrointestinal symptoms. We prescribe daily folic acid (1 mg) as it likely reduces some of the gastrointestinal and hepatic side effects. Liver and bone marrow monitoring should be performed bimonthly, and renal function should be assessed periodically. In patients with diabetes mellitus or heart disease, renal testing should be more frequent. Methotrexate is almost completely cleared by the kidney and should not be used in patients with renal insufficiency. The original concern with methotrexate use in RA was with its liver toxicity; that complication has proved uncommon with pulse use as just described, although regular liver testing is recommended. Hypersensitivity reactions involving the lungs are uncommon although often serious. If cough or shortness of breath develops in patients receiving methotrexate, drug cessation and complete evaluation of the patient for causation are warranted.

Hydroxychloroquine, Sulfasalazine, and Minocycline

Hydroxychloroquine has been used to treat inflammatory arthritis for many years. The drug is safe but generally less effective than the other disease-modifying medications. There is concern about retinal toxicity after long-term use, although that is uncommon. Ophthalmologic evaluations should be performed twice yearly. Skin rash occurs occasionally and can be severe. Hydroxychloroquine is most often used early in the course of mild RA and in combination with other medications (see following). The dose is 200mg twice daily, often reduced to 200mg daily when a good response has been obtained. We never hesitate to use it in older patients, even those with ophthalmologic disorders, but always in consultation with ophthalmologists.

Sulfasalazine has been used to treat RA since the 1940s. It is more widely used in Europe than in the United States, where it is often used in combination with methotrexate and hydroxychloroquine. We start with 1.0g daily and increase the dosage slowly to 3.0g daily in older patients. Sulfa allergy needs to be excluded before its use. Extra fluids need to be administered to prevent renal stones, and serial blood testing monitoring the bone marrow and liver should be performed.

Minocycline is another modestly effective disease-modifying drug that can slow the progression of RA.¹⁶³

Newer Agents

Tumor Necrosis Factor Inhibitors. It appears that the cytokine TNF plays a central role in chronic inflammation. Early on after its identification, TNF was thought to primarily play a role in defending the body from gram-

negative infections; it is produced by macrophages and activated T lymphocytes and is found in excess in rheumatoid arthritis and other inflammatory states. TNF stimulates the production of other proinflammatory cytokines, activates neutrophils and endothelial cells, is a pyrogen, and at higher levels causes cachexia and even hypotension and decreased cardiac contractility. Receptors for TNF are present on almost all cells.

Two biologic agents are available to decrease TNF- α . Etanercept is the soluble recombinant receptor protein for the p75 TNF- α protein combined with immunoglobulin G. This agent is self-injected subcutaneously twice weekly. Infliximab is a recombinant humanized antibody to TNF. It is administered intravenously on a regular schedule and has been successfully used in the treatment of Crohn's disease and for its complications of fistula formation. Both drugs, when administered concomitantly with methotrexate, are setting new standards for effectiveness in suppressing the inflammation in rheumatoid arthritis and delaying or stopping the progression of x-ray changes. Etanercept has recently been approved for use alone after being studied as the sole disease-modifying agent in early RA. Both etanercept and infliximab work quickly and to date are associated with few side effects. There is, however, great concern about the patient's ability to handle bacterial infections with their chronic use. As of now, the benefits of this therapy seem to greatly outweigh this concern. The medications should be stopped when infection is present.

Leflunomide. Leflunomide is a reversible inhibitor of dihydroorotate dehydrogenase, a key enzyme in pyrimidine synthesis.¹⁶⁴ It provides a novel approach to the treatment of RA and may be as effective as methotrexate. It has also been used in combination with methotrexate. The drug can cause diarrhea, hair loss, and elevation of liver enzymes.

Azathioprine. Azathioprine should be restricted to patients with severe, active, and erosive disease that has not responded to other DMARDs. The initial dose should be approximately 1.0mg/kg. Therapeutic response usually occurs after 6 to 8 weeks of treatment. The dose may be increased after several weeks if there are no toxicities and the initial response is suboptimal. Dose increments should be 0.5mg/kg daily up to a maximum dose of 2.0mg/kg/day. Patients who have no improvement after 12 weeks should be considered refractory.

Corticosteroids. The use of high-dose corticosteroids administered orally or parenterally in RA can be life-saving in elderly patients with serious systemic complications such as vasculitis. In smaller doses, corticosteroids

are helpful in maintaining mobility and reducing long-term disability. This beneficial effect of corticosteroids is particularly useful in the elderly who may have other conditions affecting ambulation and for whom superimposed RA might become the final event leading to a sedentary existence. The ability to remain ambulatory and active will generally offset the risk of osteoporosis and compression fracture due to steroid therapy. From a purely practical standpoint, the ease of administration, low cost, and relative safety of low doses make corticosteroids a reasonable alternative for the elderly with persistent disabling systemic manifestations refractory to other therapeutic modalities. The recommended dose is 5 to 10 mg of prednisone given once daily in the morning. Alternate-day regimens are usually not effective in RA. Prednisone also is useful as a therapeutic bridge between aspirin and other nonsteroidal anti-inflammatory drugs and the DMARDs, which may not become effective for several months. Finally, it is reasonable to treat the subgroup of elderly-onset RA with constitutional symptoms and proximal joint involvement in the same way as one would polymyalgia rheumatica, that is, an initial dose of prednisone of 10 to 15 mg/day. As constitutional symptoms subside and the erythrocyte sedimentation rate falls, prednisone is tapered slowly to the lowest dose that will control symptoms. The side effects of corticosteroids are legion. Adverse reactions that pertain particularly to the elderly include compression fractures, osteonecrosis, skin changes of steroid atrophy and purpura, electrolyte disturbances and fluid retention, glaucoma, and increased risk of sepsis. Osteoporosis, however, can be preempted in part with the concomitant use of bisphosphonate medications.¹⁶⁵

Combination Therapy

Most patients with rheumatoid arthritis respond best to a combination of drugs. It is usual in the United States to combine low doses of prednisone with initial treatment of RA. Reduction of the drug should start when the disease improves or stabilizes. The addition of hydroxychloroquine and sulfasalazine to methotrexate is frequently employed in patients not responding to methotrexate alone. Today, we more often add etanercept or infliximab to methotrexate if the RA is progressing or not adequately suppressed. We are using leflunomide in recalcitrant disease, often in combination with the medications already mentioned.

The potential oncogenic effects of immunosuppressive drugs have been assessed. Even in the absence of immunosuppressive treatment, patients with rheumatoid arthritis have a twofold increased risk of developing non-Hodgkin's lymphoma. This risk increases in patients treated with azathioprine or cyclophosphamide.

Intra-articular injection of "depot" corticosteroids is a useful adjunct for synovitis limited to a few joints. Repeat injections into the same joint can be associated with necrosis and collapse of bone. For this reason, injections into one joint should be spaced not less than 3 months apart, and no joint should be injected repeatedly.

Prognosis

Rheumatoid arthritis is not thought of as a fatal disease. Nonetheless, these patients have a reduced life expectancy. Patients with a more severe disease at baseline, manifested by many involved joints and poor functional status, are those at greatest risk of premature death. Most patients die of the same causes as the general population but at an earlier age. Patients with RA have an increased susceptibility to bacterial infections, and all studies have shown an increased death rate from infections. In a carefully conducted study of more than 1000 patients with RA in the Canadian province of Saskatchewan, Mitchell et al. identified 233 deaths over a mean period of 12 years, 79 more than expected in a matched control population.¹⁶⁶ Survival in rheumatoid arthritis was diminished by 4 years in men and by 10 years in women. Of the 79 excess deaths, 18 were caused by infection, particularly pneumonia and sepsis; 20 were directly related to rheumatoid arthritis, including vasculitis, rheumatoid lung disease, and cervical subluxation, whereas 8 could be attributed to complications of drug therapy, mainly gastrointestinal bleeding and perforation. Only 1 death was caused by drug-induced blood dyscrasia. Amyloidosis and renal failure appear to cause death in rheumatoid arthritis patients four to five times more frequently in Finland than in North America.¹⁶⁷

Conclusion

The diagnosis and treatment of rheumatoid arthritis should be made in concert with a rheumatologist. In the elderly, concomitant osteoarthritis can cloud the physical findings of RA, and the similarity of early RA and systemic lupus erythematosus and polymyalgia rheumatica can be striking. Treatment should be appropriately aggressive with awareness of all the complicating features of aging and diseases that occur with older age. Modification of medication regimes should always be considered. Lower doses of drugs and less frequent administration of the tumor necrosis factor antagonists may be needed in many older patients. Laboratory testing for possible drug side effects may have to be performed more often than customary in selected older patients. Close collaboration between the primary care physician, the geriatrician, the rheumatologist, and the patient will provide for the best treatment decisions.

Sjögren's Syndrome

Introduction and Demographics

It is common to attend an older patient with complaints of mucosal dryness. Tears and saliva decrease with age, although salivary and presumably lacrimal gland function is well preserved in the healthy older population. Saliva does become thicker and more viscous with aging. Medications that patients take for concurrent medical disorders are frequently associated with mucosal dryness. The diuretic, antihistamine, antidepressant, anticholinergic, and beta-blocker medications are especially associated with dryness of the oral, nasal, and eye mucosal surfaces. Chronic mouth breathing can diminish saliva, as can many systemic illnesses such as diabetes mellitus because of autonomic neuropathy and renal insufficiency. Approximately 27% of individuals aged 65 to 84 years report dry eye or dry mouth symptoms to be present often or all the time.¹⁶⁸

Sjögren's syndrome, a frequently underdiagnosed autoimmune disorder, should be considered in patients presenting with the sicca complex (xerophthalmia and xerostomia), especially if systemic features of illness are present.¹⁶⁸ Sjögren's syndrome, estimated to be the second most common autoimmune rheumatic disease after rheumatoid arthritis, affects about 2% of the adult population. This disorder may occur alone (primary Sjögren's syndrome) or in association with other autoimmune diseases, primarily rheumatoid arthritis and systemic lupus erythematosus. Secondary Sjögren's syndrome parallels the age distribution of the associated diseases whereas primary Sjögren's syndrome predominates in the older age group. More than 90% of the patients are women. Age does not modify the clinical picture; however, it does complicate the diagnosis because of the common complaint of dryness in older patients.

Henrik Sjögren was a Swedish ophthalmologist who described the syndrome bearing his name in 1933. He reported 19 adult women with sicca symptoms and systemic manifestations of illness, especially arthritis, and emphasized the systemic nature of the illness. The illness is worldwide in distribution and runs the gamut from simple xerostomia to systemic features including brain and peripheral nerve inflammation.

Pathogenesis

Sjögren's syndrome occurs more frequently in families than would be expected. There is an association between the disease and the major histocompatibility haplotype HLA-DR3 in Caucasians. There are different associations with the major histocompatibility locus in different ethnic populations. These differences may reflect influ-

ences on autoantibody production rather than disease susceptibility. The underlying process is a lymphocyte-mediated destruction of exocrine glands that leads to diminished or absent glandular secretions and mucosal dryness. Biopsies of salivary and lacrimal tissue reveal damaged acini and lymphoid infiltrates with a predominance of CD4+ T-helper cells. B-cell activation accounts for the local production of immunoglobulin and autoantibodies, including rheumatoid factor. Blocked apoptosis may be present in the lymphocytes residing in the salivary gland periductal aggregates,¹⁶⁹ and the activated T cells may induce apoptosis of the acinar cells.¹⁷⁰ In addition to lacrimal and salivary glands, other exocrine glands may be affected. In about a quarter of the patients, there is evidence of extension of lymphoproliferation to extraglandular sites, such as lymph nodes, lung, kidney, the central nervous system, and bone marrow. The lymphoid infiltrates may be benign or malignant. The term pseudolymphoma describes tumor-like clusters of lymphoid cells that do not meet the histologic criteria for malignancy. In the kidney, the histopathologic lesion is interstitial lymphocytic infiltration with tubular atrophy and fibrosis, which clinically presents as hyposthenuria and renal tubular acidosis. Involvement of the lungs leads to diffuse interstitial pneumonitis or fibrosis. There is an association between Sjögren's syndrome and lymphoma, especially lymphomas of mucosa-associated lymphoid tissue.

Clinical Presentation

Xerostomia and xerophthalmia are the most common complaints in patients with Sjögren's syndrome. Many patients present with other manifestations of the disease such as arthritis or neurologic abnormalities ranging from peripheral neuropathy to central nervous system involvement. In patients with primary Sjögren's syndrome, Raynaud's phenomenon and a nondeforming, nonerosive polyarthritis are the most common extraglandular manifestations. Sjögren's syndrome should be considered in any elderly patient with unexplained systemic features, even disorders as common as peripheral neuropathy. Asking patients about oral or lacrimal dryness or a gritty sensation in the eyes may elicit the clues that will help make the diagnosis. The lack of saliva pooling under the tongue and obvious nasal and lacrimal dryness are usually present on examination. A parched tongue on examination, complaints of fatigue, and interruptions of the patient's narrative history by frequent drinking of water may also be clues to the diagnosis. Dry skin due to immunologic injury of the exocrine glands is a common complaint. The dry throat, nose, and trachea lead to a chronic nonproductive cough and hoarseness. Upper gastrointestinal involvement may cause dysphagia and atrophic gastritis with achlorhydria. Vaginal involvement

causes dyspareunia and pruritus. Pulmonary and renal involvement with inflammation are common occurrences, leading to shortness of breath and cough and hyposthenuria and mild renal insufficiency, respectively.

Neurologic manifestations are common and protean. Peripheral nervous system involvement with sensory neuropathy are most common, followed by cranial nerve palsies, especially trigeminal sensory neuropathy. Carpal tunnel manifestations may be seen in many patients. In some small studies, the majority of patients were found to have neurologic deficits.^{171,172} Spinal cord involvement can result in neurogenic bladder and paraparesis secondary to transverse myelitis or chronic progressive myelopathy. Central nervous system involvement is more difficult to assess. Focal high dense cerebral white matters lesions are seen on MRI examinations,¹⁷³ and Sjögren's patients may present with chronic or acute CNS disturbances ranging from cognitive loss and depression to strokes and neurologic findings mimicking multiple sclerosis.

About 20% of patients with primary Sjögren's syndrome develop vasculitis, which presents with purpura and other cutaneous manifestations, myositis, or mononeuritis multiplex. Histopathologic studies have shown this to be mononuclear cell or less often a neutrophilic vasculitis. A strong association exists between vasculitis and active CNS disease. An immune complex glomerulonephritis has also been reported.

Diagnosis

Sjögren's syndrome is more common than previous estimates. This diagnosis should be considered in elderly patients with unexplained neuropsychiatric dysfunction, interstitial lung disease, or polyarthritis. Patients with Sjögren's syndrome can fall anywhere along a spectrum ranging from benign sicca syndrome with local involvement of exocrine glands to extracellular spread of benign lymphoproliferation and symptoms secondary to various organ involvement. Lymphoreticular malignancy may occur.

The combination of sicca symptoms, systemic illness, and abnormal laboratory testing will establish the diagnosis in most patients. Saliva production can usually be assessed by visual inspection. The Schirmer test is easily performed at the bedside. If the Whatman no. 41 filter paper hanging from the lower conjunctival sac has less than 5 mm of wetting within 5 min, it is considered abnormal. Other important diagnostic aids in the sicca syndrome are rose bengal or fluorescein staining of the cornea to document filamentary keratitis. However, dryness does not always mean the presence of Sjögren's syndrome, as xerophthalmia has a wide diagnostic base (see following). Laboratory testing for inflammation (the Westergren sedimentation rate, C-reactive protein, nor-

TABLE 42.3. Serologic laboratory testing for Sjögren's syndrome.

Antinuclear antibodies (ANA): almost always positive
Rheumatoid factor: 60%–80% of patients
Cryoglobulins: 15% of patients
Antineutrophil cytoplasmic antibodies (ANCA): approximately 11%, especially in cutaneous vasculitis and peripheral neuropathy
Anti-Ro/SS-A ^a : found in 50%–80% of patients with primary disease
Anti-La/SS-A ^a : found in 30%–60% of patients with primary disease

^aThese antibodies are not specific for Sjögren's syndrome; they can be present in systemic lupus erythematosus, are almost always present in subacute cutaneous lupus, and are found in other autoimmune disorders.

mocytic, and normochromic anemia) is usually abnormal. Rheumatoid factor may also be positive. The incidence of anti-Ro(SS-A) and anti-La(SS-B) antibodies is very high and serves as a reliable diagnostic marker for Sjögren's syndrome in its primary form or when it occurs in association with systemic lupus erythematosus (Table 42.3). Lip or gingival biopsy may allow for a specific diagnosis. The findings of focal lymphocytic sialadenitis in the minor salivary glands can establish the diagnosis and provide a rough estimation about the severity of the disease. Parotid gland biopsy can be performed in selected patients who have parotid gland enlargement. Salivary gland enlargement can sometimes be difficult to assess because of the commonly seen benign enlargement caused by adipose cell infiltration in older patients. The cerebrospinal fluid findings in CNS disease may include a mild mononuclear cell pleocytosis, elevated total protein and IgG, and oligoclonal bands on agarose gel electrophoresis. In contrast to multiple sclerosis, which usually has between 2 and 10 bands, patients with Sjögren's syndrome generally have only 1 or 2 bands.

Prognosis and Treatment

The course of Sjögren's syndrome is variable. Many patients just need treatment and advice regarding the sicca symptoms, but others will have life-threatening vasculitis and neuropathy that require intervention with major medications. There is always a concern about the development of lymphoma. In one study, there was increased risk for the development of lymphoma in patients with swollen salivary glands, lymphadenopathy, and leg ulcers.¹⁷⁴ In three large series, lymphomas, usually of a non-Hodgkin's, B-cell type, were diagnosed in 2.3%, 4.7%, and 5.8% of the patients. The interval between the onset of symptoms of the sicca syndrome and the diagnosis of malignancy ranged from 18 months to 12 years. The development or progression of neuropathy has not been well defined and needs to await future studies.

The symptomatic treatment (there is no curative treatment) of Sjögren's syndrome include artificial tears and

adequate oral intake. Consultation with an ophthalmologist and oral hygienist is mandatory. Local measures for relief of sicca symptoms include artificial tears for keratoconjunctivitis, oral lubricants containing a carboxymethyl cellulose base (Xero-lube, Saliva Substitute), and K-Y jelly for sicca vaginitis. Oral pilocarpine is effective in increasing saliva and is well tolerated, although excessive sweating is a common adverse effect. Recently, cevimeline, a cholinergic agonist that binds to muscarinic receptors, has been approved for use in Sjögren's syndrome. Hydroxychloroquine is used frequently by rheumatologists in the treatment of Sjögren's syndrome. The drug has proved to have salutary effects in other autoimmune diseases and may benefit some patients. There is reduction of erythrocyte sedimentation rates and other measures of inflammation.¹⁷⁵ Low-dose prednisone therapy increases saliva production,¹⁷⁶ but whether that improvement outweighs the deleterious effects of prednisone on the elderly patient remains to be determined.

Treatment of the vasculitis components of the disease includes use of all the major immunosuppressive and chemotherapy medications. Lymphoma is treated with the standard antitumor protocols.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a distinctive chronic inflammatory disorder of unknown cause that can affect any tissue and organ but predominantly affects the skin, joints, and kidney. It is the prototype for the autoimmune diseases, representing a dysregulated immune system producing autoantibodies that can damage tissues. There are variants of lupus erythematosus that involve only the skin (discoid lupus erythematosus), or predominantly the skin (subacute cutaneous lupus erythematosus), or occur because of reactions to drugs (drug-induced lupus erythematosus). There are also disorders that overlap a variety of the autoimmune disorders, such as mixed connective tissue disease and undifferentiated connective tissue disease, the latter an entity that includes SLE-like clinical or laboratory findings but with overlap of other diseases making the exact diagnosis uncertain. The antiphospholipid syndrome has been better defined, and with its considerable overlap with SLE is discussed later.

The diagnosis of SLE in older patients may present a challenge to the geriatrician. Clinical findings may be subtle or unrepresentative of the "classic" lupus-like findings, and symptoms and signs of disease may suggest a variety of other illnesses or be as nonspecific as unexplained fever or arthralgia. Laboratory testing can be helpful in establishing a diagnosis but also can be confusing if interpreted incorrectly.

Demographics and Clinical Presentation

Lupus is mainly a disease of younger women, and the late development of SLE after menopause is not common (but it is not rare by any means). In established SLE, lupus flares are less frequent and less severe after menopause.¹⁷⁷ In unselected series, elderly-onset SLE comprises from 6% to 18% of the SLE population; however, SLE is often not considered in the differential diagnosis of a debilitating illness in an elderly patient. Several studies of "late-onset SLE" have addressed age-related differences in the clinical picture at onset, course, survival, and serologic characteristics.¹⁷⁸⁻¹⁸² In these studies, the division between "old" and "young" was set at either 50 or 55 years and defined either as onset of symptoms or time of clinical diagnosis. Difficulties in comparing these series arise from differences in geographic region, racial distribution, age-related entry, and case selection of a relatively small number of patients in each study. Despite these variances, there is convincing evidence that age modifies the clinical expression of SLE.

Most studies indicate that female predominance is less marked in elderly patients. One study found that the sex ratio between women and men was 2:1 in the older age group compared to 7:1 in younger patients.¹⁸³ The mean age at diagnosis was almost 10 years higher for white men than for white women, and almost one-half of white men were diagnosed at age 55 years and older. This difference in age of onset is thought to be related to hormonal factors. The clinical onset of SLE in older patients may be more insidious with less typical SLE manifestations, and an increased time interval between onset of symptoms and establishment of diagnosis is frequently reported.^{180,184,185} In one series, the interval from onset of symptoms to time of diagnosis was 4 years when SLE developed after age 55 compared to 2 years in the younger age group.¹⁸⁰

Age also influences the pattern of organ involvement. Severe renal disease, neurologic complications, mesenteric vasculitis, cutaneous vasculitis, Raynaud's phenomenon, and alopecia are less common in the older group, whereas polyserositis, especially as a presenting syndrome, interstitial lung disease, and peripheral neuropathy occur more commonly. Some authors have likened the expression of SLE in the elderly to the clinical picture of drug-induced lupus. Two studies have identified increased frequency of secondary Sjögren's syndrome and of antibodies to SS-A and SS-B in white patients with late-onset SLE.^{180,181} These antibodies are found in approximately one-third of patients with SLE and in a much higher percentage of patients with primary Sjögren's syndrome. Cattogio et al. found that 38% of the patients who had onset of SLE after age 55 developed keratoconjunctivitis sicca, 88% had anti-SS-A antibodies,

and 62% had anti-SS-B antibodies compared to only 36% in younger patients.¹⁸⁰

Late-onset lupus is generally considered less severe.¹⁸⁶ This impression is partly based on the reduced steroid requirement in patients with older-onset SLE and the longer time lag between onset of symptoms and diagnosis. The perception of SLE being a more benign disease in older individuals may have to be revised in view of data on the survival of individuals with SLE. Studenski et al. could not show evidence of improved outcome with age.¹⁸³ These authors examined the effects of age, race, sex, and socioeconomic status on clinical outcome and survival utilizing multivariate analytic techniques in 411 patients with SLE, almost equally divided between whites and blacks. Black race and low economic status had independent negative effects on survival. The authors suggested that previously reported findings of improved survival rate with age may have been confounded by racial differences in age and mortality; viz., if younger groups were heavily weighted with blacks and older age groups were weighted with whites, age would appear, incorrectly, to be related to improved survival in pooled groups. Comparing 102 patients with late-onset SLE with an early-onset group in a predominantly Chinese population, researchers found no differences in all major organ involvement as well as steroid requirements between the two groups.¹⁸⁴

Fatigue and malaise are the most common symptoms of SLE. Arthritis and rash are the most common findings on physical examination, although the disease has such protean manifestations and presentations that almost any clinical abnormality can be due to SLE. The arthritis of SLE is similar in presentation to that of early RA. There is generally symmetric involvement of the small joints of the hand and the wrists. The distal interphalangeal joints are usually spared, but in older patients those joints are typically abnormal from involvement with OA. Sjögren's syndrome is more common in the elderly patient, and sometimes separating the two disorders, SLE and Sjögren's, is difficult. In patients with the antiphospholipid syndrome, stroke, thrombophlebitis, or peripheral arterial occlusion can be early manifestations of the disease.

Younger women with SLE are 50 times more likely to develop a myocardial infarction in later life than women without SLE of the same age. Older age at lupus diagnosis, longer duration of corticosteroid use, hypercholesterolemia, and postmenopausal status are more common in women presenting with a cardiovascular event.¹⁸⁷ The implications of this problem are underrecognized and require added vigilance in older patients with a history of lupus for cardiovascular disease.

Pathogenesis

The immunologic basis of SLE is complex and multifaceted. The pieces of the puzzle that include heredity, the

role of hormones, age, immune complex injury, abnormalities in B and T cells, and apoptosis have not yet all been found or pieced together. Apoptosis has assumed an increasingly important role in the understanding of autoimmune disorders. The process of programmed cell death includes both the killing and removal of dead cells. Apoptotic cells are characterized by translocation of autoantigens such as nucleosomes (the only way to generate nucleosomes in vivo is by the process of apoptosis) to the surface of the cell—these antigens become the targets of autoantibody production. In mice, this process produces transient hypergammaglobulinemia, anti-DNA and anticardiolipin antibody production, and glomerular deposits of protein.¹⁸⁸ Sturfelt et al. suggested that complement deficiency enhances the pathogenic properties of the immune complexes generated by antibody production to the exposed antigens on the apoptotic cells.¹⁸⁹ They also speculated that the immune complex-induced injury accelerates apoptosis and enhances tissue damage. The apoptotic “waste” itself may serve as immunogens for the induction of autoreactive lymphocytes.¹⁹⁰ Abnormalities in the regulation of apoptotic cells can lead to a breakdown in tolerance.^{191,192}

Laboratory Diagnosis

The laboratory testing for SLE is very helpful (Table 42.4; also see Table 42.3 for Sjögren's). The absence of antinuclear antibodies (ANA) makes the diagnosis unlikely, as ANAs are present in almost all patients with SLE. These autoantibodies may react with nucleoprotein, denatured and native DNA, Smith antigen, nuclear RNP, SS-A and SS-B antigens, histones, and other basic proteins. Most

TABLE 42.4. Laboratory testing for systemic lupus erythematosus (SLE).

1. Antibodies to nuclear antigens (ANA) are almost always positive. In “seronegative SLE” (no ANA), antibodies to SS-A may be present.
2. The speckled pattern of immunofluorescence is the most common pattern encountered in SLE.
3. The speckled pattern should be followed up with testing for antibodies to RNP (usually seen in mixed connective tissue disease), Smith (Sm), SS-A, and SS-B (the latter two are seen in both SLE and Sjögren's syndrome). The Sm antigen is extremely specific for SLE.
4. The homogenous pattern of immunofluorescence is seen in SLE and other illnesses such as rheumatoid arthritis and is the pattern usually encountered in drug-induced lupus erythematosus.
5. Antibodies to double-stranded DNA are usually specific for the diagnosis of SLE and are associated with kidney involvement. Rarely antibodies to double-stranded DNA can be seen in autoimmune liver disease.
6. Decreased levels of complement proteins are often found in active SLE but may be low in any immune complex disease, e.g., hepatitis B or C.

patients seen in a medicine clinic with positive antibodies to nuclear antigens do not have SLE. It can be demonstrated in 70% of patients with other autoimmune diseases in an assortment of other clinical entities, especially chronic inflammatory disorders involving the liver or lung, and be present in a low titer in about one-third of all "normal" elderly persons. False positivity increases with age. However, antibodies to double-stranded DNA and the Smith antigen are almost only found in SLE. Because antibodies to SS-A and SS-B are found with high frequency in elderly-onset SLE, they become useful in the diagnosis as well, although they cannot serologically distinguish SLE from primary Sjögren's syndrome. Antibodies to double-stranded (ds) DNA and to SS-A and SS-B do not occur with increased frequency in the normal elderly population. Some studies have reported a lower frequency of antibodies to ds DNA in elderly patients with SLE, but this has not been substantiated in other studies. Hypocomplementemia is more common in younger patients with SLE. In the extremely rare patient with SLE and a negative ANA, antibodies to SS-A or SS-B are usually present. Similar to any chronic disease, anemia, and elevation of acute-phase reactants are usual findings.

HLA-DR2 and -DR3 are weakly associated with SLE, HLA-DR2 occurring more frequently in young-onset SLE than in older-age onset and HLA-DR3 showing the reverse relationship. Further analysis has shown that the association between HLA phenotypes and antibodies to Ro and La are stronger than HLA correlation with SLE itself.¹⁸¹ In fact, when SS-A and SS-B antibody populations were removed from a group of 113 white SLE patients, the frequencies of HLA-DR2 and -DR3 were similar to those in normal Caucasians. SLE is more common in African-Americans, Latinos, and Asians (especially Filipinos and Chinese). The HLA-DR2 haplotype is significantly increased among Chinese patients with SLE. The Caucasian allele of HLA-DR3 present in African-Americans may be a factor in the higher prevalence and apparent more aggressive nature of SLE in African-Americans.¹⁹³

Drug-Induced Lupus

In contrast to idiopathic SLE, the incidence of drug-induced lupus (DIL) increases with age, in part reflecting the increased usage in the elderly of drugs that can produce a lupus-like syndrome. The incidence of DIL is probably decreasing from previous estimates of 50,000 cases, or 10% of all patients with SLE, because the two most responsible drugs, procainamide and hydralazine, are used far less frequently than they once were. More than 50 drugs have been reported to be associated with drug-induced autoimmunity or symptomatic lupus. Drug-

induced autoimmunity refers to induction of ANA, which is much more common than symptomatic DIL.

Two categories of drugs can be recognized: an unambiguous group that includes procainamide, hydralazine, phenytoin, quinidine, isoniazid, methyldopa, and chlorpromazine; and an ambiguous group of drugs for which anecdotal reporting has suggested a possible association. Recently reported drugs in the latter category include sulfasalazine and carbamazepine,^{194,195} although a prospective study of 200 patients with RA treated with sulfasalazine over 5 years showed no association.¹⁹⁶ Other drugs in this latter group include lovastatin and recombinant human interferon. Patients treated with the recombinant antibody to TNF-alpha, infliximab, have a relatively high incidence of generating ANA and ds DNA, and some of these patients develop clinical SLE. Drugs that induce lupus have widely dissimilar chemical features. The common denominator appears to depend on metabolic transformation to reactive metabolites that are cytotoxic. Jiang et al. have shown that the chemical transformation to reactive products requires the enzymatic action of myeloperoxidase in activated neutrophils and that the ability of drugs to induce lupus in vivo depends on their capacity to serve as substrates for myeloperoxidase in vitro.¹⁹⁷

Procainamide and hydralazine pose the greatest risk of inducing both ANA and DIL. Use of procainamide will generate a positive ANA in 80% of the patients. About a quarter of this group will manifest clinical symptoms. Women are at greater risk of developing procainamide- and hydralazine-induced lupus. The male-to-female ratio of 2:1 in symptomatic procainamide-treated patients is accounted for by the disproportionate use of procainamide in men. Approximately one-fifth of patients treated with isoniazid, methyldopa, or chlorpromazine develop positive ANA during treatment, but the incidence of a lupus-like syndrome induced by these drugs is less than 1%.

To make a diagnosis of DIL, it is necessary to exclude preexisting SLE. Symptoms typically occur after several months or years of drug therapy. Antinuclear antibodies are invariably present and usually in the homogenous pattern. Following withdrawal of the offending drug, there should be rapid improvement in the clinical symptoms and a gradual fall in the antinuclear antibodies. The most common features of DIL include fever, myalgias, arthralgias, and polyserositis. CNS and renal involvement is highly unusual. Severe cytopenias, butterfly rash, discoid lesions, and mucosal ulcerations are observed less often than in idiopathic SLE. A strong association between acetylator phenotype and the incidence of autoantibodies and DIL has been noted for procainamide and hydralazine. ANA appear more quickly in slow acetylators, and clinical symptoms occur earlier and

predominantly in patients with this phenotype. However, slow acetylator phenotype is not a general predisposing factor underlying autoimmunity, as indicated by a lack of association between acetylator phenotype and induction of ANA by isoniazid or by captopril, as well as in idiopathic SLE.

Antihistone antibodies occur in more than 90% of the DIL patients. Different drugs are associated with different antihistone profiles. Antihistone antibodies are not specific for DIL, as they are also found in idiopathic systemic lupus, although usually in a lower titer. Antibodies to denatured DNA are seen less often. Hypocomplementemia is rare in DIL, but in vivo complement activation can often be detected by measuring the cleavage products of C4.

The Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome has become a frequently diagnosed entity. It can be part of SLE, as approximately 25% of SLE patients have antibodies to phospholipid,¹⁹⁸ or the disease may exist alone or be associated with other autoimmune disorders. Historically it was seen in patients with SLE who had a false-positive test for syphilis or a prolonged partial thromboplastin time that was not corrected with normal serum (the lupus anticoagulant). Evaluation is now performed by the detection of antibodies to cardiolipin and beta₂ glycoprotein 1 as well as the lupus anticoagulant. It is of special importance to geriatricians as it is a cause of preventable arterial vascular disease, including cerebrovascular accidents. The syndrome is associated with heart valve lesions, including Libman–Sacks endocarditis, thrombocytopenia, lower extremity cutaneous ulcers, livedo reticularis, thrombophlebitis, and other disorders such as retinal thrombosis.¹⁹⁹ It is associated with recurrent fetal loss, and such history in an older woman with SLE should make the antiphospholipid syndrome suspect as an additional diagnosis.

The use of estrogen in SLE has always been controversial. Estrogen use is associated with thrombosis and reactivation of disease.²⁰⁰ The combination of estrogen use and the antiphospholipid syndrome may pose additional risks for the occurrence of thrombosis and thus estrogen must be used with great caution.

Treatment

The management of SLE has become relatively uniform during the past 5 years. Basic measures such as rest and sun avoidance are needed in selected patients. The control of hypertension is important in maintaining renal function in patients with renal disease. There is concern about the routine use of nonsteroidal anti-inflammatory

medications in patients because of resultant decreased renal blood flow. This result can be especially striking if there is preexisting renal insufficiency or cardiac failure. These drugs can all raise blood pressure in patients with renal insufficiency because of sodium retention. The antimalarial hydroxychloroquine is effective in the treatment of the arthritis and the rash of SLE. It may also be effective in preventing flares of disease.²⁰¹ (See hydroxychloroquine in the rheumatoid arthritis section.) Corticosteroids remain the drug of choice in treating patients with life-threatening illness, although the side effects of these medicines are magnified in older patients. High doses of corticosteroid are almost inevitably associated with deleterious events in the older patient. Osteoporosis, however, can be preempted in part with the concomitant use of a bisphosphonate medication.

Corticosteroid-sparing medication is used frequently and early in older patients with severe SLE. Azathioprine and methotrexate²⁰² can be very effective in allowing reduction of the corticosteroid. Cyclosporine may be effective as treatment in patients with or without renal disease,^{203,204} and mycophenolate mofetil,²⁰⁵ another transplant rejection drug, may be an important newer drug for the treatment of SLE. We are awaiting testing of some of the newer medications that have proved effective in rheumatoid arthritis, such as the tumor necrosis factor inhibitors and the pyrimidine antagonist leflunomide. Autologous stem cell transplantation may be useful in conventional treatment-resistant patients, although to date it is limited to experimental use and in younger patients.

Renal disease needs to be always suspected and assessed thoroughly in the older patient as it is in the younger SLE patient, and kidney biopsies should be performed if needed to help define the extent of the disease. Cyclophosphamide has remained the treatment of choice for diffuse proliferative glomerulonephritis. We have never withheld aggressive management for major organ involvement because of the patient's age. Renal transplantation in older patients with end-stage renal disease has been beneficial in selected patients. As in all the chronic diseases, consultation among specialists such as the nephrologist and rheumatologist will help the geriatrician and primary care doctor offer the best available treatment options to the patient.

Dermatomyositis and Polymyositis

Dermatomyositis and polymyositis are uncommon chronic idiopathic inflammatory disorders that affect muscle, skin, and other organs throughout the life span. The criterion for diagnosis include proximal symmetric muscle weakness, an elevated serum level of muscle

enzyme, an abnormal electromyogram, an abnormal muscle biopsy, and characteristic rash for dermatomyositis (heliotope rash and Gottron's papules). Dermatomyositis and polymyositis have long been considered to be accompanied by a higher incidence of malignancy than in the general population. The association is much stronger with dermatomyositis than polymyositis, and it increases with age. The rate of malignant disease in dermatomyositis in most population-based studies is reported at 20% to 25%.²⁰⁶ Although patients with polymyositis have been found to have a slightly increased rate of cancer, the increase is not highly significant and may be related to a diagnostic suspicion bias causing a more aggressive search for cancer. In general, no unusual concentration of one type of cancer has been observed, although gynecologic malignancies, in particular ovarian carcinoma and rectal adenocarcinoma, are thought by some to be overrepresented.^{207,208} The site of malignancy reflects the most common tumor types for any given age and sex, so that in the older population these would include breast, lung, ovary, colon, stomach, and uterus, in that order. The temporal relationship of malignancy and myositis is such that in about one-third of the cases myositis precedes the tumor by several years; in one-third, they occur concomitantly, and in another one-third myositis follows tumor by many years. Concurrent improvement of dermatomyositis with tumor therapy and relapse with recurrence of the tumor suggests a causal relationship. Because the association of dermatomyositis and cancer is high in the elderly, a search for cancer is justified in this age group. The most common malignancies occur in areas that can be evaluated by physical examination or fairly simple radiologic procedures such as chest x-ray and mammography. Finally, a lack of response of myositis to treatment with prednisone or other modalities should result in a more extensive search for malignancy.

Recent studies have found some important differences besides increased malignancies in older patients presenting with polymyositis and dermatomyositis. One study found that the lag time from onset of symptoms to diagnosis was significantly longer in older patients and that they tended to experience a more chronic form of the disease.²⁰⁸ In another large retrospective study comparing younger and older patients, dysphagia with abnormal esophageal manometry as well as the incidence of bacterial pneumonia were significantly higher in the older group.²⁰⁹

Amyloidosis

Amyloidosis is a syndrome characterized by extracellular deposits of insoluble proteinaceous amyloid fibrils in tissues that result in pressure atrophy with dysfunction of

the affected organs. Despite their very different protein components, all amyloid deposits have the following in common: fibrillar structure when examined by electron microscopy; a green birefringence when observed with Congo red stain under polarization microscopy; and an unusual beta pleated structure when examined by x-ray diffraction. The modern classification of amyloidosis is based on the biochemical composition of the amyloid fibrils. The fibrils of primary amyloidosis and of amyloidosis associated with multiple myeloma consist of portions of immunoglobulin light chains and are called AL. Amyloid deposits of secondary amyloidosis, associated with chronic inflammatory and infectious diseases, show immunochemical homology with portions of the acute-phase reactant serum amyloid A, and are called AA. In some of the familial forms of amyloidosis, such as AF, the fibrils are immunologically identical to prealbumin. Several different types of senile amyloid found in the heart and brain of elderly patients are designated AS. Amyloid deposits of endocrine origin (AEO), occurring in or adjacent to endocrine glands, are closely related to polypeptide hormones, their precursors or breakdown products.

Amyloidosis is relevant to rheumatic disease for two reasons: (1) it occurs as a potentially fatal complication of long-standing chronic inflammatory disease, such as RA; and (2) amyloid may be deposited in periarticular and synovial tissues, causing joint pain and restricted motion.

In secondary amyloidosis, deposits of amyloid AA accumulate predominantly in the kidneys, spleen, adrenal gland, and liver, resulting in dysfunction of the organs. Death as a consequence of amyloidosis, secondary to rheumatoid arthritis, is not uncommon in Europe. Although this type of amyloidosis is found at postmortem examination in 10% of RA cases in the United States, it is rarely of clinical significance.

Amyloid arthropathy is caused by deposition of amyloid AL and occurs, therefore, in multiple myeloma and in a disorder of immunoglobulin, previously known as primary amyloidosis. Amyloid arthropathy can affect any joint. Small and large joints are involved with equal frequency. When the small joints are involved, amyloidosis can be easily mistaken for RA, but joint inflammation is less conspicuous and the swelling distinctly firmer on palpation. Flexion contractures of the hand joints may appear early in the illness. Subcutaneous amyloid deposits may be mistaken for rheumatoid nodules. Amyloid arthropathy may present as massive deposition at an isolated site; an example is the so-called Hercules look, in which amyloid deposition in or around the shoulder joint produces the characteristic "shoulder pad sign." Occasionally, amyloidosis results in punched-out lytic lesions in bone; large tumefactions in bone may be complicated by pathologic fractures.

Synovial fluid analysis reveals a noninflammatory fluid with mononuclear cells predominating. Examination of centrifuged Congo red-stained sediment from synovial fluid under polarization microscopy may reveal the typical apple-green birefringence of amyloid fibrils.

Carpal tunnel syndrome occurs in approximately 25% of the cases. When elderly men present with idiopathic carpal tunnel syndrome, the possibility of amyloidosis should be entertained. The diagnostic yield from biopsy of the carpal ligament approaches 100%.

Progressive systemic sclerosis and polyarteritis nodosa have their peak onset earlier in life but may occur in the older age group. There are no data in the literature to support age-related modulation of the clinical expression of these diseases.

Paraneoplastic Syndromes

Certain musculoskeletal syndromes have a close temporal relationship to the onset of a malignancy. Hypertrophic pulmonary osteoarthropathy is perhaps the best known entity. This condition is most often associated with pleuropulmonary disease, in particular lung cancer and mesothelioma. The term pulmonary is somewhat misleading, because certain extrathoracic diseases such as nonneoplastic liver diseases and inflammatory bowel disease may be associated with hypertrophic osteoarthropathy.

The age distribution of hypertrophic pulmonary osteoarthropathy coincides with that of lung cancer, about one-half of which occurs above the age of 60 years. Approximately 10% of patients with lung cancer develop symptoms and signs of hypertrophic osteoarthropathy. Patients complain of pain in the ankles, knees, and wrists. On examination, the most conspicuous but also the least specific sign is clubbing of the fingers and toes. Diffuse periarticular tenderness is present on palpation, and knee effusion is not unusual. The skeletal symptoms may precede clinical manifestations of lung cancer by many months. When this occurs, hypertrophic osteoarthropathy may be mistaken for RA. The diagnosis is confirmed by bone scan or x-ray examination, which demonstrates periostitis with subperiosteal new bone formation along the distal or proximal ends of long bones.

Carcinomatous polyarthritis is characterized by a close temporal relationship between onset of seronegative arthritis and the discovery of malignancy. Most cases occur in the elderly age group. Clinically, it has certain similarities with rheumatoid arthritis, but is less likely to be symmetric. The onset may be explosive or insidious. Characteristically, the arthropathy remits when the tumor has been resected and reappears with recurrence of the neoplasm. In contrast to hypertrophic pulmonary osteoarthropathy, the association with carcinomatous

arthritis is not limited to intrathoracic solid tumors. Women with this syndrome have a high incidence of breast cancer. The association of palmar fasciitis and polyarthritis with ovarian carcinoma in postmenopausal women has been reported.²¹⁰ Because of prominent shoulder and hand involvement, this syndrome has a certain similarity to reflex sympathetic dystrophy; however, arthritis may involve elbows, wrists, knees, and ankles, joints that are not affected in reflex sympathetic dystrophy. Palmar fasciitis and tendon sheath thickening leading to flexion contractures of the fingers is a prominent feature.

A variety of miscellaneous musculoskeletal syndromes have been described as a manifestation of underlying malignancy. The Eaton–Lambert syndrome that commonly presents with weakness of the pelvic girdle musculature has a strong association with small cell carcinoma of the lung. Carcinomatous neuromyopathy is characterized by symmetric proximal muscular weakness out of proportion to the loss of muscle mass. Involvement of pelvic girdle muscles causes gait disturbances and difficulty in climbing stairs. These syndromes must be distinguished from polymyositis and polymyalgia rheumatica. The diagnosis is best established by electromyography.

Dermatomyositis/polymyositis that has a close temporal relationship in onset and a parallel course with a malignancy can be considered a paraneoplastic syndrome. Rarely, malignancy may present as a lupus-like syndrome. In at least some of these cases, autoantibodies are directed against nuclear antigens that are distinct from those recognized in patients with idiopathic SLE.²¹¹

Conclusion

Rheumatologic disease in older people, perhaps more than any other area of geriatrics, presents an opportunity to apply principles from two different disciplines in novel and exciting ways. The sheer numbers and vast amount of disability caused by rheumatic disease in older patients makes knowledge of these two fields important for physicians who care for this group of patients. Because of the nexus between these two fields, many rheumatologists have developed interest in geriatrics and many academic programs are now offering joint fellowships in geriatrics and rheumatology.

Skeletal Fragility in the Elderly

Angela Inzerillo, Jameel Iqbal, Bruce Troen, Diane E. Meier, and Mone Zaidi

Osteoporosis, the leading cause of serious morbidity and functional loss in old age, was once thought to be a natural part of the aging process. Although at times it is difficult to distinguish between the disease and normal skeletal aging per se in the clinical approach to osteoporosis management, progress in the scientific understanding of the underlying disease process has made it largely a preventable disease. Defining the point at which these age-related skeletal changes require intervention presents a major challenge to researchers and clinicians alike. There are several reasons for these difficulties. There is a long latent period of bone loss before the onset of clinically apparent disease. Although current diagnostic procedures have been shown to distinguish those at risk of fracture from those not at risk, there is a large overlap in bone density between persons who fracture and persons who do not. Research efforts directed at these issues have increased dramatically as a result of demographic changes leading to a large aging female population at high risk for osteoporosis and because of rapidly developing technologies in the measurement and screening of decreased bone mineral. Additionally, ongoing advances in the therapeutic modalities have allowed us to treat this disorder.

Osteoporosis is a skeletal disorder in which bone strength is compromised by loss of bone density and quality. This chapter describes the mechanisms responsible for osteoporosis, modalities used to screen and diagnose this common disorder, and current and experimental modalities.

Anatomy and Physiology of Bone

Bone consists of cells and extracellular matrix. Cell types include osteoblasts, osteoclasts, stromal cells, and osteocytes. The extracellular matrix is composed of collagen and noncollagenous proteins. Histologically there are two varieties of bone: immature or woven bone and

mature or lamellar bone. Woven bone is formed during growth and fracture repair. It is replaced by lamellar bone. Collagen fibers are found in bundles that are oriented in a specific direction and contain spindle-shaped hydroxyapatite or calcium phosphate. The direction of these fibers alternates from layer to layer, giving adult bone its characteristic lamellar structure and imparting strength to bone.

Observation of bone reveals dense areas (compact) or cortical bone and areas with connecting cavities (cancellous) or trabecular bone. There are two types of bone composing the skeleton: flat bone and long bone. Long bones of the extremities are predominantly cortical type whereas the axial skeleton is composed of trabecular bone.

The cellular organization of bone is similar for both cortical and trabecular bone. Bone is constantly undergoing a process of remodeling through the processes of resorption and formation throughout life. To understand the pathogenesis of osteoporosis, one must consider the function of normal bone cells and their activities. Bone is resorbed by osteoclasts and is formed through the action of osteoblasts. Osteoblasts can either undergo apoptosis or become buried into the matrix they form and differentiate into osteocytes, the transducers of mechanical loading. In addition, bone has continuously replicating lining cells, the osteoprogenitor cells and osteoclast precursors.

Osteoprogenitor cells are pluripotent stem cells capable of differentiation into osteoblasts upon stimulation by transcription factors. Osteoblasts are found in clusters along the surface of bone. They express receptors for estrogen and vitamin D in their nucleus, as well as integrin and cytokine receptors on their surface. Endogenous stimulants of osteoblastic activity include fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), insulin-like growth factor (IGF), and transforming growth factor- β (TGF- β).

In contrast, osteoclasts are derived from hematopoietic progenitor cells. They are giant multinucleated cells

found alone or in a cluster. An excessive level of osteoclast activity causes inappropriate bone destruction in several bone and joint diseases including osteoporosis, Paget's disease, tumor-induced osteolysis, hyperparathyroidism, and rheumatoid arthritis.

Receptor activator of NE- κ B ligand (RANK-L or osteoprotegerin ligand) is now considered to be the single most important cytokine that is both necessary and sufficient for bone formation. In addition, a variety of other factors modulate bone formation at various stages: these include interleukin-1 (IL-1), IL-3, IL-6, IL-11, tumor necrosis factor (TNF), vitamin D₃, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF).

The resorptive process includes osteoclast formation, polarization with creation of a ruffled border, induction of resorption through acidification and release of enzymes, resulting release of molecules from the matrix, and finally apoptosis of the osteoclast (Fig. 43.1). Note that bone matrix digestion releases important molecules that are stored within the matrix, including a variety of growth factors, such as IGF and TGF- β , and cytokines.

During resorption, osteoclasts generate and are consequently exposed to very high levels of ionized Ca²⁺ as a result of hydroxyapatite dissolution. A high Ca²⁺ concentration can inhibit resorption through the action of Ca²⁺ on a cell-surface receptor, the Ca²⁺ receptor; this is one

FIGURE 43.1. Scanning electron micrograph (SEM) of an osteoclast after bone resorption.

FIGURE 43.2. Inactivation of mature osteoclasts (OC): Ca²⁺ receptor.

mechanism for feedback control of resorption. Resorption can continue in spite of high [Ca²⁺] through the actions of IL-6, which is released from the cell in response to a high extracellular Ca²⁺. IL-6 inhibits the effect of high extracellular Ca²⁺ on the osteoclast (Fig. 43.2).

Once resorption is completed, the resorptive cavity is refilled by osteoblasts with matrix. Thus, resorption is closely coupled to formation. It is known that osteoblasts migrate to the site of resorption responding to likely chemotactic signals, which are possibly secreted by osteoclasts or released from the bony matrix during resorption. After migration into the resorptive cavity, new osteoblasts lay down "osteoid" (or protein matrix) that is later mineralized and becomes new bone.

Defining the Types of Bone loss

Osteoporosis, as defined by the World Health Organization (WHO) Consensus Conference, is characterized not only by low bone mass but also by microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fractures.¹ The bone mass of an individual depends not only on the amount lost as a function of age, but also upon the peak bone mass attained during growth and development. Thus, osteoporosis can occur either when there is a failure to reach peak bone mass or when resorption exceeds formation after peak bone mass is achieved.

Osteoporosis is essentially a disease in which formation and resorption become decoupled. Overall, there is either an absolute or relative increase in osteoclastic activity. There is an absolute osteoclast overactivity (possibly with increased numbers of cells) in *high turnover* osteoporosis, including the postmenopausal bone variety. In contrast, in *low-turnover* osteoporosis, such as occurs with aging, bone formation lags behind resorption; hence,

TABLE 43.1. Pathophysiology of osteoporosis.

Involuntional	Postmenopausal	Secondary
Remodeling normal or decreased	Remodeling increased	Etiology-dependent changes in remodeling
Formation less than resorption	Resorption greater than formation	
Osteoblastic defect	Osteoclastic overactivity	

the rate of resorption is relatively higher than that of formation with net bone loss.

There are a variety of causes of osteoporosis, meriting a classification into primary and secondary forms. Primary osteoporosis occurs in association with menopause or with aging. It is traditionally subdivided into types I and II (Table 43.1). Type I is referred to as postmenopausal osteoporosis and is due to estrogen deficiency. Estrogen deficiency leads to increased numbers of osteoblasts and osteoclasts, resulting in a high bone turnover state with resorption exceeding formation and consequent acceleration in bone loss. The exact cellular mechanism by which estrogen exerts this effect is not entirely known. However, with estrogen loss there is upregulation of cytokines, particularly IL-6 and M-CSF, leading to enhanced osteoclast formation and activity, which then results in bone loss (Fig. 43.3).

Type II primary osteoporosis, often called senile or involuntional osteoporosis, is associated with aging. In contrast to type I, there is decreased bone turnover with a primary defect in osteoblastic activity and decreased bone formation. Again the precise cellular details remain unclear. However, certain osteoblastic genes have been found to be up- or downregulated as a function of aging, for example, IGF-1, FGF, and their intracellular binding proteins. Normal coupling between formation and resorption is lost, with a net decrease in bone formation resulting in a relative increase in resorption. Another hypothesis is that bone loss, even in men, is caused by reductions in estrogen that occur with aging.

FIGURE 43.3. Cellular mechanism of estrogen on the regulation of bone remodeling.

Other age-related factors could contribute to osteoporosis. Aging is associated with a number of disorders of vitamin D metabolism as well as with diminished intestinal calcium absorption. Dietary calcium also decreases with age, further exacerbating this calcium-deficient state. It is important to clarify the difference between osteoporosis and osteomalacia. Osteoporosis results from abnormalities in bone remodeling, whereas osteomalacia results from defects in bone mineralization caused by calcium deficiency.

Secondary osteoporosis is osteoporosis resulting from conditions other than aging or menopause. It may arise from a variety of causes (Table 43.2). All patients with unexplained bone loss should be considered candidates for laboratory evaluation for secondary causes that may also be superimposed on primary bone loss. To exclude common secondary causes, basic laboratory tests, thyroid function tests, immunoprotein electrophoresis (IPEP), 25-(OH) vitamin D₃, 24-h urine free cortisol, testosterone and/or estrogen, 24-h urinary calcium, and intact parathyroid hormone (PTH) may be obtained. If these tests are negative or if further testing is warranted, a bone biopsy may be performed.

The most common cause of secondary osteoporosis is hypercortisolism, endogenous as in Cushing's syndrome, or more commonly iatrogenic from chronic glucocorticoid administration. Osteoporosis induced by glucocorticoid excess is characterized by decreased bone formation causing a relative increase in resorption and bone loss. Trabecular bone (as seen predominantly in the lumbar spine) is more affected than cortical bone. Research has shown that decreased bone formation results from reduced osteoblast proliferation, reduced bone matrix protein secretion, and increased osteoblast apoptosis. In addition, there is a negative calcium balance due to decreased gastrointestinal calcium absorption and increased urinary calcium loss. Secondary hyperparathyroidism can ensue with further increases in net bone resorption. Steroids may also induce hypogonadotropic hypogonadism, again with negative results on bone homeostasis.

Another common cause of secondary osteoporosis is hyperthyroidism. In hyperthyroidism, similarly to postmenopausal osteoporosis, there is increased bone remodeling with resorption exceeding formation and, hence, net bone loss. This state is mostly reversible with treatment of the hyperthyroid state. Postmenopausal women with significant hyperthyroidism are at the greatest risk

because they have increased bone loss and fracture risk. This category also includes women on suppressive doses of levothyroxine for the treatment of thyroid diseases. Several studies have shown that markers of bone turnover are often increased in patients with asymptomatic hyperthyroidism. The use of these markers in the diagnosis of pretoxic goiter has yet to be substantiated.

As transplantation medicine advances, more patients with end-stage organ failure are able to live longer after successful organ transplantation. Pretransplanta-

tion bone loss can be seen in patients with end-stage renal, hepatic, and pulmonary diseases. For cardiac transplant patients, unless there is concomitant renal failure, liver disease, or hypogonadism, the majority have normal pretransplant bone mineral density. As our aging population increasingly undergoes organ transplantation, the prevalence of low pretransplant bone mineral density (BMD) will increase.

Many of the data on transplantation osteoporosis are derived from cardiac transplant patients. These patients suffer from a dramatic severe bone loss, particularly in the first 6 months to 1 year following transplantation.^{2,3} The cause of accelerated bone loss is multifactorial, but it is principally a result of immunosuppressive therapy, primarily glucocorticoids, cyclosporine A (CsA), and tacrolimus (FK 506).^{4,5}

Epidemiology of Osteoporosis

Osteoporosis is the most common bone disease. The prevalence of low bone mass is dependent on a number of variables, including the study population utilized, diagnostic thresholds, densitometric techniques, and the skeletal sites measured. The prevalence of low bone mass increases with increasing age in both men and women, reflecting age-associated bone loss. It is higher for women (approximately 80% of all cases) than men because accelerated bone loss occurs in the immediate postmenopausal period.⁶ The differences between men and women are partially related to the achievement of higher peak bone mass and absence of an accelerated phase of bone loss in men. Low bone mass is also more prevalent in Caucasians than in blacks.⁶

Based on data from the National Health and Nutrition Examination Survey III (NHANES), 10 million people in the United States have osteoporosis at the hip and nearly 18 million more have low bone mass at the hip, placing them at risk for future hip fractures. It is anticipated that the prevalence of osteoporosis will increase as the population ages.⁷ The occurrence of osteoporotic fractures is even more striking. In the United States alone, the incidence approximates 1.5 million per year, including 700,000 spine fractures, 300,000 hip fractures, 250,000 wrist fractures, and 300,000 other fractures. One in 2 women and 1 in 8 men over age 50 will have an osteoporotic fracture in their lifetime.⁸

Although the incidence of osteoporotic fractures is high, when viewed in perspective to other common chronic ailments in the United States, the figures appear even more dramatic. For instance, after the age of 65, the incidence of hip fracture in white women is greater than the incidence of stroke, breast cancer, and diabetes.⁹ Among other chronic ailments, 28 million are affected with osteopenia and osteoporosis compared with 52 million and 42 million affected with hypercholes-

terolemia and hypertension, respectively.¹⁰ These figures are staggering and will increase as the population ages.

The economic burden this places on society is self-evident. The cost of all fractures in the United States is between \$35 and \$41 billion per year. The cost of all osteoporotic fractures totals between \$10 and \$15 billion per year. Hip fractures alone total between \$4 and \$6 billion per year.¹¹ Expected costs for the year 2025 are \$64 billion.¹²

Male Osteoporosis

Osteoporosis in men is a significant but understudied problem. According to the National Osteoporosis Foundation, approximately 2 million American men have osteoporosis. Although men are less likely to fracture, the lifetime risk of fracture is 13% to 25%.¹³ The prevalence of osteoporosis in men will increase as the population ages.

Recent studies suggest a higher prevalence of secondary causes of osteoporosis in men than in women. Specifically, more than one-third of men presenting with osteoporotic vertebral fractures have a secondary cause (such as glucocorticoid administration, hypogonadism, gastrectomy, and hypercalciuria with nephrolithiasis) and a high incidence of cigarette smoking, alcoholism, and low body weight.¹⁴ Careful evaluation for secondary and potentially remediable causes of osteoporosis is mandatory in male patients.¹⁵

There is some controversy in the diagnosis of osteoporosis in men. Currently there are no established guidelines for the use of BMD in male patients. The Rotterdam Study, a prospective cohort study, suggested the risk of hip fracture may be estimated on the basis of BMD and age in both men and women.¹⁶ Males over the age of 65 and males under the age of 65 with one or more risk factors for osteoporosis and males with fragility fractures should have BMD measurement by dual-energy x-ray absorptiometry (DEXA).

Therapeutic intervention in male osteoporosis has been poorly studied. Controlled trials utilizing available treatment modalities are few. One controlled trial of calcium (1000mg/day) with vitamin D (1000IU/day) failed to reduce radial or spinal bone loss in men.¹⁷ Replacement of testosterone in hypogonadal patients has led to increased bone mass, but there is no experimental basis for such therapy in eugonadal osteoporotic men. Routine calcium, low-dose vitamin D supplementation, and weightbearing exercise are reasonable and safe measures but are not yet supported by controlled studies. Bisphosphonates have been shown to increase BMD and decrease fracture rates in males on chronic glucocorticoid treatment.^{18,19} A recent 2-year clinical trial of alendronate in osteoporotic men revealed increases at the lumbar spine (7.1%), femoral neck (2.5%), and total body (2%).²⁰ More prospective long-term controlled trials are

required to establish the fracture reduction efficacy of these therapeutic options in osteoporotic men.²¹

Risk Factors for Osteoporosis

Although the presence of risk factors associated with osteoporosis is of clinical utility, their ability to predict bone mineral density is poor.²² However, the ability of clinical risk factors to predict fracture risk is good.²³ According to the 1998 National Osteoporosis Foundation (NOF) guidelines, family history, age, history of fracture, smoking, female sex, Caucasian race, estrogen deficiency, and low body weight are risk factors for the development of osteoporosis.²⁴ Smoking poses a major risk for the development of osteoporosis. Specifically, it increases the relative incidence of hip fracture by 1.5 to 2.0.²⁵ This incidence may increase by as much as 15% over the next several decades. Low calcium intake, below the recommended daily allowance (RDA) of 800mg/day, has been observed in about 75% of U.S. women.²⁶ Even if the increased relative risk of hip fracture due to this factor were small, the very large numbers of women affected could ultimately lead to a high percentage of fractures due to low calcium intake.²⁷ Other major risk factors associated with hip fracture are maternal history of hip fracture, past fracture, particularly after age 50, use of glucocorticoids and anticonvulsants, and hyperthyroidism (Tables 43.2, 43.3).

Fracture Risk

Although clinical risk factors for osteoporosis are of limited use in the identification of women with higher than average chance of fracture,²⁸ low bone mass has now been shown in a number of prospective studies to accurately predict fracture risk.²⁹⁻³¹ For every standard deviation decrease in bone density measured at any site, the odds ratio for a fracture at any site is 1.6 to 2.4.³²⁻³⁵ This relationship holds for both men and women.³⁵ Other

factors clearly predictive of risk are the type of fall (falls directly on the hip or wrist increase fracture risk at that site),³⁶ greater hip axis length (defined as the distance from the lower lateral aspect of the greater trochanter to the inner pelvic brim (each standard deviation decrease in hip axis length doubles hip fracture odds ratio),³³ and history of prior fractures at any site.^{34,35} A combination of low bone density plus one or more prior vertebral fractures increases relative risk of fracture by fourfold.^{34,35} Fracture risk increases progressively and exponentially with decreasing bone density (see Table 43.3 for other risk factors for osteoporotic fractures).

Genetics of Osteoporosis

A family history of osteoporosis, particularly a maternal history, is considered a risk factor for osteoporosis.²⁴ The occurrence of osteoporosis within families suggests some level of genetic etiology that manifests its phenotype in the elderly. Bone mass is a complex trait with multiple external influences; it has become difficult to separate external from genetic influences.³⁷

Genetic factors are increasingly becoming of interest in determining a contribution to osteoporosis and the possibility of novel therapeutic strategies. Unfortunately, progress in identifying genetic etiologies in osteoporosis has been slow. Several approaches have been used, including association studies where a certain gene allele is found at a higher frequency in those with a particular phenotype. The candidate gene approach has been the most widely employed. In this approach, DNA from families, first-degree relative, or siblings is analyzed with respect to polymorphic markers in genes thought to be related to a particular trait. Positive correlations have been noted between polymorphisms of several candidate genes and bone mass; these include the vitamin D receptor (VDR), collagen type I (COL1A1), estrogen receptor, transforming growth factor-beta (TGF- β), and IL-6.³⁷ These studies are limited by variable reproducibility in different study populations.

Although the potential implications for treatment and diagnosis are vast, because bone mass is a complex trait, it is unlikely that a monogenetic cause of osteoporosis will be found. More linkage studies are needed to attempt unravel the genetic predisposition to this complex trait.

Clinical Presentation

The clinical presentation of osteoporosis can vary from a symptomatic vertebral compression fracture to the observation of low bone mineral density on a baseline DEXA, screening ultrasound, or plain radiograph.

Vertebral fractures are the most common type of osteoporotic fracture. Their prevalence increases with age. Vertebral fractures often are asymptomatic and are detected on routine chest radiography. The most common sites for fractures are the lower thoracic and upper lumbar spine. Fractures occurring in the cervical and upper thoracic (above T6) vertebrae should suggest a secondary or pathologic cause, such as tumor or infection (see Table 43.2).

An acute vertebral compression fracture may present with sudden onset of pain at the site of the fracture with associated radiation of pain laterally, paravertebral muscle spasm, and signs and symptoms of spinal cord compression. Vertebral fractures may occur in clusters of five or six over short time periods. New crush fractures may result in substantial short-term pain and disability, but many patients with vertebral osteoporosis have either chronic back discomfort, height loss, postural changes, or no symptoms at all.^{38,39} In the absence of radiographic evidence of fracture or bone scan evidence of microfracture, back pain should not be attributed to a diagnosis of osteoporosis.

Sufficient numbers of wedge or crush fractures may lead to height loss and kyphosis with attendant back pain and impaired functional capacity.³⁸ Associated abdominal distension, discomfort, and pulmonary restriction also may occur in severe cases of thoracic kyphosis.

Hip fractures are second in frequency, are associated with substantial morbidity and mortality, and occur primarily in persons over age 75. Morbidity is between 30% and 50%, as most of those affected are unable to return to their previous level of function. Mortality is estimated to be between 10% and 20% and increases with age and comorbid conditions.⁴⁰ Hip fractures are almost always associated with a fall, but whether the fracture precedes or follows the fall is not always clear. Occasionally, a patient with an impacted hip fracture retains the ability to walk, but most hip fracture patients are unable to stand. The involved limb may appear shorter and externally rotated.

Patients with osteoporosis generally suffer one of two types of hip fracture, intracapsular or intertrochanteric. In the former, fracture occurs within the joint capsule and frequently results in interruption of the vascular supply to the femoral head, with a high rate of non-union and avascular necrosis. Intertrochanteric fractures are extracapsular, occur between the greater and lesser trochanter, and are not associated with non-union or avascular necrosis. (Refer to Chapters 45 and 46 for further discussion of hip fracture.)

Distal radial fractures (Colle's fracture), the third most common osteoporotic fracture, usually occur in middle-aged women who attempt to break a fall with outstretched arms and hands (parachute reflex). Some elderly patients experiencing this type of fracture with

concomitant medical problems may require hospitalization. Presentation with pain and deformity usually is straightforward. Rehabilitation exercises of the hand and forearm may be necessary.

Diagnosis of Osteoporosis

Bone mass measurements have now been shown in multiple prospective studies to accurately predict fracture risk.²⁸⁻³³ Potential uses of bone densitometry include screening of asymptomatic persons to assess their risk of future fracture, diagnostic density measurements in persons with known risk factors for osteopenia, and repeat measurements for purposes of following bone mass changes over time in response to disease or anti-resorptive treatments.⁴¹

Screening Guidelines

Screening patients with suspected osteoporosis is clearly important. The criteria for utility of a screening test for osteoporosis require that (1) the disorder causes sufficient morbidity, mortality, and cost to warrant screening; (2) the screening test is safe and affordable; (3) treatment in an asymptomatic phase would reduce fractures; (4) screening would affect a patient's decision to accept treatment; and (5) the screening test can accurately predict the risk of fracture. Densitometry has been generally acceptable to patients and involves low radiation doses.

Therapeutic interventions have been shown to decrease the risk of hip and vertebral fractures by up to 50%. Thus, a patient's decision to be treated could be substantially influenced by a low bone mass measurement.⁴² Furthermore, prospective data have demonstrated bone mass measurement as predictive of fracture risk, regardless of the site measured. The hip measurement is the best predictor of hip fracture and vertebral measurement is the best predictor of vertebral fracture.⁴³

The National Osteoporosis Foundation (NOF) has recommended densitometry for women at menopause in whom estrogen decisions would be influenced by knowledge of bone mass.⁴⁴ Other recommended indications for densitometry (Tables 43.4, 43.5) include densitometry

TABLE 43.4. 1998 National Osteoporosis Foundation (NOF) recommendations for bone mineral density (BMD) testing.

1. All postmenopausal women under age 65 who have one or more additional risk factors for osteoporosis (besides menopause)
2. All women age 65 and older regardless of additional risk factors
3. Postmenopausal women who present with fractures
4. Women who are considering therapy for osteoporosis, if BMD testing would facilitate the decision
5. Women who have been on hormone replacement therapy for prolonged periods

in patients with radiographic evidence of osteopenia, patients on chronic glucocorticoids, or those with other conditions such as asymptomatic primary hyperparathyroidism for whom knowledge of bone density will influence management.^{41,44}

Increasingly utilized for screening are peripheral measurements of bone density; these are useful for screening because of low cost, little to no ionizing radiation exposure, and portability. However, results are difficult to determine because different normative databases are utilized and *T* scores (see diagnostic guidelines below) do not correspond to the WHO criteria applicable to central DEXA measurements.

Diagnostic Guidelines

The World Health Organization (WHO) has defined osteoporosis in terms of bone mineral density in postmenopausal Caucasian women. A bone density measurement of more than 2.5 SD below the mean for young adult women, without fractures, is osteoporosis.⁴⁵ Table 43.6 outlines these criteria for diagnosis. Note that these criteria identify approximately 30% of postmenopausal women as having osteoporosis, using DEXA of spine, hip, or forearm. This diagnosis approximates equivalent lifetime fracture risk for spine, hip, and forearm as approximately 17% and lifetime fracture risk for any of the three fractures as about 40%.⁴⁵

The WHO diagnostic criteria are not appropriate for groups other than postmenopausal Caucasian women, sites other than spine, hip, or forearm, or modalities other than DEXA, partly because of the different normative databases utilized. Diagnostic criteria for osteoporosis in groups other than postmenopausal women are controversial. In these groups, the presence of fracture, second-

TABLE 43.6. World Health Organization (WHO) diagnostic criteria for postmenopausal Caucasian women.

Normal:	Bone density no lower than 1 SD below the mean for young adult women (<i>T</i> score ≥ -1)
Osteopenia:	Bone density between 1 and 2.5 SD below the mean for young adult women (<i>T</i> score between -1 and -2.5)
Osteoporosis:	Bone density more than 2.5 SD below the mean for young adult women, without fractures (<i>T</i> score ≤ -2.5)
Established osteoporosis:	Bone density below the mean for young adult women, with a history of fragility fracture (<i>T</i> score ≤ -2.5)

any causes of bone loss, or the presence of low BMD may indicate the need to treat.

Serial Measurements to Assess Bone Loss Rates

Serial densitometry can help to determine need for treatment in patients with normal baseline bone mass, but who are at risk for rapid loss, as in the immediate postmenopausal period or with the initiation of glucocorticoid therapy. Similarly, bone mass changes over time may be used to assess effectiveness of therapy. The measurement of rates of change of bone mass is dependent on the actual in vivo change in bone density, the reproducibility of the densitometric technique used, the number of measurements taken, and the type of antiresorptive therapy initiated.

Currently only serial measurements utilizing DEXA have been substantiated. Presently available methods are sufficiently precise for measurement of bone mass changes if multiple measurements are taken or expected changes in bone mass is large. The short-term precision of commonly used densitometric techniques varies from 1% to 5%, even in research settings with stringent quality control requirements. Precision is dependent on the equipment utilized in the assessment and the skill of the technologist. Long-term precision and precision in non-research settings is less defined. Because bone loss rates in humans generally do not exceed 1% per year, except during the immediate postmenopausal years or in pathologic states, the potential for error in bone loss rate assessment in individuals is obvious. Increasing the number of measurements will improve the accuracy of the estimate but at the expense of increased cost to the patient and treatment time lost while attempting to assess the true rate of bone loss.

When patients undergo treatments expected to produce large (>10%) losses or gains of bone mineral density, serial measurements may help identify non-responders or patients requiring a change in therapy. Serial measurements over relatively short intervals are not useful in assessing bone mass response to preventive measures such as estrogen replacement, because expected rates of change are small by comparison with the precision variability of the technique. There are no prospective data supporting the ability of serial measures of bone loss rates to predict fracture risk.

When a serial measurement fails to show a significant increase, or reveals a decrease in BMD, should this finding institute a change in therapy? A recent study attempted to address the question of regression to the mean.⁴⁶ This principle predicts that patients with unusual responses to treatment are likely to have more typical responses if treatment is continued.⁴⁷ The study groups

consisted of patients from the Fracture Intervention Trial (FIT) and Multiple Outcomes of Raloxifene Evaluation Trial (MORE) trials who appeared to lose BMD after the first year of active treatment. The study demonstrated that those who lost more during the first year of treatment with alendronate or raloxifene were more likely to gain in the second year of treatment. Therefore, treatment should be continued in patients who appear to lose BMD early in treatment.

Techniques Commonly Used

Dual-Energy X-Ray Absorptiometry (DEXA)

DEXA utilizes a beam of x-ray photons passing through the bone region of interest. The amount of beam passing through the bone and detected by the scintillation counter is inversely proportional to the bone mass. This technique measures the sum of cortical and trabecular bone at the midradius (95% cortical bone), lumbar spine, femoral neck, total hip, and total body with a precision of approximately 1% to 3%, depending on the operator and skeletal site measured.⁴⁴ Radiation exposure is low (1–3 μ Sv per site), and patient acceptability is high. The high reproducibility and low radiation dose of DEXA, and freedom from the error introduced by radioisotopic decay seen with older photon absorptiometry techniques, have resulted in virtual elimination of the photon absorptiometric method in recent years (Table 43.7).

For the diagnosis of osteoporosis with DEXA, measurement of at least two skeletal sites is preferable, usually PA spine and hip (Fig. 43.4 A,B). Falsely elevated bone mineral density on DEXA is important to recognize while interpreting results. Reasons for such artifacts include degenerative joint or disk disease, compression fractures, vascular calcifications, or scoliosis occurring in the path of the measurement beam. Use of femoral neck, total hip, and forearm measurement sites is usually preferable under these clinical circumstances.⁴⁴ Lateral spine measurement may also be useful in this clinical circumstance. A midradius measurement, which consists primarily of cortical bone, may be useful in hyperparathyroidism, as these patients tend to have greater cortical bone loss.

DEXA values are reported by comparison to age and gender reference groups with *T* scores (standard deviations above or below values for young normals) and *Z* scores (standard deviations above or below age-matched values).⁴⁴ A *T* score more than 2 SD below young normals indicates an increased risk of fracture and should lead to consideration of antiresorptive therapy to prevent further bone loss. A *Z* score of more than 1 to 2 SD below the age-matched mean value should prompt a thorough evaluation for secondary causes of bone loss (see Tables 43.2, 43.3).

DXA, dual-energy x-ray absorptiometry; pDXA, peripheral dual-energy x-ray absorptiometry; qCT, qualitative computerized axial tomography; pQCT, peripheral qualitative computerized axial tomography; QUS, quantitative ultrasound; LVA, lateral vertebral assessment.

^a1 Sv = 100 rem (for comparison, chest x-ray = 50–150 μSv).

Peripheral DEXA (pDEXA)

Compared to central DEXA, peripheral DEXA (pDEXA) is smaller, portable, easier to operate, and the radiation exposure is less. It requires shorter scan times and its decreased expense make it particularly suitable for screening. Sites measured include the radius, calcaneus, or phalanges. Because different normative databases are utilized, these are not used for serial measurements (see Table 43.7).

Quantitative Computed Tomography (qCT)

Because of the wide availability of CT scanners, vertebral bone densitometry by qCT is an attractive alternative to DEXA. The technique is the only method available that is able to separately quantitate cortical and trabecular bone and potentially detect signs of bone loss occurring earliest in the trabecular skeletal compartment, that is,

postmenopausal. qCT allows volumetric BMD measurement (reported in g/cm³). It is useful in degenerative disease in the spine and individuals at extremes for size and weight. Short-term precision in vivo is about 4% in research settings,⁴⁴ limiting its applicability for serial determinations of bone loss rates. Radiation dose per scan is also substantial (50–60 μSv) and patient acceptability is accordingly limited (see Table 43.7).

In theory, measurement of pure trabecular bone in the centrum of the vertebrae should result in clearer separation of at-risk from low-risk subjects.⁴⁸ However, accuracy error, due to marrow fat, which increases with age, is high, making quality assurance technically more difficult. In most hospital computed tomography centers, radiation dose is substantial and artifactual errors due to lumbar spine abnormalities do limit its regular use. Thus, DEXA is generally preferable to qCT in terms of precision, accuracy, radiation exposure, quality control, and logistics in the clinical radiology setting.⁴⁴

Quantitative Ultrasound (QUS)

Newer measures of bone strength, such as quantitative ultrasound (QUS), have been introduced. Currently only peripheral sites can be measured, including radius, phalanges, calcaneus, and tibia. Correlation with calcaneal BMD is moderately high, and correlation with spine or hip BMD is at best modest.⁴⁹ The poor correlation between QUS *T* scores and central DEXA is partly explained by the different reference population utilized.⁵⁰ Recent prospective studies using QUS of the heel have predicted hip and nonvertebral fractures nearly as well as DEXA at the femoral neck.⁵⁰ QUS or DXA at the femoral neck predict hip fracture better than DEXA at the lumbar spine.⁵¹ QUS precision is less than DEXA, other artifacts can affect measurements, and controversy exists as how to express precision of QUS devices⁴⁹ (see Table 43.7).

Other Modalities

Advances in bone density measurement include lateral vertebral assessment (LVA) using DEXA as well as magnetic resonance imaging (MRI). LVA is useful in its ability to demonstrate actual bone morphology as an interpretable image in contrast with central DEXA, which merely provides quantitative information on bone mineral density. The lateral view of LVA is useful when severe kyphosis or degenerative changes falsely elevate lumbar spine BMD measurement on a PA central DEXA image; this, in addition to a low radiation exposure, makes LVA an attractive option for future use. MRI is being utilized in research settings for microarchitectural bone morphology (see Table 43.7).

Biochemical Markers of Bone Turnover

Biochemical markers of bone turnover may be used as an adjunct in the management of osteoporosis. Although serial DEXA measurements are useful in monitoring clinical response to treatment, most antiresorptive therapies require long-term administration with little to modest increase in BMD, necessitating 2-year or more intervals before repeat determinations are obtained. High bone turnover, which can be measured by biochemical markers, is an independent predictor of increased fracture risk.⁵²⁻⁵⁸ Biochemical markers are useful in assessing rapid bone loss, risk of fracture, and monitoring therapy.⁵⁹ Common markers of bone formation available for clinical use include alkaline phosphatase, bone-specific alkaline phosphatase, and osteocalcin. Resorption markers include pyridinoline, deoxypyridinoline, and N- and C-telopeptides. The latter are collagen breakdown products that enter the circula-

tion following bone resorption; their clinical usefulness in individual patients needs to be determined.⁵⁹

Prevention and Treatment of Osteoporosis

Osteoporosis therapy should ideally be aimed at the underlying type of osteoporosis, that is, involuntal, postmenopausal, or due to secondary causes. The majority of agents available today are antiresorptive, exerting the most beneficial effect in high-turnover osteoporosis; these include estrogen, selective estrogen receptor modulators (SERMs), bisphosphonates, and calcitonins. Agents that increase formation would be most advantageous in age-related osteoporosis where the primary defect is decreased osteoblastic bone formation; these include parathyroid hormone (PTH), vitamin D analogues, fluoride, and new osteoblastic stimulatory agents.

Calcium

The physiologic roles of calcium in the body are twofold. First, calcium provides structural integrity of the skeleton. In the extracellular fluids and in the cytosol, the Ca^{2+} concentration is critical to a number of biochemical processes, and its levels are tightly regulated.⁶⁰ In high bone turnover states, as with estrogen deficiency, there is an elevation in PTH levels. The rationale for the administration of calcium in this setting is partly because calcium inhibits PTH secretion and further bone loss.

Multiple placebo-controlled studies^{61,62} have demonstrated the importance of adequate calcium intake for both primary and secondary prevention of osteoporosis. Chronic calcium deficiency inevitably leads to skeletal demineralization and enhanced fracture risk.⁶¹ The effects of calcium supplementation are maximized in patients in whom baseline intake is low, especially in the elderly.⁶¹ Nevertheless, there is continued controversy whether calcium supplementation can prevent bone loss or restore bone mass.

Premenopausal^{61,62} and menopausal women^{63,64} as well as middle-aged and older men⁶¹ and frail female nursing home residents⁶⁵ respond to calcium supplementation in terms of small to modest increases in bone mineral density. Women in early menopause, presumably because of the dominant effect of gonadal hormone loss, do not show such an effect.^{61,62} A large, randomized, placebo-controlled study of 1.2g calcium per day and 800IU vitamin D₃ per day in frail female nursing home residents revealed significantly fewer nonvertebral and hip fractures after an 18-month trial.⁶⁵ No other controlled studies have shown an effect of calcium supplements on fracture rate. These data, together with other studies on vitamin D-deficient residents in nursing homes,⁶⁶ suggest that the use

of calcium and vitamin D supplementation in institutionalized elderly should be routine, particularly in those who have subclinical secondary hyperparathyroidism.

How much calcium is enough? The 1994 Consensus Development Conference on optional calcium intake recommended increases in the RDA for calcium in most age groups, particularly during childhood and adolescence when 40% of total adult bone mineral is formed. Total, that is, diet plus supplemental, intakes of 1.5 to 2 g of "elemental" calcium per day are recommended in postmenopausal women,⁶⁷ although intake must be individualized. There is little evidence that one form of calcium supplementation is superior to another. Older persons have a high prevalence of gastric achlorhydria and should take their supplements with meals. Patients must be informed that calcium supplementation alone is not sufficient to prevent either menopausal or age-related bone loss. Risks of calcium supplementation are minimal, but persons with a personal or family history of nephrolithiasis must be screened with 24-h urinary calcium determination. In addition, some older patients suffer from constipation and/or rebound gastric hyperacidity. Calcium citrate or calcium glubionate may be better tolerated in persons unable to tolerate other forms of calcium supplementation.

Some experts recommend that a routine urinary 24-h calcium level corrected for creatinine is a useful and inexpensive tool for a regular evaluation of the adequacy of dietary calcium intake. With the recommended intake, the 24-h urine calcium should remain in the 150 to 250 mg range. Calcium supplements should be prescribed with care in patients with end-stage renal disease, mainly for phosphate control. Notably, calcium citrate should be avoided in renal failure as it enhances the absorption of aluminum, the excessive absorption of which could worsen the bone disease secondary to renal failure.

Exercise

It is evident from multiple studies that immobility and disuse lead to accelerated bone loss. This conclusion is supported by animal studies in rats and turkeys, as well as cellular studies that have investigated the consequences of cellular loading. There is increasing evidence that mechanotransduction through osteocytes and bone-lining cells play a key role in bone formation. The accelerated bone loss that accompanies immobilization correlates significantly with cellular hypoxia due to reduced blood flow in bone canaliculi.⁶⁸

Active individuals have higher bone mass than inactive individuals,⁶⁹ as has been shown in several cross-sectional studies. Correlations have been shown between muscle mass and bone density. For example, athletes have higher bone mass in skeletal regions of greatest exertion, and some prospective controlled studies in menopausal

women have demonstrated increases in bone mass, total body calcium, and improved calcium balance in the exercising groups.^{69,70} A nonrandomized study in white postmenopausal women of walking more than 7.5 miles per week demonstrated higher bone density and slower rate of bone loss in the lower extremities in the long-distance group or runners.⁷¹ It is also clear that exercise is less critical than gonadal hormone sufficiency in the prevention of bone loss because excessive weight loss in premenopausal female marathoners leads to amenorrhea, bone loss, and fractures.⁷² Similarly, only a small percentage of the variability in bone density over a broad range of ages can be accounted for by differences in physical activity.^{69,73} In addition, compliance with exercise recommendations is difficult to achieve in clinical practice, and there is some evidence that exercise-induced gains in bone mass are lost within months of discontinuation of the regimen.⁷⁰

Questions regarding timing, age at onset, frequency, duration, and type of exercise most beneficial to bone remain to be answered. Many have proposed that the principal benefit of exercise in reducing fracture is its enhancement of muscle strength, balance, and coordination and the associated reduction in fall risk.⁷³ Elderly patients may require preexercise stress testing before initiation of a new exercise program.

In summary regarding exercise, prescriptions have been developed at the Institute on Aging at the University of Pennsylvania (Table 43.8). General recommenda-

TABLE 43.8. Exercise intervention for osteoporosis based on *T* scores.^a

<1 SD below mean	Encourage weightbearing activity; low to moderate impact or loading activities: walking, jogging, running, hiking, stair climbing, stair-step machines, dancing, aerobics, weight training, ski machines
1–2.5 SD below mean	Low to moderate activities with low risk of falling or collision: stair-step machines, walking, ski machines Education on posture, fall prevention Recommend referral to physical therapy and occupational therapy
>2.5 SD below mean	Low- or no-impact exercise, risk of falling minimal: walking, water aerobics, deep-water walking, swimming, stationary cycle Education on posture and falls prevention Avoidance of activities that have a high degree of twisting or unbalancing movement, such as golf, bowling, tennis, or racquetball Recommend referral to physical therapy and occupational therapy

^aExercise prescriptions developed at the Institute on Aging at the University of Pennsylvania.

tions include duration of 30 min per day, 5 to 6 days per week, and maintenance of a high level of daily activity with adaptation according to age, lifestyle, strength, and agility.

Bisphosphonates

Bisphosphonates (BPs) are stable analogues of pyrophosphate that inhibit bone resorption. Their main effects include decreased osteoclast progenitor development, decreased osteoclast recruitment, and induction of osteoclast apoptosis leading to inhibition of bone resorption.^{74,75} In BPs, the oxygen atom of the P-O-P (pyrophosphate) is replaced with a carbon atom, resulting in a P-C-P bond (Fig. 43.5). Drug variations of BPs are possible by changing the lateral carbon side chains. The R₁

FIGURE 43.5. Biochemical structure of the bisphosphonates.

side chain is usually a hydroxyl group to enhance the affinity of the compound for bone, whereas variations in the structure and conformation of the R₂ side chain determine the antiresorptive potency.⁷⁶⁻⁷⁸ Early BPs are less potent than later bisphosphonates, which have an amino-containing R₂ side chain⁷⁸ (Table 43.9).

The drug is tightly bound to the hydroxyapatite crystal and is retained in bone for many years. Only a small percentage of an oral dose is absorbed, mandating avoidance of food and other medications for several hours before and after a dose.

Previously etidronate was the only bisphosphonate available for oral use in the United States in the management of resorptive bone disease (see Table 43.9). It is FDA approved for the treatment of Paget's disease, heterotopic ossification, and hypercalcemia of malignancy, although not FDA approved for treatment of osteoporosis.⁷⁹ Etidronate inhibits bone mineralization at a dose similar to that required to inhibit bone resorption (see Table 43.9). Therefore, it is usually given cyclically, 400 mg daily for 2 weeks every 3 months, in concert with daily calcium supplementation to prevent osteomalacia.⁸⁰

Short-term controlled trials of etidronate in postmenopausal and elderly patients have yielded slower rates of bone loss at the spine and hip, slight improvement or no change in radial cortical bone mass, and in two studies a trend toward diminished vertebral fracture rate.^{81,82} Additionally, long-term clinical trials including more than 3 years and up to 7 years of treatment with etidronate demonstrate efficacy of cyclic etidronate therapy in increasing BMD and reducing vertebral fractures.^{83,84}

Pamidronate is an intravenous BP presently FDA approved for the treatment of hypercalcemia of malignancy, Paget's disease, multiple myeloma, and breast

cancer metastatic to bone (see Table 43.9). It is not FDA approved for the treatment of osteoporosis and is not currently reimbursable by Medicare for the treatment of osteoporosis. A number of studies have shown the efficacy of pamidronate infusions in increasing BMD at the hip and spine and reducing vertebral fractures.^{85,86} It can be utilized as an alternative therapy in patients with osteoporosis who are intolerant of other forms of therapy. Treatment with pamidronate is usually well tolerated. Side effects are rare and may include fever, thrombophlebitis, and gastrointestinal symptoms. Hypocalcemia, hypophosphatemia, hypokalemia, and hypomagnesemia can occur, necessitating monitoring of these parameters. The dosage needs to be decreased in renal failure. Rapid intravenous administration has been associated with renal failure. Because of this they must be administered by slow i.v. infusion.⁸⁷

Alendronate sodium, a second-generation aminobisphosphonate, has been FDA approved for the prevention and treatment of postmenopausal osteoporosis as well as the treatment of glucocorticoid-induced osteoporosis and Paget's disease (see Table 43.9). The dose of alendronate required to inhibit bone mineralization is 1000 times greater than that required to inhibit bone resorption, allowing daily administration. The recommended dose of alendronate for treatment of osteoporosis is 10 mg and that for prevention of osteoporosis is 5 mg. It is to be taken daily in the morning on an empty stomach with 8 oz plain water. Patients are instructed to delay eating or taking other medications for a minimum of 30 min. Calcium supplements, at a different time of day, at least 1500 mg per day must be given with bisphosphonates to reduce the risk of mineralization defects. A once-weekly 70-mg dose of alendronate sodium (for the treatment of osteoporosis) and 35-mg dose (for prevention) has recently been FDA approved. Randomized controlled trial data using alendronate in postmenopausal women have demonstrated significant reductions in both vertebral and nonvertebral fractures in association with significant gains in bone mineral density.⁸⁸⁻⁹²

A new BP, risedronate sodium, is a potent third-generation bisphosphonate that was recently FDA approved for the prevention and treatment of postmenopausal osteoporosis and treatment of glucocorticoid-induced osteoporosis in men and women. The current dose is 5 mg by oral administration daily (see Table 43.9).

Several other BPs (i.e., ibandronate) are currently undergoing phase III clinical trials. These BPs also inhibit osteoclastic bone resorption at doses much lower than that which impairs mineralization, allowing continuous daily administration. This group of drugs has been shown to inhibit bone loss in early menopause, in immobilized patients, and in corticosteroid-treated patients.^{80,93}

Side Effects

Side effects, which have been generally minimal with both alendronate and etidronate, include abdominal and musculoskeletal pain. Although tolerability profiles of alendronate are similar to placebo in the literature, there is a rare association of alendronate with erosive esophagitis. More commonly patients experience nausea, dyspepsia, and other nonspecific gastrointestinal side effects, prompting their discontinuation. Recent short-term studies revealed similar increases in BMD with once- and twice-weekly dosing of alendronate to minimize GI side effects and maximize compliance.⁹⁴⁻⁹⁶ Long-term efficacy studies are needed to document increased BMD and decreased fracture rates.

Patients with renal failure or hypocalcemia of any etiology should not receive BP therapy, and active upper gastrointestinal disease poses a relative contraindication to the use of this class of drugs. Because of the potent and long-term suppression of bone turnover effected by BPs, concern about impaired remodeling, diminished ability to repair microfractures, and progressively worsening bone fragility has been expressed. Bone biopsies in subjects treated with cyclical intermittent etidronate or daily alendronate have not shown a mineralization defect, nor has suppression of bone formation been observed. Biomechanical competence of bone after BP treatment has also been maintained or improved in animal studies.

Combination Therapy

The effects of combination therapy in the treatment of osteoporosis have been studied. One study evaluated 72 postmenopausal women in a 4-year study evaluating the efficacy of etidronate plus hormone replacement therapy (HRT), HRT alone, etidronate alone, and placebo. Patients on combination therapy experienced a significant increase in hip BMD compared with monotherapy with etidronate or estrogen, although there was no statistically significant decrease in fracture rates among groups.⁹⁷ Patients on combination therapy with alendronate 10 mg and continued HRT versus placebo with HRT were studied for 12 months. The BP plus estrogen group demonstrated significant increase in BMD at the lumbar spine (3.6% versus 1.0%; $p < 0.001$) and trochanter (2.7% versus 0.5%; $p < 0.001$).⁹⁸

Estrogen

Evidence for the role of estrogen loss in osteoporosis is severalfold: bone loss is accelerated as ovarian function ceases,⁹⁹ such loss is inhibited with initiation of estrogen replacement therapy,^{100,101} and bone loss resumes when estrogen replacement is terminated.¹⁰²

At the cellular level, estrogens bind to nuclear receptors present in both osteoblasts and osteoclasts.¹⁰³⁻¹⁰⁷ Estrogen acts on osteoblasts to produce a spectrum of different effects including enhanced procollagen production and increased alkaline phosphatase expression.^{105,106,108,109} Estrogen also modulates the synthesis of certain growth factors and cytokines. For example, in osteoclast precursors, estrogen inhibits the production of interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α), and interleukin-6 (IL-6).^{103,110,111,112}

Estrogen deficiency causes increased osteoclast formation (see Fig. 43.3) by increasing production of the osteoclast-forming cytokine, M-CSF, from supporting stromal cells.¹¹³ Estrogen application inhibits osteoclast formation. Estrogen inhibits transcription of the gene for an osteoclast-forming molecule, RANK-L (receptor activator for NF κ B ligand).¹¹⁴ Therefore, in addition to modulating molecules such as M-CSF, osteocalcin, osteonectin, and osteopontin, estrogen can directly suppress RANK-L-induced osteoclast differentiation and thus bone resorption.

When estrogen treatment is begun early in menopause (i.e., within the first 5 years) and continued for at least 10 years, hip fracture incidence is reduced by 50%,¹¹⁵⁻¹²¹ and significant reductions in distal radial and vertebral fracture also occur. Optimally, hormone therapy for purposes of preventing bone loss should therefore begin as soon after menopause as possible to inhibit this accelerated loss, which ensues within 4 to 6 years of menopause. When estrogens are given during this phase, some patients may in fact gain new bone, as bone formation during this phase of intense remodeling can transiently exceed bone resorption.¹⁰⁰ Thereafter, bone mass is stabilized or the rate of loss is slowed until treatment is discontinued, whereupon rapid loss once again begins. Thus, although estrogens theoretically should be given indefinitely, every year of use delays the onset of clinically important osteopenia, as demonstrated by the reduced hip fracture incidence seen in elderly women treated in the distant past with several years of hormone replacement.^{100,116,118,119} Even in older women with established bone loss, estrogen replacement has been shown to significantly increase bone mass.^{122,123}

Studies of estrogen replacement in the elderly or in women with established osteoporosis have yielded conflicting results. Several trials have shown stabilization or improved bone density in estrogen-treated women after more than 10 years of menopause,¹²²⁻¹²⁴ but at least 7 years of treatment seems necessary to maintain any benefit in the over-75-years age group.^{125,126} This loss of benefit with shorter treatment durations may be due to resumption of rapid bone loss for several years after hormones are discontinued. Some argue that initiation of hormone replacement after age 70 might result in a substantial decrease in fracture risk and suggest that

osteopenic elderly women are, contrary to widespread assumption, good candidates for estrogen treatment for fracture risk reduction.

Dosing Regimens

A number of dosing regimens of estrogen are currently utilized, including continuous and cyclic progestins to prevent endometrial hyperplasia and cancer. The most commonly used combination is equine estrogen (Premarin) 0.625 mg plus medroxyprogesterone 2.5 mg daily. Alternatively, estrogen is administered on days 1 to 30 plus medroxyprogesterone 5 or 10 mg on days 1 to 12. The former minimizes the risk of bleeding. Estrogen alone is utilized in women without a uterus. Several studies have concluded that the minimum effective daily dose of oral conjugated estrogens is 0.625 mg or its equivalent. A recent randomized, double-blind placebo-controlled study of 128 white postmenopausal women with low BMD (*T* score < 1.3) evaluated the efficacy of low-dose estrogen 0.3 mg per day plus medroxyprogesterone 2.5 mg per day.¹²⁷ This study revealed an increase in spinal BMD of 3.5% but with no significant change at the hip after 3.5 years of treatment. Additionally, the availability of transdermal estrogen formulations (which avoid the first-pass effect of oral estrogens on hepatic protein synthesis) may prove useful in patients with hepatic disease, coagulopathies, hypertension, or congestive heart failure. The minimum transdermal estrogen dose necessary to inhibit bone loss has not yet been determined, although one study showed fracture reduction at a daily dose of 0.1 mg estradiol in a 20-cm² transdermal patch.¹²³

Other Effects

Some of the other benefits of estrogen replacement therapy include amelioration of mood disturbances, prevention of vasomotor symptoms including flushes and night sweats, and relief of symptoms of vaginal atrophy.

Estrogen replacement therapy has been associated in several prospective and case-control studies with a reduction in cardiovascular morbidity and mortality and in all-cause mortality. There is an associated increase in HDL levels.¹²⁸⁻¹³⁰ The mechanism of the cardiovascular benefit of estrogen is not known, but direct action on vascular endothelium as well as favorable changes in plasma lipoproteins have been noted. Of some concern is the adverse effect of progestational agents on HDL. The only prospective, randomized controlled trial of estrogen and progesterone in women with coronary disease indicated an early increased risk of cardiovascular mortality.¹³¹ These findings may, in part, result from the androgenic effects of medroxyprogesterone. These findings raise concern about the possible deleterious cardiovascular effects of estrogen, but the results must be interpreted with caution. The results can only be applicable to women

with preexisting coronary disease. More prospective randomized trials are under way. Additionally, epidemiologic evidence suggests estrogen may confer protection against Alzheimer's disease¹³² and colon cancer.¹³³ Prospective randomized studies are under way to determine the efficacy of estrogens in prevention of dementia.

Unopposed estrogen poses an increased risk of endometrial hyperplasia and carcinoma.¹³⁴ Cycling or continuous oral medroxyprogesterone reduces this risk.^{135,136} Other common side effects of estrogen include breast tenderness, thrombosis, weight gain, irregular bleeding, fluid retention, and worsening of hypertension.

There is widespread concern regarding the risk of breast cancer from menopausal estrogen replacement, which has not been consistently corroborated by available evidence. A recent meta-analysis reported a summary risk estimate of 1.3 (confidence interval, 1.2–1.6) in women treated with estrogen for more than 15 years compared with nonusers.^{136,137} The Nurses' Health Study showed a higher risk in current as opposed to past users or never users, independent of dose or duration.^{138,139} Notable is that in one of these studies¹³⁸ the increased risk of breast cancer associated with 5 or more years of postmenopausal hormone use was greater among older than younger postmenopausal women [relative risk (RR), 1.7 versus 1.3 among all current users].

The addition of progesterone to the regimen has unknown effects on breast cancer risk but is at least theoretically likely to increase mitotic activity in breast tissue.^{136,138} Recent data regarding estrogen and breast cancer, however, cannot be overlooked. Data from the Breast Cancer Demonstration Project included 46,355 postmenopausal women showed increased risk, 1.2 (confidence interval, 1.0–1.4), for estrogen users and 1.4 (1.0–1.8) in estrogen–progestin users.¹⁴⁰ The relative risk of breast cancer increased by 0.01 per year of estrogen replacement and by 0.08 per year for combination therapy. The relative risk was further increased in women with low body weight with body mass indices (BMI) of 24.4 or less. Additionally, a population-based case-control study on 3500 postmenopausal women also similarly concluded that the addition of a progestin increased the risk of breast cancer relative to estrogen use.¹⁴¹

The long-term effects of estrogen and progestin use on total mortality are unknown. Large-scale prospective randomized studies are required to clarify the ultimate effect of menopausal hormone replacement on overall morbidity and mortality, coronary heart disease, breast and uterine cancer, and osteoporotic fracture.¹³⁸ Physician and patient alike must balance her risk of osteoporosis and coronary heart disease against the risk of breast cancer in deciding for or against menopausal hormone replacement.¹³⁶ Despite the current knowledge of potential benefits of estrogen to inhibit bone loss, many women discontinue treatment within 1 year due to

side effects, such as bleeding, and more commonly, fears of breast cancer and thrombosis.^{142,143}

There are certain contraindications to estrogen replacement therapy, which include previous history of breast or uterine cancer, active thrombotic disorders, and liver or gallbladder disease. A positive family history in a first-degree relative of breast cancer, coagulopathy, or hypertriglyceridemia must also lessen the enthusiasm for estrogen therapy. Smoking is not a contraindication to HRT.

Selective Estrogen Receptor Modulators

An important addition to our armamentarium of osteoporosis treatment is the development of selective estrogen receptor modulators (SERMs). Raloxifene has been shown to bind with high affinity to estrogen receptors. By binding differently from parent estrogens to the same receptor, SERMs can confer a conformation that enables the receptor to interact with a different second messenger. Thus, raloxifene is an agonist at bone and with respect to lipoproteins, but in contrast to estrogen is an antagonist at the breast and uterus. Its mechanism of action in bone may involve the upregulation of TGF- β_3 expression, thus inhibiting osteoclast formation and bone.^{144,145}

The SERMs currently include tamoxifen, raloxifene, and draloxifene. Raloxifene is U.S. Food and Drug Administration (FDA) approved for the prevention and treatment of osteoporosis at a 60-mg dosage. The clinical effects of raloxifene on BMD and antifracture efficacy have been shown by a number of prospective placebo-controlled trials. Studies have demonstrated a BMD increase of 2.4% at the spine and the hip at 3 years.¹⁴⁶ Results from the Multiple Outcomes of Raloxifene Evaluation (MORE) study demonstrated a significant reduction, about 30% to 50%, in vertebral fractures but no change in nonvertebral fractures.¹⁴⁷ Additional benefits of raloxifene include its favorable lipoprotein profile and a 76% reduction in invasive breast cancer.¹⁴⁸ Its side effects include venous thromboembolism and lack of relief of postmenopausal vasomotor symptoms. More long-term studies are needed to evaluate hip fracture efficacy as well as possible side effects on the uterus and breast.

Calcitonin

Calcitonin is a 32-amino-acid peptide hormone synthesized and secreted from the C cells of the thyroid. The main action of calcitonin is on bone, although it may, at pharmacologic concentrations, increase renal calcium and phosphate excretion and 1,25-dihydroxycholecalciferol production. In bone sections, calcitonin application results in a rapid loss of ruffled borders. When applied for a longer term, there is a reduction in the number of osteo-

FIGURE 43.6. Light microscopy of an osteoclast before (A) and after the addition of calcitonin (B).

clasts in bone (see Fig. 43.6). In osteoclasts, calcitonin inhibits bone resorption, which occurs by the inhibition of cell motility and enzyme secretion.¹⁴⁹⁻¹⁵⁶

Salmon calcitonin has a 40-fold greater potency than human calcitonin, but long-term use is associated with a high rate of development of neutralizing antibodies.¹⁵⁷ Resistance to human calcitonin has also been observed, presumably due to receptor downregulation. Resistance can be minimized by use of lower doses, intranasal or rectal administration, or intermittent administration of the drug.

The utility of calcitonin as a therapeutic agent in disease states of accelerated bone resorption has been clearly demonstrated in Paget's disease and hypercalcemia of malignancy. Several prospective controlled trials have also documented stabilization of, and in some cases modest short-term increases in, bone mass in osteoporotic patients treated for 5 years or less.¹⁵⁸⁻¹⁶⁰ Much of this benefit has been observed in trabecular bone; the benefit of calcitonin in reducing cortical bone loss has not been clearly demonstrated.^{160,161} Similar effects have been demonstrated utilizing calcitonin as a preventive treatment for menopausal trabecular bone loss.^{160,162} Three

studies directly evaluating the impact of calcitonin on fracture reduction have all shown significant reduction in hip fracture, vertebral compression fracture, and peripheral limb fractures. This benefit was observed both in postmenopausal and elderly women.^{161,163,164} Long-term studies using calcitonin reveal a 1.2% increase in BMD at the posteroanterior (PA) spine over 5 years.¹⁶⁵ Preliminary data from the PROOF trial (Prevent Recurrence of Osteoporotic Fractures), a 5-year double-blind, randomized, placebo-controlled study of 1255 postmenopausal women with osteoporosis, demonstrate that 200IU salmon calcitonin nasal spray reduced the relative risk of vertebral fractures by 36% versus placebo.

Compromised trabecular microarchitecture is an important and independent causal factor in the pathogenesis of vertebral fractures in both men and women.¹⁶⁶ It is now emerging that there is a temporal dissociation between reduction in fracture risk that can occur in 12 to 18 months, bone markers, and long-term effects on BMD. Notably, a benefit in fracture risk occurs before a change in BMD. Recent clinical trials with antiresorptives, such as calcium plus vitamin D, calcitonin, and raloxifene, indicate significant protection from fracture despite only

modest increases in BMD. This finding has led to the belief that antiresorptives conserve bone microarchitecture by preventing osteoclastic resorption.¹⁶⁷

The major drawbacks of calcitonin therapy include its high cost and the need for parenteral, nasal, or rectal administration; as of 1996 both parenteral and nasal calcitonin have been FDA approved for treatment of osteoporosis in the United States. Analgesic effects of calcitonin have also been documented in multiple studies of vertebral fracture patients, but these results are compromised by failure to utilize appropriate control groups.¹⁶⁰

The major side effect of parenteral calcitonin therapy, the use of which is now restricted to acute vertebral compression syndrome, is transient nausea and vomiting, which are both self-limited. Nasal calcitonin is generally well tolerated; its use may be associated with local irritation and rhinitis, which usually subside with continued therapy. There is no evidence of any serious or long-term side effects in studies of up to 5 years duration.

Treatment of Secondary Osteoporosis

With the exception of glucocorticoid-induced osteoporosis, few studies of therapeutic measures for primary osteoporosis have assessed their utility in treatment of secondary osteoporosis. Wherever possible the underlying primary disease process leading to bone loss should be treated. When this is not possible, routine calcium and vitamin D supplementation, as well as treatment of hypogonadism in women and men, may be of benefit. Similarly, it is reasonable to utilize other antiresorptive agents (such as calcitonin or bisphosphonates) in an effort to minimize bone loss.

Osteoporosis is among the most serious consequences of long-term glucocorticoid treatment, leading to a 50% increase in risk of hip and other fractures. Glucocorticoids inhibit osteoblastic bone formation, increase osteoclastic bone resorption, and inhibit intestinal calcium absorption. In this setting calcitriol therapy has been associated with a very high incidence (25%) of hypercalcemia.¹⁶⁸ Alendronate has been shown to increase BMD on oral glucocorticoids at a daily dose of prednisone at 7.5 mg or greater. The dosage of alendronate for the prevention of glucocorticoid induced osteoporosis is 5 mg, except in postmenopausal women not receiving estrogen, for whom the dosage is 10 mg once daily. There are no data on fracture efficacy due to insufficient number of patients.¹⁸ Risedronate has also been shown to be efficacious in the treatment of glucocorticoid-induced osteoporosis.¹⁹

Currently, there are insufficient clinical data on the prevention of osteoporosis in patients who undergo transplantation. In a pilot study, two groups of cardiac

transplant patients were studied for 1 year.¹⁶⁹ After transplantation, all patients received 500 mg elemental calcium twice daily and 400 IU vitamin D. The intervention group ($n = 18$ subjects) were given calcitriol and bisphosphonate therapy in addition to calcium and vitamin D during the first year after transplantation (intravenous pamidronate, 60 mg administered within 10 days after transplantation, followed by four courses of oral etidronate, 400 mg daily for the first 14 days of every third month). Forty-one control patients in the calcium and vitamin D only group were observed for 1 year. The bisphosphonate-treated group had no lumbar spine bone loss (0.2%) versus 6.8% loss per year ($p < 0.0001$) in the untreated group. Significantly less bone loss was also observed at the femoral neck in the treated group. There were 3 incident vertebral fractures in the treated group versus 30 in the untreated group. This study demonstrates the potential treatment benefits in cardiac transplant patients of preventative therapy with bisphosphonates.

Other Treatments for Osteoporosis

Sodium Fluoride

Fluoride is an agent capable of stimulating new bone formation by increasing osteoblastic activity. Bone biopsies demonstrate increased trabecular volume and thickness and increased osteoid surfaces. Initially, the new bone formed may be poorly mineralized woven bone, which is eventually replaced by a lamellar bone structure. Prospective controlled clinical trials have demonstrated linear increases in spine and hip bone mass but decreased radial cortical bone mass.^{170,171} No significant decreases in vertebral fractures and a significant increase in non-vertebral fractures at sites high in cortical bone were observed in these studies.^{170,171} This finding suggests that fluoride therapy may preferentially cause new trabecular bone formation but at the expense of appendicular cortical bone. Fluoride remains an experimental drug, has not been shown to decrease fracture risk, and is not approved for treatment of osteoporosis by the FDA.¹⁷⁰⁻¹⁷² Because of its substantial side effects, fluoride is best used only in clinical trials.¹⁷²

Parathyroid Hormone

Parathyroid hormone (PTH) acts on osteoblasts to modulate the expression of a variety of growth factors, including IGF-1, TGF- β_1 , and TGF- β_2 , as well as certain cytokines.^{173,174} The precise mechanism underlying the anabolic effects of PTH on bone is just beginning to be unraveled.¹⁷⁵⁻¹⁷⁷

When administered at a low dose, intermittently, PTH stimulates bone formation. Several clinical trials have demonstrated increases in bone mass and volume with

low intermittent doses of PTH.¹⁷⁸ One study evaluated the use of PTH administration daily in a randomized clinical trial for 12 months in women treated with gonadotropin-releasing hormone (GnRH) antagonists for endometriosis. PTH administration increased BMD at the AP spine by 2.1% and lateral spine by 7.5% and prevented bone loss at the hip and total body.¹⁷⁹ Although results to date show promise, PTH(1–34) remains experimental until larger controlled clinical trials evaluating fracture rate are completed. The major drawback to utilizing PTH is its need to be given parenterally and in achieving the pulses in the circulation necessary to enable bone formation.

To modulate the endogenous secretion of PTH, antagonists of the parathyroid Ca^{2+} -sensing receptor called calcilytics have been developed. Antagonizing the Ca^{2+} receptor imitates a state of hypocalcemia and stimulates PTH secretion. Animal studies with such compounds found that bone turnover increased, unless estrogen was coadministered.¹⁸⁰ Another way of inducing PTH anabolic effects on bone is by using Ca^{2+} -sensing receptor agonists (calcimimetics) to intermittently decrease PTH levels. Animal studies have shown an increase in bone mineral density and cancellous bone volume using such a technique.¹⁸¹

Vitamin D

Gastrointestinal calcium absorption diminishes with age and is abnormally low in patients with osteoporosis, in association with diminished calcitriol levels and decreased responsiveness of the 1α -hydroxylase enzyme to parathyroid hormone stimulation.^{182,183} Although vitamin D may indirectly stimulate bone resorption, it also enhances gastrointestinal calcium absorption, pro-

motes mineralization, and inhibits PTH-induced bone resorption.¹⁸³

One clinical trial utilizing cholecalciferol (800 IU daily) in combination with calcium supplements (1200 mg daily) significantly reduced hip and other fractures in a nursing home population.⁶⁵ Another controlled trial of annual injection of 150,000 IU of vitamin D alone also demonstrated a significant reduction in fracture rate in an elderly population.¹⁸⁴ However, results from multiple trials of calcitriol (1,25-dihydroxyvitamin D) have been contradictory, with four showing increased bone mass or fewer fractures, three showing lower bone mass or more fractures, and three showing no effect.¹⁸³ Because of the risk of hypercalcemia and hypercalciuria with calcitriol, regular monitoring of calcium intake and serum and 24-h urinary calcium is required. Given the risks and the contradictory findings of available clinical trials, pharmacologic doses of active vitamin D metabolites must be considered experimental. However, physiologic replacement of vitamin D (800 IU per day) has demonstrated efficacy in reducing fractures in the elderly and should now be considered routine treatment.

HMG-Co A Reductase Inhibitors

Recent animal studies have shown that the inhibition of HMG-Co A reductase by the lipid-lowering statins activates osteoclast apoptosis, reduces osteoclast recruitment, and promotes osteoblastic bone formation.^{185,186} In vitro and in vivo evidence has demonstrated that amino bisphosphonates inhibit the biosynthetic pathway from mevalonate to cholesterol, resulting in decreased farnesyl or geranylgeranyl pyruvate.¹⁸⁵ Decreased prenylation of GTP-binding proteins resulted in osteoclast apoptosis (see flow diagram in Fig. 43.7).

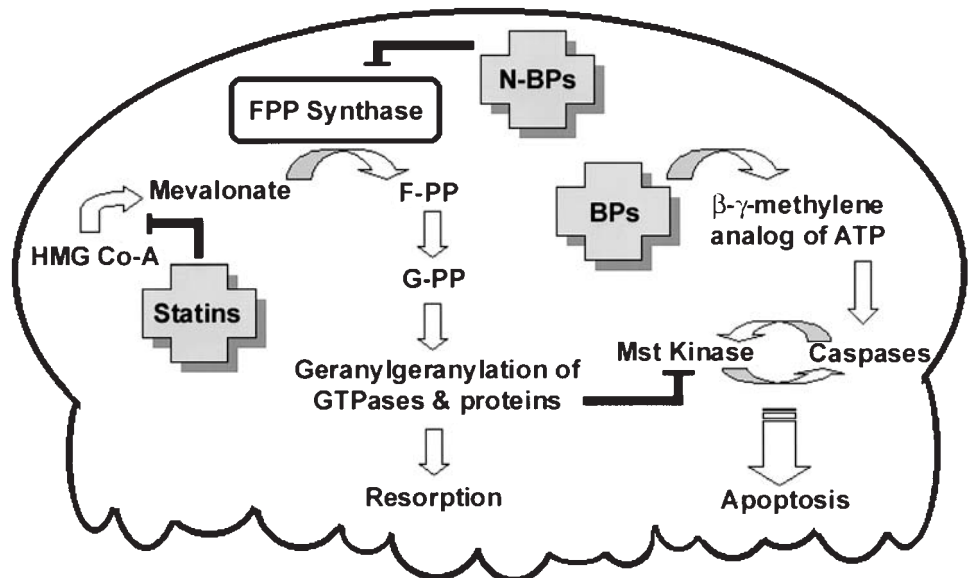

FIGURE 43.7. Cellular mechanism of bisphosphonates (BP) and statins in the mevalonic acid pathway.

Promising clinical trials have become recently available. Patients with type II diabetes mellitus exhibited significant increases in BMD at the lumbar spine and the hip in those treated with lovastatin, pravastatin, or simvastatin compared to controls.¹⁸⁷ Other studies document a decreased fracture risk in those treated with statins.^{188,189} Further controlled studies are necessary to determine the clinical applicability in the treatment of osteoporosis.

Other Treatment Strategies

Growth factors [insulin-like growth factor (IGF) I and II and transforming growth factor- β (TGF- β)] act to increase proliferation of osteoblasts and are currently undergoing evaluation for methods of localizing their effects to the skeleton. Anabolic steroids are potent antiresorptives, but androgenic side effects, adverse lipid changes, and hepatotoxicity limit their use. Flavinoids¹⁸³ are common plant metabolites with some indirect estrogenic properties, and ipriflavone has been shown in animal and human studies to prevent bone loss or increase bone mass in diverse research settings. It has not yet been shown to reduce fracture rates, and long-term evaluation of both efficacy and toxicities is needed.

Primary Hyperparathyroidism

Primary hyperparathyroidism is a metabolic bone disorder caused by excess secretion of parathyroid hormone from hyperplastic or, more commonly, adenomatous parathyroid glands and manifested by hypercalcemia. Increased use of multichannel autoanalyzers has led to greater and earlier detection of asymptomatic hypercalcemia due to hyperparathyroidism. From 25% to 50% of cases occur between age 60 and 90 years, and the distinction between the myriad manifestations of the disease versus other concomitants of old age presents a major clinical challenge.^{190,191}

Clinical Manifestations

The skeletal manifestations of primary hyperparathyroidism include primarily osteoporosis with loss of cortical bone and increased risk of fracture. The classic findings of osteitis fibrosa cystica are only rarely seen today. Additionally, dental problems with tooth loss and generalized arthralgias may be manifested. Gastrointestinal signs and symptoms include peptic ulcer disease, pancreatitis, constipation, and nausea and vomiting. The latter are observed in those with severe elevations of serum calcium or hypercalcemic crisis, generally when serum calcium is greater than 14mg/dL. Renal effects include polyuria due to hypercalciuria-induced osmotic

diuresis, nephrolithiasis, nephrocalcinosis, and diminished glomerular filtration rate.¹⁹² Although hypertension is more prevalent among patients with hyperparathyroidism, the underlying mechanism is not well defined. Neuromuscular manifestations include muscle weakness, paresthesias, and fatigue, although the typical neuromuscular findings are uncommon today. Finally, and of great importance in the elderly, primary hyperparathyroidism may become manifest with memory loss, delirium, personality changes, or depression.^{191,193} Thus, while as many as 50% of hyperparathyroid patients are reported to be asymptomatic, many manifestations of the disease may have been inappropriately attributed to the aging process alone.

Diagnosis

The diagnosis requires the presence of hypercalcemia, which may be intermittent, in association with an elevated or inappropriately normal parathyroid hormone concentration. Other laboratory findings may include hypophosphatemia, hyperchloremia, hypercalciuria, and elevated measures of bone turnover including serum or bone-specific alkaline phosphatase, osteocalcin, and other measures of bone turnover.^{192,194} Classic bone densitometry findings include decreased BMD at the distal one-third radius, which is composed principally of cortical bone.

It is necessary to obtain complete laboratory evaluation in a patient presenting with hypercalcemia, particularly in those presenting with hypercalcemic crisis; this includes intact PTH, 1,25(OH)₂ vitamin D₃, 25OH vitamin D₃, and PTH-related protein (PTH rp). The differential diagnosis of hypercalcemia includes various neoplasms (especially lung, breast, GI tract, kidney, lymphoma, and multiple myeloma), vitamin D intoxication, milk alkali syndrome, hyperthyroidism, sarcoidosis, tuberculosis, drugs (lithium and thiazides), and immobilization (especially in active Paget's disease). Thiazide diuretics and lithium may cause small elevations in serum calcium levels that should resolve upon discontinuation of the drug.

An important entity to exclude before consideration of surgery in patients with hypercalcemia would be familial hypocalciuric hypercalcemia (FHH), where serum PTH and calcium are elevated but urinary calcium is depressed. The underlying mechanism is an inactivating mutation of the calcium-sensing receptor in the parathyroid glands. Normally, elevated ionized calcium levels should inhibit PTH synthesis and secretion from the parathyroid gland. However, these individuals have a higher "set point" for calcium recognition; thus, PTH is inappropriately elevated for their level of ionized calcium. This fact should be considered in patients with a family history of hypercalcemia. It may also be necessary to obtain previous laboratory data on the patient if they

have a lifelong history of hypercalcemia; in the setting of low urinary calcium excretion, the diagnosis of FHH is more likely. This is a clinically important entity to recognize as one would not expose a patient to unnecessary surgical treatment.

Severe elevations in serum calcium with associated suppressed parathyroid hormone concentrations suggest a diagnosis of neoplasm with increased PTH rp or granulomatous disorder with increased 1α -hydroxylase activity and increased $1,25(\text{OH})_2$ vitamin D levels, as opposed to primary hyperparathyroidism. Because primary hyperparathyroidism is an increasingly recognized disease entity, it would not be rare to find concomitant hypercalcemia of malignancy and primary hyperparathyroidism in the same individual.

Treatment

In those affected, who have definite signs and symptoms of the disease or severe hypercalcemia, appropriate management requires surgical neck exploration and removal of the adenomatous or hyperplastic tissue. The risk of neck exploration is greatly reduced when performed by a highly experienced surgeon. Postoperative hypocalcemia and tetany occur rarely, caused by hypoparathyroidism or hungry bone syndrome, primarily in patients with severe bone disease or hyperplastic glands, mandating frequent monitoring and replacement of calcium, magnesium, and vitamin D as needed to restore normocalcemia. Marked improvement in subtle symptoms of fatigue or memory loss may follow surgery, especially in the elderly.

Treatment of asymptomatic hyperparathyroidism remains controversial. A 1991 NIH Consensus Conference set forth recommendations for surgical intervention in patients with asymptomatic hyperparathyroidism; these include hypercalcemia (greater than 1–1.6 mg/dL over the upper limit of normal), a 30% decrease in creatinine clearance compared to age-matched normals, a 24-h urinary calcium determination of greater than 400 mg, and a Z score on bone densitometry of less than -2.0 . Additionally, surgery is preferable for those patients who request surgery, where consistent follow-up would be unlikely, when coexistent illness complicates management, and if the patient is less than 50 years of age.¹⁹⁵

In asymptomatic patients with milder hypercalcemia, general recommendations include appropriate hydration, exercise, and avoidance of diuretics. Restriction of dietary calcium has not been shown to be of clear benefit and should not be employed unless this measure results in reduced serum and urine calcium levels without a concomitant rise in parathyroid hormone concentration.

In one 10-year study, 23% of untreated asymptomatic patients ultimately required surgery because of development of clinical manifestations of disease.¹⁹⁶ Indications

for consideration of surgery in these patients include declining renal function, hypercalciuria, nephrolithiasis, poorly controlled hypertension, a rise in serum calcium (more than 1 mg above the upper limit of normal), rapid decline in bone density or appearance of osteoporotic fractures, peptic ulcer disease, or altered mental status. In the absence of these manifestations, continued conservative management, including hydration, regular bone densitometry, and careful observation, is a reasonable alternative.

Some have argued that most of the osseous complications of hyperparathyroidism could be prevented and bone loss reversed if parathyroidectomy were performed early in the course of the disease. A 10-year prospective cohort study of patients with symptomatic and asymptomatic hyperparathyroidism defined the natural history of disease and assessed the differences between surgical versus nonsurgical patients.¹⁹⁷ During the course of the study, 121 patients were followed, 61 patients underwent parathyroidectomy, and 60 patients were followed without surgery. Parathyroidectomy in patients with or without symptoms led to normalization of biochemical parameters and significantly increased lumbar spine and femoral neck bone mineral density. In 52 asymptomatic patients followed without surgery, none had changes in biochemical parameters; however, 27% had progression of disease or development of at least one indication for parathyroidectomy.

The conservative approach to management of asymptomatic hyperparathyroidism may undergo transformation, based on the findings that parathyroidectomy leads to normalization of biochemical parameters and increases in BMD, as well as the advent of new surgical techniques and imaging studies. Minimally invasive parathyroidectomy^{198,199} under local anesthesia with a skilled surgeon demonstrates a high success rate and decreased surgical risks compared to general anesthesia. This approach is a relatively new technique available only in a few centers; more long-term studies are necessary before general recommendations can be made. There may be a shift toward early surgical intervention before bone loss ensues and renal function declines, with the ultimate goal of preservation of bone mass and subsequent decrease in fracture rates. Prospective long-term data on fracture prevention have not been established.

Patients who refuse or are poor candidates for surgery should be considered for efforts to inhibit the effect of parathyroid hormone on bone. Possible agents for this purpose include oral phosphate, which is used rarely because it requires careful monitoring due to the risk of ectopic calcification. Oral bisphosphonates, because of their poor absorption and short half-life, are ineffectual and may further exacerbate an autonomously functioning gland. Estrogen in the treatment of postmenopausal women with primary hyperparathyroidism shows

promise. A higher bone density and biochemical evidence of diminished bone turnover and decreased serum and urinary calcium without change in parathyroid hormone concentration has been observed in estrogen-treated patients.^{200,201}

A new promising treatment possibility is calcimimetic drug therapy. The search for an effective medical therapy has been stimulated in part by the discovery of a calcium-sensing receptor in the parathyroid and the kidney that regulates the synthesis and secretion of PTH. R-568 or phenylalkylamine (*R*)-*N*-(3-methoxy- α -phenylethyl)-3-(2-chlorophenyl)-1-propylamine is a calcimimetic compound that increases cytoplasmic calcium and decreases parathyroid hormone secretion. In a randomized placebo-controlled trial, single doses of the drug decreased serum PTH and ionized calcium in postmenopausal women with mild primary hyperparathyroidism.²⁰² More long-term controlled studies are needed to determine the implications in the medical treatment of hyperparathyroidism.

Paget's Disease of Bone

Paget's disease of bone is a chronic focal disorder of the skeleton that is asymptomatic in most affected individuals. It is characterized by an early period of sharply demarcated areas of bone resorption, followed by rapid formation of disorganized new bone, resulting in histologically abnormal bone, skeletal deformity, and increased fracture risk.

Epidemiology

Paget's disease of bone affects 1% to 4% of persons over age 40 and greater than 10% of those over age 80. It is common in Northern European (except Scandinavia) and North American temperate regions and rare in tropical and Asian nations. A slight predominance of males has been observed and some familial clustering disease has been reported, suggesting a genetic susceptibility to the disease.²⁰³

Etiology

Although the etiology of Paget's disease is unknown, the osteoclasts in pagetic bone contain typical nuclear and cytoplasmic inclusions in a random or paracrystalline microfilament array, suggestive of a slow viral etiology. However, no infectious agents have been found. No single etiologic agent has been identified to date. In situ hybridization studies have yielded conflicting results, including paramyxovirus, respiratory syncytial virus, measles, and canine distemper.

Pathology

The early pagetic lesion is characterized by a well-defined focal area of osteolytic bone resorption, resulting from the proliferation of large multinucleated osteoclasts, each containing more than 100 nuclei. Increased osteoclastic activity is associated with greatly increased osteoblast activity with enlarged osteoblasts lining the bony lacunae. Pagetic bone has a mosaic pattern resulting from the simultaneous appearance of disordered and accelerated bone resorption and formation and replacement of displaced hematopoietic marrow with fibrovascular connective tissue. "Burned-out" lesions or areas in which accelerated osteoclastic and osteoblastic activity have ceased can be seen. This bone is poor quality due to disorganized collagen deposition and poor mineralization.²⁰³

Clinical Presentation

Paget's disease is rare in persons under 45 years of age. It is typically asymptomatic, requiring treatment in less than 1% of affected individuals. It is commonly detected by an incidental elevation of serum alkaline phosphatase or an abnormal X-ray. The disease may be mild or severe, occur in single or in multiple skeletal locations, and result in a variety of possible clinical presentations.²⁰³ Deformity of skull and clavicle, bowing and fracture of weightbearing bones, and associated mild to moderate bone pain are typical signs and symptoms. Severe bone pain in a patient with Paget's disease should suggest coexisting arthritis, acute fracture, neurologic impairment, or sarcomatous degeneration of a bone lesion. Enlargement of skull structures may lead to headache, cranial nerve deficits (vertigo, tinnitus, and hearing loss) and, if pressure on the base of skull occurs, diplopia, incontinence, abnormal gait, slurring of speech, and abnormal swallowing may result. Involvement of spinal vertebrae with subsequent spinal cord compression may also be observed.

Neoplastic transformation occurs in less than 1% of patients and is characterized by rapid increase in alkaline phosphatase, severe bone pain, or accelerated deformity. It requires bone biopsy for diagnosis. Other complications include ectopic calcification (of vessels, heart valves, joints, and Bruch's membrane with angioid streaks), high-output congestive heart failure from increased shunting of blood flow through bone, and hyperuricemia and gout from increased cell turnover. Hypercalcemia and hypercalciuria with nephrolithiasis secondary to immobilization after a pathologic fracture or neurologic complication may also occur. These symptoms and complications are indications for aggressive therapy.²⁰³

Diagnosis

Laboratory Studies

Elevation in serum alkaline phosphatase is an early herald of the disease, correlates well with extent of bony involvement, and is a reliable indicator of disease activity and response to therapy. Urinary hydroxyproline elevation is a measure of increased osteoclastic activity and is also a useful guide to response to therapy. Serum osteocalcin, bone-specific alkaline phosphatase, urinary pyridinoline cross-links, and other biochemical markers of bone turnover are increasingly utilized in diagnosis and management of Paget's disease. Serum and urinary calcium and phosphorus are normal unless immobilization of a patient with active disease occurs or a neoplasm supervenes.²⁰³

Radiologic Studies

Radiographic appearance of bone typically reflects the stage and extent of disease. Early well-defined lucent areas (osteoporosis circumscripta) may be adjacent to areas of dense or sclerotic bone in later stages of disease. Osteoblastic bone metastases may have a similar radiographic appearance. Bowed and thickened cortex of long bones with an advancing V-shaped osteolytic front, thickened iliopectineal line, sclerotic vertebral margins, and honeycomb or cotton wool-like mottling of the skull also may occur. Radioisotope bone scans are highly sensitive, but not specific, for Paget's disease and are useful to define the activity and skeletal distribution of the disease.²⁰³ These scans may also be useful in monitoring disease activity during the course of treatment.

Differential diagnosis requires consideration of diseases resulting in substantial elevations of serum alkaline phosphatase that include metastatic prostate carcinoma, osteogenic sarcoma, and recent fracture. Osteoporotic fractures and accompanying pain may present some difficulties in differential diagnosis. However, the postfracture elevation in alkaline phosphatase is usually mild and transient, and the radiographic characteristics of simple osteopenia are not typical of Paget's disease. The two diseases may occur simultaneously in the elderly. Distinguishing osteoarthritis from Paget's disease is also difficult because of the frequent coexistence of these conditions. Appropriate radiographic and laboratory studies usually clarify the etiology of the pain. Treatment may require use of both anti-inflammatory agents for the arthritis and specific therapy of Paget's disease.

Treatment

Indications for treatment of Paget's disease include skeletal pain, bony deformity, neurologic complications,

presence of medical complications (such as high-output congestive heart failure, hypercalcemia, and hypercalciuria), and preparation for orthopedic surgery. With the exception of skull or facial bone involvement, preventive intervention in asymptomatic patients with active disease is of uncertain utility. However, given the advent of newer high-potency bisphosphonates and greater tolerability, this approach may change.

Efficacy of therapy depends on reducing osteoclast and osteoblast activity. Response is evaluated by reduction in pain and other symptoms, reduced alkaline phosphatase, reduction in urinary hydroxyproline levels or other measures of bone turnover, and improved radiographic findings. Surgical intervention may be required in patients with symptoms of bone pressure on brain or spinal cord, severe hip dysfunction, and long bone bowing sufficient to precipitate fracture.²⁰³

Bisphosphonates

This class of drugs constitutes the choice of therapy in patients with Paget's disease of bone. Etidronate previously was most commonly used to induce remission. With the advent of second- and third-generation bisphosphonates with greater antiresorptive specificity, etidronate, although efficacious, is rarely used today. Alendronate, risedronate, and tiludronate are oral bisphosphonates FDA approved for use in the treatment of Paget's disease²⁰⁴⁻²⁰⁶ (see Table 43.10 for dosing schedules of bisphosphonates).

The clinical effects of bisphosphonates are dose related and include relief of bone pain and complications of disease, as well as about a 50% reduction in biochemical indices of disease after a standard treatment course. Calcium supplementation should be given in an effort to reduce the risk of clinically significant osteomalacia. Because of poor gastrointestinal absorption, oral bisphosphonates should be taken daily first thing in the morning with water, 30 min before food, other pills, or other

TABLE 43.10. Treatment regimens for Paget's disease of bone.

Alendronate sodium: 40 mg p.o. daily for 6 months
Risedronate sodium: 30 mg p.o. daily for 2 months
Tiludronate: 400 mg p.o. daily for 3 months
Pamidronate ^a : 30–60 mg in normal saline i.v. infusion over 4–6 h ^b
Etidronate: 400 mg p.o. daily for a 14-day course cycled every 3 months for a 6-month course
Salmon calcitonin: 0.25–1.0 mL (50–200 MRC units) i.m. or s.q. at bedtime every other day or every day
Human calcitonin: 0.25–1.0 mL (50–200 MRC units) i.m. or s.q. at bedtime every other day or every day

^aLower doses must be used in renal insufficiency. Monitoring of serum calcium, phosphorus, and renal function is required.

^bNo standardized dosing regimen; this allows for individualized dosing depending on disease extent.

liquids. Treatment for 3 to 6 months is usually sufficient to achieve remission or biochemical plateau, and symptoms may not recur for variable periods thereafter. A drug-free interval of 6 months is recommended. Recurrent signs and symptoms of disease are indications for a repeat course of therapy.

Side effects are seen more often with bisphosphonates than with calcitonin and include abdominal pain, muscle or skeletal pain, diarrhea, nausea, and, in patients treated at high doses, hyperphosphatemia and mineralization defects. High-dose etidronate or alendronate are more effective than lower doses in reducing disease activity but may be associated with more serious mineralization defects, worsening of osteolysis, and pathologic fracture. Thus, high-dose bisphosphonate should be used only if a poor response to lower doses is obtained and then only for short (1- to 3-month) intervals.

During periods of immobilization, Paget's disease may lead to accelerated bone resorption. Treatment with bisphosphonates may be useful in reducing hypercalciuria, stone formation, and bone loss under these clinical circumstances.

Calcitonin

Experience with calcitonin in the treatment of Paget's disease is extensive. Treatment with calcitonin is followed by a rapid decrease in urinary hydroxyproline and a slower decline of serum alkaline phosphatase, healing of bone lesions, and reduction in symptoms and complications of the disease. Treatment may be discontinued after 1 year of therapy, and symptoms may not recur for months to years thereafter. Response to calcitonin appears to plateau after approximately a 50% reduction in disease activity in most patients, for reasons that are not well understood. More than half of treated patients develop antibodies to salmon calcitonin, which may result in resistance to therapy. Human calcitonin therapy does not appear to result in antibody formation and may be utilized if responsiveness to salmon calcitonin is lost; however, a similar plateau effect of uncertain cause has also been observed with human calcitonin treatment²⁰⁷ (see Table 43.10 for dosing schedules of calcitonin).

Calcitonin is extremely costly and must be administered by subcutaneous or intramuscular injection. Side effects occur in 10% to 20% of patients and include nausea and vomiting, flushing, polyuria, hypercalciuria, paresthesias, nasal irritation, and local injection site irritation. Continuation at a reduced dose usually resolves these symptoms. Hypersensitivity reactions are rare, but a dilute initial test dose is recommended by the manufacturer for parenteral use. Combination therapy with etidronate and calcitonin has been reported to prevent progression and permit healing of osteolytic areas. Dosage and administration are listed in Table 43.10.

Other Therapies

Aspirin or other nonsteroidal anti-inflammatory agents may relieve bone pain. Surgical intervention for decompression of neurologic deficits, total hip replacement, tibial and fibular osteotomy, or fracture fixation may be complicated by hemorrhage. Presurgical treatment is usually recommended with intravenous pamidronate or calcitonin to decrease the vascularity of bone. A 50% reduction in biochemical indices of disease is usually sufficient to prevent major bleeding. Fracture and postoperative healing in Paget's disease is generally excellent.²⁰³

Orthopedic Problems with Aging

Lawrence A. Pottenger

Musculoskeletal problems are frequently perceived by people as the first concrete signs of aging. The problems tend to be chronic in nature with little or no hope of complete return to the premorbid condition. Although the pains are usually not severe, they make people feel tired, which is interpreted as feeling “old.” Increased pain with activity accentuates the feeling of aging by forcing people to accept more sedentary lifestyles. A patient typically complains that she feels like a “45-year-old woman in an 80-year-old body.” Depression, which is associated with all forms of chronic pain, can be particularly severe if the patient relates it to fundamental changes such as decreased mobility and growing old.

On the other hand, the presence of musculoskeletal problems can mask heart and lung diseases. Patients may blame their lack of stamina on joint and muscle pains when it is really due to poor oxygenation from heart failure, peripheral vascular disease, or chronic lung disease. It is very important that older patients see a cardiologist or geriatrician before major orthopedic surgery, preferably with a drug-induced stress test, if the patients can barely walk. Their restricted ambulation may be the result of heart disease, and restrictions due to joint pains can reduce patient activities to the point that they do not notice their heart and lung problems.

Osteoarthritis

Age-related changes in joints are different from those of other musculoskeletal tissues. The strength of cartilage does not appear to decrease with age, but cartilage at all ages has very little ability to heal. Injuries to cartilage therefore tend to accumulate with age. Because the function of cartilage is to provide a smooth surface for weight-bearing, disruptions of the surface produce friction that leads to further disruption. Eventually, changes typical of osteoarthritis appear.¹ Although any one particular joint may have escaped injury throughout life, it is virtually

impossible to find people over 65 years of age who do not have at least one osteoarthritic joint somewhere in their bodies. Indeed, anthropologists use evidence of degenerative joint changes in human skeletons to determine the age at time of death.

Any irreversible damage to the cartilaginous surface of a joint will proceed to osteoarthritis if the joint continues to function; this includes damage from trauma, infections, and inflammatory conditions. The rate of progression of osteoarthritis cannot be estimated from a single roentgenograph because it depends upon the degree to which the patient continues to use the joint and the amount of inflammation in the joint.

Roentgenographs of early osteoarthritic joints may show only slight joint space narrowing where some cartilage has been lost. It is therefore very important to take roentgenographs of knees with the patient bearing weight on the affected extremity to detect the narrowing because the articular surfaces of arthritic knees tend to separate when not bearing weight, thus underestimating the severity of the arthritis. As osteoarthritis progresses, the subchondral bone in areas of stress becomes sclerotic with cystlike areas filled with fibrofatty tissue. The edges of the joint develop osteophytes, which are areas of new bone formation with new cartilage on surfaces that face the joint.

Osteophytes are thought, by some people, to make the joints more stable by broadening the surface of weight-bearing. Osteophytes may also stabilize joints by applying lateral pressure on ligaments that have become slack because of loss of cartilage and bone within the joint. Large osteophytes can limit normal motion and cause fixed angular deformities of the joint.²

It is generally agreed that the first lesion seen in osteoarthritis is disruption of the articular cartilage in the area of the joint that sustains the greatest loads. In some cases, there is superficial fissuring of the cartilage that propagates down to the subchondral bone. With continued use of the joint, the fissures spread out to form an

area of fibrillation, which is a hairlike patch where the cartilage matrix components are lost, leaving only a skeleton of disrupted collagen fibers attached to the bone below. These areas are unable to bear weight because of the loss of proteoglycans from the matrix. The weight then becomes focused upon the intact cartilage surrounding the area of fibrillation, which, in turn, becomes disrupted and fibrillated from the increased stresses. Recent studies indicate that progressive loss of matrix components is related to enzymatic destruction from inflammation.³

Sometimes a "blister" lesion forms in an area of normal-looking cartilage. Collagen fibers deep within the cartilage are sheared from their anchorage to the underlying zone of calcified cartilage, whereas the superficial fibers are still intact. Blister lesions eventually break through to the joint, forming a crevice surrounded by undermined flaps of cartilage.

Early cartilage lesions are frequently asymptomatic because cartilage contains no nerves. It is not surprising to see a patient with only a 2-week history of knee pain who has roentgenographic evidence of advanced osteoarthritis. Pain inevitably arrives when cartilage has disappeared from both sides of the joint in an area of weightbearing. Bone contains nerves. Activity-related pain in osteoarthritis is in large part caused by friction from bare bones rubbing together. It responds to analgesics but probably not to anti-inflammatories.

Early cartilage lesions can become painful for several reasons. Large amounts of cartilage debris within the joint cause inflammation of the synovial lining of the joint with swelling and generalized aching in the anterior part of the joint. The inflammation is considered to play a large role in perpetuating the arthritic process. Flaps of undermined cartilage can become painfully caught in the joint and can break off, creating loose bodies that might later become caught in the joint. Osteophytes can also break off the bone to become loose bodies. In the patellofemoral joint, long superficial collagen fibers can partially separate from the cartilage and become caught in the joint even though they are still attached to the bone. If you place your hand on the patella as the knee is bending, you will feel crepitus from catching and giving way of the fibers.

Broken osteophytes that do not separate from the bone can cause pain as the bones rub together at the point of the fracture. Osteophytes can also cause chronic inflammation if they protrude against tendons, ligaments, or joint capsule that move across the joint during motion; this is frequently seen in the knee joint. The quadriceps expansion on both sides of the patella rubs against osteophytes of the anterior femoral condyles as the joint flexes. The synovium under the expansion becomes inflamed because of the increased pressure. The inflamed area becomes fibrotic. The fibrous tissue causes focal eleva-

tions of the synovium, which leads to even greater focal pressures and more inflammation. As the process becomes self-perpetuating, fibrous nodules a centimeter or more in diameter can develop and the pain can become disabling. This condition can easily be diagnosed by placing a hand on the affected knee as it flexes. One feels crepitus on both sides of the patella as the knee is flexed. Patients often get dramatic relief from intra-articular corticosteroid injection, which reduces the inflammation and tends to make the nodules melt away. Large nodules occasionally require excision through an arthroscope.

Chronic entrapment of material within the joint causes a "locked joint." This effect is most often recognized in the knee, although it probably happens in many joints throughout the body. The patient is unable to fully extend the knee. Attempts to forcibly extend the joint cause severe pain in the anterior part of the knee on the side where the material is caught. The patient walks with a painful bent knee. Some knees unlock spontaneously as trapped material escapes from the joint. Others require removal of debris with an arthroscope. A locked knee should be treated with some urgency because material trapped in the knee can cause further cartilage damage during weightbearing. In addition, patients with osteoarthritis who do not fully extend their knee can develop osteophytes on the anterior part of their femoral condyles that permanently prevent the knees from extending. The time required for development of anterior osteophytes varies, but it is probably unwise to leave a knee locked for more than a month.

A torn meniscus in the knee is a frequent cause of locking that may not be associated with osteoarthritis. The menisci are semilunar wedges of fibrocartilage that fit around the outside edge of the medial and lateral compartments of the knee. They function to broadly distribute the weight from the round ends of the femoral condyles onto the flat surface of the tibial plateau. A tear of the meniscus tends to get caught in the part of the joint where the femoral condyle has direct contact with the tibial plateau. In young patients the tears are well defined and are usually the result of a traumatic episode, whereas older patients have "degenerative tears" where the substance of the meniscus has degenerated before the tear. Tears in a front and midportion of the meniscus lead to locking of the knee. Posterior tears cause pain with knee flexion and can actually prevent full flexion. The menisci of obese patients frequently tear at the anterior attachment of the meniscus to the tibial plateau.

There is still much controversy concerning the extent to which tears in the meniscus might initiate cartilage damage, leading to osteoarthritis. Although meniscal degeneration and even total loss of the menisci are frequently seen in knee osteoarthritis, there are also many cases where the femoral and tibial cartilage is

severely eroded and the menisci are relatively intact. At arthroscopy, however, focal areas of degenerative loss of femoral cartilage are often seen directly over a torn meniscus, which appears to indicate that the loss of cartilage was caused by abrasion from the piece of torn meniscus trapped in the joint. It is not known if these small areas of cartilage disruption progress to generalized knee osteoarthritis. Doctors frequently mistake the pain of a torn meniscus for “early” arthritis. Meniscus pain is accompanied by focal joint line tenderness where the meniscus is attached to the tibial plateau.

Treatment of Osteoarthritis

In the early stages of osteoarthritis, one can often mitigate the effects of the disease without medications or surgery. The most important way is to reduce the forces transmitted across the affected joints. In the upper extremity, patients find ways to avoid using painful joints by substituting other motions. In the lower extremities where all the joints are used during most activities, the emphasis must be placed on decreasing the forces across the joint by decreasing body weight. For instance, it has been estimated that, during stair climbing, forces of four to six times body weight are placed across the knee joint. Obese patients should at least be encouraged to lose weight because weight loss could have a very beneficial effect on both the symptoms and the progress of the disease.

A cane to help relieve some of the weightbearing on the affected side can also be very beneficial, and is particularly important when medications fall short of relieving the symptoms. Many patients under age 75 refuse to use a cane because they see it as a sign of old age. Some of these patients can be persuaded to use one crutch. The crutch indicates the presence of a physical problem rather than an infirmity of aging.

Exercise can be very beneficial for arthritic patients. Increased activity has both positive and negative influences on the course of arthritic diseases. It causes cartilage wear, but it also keeps muscles and bones strong. With respect to the lower extremities, the best exercises are those that minimize the effects of weightbearing on the joints while promoting muscle strengthening. Swimming, riding a stationary bicycle, and doing low-impact exercises are generally beneficial in moderation, and they give the patient a feeling of well-being that counteracts some of the chronic pain. Walking, if it is not painful, is also very beneficial. It is a well-known phenomenon that patients with complete loss of cartilage from their joints have less pain if the bone in their joints is very hard, “eburnated,” bone with few cysts. It is possible that the nerves in the bone are better protected by the hard bone. These people often have very little inflammation, presumably because there is less wear debris from the harder

bone. They are generally very active people and they appear to be able to tolerate their disease much longer before requiring surgery.

Any exercise that causes joint pain, either at the time of the activity or later, is probably not beneficial. Range of motion exercises in moderation are generally good, but it should be kept in mind that joint contractures in osteoarthritis frequently develop because the muscles have restricted movements that would otherwise be painful. Overcoming that restriction can cause the joint to become more painful.

Braces are generally of little help in lower extremity osteoarthritis. A plastic ankle-foot orthosis that limits ankle motion is sometimes helpful in severe ankle osteoarthritis. Osteoarthritic knee joints tend to collapse toward the most involved side of the knee, so that eventually all the weight is carried by that side. The opposite side of the knee often remains relatively free of arthritis. For a brace to be effective, it would have to apply a great deal of pressure to transfer the weight to the unaffected side; this would be uncomfortable and would rapidly cause skin problems. Small braces around the knee can sometimes be helpful if there is gross instability, but they cannot take the weight off the diseased side of the joint. Many patients get comfort from elastic knee sleeves. Tactile sensations from the sleeve may compete with pain sensations. The sleeves may also enhance proprioception. Braces are of no value in hip arthritis and are generally not useful for upper extremity arthritis.

Medications

Nonsteroidal anti-inflammatory drugs (NSAIDs) can cause dramatic relief of the symptoms of osteoarthritis, but there is little evidence that they slow the progression of the disease, and they may hasten it by allowing the patients to increase their activity levels to the point of causing increased cartilage degeneration. NSAIDs are generally effective in reducing joint inflammation and they have an analgesic effect similar to acetaminophen, but they have no effect upon the frictional pain of bones rubbing together, other than the analgesic effect. Patients frequently report that the drugs lose their effect after about 3 weeks. When one questions them closer, it becomes obvious that they are adjusting their activity by their level of pain and that the NSAIDs have made them more active at the expense of maintaining the same level of pain. It is often necessary to have patients go off the medications, temporarily, so that they can appreciate the benefit they receive from them.

NSAIDs have serious potential side effects including ulcers, gastrointestinal bleeding, renal and liver toxicity, and excessive bleeding secondary to platelet abnormalities. The cyclooxygenase 2 inhibitors have fewer side effects.⁴ These drugs should be considered for patients

who do not tolerate other NSAIDs, but they are not more clinically effective than other NSAIDs. In the absence of signs of inflammation, NSAIDs should only be employed if they substantially improve the patient's symptoms. Even severely osteoarthritic joints may have only bone pain. Patients often find that one specific NSAID gives them more symptomatic improvement than others they have tried. If one drug is not effective, others should be tried. Alternative oral medications include acetaminophen if the joints are not inflamed.⁵ Glucosamine/chondroitin (1500mg/1200mg per day) often can relieve arthritic symptoms as effectively as NSAIDs with fewer side effects,⁶ but the medication must be taken for several weeks to obtain relief.

Patients frequently show dramatic relief from a corticosteroid injection.⁷ Cortisone effectively treats inflammation, but it also has the capacity to inhibit cartilage repair by slowing the metabolism of chondrocytes. Multiple injections at short intervals can damage cartilage. Crystalline corticosteroids that dissolve over several months are probably the most benign. The number of injections into any one joint should be limited unless the joint has degenerated to the point that the only alternative is total joint arthroplasty. Viscosupplementation with intra-articular hyaluronic acid injection can also be effective in eliminating arthritic symptoms.⁸ Hyaluronic acid is not as universally effective as corticosteroids, but the effects of one hyaluronic acid injection can last up to 6 months.

Surgery for Osteoarthritis

Current surgical methods cannot restore damaged cartilage or recreate the original anatomy of the joint. Surgery is performed for four reasons: to debride areas of symptomatic cartilage, to redirect the loadbearing to a relatively unaffected part of the joint, to fuse the joint, and to "replace the joint" by attaching artificial surfaces to the ends of the bones comprising the joint.

Arthroscopic Joint Debridement

Flaps of undermined cartilage and frayed cartilage can cause pain and muscle spasm if they become caught in the joint; this is particularly evident in knee arthritis, but can also be present in ankle, hip, and shoulder arthritis. The range of motion of the joint may be limited by reflex muscle spasm or by entrapped cartilage material within the joint. Entrapped meniscal tears are also seen in the older population. Material caught within a joint can cause rapid destruction of the cartilage on both sides of the joint by a process called "three-body wear" that is similar to that seen when a piece of sand is caught in a metal bearing. The treatment for this condition is to remove the symptomatic cartilage by arthroscopy.

Arthroscopic debridement⁹ is most effective in early osteoarthritis when the symptoms appear to be much greater than would be predicted by the roentgenographs. The symptoms can be chronic effusions despite NSAIDs or they can be a sudden decrease in range of motion of the joint with pain on attempting to manually increase the motion. Arthroscopic debridement is usually of little benefit in severe osteoarthritis even if a meniscal tear is present. Severely arthritic joints may temporarily benefit from irrigation of the joint, but the effect is usually short lived and in most cases is not justified.¹⁰

Knee and ankle arthroscopy can usually be performed as an outpatient procedure using only local anesthetic. The risks of complications are small. The possibility of infection is so small that many orthopedists do not use prophylactic antibiotics. The relatively benign effects of arthroscopy make it tempting to expand the indications for its use. This temptation should be resisted because "exploratory arthroscopies" often are not beneficial. Arthroscopy should not be performed for osteoarthritis unless the physical examination and roentgenographs indicate a specific condition, such as a meniscal tear, that is known to benefit from arthroscopic surgery. A preoperative MRI may be needed to have better understanding of the condition of the joint. If there is a question concerning the cause of the arthritis, arthroscopy is a safe way to obtain synovial biopsies for diagnosis.

Realignment Osteotomies

In the early stages of osteoarthritis of the hip and knee, the weightbearing areas of the joint are primarily affected. Osteotomies¹¹ have been used to redirect body weight to areas of cartilage that have remained relatively intact. Hip osteotomies are rarely performed in the United States because their results are unpredictable, but they continue to be popular in Europe. Knee osteotomies continue to be universally popular, but the effective use of NSAIDs and injections often reduces joint symptoms to the point that surgery is not considered until the joint has degenerated beyond the point that osteotomy would be beneficial. Mild to moderate osteoarthritis of the knee generally affects only the medial or lateral compartments. Knee osteotomy consists of removing a wedge of bone from above or below the knee such that the direction of weightbearing is oriented to the unaffected compartment.

The advantage of osteotomy over total joint replacement is that it does not involve placement of artificial materials within the joint that might wear out or become loose. However, patients with knee osteotomies frequently have return of their symptoms within 5 to 10 years, and some never experience significant relief of pain. In addition, the recovery time following an osteotomy is much longer than for a routine total joint

replacement because bone healing is required. Osteotomies should be considered for relatively young patients for whom it is likely that a total joint arthroplasty will fail within the patient's lifetime. Older people who continue to participate in high-impact activities, such as running, should also consider osteotomies as opposed to total joints. Patients over 70 years of age who are not participating in high-impact activities would probably have better results from a total knee arthroplasty.

Joint Fusion

Joint fusion means to remove the joint and hold the bones on either side of the joint together so that they heal to form one longer bone. Joint fusion has always been the most effective way to permanently eliminate the pain of osteoarthritis. In addition, joint fusion is often preferred for manual laborers because it maintains the strength of the extremity better than arthroplasty and it is not as likely to require future surgery. Fusion is the only possible surgical treatment for many of the small joints of the body that become arthritic, including ankles.

Patients are frequently unhappy with fusions. Prolonged postoperative periods of immobilization in a cast are often necessary to obtain a solid fusion, and reoperation may be necessary if the fusion is not successful. In addition, fusion of a large joint such as the hip and knee changes the normal walking pattern, makes it difficult to sit in a chair, and puts additional stress on other joints. Fusions of the hip and knee are generally reserved for young patients with monoarticular disease. Fusions are contraindicated in the lower extremity if more than one joint is arthritic, even if the second joint is only mildly arthritic, because the additional stress can cause rapid degeneration of the second joint. In the geriatric population, the most common indication for a knee fusion is a chronic knee infection from a failed total knee arthroplasty.

Total Joint Arthroplasty

Total joint arthroplasties¹² are procedures that replace the articular surfaces of joints with one or more artificial substances including metal, high-density polyethylene, and ceramic. In most cases, only a small amount of bone is removed to install the joint. Ligaments, joint capsule, and muscles continue to hold the two sides of the joint together. Patients frequently think that a joint arthroplasty involves replacement of a large segment of the extremity and are relieved to find how little bone is actually replaced. Hips and knees are the joints most frequently replaced. Less frequently replaced joints include finger and toe joints, ankles, shoulders, wrists, and elbows.

Arthroplasties of the hip and knee should not be considered unless the joint is irreversibly damaged, with areas of full-thickness loss of cartilage, and the patient's

walking capacity is limited to only a few blocks in spite of intensive medical treatment. Roentgenographic indications of the severity of the disease plays little role in the decision to have an arthroplasty except to indicate that the arthritic condition is irreversible because areas of the joint have completely lost their cartilage. Many patients have severe roentgenographic changes with only mild symptoms. Delaying surgery until symptoms become worse rarely makes the surgery more complicated. The best considerations for surgery are the amount of suffering and the degree to which the patients have had to change their lifestyles because of the arthritis.

As with all elective surgeries, the final decision as to whether to have an arthroplasty must be made by an informed patient. The potential benefits of arthroplasty have to be weighed against the risks of surgery. The most common severe complications include infections, pulmonary embolus, cardiac problems, and revision due to mechanical problems such as loosening and malalignment.^{13,14} Current hip and knee arthroplasties can be expected to last on average 10 to 15 years. If the patient is active in sports or high-impact physical training, where both feet are off the ground at the same time, alternatives such as fusion or osteotomy must be considered. Arthroplasties are not capable of returning people to high-impact sports and rarely do they make the joint feel completely normal. Patients who can barely function before surgery are usually extremely pleased with their arthroplasty, but those who have an arthroplasty because of mild pain are often unhappy.

Before considering hip or knee arthroplasty, it is necessary to assess all the joints of both lower extremities. Pain from hip arthritis often radiates to the knee. If the ipsilateral hip and knee are both arthritic, sequential intracapsular injections of procaine may be necessary to determine the source of the pain. Osteoarthritis that is well controlled with anti-inflammatory drugs usually hurts only with activity. Pain in a particular joint is often directly related to the amount of activity. An arthritic right knee may not hurt until a patient has walked more than a block. If the left hip hurts after half a block of walking, the patient may not realize that his right knee is severely arthritic until after the left hip has been replaced. Patients become angry and depressed when they realize that they have undergone a major operation with only slight improvement in their ambulatory capacity. This situation is particularly true for patients with rheumatoid arthritis because of the frequent occurrence of arthritis in the joints of the foot and ankle. When a person has extensive arthritic damage in many joints, several arthroplasties as well as other procedures may be necessary to significantly improve the patient's function. Careful preoperative planning and absolute candidness with the patient are very important for a successful outcome.

Operations for hip and knee replacement usually take from 2 to 4 h. The patients are usually out of bed the next day and ambulating in physical therapy on the second postoperative day. The length of stay in the hospital is usually 4 days. Patients are discharged when their wounds are healing well and they can walk independently with crutches or a walker. At home, they do muscle-strengthening exercises and range of motion exercises daily. They continue on protective weightbearing for 1 to 2 months. If a patient has two severely arthritic joints, it is often beneficial to replace both joints during the same hospitalization to reduce the total length of disability and maximize the benefits of postoperative physical therapy. Simultaneous replacement of ipsilateral hips and knees is not recommended because of the high incidence of peroneal nerve problems.

In most cases, two to four units of blood are required for hip replacement and two for knee replacement. Much of the blood loss occurs because patients must receive prophylaxis for deep vein thrombosis before surgery to prevent pulmonary embolism. When medically possible, the patients should be asked to donate their own blood for the operation.

Prophylactic antibiotics are used to reduce the possibility of infection. The antibiotic coverage should include *Staphylococcus aureus* and *Staphylococcus epidermidis*. In uncomplicated cases, the infection rate is less than 2%.¹³ Deep wound infections may require removal of the prosthesis. Reimplantation is often possible when the infection is under control. If the infective organism is sensitive to oral antibiotics, older patients are often treated with an irrigation and debridement followed by chronic oral suppression with the prosthesis intact. Patients also need prophylaxis to prevent deep vein thrombosis after surgery.¹⁵

Most of the newer designs of hip and knee arthroplasties have a coating of porous metal on the side of the prosthesis that faces the bone. The coating is designed to take advantage of the fact that healing bone will grow into porous materials. Loosening of cemented prostheses often occurs at the cement–bone interface with fracture of the cement. A direct bond between the bone and prosthesis eliminates the need for bone cement (methylmethacrylate). Presently, most of the advantages of using cementless prostheses remain theoretical; they have not been implanted long enough to determine if they will last longer than cemented prostheses. If the patient's bones are severely osteoporotic, cement should be used if the replacement is absolutely necessary.

Degenerative Arthritis of the Spine

Degenerative arthritis of the spine is a common problem in older people. Both the intervertebral disks and the posterior facet joints are generally involved. There may

be a history of trauma, sports injuries, or occupations that have stressed the neck and back, but many people have no known cause. Intervertebral disk material tends to desiccate and fragment with age. The annulus fibrosus may weaken, allowing disk material to protrude into the spinal canal or laterally into the neural foramina. The arthritic posterior facet joints can develop osteophytes so large that they significantly narrow the foramina.

Pain may be from the arthritic joints or it may be caused by neural impingement. In addition, pain within the spine usually causes reflex spasm of paravertebral muscles, which can also become painful from overwork. Patients with vertebral osteoarthritis tend to restrict their motion to relieve the pain. At first, the loss of disk material may cause painful joint instability. Later, the ligaments tighten with relief of pain, and the joints become nearly fused. Patients with generalized ligament laxity and joint hypermobility tend to have much more back pain because they cannot stabilize their joints to prevent the pain.

Nearly everyone over the age of 60 years has roentgenographic evidence of spinal osteoarthritis. Because of the tendency for ligament tightening to reduce the symptoms of arthritis, there is no correlation between the degree of symptoms and the severity of the arthritis as judged by roentgenographs.¹⁶ Indeed, the worst appearing spines are frequently asymptomatic. Because there are many different causes of back pain, arthritis should be considered as a cause of pain only after other common causes have been ruled out.

Pain from arthritis alone, without nerve compression, can radiate into the shoulder and arm from the neck and into the buttock and thigh from the lumbar spine. The presence or absence of numbness, paresthesias, and specific muscle weakness is very important to differentiate nerve impingement from arthritic pain. Any of these symptoms would suggest nerve root compression. Further workup for nerve root compression can include electromyographic studies to determine which nerve roots are involved and myelographic studies and magnetic resonance imaging to determine the site of compression.

In the neck, the initial treatment of an acute episode of either nerve root compression or arthritis is immobilization with a soft collar. Analgesics and NSAIDs are also helpful. Intermittent cervical traction that can be used in the home can often give dramatic relief of symptoms. Patients with nerve root compression who have persistent symptoms in spite of conservative treatment may require excision of the disk and fusion of the involved vertebrae. Arthritic pain without nerve root involvement usually responds to conservative treatment. Severe unremitting pain can be treated by discectomy and fusion if it is localized to one level. Fusion of multiple levels is usually unwise because it increases the demand for motion at the remaining levels.

For the lumbar spine, analgesics and anti-inflammatory drugs have been used effectively for acute episodes of both arthritis and radiculopathy secondary to a herniated disk. Treatment beyond medication comes from an understanding of the forces acting upon the vertebrae. The lumbar spine is arched forward (lordotic) to allow upright ambulation. Weight that has been borne primarily through the vertebral bodies in the cervical and thoracic spine is transferred to the facet joints in the lower lumbar spine because of the arch. With good abdominal muscle tone, approximately half the weight of the upper torso is transmitted through the abdomen to the pelvis by hydrolic pressure. With poor abdominal muscle tone, all the weight is transmitted through the spine. Abdominal muscles relax during sitting. Pressures on the spine are therefore greater while sitting than with lying, standing, or walking.

All obese patients with chronic low back pain would benefit from weight reduction to relieve the pressure on the disks and facet joints. Bed rest is frequently advised for patients with disk disease. It has no proven value in treating lumbar arthritis. Bed rest makes all the muscles of the body weak, including the back muscles, which are then less able to stabilize a painful arthritic spine. If patients have acute lumbar arthritis primarily in the area of the vertebrae and disks, a combination of lying with frequent walking and little or no sitting is probably best. Patients with lumbar arthritis primarily in the area of the posterior facet joints have greater pain with standing than with sitting because greater weight is transmitted across the facet joints when the spine is lordotic. They should be allowed to sit. After the arthritic pain has abated, it is important to start an exercise program that strengthens both back and abdominal muscles.

Lumbosacral braces function by increasing intra-abdominal pressure, thus taking the weight off the spine. If the brace is tight, there is some effect even during sitting. The braces also reduce the lumbar lordosis during standing and immobilize the spine to the extent that muscles in spasm may relax. Braces should not be worn constantly because they cause rapid atrophy of back and abdominal muscles. In general, older people do not tolerate lumbosacral braces unless they are accustomed to wearing girdles.

Patients with painful herniated disks that have not responded to conservative therapy may require surgical discectomy. In cases where nerve roots are compressed by osteophytes of facet joints, resection of the osteophytes with decompression of the nerve roots may be necessary. There is no effective surgery for painful osteoarthritis of the lumbar spine not associated with nerve compression. Lumbar fusions, which have been performed in the past for osteoarthritis, are now indicated only in situations where pain is caused by instability of the joints.

Cervical Spondylotic Myelopathy

In both the cervical and lumbar regions, degenerative arthritis of the spine can cause narrowing of the spinal canal. Cervical myelopathy¹⁷ is the result of bony or soft tissue compression of the spinal cord in the neck that frequently appears in the fifth and sixth decades. Although the signs and symptoms may vary greatly, the sign most frequently found is spasticity of the extremities followed by weakness. Pain is present in less than half of patients. Numbness and painful paresthesias can also be present, as well as fasciculations and sphincter disturbances. Clinical symptoms vary with the part of the cord that is compressed. Patient symptoms can be so vague that their etiology is easily missed if the possibility of myelopathy is not constantly kept in mind. Electromyographic studies are helpful to document the degree of nerve involvement. Magnetic resonance imaging usually can demonstrate the site of compression.

Nonoperative treatment includes use of cervical orthotics, NSAIDs, and isometric neck muscle strengthening. Traction and manipulation of the neck are contraindicated because they may cause further compromise of the spinal cord.

Cervical myelopathy tends to progress to severe disability if left untreated. Surgical decompression of the spinal cord should be considered if progression of the neurologic deficit is observed, or symptoms that have been present for more than 6 months do not improve with conservative treatment or the MRI demonstrates either severe compression of the cord or changes within the substance of the cord.

Lumbar Spinal Stenosis

In the lumbar region, bone hypertrophy from osteoarthritis often narrows both the spinal canal and neural foramina. This condition is called spinal stenosis. Although arthritis of the lumbar spine is frequently seen in the fifth and sixth decade, symptoms of spinal stenosis usually appear in the seventh decade. The first symptoms are vague leg pains, paresthesias and dysesthesias brought on by walking or standing. Patients experience symptoms similar to vascular claudication. After walking a certain distance they find that they have to stop because of increasing leg pain and weakness that abates rapidly if they sit or stand leaning forward. In severe cases, patients walk bent forward at the waist. By bending forward, they are straightening the lordosis in their lumbar spine so that their spinal canal has a maximal diameter. Neurologic deficits are present at rest only in severely affected patients.¹⁸

The diagnosis of spinal stenosis is made by MRI scan. Most patients with intermittent symptoms respond to rest, anti-inflammatory medications, and back and

abdominal strengthening exercises. Severely affected patients may require laminectomy and decompression of neural foramina with approximately an 85% chance of a good result,¹⁹ although stenosis can recur at different lumbar levels.

Pyogenic Osteomyelitis

Bacterial infections in bone can be extremely difficult to eradicate if the circulation to the bone is impaired. Circulation may be disrupted by arterial insufficiency, such as in arterial occlusive disease, by fracture of the bone, or by abscesses caused by the infection itself. Without adequate circulation, antibiotics cannot reach the bacteria. The infection cannot be eliminated unless either circulation is reestablished or the infected bone is removed.²⁰

Bacteria reach bone by one of three pathways: hematogenous seeding, direct inoculation, or contiguous spread from a nearby soft tissue infection.

Hematogenous Infection

Hematogenous seeding of the bone by a transient bacteremia is frequently caused by an infection elsewhere in the body, such as pneumonia, cutaneous infection, or urinary tract infection. Bacteremias can also occur during dental and urologic procedures.

Vertebral Osteomyelitis

Vertebral osteomyelitis is the most common type of hematogenous osteomyelitis in adults. Vertebral bodies may be predisposed to hematogenous seeding of bacteria because their marrow is actively producing blood components. The sinusoidal system of the marrow reduces the blood flow greatly and may allow bacteria to move into the tissue. In addition, urologic infections and other pelvic infections can easily spread through Batson's plexus, which is a system of communicating veins that connect the pelvic venous plexus with the venous plexus of the spine.

For many patients, the source of the organism cannot be found. A large majority of the patients have *Staphylococcus aureus* infections. Any vertebra can be involved, but the lower thoracic and lumbar vertebrae have the greatest incidence. All patients have symptoms of back pain that may have been present for as long as several years. A small percentage have symptoms of septicemia such as fevers, night sweats, elevated leukocyte counts, and positive blood cultures. Paraparesis due to neural compression may be present. Surgery is indicated for vertebral osteomyelitis if the spine is unstable, if a large soft tissue abscess is present, or if the infection has not responded to antibiotic therapy.

Direct Inoculation

Infection from direct inoculation of bacteria commonly results from bites and puncture wounds in hands and feet. In older patients, surgery involving bones is also a common cause. The presence of metallic implants or dead bone in the area of the infection can make eradication difficult. Prevention is definitely the best way to treat orthopedic infections. Surgeries should be performed with scrupulous aseptic technique and minimal dissection. Prophylactic antibiotics should be used for all major operations involving implantation of prosthetic materials.

Contiguous Spread of a Soft Tissue Infection

Contiguous spread of soft tissue infection occurs most frequently in areas of poor blood supply, such as decubitus ulcers and ischemia of the lower extremities. Treatment must first be directed toward increasing blood flow to the involved area, which may require arterial bypass procedures or the use of vascularized muscular flaps. Necrotic bone must be completely removed, and intensive soft tissue wound care must be instituted. If amputation is required, it should be performed at a level that is known to have sufficient blood flow to allow healing.

Fractures

Hip Fractures

Fracture of the hip is a frequent occurrence in elderly people and is one of the few orthopedic conditions in aged people that is associated with significant mortality. Mortality rates for older patients in the first year following hip fracture have been found to be 14% to 36%.²¹ Patients seldom die as a direct result of hip fractures, but hip fractures generally occur in debilitated people. The mortality rate increases in patients with poorly controlled systemic diseases, multiple comorbidities, and dementia.²² Elderly people tend to think of hip fractures as occurring very close to the end of life because they remember friends and relatives who died shortly after fracturing their hips. If a patient's prognosis for recovery is good, it should be discussed with them because they may hold dark thoughts about their future that would delay recovery and rehabilitation.

Hip fractures are generally the result of trivial trauma. Patients often feel their hips break before they fall. Bedridden patients frequently sustain hip fractures falling out of bed. Inactive elderly patients develop disuse osteoporosis, which, superimposed upon senile osteoporosis, can cause extreme softening of the bone. In addition, poor dietary habits or malabsorption can cause osteomalacia with further softening.

Immediate medical evaluation of patients with hip fractures is very important. Hip fractures can cause rapid loss of several units of blood into the thigh, which can lead to hypotension and possible cardiac ischemia. In addition, patients may have fallen as the result of hypotensive events from cardiac arrhythmias. By the time they arrive at the hospital, they may no longer be hypotensive, but they should still be evaluated for the possibility that they might have sustained myocardial damage immediately after the fracture.

People who sustain hip fractures usually require surgery to stabilize the fracture and allow early ambulation. Some types of hip fractures have almost no chance of healing without surgery whereas other types would heal but only after weeks or months of bed rest. The potential morbidity and mortality of bed rest in elderly, debilitated patients is usually greater than the risks of surgery, but bed rest may be the only option for severely ill patients. Each patient must be evaluated with both possibilities in mind.

Hip fractures occur primarily in two areas of the proximal femur, the intratrochanteric region and the femoral neck. Fractures in the intratrochanteric area have a high chance of healing because the fractures have a broad cross-sectional area with good blood supply from both sides. However, if surgery is not performed, several weeks of bed rest are required and the fractures tend to heal in shortened, externally rotated positions. Femoral neck fractures occur between the trochanters and the femoral head. The blood supply to the femoral head comes from the trochanteric region through the femoral neck and vessels surrounding the femoral neck. Displaced femoral neck fractures often totally disrupt the blood supply to the femoral head. If the blood supply is disrupted, the femoral head will become necrotic even if the fracture is surgically stabilized. For these fractures, the femoral head is usually replaced by a prosthesis called a hemiarthroplasty, although in younger patients a trial of internal fixation may be indicated if there is a chance that the blood supply is still intact. If the ends of the fracture have not displaced, the blood supply is usually intact and the fracture can be successfully treated with screws to hold the fracture in place during healing. Very active people with displaced femoral neck fractures should probably have total hip replacements rather than hemiarthroplasties because hemiarthroplasties can be painful in active people.²³ In general, if a patient is community dwelling, ambulatory, and in good health, a total hip replacement should be performed.

Patients occasionally have impacted femoral neck fractures where one side of the fracture becomes stably impacted into the bone of the other side. Patients with these fractures frequently can walk with minimal pain. Sometimes the fractures come apart later, necessitating surgery. If the fracture has impacted in a good position

and is relatively painless, it can be treated with protected weightbearing with crutches or a walker.

The goal of surgery for fractured hips is stabilization of the bones of the fracture to the point that the patient can be rapidly mobilized after surgery. Patients are usually allowed to sit up the day after surgery. Physical therapy for ambulation with protected weightbearing is started as soon as medically possible, which is usually the second day after surgery. Prophylaxis to prevent deep vein thrombosis should continue throughout the recovery period.

The possibility of a fractured hip is frequently one of the greatest fears of elderly people who live alone. They have all heard stories of people who have broken their hips and languished for days on the floor of their home unable to get to the telephone. Establishing a system in which they are contacted every day can be very reassuring. Many elderly people carry portable telephones with them while in their home. A home exercise program to strengthen their lower extremities will help prevent falls and alleviate fears of falling.

Vertebral Compression Fractures

Vertebral compression fractures²⁴ are a major cause of back pain in osteoporotic patients. These fractures are frequently undiagnosed or misdiagnosed as arthritic pain. However, the pain tends to be much more acute and is usually in the middle and upper regions of the back. Some patients give a history of apparently trivial trauma whereas others merely note gradually increasing back pain. The pain can be severe and often radiates in the direction of the dermatome at that level. It is exacerbated by sitting, standing, and mild percussion of the spine at the level of the fracture.

The diagnosis is made with a lateral roentgenograph of the thoracolumbar spine. The silhouettes of the vertebral bodies are normally rectangular. Compression fractures usually cause wedging of the vertebra with loss of anterior height compared to posterior height. In mild cases where the loss of height is minimal, one may see only an increased density of the bone where the collapse has occurred below the endplate of the vertebra. Sometimes, instead of wedging, disk material protrudes through a fracture in the endplate of the vertebra, creating a cystic area within the vertebra called a Schmorl's node.

It is difficult to roentgenographically determine the age of a compression fracture. Previous roentgenographs, if they exist, are often the only way to determine if a fracture is new, because previous compression fractures may have gone undiagnosed and bone scans often show increased activity in the area of a fracture for many years. Mild compression fractures and Schmorl's nodes are frequently missed on the original roentgenographs. Patients with clinical indications of a compression fracture should

be treated with the presumptive diagnosis if other causes of the pain have been ruled out.

If there is a history of severe trauma or clinical evidence of a neurologic deficit, computerized tomography or magnetic resonance imaging (MRI) of the spine should be performed to determine if loss of the integrity of the posterior elements of the spine has led to pressure on neural structures. Similar procedures should be performed if there is a significant possibility that the collapse may be due to the presence of tumor.

Osteoporotic compression fractures almost invariably heal because the collapse increases the amount of bone in the area of the fracture. Treatment of the patient is directed toward providing symptomatic relief and preventing possible complications. Originally, the pain may be severe. Patients should be treated with rest in a firm bed until the initial severe pain has abated, which usually takes 3 to 5 days, although some relatively unstable fractures can be painful for as long as 2 months. Strong analgesics may be necessary at first. Patients may have a transient ileus secondary to pain and retroperitoneal hemorrhage. They should not eat if there is abdominal distension or if they are not hungry. Reintroduction of food should be started with a liquid diet. Routine precautions for bedridden patients to prevent thromboembolic disease should be taken. When the patients can sit comfortably, physical therapy for progressive ambulation should be started with a walker or crutches to reduce the weight that is transmitted through the spine.

Soft Tissue Injuries

Chronic soft tissue injuries, also called tendinitis or soft tissue rheumatism, are a common cause of chronic pain in elderly people (Fig. 44.1). There is a tendency for all musculoskeletal tissues to atrophy with age. This atrophy is most apparent with the skin, which slowly becomes thinner and more transparent, and the bones, which show thinning and osteopenia on x-ray, but similar phenomena occur with muscles, tendons, ligaments, and other soft tissues that cannot be as readily assessed. The natural tendency for people to gain weight as they grow older puts increased demands upon weakened tissues. Minor injuries in elderly people heal slowly and have a greater tendency not to heal if there are continued stresses.

Tendons, ligaments, and other tissues that provide tensile strength have very well organized collagen bundles for maximum strength. Chronic stresses on these structures cause fatigue disruption of the collagen that is replaced by relatively weak, poorly organized scar tissue.²⁶ With rest the patient's symptoms often completely abate but later return after episodes of activity that would not have caused injury to the original tissue but is sufficient to cause injury to the scarred tissue. The result is permanent tissue weakness, frequently accompanied by chronic pain. It is not unusual for a patient to present with a several-year history of intermittent pain in a specific soft tissue structure. They know what makes it worse and what makes it better, and they are not

FIGURE 44.1. Rotator cuff and associated structures commonly involved in pain syndromes.

surprised to hear that the pain may never completely disappear.

Commonly affected areas in the upper extremity include the biceps tendon and rotator cuff of the shoulder, the origin of the finger and wrist extensors (tennis elbow), and extensor pollicis longus and abductor pollicis brevis tendons (de Quervain's). In the back, the fascial attachment of the erector spinae muscles and the interspinous ligaments are common sites of soft tissue injuries. In the lower extremity, the most commonly affected areas in older people are tendons of gluteus medius at the greater trochanter, the pes anserine (conjoint tendon of the sartorius, gracilis, and semitendinosus) on the medial side of the knee, and the insertion of the plantar fascia of the foot onto the calcaneus (heel spur). In each case, there is an element of overuse. Tendinitis around the hip and knee is frequently associated with intra-articular pathology. Presumably, the tendon damage is caused by increased use of the muscles that protect the knee joints; this is particularly true of the pes anserine, which almost always becomes painful from either a degenerative meniscus tear or osteoarthritis in the medial compartment of the knee.²⁷ These same conditions can cause gluteus medius tendonitis because the gluteus medius stabilized the medial compartment of the knee by abducting the thigh when the knee is planted on the ground.

The subjective nature of the symptoms of chronic soft tissue injuries creates multiple problems for physicians trying to treat the diseases. Roentgenographs and laboratory studies are usually not helpful except to rule out other conditions. The patient is often unable to localize the pain that tends to radiate distally away from its source. The tenderness associated with soft tissue injuries, however, can be well localized to the injured tissue. The diagnosis is made by a physical examination that requires the patient to describe the area of tenderness and the physician to identify the area with regard to underlying anatomic structures.

Treatment of Tendinitis/Bursitis Syndromes

Throughout the body, treatment of tendonitis/bursitis syndromes is similar. It should be kept in mind that these syndromes are primarily caused by overuse of specific muscle groups. The patient history should be carefully examined to determine if they are engaging in activities that might have led to excessive stress of the injured tissues. Obesity is a common contributing cause of lower extremity tendinitis. It may be difficult or impossible to obtain symptomatic relief without weight loss.

Exercise

Patients frequently want to know what exercises might help their tendinitis. Because tendinitis can appear after

excessive exercise, it is important to limit exercises that focus on painful muscle groups. Rest, on the other hand, gives rapid relief of symptoms, but also leads to tissue atrophy that renders the tendons more susceptible to future injury when activity is resumed. Gentle muscle-strengthening exercises are probably beneficial. Mild stretching exercises are also important to prevent stiffness and contractures that might render the muscles more susceptible to future injuries. In general, any exercise that does not cause increased pain in the affected tendons is probably beneficial.

NSAIDs

A short trial of oral anti-inflammatory medications may be of benefit. In view of the potential complications, prolonged use of these drugs is probably not warranted except in cases of severe, chronic tendinitis, which have a good response to NSAIDs.

Corticosteroid Injection

There is an acute form of tendinitis that may actually be a different disease in which the patient experiences sharp, incapacitating pain and tenderness without a prior history of pain in the area. Injection of corticosteroids into the affected area frequently provides permanent relief. This acute form is probably an inflammatory condition with little or no damage to the collagen fibers of the tissue. Patients tend to think that all forms of soft tissue pain syndromes can be cured with corticosteroid injections because they know people who have had a good response to the acute form of the disease. Cortisone injections inhibit tissue repair. Repeated injections into chronically weakened tissues are probably detrimental. True bursitis, which is inflammation of a bursa at a bony prominence, is much rarer than tendinitis and can often be cured with cortisone injections.

Palliative Treatments

There are a host of treatments that provide at least temporary relief of the symptoms of soft tissue injuries. These measures include heating pads, liniments, transcutaneous neural stimulation (TENS), acupuncture, aquatic exercising, and ultrasound therapy. These methods are particularly effective if the tendinitis is caused by pain-induced muscle spasms. The treatments relax the muscles, thus reducing the load on the tendons.

Shoulder Pain

Shoulder pain is often very difficult to diagnose because it can have many different causes, including (a) cervical osteoarthritis or a degenerative cervical disk radiating to the shoulder, (b) osteoarthritis of the shoulder or

acromioclavicular joint, (c) tendinitis of the long head of the biceps tendon, (d) tears in the rotator cuff, and (e) impingement of soft tissue on the coracoclavicular ligament and anterior border of the acromion (Fig. 44.2). Even carpal tunnel syndrome, which is caused by compression of the median nerve in the carpal canal, can cause pain radiating to the shoulder. In addition, pain from the diaphragm and heart are often felt in the shoulder and arm, and tumors of the periphery of the lung can present as shoulder and arm pain (Pancoast syndrome).

Pain from the shoulder joint and surrounding soft tissues is usually poorly localized and is frequently most severe along the lateral part of the arm just distal to the insertion of the deltoid muscle. Except in cases of severe inflammation, the pain tends to be dull in character. It is often exacerbated by specific shoulder movements.

Primary shoulder pain rarely, if ever, radiates to the neck. If there is a history of neck pain, numbness, paresthesias, or muscle atrophy in the arm, the neck should be considered as a source of the pain. Pain from the neck is usually increased with movement of the neck, and there may be tenderness of the paravertebral muscles and trapezius. Significant limitation of neck motion may also be present. Roentgenographic evidence of cervical arthritis, alone, is insufficient to conclude that the shoulder pain is coming from the neck because even severe cervical arthritis is often asymptomatic.

Osteoarthritis of the shoulder and acromioclavicular joint is easily seen on roentgenographs. Superior displacement of the head of the humerus with respect to the glenoid indicates that the rotator cuff has a significant tear. The area of the lung near the shoulder should always be inspected to rule out Pancoast syndrome.

FIGURE 44.2. Common sites of soft tissue pain in the geriatric population.

Rotator Cuff and Bicipital Tendinitis

Tears of the rotator cuff are frequently seen in the older age groups.²⁸ Patients complain of pain in the shoulder radiating down the lateral part of the arm that is accentuated by abduction or flexion of the shoulder. Combing the hair and putting on a hat can be very painful and sometimes impossible. When much inflammation is present, the pain that normally is present only with movement becomes constant. Normal movements of the shoulder during sleep can wake the patient and exacerbate problems of insomnia frequently seen in older people.

The rotator cuff is formed from the combined tendons of teres minor (from the lateral border of the scapula), infraspinatus (from the dorsal scapular surface below the spine), supraspinatus (from the dorsal scapular surface above the spine), and subscapularis (from the ventral scapular surface). The tendons converge to form the rotator cuff that covers the top and sides of the humeral head superficial to the joint capsule. Laterally, the rotator cuff inserts into the greater tuberosity of the humerus. The tendon of the long head of the biceps courses in the bicipital groove of the humerus anteriorly and then into the shoulder joint under the rotator cuff where it inserts onto the scapula just above the glenoid rim.

Many factors appear to contribute to degeneration of the rotator cuff. The area of the cuff near its insertion on the greater tuberosity has a very limited blood supply, which may at times be insufficient to sustain the cuff.²⁹ In addition, with flexion of the shoulder the rotator cuff tends to impinge upon the acromion and coracoacromial ligament, causing local abrasion and thinning. Actual tearing of the cuff may be the result of many years of repetitive movement. The biceps tendon can also be similarly damaged. Tenderness of the tendon is often the first sign of impingement. Crepitus is frequently felt over the anterior part of the shoulder when it is put through a full range of motion, and impingement can be demonstrated by forcibly forward flexing the shoulder when the arm is in neutral rotation.³⁰

The muscles of the rotator cuff function to maintain the head of the humerus in the glenoid during arm motion. Tears of the rotator cuff allow the head of the humerus to sublux superiorly during contraction of the deltoid, which would normally cause abduction of the arm. If the tear is large, the superior subluxation of the humeral head can be noted on a roentgenograph of the shoulder. The space between the bottom of the acromion and the top of the head of the humerus is occupied by the joint capsule and rotator cuff. If the space is greatly diminished, the cuff must be torn. Small tears of the rotator cuff often can be demonstrated by MRI.

The treatment of shoulder impingement and rotator cuff tears must be closely tailored to the individual. Patients presenting with shoulder pain who have no loss

of motion should be treated with rest, NSAIDs, and gentle range of motion and muscle-strengthening exercises. In particular, strengthening of the posterior shoulder muscles can often pull the femoral head posteriorly with reduction of impingement pain and crepitus. Corticosteroid injections can be tried if NSAIDs are ineffective. Surgical resection of the anterior acromion and coracoacromial ligament, which can be performed arthroscopically, should be considered for those patients with prolonged pain that is not responsive to conservative treatment.

If the patient has recently developed limitation of shoulder motion, an MRI should be performed to determine if the rotator cuff has a complete tear. Large tears should be repaired if the patient's condition permits. Chronic asymptomatic rotator cuff tears in people over 70 years of age are frequently seen on chest roentgenographs as superior subluxation of the humeral head. Although these patients usually have limited shoulder abduction and flexion, the remnants of the rotator cuff are usually so atrophic that surgical reconstruction would be of little benefit.

Frozen Shoulder

The first symptom of frozen shoulder³¹ is insidious onset of dull shoulder pain, usually with no prior history of trauma. The pain is worse at night and with activity. Patients often have trouble sleeping and tend to hold their arms tightly against their sides. At first, with some encouragement, the shoulder can be put through a full range of motion. Later, all directions of motion become restricted and the pain subsides so long as the shoulder is not moved.

Frozen shoulder is a diffuse inflammation of the rotator cuff. Frequently there is degeneration of the intra-articular portion of the biceps tendon. Contracture of the subscapularis tendon limits abduction and external rotation of the shoulder. Eventually the shoulder capsule itself becomes contracted. Arthrogram of the shoulder shows decreased potential volume of the joint and obliteration of the normal synovial folds and recesses that allow motion.

Frozen shoulder tends to be a self-limiting disease with spontaneous recovery for most patients within 2 years. Early physical therapy probably reduces the length of disability. Patients are often very reluctant to move the joints. The patient should use a sling to rest the shoulder. Gentle range of motion exercises should be performed in the sling to maintain motion. Pendulum exercises in which the patient bends forward and lets his arms sway in a circular motion like a pendulum are particularly good because they do not require shoulder muscle activity and the natural feeling of the sway tends to relieve the patient's apprehensions about moving their arms.

NSAIDs may help to reduce the pain and stiffness. Occasionally, injections of corticosteroid into the sub-acromial bursa are helpful. Gentle manipulation of the shoulder under anesthesia may be necessary for patients who are not responding to physical therapy. Patients not responding to manipulation may need arthroscopic debridement of intrascapular adhesions.

Carpal Tunnel Syndrome

Compression of the median nerve at the wrist causes a constellation of signs and symptoms known as carpal tunnel syndrome.³² The median nerve transverses the carpal canal in conjunction with the long flexor tendons of the fingers. The volume of the carpal canal is limited by the carpal bones dorsally, medially, and laterally, and by the flexor retinaculum ventrally. Swelling of the synovium of the tendons increases the pressure within the canal, which causes nerve compression.

Patients most often complain of painful burning and paresthesias of the first four fingers that is usually most severe at night and often causes insomnia. They report that they have to shake their hands to relieve the tingling. They may say that all their fingers feel numb, but examination demonstrates that numbness, if present, is confined to the first three fingers and the radial side of the fourth. The thenar muscles can be atrophic as a result of compression of the motor branch of the median nerve. Pain will occasionally radiate up the arm to the shoulder.

The most sensitive provocative test for carpal tunnel syndrome is the Phalen test.³³ The patient is asked to completely flex his wrist. Within 1 min, numbness and tingling will be produced, or exaggerated if already present. This test is positive in only 75% of patients. When a Tinel sign (shocklike sensations on percussion of the median nerve at the wrist) is present, the likelihood of carpal tunnel syndrome is great, but absence of a Tinel sign does not preclude the possibility of carpal tunnel syndrome. Electromyography should be performed if the Phalen test is negative in the presence of a high clinical suspicion of carpal tunnel syndrome, or if surgery is being contemplated. Slowing of the nerve conduction velocities is seen when compression of the median nerve is present.

Many diseases are known to cause carpal tunnel syndrome, including all the common chronic inflammatory arthritides, amyloidosis, myxedema, diabetes, and acromegaly. It is frequently seen during pregnancy. An acute form of carpal tunnel syndrome is seen in people who abruptly increase their wrist usage, such as when using crutches. In a large percentage of patients, no etiologic factor can be found. If an etiologic factor is present, therapy should be focused on correcting the problem if possible.

Cock-up splints prevent wrist flexion that causes further compression of the carpal canal. They can be

worn at night and also during the day in severe cases. Injection of the carpal canal with corticosteroids often dramatically relieves the symptoms. If the symptoms are not relieved by injection or if they continue to return after multiple injections, surgical release of the flexor retinaculum should be considered. Atrophy of the thenar muscles is an indication for early surgical intervention because patients often have poor return of muscle strength even with surgery.

Foot Problems in the Elderly

Foot problems are often a major source of concern of elderly people. Diseases of aging that affect the musculoskeletal system are frequently first seen in the foot. Osteoarthritis is often first manifested as a bunion of the first metatarsal phalangeal joint. Muscle weakness appears as loss of strength of the interosseous muscles of the foot leading to claw toes. Arterial insufficiency often appears first as pain in the feet. Diabetic vasculopathy and neuropathy often become clinically significant first in the feet.

Shoe Wear

Many of the chronic foot problems seen in older patients are caused by inappropriate footwear. Bunions are not seen in populations that do not wear shoes. High heels can cause contractures of the Achilles tendon and claw toes. Shoes with narrow toes can cause corns as well as bunions. Shoes with hard soles can cause callosities on the bottom of the feet. The time to start wearing appropriate shoes is before the foot deformities appear. After a deformity is present, proper shoes may reduce its effects but cannot correct it.

Fortunately, shoe companies are beginning to make shoes that are both comfortable and acceptable in most social settings. Shoe soles of soft material such as polyurethane have several beneficial effects. They prevent callosities on the bottom of the foot where the soft tissue padding under bony prominences has been lost. Ample arches in the shoes protect the tibialis posterior tendons. They also reduce the amplitude of the forces transmitted from the ground through the foot while walking (ground reactive forces). Reduction of these forces has mitigating effects upon hip and knee osteoarthritis and all types of musculoskeletal low back pain. It may also prevent osteoarthritis in the joints of the foot.

Tarsal Tunnel Syndrome

Compression of the posterior tibial nerve at the ankle causes burning pain on the plantar aspect of the foot known as tarsal tunnel syndrome.³⁴ The burning is often

accompanied by tingling and numbness that is poorly localized. In most patients it is aggravated by activity, but it may also be severe at night. It appears to be analogous to carpal tunnel syndrome in the hand, which is caused by compression of the median nerve in the carpal canal.

Patients usually have a positive Tinel's sign, which is a feeling of electrical shocks when the injured part of the nerve is percussed. The tarsal canal extends around the medial malleolus into the plantar aspect of the foot. The Tinel's sign may be positive anywhere within the tunnel and is sometimes positive along the distal calf, proximal to the medial malleolus. The diagnosis is established by demonstration of decreased nerve conduction velocities of the posterior tibial nerve or one of its branches.

Tarsal tunnel syndrome can often be treated by local injection of steroids or NSAIDs. Occasionally, casting for short periods of time is beneficial. If conservative methods fail, the tarsal tunnel can be surgically released, but the patients should be warned that symptoms often persist after the release.³⁵

Hallux Valgus (Bunion)

Bunions³⁶ are medial protuberances of the first metatarsal phalangeal joints that appear if the first toes deviate laterally. The joints frequently have roentgenographic signs of osteoarthritis. Pressure from shoe wear causes the medial capsule of the joint to become thickened and inflamed, and an exostosis develops on the head of the metatarsal. Superficial nerves that course over the top of bunions often become inflamed, causing feelings of numbness along the medial side of the great toe. In older people, the great toe frequently crosses above or below the second toe, and this can lead to painful sores or areas of maceration. Interposition of a pad between the two toes is frequently helpful.

Although proper footwear helps prevent the appearance of bunions, it cannot correct bunions after they have formed. Abnormal pull of the tendons around the deformed joint with contracture of the joint capsule prevent return of the toe to its correct position. If a bunion is painful and disabling, surgical reconstruction may be necessary. Bunionectomies can usually be performed under local anesthesia, often without hospitalization of the patient. If the bony deformities are mild, removal of the exostosis and soft tissue realignment may be all that is necessary. More complicated bunions require osteotomy of the metatarsal or first phalanx as well.

A "bunionette" or "tailor's bunion" is a prominence along the lateral side of the forefoot resulting from lateral protrusion of the head of the fifth metatarsal bone. At least some prominence of the fifth metatarsal head is a normal finding in most people. The prominence is accentuated by wearing shoes with narrow toes. The fifth toe is

pushed medially, and the prominence becomes irritated by direct pressure from the shoe. A callous forms on the skin over the prominence and a bursa often forms between the skin and fifth metatarsal phalangeal joint. In general, bunionettes can be successfully treated by wearing shoes with wide toes and by padding over the painful prominence.

Claw Toes

Claw toes is a common foot deformity that appears to be due to ineffective action of the intrinsic muscles of the foot. Although the leg muscles provide most of the strength of the toes, the lumbricals and interosseous muscles of the foot help to keep the toes elongated during flexion by flexing the metatarsophalangeal joints and extending the interphalangeal joints. Without the intrinsic muscles, flexion of the toes by the leg muscles alone causes hyperextension of the metatarsophalangeal joints and flexion of the interphalangeal joints, which is claw toes. Painful corns develop over the hyperflexed proximal interphalangeal joints, and callosities develop on the tips of the toes that are pushed into the sole of the shoe while walking. Claw toe deformities usually involve all the toes of the foot including the great toe. The deformity of claw toes may be accentuated by wearing high-heeled shoes or shoes that are too narrow and short at the toe.

Conservative treatment for claw toes includes shoes with broad toe width and soft soles to distribute the pressure. In severe cases, surgery to straighten the toes may be necessary.

Heel Spur

Pain in the heel during weightbearing is often caused by inflammation where the plantar aponeurosis attaches to the tuberosity of the calcaneus. As with other forms of tendinitis, the point of attachment to bone appears to be the weakest area and the one most likely to be chronically inflamed, presumably due to microtears. Prolonged inflammation leads to accretion of new bone, called a spur. Tenderness is usually found at the point where the plantar aponeurosis attaches to the calcaneus, which starts in the middle of the bottom of the heel and extends medially.

The distal part of the plantar aponeurosis attaches to the base of the proximal phalanges. Dorsiflexion of the phalanges during normal gait accentuates the arch and therefore shortens the foot. If the heel is everted and the arch is relatively flat, large stresses are put upon the aponeurosis with toe dorsiflexion. The stresses can be relieved by wearing soft-soled shoes with good arch supports. If pain persists, many conservative approaches are possible including foot orthotics to keep the heel

inverted, oral anti-inflammatory medications, and local injection of corticosteroid.³⁷ When pain is unremitting despite conservative measures, surgical excision of the spur is often beneficial.³⁸

Diabetic Foot Problems

Foot infection is the most common infection in diabetics that requires hospitalization.³⁹ Almost all patients with long-standing diabetes have peripheral neuropathies that lead to severe arthropathies (Charcot joints) because the patients are unable to perceive when their joints are being damaged. As the joints are destroyed, the bones around the joints become deformed and often form protuberances below the skin. Foot ulcers appearing over the protuberances inevitably become colonized with bacteria that penetrate the foot because the vascular status of the foot is so poor that it is unable to form a protective barrier against bacterial invasion. Ischemia of the foot appears to be caused by both atherosclerotic narrowing of large arteries and diabetic microangiopathy.

Prevention is the best approach to dealing with diabetic ulcers. Prominences that cause focal pressures with weightbearing should be treated with local padding, soft-soled shoes, and padded stockings. Pressing against the sole of the foot with a nylon fiber can indicate which patients have developed peripheral neuropathy to the point that they no longer have protective sensation.⁴⁰ These patients should have frequent inspections for early skin changes.

Treatment of superficial ulcers includes padding to take the weight off the region of the ulcer, intensive wound care, and elevation to reduce swelling. If the arterial blood pressure at the ankle is greater than half the brachial artery pressure, the ulcers have an excellent chance of healing.⁴¹ Treatment of deep infections consists of excision of infected bone, intensive wound care, and intravenous antibiotics.⁴² Deep infections can be difficult to diagnose by physical examination alone because of the poor circulation and neuropathy.

Medical Aspects of Hip Fracture Management

R. Sean Morrison and Albert L. Siu

Hip fractures are an important cause of mortality and functional dependence in the United States. Approximately 250,000 hip fractures occur annually in this country, and this number is expected to increase to more than 650,000 by the year 2040.^{1,2} For adults over age 65, the annual incidence of hip fracture is 818 per 100,000 persons,³ and women are two to three times more likely to experience a fracture than men.^{4,5} Indeed, it is estimated that a white woman with an average life expectancy of 80 years has a 15% lifetime risk of fracture and that, by age 80, she has a 1% to 2% annual risk.⁶ The mortality seen in the Medicare population following fracture is 7% at 1 month, 13% at 3 months, and 24% at 12 months.⁷ For those patients who survive to 6 months, 60% will have recovered their prefracture walking ability, 50% will have recovered their prefracture ability to perform their activities of daily living, and about 25% will have recovered their prefracture ability to perform instrumental activities of daily living.⁸ However, after 1 year, only 54% of surviving patients are able to walk unaided, and only 40% are able to perform all physical activities of daily living independently.⁸ The costs associated with a single hip fracture episode (acute care, rehabilitation, home care services) range between \$30,850 and \$37,250 in the United States,⁹⁻¹¹ and the annual total costs associated with this disease exceed \$5 billion.¹² Furthermore, it is estimated that these total annual costs will increase to \$16 billion by the year 2040 as a result of the projected increase in the number of adults over age 65.

Although surgical repair of the fractured extremity is the cornerstone of therapy, available data suggest that the crucial factors that determine optimal functional recovery in hip fracture are independent of the fracture repair but instead are related to prefracture conditions and postfracture complications.¹³ Thus, the successful care and outcome of the hip fracture patient require an active partnership between the orthopedic surgeon and medical consultant—the latter's role being to serve as the primary care physician, to medically evaluate and stabilize the patient before surgery, and to prevent and manage post-

operative complications (e.g., delirium). In this chapter, we focus on the medical care processes relevant to the hip fracture patient, with the exception of fall prevention and osteoporosis, which are covered in Chapters 66 and 44, respectively. Readers interested in the surgical management of the hip fracture patient are directed to the article by Zuckerman and Schon.¹⁴

Diagnosis and Surgical Repair

The majority of hip fractures are easily diagnosed on the basis of history, physical examination, and standard radiographs. Ninety percent of hip fractures result from a simple fall, and the characteristics of the fall (direction, site of impact, and protective response), as well as certain patient characteristics, are recognized as important factors influencing the risk of fracture.¹³ A diagnosis of osteoporosis is the leading factor that places patients at increased risk for hip fracture.¹³ Other patient characteristics that have been shown to be associated with hip fracture include female sex, white race, maternal history of hip fracture, physical inactivity, low body weight, consumption of alcohol, previous hip fracture, nursing home residence, visual impairment, cognitive impairment, and psychotropic medication use.¹³ Patients with hip fracture typically report hip pain on weightbearing following a fall, and on physical exam the involved leg is often foreshortened and externally rotated. Plain radiographs (an anteroposterior view of the pelvis and a lateral view of the femur) of the hip confirm the diagnosis in the majority of circumstances. Occasionally, however, plain films do not reveal evidence of a fracture despite a high clinical suspicion (e.g., pain with weightbearing after a fall). In these cases, an anteroposterior view obtained with the hip internally rotated 15° to 20° may reveal a fracture by providing an optimal view of the femoral neck.¹³ In circumstances in which all plain films are negative but clinical suspicion is still high, either a technetium-99m bone scan or an MRI should be under-

taken to rule out an occult fracture. The MRI appears to be a more sensitive test to detect early fractures as the bone scan can be normal within the first 72 h following a fracture. If all tests or imaging studies are unrevealing, other diagnoses to consider include fractures of the pubic ramus, acetabulum, or greater trochanter, trochanteric bursitis, or trochanteric contusion.

Hip fractures may be classified as femoral neck (intra-capsular), intertrochanteric, or subtrochanteric. Femoral neck fractures occur distal to the femoral head but proximal to the greater and lesser trochanters and are thus located within the capsule of the hip joint. The location of the fracture has important implications for healing and operative repair. Fractures in this region can disrupt the blood supply to the femoral head and can result in complications such as nonunion and avascular necrosis of the femoral head. Thus, although nondisplaced and minimally displaced femoral neck fractures can often be treated by insertion of cannulated screws, displaced femoral neck fractures typically require a hemiarthroplasty procedure to ensure appropriate fracture healing.

Intertrochanteric fractures are located lateral to the femoral neck. These fractures occur in a well-vascularized metaphyseal region between the greater and lesser trochanters, and although intertrochanteric fractures can be associated with considerable blood loss, typically they are not associated with the healing complications associated with femoral neck fractures. Intertrochanteric fractures are typically repaired by open reduction and internal fixation with a compression screw device.

Subtrochanteric fractures occur just below the lesser trochanter and account for only 5% to 10% of hip fractures. These fractures behave clinically like long bone fractures and are repaired either by insertion of an intramedullary device or by placement of a compression screw and long side plate.

Nonoperative management should be considered for nonambulatory patients with advanced dementia. One recent study suggested that mortality following fracture in patients with end-stage dementia exceeds 50% at 6 months.¹⁵ For such patients, aggressive pain management and a return to their previous home environment may be the optimal treatment plan given the burdens associated with routine hospitalization, such as delirium, restraints, and painful therapeutic interventions (phlebotomies, arterial blood gas monitoring, intravenous catheter insertions).^{15,16}

Medical Processes of Care

Timing of Surgery

The timing of surgical repair of hip fracture may affect patient outcome in two ways. Delay in surgical repair, and hence delay in return to weightbearing, could affect func-

tional recovery. Conversely, failure to stabilize medical problems before surgery could increase the risk of perioperative complications. Although the scheduling of surgery is set by the orthopedist, the rate-limiting step in this process is often the internist's preoperative medical evaluation.

Ten case series,¹⁷⁻²⁶ one randomized controlled trial of anesthetic techniques that included surgical delay as an independent variable,²⁷ and one autopsy series²⁸ have examined the impact of operative timing on postoperative outcome in hip fracture. The results of these 12 studies suggest that early surgical repair (within 24-48h) is associated with lower mortality rates at 1 year. However, the majority of these studies did not adjust for the presence and severity of comorbid illness, preoperative functional status, or other physiologic parameters. Additionally, many of the studies excluded patients with complicating medical conditions. Of the 6 studies that did attempt to control for comorbidities,^{20,23,25-27} 4 revealed lower mortality rates, 1 revealed shorter length of hospital stay, and 1 reported a lower incidence of confusion and pressure ulcers in patients who underwent surgical repair within 48h.

In summary, there is evidence from case series that for patients who are medically stable without active comorbid illness (e.g., active heart failure), surgical repair of hip fracture within the first 24 to 48h of admission is associated with a lower 1-year mortality as compared to patients whose surgery is delayed. Patients who would benefit from delay and further medical evaluation have not been well characterized. Until further data are available, it seems reasonable to attempt surgical repair for the majority of patients with hip fracture within 24 to 48h of admission to the hospital. Patients with active comorbid medical illness such as congestive heart failure, active infection (e.g., pneumonia), unstable angina, or severe chronic obstructive pulmonary disease probably would benefit from a more extensive preoperative evaluation and medical management of their comorbid condition before repair of their fracture.

Prophylactic Antibiotics

Antibiotic prophylaxis has become the standard of care for major surgical operations to prevent postoperative wound complications. In hip fracture, the timing of administration, the duration of antibiotic therapy, and the effectiveness of antibiotic prophylaxis has been the subject of some debate in the literature.

A recent Cochrane Collaboration Review²⁹ identified 21 studies that addressed the issue of prophylactic antibiotics in hip fracture. Overall, the quality of the studies was poor to moderate. Although the regimens of antibiotic prophylaxis differed in most of the studies, all reported trials employed agents likely to be widely effec-

tive at the time the study was performed against *Staphylococcus aureus*, the principal organism implicated in postoperative wound infections. Pooled data from six trials that examined a single preoperative dose of parenteral antibiotics versus placebo or no treatment found reductions in the incidence of deep wound infection (odds ratio, 0.42; 95% CI, 0.26, 0.68), of superficial wound infections (odds ratio, 0.67; 95% CI, 0.47, 0.94), of respiratory infections (odds ratio, 0.42; 95% CI, 0.29, 0.61), and of urinary tract infections (odds ratio, 0.51; 95% CI, 0.39, 0.66). Pooled data from 10 trials that examined the effect of a single preoperative dose and two or more postoperative doses compared to placebo or no treatment revealed similar risk reductions.

Five trials have compared single doses of antibiotics to multiple dose regimens. Pooled data from two trials that compared a single dose of a short-acting parenteral antibiotic with multiple doses of the same antibiotic suggest that a single dose of a short-acting antibiotic is significantly less effective in preventing deep wound, superficial wound, and urinary tract infections as compared to a multiple dose regimen. Three additional trials compared a single dose of a parenteral antibiotic with a long half-life to multiple doses of another agent with a short half-life. Pooled data from these trials revealed no difference in deep wound infections, superficial wound infections, urinary tract infections, or respiratory infections.

The timing of administration of antibiotic prophylaxis has not been well studied. A recent review of the literature³⁰ found only one study³¹ that examined this topic, and this was a cohort study of 2847 elective surgical procedures. In this study, patients administered their first dose of antibiotics less than 2h before surgery had the lowest incidence of postoperative infections as compared to those receiving antibiotics within 3h following surgery (odds ratio, 2.4; 95% CI, 0.9–7.9), 3 to 24h following surgery (odds ratio, 5.8; 95% CI, 2.6–12.3), or more than 2h before surgery (odds ratio, 6.7; 95% CI, 2.9–14.7). These data, in combination with those data described earlier, suggest that the minimum inhibitory concentration of the antibiotic in the tissues must be exceeded for at least the period from incision to wound healing to minimize the risk of postoperative infection.

In summary, the available evidence support the use of a single dose of an intravenous antibiotic with a long half-life to reduce the incidence of deep wound infection, superficial wound infection, urinary tract infections, and respiratory tract infections. Furthermore, economic cost data from two studies^{32,33} suggest that antibiotic prophylaxis is cost-effective, with a conservative estimate of cost savings of about \$500 per patient given prophylaxis. Given that the major pathogen appears to be *S. aureus*, we recommend administration of a first-generation cephalosporin (e.g., Cefazolin 1–2g intravenously). For patients allergic to penicillins and cephalosporins and for

patients admitted to hospitals in which methicillin-resistant *S. aureus* and *Staphylococcus epidermis* are frequent causes of postoperative wound infections, vancomycin is probably the most appropriate prophylactic agent (1g intravenously).³⁴ Based upon one large cohort study,³¹ prophylactic antibiotic therapy should probably be initiated within 2h before surgery and continued for 24h following surgery.

Thromboembolic Prophylaxis

Venous thromboembolism is an important cause of morbidity and mortality in postoperative hip fracture patients. Although thromboembolic prophylaxis is becoming a routine aspect of the care of the patient with hip fracture, a number of questions remain as to the choice of the optimal agent, the timing of prophylaxis, and the duration of prophylaxis after fracture repair. Studies to date have focused on four classes of agents—heparanoids, antiplatelet agents, warfarin sodium, and dextran—and on the use of compression stockings.

Three meta-analyses^{35–37} have included hip fracture patients and an additional 11 randomized controlled trials have examined prophylactic antithromboembolic agents in hip fracture.^{38–48} There is strong support for the use of prophylactic antithromboembolics based upon the studies reviewed, although the choice of the optimal agent is less clear. Low-dose heparin (5000 international units given subcutaneously twice a day) has been the agent most frequently studied in hip fracture and has been associated with about a 60% reduction in deep venous thromboses by one meta-analysis.³⁵ Low molecular weight heparin has also been evaluated by meta-analysis and shown to lead to a similar reduction in deep venous thrombosis.³⁶ This latter meta-analysis also pooled data from four studies that compared low molecular weight heparin to low-dose heparin and found no significant differences between the two agents in the development of deep venous thrombosis. It has been reported recently that low molecular weight heparins, when used concurrently with spinal or epidural anesthesia, may cause bleeding or hematomas within the spinal column.⁴⁹ In the trials to date that have involved low molecular weight heparin and hip fracture, there have not been any reported episodes of epidural bleeding. However, these trials were not powered to detect this uncommon complication in the subgroups receiving spinal or epidural anesthesia. Until more data are forthcoming, we believe that the current FDA recommendations, that patients receiving epidural or spinal anesthesia and receiving concurrent low molecular weight heparin be monitored frequently for signs and symptoms of neurologic impairment, are appropriate.⁴⁹ It should be noted that this recent FDA report only involved patients receiving low molecular weight heparin and should not deter

prophylaxis with low-dose heparin where indicated. Low-dose heparin appears to increase the risk of major bleeding episodes by about 30% to 41% as compared to patients receiving placebo, but the actual percentage increase is small (overall rates, 3.5% in heparin groups as compared to 2.9% in placebo).³⁵

The use of aspirin as prophylaxis has been examined in one meta-analysis of 10 orthopedic trauma trials, 9 of which included only hip fracture patients and 1 of which included hip and pelvic fracture patients.³⁷ Additionally, the efficacy of aspirin has been recently examined in a large randomized controlled trial that enrolled more than 13,000 hip fracture patients.⁴⁸ Aspirin has been found to significantly reduce the risk of deep venous thrombosis and pulmonary embolism by about one-third, with much of this benefit appearing to occur after the first post-operative week. Head-to-head comparisons of aspirin to other agents have been limited. In the one study where aspirin was compared to low molecular weight heparin in the prevention of deep venous thrombosis,⁴⁷ low molecular weight heparin was found to result in a relative risk reduction of 37% with no significant difference in bleeding complications as compared to aspirin.

A number of other prophylactic agents have been evaluated. Low-dose warfarin (1.5 times control) has been compared to placebo in two studies^{38,39} and additionally to low molecular weight heparin⁴⁰ and to aspirin.³⁸ Warfarin significantly reduces the risk of thromboembolic disease as compared to placebo and aspirin, and the magnitude of risk reduction appears to be comparable to that of low-dose unfractionated heparin.³⁰ When compared directly to low molecular weight heparin, warfarin appears to be less effective (odds ratio, 0.27 for low molecular weight heparin). In summary, low-dose warfarin appears to be an effective agent for thromboembolic prophylaxis. It appears more effective than aspirin but is probably less effective than low molecular weight heparin. The required international normalized ratio (INR) monitoring required for appropriate treatment with warfarin to prevent either over- or underanticoagulation is a potential drawback. Conversely, it might be a better tolerated agent for patients wishing to avoid the discomfort of a twice-daily injection.

Dextran, although not widely employed in the United States, has been perhaps the most extensively studied prophylactic agent after heparin. Five trials have examined the use of dextran, with somewhat conflicting results.⁴⁰⁻⁴⁴ Dextran clearly appears to be more efficacious than placebo [odds ratio, 0.09 ($p < 0.05$)]⁴¹ and appears to be as effective as aspirin [odds ratio, 0.56 ($p > 0.05$)].^{41,43} Two studies that compared dextran to low-dose unfractionated heparin observed no significant differences between the two groups in the development of thromboembolic complications.^{41,42} However, both these studies were quite small, and it is questionable whether they had

adequate power to detect a true difference. In contrast, two larger studies that compared dextran to low molecular weight heparin observed a significant reduction in thromboembolic events in the heparin groups [odds ratios, 0.25 ($p < 0.001$) and 0.49 ($p < 0.005$)] as compared to the dextran groups.^{44,45} In summary, dextran appears to provide protection against the development of thromboembolic events at a level comparable to aspirin. It is probably less efficacious, however, than warfarin or heparin. The potential for dextran administration to cause volume overload resulting in congestive heart failure or renal insufficiency, and the small risk of anaphylaxis associated with this agent argues against its routine use in the geriatric population, particularly given the availability of equally or more efficacious agents. Typically, dextran is administered as a 10% solution in 500 to 1000 mL normal saline per day.

Pneumatic sequential leg compression devices have been shown to decrease the incidence of postoperative deep vein thrombosis in urologic, neurosurgical, and general surgical patients.⁵⁰ Compression stockings have also been recently evaluated in patients with hip fracture and have been shown to significantly reduce the incidence of thromboembolic events as compared to no treatment.⁴⁶ Given these data, we recommend the routine use of intermittent pneumatic compression devices until the patient is ambulating on a routine basis.

When to begin and how long to continue anticoagulation therapy following fracture is currently not known, and there are no data available with respect to hip fracture that address this issue. Most of the studies have begun anticoagulant therapy on admission, although this has not been studied in a systematic manner. Two autopsy series involving hip fracture patients suggest a role for continuing prophylaxis following hospitalization. In a group of patients who did not receive any form of prophylaxis, the rate of fatal pulmonary embolism declined from 1% at 30 days to 0.4% at 60 days and 0.2% at 90 days.⁵¹ Conversely, in a second autopsy series of patients, all of whom received prophylactic thromboembolic agents, the majority of fatal pulmonary embolisms were observed 30 days or more following fracture repair.⁵² The results of these two studies suggest that prolonged prophylaxis might be helpful in some patients, although which patients and for how long need to be empirically studied. At present, it seems reasonable to begin anticoagulation on admission and continue prophylaxis until the patient is fully ambulatory and to extend prophylaxis further in patients in whom the risk of deep venous thrombosis may be increased (patients who experienced prolonged immobility postrepair or patients in whom surgery was delayed).

In summary, there is strong evidence supporting the use of either low-dose heparin or low molecular weight heparin as prophylaxis for deep venous thrombosis. The latter may be slightly more effective but is more expen-

sive and has been associated with bleeding or hemorrhage in the spinal cord following epidural anesthesia in nonhip fracture populations. For these reasons, and until further data are available, low-dose heparin is probably the preferred agent. Aspirin also appears to have some benefit but to a lesser extent and may be considered in patients at high risk for hemorrhagic complications. Several studies support the use of low-dose warfarin; however, the required INR monitoring and risk of over- or underanticoagulation are potential drawbacks. Some patients, however, might strongly prefer weekly INR monitoring to the twice-daily injections required for heparin or low molecular weight heparin. Compression stockings appear to impart benefit with negligible risk and should be utilized. No data are yet available as to the timing of prophylactic thromboembolics and the optimal duration of therapy.

Nutritional Management

Malnutrition has been associated with increased surgical morbidity and mortality,^{53,54} increased hospital length of stay,⁵⁴ and poorer functional outcomes.⁵⁴ It has been reported that as many as 20% of patients experiencing a hip fracture suffer from severe malnutrition.⁵⁵ Interventions to improve nutritional status might therefore improve outcomes and decrease complications.

To date, there have been five randomized controlled trials of nutritional supplementation in patients undergoing surgery for hip fracture. Three of the studies examined oral protein supplementation⁵⁶⁻⁵⁸ and two studies examined supplemental nasogastric tube feeding.^{59,60} All the studies suggest that oral protein supplementation can improve outcomes following fracture.

Stableforth⁵⁸ compared hip fracture patients randomized to protein supplementation versus usual care and reported significantly improved nitrogen and calorie balance in the supplemented group. Delmi and colleagues⁵⁷ and Tkatch and colleagues⁵⁶ randomized hip fracture patients to receive either protein supplementation or usual care⁵⁷ or placebo.⁵⁸ Patients receiving protein supplementation were found to have significantly fewer complications at 6 months, significantly higher albumin levels, and significantly shorter overall lengths of stay than nonsupplemented subjects.

Bastow and colleagues⁵⁹ examined the effect of nocturnal nasogastric tube feeding in 122 patients at increased risk for nutritional compromise (arm and trifold skin circumference less than 1 SD below the mean) for home and hospitalized elderly patients.⁶¹ Patients were randomized to usual care or nocturnal tube feedings. There were no significant differences in mortality, although the study lacked statistical power to detect this difference. Very thin patients had a significant reduction in overall length of stay and had significant increases in weight (+4.2 kg;

$p < 0.01$)) as compared to controls. Tube-fed patients achieved independent mobility significantly faster than nontube-fed patients. One-fifth of patients could not tolerate the nocturnal feedings. Hartgrink and colleagues⁶⁰ examined the effect of supplemental nocturnal tube feeding on the development of pressure ulcers, serum protein, and serum albumin. No significant differences were found in any of the three outcome measures, although only 26 percent of patients tolerated the tube feedings for the 2-week study period.

Oral protein supplementation appears to be beneficial in reducing minor postoperative complications, preserving body protein stores, and reducing overall length of stay. Patients with evidence of moderate to severe malnutrition may benefit from nocturnal enteral tube feeding if tolerated.

Urinary Tract Management

Urinary retention, incontinence, and urinary tract infections are commonly observed in postoperative hip fracture patients.⁶² Because of the frequency of postoperative bladder problems, successful strategies to reduce voiding problems might lead to decreased morbidity. There have been two randomized controlled trials of urinary bladder management in patients undergoing orthopedic surgery.^{63,64} One study examined patients with recently sustained hip fracture and the other examined patients undergoing hip or knee replacement.

Michelson and colleagues⁶⁴ randomized 100 patients with knee or hip replacement to removal of their indwelling urinary catheter immediately postoperatively or the morning following surgery. The group whose indwelling catheter was removed the morning after surgery had significantly lower rates of urinary retention. Skelly and colleagues⁶³ randomized 67 hip fracture patients to receive an indwelling catheter for 48h postoperatively, followed by intermittent straight catheterization or intermittent straight catheterization immediately postoperatively. Spontaneous voiding occurred significantly earlier in the intermittent catheterization group. There were no significant differences in the incidence of urinary tract infections in either of the two studies between control and intervention subjects.

Indwelling catheters should probably be removed within 24h of surgery and patients managed by intermittent straight catheterization. Evidence does not exist regarding the management of patients who continue to experience urinary retention following 48h of intermittent catheterization.

Delirium

Delirium, a transient global disorder of cognition and attention characterized by concurrent disorders of atten-

tion, perception, thinking, memory, psychomotor behavior, and the sleep-wake cycle,^{65,66} may be the most frequent medical complication observed following hip fracture.⁶⁷ Delirium occurs in an estimated 11% to 30% of elderly general medical patients⁶⁸ and in 13% to 61% of patients with hip fracture.⁶⁹ The occurrence of delirium in hospitalized patients has been shown to increase length of stay, risk of complications, mortality, and institutionalization.⁷⁰⁻⁷⁴ Further, the majority of patients who develop delirium have at least some persistent symptoms as much as 6 months later. In patients with hip fracture, delirium has been associated with poorer functioning in physical, cognitive, and affective domains 6 months post-fracture and with slower rates of recovery.^{75,76} In this section, we focus specifically on the problem of delirium following hip fracture. A more thorough review of delirium may be found in Chapter 76.

For this discussion, we focused on three types of investigations. First, we identified studies that employed multivariate methods to identify risk factors that, if modified, might prevent delirium; 15 studies met these criteria.^{69,74,77-89} Second, because the treatment of the underlying etiology is a cornerstone of the management of delirium, we reviewed studies that systematically described the frequency of different etiologies for this syndrome. We found 4 cohort studies,^{79,90,91} 1 of which involved exclusively hip fracture patients. Finally, we identified studies that focused on the prevention and management of delirium in hip fracture patients. We found 2 nonrandomized studies that examined supportive treatment of delirium.^{92,93}

The findings with regards to baseline risk factors for delirium appear to be fairly consistent across most studies. Advanced age, history of cognitive impairment, greater illness severity, and history of alcohol use appear to place hospitalized medical and surgical patients at increased risk for the development of confusion. In the two studies of hip fracture patients, only age, dementia, and prefracture functional status predicted the development of delirium.^{69,77} Precipitating risk factors have been more difficult to identify and, with few exceptions, a clear understanding of the iatrogenic conditions that place elderly patients at increased risk for delirium has yet to emerge. Although many risk factors have been proposed in the literature (e.g., metabolic disturbances, dehydration, alcohol withdrawal, urinary retention, changes in environment, psychosocial factors, and medications),⁹⁴ only a few factors have been consistently identified as precipitating factors in prospective trials, and even these relationships are not consistent across studies. One particularly noteworthy finding, however, has been that two recent studies^{88,89} have suggested that untreated or undertreated postoperative pain places patients at increased risk for delirium and that, in this setting, opioid analgesic use does not increase the risk of delirium. No precipitat-

ing factors were identified in the two studies of hip fracture patients.^{77,93}

Regarding the etiology of delirium, there have been three case series^{79,90,91} that examined this issue in medical and surgical patients and one study that examined the etiology of delirium in hip fracture.⁹⁵ Delirium in hip fracture appears to result from different etiologies and appears to follow a different clinical course from that observed in the medically ill. Brauer and colleagues⁹⁵ found that in more than 60% of observed cases of delirium following hip fracture, the etiology could not be determined. In the majority of cases (74%), the delirium resolved or was nearly resolved at the time of hospital discharge without active intervention. These findings are in contrast to data in the medically ill that suggest that an etiology for delirium can be determined in the majority of circumstances, that delirium tends not to resolve spontaneously but improves only after therapeutic intervention.^{72,74}

The management of delirium has been based largely on clinical experience because few systematic and controlled studies have been performed.⁹⁴ There have been two nonrandomized studies involving hip fracture patients. Williams and colleagues⁹² conducted a time sequence trial using pre- and postoperative nursing interventions (e.g., environmental manipulation, reorientation, reassurance) in hip fracture patients. The incidence of delirium was 44% in the treatment group as compared to 52% in the control ($p < 0.02$). Gustafson and colleagues⁹³ compared 103 treatment subjects with 111 historical controls admitted 2 to 5 years before the intervention cohort. The intervention in this study consisted of pre- and postoperative geriatric assessments, oxygen therapy for hypoxia, early surgery (performed as soon as patients were medically stable), and aggressive treatment of perioperative blood pressure falls. The incidence of delirium was 61% in the historical controls and 48% in the treatment group ($p < 0.05$). Subjects in the treatment group were less likely to be confused for more than 7 days (9% versus 28%) and had a shorter length of stay (11.6 versus 17.4 days). The individual contributions of each of the various components of the intervention to the reduction in delirium are unknown.

In summary, although many cohort studies have examined the risk factors for developing delirium, most analyses have not specifically focused on hip fracture patients and many studies have lacked adequate statistical power. Nevertheless, the assembled studies indicate a number of recurring potentially modifiable risk factors for developing delirium including electrolyte and metabolic laboratory abnormalities, medications with psychoactive properties, and infection. Environmental manipulation and supportive reorientation appear to reduce the incidence of delirium and benefit the acutely delirious patient, although more research addressing the optimal symptomatic management is needed.

Rehabilitation

Rehabilitative services for hip fracture patients may include limb and joint mobilization and progressive exercises; physical and occupational therapy to regain mobility and independence in activities of daily living; physician oversight of the therapy; psychologic counseling; social work; restorative nursing services; and recreational services. For the purposes of this chapter, we focused on selected aspects of rehabilitation that are particularly salient to the primary care provider (e.g., internist, family practitioner, nurse practitioner), recognizing that rehabilitation is a shared responsibility with the surgeon who, depending on the fracture and type of surgery, may have specific recommendations about mobilization and weightbearing. Specifically, we address the value of (a) early mobilization, (b) intensified interdisciplinary rehabilitation approaches, and (c) intensity and frequency of therapy.

There have been a number of reports of programs that employed early mobilization or early weightbearing policies. From these reports, we excluded studies, primarily from the 1960s through 1970s, that reviewed the experience of "early weightbearing" initiated many days or weeks after the perioperative period and focused only on those studies that reported on early mobilization in the first 24 to 48 h. For this group of interventions, we identified one randomized trial⁹⁶ that included early mobilization as part of a larger program of accelerated rehabilitation; we also identified a large number of trials that employed early mobilization policies in the first 24 to 48 h for all subjects.⁹⁷⁻¹⁰⁸ In the case of intensified interdisciplinary rehabilitation programs, we identified four randomized trials.¹⁰⁹⁻¹¹² For the intensity and frequency of physical therapy, we identified two small randomized trials^{102,112} and three cohort studies that attempted to control for potential confounding between patient characteristics and receipt of services.^{8,26,113}

The one randomized trial that evaluated early mobilization (usually within 24 h of surgery) did so as part of a program that also included early discharge from the hospital and a comprehensive rehabilitation program during and after hospitalization.⁹⁶ Although that trial of 252 patients found no differences in physical independence of patients at 4 months, it showed that so-called accelerated rehabilitation could reduce health care costs. Other studies⁹⁷⁻¹⁰⁸ have shown that policies on early mobilization from the first postoperative day can be implemented without an increased risk of surgical complications,⁹⁷⁻⁹⁹ change in discharge destination,^{97,101} poorer functional outcomes,^{97,100,102} and increased mortality.^{99,101}

There have been four, relatively small, randomized trials that evaluated the benefits of geriatric interdisciplinary rehabilitation.¹⁰⁹⁻¹¹² Two of the studies found no differences in functional outcomes,¹¹² mortality, or

placement.¹¹⁰ Two studies, however, found positive effects associated with these programs. Kenzie and colleagues,¹⁰⁹ in a study of 112 patients, reported improved functional status and found that patients were more likely to be discharged to their own home than to a nursing home following interdisciplinary rehabilitation. Additionally, a randomized trial of geriatric assessment and rehabilitation in which hip fracture was the most common diagnosis (occurring in 18% of the patients) found that geriatric rehabilitation improved the chances of returning to the community.¹¹¹

Two randomized trials have evaluated intensified physical therapy (e.g., therapy sessions twice rather than once a day or supplemental individualized educational sessions).^{102,112} Both trials failed to show any benefit in functional outcomes; however, they were both quite small. For that reason, we sought additional evidence of efficacy from cohort studies that attempted to control for potential confounding between patient characteristics and receipt of services. In a cohort study of 162 hospitalized patients, Guccione and colleagues¹¹³ found that more than one physical therapy session per day was associated with improved functional outcome after adjusting for age, prefracture ambulation, and length of stay. In another study of 536 patients, Magaziner and colleagues⁸ reported that the number of physical therapy sessions (after adjustment for prefracture and other hospital care variables) was associated with improved physical independence at 1 year but did not affect walking ability or ability to perform instrumental activities of daily living. Finally, in a multisite study involving 284 acute care hospitals in five states, Hoenig and colleagues²⁶ found that more than five physical therapy/occupational therapy (PT/OT) sessions per week was associated with earlier ambulation [odds ratio (OR), 1.76; 95% confidence limits (CL), 1.50, 2.07], and patients who ambulated earlier had shorter lengths of stay (6.5 fewer days; $p < 0.001$) were more likely to return to the community (OR, 1.45; 95% CL, 1.16, 1.81) and had better than a 6-month survival (OR, 2.8; 95% CL, 2.06, 3.88).

In summary, the available data suggest that early mobilization can be done safely in selected patients, although the potential benefits of early mobilization have not been well studied and quantified. In the case of interdisciplinary rehabilitation featuring geriatric assessment, there is some suggestion from randomized trials that these programs can improve functional outcome and increase the likelihood of patients returning to the community. These trials, however, have been small and limited to programs with personnel with special interests in orthogeriatrics. For physical therapy services, cohort studies that have adjusted for potential confounders suggest that the frequency of physical therapy is likely to have an important impact on outcome and that more than one session per day is probably beneficial.

Falls Assessment

Patients who have fractured a hip have an increased risk of a subsequent fracture.¹¹⁴ Interventions to reduce the likelihood and number of subsequent falls might therefore have beneficial effects on outcome. A comprehensive review of fall assessment and prevention may be found in Chapter 66.

To date, there have been a number of randomized controlled trials¹¹⁵⁻¹²¹ and one preplanned meta-analysis¹²² of clinical and social interventions to reduce falls. None of the studies were specifically targeted to hip fracture patients. Two of the six studies^{116,117} focused on patients at risk for falling on the basis of other factors. Four studies^{115,119-121} focused on older persons in the community who were otherwise unscreened for fall risk, and one study focused on frail nursing home residents.¹¹⁸ The meta-analysis¹²² included eight trials, two of which are cited above,^{116,118} and examined the impact of exercise and balance on fall prevention.

The five studies^{115,118-121} that focused on subjects previously unscreened for fall risk randomly assigned either nursing home residents,¹¹⁸ senior centers, or households to interventions that included low-intensity exercises, counseling on risk factor reduction, and efforts to identify and correct environmental hazards. Two of the studies^{115,119} showed that the intervention slightly reduced the risk of falling (but not that of fractures or falls requiring medical attention). The interventions that targeted older persons at risk of falling were more efficacious. Rubenstein and colleagues¹¹⁷ randomly assigned ambulatory nursing home residents to either usual care or detailed clinical and environmental assessments within a week of the fall. The intervention did not significantly reduce the risk of subsequent falls, but the intervention group was hospitalized less frequently over the next 2 years. Tinetti and colleagues¹¹⁶ identified community-dwelling older persons with specific risk factors (e.g., postural hypotension or difficulty in transferring) for falling and randomly assigned them to either social visits or a targeted multifactorial intervention that featured medication adjustment, behavioral instruction, and exercise activities targeted to the patient's risk factors. This intervention reduced the risk of falling (relative risk = 0.69) and the prevalence of targeted risk factors. Province and colleagues¹²² performed a meta-analysis of eight trials involving diverse patient populations and several different interventions, all of which, however, included an exercise component. These eight trials demonstrated an adjusted fall incidence rate of 0.90 (95% confidence limits, 0.81–0.99). An adjusted fall incidence rate of 0.83 (95% confidence limits, 0.70–0.98) was observed for treatment groups that included balance training as compared to controls. No specific exercise component was signifi-

cant for injurious falls, but the studies did not have adequate power to detect this outcome.

These studies suggest that interventions to reduce the incidence of falls are more likely to be beneficial if they focus on persons at risk for falls and if the interventions target specific risk factors or behaviors. Exercise and balance training also appear to be somewhat effective in decreasing fall risk. Because persons who have sustained hip fractures are at higher risk of subsequent falls, these findings may be generalizable to this population.

Conclusion

Hip fracture is a common disorder that results in death or significant loss of function for more than 150,000 Americans annually. Furthermore, the number of hip fractures occurring annually in this country is expected to double by the year 2040.^{6,123} Clinical outcomes of hip fracture patients should be improvable by evidence-based medical care. This chapter has identified processes of medical care for which the data are unambiguous (e.g., prophylactic antibiotics and antithrombotics) and others for which the data are less clear and for which more research is needed (e.g., management of delirium, prevention of falls, duration of prophylactic thromboembolics, and cost-effectiveness of low molecular weight heparin as compared to other agents). The recommendations proposed in this chapter should enhance our ability to predict and manage the common complications of hip fracture, improve function and quality of life, and improve the quality of medical care afforded these patients.

Treatment of Diabetes

Kenneth L. Minaker

Sites of Care

Care of the older diabetic patient, similar to the care of other complex geriatric patients, has become a multidisciplinary issue with very high stakes in terms of vascular, renal, and ocular disability. Recent studies have demonstrated the value of careful management on the improvement in patient outcomes, and large-scale studies are under way to deter or prevent the emergence of clinical disease.

Increasingly, the focus of care is planning a comprehensive, multidisciplinary treatment and assessment program designed to prevent end-organ injury and to intervene early in the course of illness. It is an encouraging time to be involved in the treatment of diabetic patients, particularly outpatients treated early in the course of their illness. Improved care of the vascular and renal complications in those with advanced disease has also produced promise for their higher quality of life.

Demographics, Epidemiology, and Risk Factors

Diabetes mellitus prevalence increases with age, and the numbers of older persons with diabetes are expected to grow as the elderly population increases in number¹⁻³ (Fig. 46.1). The National Health and Nutrition Examination Survey (NHANES III) demonstrated that, in the population over 65 years old, almost 18% to 20% have diabetes. Of great diagnostic and clinical significance is that one-half of those with diabetes mellitus are not aware they have the disease. Other abnormalities in carbohydrate metabolism that have been observed include an additional 20% to 25% older patients meeting the criteria for impaired glucose tolerance. These unknown diabetic individuals and those potentially at risk were uncovered using glucose tolerance tests, which are very sensitive to abnormalities in carbohydrate economy. The incidence of

diabetes mellitus is approximately 2 per 1000 among those older than 45 and increases for those individuals more than 75 years old.⁴ Prevalence is much higher in older Hispanics, African Americans, Native Americans (Indians), Scandinavians, Japanese, and Micronesians.

Individuals with diabetes mellitus who are older than 65 usually have noninsulin-dependent diabetes (NIDDM). Insulin-dependent diabetes mellitus (IDDM) accounts for only 5% to 10% newly diagnosed diabetes mellitus in late life.⁵ In addition, a small proportion of older individuals who initially have NIDDM appear to become insulin dependent over time. A few clues as to who will require insulin exist. Ketosis at the time of diagnosis suggests that insulin therapy will be necessary. However, some elderly individuals with diabetes and ketosis can subsequently be treated with oral agents. The human leukocyte antigen (HLA)-DR3 serotype is more common in older adults who require insulin treatment. The frequency of antibodies to islet cells in older diabetic patients is not increased.⁵

Specific Clinical Patterns with Aging

A variety of metabolic, sensory, and cardiovascular conditions accompany the widespread prevalence of diabetes in the elderly and contribute to the reduced life expectancy that occurs with diabetes. Life expectancy reductions in diabetic individuals at ages 50 to 59 are 6 to 7 years, at ages 60 to 69 are 4 to 5 years, and at age 70 and above life expectancies are reduced by 3 years. In addition, the longer diabetes has been present, the greater the life expectancy reduction.

Hypertension occurs in 30% to 50% of those with diabetes in 45- to 64-year-olds but is present in 70% of diabetic patients aged 65 to 74. Diabetic ketoacidosis mortality is greater in individuals over age 75 (50 per 100,000 diabetic patients) than age 65 to 74 (20 per 100,000 diabetic patients). Hyperosmolar nonketotic

FIGURE 46.1. Prevalence of diabetes in men and women in the U.S. population age 20 years or older, based on NHANES III. Reproduced with permission from Ref. 3.

coma is essentially a disorder of the elderly diabetic.⁶ Twenty-four percent of all cases of legal blindness occur in diabetic individuals over age 65 years. Peripheral neuropathy, the most common diabetic neuropathy, has a prevalence of 25% to 35% in diabetic patients between 65 and 74 years of age. Absent pulses are twice as frequent in diabetic versus nondiabetic individuals (20% versus 13%) in the age group 55 to 74 years. The risk of leg amputations is 15 to 40 times greater for a person with diabetes. Renal failure requiring dialysis occurs most often from the pool of patients with diabetes mellitus, and recent evidence suggests progression to renal failure is more rapid in older patients.

The incidence of stroke is almost twice as great in diabetic individuals at all ages. Stroke incidence increases with advancing age to incidence rates four times greater: the rate at age 45 to 49 is 30 per 1000 and at age 65 to 69 is 133 per 1000. Between the ages of 45 and 64, 8.4% of diabetic individuals have had a stroke, a prevalence that increases to 12.7% in individuals more than 65 years of age.⁷ The incrementally greater impact of the number of risk factors for stroke in the elderly diabetic population has been studied in the Framingham Heart Study. With increasing numbers of risk factors, including hypertension, hypertension treatment, diabetes mellitus, cigarette smoking, preexisting heart disease, atrial fibrillation, and ECG changes compatible with left ventricular hypertrophy, 10-year stroke probability increases geometrically.⁸

Advancing age in diabetic individuals is associated with increasing prevalence of a host of gastrointestinal diseases including hiatus hernia, ulcers, and gallstones, trends that are more apparent in females than males with diabetes mellitus (NHANES II).

Infection rates, particularly urinary tract infections and viral pneumonia, are twice as frequent in diabetic individuals than nondiabetic individuals. Current evidence suggests no age-related increase in infection rates. Periodontal disease shows a linear increase with age in diabetic individuals.⁹

The overall impact of comorbid disease, being more prevalent in older diabetic individuals, is substantial. Although hospital discharges primarily for diabetes mellitus decrease with advancing age, those for associated diseases increase dramatically. Hospitalization rates are 40% to 80% higher in diabetic patients than nondiabetic patients depending on age.¹⁰

Advancing age is also associated with a progressive increase in length of hospital stay with diabetes mellitus.

Pathogenesis of Age-Associated Glucose Intolerance

Glucose intolerance associated with aging itself may predispose to the development of overt diabetes mellitus. Glucose intolerance is present even in very healthy older individuals. Postprandial blood glucose increases by

5.3 mg/dL per decade after the age of 30^{11,12} (Fig. 46.2). Age-related changes in fasting blood glucose levels are 1 to 2 mg/dL (0.05–0.09 mM) per decade after age 30.^{13,14}

Several factors appear to contribute to age-associated glucose homeostatic changes. Glucose absorption slows with increasing age, and hepatic glucose production shuts down after food and glucose is delayed, most likely as a result of delayed insulin secretion.¹⁵ Subtle age-related changes in regulation of insulin secretion have been described.¹⁶ The presence of insulin resistance in the elderly has been confirmed in multiple studies.^{14,17,18} It is a result of postreceptor events, the specific site(s) of which are not yet understood.^{19–21}

Other factors may contribute to glucose intolerance. Both the decline in lean body mass and the increase in body fat that accompany aging may contribute to insulin resistance.²² Reduced levels of physical activity and altered diet may cause these changes in body composition.²³ Studies of master athletes suggest that some of these changes can be either prevented or modified with exercise.²⁴ High-carbohydrate, low-fat diets improve insulin sensitivity in older individuals.²⁵ Drugs commonly used by older individuals, including diuretics, tricyclic antidepressants, estrogen, sympathomimetics, glucocorticoids, niacin, and phenytoin may adversely affect glucose metabolism. Stress states such as myocardial infarction, infection, burns, and surgery may also worsen glucose tolerance.

Impaired glucose tolerance is a risk factor for the development of cardiovascular disease and diabetes mellitus. The Honolulu Heart Study demonstrated that fatal myocardial events among older nondiabetic men were 2.4 times higher in those in the highest quintile for 1 h postchallenge glucose levels than in those in the lowest quintile.²⁶ The risk of development of diabetes mellitus among those over age 70 who are glucose intolerant is

2% per year, as compared with a risk of 0.04% per year for those with normal glucose tolerance.²⁷

The reduction in glucose tolerance associated with aging is correlated with insulin resistance, obesity, hyperlipidemia, and hypertension. The pathogenesis of these associated and interrelated conditions is referred to as the metabolic syndrome or syndrome X. Although the pathogenesis is currently under detailed study, the emergence of insulin resistance as a central feature of diabetes mellitus in the elderly appears secure.

Pathogenesis of Diabetes Mellitus in the Elderly

A strong genetic predisposition to type 2 diabetes in middle-aged and elderly patients exists. The specific genes responsible have not been discovered.³ Patients with a family history of diabetes are more likely to develop the illness as they age.⁴ Elderly patients with peripheral insulin resistance and reduced glucose-induced insulin release are more likely to develop type 2 diabetes than those without.²⁸ In elderly identical twins discordant for type 2 diabetes, subjects without diabetes have evidence of impaired glucose metabolism.²⁹ Physiologic and environmental factors compound genetic predisposition. Lower testosterone levels in men³⁰ and higher testosterone levels in women³¹ are risk factors for diabetes development. Elderly individuals who have a high intake of fat and sugar and a low intake of complex carbohydrates are more likely to develop diabetes.^{32–35} Physical inactivity and central fat distribution predispose to diabetes in the elderly.^{36–46} Unlike younger patients, fasting hepatic glucose production is normal in elderly patients with type 2 diabetes.⁴⁷ Elderly type 2 diabetes patients have specific alterations in carbohydrate metabolism. The primary metabolic defect in lean elderly subjects is an impairment in glucose-induced insulin release; the primary abnormality in obese elderly subjects is resistance to insulin-mediated glucose disposal.^{47,48}

Glucose uptake occurs by insulin-mediated and noninsulin-mediated mechanisms. Recently, it has been demonstrated that nonmediated glucose uptake (glucose effectiveness) is markedly impaired in elderly patients with type 2 diabetes. The mechanism for this defect is unclear, but impaired glucose effectiveness is a contributing factor to elevated glucose levels in elderly diabetes patients. Given that several interventions, including glucagon-like peptide 1 (GLP-1), have been shown to enhance glucose effectiveness in younger patients, these findings may have important therapeutic relevance for elderly patients with diabetes.^{49–51}

Few studies have evaluated molecular biologic abnormalities in elderly patients with diabetes and more are

FIGURE 46.2. Changes in blood glucose levels with age.

required. The glucokinase gene is the glucose sensor for the β -cell. Some studies have found that this gene acts as a marker for abnormal glucose tolerance in the elderly, but others have not.^{52,53} Insulin receptor number and affinity are normal in elderly patients, but insulin receptor tyrosine kinase activity in skeletal muscle is reduced.⁵⁴

Clinical Presentation

Classic symptoms of polyuria or polydipsia are rarely present. Glucose is not spilled into the urine until the plasma glucose is markedly elevated because the renal threshold for glucose increases with age. Polydipsia is also less common, because thirst is impaired. When symptoms are present, they are generally atypical (falls, failure to thrive, urinary incontinence, or delirium).

Diabetes may present for the first time in elderly individuals as a result of a fasting screening glucose level or be concurrent with the presentation at the time of illness with a complication of illness, such as a myocardial infarction or stroke. Finally, nonketotic hyperosmolar coma may be the first sign of diabetes in older individuals, particularly in older nursing home patients; this results from decreased access to water associated with osmotic diuresis, impaired thirst, and cognitive dysfunction.

Unusual clinical findings also develop in older patients with established diabetes.^{55,56} Intradermal bullae of the feet that resolve spontaneously have been described.⁵⁷ Painful limitation of the shoulder joints occurs frequently and may be related to nonenzymatic glycation of proteins.⁵⁸ Diabetes increases the risk for accidental hypothermia in older individuals.⁵⁹ Malignant otitis externa is a necrotizing infection caused by *Pseudomonas*, occurring almost exclusively in elderly patients with diabetes.⁵⁶ Renal papillary necrosis can occur in association with urinary tract infections.

Diabetic amyotrophy causes asymmetric and painful weakness of the muscles of the pelvic girdle and thigh, and usually resolves spontaneously in a few months. It is most prevalent in older males.⁵⁶ Diabetic neuropathic cachexia occurs in older patients with diabetes, causing weight loss, depression, and painful peripheral neuropathy.⁶⁰

Diagnosis and Differential Diagnosis of Diabetes Mellitus in the Elderly

The diagnosis of diabetes mellitus is made primarily through the findings of elevated glucoses on fasting laboratory samples, random glucoses during outpatient or inpatient care, and, much less commonly now, after formal oral glucose tolerance testing (OGTT). In 1997, the American Diabetes Association (ADA) revised its diagnostic criteria⁶¹ to rely solely on a fasting plasma

glucose value greater than 126 mg/dL (7.0 mmol/L), rather than on a fasting glucose over 140 mg/dL or a 2-h oral glucose tolerance test plasma glucose value over 200 mg/dL, as had been recommended by the 1980–1985 World Health Organization (WHO) diagnostic criteria⁶² and the ADA 1979 criteria for diabetes.⁶³ The new ADA criteria also recommended two other diagnostic classes. Impaired fasting glucose (IFG) is defined as a fasting plasma glucose (FPG) between 110 mg/dL (6.1 mmol/L) and 126 mg/dL (7.0 mmol/L); normal fasting glucose is defined as a fasting plasma glucose less than 110 mg/dL. The OGTT is not recommended for routine diagnosis of glucose intolerance or diabetes. The 1998 preliminary report of WHO essentially endorses the ADA 1997 recommendation, with the exception that they advocate the use of OGTT.⁶⁴

The new ADA 1997 criteria change the incidence of diabetes by age, sex, and ethnicity, resulting in a significant increase in the number of individuals diagnosed with diabetes mellitus while perhaps excluding significant numbers of individuals who would have gained the diagnosis through postchallenge glucose elevations.⁶¹ From all the population data available, the criteria of a 2-h plasma value greater than 200 mg/dL (11.1 mmol/L) would be met by almost all patients who met the older fasting value of 140 mg/dL (7.8 mmol/L). However, it would also be met by many individuals with a lower fasting value.

The new fasting value of 126 mg/dL (7 mmol/L) is reported to be more in agreement with the diagnosis of diabetes by the 2-h post-OGTT plasma glucose value of 200 mg/dL. However, the data suggest this may not be the case. At least 25 studies have examined the impact of the new 1997 ADA criteria with the older 1985 WHO criteria. These reports indicate that 11% to 80% of the individuals diagnosed with diabetes mellitus by the WHO criteria will be missed if the diagnosis is solely based on the lower FPG, which appears to particularly include the elderly. The observations leading to the use of 200 mg/dL level and the difficulties with this level suggest further revisions may be needed. Using data from the NHANES III survey, comparisons of the results of FPG with the 2-h post-OGTT plasma glucose level are more than 50% discrepant.⁶⁵ The ADA's 1997 report has stated that the justification for the cut point for the 2-h post-OGTT glucose level of 200 mg/dL is derived, in part, from the evidence that the prevalence of microvascular complications increases dramatically at this point. In addition, the 2-h plasma glucose value following an OGTT from many large populations has a bimodal distribution. The nadir intersection of the two modes is known as the antimode and it shifts to the right with advancing age.⁶⁶ The 200 mg/dL level represents the average level of the antimodes from several large population studies (Pima Indians, Nauruans, Samoans, Mexican-Americans, and East Indians). However, the antimodes from these pop-

ulations are quite variable (range, 143–310 mg/dL) and do not support the average 200 mg/dL level. They do, however, increase with age.

Many of the reported studies show that the 1997 ADA diagnosis standards do not result in equal sensitivity for fasting and 2-h glucose levels, especially in older individuals. Although the use of fasting plasma glucose alone for diabetes diagnosis may simplify testing, the WHO criteria would identify a much greater percentage of elderly subjects with diabetes or impaired glucose testing and move ahead the diagnosis by 5 to 8 years over criteria based on fasting glucose levels. As diabetes prevention efforts increase, a move to a more sensitive bias in diagnosis may be needed. The majority of newly diagnosed diabetic patients (>90%) emerge from the population with impaired glucose tolerance (IGT), no matter how it is defined, and are at higher risk for cardiovascular disorders.²⁷

Prognosis and Course of Illness

It had been hoped for many years that intensive treatment of diabetes mellitus would reverse or defer significantly its major complications of microvascular and macrovascular disease, stroke, and heart attack, and be compatible with a healthy lifestyle. While a general impression indicating that intensive and aggressive therapy was potentially a benefit, two major studies have recently provided much greater justification and clarification for control of diabetes mellitus. These two studies, the Diabetes Control Complications Trial research group and the United Kingdom Prospective Diabetes Study Group investigations, are reviewed in detail here to establish more clearly the rationale for close control of diabetes.

Glucose Control

The Diabetes Control and Complications Trial (DCCT)⁶⁷ was a randomized, controlled trial of individuals with type 1 diabetes mellitus (aged 13–39 years) comparing the effect of intensive blood glucose management to conventional management on diabetic outcomes over a mean 6.5-year follow-up. Subjects in general were in good health and had diabetes for 1 to 15 years. Patients were stratified by the presence of retinopathy into a primary prevention cohort (no baseline retinopathy) and a secondary prevention cohort (mild retinopathy), and then randomized to either intensive insulin management consisting of three or more insulin doses per day to keep glucose levels as close to normal as possible or to conventional therapy consisting of standard insulin therapy to keep glucoses within accepted guidelines ($A_{1c} < 7.0$).

For primary prevention, the adjusted relative risk of retinopathy was reduced by 76% (95% CI, 62%–85%) in

the intensively treated group compared to the conventionally treated group. For secondary prevention, the risk of retinopathy progression was reduced by 54% (CI, 39%–66%) in the intensively treated group. In both cohorts, the reduction in risk increased with time and was not evident until 36 months into the treatment.

When the two cohorts were combined, intensive therapy reduced severe retinopathy and need for laser treatment by 47% and 51%, respectively, clinical neuropathy by 60% (CI, 38%–74%; $p \leq 0.002$), microalbuminuria ($p \leq 0.002$), and albuminuria ($p < 0.04$). Severe hypoglycemia was more common (62 versus 19), as were coma (16 versus 5) and emergency room admission (9 versus 4 cases per 100 patient-years) in the intensively managed group. No significant differences in mortality were observed between the two groups (7 intensive versus 4 conventional).

The DCCT resulted in a number of important recommendations. Intensive therapy with a goal of achieving glucose levels as close to the nondiabetic range as possible should be employed in most IDDM patients. Intensive therapy should be implemented in centers with the requisite nursing, dietary, behavioral, and clinical expertise to ensure safe and effective therapy. Although most diabetes in late life is not of the type 1 variety, this study provided important principles and hopes for improving the long-term prognosis for diabetes patients.

The most comprehensive study of type 2 diabetes to date has been the United Kingdom Prospective Diabetes Study Group.

United Kingdom Prospective Diabetes Study (UKPDS 33)

The UKPDS 33⁶⁸ investigated whether tight control of blood glucose in type 2 diabetic patients reduced the risk of microvascular or macrovascular disease. Patients over age 65 were excluded from this multicenter RCT; mean age was 54. Of the 3867 patients, 2729 were randomized to open-label intensive drug therapy with either chlorpropamide, glibenclamide, or insulin, with the goal of lowering FPG to less than 108 mg/dL. The 1138 other patients were randomized to conventional therapy that aimed for the lowest FPG possible with diet alone (although drugs were added if FPG reached as high as 270 mg/dL or in the presence of hyperglycemic symptoms).

Compared to conventional therapy, intensive therapy significantly reduced the risk of microvascular complications, but not macrovascular complications or macrovascular subclinical surrogate endpoints over the 10-year study period. Median hemoglobin A_{1c} levels were significantly lower in the intensive group (7%) than in the conventional group (7.9%). Three grouped endpoints

were assessed: all-cause mortality, diabetes-related deaths [myocardial infarction (MI), stroke, peripheral vascular disease, renal disease, hyperglycemia or hypoglycemia, and sudden death], and any diabetes-related endpoint (death from any of the preceding, as well as nonfatal MI, angina, heart failure, stroke, renal failure, amputation, vitreous hemorrhage, retinopathy, blindness, or cataract). Only diabetes-related endpoints were significantly reduced with intensive therapy, with a risk reduction of 12% (95% CI, 1%–21%). Most of this reduction was due to reduction in microvascular outcomes, especially the need for retinal photocoagulation, which was reduced 25% (95% CI, 7%–40%). All three intensive drug regimens reduced microvascular endpoints equally.

Neither all-cause mortality nor diabetes-related deaths differed by intensity of treatment, although a non-significant trend ($p = 0.052$) toward reduction in risk of myocardial infarction was observed in the intensive therapy group, with an RRR of 16% (95% CI, 0–29%). Compared to conventional treatment, intensive therapy was associated with a mean 6.4-pound weight gain (most prominently in the insulin group) and an increased risk of hypoglycemia. Treatment for hypertension was more common with chlorpropamide than with any other regimen, including conventional therapy.

A substudy examined 342 newly diagnosed obese diabetic patients randomized to metformin during UKDPS 33 and compared them to the overweight patients who were included in the UKDPS 33 study already discussed [conventional treatment (411) or intensive treatment (951)]. Based on absolute risk (events per 1000 patient-years) and relative to conventional therapy, metformin treatment reduced risk of any diabetes-related endpoint by 32% (NNT, 10; CI, 6–32), diabetes-related deaths by 42% (NNT, 19; CI, 10–97), and all-cause mortality by 36% (NNT, 15; CI, 8–83). Relative risk of myocardial infarction was also significantly reduced. Metformin was also significantly better than all other drugs used in the intensively treated group in reducing risk of reaching any diabetes-related endpoint, stroke, and all-cause mortality. In these already overweight patients, weight gain was less common with metformin than with other intensive therapies, as were hypoglycemic episodes.⁶⁹

Metformin/Sulfonylurea combined therapy was found to perhaps have less benefit than either drug alone. This observation is important as the popularity of combined drug therapy is increasing.

Blood Pressure Control and Complications in Type 2 Diabetes

UKPDS 38 evaluated the effect of hypertension control on diabetic outcomes. The study involved the randomization of 1148 hypertensive patients (mean age, 56.4

years), to either tight blood pressure control (blood pressures less than 150/85) with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta-blocker (atenolol), or to less tight control (blood pressures less than 180/105) without these drugs. The actual mean blood pressures obtained were 144/82 in the tight control group and 154/87 in the “less tight.”

Endpoints were identical to those in the main study just described. Mean follow-up time was 8.4 years. Tight blood pressure control reduced diabetes-related endpoints by 24% (95% CI, 8%–38%; $p = 0.0046$), diabetes-related deaths by 32% (CI, 6%–51%; $p = 0.019$; NNT = 15), and stroke by 44% (CI, 11%–65%; $p = 0.013$) compared to less tight control. Microvascular endpoints were reduced by 37% (CI, 11%–56%; $p = 0.0092$), with 35% reduction in risk of retinal photocoagulation ($p = 0.023$). There was no difference in all-cause mortality. There were also no differences between captopril or atenolol in terms of treatment benefits.⁷⁰

The DCCT and UKPDS give us important information related to the rationale for treatment of diabetes mellitus in late life. It is clear that microvascular and macrovascular events can be influenced by careful control of diabetes mellitus. As a result, the management of both blood pressure and blood sugar in diabetes mellitus has a sound rationale.

The use of ACE inhibitor therapy in minimizing the development of and the progress of renal damage as measured by micro- and clinical-grade albuminuria has now become an important standard of care in the management of type 2 diabetes. Whether ACE inhibitor itself or blood pressure reduction alone is the factor reducing albuminuria is not fully answered. Additionally, the importance of high lipids as a strong risk factor for future cardiovascular disease in diabetic individuals is gaining attention, and aggressive treatment is becoming the norm.

Treatment and Management of Diabetes Mellitus

The benefits of aggressive treatment in terms of delaying or preventing complications in the elderly diabetic are clear. Life expectancy for the older diabetic person is approximately two-thirds that of a healthy elderly individual. This fact is not an argument against aggressive treatment; in fact, reductions in life expectancy are in large part because most older diabetics have adequate time to develop and suffer from chronic complications of diabetes mellitus. Recent studies confirm that many of the vascular and renal complications of diabetes develop at a relatively similar rate in types 1 and 2 diabetes.⁶⁹ Other diabetic complications are aggravated by changes inherent in aging. Creatinine clearance declines with

normal aging⁷¹ and may accelerate or enhance risk for diabetic renal failure. Age is also an independent risk factor for the development of peripheral neuropathy, a common condition in diabetes mellitus.^{72,73}

The initial approach to the older adult with diabetes mellitus requires assessment of the patient's current medical status and estimated life expectancy. Motivation and commitment of the patient and family also play a large role in determining what level of treatment is appropriate. Support services available in the community and financial status should also be considered.

Following evaluation, one of two levels of care can be recommended: symptom-preventing care or aggressive care. The decision is made jointly by the patient and the primary caregiver. Family members and consultants such as geriatricians, diabetologists, cardiologists, and nephrologists may be helpful. These consultants provide a clearer picture of the current medical condition and estimates of life expectancy.

Symptom-preventing care is indicated for those individuals for whom the primary goal of treatment is avoidance of metabolic complications. The average glucose levels necessary to achieve this goal are approximately 200 mg/dL (11 mM) or the glucose level at which glycosuria is minimal. The elimination of glycosuria removes the risk of volume depletion and the risk of secondary problems related to hypotension and poor tissue perfusion. Hyperglycemic hyperosmolar nonketotic coma due to dehydration and glycosuria is the most dramatic expression of this phenomenon. Glycosuria also is associated with weight loss caused by the loss of calories in the urine. The resultant catabolic state leads to a loss of lean body tissue. The long-term consequences of poor nutrition include increased risk of infections.

Aggressive care has prevention of long-term complications as its goal. Euglycemia is defined as (1) a fasting glucose level lower than 115 mg/dL (6.4 mM), (2) a mean glucose level between 110 and 140 mg/dL (6–8 mM), and (3) normal levels of glycosylated hemoglobin. Prevention of long-term complications in type I patients results from this level of control. These benefits are believed to extrapolate to elderly patients within NIDDM.

Aggressive management programs for older adults with diabetes require high levels of skill, commitment, and diabetes education. Most older individuals are fully able to learn the complicated concepts and tasks required.^{74–76} Older adults lead a less hectic, more ordered life than younger adults. Consequently, making the adjustments in lifestyle necessary for adherence to a good diabetes treatment program may at times be easier.

All older adults with diabetes mellitus should receive a standard basic care program regardless of the treatment goal chosen. These standards⁷⁷ (Table 46.1) include a complete history and physical examination to detect any complications of diabetes mellitus and any risk factors for

TABLE 46.1. Minimum standards of care for older adults with diabetes mellitus.

Initial evaluation
Complete history and physical examination
Geriatric assessment
Laboratory examination: fasting blood glucose, glycosylated hemoglobin, fasting lipid profile, creatinine, urinalysis, electrocardiogram
Ophthalmologic examination
Dietary assessment
Continuing care
Use of treatment as needed to meet target glucose levels: diet, oral agents, or insulin
Assessment of blood glucose levels as frequently as needed to ensure that treatment goals are being met
Annual assessment for diabetes complications
Annual review of geriatric assessment

complications. A geriatric assessment, emphasizing a functional assessment, should be performed at the time of diagnosis. Skills in the basic activities involved in daily life (bathing, grooming, dressing, feeding, toileting, and transferring) and the instrumental activities of daily life (e.g., shopping, telephoning, finances, and housework) should be assessed. Social support systems and financial and insurance status often should also be assessed, by nursing and social work staff. Laboratory evaluation at diagnosis includes determinations of fasting serum glucose level, glycosylated hemoglobin (to assess previous level of control and to be used as a baseline), fasting lipid profile, and serum creatinine; urinalysis with examination for proteinuria; and an electrocardiogram. Ophthalmologic evaluation at the time of diagnosis is recommended by the American Diabetes Association for all patients with NIDDM.⁷⁸ This recommendation is particularly relevant for elderly patients who are at high risk for ocular diseases including cataract and glaucoma. Dietary assessment provides an initial dietary therapy for the diabetic patient.

Standard diabetes therapy includes diet, exercise, and if necessary use of oral hypoglycemic agents or administration of insulin.

Oral Hypoglycemic Agents

Increasingly, therapy for type 2 diabetes builds on diet and exercise and has become more mechanistically focused. Single or combination chemotherapy is used. A significant amount of improvement can be expected with improved therapy. Currently, 54% of elderly diabetic patients have hemoglobin A_{1c} levels above normal and 27% of the total had A_{1c} levels greater than 8. Thus, nearly a quarter have “poor” control.⁷⁹ Current best practices require a normal hemoglobin A_{1c}, certainly less than 7. For those individuals in whom the demands of therapy are too great, medication side effects are too great, or

TABLE 46.2. Dietary therapy: special considerations for older adults with diabetes.

Financial difficulty
Difficulty with shopping because of transportation or mobility problems
Poor food preparation skills (particularly elderly widowed men)
Ingrained dietary habits
Difficulty following dietary instruction because of impaired cognitive function
Decreased taste
Increased frequency of constipation

access to monitoring is not possible, a reduction in expectations and greater complication rates will be higher. Medications currently available can promote insulin secretion, increase insulin sensitivity, or slow the digestion/processing of complex carbohydrates.

Diet

Diet alone has varying degrees of success. Elderly patients with diabetes are able to improve diabetes control with diet and weight loss.⁸⁰ However, they may find it difficult to adhere to a strict dietary regimen and maintain weight loss. Older adults with mobility problems may find exercise to increase caloric expenditure impossible. If dramatic dietary restriction is employed to reduce weight, nutrient and vitamin deficiencies may develop. Aggressive dietary management cannot be recommended under these circumstances. Other considerations specific to older adults may limit the effectiveness of dietary therapy (Table 46.2).¹⁸

A diabetic diet is relatively high in carbohydrates (50%–60% of total calories), low in fat (<30% of total calories from fat, with 10% saturated fat, 10% polyunsaturated fat, and 10% monosaturated fat), and moderate in protein (~20% of total calories). If malnourished or chronically ill, the elderly patient should increase protein and energy intake. Vitamin and mineral supplements are indicated when caloric intake falls below 1000 kilocalories per day.

Exercise

The role of formalized exercise programs in the management of diabetes mellitus remains controversial. The beneficial effects of exercise on glucose tolerance have been well documented.⁸¹ The effectiveness of exercise in lowering plasma glucose levels is unclear. The effects of exercise on glucose tolerance are disappointingly transient, lessening within days of stopping an exercise program.⁸² Exercise for older adults with diabetes may pose additional problems. Perhaps four-fifths of older men with newly diagnosed mild diabetes are unable to participate in a regular training program because of other diseases or treatments.⁸³ Exercise for control of hyper-

glycemia may thus not be feasible for many older adults. These benefits and the risks of exercise in older adults are outlined in Table 46.3.⁷⁷ Because of the prevalence of silent coronary artery disease in this population, older adults with diabetes should be given an exercise tolerance test before they begin any exercise program.

Agents Increasing Insulin Secretion

Sulfonylureas

First-generation agents such as chlorpropamide (Diabinese) are largely of historical interest. Because of chlorpropamide's very long half-life (up to 60h), risk of hypoglycemia, and production of hyponatremia from stimulation of excess antidiuretic hormone, it is rarely used today. Second-generation agents in the sulfonylurea class have largely replaced chlorpropamide. Glipizide (Glucotrol and Glucotrol XL) and Glyburide (Micronase, Glynase, and Diabeta) have been standards for many years. All, however, are associated with weight gain and hypoglycemia and are of less utility the higher the fasting glucose. These drugs rarely produce hyponatremia from central stimulation of antidiuretic hormone. Once fasting glucose levels rise above 200mg/dL, insulin secretory reserve is very limited and these agents are less likely to be successful. As a general principle, dosing with second-generation agents should be initiated at the lowest end of the dosing range until individual susceptibility to hypoglycemia is known. Dosing is each morning, or twice a day.

Meglitinides

Repaglinide (Prandin) is an agent given before each meal, as it has a short half-life and is a shorter and more rapidly acting agent than classic sulfonylureas. It is therefore most useful when postprandial elevation of glucose dominates the clinical picture. Weight gain and hypoglycemia are shared side effects with sulfonylureas. However, in the treatment design for an individual experiencing between-meal hypoglycemia while taking sulfonylureas, Repaglinide is attractive.

TABLE 46.3. Potential benefits and risks of exercise for older adults with diabetes.

Benefits	Risks
Improved exercise tolerance	Sudden cardiac death
Improved glucose tolerance	Foot and joint injuries
Improved maximal oxygen consumption	Hypoglycemia
Increased muscle strength	
Decreased blood pressure	
Decreased body fat and increased muscle mass	
Improved lipid profile	
Improved sense of well-being	

D-Phenylalanine

Nateglinide (Starlix), which is a chemical derivative of the amino acid phenylalanine, has a similar profile and mode of action as Repaglinide. Because of its very short action, it is most useful in early diabetes when fasting glucoses are only mildly elevated.

Agents Increasing Insulin Action

Because of the recognition of insulin resistance as a fundamental component of noninsulin-dependent diabetes mellitus, agents increasing tissue sensitivity and responsiveness to endogenous insulin have become cornerstones of treatment. A very beneficial treatment side effect is the promotion of weight loss by these agents.

Metformin

Metformin (Glucophage, Glucophage XL) is given once (XL) or twice a day and assists altered diabetes physiology by improving insulin-mediated effects on the liver. The result is improvement in fasting hyperglycemia. On initiating treatment, bloating, cramps, and diarrhea may result. There is still a rare risk of lactic acidosis in individuals with renal, cardiac, or liver failure or in individuals undergoing contrast studies where borderline renal function is already present. Because of this, it is suggested that metformin doses be withheld temporarily in high-risk settings, such as hospitalization, dehydration, or planned radiologic studies. When creatinine clearance is low (when serum creatinine is greater than 1.5 mg/dl), or there is advanced liver, cardiac, or pulmonary disease, this agent should be avoided. Creatinines greater than 1.5 are seen in approximately 5% of all elderly individuals.

Thiazolidinediones

Rosiglitazone (Avandia) and Pioglitazone (Actos), both once or twice per day medicines taken with food that specifically assist in insulin action on muscle and fat, are useful alternatives to metformin. As with metformin, hypoglycemia is rare. However, monthly monitoring of liver function is required as approximately 10% develop hepatic enzyme elevations, and rare fatal hepatitis has occurred. Being new, these drugs are much more expensive than sulfonylureas.

Agents Slowing Carbohydrate Processing in the Gut

The alpha-glucosidase inhibitors Acarbose (Precose) and Miglitol (Glyset) both reduce postprandial increases in blood sugars by inhibiting the breakdown of dietary carbohydrate. These agents are taken with the first food intake of every meal. While they are useful adjunctive

therapy for more severe diabetes, Acarbose and Miglitol are helpful in impaired glucose tolerance and mild diabetes as well. High doses of bran have also been associated with improved glucose intolerance and have the additional benefit of lowering cholesterol. The common side effect of all these agents is gas, bloating, and diarrhea.

Combination Therapy

In recent times, the use of drug combinations has increased to avoid or minimize insulin therapy and its inconvenience, hypoglycemia, weight gain, and possible acceleration of other atherogenesis. Several drug combinations have emerged, based on successful experience in combining drugs with complementary mechanisms of action.

Stepwise addition of agents is the practical approach. The most studied combination is sulfonylurea and insulin. Clearly some secretion of endogenous insulin must still be present. In this combination, insulin is given at night and sulfonylurea is given before each meal to produce insulin increments in the postprandial state. Insulin and metformin have been used in combination, with the goal of improving insulin action. Two oral hypoglycemics have been studied in combination, sulfonylurea and metformin; this is an attractive combination as the first produces insulin release, now able to stimulate tissues that have been sensitized by metformin. A three-drug regimen has been described combining NPH insulin at night, preprandial glipizide three times a day, and metformin twice a day. Although this intense regimen will minimize weight gain due to lower overall dosing with insulin, it poses a complexity challenge for elderly individuals.

Combination therapy will be increasingly popular, as combination effects on lipids, hypoglycemic events, and progression of disease is better defined in future years.

Management During Terminal Phases of the Illness: The Elderly Nursing Home Patient

Approximately 3% to 5% of the population over the age of 65 live in nursing homes.⁸⁴ One-third of elderly individuals will spend some time in a nursing home.^{85,86} Diabetes prevalence in the nursing home population is about twice that in the general population⁸⁷ and has progressively increased since 1964.^{88,89} The 1987 National Medical Expenditure Survey found that diabetic patients in nursing homes had a high prevalence of diseases associated with diabetes, such as heart disease, and a high prevalence of amputations and immobility.^{90,91} Chronic

renal failure, retinopathy, neuropathy, urinary tract infections, and skin infections are also more common among the patients with diabetes than among a similarly aged group of patients without diabetes.⁹² In contrast, the prevalence of dementia is low in diabetic nursing home residents.

A significant degree of functional limitation occurs in this population. As life expectancy is markedly reduced for most individuals admitted to nursing homes, the primary goal of therapy is symptom prevention. A recent study of 563 individuals from 24 nursing homes revealed that 75.8% died within 2 years.⁹³ Poor functional status was a major predictor of mortality.

Control of hyperglycemia in patients in nursing homes is achieved primarily by diet and medication. Exercise does not play a major role. Diet is an important therapeutic option, but weight maintenance may be as important as weight loss for many elderly patients with diabetes in nursing homes. One study found that more than 20% of patients with diabetes in nursing homes were more than 20% underweight.⁹² Malnutrition in this population is common. Patients should be weighed monthly, and active dietary adjustments should be made.⁹⁴

The choice of sulfonylureas or insulin therapy should be based on the level of glycemic control desired. Sulfonylureas are preferable both to the patient and to the nursing home staff.⁹⁵ Insulin, however, is needed for those patients for whom glycemic goals cannot be achieved with a sulfonylurea. In the nursing home setting, glucose monitoring may be done more frequently, a major asset in the management of diabetes mellitus, resulting in low levels of glycosylated hemoglobin and few episodes of hypoglycemia.^{92,96}

Nursing home patients are prone to conditions that may be related to, or are exacerbated by, diabetes mellitus, particularly skin and urinary tract infections. Limiting the use of indwelling bladder catheters and ensuring good urinary output through adequate hydration may reduce urinary tract infections in this population. Skin infections may be prevented by strict pressure ulcer precautions, including frequent turning of immobilized patients, the use of adequate bed and wheelchair cushioning, and the use of heel protectors. The prevalence of all infections is reduced with strict hand-washing regimens. Annual influenza and 5-year pneumococcal vaccination will protect against epidemics of these illnesses in the nursing home. Immunization and PPD (purified protein derivative) status should be verified and documented for all new admissions to the nursing home. Patients with diabetes who have a positive PPD reaction should be considered for prophylaxis with isoniazid if they have not been treated previously for tuberculosis.

Regular ophthalmologic, dental, and foot care services should continue in the nursing home.

Management of the Hospitalized Diabetic Patient

Elderly diabetic individuals are hospitalized about twice as often as elderly people without diabetes. In the NHANES II study, only 16.5% of individuals 65 to 74 years old without diabetes reported having been hospitalized once or more within the previous year, whereas 29.8% of those with known diabetes reported having been hospitalized.⁹⁷

In the hospital, the goal for glycemic management is to minimize the likelihood of insulin deficiency, which can contribute to a catabolic state. Tight control is not necessary to achieve this goal. Reasonable goals would be a mean plasma glucose level of less than 250 mg/dL (14 mM) and minimal glycosuria. Stressful illnesses such as myocardial infarction, pneumonia, influenza, and stroke can exacerbate hyperglycemia and may even precipitate hyperosmolar hyperglycemic nonketotic coma in a patient who is already hospitalized. Fifty percent of all severe episodes of dehydration develop in the hospital.⁹⁸ This setting is thus a high-risk environment that could lead to hyperglycemia. Thus, elderly patients usually treated with oral agents may need to be treated temporarily with insulin. Appropriate intravenous fluid therapy to prevent dehydration and worsening of hyperglycemia should be given. Frequent glucose monitoring is recommended to prevent wide variations in glycemia. Sliding scales of regular insulin can be useful for the acutely ill patient or postoperative patient who is unable to eat. However, once oral intake is adequate, split dosing of insulin with adjustments made as needed on the basis of results of frequent glucose monitoring is possible.

Hypoglycemia is a significant problem for all hospitalized patients with diabetes. In general, hypoglycemia in the hospital results from decreased caloric intake or inappropriate changes in insulin dosage.⁹⁶ Hypoglycemia may be prevented by frequent glucose monitoring, with adjustments being made in the insulin dose as the patient's medical condition changes.

Prevention of Clinical Diabetes Mellitus

Diabetes mellitus affects more than 100 million individuals worldwide and, because of known risk factors common to many individuals that can be manipulated, the development of type 2 diabetes may potentially be modifiable. A number of clinical trials have addressed this hypothesis through dietary modification, physical activity, and drug treatment. Although some studies indicate protection against diabetes development, conclusions remain limited for reasons of study design problems

with randomization, subject selection, or intervention intensity.

Six prospective studies have examined the predictors of progression from impaired glucose tolerance to type 2 diabetes.^{99,100} Across the six studies (n , 177–693), the incidence rates averaged 57.2 per 1000 patient-years. Incidence rates were sharply higher for those in the top quartile of fasting glucoses, but increased linearly with increasing 2-h postchallenge glucose levels. Native and Hispanic incidence rates were higher than those of Caucasians. Baseline age showed no consistent pattern. Obesity was positively associated with future diabetes mellitus, no matter how body fatness was measured.

One study in the elderly and two in younger patients suggest that diet and exercise may prevent diabetes mellitus in patients with impaired glucose tolerance. In Da Qing, China, a screening program detected 577 individuals (mean age, 45.0) with impaired glucose tolerance (IGT).¹⁰¹ Following stratification by body weight, patients were assigned to either active treatment (one of three possibilities: diet, exercise, or a combination of both) or to a control group who received brochures on diet, exercise, and IGT. At 6 years, more than two-thirds of the control group (67.7%) developed diabetes, compared to less than half in each of the active treatment groups (43.8% of diet group, 41.1% of exercise group, and 46% in the exercise plus diet group; all $p < 0.05$ compared to control but no significant differences compared to each other). After adjustment for differences in baseline obesity and fasting glucose, reductions in risk of developing diabetes were 31% for diet, 46% for exercise, and 42% for diet plus exercise, each highly significant compared to control.¹⁰¹

Another multicenter, partially blind study in Finland identified 522 overweight middle-aged persons with IGT (mean age, 55; persons over age 65 were excluded) who were randomly assigned to usual care or to individualized counseling aimed at reducing weight and total fat intake while increasing fiber intake and exercise.¹⁰² Mean weight loss at 2 years was significantly different between the two groups; 7.7 pounds in the intervention group and 1.8 pounds for the control group. At 2 years, the cumulative incidence of diabetes was 6% in the intervention group versus 14% in controls (at 4 years, 11% and 23%, respectively), a risk reduction of 58% (95% CI, 0.3–0.7; $p < 0.001$).

The largest U.S. study, the Diabetes Prevention Program, recently announced dramatic reductions in the appearance of diabetes in overweight persons with IGT (mean age, 51) through lifestyle modifications.¹⁰³ A total of 3234 people were randomized to either metformin (850 mg twice a day), placebo, or 150 min of weekly exercise with a low-fat diet and a goal of 7% weight loss. The incidence of type 2 diabetes over a 3-year period was 4.8% with lifestyle intervention, 7.8% with metformin,

and 11% in the control group. In the subgroup of patients over 60 years of age, reductions in risk of diabetes through lifestyle changes were at least as great as that observed in the overall study population. Thus, substantial reductions in the incidence of diabetes were produced by lifestyle (58%) or metformin (31%). The era of identification of individuals at risk and preventing future disability from targeted practical intervention is well under way.

Thyroid Disorders

David S. Cooper

Thyroid problems in the elderly are commonly encountered and are challenging to diagnose and treat. In the geriatric population, the prevalence of certain thyroid diseases (e.g., nodules, goiter, hypothyroidism) is high, and some thyroid disorders (e.g., hyperthyroidism) may have subtle or atypical presentations.¹ In older patients with common nonthyroidal illnesses, thyroid function tests may be altered, making their interpretation all the more difficult. Finally, therapy may be more complex than in younger patients because of the presence of underlying chronic illness, especially cardiac disease, and because of altered thyroid hormone metabolism.

Regardless of age, thyroid disorders can be conveniently categorized as functional (hyperthyroidism and hypothyroidism), inflammatory (thyroiditis), or neoplastic (nodules, carcinoma). For unknown reasons, virtually all thyroid problems occur more commonly in women. Before discussing thyroid diseases in depth, however, it is necessary to review normal thyroid function and to emphasize the alterations in thyroid structure and function that occur in the elderly. Fundamental but unanswered questions are whether such changes are part of normal senescence and whether they contribute materially to the aging process itself.

Aging and Thyroid Anatomy and Physiology

Thyroid Anatomy

During normal aging, atrophy and fibrosis of the thyroid occur.² There is a corresponding reduction in thyroid weight, making palpation of the normal thyroid more difficult. To an unknown extent, these anatomic and histologic changes reflect autoimmune phenomena,³ because prevalence of antibodies to thyroglobulin and microsomal antigens approaches 20% in women over age 60 years.⁴ In addition, the prevalence of microscopic and

macroscopic thyroid nodules rises with age, with a marked increase in clinically palpable disease. However, there does not appear to be a correlation of thyroid weight or histology with thyroid function,⁵ at least as assessed by circulating thyroxine concentrations.

Thyroid Physiology

Control of Thyroid Function

The hypothalamic–pituitary–thyroid axis functions as a classic negative feedback system (Fig. 47.1). Thyrotropin-releasing hormone (TRH), a hypothalamic tripeptide, stimulates the thyrotropes in the pituitary to synthesize and release thyroid-stimulating hormone (TSH, thyrotropin). In turn, TSH binds to specific receptors on thyroid follicular cells to stimulate virtually all aspects of thyroid growth and function from the trapping of iodide from the blood to the synthesis and secretion of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3).

Circulating thyroid hormone exerts negative feedback at the pituitary level, and, as has been recently elucidated, at the hypothalamic level as well. Thus, a rise in thyroid hormone concentrations suppresses TSH and, quite likely, TRH biosynthesis and secretion. On the other hand, a fall in serum thyroid hormone levels stimulates pituitary TSH (and presumably hypothalamic TRH) biosynthesis and secretion. The hypothalamus and pituitary both respond to changes in thyroid hormone concentrations with exquisite sensitivity. Thus, serum TSH levels can fall or rise in response to seemingly minor reciprocal changes in thyroid hormone concentrations, often still within the normal range but not drastic enough to cause clinical evidence of altered thyroid function. For this reason, serum TSH levels are extremely valuable in diagnosing subtle disturbances in thyroid function, which are particularly common in the elderly.

Although the hypothalamic–pituitary unit is of primary importance in the overall control of thyroid function,

there is solid evidence that iodide also serves as a regulator of thyroid hormone biosynthesis and secretion. In pharmacologic doses ($>30\text{mg}$), iodide inhibits thyroid hormone release and blocks thyroidal iodide uptake. Iodide also causes a transient decrease in thyroid hormone biosynthesis, the so-called Wolff–Chaikoff effect. These actions of iodide are probably important in protecting the organism against hyperthyroidism in the event of large iodide loads. Because of its inhibitory effects on thyroid function, iodide occasionally is used to treat hyperthyroidism, but, as is discussed here, it also can cause either hyperthyroidism (the Jod–Basedow phenomenon) or hypothyroidism, given the appropriate clinical substrate.

Thyroid Hormone Synthesis and Transport

Thyroid hormone synthesis is a multistep process that begins with the trapping of iodide by the thyroid follicular cell. Iodine is an essential nutrient and is abundant in the diet of most Western countries. In the United States, the average daily urinary iodine excretion, which reflects dietary iodine intake, has fallen from a mean of $32\mu\text{g/dL}$ in 1971 to 1974 to $14.5\mu\text{g/dL}$ in 1988 to 1994.⁶ Fifteen percent of women over age 60 had low urinary iodine levels ($<5\mu\text{g/dL}$), indicative of mild iodine deficiency. The clinical consequences of this nutritional phenomenon, which has also occurred in young individuals, is uncertain.

FIGURE 47.1. Regulation of thyroid-stimulating hormone (TSH) and thyroid hormone secretion. The relationship between bound and free thyroid hormones in the serum is depicted, emphasizing the importance of the free thyroid hormone concentration in the feedback control of TSH release and in peripheral tissues.

Trapped iodide is oxidized and bound to tyrosine residues in the large protein thyroglobulin via a process known as organification. The next step is the “coupling” of two iodinated tyrosines to form the *iodothyronines*, T_4 and T_3 . Following synthesis, T_4 and T_3 are stored as colloid in the follicular lumen. With TSH stimulation, the colloid (i.e., thyroglobulin) is hydrolyzed inside vacuoles and the free thyroid hormones are released into the bloodstream. The daily T_4 secretion is 10- to 20-fold greater than T_3 secretion ($75\text{--}100$ versus $5\text{--}10\mu\text{g/day}$). Once secreted, they are bound ($>99.9\%$) to transport proteins, principally thyroid-binding globulin (TBG), thyroid-binding prealbumin, and albumin. It is believed that only the unbound, or free, hormone is available to enter cells and exert its metabolic effects. Because of the tight binding of thyroid hormones to serum proteins, their clearance is prolonged significantly: the half-life of T_4 is approximately 7 days; because it is less firmly bound, T_3 has a shorter half-life, approximately 1 day.

It is important to emphasize that quantitative and qualitative changes in the binding proteins alter the serum total T_4 and T_3 concentrations but do not affect free thyroid hormone levels. Thus, situations in which thyroid-binding proteins are altered may be confused with true thyroid dysfunction if only total thyroid hormone concentrations are considered.

Thyroid Hormone Metabolism

Although thyroid hormones are metabolized in a variety of ways, the deiodination pathway is the most relevant clinically (Fig. 47.2). Via this route, approximately 50% of the daily T_4 production is converted to T_3 by removal of a single iodine atom from the outer ring of the T_4 molecule. This reaction is catalyzed by a ubiquitous enzyme, 5'- or outer-ring deiodinase, which also degrades the non-biologically active compound, reverse T_3 (rT_3), to another inert product, T_2 . About 80% of the daily T_3 production derives from T_4 deiodination in the peripheral tissues. Because T_3 is the more metabolically active hormone and binds to nuclear thyroid hormone receptors with far greater affinity than does T_4 , it is likely that T_4 is merely a “pro-hormone” for T_3 . In fact, virtually all the biologic effects of thyroid hormone can be accounted for by the actions of T_3 alone.

A variety of clinical states can decrease the conversion of T_4 to T_3 via inhibitory effects on outer-ring deiodinase activity. Starvation, systemic illness, and certain drugs (propranolol, amiodarone, iodinated contrast agents) all cause a fall in serum T_3 concentrations and a reciprocal rise in serum rT_3 , resulting from a fall in T_4 to T_3 conversion and in rT_3 degradation. The fall in T_3 concentration reduces protein catabolism and tissue oxygen consumption, which may be beneficial to the organism during periods of illness or decreased caloric intake.

FIGURE 47.2. Peripheral metabolism of T₄ and factors that influence the tissue conversion of T₄ to T₃.

Age-Related Changes in Thyroid Function and Metabolism

A number of studies have examined possible changes in thyroid function with advancing age. Most studies show little, if any, change in circulating T₄ or free T₄ levels in the blood. Plasma iodide levels increase, due to a decrease in thyroidal iodine accumulation. This fall in thyroidal iodine uptake is accompanied by a decrease in T₄ secretion. However, decreased T₄ secretion in the elderly is not necessarily indicative of thyroid failure because it is not accompanied by elevations in serum TSH. Studies of elderly men⁷ have also revealed reductions in the T₄ metabolic clearance rate resulting from possible decreases in outer-ring deiodinase activity, lean body mass, or both.⁸ Thus, there are two distinct changes in T₄ economy that occur with aging: a decrease in T₄ secretion counterbalanced by a decrease in T₄ degradation, with no net change in T₄ concentrations in the blood.

Possible alterations in serum T₃ concentrations are more controversial. Although several studies have shown age-related reductions in serum T₃ and free T₃ levels, particularly after age 90 years,⁹ others have found no significant decline during the fifth through the ninth decade.^{10,11} One potential explanation for the discrepancies among the various reports is the inclusion of individuals with subclinical illness in the study populations. Thus, the reported decline in serum T₃ noted by some investigators may be secondary to the presence of subtle or occult infirmities associated with aging, rather than being caused by the aging process itself.

Despite the tentative conclusion drawn by many investigators that serum T₃ levels do not fall with age, it is clear that T₃ levels often are low in randomly selected elderly individuals without obvious illness. Because the major source of daily T₃ production derives from outer-ring

deiodination of T₄, one possible explanation for the low T₃ levels in some aged individuals is the well-established decrease in the T₄ secretion rate. Another possible reason is a decline in the T₄ deiodination rate, which is the hallmark of systemic illness or decreased caloric intake. If a fall in deiodination were the explanation, a reciprocal rise in rT₃ would be expected; this has recently been reported in a group of healthy centenarians.⁹ Thus, the fall in serum T₃ may be due to the decrease in T₄ production by the thyroid gland or a decrease in peripheral T₄ deiodination or both.

As noted earlier, the decline in thyroidal T₄ secretion is not accompanied by an elevated serum TSH level, which is the most sensitive indicator of thyroid hypofunction. Indeed, some studies using highly sensitive TSH assays have shown a decline in mean TSH levels with age.^{10,12} However, other reports suggest that mean TSH levels in the elderly are higher than values observed in younger individuals.¹³ Because most studies have shown that elderly women more often have high-normal or frankly elevated TSH levels, and antithyroid antibodies are often (although not always) present in such patients, it is reasonable to conclude that the slight elevation in mean TSH noted in most reports results from the inclusion in the study population of patients with subclinical autoimmune thyroiditis.² Thus, the normal range for TSH should not differ between younger and older individuals.

Thyroid Hormone Action

Thyroid hormones enter the cell by diffusion and bind to specific receptors located in the nucleus. The thyroid hormone receptor was recently discovered to be a homologue of the protein product or products of a family of oncogenes (*erb-A*), and shares common structural features with the steroid hormone and retinoic acid

receptors.¹⁴ The thyroid hormone receptor protein acts to modify DNA transcription and the synthesis of new proteins by the cell (e.g., angiotensin-converting enzyme, sex hormone-binding globulin, the beta-adrenergic receptor, factor VIII), while it inhibits the transcription and synthesis of other proteins (e.g., TSH and TRH). Future studies of thyroid hormone receptors will undoubtedly enhance our understanding of thyroid hormone action, particularly the reasons why older thyrotoxic individuals have few or no symptoms or signs of thyroid hormone excess (see following).

Virtually all tissues contain thyroid hormone receptors in varying amounts; the degree to which a tissue responds to thyroid hormone is proportional to the thyroid hormone receptor density within that tissue. Clinical observations suggest that elderly persons have decreased responsiveness to thyroid hormones, which is particularly striking in the older patient with thyrotoxicosis, as discussed in the next section. Experimentally, the thyroid hormone response of erythrocyte Ca^{2+} /adenosine triphosphatase (a nonreceptor-mediated activity) falls with age,¹⁵ and in aging rats there is a decrease in hepatic malate dehydrogenase mRNA induction by T_3 compared to young rat.¹⁶ There may also be an age-related decrease in lymphocyte nuclear thyroid hormone receptors.¹⁷ Despite these intriguing data, the decrease in thyroid hormone action that is obvious clinically has yet to be explained at the molecular level.

Thyroid Function Testing

The many recent advances in the laboratory measurement of thyroid function have greatly simplified the evaluation of thyroid dysfunction. Even subtle forms of hypo- and hyperthyroidism can be diagnosed easily, and thyroid hormone therapy can be adjusted with great precision.

Measurement of Thyroid Hormone Concentrations

Radioimmunoassays for T_4 and T_3 are routinely available, with rapid turnaround times. It must be recalled that alterations in TBG affect the total T_4 and T_3 concentrations but not the circulating free thyroid hormone concentrations. Thus, patients with TBG excess or deficiency

have high or low T_4 and T_3 concentrations, respectively, but are clinically and biochemically euthyroid (Table 47.1). It behooves the clinician to determine the true thyroid status of the patient to avoid erroneous diagnoses and inappropriate therapy. Direct measurement of free T_4 has become more popular due to improved cost-effectiveness; it has rapidly replaced the free thyroxine index (FTI), which is the product of total T_4 and the T_3 resin uptake (T_3 RU). The T_3 RU is an indirect approximation of TBG binding capacity, and, when used in concert with the total T_4 concentration, it permits distinguishing true thyroid disease from perturbations in TBG concentration. It is important not to confuse the T_3 RU, which uses radioactive T_3 in vitro, with the direct assay of serum T_3 (the T_3 radioimmunoassay).

Low Serum Total T_4 Levels

Hypothyroxinemia is characteristic of hypothyroidism, but other conditions also must be considered (Table 47.2). A decrease in serum total T_4 often results from TBG deficiency or inhibition of T_4 binding to TBG by drugs (salsalate, high-dose salicylates) or endogenous factors. A circulating inhibitor of T_4 binding to TBG has been described in nonthyroidal illness and may account for the often extraordinarily low total serum T_4 values ($<3\mu\text{g/dL}$) observed in critically ill patients. Unfortunately, most conventional free T_4 assays also yield low results in patients with severe illness that are probably artifactual in nature. Using a technique known as equilibrium dialysis, free T_4 levels are usually found to be normal or even slightly elevated in such circumstances, and most patients are considered to be euthyroid. Low total T_4 and free T_4 levels are also seen in patients taking antiseizure medications because of accelerated hepatic T_4 metabolism and assay artifact, respectively.¹⁸ Because TSH values are normal in this circumstance, these individuals are considered to be euthyroid.

High Serum Total T_4 Levels

Hyperthyroxinemia is seen in most patients with hyperthyroidism. Approximately 10% of patients, however,

have T_3 toxicosis, with normal serum T_4 but elevated serum T_3 levels. This circumstance is particularly common in patients with toxic nodules and toxic multinodular goiter. Interestingly, elderly thyrotoxic patients often also develop " T_4 toxicosis," with normal serum T_3 levels, a finding that is rare in younger hyperthyroid patients; this is discussed in more detail in the section on hyperthyroidism.

Euthyroid hyperthyroxinemia (see Table 47.2), that is, a high total T_4 level caused by elevations in TBG or other binding proteins, is commonly confused with biochemical hyperthyroidism. However, use of the free T_4 (f T_4) assay circumvents most problems that arise from alterations in thyroid binding protein levels, and usually permits the correct interpretation of an elevated serum T_4 level and a normal TSH level.

Measurement of TSH

The pituitary gland is exquisitely sensitive to changes in circulating thyroid hormone concentrations. Serum TSH levels therefore are elevated even in mild primary hypothyroidism and, theoretically, TSH levels should be low in virtually all forms of hyperthyroidism. Of course, the serum TSH level will be inappropriately low in hypothyroid patients with pituitary or hypothalamic failure, and, in the rare patient with a TSH-secreting pituitary adenoma causing hyperthyroidism, the TSH level will be inappropriately elevated or normal.

In recent years, TSH assays have been refined, with improvements in their level of sensitivity. Modern techniques can reliably distinguish the low TSH levels in hyperthyroidism from normal TSH levels, which was not possible with older TSH assays. This important modification permits the clinician to diagnose hyperthyroidism (which should yield low or undetectable TSH levels) with greater ease. Most assays in general use are termed sensitive or second-generation assays and typically have a functional detection limit for TSH of approximately 0.1 mU/L. Newer assays, termed ultrasensitive or third generation, are becoming more widespread and have a detection limit in the range of 0.01 to 0.005 mU/L. In both assays, patients with clear-cut hyperthyroidism have undetectable TSH values. Although these new assays have revolutionized the diagnosis of thyroid disease, they have also created difficulties, particularly because a significant fraction of hospitalized patients have TSH values that are subnormal,¹⁹ related to illness or to suppression of serum TSH by high-dose glucocorticoid or dopamine therapy.

A recent metaanalysis of thyroid function screening of geriatric inpatients concluded that there was a high rate of false-positive tests and that the true prevalence of thyroid disease (both hyperthyroidism and hypothyroidism) was similar to that seen in the general population.²⁰ Screening was not recommended in the absence

of symptoms or signs of thyroid disease, but these too lack specificity and sensitivity, it was also pointed out that the likelihood ratio for true thyroid disease was higher (in the range of 7 to 11) with more severely deranged test results (i.e., TSH <0.1 or >20 mU/L).

Recent studies have revealed the existence of a subset of seemingly healthy elderly individuals who have TSH levels that are subnormal and occasionally below the limits of detection in sensitive assays, without evidence of thyroid disease clinically or biochemically.²¹ A TSH that is below the detection limit of a third-generation assay (i.e., <0.005 mU/L) is much stronger evidence for true hyperthyroidism than a TSH that is undetectable in a second-generation assay. TSH values will be normal in some patients on repeat testing, but low values will persist in others.¹² Some, perhaps most, of these patients have mild (subclinical) hyperthyroidism, as discussed next, whereas others have no obvious abnormality on long-term follow-up. An isolated subnormal TSH level may be a risk factor for the development of atrial fibrillation,²² suggesting that seemingly minor changes in T_4 and T_3 levels may be biologically significant.

Radionuclide Evaluation of Thyroid Structure and Function

The thyroid gland traps iodide and other ions, permitting glandular morphology and function to be assessed with isotopes of iodine (^{123}I and ^{131}I) and technetium ($^{99\text{m}}\text{TcO}_4$). Technetium is used frequently to image the thyroid because it is inexpensive and convenient (imaging after 20 min). However, as it is trapped but not organized (unlike iodide), it cannot provide as much useful information about overall thyroid function as does iodide, with imaging after 6 to 24 h.

Unfortunately, the radioiodine uptake (RAIU) is only occasionally helpful in diagnosing hypo- or hyperthyroidism. The normal 24-h RAIU is between 5% and 25% in most radiology departments, so there is a great deal of overlap between normal and hypothyroid values. Furthermore, many elderly hyperthyroid patients, especially those with toxic nodular goiter, have 24-h RAIU values in the normal range. Additionally, some hypothyroid patients with Hashimoto's thyroiditis can actually have elevated RAIU, whereas patients with hyperthyroidism caused by thyroiditis have low RAIU. Thus, the test is very nonspecific. Stable iodide blocks the uptake of radioactive iodide by the thyroid; therefore, isotopic studies should not be performed within several weeks of receiving iodinated contrast dyes or while patients are taking iodinated drugs such as the antiarrhythmic amiodarone.

Although the 24-h RAIU is of limited usefulness, thyroid scanning is helpful in determining the size and location of thyroid tissue and the functional nature of

thyroid nodules. Thyroid scanning is also invaluable in the diagnosis of functioning metastases from well-differentiated thyroid cancer.

Other Thyroid-Related Tests

Antithyroid antibodies are important in establishing the diagnosis of autoimmune thyroid disease. Anti-thyroglobulin antibodies are thought to be less specific than antithyroid peroxidase (anti-TPO antibodies). Thyroglobulin is released from the thyroid in a host of thyroid disorders, so it is not useful diagnostically. Its measurement is most crucial in the follow-up of patients with well-differentiated thyroid cancer. Thyroid needle biopsy, thyroid ultrasonography, and neck computed tomography are discussed in the section on thyroid neoplasia and goiter.

Disturbances of Thyroid Function

Thyrotoxicosis

Thyrotoxicosis is being recognized with increasing frequency in the elderly. Although most reports indicate that the peak incidence is in the second and third decades of life, one prospective study found that, of 49 cases of thyrotoxicosis diagnosed over a 3-year period, 28 (57%) were in individuals over the age of 60 years.²³ Graves' disease is the most common cause of thyrotoxicosis in all age groups, but the proportion of patients with toxic multinodular goiter (Plummer's disease) increases with age. Because the prevalence of thyroid nodularity in general is higher in the elderly, some older patients with preexisting nontoxic nodules undoubtedly develop thyrotoxicosis due to Graves' disease, accounting for diagnostic difficulty (Table 47.3). On the other hand, 20% to 50% of elderly thyrotoxic patients have nonpalpable thyroid glands, also making the diagnosis more obscure.²⁴ In a study of hyperthyroidism in 21 individuals over age 75 years, only 3 had a palpable gland.²⁵

Clinical Features

In contrast to the classic symptoms and signs of hyperthyroidism in younger individuals, elderly patients typically display few of the sympathomimetic features that are characteristic of the thyrotoxic state. Thus, the apt term "masked" or "apathetic" thyrotoxicosis has been applied to the elderly thyrotoxic patient who presents with depression, lethargy, weakness, and cachexia. However, most older patients do have symptoms that should bring the diagnosis to mind^{26,27} (Table 47.4). Agitation and confusion ("thyrotoxic encephalopathy") can mimic dementia²⁸ (Table 47.5). Unexplained weight loss, nervousness, palpitations, and tremulousness are present in well over half the patients, with weight loss occurring in up to 80%.²⁸ In contrast to younger thyrotoxic patients however, elderly patients frequently (but not invariably) have a poor appetite, and constipation is present in a significant minority. The combination of weight loss and diminished appetite often triggers a fruitless evaluation for occult malignancy. Hyperthyroidism causes increased bone turnover, and the presence of what appears to be typical postmenopausal osteoporosis should prompt screening for hyperthyroidism. In a recent prospective study of 9516 white women over age 65 years, a history of hyperthyroidism was an independent risk factor for the development of hip fracture [relative risk (RR), 1.7; 95% CI, 1.2–2.5].²⁹

It is well known that the cardiovascular system retains its sensitivity to thyroid hormone action in the elderly. Coupled with a high prevalence of atherosclerotic coro-

nary disease, this probably is the explanation for palpitations, worsening angina, and, more rarely, symptoms of congestive heart failure. Atrial fibrillation, often with a relatively slow ventricular response,²⁸ is the presenting feature in up to 20% of patients, and the development of atrial fibrillation should always prompt a thorough screen for thyrotoxicosis. One study of nursing home residents over age 65 years found that 11% of men and 31% of women with atrial fibrillation were thyrotoxic.³⁰ Atrial fibrillation typically develops in patients with dilated left atria, which is apt to be more common in elderly persons.³¹

Despite the fact that Graves' disease is the most common form of thyrotoxicosis in the elderly, infiltrative ophthalmopathy is present less often than in younger of patients,³² although it may be more severe when it does occur.³³ The reasons for this are unknown.

Laboratory Testing

In contrast to the ease with which the laboratory diagnosis of thyrotoxicosis is made in younger patients, thyroid function test interpretation in the elderly can be a vexing problem. As in younger patients, the serum free T_4 index or free T_4 level, and the T_3 level all are elevated in the average patient. There is controversy, however, regarding the degree of biochemical abnormalities, with one study suggesting that older and younger thyrotoxic patients have similar thyroid function abnormalities³⁴ and others indicating that the biochemical perturbations are milder in the elderly.³⁵⁻³⁸ " T_3 toxicosis" is common in patients with solitary toxic nodules and toxic multinodular goiter. Because these diagnoses occur more frequently in the elderly, the possibility of thyrotoxicosis with normal serum T_4 and free T_4 levels, but an elevated T_3 level, must be kept in mind. Even more problematic is " T_4 toxicosis," which typically occurs in elderly hyperthyroid patients who have concurrent nonthyroidal illness. The decrease in T_4 to T_3 conversion, brought about by the illness, produces normal or even low serum T_3 values. Although the serum T_3 level is virtually always elevated in younger thyrotoxic patients, it is normal in a significant minority of elderly thyrotoxic patients. However, it is of great importance to distinguish T_4 toxicosis from "euthyroid hyperthyroxinemia" because of abnormal protein binding and drugs that inhibit T_4 to T_3 conversion,³⁹ including amiodarone. It should also be recognized that the serum total T_4 and T_3 levels may actually be normal in debilitated elderly thyrotoxic patients, due to a decrease in serum TBG and a decrease in T_4 to T_3 conversion, respectively. Although the free T_4 index should correct for changes in TBG, it is frequently unreliable in ill patients, and direct measurement of free T_4 is preferable in most cases.

Most truly hyperthyroid individuals have TSH levels that are below the limit of detection in a sensitive or a

third-generation assay. Some TSH assays will not distinguish hyperthyroid from normal individuals and yet are called "sensitive" assays.¹⁹ Therefore, a reliable TSH assay is crucial in diagnostic decision making. A low serum TSH is not always the sine qua non of overt hyperthyroidism; some "euthyroid" individuals with nontoxic multinodular goiter may have subclinical hyperthyroidism with normal T_4 , free T_4 , and T_3 levels, but suppression of the hypothalamic-pituitary axis.²⁰ One study suggested that measurement of free T_3 could distinguish truly thyrotoxic individuals from those with subclinical hyperthyroidism.⁴⁰ TSH levels also may be low in hospitalized patients and may be undetectable even in third-generation TSH assays in critically ill patients.⁴¹ However such patients usually have low rather than high serum T_4 levels, and exclusion of central hypothyroidism is the diagnostic problem, rather than hyperthyroidism.

The 24-h RAIU is normal in up to 30% of elderly patients with Graves' disease and in over two-thirds of elderly individuals with toxic multinodular goiter (Plummer's disease),³⁴ and is therefore often not helpful in ruling in hyperthyroidism. The measurement of serum T_3 and possibly free T_3 in patients with normal serum T_4 levels and low TSH levels should facilitate the laboratory evaluation and maximize diagnostic accuracy.

Differential Diagnosis

Before initiating a therapy for the thyrotoxic patient, the etiology of hyperthyroidism must be known (see Table 47.3). As stated earlier, Graves' disease is the most frequent cause (in 50%–70% of cases), followed by toxic multinodular goiter. Together, these two account for well over 95% of hyperthyroid patients. Two uncommon forms of thyroiditis cause transient and self-limited hyperthyroidism and are very uncommon in the elderly population. Subacute thyroiditis (De Quervain's) typically presents with severe anterior neck pain, fever, and general malaise and is thought to be viral in origin. Thyroid function test results are elevated due to release of stored hormone into the blood, but the 24-hour RAIU is low, because of damage to the thyroid gland as well as suppression of endogenous TSH by the high thyroid hormone levels. Treatment consists of anti-inflammatory agents (salicylates and other nonsteroidal anti-inflammatory agents, glucocorticoids in severe cases) and beta-adrenergic blocking drugs for symptomatic relief. Painless ("silent") or lymphocytic thyroiditis, rare in the elderly, presents with thyrotoxicosis and small painless goiter.⁴² It can be extremely difficult to distinguish from Graves' disease by laboratory testing, except that, as in subacute thyroiditis, the 24-h RAIU is very low. Therapy is limited to the use of beta-adrenergic blockers until the thyrotoxicosis has resolved.

Another diagnosis that should be considered in the elderly patient with thyrotoxicosis is the possibility of a TSH-secreting pituitary tumor. The hallmark is the presence of serum TSH levels that are inappropriate given the elevations in serum T_4 and T_3 levels (i.e., instead of being suppressed, TSH levels are normal or high). A full discussion of inappropriate TSH syndromes is beyond the scope of this chapter but is the subject of a recent review.⁴³

Finally, iodine-induced thyrotoxicosis (Jod-Basedow phenomenon) occurs in individuals exposed to iodide or iodide-containing compounds who have an underlying multinodular goiter. The problem has become more common with the recent introduction of the antiarrhythmic amiodarone. There may be two types of amiodarone-induced thyrotoxicosis: one developing in patients with a preexisting multinodular goiter and a second, inflammatory type that resembles painless thyroiditis and may respond to steroid therapy, rather than to antithyroid drugs.⁴⁴⁻⁴⁶ Although both types of amiodarone-induced thyrotoxicosis are self-limited, they can be very severe, requiring large doses of antithyroid drugs, glucocorticoids, and occasionally even surgery. Although discontinuation of amiodarone would be expected to ameliorate the situation, this is not always possible because of the patient's underlying cardiac disease. Also, the half-life of the drug may be as long as several months, so that stopping it may not afford any immediate benefit.

Treatment

The three treatments for hyperthyroidism are antithyroid drugs, radioactive iodine, and surgery. In elderly patients, surgery is rarely employed because of its attendant morbidity, unless a large toxic multinodular goiter is present and causing local symptoms (dysphagia or dyspnea). Antithyroid drugs (propylthiouracil and methimazole) often are used as primary therapy for Graves' disease in younger patients, for a variety of reasons, including the possibility of spontaneous remission and theoretical but unproved concerns about long-term consequences of radioiodine. In elderly patients, late complications of radioiodine are less relevant and the major goal is definitive therapy with permanent cure. Thus, radioiodine ablation is the treatment of choice for virtually all older thyrotoxic patients.⁴⁷

It must be emphasized, however, that radioiodine therapy cannot be given with impunity to elderly patients. A major concern is possible exacerbation of thyrotoxicosis after radioiodine treatment, due to the release of preformed thyroid hormone into the circulation from radiation-induced thyroiditis. This problem can be life threatening in the elderly thyrotoxic patient, particularly in the presence of underlying cardiac disease. Therefore, many thyroidologists render such patients biochemically

euthyroid with antithyroid drugs before the administration of radioiodine. These drugs impair the biosynthesis of thyroid hormone but not its release. Therefore, at least theoretically, the thyroid is depleted of hormonal stores within 4 to 8 weeks, and radioiodine can be given safely. Traditionally, antithyroid drugs are discontinued for 3 to 5 days before radioiodine administration and are not resumed for 3 to 5 days afterward, so as not to interfere with the intrathyroidal effects of radioiodine. The dosage of the antithyroid drug is tapered over the ensuing months, as the effects of radioiodine are becoming manifest. There is evidence that the use of antithyroid drugs before and after radioiodine therapy results in a higher failure rate of the radioiodine,⁴⁸ which can be overcome by using a higher therapy dose of radioiodine.

Antithyroid drugs cause fever, rash, and arthralgias in 1% to 5% of individuals. Agranulocytosis occurs in approximately 1 in 300 to 500 patients (usually in the first 2 months of treatment) and may be more common in elderly patients.⁴⁹ Methimazole in low doses (<20 mg/day) may pose less of a risk of agranulocytosis than propylthiouracil, and methimazole has the added advantage of being a once-a-day agent, which improves compliance. Patients beginning antithyroid drug therapy should be warned that if fever or oropharyngitis develops, the medication should be stopped immediately and the physician contacted.

The beta-adrenergic blocking agents are an important adjunct in the management of thyrotoxicosis.⁵⁰ Rapid and almost complete resolution of cardiac and neuromuscular symptoms can be accomplished with agents in this class. They do not normalize oxygen consumption or reverse the negative nitrogen balance that typifies the thyrotoxic state, and they should therefore not be used as sole therapy except in those rare patients with self-limited disease due to thyroiditis. These agents are extremely useful before and after antithyroid drug and radioiodine therapy, because euthyroidism generally is not attained for 1 to 2 months after antithyroid drugs are started or for up to 12 months after radioiodine. Propranolol, with its short serum half-life, is not so useful as nadolol or long-acting propranolol. Atenolol and metoprolol, two long-acting cardioselective agents, also are used frequently. The beta-blockers are contraindicated in patients with asthma, and should be used cautiously in patients with congestive heart failure (unless rate related), diabetes treated with oral hypoglycemic agents or insulin, and in patients with Raynaud's phenomenon or intermittent claudication.

Following radioiodine therapy, patients must be followed up expectantly for the development of iatrogenic hypothyroidism. This complication occurs almost inevitably in patients with Graves' disease but is less common in toxic nodular goiter,⁵¹ presumably a result of the failure of radioiodine to be concentrated in suppressed

regions of the gland. Posttherapy hypothyroidism develops within 12 months in 40% to 50% of patients with Graves' disease and then occurs at a rate of 2% to 3% per year thereafter. Some patients develop transient hypothyroidism 1 to 6 months after radioiodine therapy, which resolves after a few weeks, then only to be followed by permanent hypothyroidism.⁵² The presence of a persistent goiter is a clinical clue that the hypothyroidism is likely to be transient, rather than permanent. Two recent studies suggest that there is an association between radioiodine therapy and subsequent thyroid cancer development, especially in patients with multinodular goiter.^{53,54} However, this association may be due to a higher frequency of thyroid cancer in multinodular goiter, rather than a true cause-and-effect relationship.

Atrial fibrillation, especially when present for a relatively short time (less than 6 months), frequently spontaneously converts to normal sinus rhythm with control of thyrotoxicosis. In one study,⁵⁵ 62% of patients converted, with 75% converting within 3 weeks of becoming euthyroid; no patient converted after euthyroidism had been established for 4 months. Although age was not predictive of spontaneous conversion in this study, other reports suggest that spontaneous conversion occurs less frequently in elderly patients. Embolic stroke is a recognized complication of atrial fibrillation in thyrotoxicosis. Therefore, routine anticoagulation has been recommended for patients with atrial fibrillation caused by thyrotoxicosis,⁵⁶ but therapy must be individualized, and no firm recommendations can be made. If anticoagulation is undertaken, it should be recognized that thyrotoxic patients are *more* sensitive to the effects of coumarin derivatives than are euthyroid patients,⁵⁷ and hence require smaller doses to achieve comparable degrees of anticoagulation.

Severe Hyperthyroidism and Thyroid Storm

For those patients who are so severely ill with thyrotoxicosis that hospitalization is required, or if thyrotoxicosis occurs in the setting of severe medical illness (e.g., myocardial infarction), more rapid control of the disease is desirable. Large doses of antithyroid drugs are typically employed (e.g., 200 mg propylthiouracil every 6 h or 40–80 mg methimazole per day as a single dose), which theoretically blocks thyroid hormone production completely. However, because thyroid hormone release is unaffected by antithyroid drugs, other agents must be employed to achieve an expeditious resolution of the thyrotoxic state. Traditionally, potassium iodide (as SSKI, [saturated solution of potassium iodide] containing 35 mg iodide per drop or Lugol's solution, containing 8 mg iodide per drop) has been used for this purpose, because iodine is a potent inhibitor of thyroid hormone release. Doses range from 100 to 500 mg/day in divided doses; iodide should be given only after the patient has been started on antithyroid drugs.

More recently, the iodinated oral cholecystographic contrast agents sodium ipodate (Telepaque) and sodium iopanoate (Oragraffin) have been used in dosages of 1 to 2 g daily in divided doses. These compounds have two beneficial effects. First, they release free iodide into the circulation, which, in turn, inhibits thyroid hormone secretion. Second, these compounds are potent inhibitors of T₄ to T₃ conversion, and they rapidly lower serum T₃ levels toward normal. Thyroxine has a half-life in serum of about 7 days; blocking both synthesis and release does not improve symptoms and signs due to hormone already present in the circulation. By lowering the serum T₃ levels, the iodinated contrast agents should be very useful in this regard. However, it must be acknowledged that there are no clinical trials reporting outcomes with the use of these agents.

The adrenergic blockers also are efficacious in reversing sympathomimetic symptoms and signs caused by circulating thyroid hormone. For life-threatening tachyarrhythmias, 1 mg propranolol hydrochloride can be given slowly intravenously, with the dose repeated every 5 min, or esmolol, a shorter-acting agent, can be employed. For those patients in atrial fibrillation in whom beta-blockers are contraindicated, a calcium channel blocker such as diltiazem can be used.⁵⁸

Thyroid storm is a state of decompensated thyrotoxicosis, defined by severe hypermetabolism, fever, neuropsychiatric changes, and, often, congestive heart failure. Thyroid function test results are no different in patients with thyroid storm than in those with less severe clinical disease. Rather, the ability to deal with the hypermetabolic state is compromised, often by the superimposed stress of acute illness (e.g., infection) or trauma (e.g., surgery). Therapy consists of fluid and electrolyte support, active cooling, and large doses of antithyroid drugs, iodide or iodinated contrast agents, and beta-blockers. Additionally, stress doses of glucocorticoids are usually employed. Because the presentation of hyperthyroidism is relatively more apathetic in elderly patients, they tend to have a better prognosis than younger patients in thyroid storm.⁵⁹

Subclinical Hyperthyroidism

With the development of sensitive TSH assays came the ability to detect a more subtle form of thyroid dysfunction, in which the TSH levels are low or undetectable, but the T₄, free T₄, and T₃ levels are within normal limits. Patients with this constellation of laboratory results generally have few or no symptoms of hyperthyroidism and may or may not have a palpable goiter on physical examination.⁶⁰ Subclinical hyperthyroidism has been noted in 1% to 5% of older persons, with a higher frequency if those who are taking excessive quantities of thyroxine are included.⁶⁰ Although this syndrome may resolve in

FIGURE 47.3. Incidence of atrial fibrillation in subjects 60 years of age or older, according to serum TSH levels at baseline; 13 of 61 patients developed atrial fibrillation ($p < 0.005$).²²

FIGURE 47.4. Mean (\pm SEM) percentage of baseline bone mineral density in distal forearm in postmenopausal women with subclinical hyperthyroidism randomized to receive methimazole (●, $n = 8$) or no treatment (○, $n = 8$) ($*p < 0.05$).⁶³

some patients upon later testing,¹² suggesting that it can be caused by transient intercurrent illness, it usually persists and may evolve into overt hyperthyroidism over time.⁵⁹

One long-term follow-up study found that patients with subclinical hyperthyroidism had a two- to three-fold higher rate of atrial fibrillation than euthyroid controls, suggesting that the low TSH levels have biologic significance²² (Fig. 47.3). Subclinical hyperthyroidism may⁶¹ or may not⁶² be associated with a bone mineral density that is lower than that seen in age-matched controls. However, two recent reports noted an increase in bone mineral density in patients with subclinical hyperthyroidism after either a 2-year course of antithyroid drug therapy⁶³ (Fig. 47.4) or following radioiodine.⁶⁴ Therefore, although treatment of elderly asymptomatic individuals with subclinical hyperthyroidism could be justified to protect the cardiovascular system or the skeleton, it remains controversial.⁶⁵ Certainly, if subclinical hyperthyroidism is due to overzealous thyroxine replacement

therapy, the dose of medication should be adjusted until the TSH levels are normal.

Hypothyroidism

Approximately 70% of hypothyroid patients are over age 50 years at the time of diagnosis.⁶⁶ The prevalence of hypothyroidism in the population depends on how the condition is defined: if a low serum T_4 or free T_4 level is the criterion, approximately 0.5% of individuals (largely women) over age 65 years will be found to be overtly hypothyroid.^{1,2} If the more liberal definition of an elevated serum TSH level with or without a low T_4 level is employed, up to 17.5% of individuals over age 75 years will have mild hypothyroidism.^{2,59,67,68} This latter situation may be more appropriately termed subclinical hypothyroidism because serum T_4 and free T_4 levels are still within the broad range of normal.

Etiology

The most common cause of hypothyroidism in the elderly is autoimmune thyroid failure (Hashimoto's thyroiditis, chronic lymphocytic thyroiditis) (Table 47.6). In parallel with the high prevalence of autoimmune thyroiditis in the elderly, the prevalence of antithyroid antibody positivity also rises with age.⁶⁹ Over two-thirds of patients with thyroid failure have antithyroid antibodies.⁷⁰ Two types of antithyroid antibodies have been described in Hashimoto's thyroiditis: antimicrosomal (now termed antithyroid peroxidase or anti-TPO antibodies) and antithyroglobulin. Antimicrosomal antibodies are highly specific for autoimmune thyroiditis. Antithyroglobulin antibodies, on the other hand, are not as specific for autoimmune thyroid disease, and their presence in the absence of antimicrosomal antibody is not sufficient to establish the diagnosis.

Iatrogenic hypothyroidism is an additional important, although less frequent, cause of thyroid failure. Radioiodine and surgical therapy for Graves' disease usually lead to permanent hypothyroidism. Additionally, several studies suggest that permanent hypothyroidism is a late phase in the evolution of drug-treated Graves' disease. Not surprisingly, external beam radiotherapy to the head and neck region also can cause late thyroid hypofunction. Lithium- and iodine-containing medications can provoke hypothyroidism; this has become an increasing problem with the antiarrhythmic amiodarone, which is used widely in older patients.⁷¹ Finally, many patients with subacute or painless thyroiditis have mild transient hypothyroidism following hyperthyroidism, but this rarely requires therapy. Hypothalamic or pituitary disease are unusual causes of hypothyroidism.

Diagnosis

The diagnosis of hypothyroidism is not difficult in a young patient with typical symptoms of fatigue, weight gain, dry skin, cold intolerance, and constipation. In elderly patients, however, these same complaints are attributed all too often to the aging process itself. The problem is further complicated by the insidious development of symptoms, often over a period of years, and by patients who present in an atypical manner⁷² or with no symptoms at all.⁷³ In a recent study of 67 older hypothyroid patients (mean age, 79 years), they were more likely to present with fatigue and weakness, and less likely to have cold intolerance, weight gain, paresthesiae, and muscle cramps compared to 54 younger hypothyroid patients with a mean age of 41 years.⁷² Thus, it behooves the physician to be creative and vigilant and to resist the stereotypical image of the "normal aging process."

Certain findings on physical examination should alert the clinician to the possibility of hypothyroidism. Hypertension, for example, can be a presenting sign, as can bradycardia and, surprisingly, various tachyarrhythmias. Hypothermic patients always should be evaluated for hypothyroidism, hypoglycemia, and sepsis. Although nonpitting edema of the face and limbs is a hallmark of hypothyroidism, pitting edema also is frequently found, possibly due to a lowered glomerular filtration rate and decreased cardiac output. Frank congestive heart failure is unusual in hypothyroidism, and cardiomegaly more often is a result of the presence of pericardial effusion; although the pericardial effusions in hypothyroidism are usually not hemodynamically significant, tamponade has been described. Pleural effusions and ascites also can be seen.

In contrast to younger hypothyroid patients, older individuals rarely have a goiter. Whether this represents the natural history of goitrous autoimmune thyroiditis or a separate, atrophic variant of autoimmune thyroiditis is

unclear.⁷⁴ Ophthalmopathy also may be present, even in the absence of a history of Graves' disease. Neuropsychiatric signs, including depression, lassitude, impaired cognition, and poor memory, are common; muscle cramps, peripheral neuropathy (carpal tunnel syndrome), and cerebellar ataxia are additional features of hypothyroidism, along with ileus, urinary retention, and sleep apnea. All patients with dementia should be evaluated for possible hypothyroidism.⁷⁵ Recent epidemiologic studies suggest an association between Alzheimer's disease and hypothyroidism, but no causal relationship has been proven.⁷⁶

Sometimes hypothyroidism is found serendipitously because of abnormal laboratory data. Elevations in serum cholesterol levels (when previously normal) and high creatine kinase levels are hallmarks of hypothyroidism and are caused by decreased clearance. Hyponatremia commonly is seen in elderly patients and should always prompt an evaluation of thyroid status. Its origin is controversial but probably relates to both decreased glomerular filtration and the inappropriate secretion of vasopressin. A normochromic normocytic anemia, possibly due to decreased erythropoietin secretion, commonly is seen in hypothyroidism, and pernicious anemia occurs frequently in association with autoimmune thyroid disease.

Laboratory Diagnosis

Hypothyroidism is perhaps the simplest thyroid functional abnormality to diagnose. The hallmark of primary hypothyroidism is a low serum free thyroxine index or free T_4 , with concomitant elevation of the serum TSH. As previously noted, "subclinical" hypothyroidism is characterized by normal serum T_4 levels with only minimal to modest increases in TSH levels (e.g., 5–20 mU/L, with normal values <5 mU/L). Measurement of T_3 is of little use in the diagnosis of hypothyroidism, because normal serum levels are often maintained until severe hypothyroidism supervenes; this may be related to a shift from T_4 to T_3 secretion by the thyroid gland, under intense stimulation by high levels of TSH.

Several pitfalls in the laboratory diagnosis of hypothyroidism deserve mention. First, some patients with secondary hypothyroidism (i.e., due to hypothalamic or pituitary disease with TSH deficiency) have low T_4 values with inappropriately low or normal serum TSH levels. In hypothalamic/pituitary disease, the pituitary may secrete a TSH molecule that is immunologically active in the radioimmunoassay but has lower than normal bioactivity. Thus, if hypothyroidism is suspected clinically and serum T_4 values are low, evaluation of hypothalamic and pituitary anatomy and function is indicated, even if the serum TSH level is "normal." Generally, other hormonal deficits will be present in this clinical circumstance

(e.g., adrenal insufficiency, low FSH and LH in a postmenopausal woman, or hypogonadotropic hypogonadism in a man).

A second problem that confounds the diagnosis of hypothyroidism is severe illness.^{40,77} It may be extremely difficult to distinguish a critically ill patient with low T_4 and normal or low TSH levels from one with secondary hypothyroidism (see previous discussion). To further complicate matters, serum TSH levels occasionally rise during the recovery phase of illness, often to levels consistent with primary hypothyroidism. In this circumstance, repeating the TSH measurement after recovery is complete is the appropriate strategy.

Treatment

Once the diagnosis of primary hypothyroidism is made, therapy with thyroxine should be initiated; patients with chronic fatigue or obesity who are not hypothyroid should never be treated with this drug. Thyroxine is generally well absorbed from the gastrointestinal tract, although the fractional absorption may decline slightly with age.⁷⁸ Its long serum half-life produces nonfluctuating serum levels. Cholestyramine, sucralfate, aluminum hydroxide, and possibly ferrous sulfate and calcium supplements interfere with its absorption and should not be taken concurrently. As in healthy untreated individuals, much of the orally administered thyroxine is deiodinated to T_3 , at a rate determined by the patient's clinical status (i.e., decreased in illness or starvation). Thyroxine is available in proprietary forms (Synthroid, Levothyroid, and Levoxyl) and in generic form. Although most generic brands probably are equivalent to the proprietary preparations in hormonal content, some have been shown to be inferior with respect to hormonal content or bioavailability. And unfortunately, because it is often quite difficult to determine the ultimate manufacturer of a generic product, patients may unknowingly be switched from one generic to another when prescriptions are refilled. Therefore, most endocrinologists prefer the proprietary forms of thyroxine for their proven reliability and consistency.

The dictum "start low, go slow" should be followed in elderly patients when initiating thyroxine therapy, because rapid increases in myocardial oxygen consumption theoretically could trigger or worsen angina. Therefore, it is best to be prudent and initiate treatment with doses of 25 to 50 $\mu\text{g}/\text{day}$, with monthly monitoring of thyroid function. The biochemical goal of therapy is the normalization of serum TSH levels in a sensitive TSH assay; the TSH level should not be below the normal range, which would suggest overreplacement. Even seemingly minor changes in dose can cause large changes in serum TSH values.⁷⁹ As discussed earlier, the daily thyroxine production rate declines with age, and consequently, as has been noted by most investigators, the daily

thyroxine replacement dose is approximately 10% lower in elderly patients than in young or middle-aged adults.⁸⁰ In general, doses of 0.8 to 1.2 $\mu\text{g}/\text{kg}$ of lean body mass (LBM) are sufficient to normalize serum TSH levels in patients over age 70 years. The thyroxine replacement dose for elderly patients can be predicted by the following formula:⁸¹

$$T_4 (\mu\text{g}/\text{day}) = 3.6 \times \text{LBM} - 30$$

$$\text{LBM}(\text{males}) = (79.5 - 0.24M - 0.15 \times A) \times M / 73.2$$

$$\text{LBM}(\text{females}) = (69.8 - 0.26M - 0.12 \times A) \times M / 73.2$$

where M indicates body weight in kilograms and A indicates age in years. Overreplacement is to be avoided, not only because of untoward cardiac effects⁸² but also because of convincing data in postmenopausal women showing that even mild asymptomatic iatrogenic hyperthyroidism can be associated with accelerated bone loss.⁸³ The dose requirement may be higher in patients with malabsorption or in those taking anticonvulsants or amiodarone.

A large and potentially bewildering number of thyroid hormone preparations are available (Table 47.7). These formulations are traditionally classified as "synthetic" or "biologic." As already described, synthetic thyroxine is the therapy of choice. Another synthetic preparation, liotrix, is a combination of T_4 and T_3 (Thyrolar). This product was developed decades ago, before it was known that T_3 arose from peripheral conversion of T_4 , rather than from direct thyroidal secretion. It is now clear that providing T_3 to the patient is unnecessary and theoretically could raise serum T_3 levels to above normal, causing palpitations, anxiety, and other bothersome symptoms. Furthermore, liotrix is more expensive, and its use makes monitoring of therapy more difficult and expensive, because of the necessity of measuring serum T_3 levels as well as T_4 levels. An additional synthetic thyroid hormone, pure L-triiodothyronine (Cytomel), should never be used for long-term replacement therapy. It is often used for short periods in patients with thyroid cancer preparing for radioiodine scanning.

The "biologic" thyroid hormone preparations include desiccated thyroid, derived from the thyroid glands of

slaughterhouse animals. The generic biologic preparations are notorious for their lack of standardization. The proprietary preparations have better quality control but suffer from the same problem as liotrix and T₃, that is, they contain T₃, which is an undesirable drug for chronic replacement therapy. Most endocrinologists agree that the biologic preparations are of historical interest only; patients who are taking them should be switched to synthetic thyroxine at doses of 0.8 µg/lb body weight per day.

Special Therapeutic Considerations

Hypothyroid Patients with Severe Coronary Artery Disease

Elderly hypothyroid patients not infrequently have concomitant coronary artery disease.⁵⁶ Long-standing hypothyroidism, with its attendant hypercholesterolemia, may be an important contributing factor in the development of atherosclerosis. A recent Dutch study found that subclinical hypothyroidism was also an independent risk factor for atherosclerosis (RR, 1.7; 95% CI, 1.1–2.6) and myocardial infarction (RR, 2.3; 95% CI, 1.3–4.0), independent of serum lipid levels.⁸⁴ In the setting of overt or silent ischemic heart disease, it may be difficult to replace thyroxine fully without provoking or exacerbating angina. Every effort should be made to maximize the antianginal regimen medically. If that fails, and if the patient remains clinically hypothyroid because of the inability to prescribe an adequate dosage of thyroxine, coronary artery bypass surgery should be considered.⁸⁵ Open heart surgery, and, indeed, any surgery, can be performed safely in patients with severe hypothyroidism, so long as scrupulous attention is paid to the patient's pulmonary status and fluid balance in the perioperative period.⁸⁶ In the untreated hypothyroid patient with unstable angina, it is probably best to send the patient to surgery or percutaneous transluminal coronary angioplasty (PTCA) rather than risk myocardial infarction by treating the hypothyroidism and delaying surgery.⁸⁵

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined biochemically as normal serum T₄ and free T₄ levels with an elevated serum TSH level. As noted earlier, it is one of the most common thyroid disorders among elderly persons, being present in up to 17.5% of women over age 60 years.⁵⁹ Most patients have circulating antithyroid antibodies, suggesting that the condition is autoimmune in nature.⁵⁹ Some patients have a history of Graves' disease, while others are taking drugs (lithium- or iodide-containing compounds) that are known to inhibit thyroid function, especially in the presence of underlying autoimmune thyroid disease. Because of the high prevalence of subclinical hypothyroidism in elderly women, routine

screening (every 5 years) of older individuals for hypothyroidism with a serum TSH determination has been recommended by the American Thyroid Association⁸⁷ and several other professional organizations, including the American College of Physicians.⁸⁸

A central question is whether patients with subclinical hypothyroidism, who are seemingly asymptomatic and appear to be suffering solely from a biochemical abnormality, should be treated. Although no definite answer can be provided at this time, one study indicated that patients with subclinical hypothyroidism do have subtle symptoms consistent with mild thyroid failure.⁸⁹ Furthermore, treatment with small doses of thyroxine (50–100 µg/day) resulted in a statistically significant symptomatic improvement compared with placebo treatment. Improved performance in cognitive function tests^{90,91} and serum lipid profiles⁹² has been reported, but these findings have not been noted in all studies.⁶⁷ In reviewing the results of three randomized trials,^{89,90,93} it was concluded that 0 to 28 of 100 symptomatic patients would benefit from thyroxine therapy.⁹⁴ However, these authors did not review other studies showing benefit in cognitive function,⁹¹ improvements in intraocular pressure,⁹⁵ and possible improvement in coronary angiograms⁹⁶ with thyroxine therapy. On the basis of these data, therapy can be justified, if there are no contraindications (e.g., severe angina).

Replacement therapy also can be used as prophylaxis against overt hypothyroidism. Several studies have shown that those patients with subclinical hypothyroidism who also have circulating antithyroid antibodies are likely to develop overt hypothyroidism; in the elderly, the rate may be as high as 20% per year.⁹⁷ In a large prospective 20-year follow-up study of 2779 adults, the risk of developing overt hypothyroidism was assessed according to sex, baseline serum TSH level, and antithyroid antibody positivity.⁹⁸ In women, the odds ratios (with 95% confidence intervals) for progression to overt hypothyroidism were 8 (3–20) for raised serum TSH alone, 8 (5–15) for positive antithyroid antibodies alone, and 38 (22–65) in women with both elevated serum TSH and antibody positivity. Based on an analysis of the annual incidence data, it was calculated that a woman with a baseline serum TSH of 6 mU/L and positive serum antibodies had a 57% risk of developing overt hypothyroidism over a 20-year period. Helfand and Redfern analyzed these data to examine the implications of therapy in antibody-positive individual.⁹⁴ If 1000 people over age 35 are screened, 80 (8%) will be found to be hypothyroid and about half of these will have positive antibodies. By 5 years, very few women will have become hypothyroid (approximately 3 of 40), so the number needed to treat to prevent 1 person from becoming hypothyroid is 13. By 20 years, many more women will have become hypothyroid (roughly 24 of 40), so that 16 of 40 would have taken

thyroxine who would not have progressed to overt hypothyroidism. However, such women might have received the benefits alluded to above (improved mild hypothyroid symptoms and cognitive function, etc.). Although definitive data from large randomized trials are lacking, many experts prefer to treat subclinically hypothyroid individuals when they have symptoms consistent with mild hypothyroidism, when antithyroid antibodies are positive, or when there is evidence of an abnormal lipid profile. Hypercholesterolemic patients with serum TSH levels above 10mU/L are the most likely to benefit from thyroxine therapy, whereas lipid levels are unlikely to change in patients with serum TSH values below 10mU/L.⁹⁹

If it is elected not to treat a patient with subclinical hypothyroidism, it would be reasonable to test for antithyroid antibodies, because careful monitoring for thyroid failure is necessary if they are present. It should be pointed out, however, that hypothyroidism can develop even in the absence of antithyroid antibodies,⁹⁸ so that continuous monitoring of thyroid function is necessary in all untreated patients with subclinical hypothyroidism.

Myxedema Coma

Myxedema coma, as does its hyperthyroid counterpart thyroid storm, results from the physiologic decompensation of a hypothyroid individual.^{100,101} Generally, there is a precipitating factor, most often an undiagnosed infection. Patients with myxedema "coma" are not necessarily comatose and can present with stupor, seizures, or psychotic manifestations. Myxedema coma is most often a disease of elderly hypothyroid individuals and generally occurs in the winter months.

The diagnosis of myxedema coma usually is difficult, although it is made easier if there is a history of thyroid disorder or a neck scar or proptosis on physical examination. Hypothermia is a frequent, but not invariable, manifestation; its absence should suggest an occult infection. If the diagnosis is considered, therapy should be initiated, because mortality approaches 50%, even with treatment. Optimal management consists of scrupulous attention to the patient's pulmonary, cardiovascular, gastrointestinal, and renal status. Often intubation and ventilatory assistance are necessary because of carbon dioxide retention. Active warming is contraindicated, because severe hypotension may supervene. A search for infection and prompt treatment is mandatory. Hyponatremia is common, and free water must be administered judiciously. Sedatives and narcotics should be avoided because of the risk of further respiratory depression. Stress doses of glucocorticoids are usually given until adrenal insufficiency has been formally ruled out.

Thyroxine should be administered intravenously because gastrointestinal absorption may be altered

because of hypomotility. Initial doses of 0.3 to 0.5 mg have been traditionally recommended to replace the total body thyroid hormone pool, with daily doses of 0.1 mg thereafter. However, lower doses may be more appropriate in older patients (see following). It has been suggested that T₃ therapy might be preferred, because T₃ is the active thyroid hormone and, in the presence of severe illness, insufficient quantities of T₄ might be converted peripherally to T₃. However, it can also be argued that the body's controlled formation of T₃ and T₄ is more desirable than a sudden and dramatic increase in serum T₃. Indeed, a number of deaths have been attributed to T₃-induced cardiac arrhythmias.¹⁰⁰ Therefore, most experts recommend thyroxine rather than T₃ for myxedema coma,¹⁰¹ although controlled studies are lacking. If the patient fails to respond to T₄ therapy, intravenous T₃ (Triostat) in doses of 10 to 25 µg every 8 to 12 h might be tried.

Because of the rarity of myxedema coma, there are no randomized clinical trials comparing various replacement regimens. In a recent retrospective analysis of 87 cases of myxedema coma, it was observed that higher mortality was associated with greater patient age, cardiac disease, and higher doses of thyroid hormone replacement (T₄ doses >500 µg/day or T₃ doses >75 µg/day), especially when given intravenously.¹⁰⁰ The authors concluded that elderly individuals with myxedema coma should receive lower than conventionally recommended doses of thyroid hormone. Because the study was retrospective, it is possible that sicker patients received the highest doses of thyroid hormone, which might account for the apparent association between higher mortality and thyroid hormone dose. However, the Acute Physiology and Chronic Health Evaluation (APACHE) scores calculated by the authors did not differ between fatal and nonfatal cases. Myxedema coma may be treatable with relatively low doses (e.g., 25 µg) of thyroxine, and very high intravenous doses (>500 µg) may not be suitable for older patients.

Thyroid Neoplasia and Goiter

Thyroid nodularity increases in frequency with age. Autopsy data suggest that 90% of women over age 70 years and 60% of men over age 80 years have one or more thyroid nodules,¹ and ultrasound studies reveal a 40% to 60% prevalence of thyroid nodules in unselected elderly populations.¹⁰² Clinically significant nodules, that is, those that come to medical attention because they are palpable, are also more prevalent in the elderly, with approximately 5% of adults having a palpable nodule in the Framingham study population.¹⁰³ As would be expected, palpable nodules are also much more common in women than in men (6% versus 2% in the Framing-

FIGURE 47.5. Prevalence of thyroid nodules detected at autopsy or by ultrasound (●), or by palpation (□) in subjects without a prior history of radiation exposure or known thyroid disease.¹⁰⁵

ham study)¹⁰³ (Fig. 47.5). In the Wickham survey, thyroid nodules were found in about 1% of males and in 9% of women over age 75.⁴

It is clear from surgical or thyroid imaging data that at least one-quarter of nodules that are thought to be solitary on palpation are, in reality, part of a multinodular gland. Nevertheless, it is useful to distinguish clinically solitary nodules and so-called dominant nodules (nodules that are larger than the others that may be palpably present within the gland) because these have a greater likelihood of being malignant. Fortunately, malignancy is present in only about 10% of nodules, a frequency that is no higher and is perhaps lower than in younger patients with thyroid nodules. Given the low likelihood of malignancy, it is a challenge to diagnose and treat those nodules that are cancerous while at the same time avoiding unnecessary surgery in the 90% of patients who have benign disease.

Thyroid Nodules

Clinical Assessment

Although excision of all nodules would be simultaneously diagnostic and curative, surgery, particularly in the elderly, is associated with excess morbidity as well as great potential expense. Although a number of historical features (older-age male,¹⁰⁴ rapid growth, compressive symptoms) and physical findings (firm or rock-hard consistency, fixation to underlying neck structures, and cervical adenopathy) are important clues that suggest malignancy, there is considerable overlap in findings with benign nodules. Indeed, only a distinct minority of malignant nodules have a “classic” clinical presentation.

A history of head, neck, or upper thoracic radiation in childhood or adolescence is important to elicit. From the 1920s through the early 1960s, several million people received external x-irradiation for thymic enlargement, tonsillitis, mastoiditis, acne, and a host of other benign conditions. Many thousands of irradiated patients who are now in the geriatric population are at excess (3- to 10-fold) risk for the development of thyroid cancer, as well as benign nodular disease. In addition, it is becoming clear that radiation for malignancies that included the thyroid gland in the radiation port, for example, the mantle area for Hodgkin’s disease, can also be associated with thyroid carcinoma. Thus, a history of radiation exposure warrants a prompt and definitive evaluation.

Differential Diagnosis

Although most thyroid nodules are, in fact, benign tumors, any generalized thyroid disease can present as a thyroid nodule. Thus, the various forms of thyroiditis (subacute, Hashimoto’s) are not infrequently asymmetric in their involvement and can mimic a solitary nodule. Other rare causes of an apparent thyroid nodule include congenital hemiagenesis of the opposite lobe of the thyroid, cystic hygromas, and teratomas. Thyroid cysts and neoplasms (benign follicular adenomas, colloid nodules, nodular adenomatous hyperplasia, and carcinomas) comprise the majority of all nodules, however. Although most forms of thyroid cancer (papillary, medullary, anaplastic) are easily diagnosed by means of biopsy, follicular lesions are notoriously difficult to evaluate cytopathologically. The majority of follicular neoplasms are benign, but it can be extremely difficult to distinguish a more atypical benign tumor from a minimally invasive follicular carcinoma. Hürthle cell tumors, a variety of follicular adenoma once thought to always be malignant, are usually benign. Rarely, thyroid nodules are due to metastatic spread of cancer to the thyroid gland.

Laboratory Evaluation

Although a large number of blood tests and radiologic procedures are available to aid in the evaluation of thyroid nodules, most are, unfortunately, of little practical use. Results of routine thyroid function tests are almost always normal, but are worth obtaining to find the rare patient with hyperthyroidism caused by an autonomously functioning nodule and to enable the diagnosis of hypothyroidism, which would suggest Hashimoto’s thyroiditis as the underlying disease process.

Other blood tests should be used more selectively. A serum calcitonin determination should be obtained only if there is a family history of medullary thyroid carcinoma or other condition suggestive of multiple endocrine neo-

plasia syndrome type 2. Antithyroid antibody assays might be performed if the serum TSH level is elevated, suggesting Hashimoto's thyroiditis. Serum thyroglobulin levels are nonspecifically elevated in a host of thyroid diseases, and this determination is used mainly in the follow-up of patients with thyroid cancer.

Traditionally, after routine blood tests, thyroid scanning with radioiodine or technetium has been the next step in the workup of a thyroid nodule. Nodules that concentrate the radionuclide ("hot" nodules) are, for practical purposes, never malignant, and require no further evaluation other than to be sure that hyperthyroidism is not present. On the other hand, hypofunctioning nodules ("cold" nodules) require further evaluation with needle biopsy.

Although categorizing nodules as hot or cold is intellectually satisfying, it is not cost-effective, because at least 90% of all nodules are hypofunctioning. An approach that is gaining wider acceptance is the performance of needle biopsy as the initial diagnostic step.^{105,106} The advantage of this scheme is that a scan is avoided in the 90% of patients who would require a biopsy. The disadvantage is that the 10% of patients with hot nodules undergo biopsy needlessly. On the other hand, the fine-needle aspiration biopsy is a relatively painless procedure with virtually no morbidity (see following).

Thyroid ultrasonography, once considered a valuable tool in the evaluation of thyroid nodules, is being used with less frequency nowadays. Although purely cystic lesions are not malignant, pure cysts of the thyroid are rare. In fact, more than 95% of nodules are either solid or complex (having solid and cystic components), the latter having the same clinical implications as a solid lesion. Thus, routine ultrasonography is not a cost-effective initial diagnostic test. It can be a useful technique for monitoring the size of nodules, particularly those that are difficult to palpate.

Incidentalomas of the Thyroid

Studies of normal individuals undergoing thyroid ultrasound have shown a surprisingly high rate of thyroid nodularity, especially in middle-aged and older women. In one report, small, often multiple subcentimeter thyroid nodules were found in 72% of women aged 25 to 75 years, with a nonsignificant trend toward increasing nodule frequency with age.¹⁰⁷ The prevalence of thyroid nodules in similarly aged men was 41%, which was significantly different from that seen in women. When small (<1–1.5 cm), nonpalpable nodules are found serendipitously, most experts recommend monitoring with serial ultrasound examinations, rather than attempting fine-needle aspiration or other diagnostic procedures.¹⁰⁸ If the nodule grows to a size greater than 1.5 cm, needle aspiration using ultrasound guidance would be indicated.

Fine-Needle Aspiration Biopsy of Thyroid Nodules

Thyroid needle biopsy, and more specifically, fine-needle aspiration biopsy, has revolutionized the care of patients with thyroid disease.^{105,106} Its diagnostic accuracy depends on the skill of the person performing the procedure, and, even more importantly, on the expertise of the cytopathologist who is interpreting the aspirate. For malignancy, the false-negative rate is low (<1%–5%),^{105,106} although the specificity is only about 70% (if suspicious nodules are included). The positive predictive value approaches 99% in most series.^{105,106} Most series report that 60% to 70% of lesions are benign and 5% are malignant. About 25% are "indeterminate" or "suspicious," and these include less well differentiated benign follicular adenomas, Hürthle cell neoplasms, and follicular carcinoma. Only 15% of suspicious lesions prove to be malignant at the time of surgery.¹⁰⁹

Management of Thyroid Nodules

If the nodule is benign, then no further diagnostic evaluation is necessary, although continued follow-up is important. The wisdom of routine suppression therapy with thyroxine has been questioned, especially in the elderly (see following). Malignant nodules, of course, require surgery. If a nodule is suspicious cytologically, the next step would be a thyroid scan, if it had not been performed before the biopsy, because suspicious lesions can be benign functioning (hot) follicular adenomas. If the nodule is hot, then additional laboratory studies should be performed to rule out hyperthyroidism. If the suspicious nodule is cold, then excision is generally recommended. An alternate approach would be a 3- to 6-month trial of suppression therapy with thyroxine. If the nodule fails to decrease in size, then surgery is indicated. If the nodule shrinks, then close follow-up with continued thyroxine therapy is reasonable.

The rationale for thyroxine suppression therapy of suspicious nodules rests with the belief that thyroid growth is dependent upon continued stimulation by TSH. Theoretically, when pituitary TSH secretion is suppressed with exogenous thyroid hormone, both the thyroid and benign nodules should decrease in size. Unfortunately, many benign nodules do not shrink with thyroxine therapy, probably because TSH is not the only factor controlling thyroid growth. Several recent prospective trials comparing thyroxine with placebo have shown little apparent benefit of thyroxine treatment.^{110,111} However, decades of clinical experience have shown that some nodules do respond to thyroxine; also, one controlled study indicated that thyroxine is better than placebo in the treatment of multinodular goiter,¹¹² which might be present in patients with seemingly "solitary" thyroid nodules. Thus, suppression therapy for suspicious thyroid nodules may be an

attractive approach in elderly patients in whom coexisting disease makes surgery less appealing.

It should be recognized, however, that suppression therapy is effective in only a minority of patients. In a recent meta-analysis of randomized trials of thyroxine therapy, a decrease in nodule volume of 50% was seen in 17% of patients.¹¹³ Thus, the failure of a nodule to decrease in size with a suppressive dose of thyroxine (1–2 µg/kg of body weight) is not necessarily an indication of malignancy and, in the presence of a benign biopsy, should not be an indication for surgery. If the biopsy is suspicious, however, surgery should be more strongly considered. Continued enlargement despite adequate suppression, even with a benign biopsy specimen, should prompt reevaluation, including repeated biopsy or surgical excision.

Routine suppression therapy in elderly patients with thyroid nodules that are unequivocally benign has been questioned,^{114,115} because the benefits of treatment are uncertain, and there are potential risks, especially in elderly patients, because of the intentional production of mild iatrogenic hyperthyroidism. This problem can be compounded if the nodule is part of a multinodular goiter, in which areas of autonomous (i.e., nonsuppressible) function are present. Recent data have documented bone loss in postmenopausal patients undergoing thyroid hormone suppression, with attenuation by concomitant estrogen therapy.¹¹⁶ Suppression therapy can also cause tachycardia,⁸¹ with the potential for arrhythmias.²² Therefore, a period of observation without treatment is reasonable, because benign nodules often remain stable or can even resolve spontaneously. If a biopsy-proven benign nodule enlarges, thyroxine therapy might be employed, but care should be taken to employ a dose of thyroxine that will keep the serum TSH level below the lower limit of normal, but above the limit of detection, to avoid skeletal or cardiac complications.¹¹⁴

Goiter (Diffuse or Nodular)

Goiter, or a generalized enlargement of the thyroid, is a common problem in the elderly. Indeed, large, nodular, compressive goiters are seen almost exclusively in this age group. Goiters are termed diffuse or nodular, depending on their surface characteristics on physical examination. A significant minority of goiters are caused by Hashimoto's thyroiditis, but most are idiopathic. Pathologically, most idiopathic multinodular goiters consist of areas of nodular adenomatous hyperplasia, interspersed with hemorrhagic cysts, fibrosis, and calcification.

Goiters usually are discovered at physical examination or visualized on routine chest radiographs as a mass in the anterior superior mediastinum. Mild tracheal deviation is frequent and does not necessarily indicate

respiratory compromise. Goiter uncommonly causes symptoms by compressing adjacent neck structures (e.g., dysphagia, respiratory difficulty, superior vena cava syndrome). It should be emphasized, however, that such symptoms are most often due to benign disease and not thyroid cancer. A history of rapid growth is worrisome, although benign hemorrhagic cysts frequently present in this manner, often with concomitant pain radiating to the ear. Even recurrent laryngeal nerve paralysis can be caused by benign thyroid enlargement, rather than malignancy.

Aside from the history and physical examination, routine thyroid function tests, including a serum T₃ and/or a high-sensitivity serum TSH determination, should be performed in all patients with goiter because of the possibility of subtle thyrotoxicosis. Antithyroid antibodies (especially antithyroid peroxidase antibodies) are also helpful in diagnosing autoimmune thyroiditis, especially in patients whose goiter is diffuse and firm on palpation. Computed tomography or MRI of the neck and chest can be helpful in delineating the extent of the goiter in the thorax, or the degree of tracheal deviation or compression, but generally these procedures are unnecessary.

The central issues in the patient with a large goiter are (1) whether malignancy is present and (2) whether there is clinically significant compression of adjacent neck structures. Regarding malignancy, if there is any suggestion of a recently enlarging goiter or if there is a dominant nodule within a multinodular goiter, a biopsy should be performed. With respect to esophageal or tracheal compression, a history of dysphagia or dyspnea is usually obtained. It should be emphasized, however, that upper airway compromise may be subtle or asymptomatic or may present as "asthma" or wheezing. Pulmonary function testing, with evaluation of upper airway function by means of flow-volume loops, should be performed in all patients with large goiters who have suggestive respiratory symptoms or evidence of tracheal compression, even in the absence of symptoms.

The indications for surgery in elderly patients with large goiters are more stringent than in younger individuals. Obviously, malignancy or significant esophageal, tracheal, or venacaval compression mandate surgery. Although thyroid surgery is generally well tolerated, even by octogenarians,¹¹⁷ there is no reason to remove a large asymptomatic goiter simply because "it is there" and may cause trouble "in the future," especially if it is cytologically benign. Suppressing therapy with thyroxine may be helpful¹¹² but usually is of no benefit in long-standing large goiter and may be potentially hazardous in elderly patients. Recent reports suggest that compressive symptoms can be improved with radioiodine ablation, even in patients who are euthyroid,^{118,119} but additional studies are needed before this can be recommended as a routine practice.

As indicated earlier, patients with nontoxic multinodular goiter are susceptible to iodine-induced thyrotoxicosis. Iodine-containing compounds, including iodinated contrast media, should be avoided, if possible, in such patients.

Thyroid Cancer

Thyroid cancer in elderly patients shares many features with that seen in younger patients, but there are dramatic differences as well. The histologic types (papillary, follicular, medullary, anaplastic, lymphoma) all occur, but with a shift in histologic type from the more indolent (papillary) to the more aggressive (Hürthle cell, medullary, anaplastic) (Fig. 47.6).¹²⁰ Even within a histologic category, advanced age portends a far worse prognosis.^{120,121}

Papillary Carcinoma

Papillary carcinoma is the most common kind of thyroid malignancy in the elderly, accounting for approximately 70% of tumors. This tumor often involves ipsilateral cervical lymph nodes, and recent data suggest that nodal involvement confers a higher recurrence rate.^{121,122} Although the outlook is generally good, this form of cancer is often aggressive in elderly patients, with local invasion into the trachea or lung metastases. Primary therapy consists of near-total thyroidectomy, whereas in younger patients less extensive surgery is acceptable. Postoperatively, whole-body radioiodine scanning establishes whether residual thyroid tissue or local or distant metastases are present. Radioiodine is administered if the scan reveals remnants or metastatic disease. Follow-up with periodic total body radioiodine scanning, serum thyroglobulin measurements, and other imaging modalities (especially thyroid ultrasound) is important in the detection of recurrent or persistent disease. Patients usually succumb from recurrent local disease, rather than

from distant metastases. The recent availability of human recombinant thyrotropin¹²³ now permits radioiodine scanning and stimulated thyroglobulin measurements without the need for thyroid hormone withdrawal and the unpleasant and occasionally debilitating symptoms of hypothyroidism, which are especially prevalent in older patients.

All patients require lifelong suppressive doses of thyroxine, with doses sufficient to suppress serum TSH to undetectable levels in a sensitive TSH assay. Recently, some have questioned the necessity of maintaining such low TSH levels in elderly postmenopausal women who have been disease free for more than 10 years, given the risk for osteopenia and the low risk of recurrence.¹²⁴ Theoretically, patients who have undergone total thyroidectomy and who do not have distant metastases should have undetectable thyroglobulin levels ($<2\mu\text{g/L}$). Thyroglobulin levels above 5ng/dL on thyroxine and above 10 to 20ng/mL off thyroxine or after human recombinant thyrotropin suggest recurrent or metastatic disease. Details regarding the specifics of management of papillary carcinoma are discussed elsewhere.¹²⁵

Follicular Carcinoma

Follicular carcinoma comprises about 20% of thyroid cancer in the elderly. Tumors tend to spread hematogenously to bone, lungs, and liver. Approximately one-third of patients present with metastases (usually to the bone) as the initial manifestation of disease. The prognosis of follicular cancer is worse in elderly patients, especially in those with metastatic disease.¹²⁶ The management is similar to that outlined for papillary cancer. Hürthle cell carcinoma is considered to be a variant of follicular cancer, with a somewhat less favorable prognosis, due to a greater tendency for local and regional metastatic disease, that does not usually concentrate radioiodine.¹²⁷

FIGURE 47.6. Age distribution of thyroid cancer by histologic type.¹²⁰

Medullary Cancer

Medullary cancer of the thyroid arises from the calcitonin-producing “C” cells in the thyroid, rather than the follicular cells. This tumor type accounts for 5% to 10% of thyroid cancer in the elderly; it is sporadic in approximately 75% of older patients, with only a minority of tumors being associated with multiple endocrine neoplasia syndrome type 2 (medullary cancer of the thyroid, pheochromocytoma, hyperparathyroidism).¹²⁸ Medullary cancer of the thyroid is almost always metastatic to regional cervical nodes at the time of diagnosis, and it frequently metastasizes to the liver and bone. The diagnosis is usually made by means of needle biopsy or after surgical removal of a suspicious nodule. The tumor is frequently bilateral, even in sporadic cases, and total thyroidectomy and central compartment lymph node dissection are recommended because of the high rate of nodal disease. Because it is a neoplasm of calcitonin-producing cells, serum calcitonin can be used as a tumor marker to detect recurrence and to monitor therapy.

Carcinoembryonic antigen is also frequently secreted by medullary cancer of the thyroid and is another useful tumor marker. Because the tumor does not arise from the follicular cells of the thyroid, it does not concentrate radioiodine. Furthermore, suppressive doses of thyroxine are not indicated as the tumor is not dependent upon TSH for growth. Screening of family members for this tumor is indicated because the patient, even if elderly, could be the index case of a kindred with multiple endocrine neoplasia (MEN) syndrome type 2. Family screening involves analysis of germline DNA for mutations in the *ret* proto-oncogene, located on chromosome 10, which have been found in all patients with MEN 2. Screening for these mutations has supplanted the less sensitive screening tests using calcitonin stimulation.

Thyroid Lymphoma

Thyroid lymphoma was once thought to represent a distinct form of “small cell” cancer. It is now known that lymphoma may arise primarily within the thyroid and that it is often, but not always, associated with disseminated extrathyroidal lymphoma.¹²⁹ Most thyroid lymphomas are diffuse B-cell lymphomas that arise from mucosa-associated lymphoid tissue (MALT).¹³⁰ Typically, thyroid lymphoma presents as a rapidly enlarging neck mass in an elderly woman with a history of Hashimoto’s thyroiditis; however, there may be no previous thyroid disease, and antithyroid antibodies are often negative. The diagnosis of thyroid lymphoma is difficult to make with needle biopsy because the cytologic appearance is similar to that of lymphocytic thyroiditis; open biopsy with special immunohistochemical staining for monoclonal B-cell markers often is necessary to establish the

diagnosis. Staging for disseminated disease is indicated for all patients. Treatment consists of local radiotherapy and combination chemotherapy, rather than surgery.

Anaplastic Thyroid Cancer

Anaplastic thyroid cancer is one of the most aggressive malignancies of humans.¹³¹ It occurs almost exclusively in elderly persons, often arising in preexisting goiters or in patients who previously have been treated for well-differentiated cancer. Anaplastic cancer presents as a rapidly enlarging mass that quickly produces compressive symptoms. There is no effective treatment. Palliation with radiation therapy and/or chemotherapy to protect the airway should be considered, but surgery is not usually recommended. The median survival is measured in months.

Changes in Male Sexuality

Thomas Mulligan and Waleed Siddiqi

As men proceed through life, there is a clear change in their sexuality. For example, among men aged 18 to 29 years, 29% report intercourse three or four times per week, whereas only 7% of men aged 60 to 69 years and 2% of men 70 years or older report this same frequency. Years ago, Kinsey et al. first reported that, by age 80 years, the average frequency of intercourse decreases to once every 10 weeks.¹ Pfeiffer et al. corroborated this finding, reporting that 95% of men aged 46 to 50 years had intercourse weekly whereas only 28% of 66 to 71-year-old men reported having intercourse once a week.² In healthy Caucasian, upper middle class men aged 80 to 102 years, 26% reported their frequency of sexual intercourse to be several times per month or several times per week. In contrast, among male nursing home residents, 80% no longer engaged in coitus at all despite availability of a sexual partner, moderately strong libido, and preference for vaginal intercourse. Thus, although there is a decline in sexual activity with aging, this decline appears associated with declining health rather than simply advancing age.³

Sexual interest seems to decline less than sexual activity. In men 30 to 99 years old, sexual interest decreased with age, but total absence of interest was never reported. In a survey of healthy couples, the desired frequency of sexual contact decreased from a mean score of 6 (based on a scale where 1 = never to 8 = daily) in 45 to 54-year-old men to a mean score of 3 for men aged 65 to 74 years. In another study, of healthy, well-educated men attending a sexuality and aging lecture series (age, 56–85 years), 92% reported that they would like to have sexual activity at least once per week. However, only 33% of this group engaged in sexual activity on a weekly basis.⁴ Even in nursing home residents, continued sexual interest, especially among those with partners, has been reported.

The preferred sexual activity remains vaginal intercourse despite aging. With the decline in intercourse, however, some investigators have found a compensatory increase in other forms of sexual contact, such as kissing,

caressing, petting, oral sex, or masturbation. Bretschneider and McCoy reported that 83% of their very old subjects engaged in touching or caressing, without sexual intercourse, at least several times per year.⁵ Furthermore, 74% expressed moderate to great enjoyment from this activity. Similarly, in the self-selected group of attendees at sex lectures, sexual intercourse and orgasm were the highest rated forms of sexual activity. With aging, however, these forms of sexual expression declined but with an increase in expressions of intimacy without intercourse. Even nursing home residents prefer vaginal intercourse, though 21% prefer hugging or caressing, 5% prefer kissing, and 2% prefer masturbation.⁶

An important factor in sexual behavior during aging is availability of a socially acceptable sexual partner. As one might expect, availability of a marital partner is an important factor, with sexual activity occurring in 74% of older married men and 31% of older unmarried men. Among those with sexual partners, men tended to attribute cessation of sexual intercourse to themselves, which was corroborated by 74% of the women. The main reasons cited were loss of erectile function, decreased libido, and medical illness.⁷ In those men who blamed their spouses for stopping, 62% attributed the cause to illness and 37% to loss of interest.

The causes of the age-associated changes in sexual behavior are multifactorial, including organic and social factors. To understand these causes, we review here the anatomy and physiology of male sexual function, then the pathophysiology and treatment of dysfunction.

Physiology of Sexual Function

Libido

In men, libido results from an interplay of psychologic, social, physical, and endocrine factors. Animal research suggests that libido is centered in the medial preoptic

area of the hypothalamus.⁸ This area of the brain has androgen receptors, and it appears that testosterone (and/or its metabolite dihydrotestosterone) is necessary for normal sexual desire. In data obtained by self-administered questionnaires and serum hormone assays in 102 adolescent boys, serum free testosterone concentration was a strong predictor of sexual motivation and behavior.⁹ When the free testosterone index (FTI) was divided into quartiles, 16% of those with the lowest FTI reported having had intercourse, whereas 69% of boys in the highest FTI quartile reported intercourse. Similar findings occurred for noncoital sexual activity and libido. This result suggests that the serum free testosterone concentration affects sexual desire and activity.

In a randomized, double-blind study of healthy, eugonadal men, a gonadotropin-releasing hormone (GnRH) antagonist, Nal-Glu, without testosterone replacement was used to produce acute and profound reversible androgen deficiency. The subjects experienced decreased frequency of sexual desire, fantasies, and intercourse. There was also a decrease in noncoital sexual activity such as kissing, fondling, and masturbation.¹⁰ However, even low-dose testosterone replacement was adequate to maintain normal sexual function and behavior. In eugonadal men complaining of loss of sexual desire, testosterone injection therapy resulted in a modest increase in sexual desire, but no effect on erectile function. Supraphysiologic levels of testosterone increased sexual awareness and arousability but did not modify overt sexual behavior. This finding was in contrast to hypogonadal men, in whom testosterone replacement stimulated both sexual interest and activity. From these and other studies, it appears that the major contribution of testosterone to sexuality is related to libido.¹¹

Anatomy

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis. A thick fibrous sheath, the tunica albuginea, surrounds each of the corpora cavernosa, and all three corpora are bound together by Buck's fascia. The ischio-cavernosus and bulbospongiosus muscles surround the proximal portions of the corpora cavernosa. Each corpus consists of smooth muscle bundles, elastic fibers, collagen, and loose fibrous tissue that forms the trabeculae. In between the trabeculae are blood-filled lacunar spaces that are lined by flat endothelial cells.

The arterial supply to the penis consists of the internal pudendal arteries, which become the penile arteries. Each penile artery terminates in bulbar, urethral, dorsal, and cavernosal arteries. The paired cavernosal arteries penetrate the tunica albuginea and enter the crura of the corpora cavernosa. Each ends in multiple twisted

branches called helicine arterioles that supply the lacunae. There may be two circulatory routes in the human corpora. One route goes from the cavernosal artery to capillary networks underlying the tunica albuginea with the capillaries serving as nutritional vessels. This pathway is the main circulatory route during the flaccid state. The second route is via anastomoses from the cavernosal artery through the helicine arterioles to the cavernosa, which then empties into the postcavernous venules and serves as the main vascular pathway in the mechanism of erection.

Venous return from the penis occurs through the deep and superficial dorsal veins of the penis. Subtunica venules located between the periphery of the erectile tissue and the tunica albuginea drain the lacunar spaces. They coalesce to form emissary veins that penetrate the tunica albuginea and drain into the deep dorsal vein or the circumflex system. Drainage from the proximal crura is mainly through the cavernosal and crural veins. Superficial dorsal veins communicate with the external pudendal vein and/or the saphenous vein to drain the skin and prepuce of the penis.

Mechanism of Erection

Neural Component

Penile erection is a complex event, occurring as a result of the integration of central (cerebral and spinal) and local (smooth muscle and endothelial) factors.¹² It arises in response to sensory stimuli, fantasy, or genital stimulation. Specialized areas in the hypothalamus and thalamus organize the autonomic response to these stimuli.¹³

Sympathetic preganglionic nerve fibers to the penis arise from neurons in the intermediolateral cell columns of T12–L2 spinal cord segments, whereas parasympathetic input to the penis arises in the S2–S4 sacral spinal cord segments. Sympathetic impulses travel via the hypogastric nerve, and parasympathetic impulses travel via the pelvic nerve. The pelvic plexus serves as the peripheral integration center for autonomic input to the penis. The pelvic plexus then branches into the cavernous nerves that traverse the posterolateral aspect of the prostate and continue on both sides of the urethra as the cavernosal nerves.¹⁴

In the flaccid state, tonic contraction of the arterial and corporal smooth muscles is mediated by α -2-adrenergic receptors, which maintains high penile arterial resistance. With erotic stimulation, there is a decrease in sympathetic tone and an increase in parasympathetic activity. Central to erection is a hemodynamic change that decreases penile arterial resistance, with resultant increased penile blood flow.

Parasympathetic stimulation activates cholinergic receptors via acetylcholine, stimulating endothelial cells

to produce a nonadrenergic, noncholinergic transmitter nitric oxide (NO). NO relaxes trabecular smooth muscle, and is considered the major neurotransmitter controlling relaxation of penile smooth muscle. NO is formed by conversion of L-arginine into L-citrulline by the enzyme, nitric oxide synthase (NOS). NOS is activated by the influx of calcium ions that occurs with parasympathetic stimulation. The increased oxygen levels derived from the arterialization of cavernosal blood flow further activates NOS and thereby maintains erection.¹⁵

NO moves from cell to cell through gap junctions and by diffusion into smooth muscle cells, providing the rapidity of the response within the penis. NO activates guanylate cyclase, thereby increasing production of cyclic guanine monophosphate (cGMP). cGMP depletes intracellular calcium and further induces smooth muscle relaxation with resultant penile vasodilation.¹⁶

Other chemical entities have been implicated in the control of erection, including prostaglandins E₁ (PGE₁) and E₂ (PGE₂) and vasoactive peptide (VP). PGE₁, PGE₂, and VP stimulate the production of cyclic adenosine monophosphate (cAMP), which decreases intracellular calcium and induces smooth muscle relaxation. VP may also interact with either endothelial or corporal smooth muscle cells to stimulate local formation of NO and thereby sustain penile erection.

Genital stimulation elicits neural impulses that traverse the dorsal nerve of the penis to the pudendal nerve. From the pudendal nerve, the impulses travel to the sacral spinal cord (S2–S4). Efferent impulses travel along the parasympathetic pelvic nerves and produce an erection, as described above.

Vascular Component

Tonic sympathetic stimulation constricts the trabecular smooth muscle and helicine arterioles, keeping the penis flaccid. During flaccidity, blood pressure in the cavernosal lacunae is similar to venous pressure. With sexual stimulation, sympathetic tone decreases and there is parasympathetic-mediated relaxation of arteriolar and trabecular smooth muscle. Penile arterial resistance decreases, resulting in increased blood flow into the corpora cavernosa. The increase in blood volume expands the lacunar spaces and compresses the subtunical venules between the expanding corpora cavernosa and the unyielding tunica albuginea, which results in reduction of venous outflow and trapping of blood within the penis. Penile rigidity develops as intracavernosal pressure rises to mean arterial pressure. Detumescence typically occurs after orgasm. During detumescence, there is a decrease in the arterial flow into the penis, decrease in intracavernosal pressure, increased venous drainage, and restoration of sympathetic nerve impulses, returning the penis to the flaccid state.¹⁷

Orgasm

Sexual intercourse usually terminates with the motor acts of emission and ejaculation, along with the sensory perception of orgasm. Orgasm occurs in conjunction with the physical events of contraction of smooth muscle of vas deferens, prostate, seminal vesicles, and the buildup of pressure within the proximal urethra. The pleasure of orgasm may derive from the development of this pressure, its release by relaxation of the distal sphincter, and the clonic striated muscle contractions of ejaculation.¹⁸ Electromyography reveals that the onset of the perception of orgasm precedes ejaculation by a few seconds. Also, orgasm may be elicited cerebrally without afferent input from the penis. For example, orgasm has been reported during psychomotor seizures in patients with temporal lobe lesions. Clearly, this area of human sexuality is in need of further research.

Emission and Ejaculation

Emission is the propulsion of semen into the posterior urethra. It is accomplished by peristaltic contractions of the vas deferens, seminal vesicles, and prostatic smooth muscles. Emission is a spinal reflex in response to genital stimulation; but it may be voluntarily stopped, indicating partial cerebral control. It can also be elicited by cerebral erotic stimulation in the absence of afferent genital stimulation.

Expulsion of semen from the urethra marks ejaculation. Intermittent relaxation of the distal sphincter allows semen to enter the bulbous urethra. Contraction of the bulbocavernosus muscle propels the semen through the pendulous urethra. Ejaculation is a reflex reaction in response to semen entrance into the bulbous urethra. Its neural center resides in the spinal cord between T12 and L2. The integrity of the vesicle sphincters determines the direction of seminal expulsion. Antegrade ejaculation is achieved by firm closure of the proximal sphincter and a functional distal sphincter. Dripping emission occurs if the distal sphincter is paralyzed, and retrograde ejaculation into the bladder occurs if the proximal sphincter is malfunctioning.

Libido and Aging

Despite the markedly increased prevalence of erectile dysfunction, libido varies much less with advancing age. In an ambulatory geriatric clinic population, 53% of those over the age of 75 years still reported intact libido. When a decline in libido occurs, it is often associated with androgen deficiency.¹⁹ Low sexual interest is typically found in hypogonadal subjects, and testosterone replacement increases libido in a dose-dependent manner. Decreasing serum total and free testosterone concentrations with aging approximate the decline in libido.

Bioavailable testosterone is positively correlated with sexual desire and arousal in the healthy older population.

Erectile Dysfunction and Aging

The National Institutes of Health (NIH) consensus panel suggested that the term erectile dysfunction be used to describe the inability to achieve an erection.²⁰ It is estimated that 10 to 30 million American men have erectile dysfunction. In a community-based, random sample of men age 40 to 70 years in the Boston area, the overall prevalence of erectile dysfunction was 52%.²¹ Kaiser found complete erectile failure in 41% of the men aged 60 to 79 years in a cross-sectional study; none of the men above the age of 70 years was able to achieve a full erection.⁷ This high prevalence of sexual dysfunction is important because men with erectile dysfunction report impaired quality of life when compared with unaffected men.

Vascular Disease

The most common etiology of erectile dysfunction in aged men is vascular disease. In a study of 178 men with organic erectile dysfunction, arteriograms revealed lesions in 68%. The investigators also found that the risk of erectile dysfunction increased with the number of vascular risk factors (diabetes mellitus, smoking, hyperlipidemia, and hypertension); 100% of the patients with three or more risk factors had erectile dysfunction.

Vascular disease results in erectile dysfunction by two mechanisms, arterial insufficiency and venous leakage. Obstruction from atherosclerotic arterial occlusive disease of the hypogastric-cavernous arterial bed decreases the perfusion pressure and arterial flow to the lacunar spaces that is necessary to achieve a rigid erection. In an animal model, the hemodynamic alterations created by atherosclerotic occlusive disease of the iliac arteries caused erectile dysfunction. Additionally, atherosclerotic vascular disease may cause ischemia, which results in replacement of smooth muscle by connective tissue. Electron microscopy of cavernosal tissue from men with erectile dysfunction shows marked thickening of the basal lamina, a paucity of contractile filaments, minimal or no glycogen, and fewer vesicles on the cell surface. The degree of smooth muscle cell alterations is correlated with the severity of symptoms. In a rabbit model, the severity of arterial occlusion correlated with the decrease in trabecular smooth muscle content in the corpus cavernosum. This decrease in smooth muscle content impaired cavernosal expandability.²²

Veno-occlusive dysfunction or venous leakage is characterized by excessive outflow through the subtunical venules, preventing the development of high pressure within the corpora cavernosa and, thereby, interfering

with the maintenance of a rigid erection. Venous leakage can result from Peyronie's disease, arteriovenous fistula, or trauma-induced communication between the glans and the corpora.²³ There is an increase in both the size and number of venous outflow channels with advancing age in human cadavers. The structural alteration in the fibroelastic components of the trabeculae causes a loss of compliance and inability to expand the trabeculae against the tunica albuginea, which is necessary to compress the subtunical venules. This decrease in fibroelasticity may result from increased cross-linking of collagen fibers induced by nonenzymatic glycosylation or from hypercholesterolemia associated with altered collagen synthesis. Finally, veno-occlusive dysfunction can occur from insufficient relaxation of trabecular smooth muscle in an anxious patient who has excessive adrenergic-constrictor tone and in patients with injured parasympathetic dilator nerves.

Neurologic Disease

Neurologic disease accounts for the second most common cause of erectile dysfunction in elderly men. Partial or complete erectile dysfunction can result from disorders that affect the parasympathetic sacral spinal cord or the peripheral efferent autonomic fibers to the penis. Such disorders impair penile smooth muscle relaxation and prevent the vasodilation needed for erection. In older men, diabetes mellitus, stroke, and Parkinson's disease can cause autonomic dysfunction, resulting in erectile failure. Additionally, surgical procedures such as radical prostatectomy, cystoprostatectomy, and proctocolectomy frequently disrupt the autonomic nerve supply to the corporal bodies and result in postoperative erectile dysfunction.

Diabetes Mellitus

The prevalence of erectile dysfunction in diabetes mellitus has been reported to be as high as 75%. Greater than 50% of male diabetic patients report erectile dysfunction within 10 years of the diagnosis of diabetes; for some it is the presenting symptom. Although the etiology of diabetic erectile dysfunction is multifactorial, the major cause in older diabetic patients is vascular disease; autonomic neuropathy plays a more important role in younger patients.²⁴

The importance of neurologic factors in diabetic erectile dysfunction may be confounded by the fact that many studies fail to categorize diabetic patients into type 1 versus type 2. In a study of type 1 diabetic patients, neuropathy was present in 85% of the impotent diabetic patients. However, 58% of these impotent diabetic patients were still unable to achieve an erection with intracavernosal injection of papaverine, suggesting a vascular component. Nevertheless, the authors conclud-

ed that, in type 1 diabetic patients, neurologic factors have a crucial role in the etiology of diabetic erectile dysfunction.²⁵

Diabetic men with erectile dysfunction may also have impaired penile cholinergic nerve synthesis and release of acetylcholine, resulting in decreased ability to relax trabecular smooth muscle. In vitro study of human corpus cavernosum tissue from diabetic and nondiabetic patients with erectile dysfunction revealed that impotent diabetic men have impairment in both the autonomic and the endothelium-dependent mechanisms that facilitate relaxation of smooth muscle. Autonomic-mediated contractions were maintained despite impairment in autonomic-mediated relaxation of corporal tissue from diabetic subjects. Thus, there was an imbalance favoring detumescence rather than erection. The decreased response to acetylcholine in tissue from impotent diabetic men is likely caused by decreased synthesis or release of NO, the endothelium-derived relaxing factor.

Another factor contributing to decreased vasodilation in diabetic impotent men may be the inactivation of endothelium-derived NO by basement membrane advanced glycosylation end products (AGE). AGE, which accumulate on tissue proteins such as basement membrane collagen, have been implicated in other long-term complications of diabetes mellitus such as vascular disease.²⁶

Testosterone and Erectile Dysfunction

The role of androgens in erection is controversial. Androgen receptors have been demonstrated in sacral parasympathetic nuclei and hypothalamic and limbic system neurons, suggesting potential hormonal regulation of centers involved in erectile function. However, patients with castrate levels of testosterone can attain erections in response to some sexual stimuli. Hypogonadal patients have smaller and slower to develop erections in response to fantasy, and androgen replacement improves erectile response. In hypogonadal men there was also a dose-related response to androgen treatment and the frequency of nocturnal erection and coitus. These findings suggest that erections to certain types of sexual stimuli (i.e., direct penile stimulation) may be androgen independent whereas response to fantasy may be androgen dependent.

Androgen may indirectly affect penile smooth muscle relaxation and resultant rigidity through NOS. Chamness²⁷ demonstrated decrease in NOS activity and amount of NOS protein in the penis of adult rats after castration. These changes were reversed by testosterone replacement. These investigators also demonstrated a decrease in erectile response with castration and a concomitant decrease in total penile NOS activity.

Drug-Induced Erectile Dysfunction

Many commonly used medications have been associated with erectile dysfunction; there is a reported 25% incidence of drug-induced erectile dysfunction in the medical outpatient clinic population.²⁸ However, almost all the data available on drug-induced erectile dysfunction are subjective, based on observations, case reports, patient and physician surveys, and pre- and postmarketing drug studies.

The mechanism of drug-mediated erectile dysfunction is often uncertain. Medications such as antidepressants, antipsychotics, and antihistamines have anticholinergic effects that may contribute to erectile dysfunction by blocking parasympathetic-mediated penile artery vasodilation and trabecular smooth muscle relaxation. Antipsychotic medications such as phenothiazines, thioxanthenes, and butyrophenones can cause erectile dysfunction through sedation, elevation of the serum prolactin concentration, or anticholinergic or central antidopaminergic effect.

Psychogenic Erectile Dysfunction

Reports on the prevalence of psychogenic erectile dysfunction vary from 10% to 90%. It appears, however, that the likelihood of psychogenic impotence inversely correlates with age. Psychopathology was the cause of erectile dysfunction in only 9% of an aged male veteran population.²⁹ Psychogenic erectile dysfunction may occur via increased sympathetic stimuli to the sacral cord, inhibiting the parasympathetic dilator nerves to the penis and thereby inhibiting erection. Common causes of psychogenic erectile dysfunction include performance anxiety, conflicts in relationships, sexual inhibition, childhood sexual abuse, and fear of sexually transmitted diseases. A classic psychogenic cause of erectile dysfunction in older men is the "widower's syndrome," where the older man involved in a new relationship feels guilt and develops erectile dysfunction as a defense against perceived unfaithfulness to his dead spouse.

Other Factors in Erectile Dysfunction

In addition to hypogonadism, other endocrine abnormalities have been implicated in the etiology of erectile dysfunction, albeit infrequently.³⁰ Hyperthyroidism, hypothyroidism, and hyperprolactinemia have been associated with impotence. In hyperprolactinemia, there is an associated decrease in serum testosterone concentration due to inhibition of gonadotropin-releasing hormone secretion. However, normalizing the serum testosterone concentration does not restore erectile function in many patients with hyperprolactinemia, which suggests antagonism by prolactin to the peripheral action of testosterone. Low testosterone secretion and elevated prolactin may also

contribute to the erectile dysfunction seen with hypothyroidism. Hyperthyroidism is more often associated with decline in libido rather than with erectile dysfunction.

Chronic alcoholism with associated hypogonadism and peripheral or autonomic neuropathy can also impair erectile function. Hypogonadism in alcoholism occurs through alcohol toxicity at the hypothalamic-pituitary or gonadal levels. Spontaneous reversal of erectile dysfunction occurs with sobriety for at least 1 year, but only if there is no gonadal atrophy or neuropathy. Chronic obstructive lung disease is thought to contribute to erectile dysfunction through hypoxia suppressing the hypothalamic-pituitary-gonadal axis.

Alterations in Emission, Ejaculation, and Orgasm with Aging

In addition to alterations in erectile function, the four stages of sexual response—excitement, plateau, orgasm, and resolution—change with aging.^{31,32} During the excitement phase, there is a delay in erection, tensing of the scrotal sac decreases, and testicular elevation may not occur. There is a prolonged duration of the plateau stage and decreased preejaculatory secretion from Cowper's gland. Orgasm is diminished in duration, and there are decreased or spastic prostatic contractions, decreased urethral contractions, and decreased force of emission. Orgasm is less intense, with a smaller quantity of ejaculate being expelled. In the resolution stage, there is rapid detumescence and testicular descent. The refractory period between erections is prolonged with aging. Most young healthy males are capable of achieving an erection, engaging in intercourse, attaining a climax, and repeating this process within minutes. With aging, the rest or refractory period needed before erection and sexual intercourse can be repeated, gradually lengthens. This prolonged refractory period may contribute to the decline in the frequency of sexual intercourse in older men. Older males may experience retrograde ejaculation due to a damaged proximal sphincter following transurethral prostatic resection. Diabetic autonomic dysfunction can also cause retrograde ejaculation and a decline in orgasmic sensation. Last, there is a decrease in penile sensitivity to vibration and light touch with aging. Sexual function and penile sensitivity may be closely related because penile vibrotactile thresholds are higher in subjects with erectile dysfunction than in age-matched control subjects.

Treatment of Erectile Dysfunction

Ideally, treatment of men with erectile dysfunction should be based on the underlying etiology. For example, medications that increase arterial inflow to the penis will

not be effective in men with severe arterial occlusive disease. Thus, initial evaluation should include a medical history, focused physical examination, and limited diagnostic tests. The history should include whether the onset of erectile dysfunction was abrupt (suggesting a psychogenic etiology or adverse drug reaction) or gradual (suggesting one of the various organic etiologies). It should also determine which medications (including non-prescription and herbal products) the patient is ingesting, especially whether the patient ingests any nitrates (even illicit use of amyl nitrate). The physical exam should search for gynecomastia, femoral bruits, penile plaques, testicular atrophy, and penile or peripheral neuropathy. There are few laboratory-based tests that are essential, but many authors recommend blood glucose, testosterone, and cholesterol. Also, some investigators recommend a diagnostic penile injection of a vasoactive medication.³³ Based on the history, physical exam, and laboratory assessment, the clinician can then select a treatment strategy that is likely to work and have limited adverse drug reactions.

Sildenafil (Viagra; Pfizer Pharmaceuticals) is the first available orally administered treatment for erectile dysfunction. It is a phosphodiesterase inhibitor that blocks cyclic GMP degradation. Sildenafil has been evaluated in 21 clinical trials with more than 3000 men. In these studies, it was efficacious in approximately 65% of men with organic erectile dysfunction. It has limited effectiveness in men with serious arterial or venous disease. Headache, flushing, and dyspepsia were the most common adverse effects, occurring in 6% to 18% of men. The initial dose should be 50 mg, and should be reduced to 25 mg if side effects occur, or increased to 100 mg if necessary. Each sildenafil dose costs about \$9. Importantly, concurrent use of sildenafil and nitrates, in any form, can be fatal. If a man who has taken sildenafil has an ischemic cardiac event, nitrates should not be prescribed within 24 h. A consensus statement from the American College of Cardiology/American Heart Association also urged caution in men with coronary ischemia, congestive heart failure, and low blood pressure as well as those taking a multidrug antihypertensive regimen.³⁴

Penile injection therapy with alprostadil (prostaglandin E₁), papaverine, or phentolamine has also been used to induce erection. These drugs, when injected into the corpora cavernosa, induce relaxation of the smooth muscle within the penile erectile bodies. Blood engorges the corpora cavernosa with sufficient pressure to compress the emissary veins that normally drain blood from the penis. The combination of increased arterial inflow and impeded venous outflow creates an erection.

Men can be trained to inject vasoactive medications into one corporal body. Cross-circulation of the penile corpora allows medication to diffuse into the contralat-

eral side. A firm erection can be expected within a few minutes after intrapenile injection.

Three formulations of alprostadil have been used for intracavernous injection: Prostin VR (Pharmacia & Upjohn), Caverject (Pharmacia & Upjohn), and Edex (Schwarz Pharma). The usual dose ranges from 5 to 20 µg. Alprostadil results in erection in more than 70% of patients with organic erectile dysfunction. Depending on which formulation of alprostadil is chosen, the price per dose ranges from \$3 to \$10.

Papaverine is a nonspecific phosphodiesterase inhibitor that increases cyclic AMP and cyclic GMP concentrations in penile erectile tissue. The usual dose is 15 to 60 mg. It is effective (up to 80%) in men with psychogenic and neurogenic erectile dysfunction, but less effective in men with vasculogenic erectile dysfunction (36%–50%). Its advantages include low cost and stability at room temperature; its major disadvantage is priapism (in up to 35% of cases). The price per dose is approximately \$5 (primarily for the syringe, needle, and alcohol pad).

Phentolamine is an alpha-adrenergic receptor antagonist. When used alone, it does not produce rigid erections. Combined with papaverine, success rates range from 63% to 87%. A combination of 30 mg papaverine and 0.5 to 1 mg phentolamine is the usual dose. Side effects include hypotension and reflex tachycardia. The price per dose is approximately \$10, primarily because of the compounding fee.

Combinations such as papaverine, phentolamine, and alprostadil (Trimix) are very effective, with response rates as high as 90%. However, this regimen should be reserved for patients who failed to respond to other treatment strategies. The price per dose is approximately \$15.

The major side effect of intrapenile alprostadil therapy is penile pain, occurring in about 20% of men. Pain was the side effect most often cited by men who discontinued therapy and is more prominent in men with neuropathy. Priapism, a prolonged erection lasting more than 4 h, is a medical emergency requiring immediate attention. Prolonged erections occur in about 5% of men who use intrapenile alprostadil and 10% of those who use papaverine.

Intraurethral administration of alprostadil (Medicated Urethral System for Erection, MUSE) provides a less invasive alternative to intrapenile injection. The efficacy of intraurethral alprostadil has been evaluated in 1500 men. Two-thirds of these men responded with an erection sufficient for intercourse. Complications such as priapism and penile fibrosis were less common than after penile injection. The cost per dose is approximately \$20.

Several mechanical devices have been developed that utilize vacuum pressure to increase arterial inflow and occlusive rings to impede venous outflow from the corpora cavernosae. Mechanical dexterity is required to use these devices. Efficacy is reported to be 67%, and

satisfaction with vacuum-assisted erections has varied from 25% to 49%. The cost per device is \$200 to \$400.

With the availability of less invasive approaches, enthusiasm for surgical implants has waned. Nevertheless this form of therapy remains a viable option for men who do not respond to sildenafil and find penile injection, urethral, or vacuum therapy unacceptable. Side effects include those related to the anesthesia, local wound infection, and mechanical failure necessitating surgical removal and reimplantation of a new prosthesis. The cost per implant is approximately \$5000.

Testosterone supplementation should be discouraged in men in whom erectile dysfunction is not associated with hypogonadism. In men with normal gonadal function, androgen therapy enhances sexual interest without enhancing erectile capacity.

Yohimbine blocks presynaptic alpha-2-adrenergic receptors, and presumably acts in brain centers associated with libido and penile erection. Although folklore has imbued yohimbine with aphrodisiacal properties, it has limited clinical effectiveness. Optimal results are achieved when yohimbine is restricted to men with psychogenic erectile dysfunction.

Summary

Sexuality remains an important issue in the older population. In spite of a decreased ability to achieve an erection, there clearly is continued sexual desire. Many studies suggest that erectile dysfunction in the aged is primarily caused by age-associated chronic disease rather than normal, healthy aging. Therefore, preventive measures aimed at the underlying diseases should be sought. Nevertheless, effective treatment options are now available to successfully regain sexual function and thereby, improve quality of life.

Sexual Function and the Older Woman

Fran E. Kaiser

Sexual function and dysfunction after menopause and into the later years of a woman's life are poorly defined and even less well studied. However, recognition that sexual function goes well beyond the usual matrix of activity—intercourse—is just beginning to be reconciled to the types of information and data gathered. Sexual function encompasses sense of self, interaction with others, culture, environment, cohort contexts, and myriad levels of affections and expression.¹ It is shaped by these factors, as well as the overlay of physiologic and pathologic and psychologic changes encountered by an individual or her partner. Despite the myths and caricatures created (particularly in females) relating to maintaining sexual interest and performance with aging, the inexorable increase in the population of aging women (and men) and the desire for continued quality of life bring this issue to attention.^{1,2} The need for intimacy, touch, and sexual thoughts and fantasies does not end at any age.

More than half a century ago, Kinsey and colleagues noted a general decline in sexual interest and activity that was attributed to age.³ Subsequent data related to the impact of menopause and the years following have almost invariably reported a decline in both sexual interest and desire.¹ In 1000 consecutive patients who were questioned, patients over age 50 had more sexual complaints than younger individuals.⁴ Data from a longitudinal study begun in 1969 with 241 women aged 46 to 71 noted a decline in sexual interest and frequency of intercourse with age.^{5,6} Partner issues (death, illness, or performance issues) were noted to be causally linked to women's lack of sexual activity in three-fourths of cases. Postmenopausal status did appear to contribute to diminished sexual interest and frequency but did not appear to mar sexual enjoyment. Some investigators have found an inverse relationship between menopause and sexual interest; however, other data have linked these findings with other life-altering events—partner issues, work or life stressors.^{1,7-10} Stress causes a 2.7 times greater

risk of lack of interest in sex; and stress related to diminished arousal has an odds ratio of 4.6 or more.¹⁰ Some studies have shown little or no alternation of sexual desire, response, and satisfaction following menopause.^{8,11-13}

In the Massachusetts Women's Health Study II, a longitudinal study of change related to menopausal transition, sexual function data were obtained from 200 women aged 51 to 61 not on hormone replacement.¹⁴ Menopausal status did not relate to sexual satisfaction, frequency of intercourse, orgasmic ability, or dyspareunia. In the Postmenopausal Estrogen/Progestin interventions trial (PEPI), 60% of women 55 to 64 years old were sexually active.¹⁵ Nearly 50% of healthy women over 60 practice masturbation,¹ whereas 25% of women over 70 in nursing homes engage in masturbation.¹⁶

Menopausal Changes

Hormones, Sexual Responses, and Symptoms of Menopause

The clinical diagnosis and definition of menopause is amenorrhea for 12 months for which there is no other obvious pathologic or physiologic cause. Menopause may occur following irregular menses (perimenopause), which is part of the continuum of change. Perimenopause may be accompanied by symptoms such as hot flashes that predate actual menopause by months or years and are associated with varied hormonal patterns in different women.^{17,18} "Natural" menopause (as opposed to surgical menopause) is really only recognized retrospectively a year or more following a final menstrual period and is an event for which a singular biologic marker does not exist. The age at which menopause occurs (mean age, 51) has not substantially changed in the past century, but life span has dramatically altered. Life expectancy was 18 in

1000 B.C., 25 in 100 B.C., and 49 in 1900. Women in 2000 have a life expectancy of 79.7 years (nearly 7 years greater than for men), and nearly two-thirds of women will survive to age 85 or more.^{19,20} Thus, women will spend at least one-third or more of their lives postmenopausally. In 2000, there were approximately 41.75 million women in the United States over age 50.

Earlier onset of menopause has been associated with a family history of earlier menopause, and smoking appears to be a dose- and duration-related effect.^{17,21–23} The majority of studies indicate that neither age at menarche, number of pregnancies, socioeconomic status, nor race appear to influence the age at which menopause occurs, although increasing parity may be associated with later menopause.

Hormonal Change

Perimenopausally, ovarian follicles decrease, potentially through apoptosis of granulosa cells and oocytes; along with this, ovarian estrogen production diminishes.²⁴ Serum gonadotropins rise, with follicle-stimulating hormone (FSH) rising to a greater degree than luteinizing hormone (LH).²⁵ FSH is responsible for follicular maturation and ovulation, while LH provides the stimulation for ovulation and corpus luteum steroid secretion. The etiology of the incremental rise of FSH is not only due to the loss of negative feedback by gonadal steroids but also the cessation of ovarian follicular production of inhibin. In the pituitary, FSH secretion is inhibited by inhibin. In the gonads, gonadotropin-dependent steroidogenesis and cell proliferation are potentiated by inhibin. Ovarian production of androgens continues under the elevated LH concentration. Inhibin B appears to fall before Inhibin A.²⁶ Activin [a member of the transforming growth factor-beta (TGF- β) superfamily] functions as an autocrine/paracrine regulator and plays a role in folliculogenesis and in inducing FSH receptors.²⁷ Indeed, with postmenopausal estrogen administration, FSH may not be likely to return to premenopausal concentrations. FSH, predominantly under the control of inhibin, which remains low in menopause, will remain somewhat elevated even in the face of estrogen administration, and thus FSH may not be completely reliable as a measure of sufficient or physiologic estrogen administration. Gonadotropins may decline with further aging or with medical comorbidity.²⁸ During the transition along the way to menopause (perimenopause), both estradiol and estrone concentration fall, although the concentration of estrone is higher than that of estradiol, a reversal of the pattern seen in younger women. In most postmenopausal women the major contribution to circulating estradiol results from peripheral aromatization of androgen (androstenedione) from ovarian and adrenal sources.

Menopause is also associated with decreased ovarian androgen production as well as decreased adrenal androgens, dehydroepiandrosterone (DHEA) and DHEAS.^{29,30} If ovarian stromal hypertrophy or hyperplasia develops because of elevation in LH concentration, this can result in increased testosterone levels. If the ovaries are fibrotic, the adrenal becomes the main androgenic source following menopause. In postmenopausal women, both total testosterone and bioavailable testosterone are reduced in women undergoing TAHBSO (total abdominal hysterectomy with bilateral salpingo-oophorectomy) compared with hysterectomized women who have conservation of one or both ovaries.³¹ These data support the importance of the ovary in androgen production. Data related to longitudinal hormonal studies during the menopausal transition reveal declines in both androstenedione and testosterone approximately 3 years before the occurrence of menopause.³² In postmenopausal women with intact ovaries, low testosterone levels at the time of menopause are found, with a later increment in ovarian synthesis of testosterone, with levels rising to those of premenopausal women. However, because production of androgens is far less altered than estrogen, the estrogen/androgen ratio falls. The hormonal milieu of women also depends to some degree on sex hormone-binding globulin (SHBG). In a recent study of 172 midlife women followed for 7 years, SHBG decreased a mean of 43% from 4 years before the final menstrual period to 4 years after that event.³³ Further, increased levels of estradiol and thyroxine will increase SHBG, whereas testosterone, glucocorticoids, insulin, and obesity decrease SHBG. It seems likely that, in a fashion similar to that of thyroid hormone, it is free bioavailable hormone levels (estradiol and/or estrone, as well as testosterone) rather than total hormone levels that have clinical relevance, but this has not been well studied in women.

Female Sexual Response and Hormonal Change

The complexity of female sexuality comprising libido (desire, drive, interest) and sexual response (biologic, physical ability, view of self, roles, and behavior) has come a long way from the initial physiologic data of Masters and Johnson.³⁴ In Kaplan's modification of that model³⁵ in the older woman, desire/libido may show little to mild decrease in both intensity and frequency of desire. The arousal phase is associated with diminished vaginal blood flow and genital engorgement and decreased vaginal lubrication. During the prolonged plateau phase, lessened color change of the labia, indicating lesser blood flow, may occur. Although the multiorgasmic capacity of women is maintained, weaker and less frequent contractions occur. Resolution is associated with a more

rapid loss of vasocongestion than in younger years. However, a broadened view of female sexual response that expands to fit different situational roles, those stressing intimacy and relationship with self and others, has been postulated and is likely to be further utilized over time.³⁶ The loss of estrogen has also been associated with marked diminution of vaginal lubrication, as well as vaginal narrowing and shortening. These changes are less marked in women who have maintained regular sexual activity following menopause. Diminished sensitivity of the clitoris and vulvar area may occur, although whether this is a result of hormonally mediated neuropathy or a direct impairment of vascular flow and ischemic change is unclear.

Androgens and Sexual Function

Although estrogen is a defining hormone for primary and secondary sex characteristics in women, an increasing consensus has developed regarding the role of androgens as a major factor in enhancing libido. In prospective placebo-controlled crossover trials examining androgen administration compared to estrogen, or estrogen plus a progestin (and placebo), androgen or androgen plus estrogen was noted to be more effective in increasing libido, sexual arousal, and the frequency of sexual fantasies in surgically oophorectomized women than the other modalities.³⁷⁻³⁹ Low testosterone levels in women have been found to correlate with reduction in the frequency of intercourse and in a study of sexagenarian women, circulating free testosterone positively correlated with sexual desire.^{7,13} Testosterone also appears to have benefit in terms of general energy levels and feelings of well-being. Long-term effects of testosterone, especially on cardiovascular risk in women, remain to be determined.

Testosterone administration in women may decrease HDL cholesterol. Methylated testosterone should be avoided as hepatic dysfunction may result. Just as with testosterone replacement in men, only 17 β -testosterone should be considered for administration. It is also unclear as to whom and when androgens should be utilized in women. In the absence of depression, low

libido is the most compelling reason to consider androgenic therapy. The risk and potential benefits of androgens in women remain to be elucidated. Doses for women must be individualized and the patient carefully monitored for the potential side effects of hirsutism, lipid disorders, hepatic dysfunction, fluid retention, and potential polycythemia. Individual variations in localized production of androgen and estrogens from precursors such as DHEA or DHEAS make clinical application and evaluation of serum concentrations problematic. The roles of hormones on other parameters of sexual stimuli that affect sexual function—touch, vision, hearing, taste, smell—are just beginning to be considered.⁴⁰

Menopausal Symptoms Affecting Sexual Function

Hot Flashes

Hot flashes are one of the characteristic symptoms of menopause, occurring in up to 82% of menopausal women⁴¹ (Tables 49.1, 49.2). Hot flashes may occur for years in the perimenopausal period. About two-thirds of women experience hot flashes for 1 to 5 years, although some (nearly 10%–15%) women experience hot flashes for more than 5 years. There is cultural variability in reports of hot flashes,⁴² with reports of fewer hot flashes in women from Indonesia, China, and other cultures. Whether this relates to perceptions of menopause, differences in reporting of symptoms, use of plant/herbal phytoestrogens, genetics, or other factors is unclear. The impact of hot flashes on one's physiology can be extensive. In 506 women with hot flashes, ranging in age from 29 to 82, of those who reported current symptoms 87% had hot flashes daily, 1% reported more than 10 hot flashes per day, lasting 1 to 5 min, but 6% reported flashes that lasted more than 6 min.⁴³ Described as heat/flushing on the face and/or chest, this can be generalized over the

body (less on lower body), accompanied by sweats, palpitations, chills, shivering, clamminess, and anxiety. Symptoms tend to be reported when the rise in cutaneous temperature exceeds 0.3°C. The rise in cutaneous temperature tends to be inversely proportional to the ambient temperature. Hot flashes can be virtually eliminated with hormonal replacement, but this effect does not occur instantaneously, and up to 12 weeks may be needed for improvement in symptoms to occur. Hot flashes respond to estrogen in a dose–response fashion.⁴⁴ Hot flashes can disrupt sleep, work, and social relationships. Body contact may even bring on a hot flash and can clearly be disruptive to intimacy. It is an abrupt drop in estrogen concentration, rather than hypoestrogenemia per se, that appears to be important in the etiology of the hot flash.⁴⁵ There are multiple hormonal changes during a hot flash. Although LH pulses are temporally related to the occurrence of a flash, they do not appear to cause the flash. ACTH, cortisol, and neurotensin all increase during a hot flash.^{46–48} The central adrenergic system remains an area of active interest. Clonidine, an α_2 -adrenergic receptor agonist, has been shown to reduce vascular responsiveness to norepinephrine, epinephrine, and angiotensin.⁴⁹ Additionally, it appears to be effective in diminishing hot flashes in women with breast cancer on tamoxifen, whose flashes relate to tamoxifen administration.⁵⁰

Sleep/Depression

Although sleep disruption brought on by hot flashes may produce fatigue and situational loss of coping mechanisms, the majority of studies do not indicate that postmenopausal women have prominent symptoms of depression.^{51,52} Clustering of both life events (as well as hormonal change) may appear to link to any temporal peak of depressive symptoms at the time of menopause.

Estrogen replacement appears to enhance mood, although this may relate to improvement in vasomotor symptoms. There are some alterations that may explain estrogenic effects on mood. The association of estrogen with an increase in β -endorphins is one example. In a study of depression that included postmenopausal women (11/18 on estrogen), a serotonin antagonist was administered, and the response of cortisol and prolactin to the antagonist (1-metachlorophenyl piperazine) was blunted in postmenopausal women compared with younger controls or those on estrogen.⁵³ This diminished response to serotonin (5-HT) may explain some of the mood-altering effect of estrogen; however, it is not clear that these changes are persistent.⁵⁴ The combination of hormone replacement therapy (HRT) plus a selective serotonin reuptake inhibitor (SSRI) may confer benefit in treating depression⁵⁵ relative to either estrogen or SSRI alone, and might be considered in postmenopausal

patients who fail an SSRI as monotherapy. The impact of progesterone on mood is also unclear, with studies providing conflicting results, and, as with studies of estrogen, differences in type, dose, and duration of use make cross-comparison of data difficult.^{56–58} Lack of compliance with HRT because of effects that are seen as largely gestational—bleeding, mood changes, irritability, cramps, and bloating, to name a few—create a need to advocate the lowest dose that will eliminate endometrial hyperplasia.

Urogenital Atrophy

Vulvovaginal changes are gradual and, unlike vasomotor symptoms that may spontaneously disappear, inexorably worsen if not treated (Tables 49.2, 49.3). Vaginal dryness, soreness, and dyspareunia have been described in 27% of 1761 women.⁵⁹ In this same study, 36% complained of micturition symptoms, incontinence, or urinary tract infections. Half of the symptomatic women noted moderate to severe discomfort as a result of these changes. Symptoms can include itching, burning, incontinence, dyspareunia, and other disabling problems.⁶⁰ Although the true prevalence of urogenital atrophy is unknown, estimates range from 10% to 40%.⁶¹ About 30% to 65% of women complain of dyspareunia.^{62–64} Loss of subcutaneous fat in the labia majora results in shrinkage. The prepuce of the clitoral glans atrophies, and the decrease in lubrication adds to irritation. Loss of vaginal muscularity and the lack of lubrication cause easier trauma to the vagina. Dyspareunia with intercourse and vaginal bleeding may occur.

In the presence of estrogen, vaginal colonization with lactobacilli, which maintain the vaginal pH at 4.5 to 5.0 via lactic acid production, inhibits *Escherichia coli* and other gram-negative organisms that can contribute to urinary tract infections (UTIs). With the loss of estrogen, the rise in vaginal pH results in bacterial population shifts toward coliforms, with staphylococci and streptococci becoming more prominent. Recurrent UTIs are esti-

FIGURE 49.1. Urogenital symptoms in 902 women. (Adapted from Iosif CS, Bekassy Z. Prevalence of genitourinary symptoms in the late menopause. *Acta Obstet Gynecol.* 1984;63:257-260, with permission.)

ated to occur in 10% to 15% of women over the age of 60⁶⁵ (Fig. 49.1).

With menopause, the cervix atrophies and the transitional zone may be located on the lower endocervix; also, the prevalence of abnormal Pap smears increases with age. Other aspects of urogenital change may include thinning of the urethral epithelium, which reduces the closing pressure for continence. Urethral prolapse may occur, with loss of collagen supporting endopelvic fascia. With menopause and aging, stress as well as urge incontinence may occur. Resultant fears of incontinence may inhibit sexual function. These symptoms are readily reversible with estrogen, and it is important to note that localized application of estrogen may produce a better resolution of urogenital atrophy than is seen with systemic administration. Local absorption is high in the presence of an atrophic vaginal mucosa. Vaginal creams, tablets, or estro-

gen-containing vaginal rings can all provide relief^{66,67} (Table 49.4). The tablets and rings appear to have greater acceptance than cream or pessaries. Concern over systemic effects remains even with localized vaginal administration, especially with vaginal cream at a dose the equivalent of 0.625 mg three times a week or more. However, before increasing a systemic dose of hormones to control symptoms, a trial of local administration should be considered.

Urogenital-Vascular Alterations

As part of the urogenital changes seen with menopause, some investigators have postulated a vasculogenic urogenital cause for sexual dysfunction in women,^{68,69} similar in nature to the changes that have been described as the primary etiology of sexual dysfunction in aging

TABLE 49.4. Vaginal estrogen preparations.

Generic	Trade name	Content	Administration	Effect beyond local
Estrogen cream	Premarin Cream	0.625 mg conjugated estrogen per gram	Daily for 3 weeks, then 1 week off	Can have systemic effects, elevated E ₂ , elevated triglycerides
Estriol Cream	Ovestin, Synopause	1 mg/g estriol	0.5 mg estriol twice a week	Low E ₁ , E ₂ , elevated E ₃ , no endometrial hyperplasia noted
Estradiol tablets	Vagifem	25 µg 17β-estradiol	One tablet intravaginally twice a week	Low E ₁ , E ₂ , no endometrial hyperplasia
Estradiol ring	Estring	Silicon elastomer ring with 2 mg estradiol releasing 7.5 µg/24 h	Replace every 90 days	Low E ₁ , E ₂ , no endometrial hyperplasia

males, that is, atherosclerotic changes. These atherosclerotic changes appear to result in delayed vaginal engorgement, loss of lubrication, diminished vaginal and/or clitoral sensation, and decreased vaginal and/or clitoral orgasm.

Pressure stimulation along the lower third of the vagina increases blood flow and velocity in clitoral arteries.⁷⁰ However, it is also clear that sexual function in women goes well beyond any clitoral or vaginal engorgement issues.

Other Factors Affecting Sexual Function in Women

Partner Issues

For women, one of the leading reasons for sexual inactivity is the lack of a partner, even in younger cohorts (under age 70); an assessment of 874 postmenopausal women revealed that although 64% were sexually active, 64% also noted inactivity because of lack of a partner.⁷¹ Erectile dysfunction is a common problem for many older men, so even those women with partners may have some difficulty. A woman may perceive withdrawal of the male, because of libido or erectile difficulties on his part, as loss of interest in her. Depending on the nature of the relationship, a frank discussion of sexual issues and difficulties between the partners may not take place. In the scarce literature on older lesbians, lack of a partner is also cited as the reason for not being sexually active.⁷² Few if any recent surveys evaluate masturbation or other activities that can be performed unpartnered.

Medication

The use of medication and its effect on sexual function in women has not received the degree of attention seen in evaluation of drugs that cause erectile dysfunction in men.⁷³ Although medications can affect libido, arousal, orgasm, or any combination of these, questions related to sexual function are often not assessed in women on medications. Antihypertensive agents can be associated with decreased libido or arousal, whereas antidepressant agents such as SSRIs and tricyclics can decrease libido and inhibit orgasmic function. Depression itself, as well as the therapies directed at its treatment, can be associated with sexual dysfunction. Even over-the-counter agents such as antihistamines may diminish sexual arousal and may often be overlooked in the evaluation of the patient.

Environmental Issues

Women living with their children or in institutional settings such as nursing homes may face environmental barriers to privacy, including the biases and potential

disapproval of caregivers or administrators/staff in nursing homes. Maintaining sexual autonomy, avoiding sexual coercion or abuse, and determining capacity for consent in individuals whose cognitive function may not be intact poses another set of issues.^{74,75} Neutral or supportive responses by caregivers and recognition that not all touch is sexual and that touching, caressing, and massage are powerful therapies, especially when patients are “touch deprived,” are important.

Additional Issues

Surgery: Hysterectomy and Sexual Function

Although the number of women undergoing hysterectomy has decreased from 670,000 in 1985 to 580,000 in 1992, it remains the second most common surgical procedure (following childbirth) in women.⁷⁶ Deterioration in sexual function following hysterectomy has been reported in up to 37% of women.^{77,78} However, in a 2-year prospective study of 1101 women, dyspareunia, anorgasmia, and rates of low libido all improved following hysterectomy.⁷⁹ Shortening of the vaginal vault, loss of uterine contractions, and elimination of cervical movement during orgasm have been cited as contributing to altered sensation during intercourse posthysterectomy but do not appear to produce impaired sexual enjoyment in most women.

Classification of Female Sexual Dysfunction

For the very first time, sexual dysfunction that relates to organic disorders has been classified. Previous definitions of sexual dysfunction noted in the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Society (DSM IV) were not intended to classify organic etiologies of female sexual dysfunction.⁸⁰ A recent First Consensus Development Panel on Female Sexual Dysfunction was convened in 1998 and came forward with the following classification⁸¹:

1. Sexual desire disorders
 - A. Hypoactive sexual desire disorder
 - B. Sexual aversion disorder
2. Sexual arousal disorder
3. Orgasmic disorder
4. Sexual pain disorders
 - A. Dyspareunia
 - B. Vaginismus
 - C. Other sexual pain disorders

Definitions

Each of the following can be further subdefined as lifelong versus acquired; generalized versus situational; and of etiologic origin (organic, psychogenic, mixed, unknown).

Hypoactive sexual desire disorder is the persistent or recurrent deficiency/absence of sexual fantasies/thoughts and/or desire for, or receptivity to, sexual activity, which causes personal distress.

Sexual arousal disorder is the persistent or recurrent inability to maintain sufficient sexual excitement, causing personal distress, which can be expressed as a lack of subjective excitement or lack of genital (lubrication/swelling) or other somatic responses.

Orgasmic disorder is the persistent or recurrent difficulty, delay, or absence of attaining orgasm following sufficient sexual stimulation and arousal, which causes personal distress.

Sexual pain disorders: dyspareunia is the recurrent or persistent genital pain associated with sexual intercourse. Vaginismus is the recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with vaginal penetration, which causes personal distress. Noncoital sexual pain disorder is recurrent persistent genital pain induced by noncoital sexual stimulation.

Evaluating the Patient

Evaluation begins with a careful history. Very few women with sexual problems initiate discussion about them with their physician, but when specifically asked about sexual problems, 19% of women surveyed reported a problem.⁸² If the patient is uncomfortable talking about sex, open-ended questions may help create a milieu of a greater level of comfort, such as "Do you have any difficulty with your ability to have sex? Does that refer to intercourse or masturbation or other form of sexual activity?" Non-judgmental attitudes are paramount in eliciting a sexual history. Specific details on the type of problem, its duration, the rate of progression, and how it has affected sexual function should be obtained. If the patient is not comfortable about providing information that would help define the problem, ask if she would like to speak with someone else, or write out these issues. Libido and orgasmic capacity should be queried as part of both present and past history. Medication, over-the-counter medications, and medical comorbidities and their relation to sexual dysfunction should be explored.

Questions regarding their partner's sexual function and relationship should also be addressed, both as an interview with the patient, regarding their perceptions of the partner issues, and, ideally, with the partner alone. Suggestions for alternatives for those without partners may ease discomfort related to the practice of masturbation. Changes in medication, assessing whether depression is present and addressing that, as well as the recognition of issues such as dyspareunia due to vaginal dryness or vaginitis, may assist in providing appropriate

remedies for these problems. Encouraging frank and open discussion between partners, or, in the nursing home, providing privacy for those whose sexual activity is not coerced, can allow sexual expression and intimacy to continue.

Gynecologic and Urologic Problems of Older Women

M. Chrystie Timmons

It is well established that the population of the United States and the world is becoming proportionately older.¹ In industrialized countries, there are currently 100 women to 75 men in the 60- to 69-year-old age group but 100 women to only 50 men in the over-80 age group. Women 75 and older continue to be one of the most rapidly growing segments of the population. In response to this demographic change, there is increased interest in treatment of the aging woman. New diagnostic and treatment modalities have been developed for both prevention and treatment of health problems associated with gynecologic aging. All physicians, be they internists, family practitioners, geriatricians, or gynecologists, will need to become adept in evaluation, diagnosis, and management of the common gynecologic and urologic problems of older women.

The concept of geriatric gynecology has evolved since the beginning of the twentieth century because the average life expectancy for women did not reach 50 years until approximately 1900. Now, the life expectancy for a healthy 50-year-old woman is 85 years because, before the past century, women died primarily from infectious diseases and childbirth. Most did not live to suffer conditions associated with aging, such as cardiovascular disease, malignancies, and osteoporosis. Therefore, the challenge to health care providers of the aging woman is to incorporate medical management that includes both prevention and treatment of gynecologic and urologic conditions so that each woman has the optimal chance of health maintenance. Early intervention with consideration of quality of life issues is especially important for this patient group.

The three gynecologic phases of life are prepubertal, reproductive, and peri/postmenopausal. Because of the shorter life expectancy before 1900, women passed through only two gynecologic phases—childhood and reproductive age—before death. The management of conditions in each phase has an impact on a woman's

subsequent health in the phases that follow. For example, obstetric management in the reproductive phase may predispose to or help to prevent urogenital prolapse in later years. Healthy lifestyle changes incorporated in the reproductive years can lead to a healthier postmenopausal life. Administration of hormonal replacement therapy in the menopausal years may significantly diminish a woman's risk of developing cardiovascular disease or osteoporosis in the postmenopausal years.

This chapter gives an overview of the effects of aging and hormonal changes on the urogenital system in women, outlines the main features of gynecologic evaluation and diagnosis for these patients, and discusses the common conditions encountered in older women. Practical treatment guidelines are given and the indications for referral are discussed.

Urogenital Changes in Aging Women

Three factors cause urogenital change in the aging woman: the aging process itself, hormonal changes associated with the menopause, or a combination of both. Factors that contribute to the health of the urogenital system include obstetric history and good physical condition and muscle tone with the avoidance of obesity, and heredity. Estrogen deprivation is associated with atrophic changes of the urogenital system. Some of these changes, such as vaginal atrophy, are reversible with the institution of estrogen therapy; others such as prolapse are not. Many of the changes described here are not seen in an older woman who has had hormonal maintenance in the perimenopausal/menopausal years and never experienced any prolonged interval of estrogen deprivation. In this section, the effects of both aging and estrogen deprivation on urogenital anatomy are discussed.

External Genitalia

The vulvar changes seen in the older woman are thinning and graying of the pubic hair, decreased fat content in the labia majora, leading to a shrunken and wrinkled appearance, and dryness and paleness of the labia minora. There may be areas of erythema in the periurethral tissues. The clitoris may appear prominent secondary to relative androgen predominance in a hypoestrogenic woman.

Vagina

Some degree of vaginal atrophy is inevitable in women without estrogen supplementation after menopause. Apical constriction and agglutination leads to vaginal foreshortening, and the caliber of the vagina decreases with age and estrogen deprivation. Women who continue to be coitally active have better preservation of the vagina and a decreased degree of vaginal atrophy.² The hypoestrogenic vaginal mucosa has an increased pH, decreased blood flow, and decreased vaginal secretions. These changes can be reversed with estrogen therapy.³ The appearance of the vaginal mucosa is pale, dry, smooth (denoting decreased rugae and elasticity), mottled, and friable. The associated histologic changes include thinning of the mucosa, loss of squamous cell maturation with basal cell predominance, and a leukocytic inflammatory reaction.

Cervix and Uterus

The cervix undergoes significant change and change in position with aging. The cervical os becomes stenotic and decreases in caliber, often to be virtually unidentifiable in the elderly woman. The cervix itself may become completely flush with the vaginal wall, which has important considerations for potential diagnostic capability for endometrial assessment. The ability to identify or dilate the cervix for endometrial assessment in the office may be limited. The cervix also loses sympathetic and parasympathetic innervation, but this has little clinical significance. In terms of position, the cervix regresses to the top of the vagina. With the decrease in uterine size and volume, the cervix may actually appear elongated when compared with the size of the uterus.

Both the myometrium and the endometrium undergo atrophy with aging. The postmenopausal uterus diminishes in size and weight, with associated decrease in capacity of nuclear binding of estrogen.⁴

Ovaries

The size of the ovary has been noted to decrease beginning at age 35, with a marked decrease after age 45.⁵ Histologically, the atrophic ovary has lost primordial

follicles, granulosa cells, and theca cells (converted to stromal cells). There are more corpora albicans and stromal cells.

Urethra and Bladder

With aging and progressive hypoestrogenism, the urethral functional length and maximal urethral closure pressure decrease. Because the urethral mucosa and bladder mucosa in the base of the bladder have estrogen receptors, they mimic the changes of the estrogen-deprived vaginal mucosa in undergoing atrophy.

The Gynecologic Examination of the Older Woman

A comprehensive urogynecologic history should be obtained before the urogynecologic examination of the older woman. The important system symptoms to be evaluated are shown in Table 50.1. A review of urogynecologic symptoms is important to anticipate the areas of potentially necessary detailed or procedural evaluation. The elderly patient may tolerate prolonged lithotomy position poorly, so an efficient examination is important. For example, if a patient gives a history of abnormal postmenopausal bleeding, the instruments necessary for

TABLE 50.1. Focused system history for the geriatric woman.

Gynecologic	Urologic
Health maintenance: most recent	Urethral syndrome/irritative symptoms
PAP smear	Dysuria
Mammogram	Frequency
Thyroid-stimulating hormone (TSH)	Urgency
	Hematuria
Menopausal status	Nocturia
Age at menopause	
Natural or surgical	Urinary incontinence
Hormone replacement	Duration, worsening
Ever or current (regimen)	Stress related
Most recent bleeding	Urge related
	Amount of urine lost (spurt, large amount, variable)
Estrogen deprivation symptoms	Fluid intake and pattern
Hot flashes	Caffeine and alcohol
Night sweats/sleep disturbance	
Vaginal dryness/dyspareunia	Voiding dysfunction
Vaginal discharge	Difficulty initiating stream
	Weak stream
Prolapse symptoms	Prolonged voiding
Protrusion	Feeling of being unemptied
Pelvic pressure	Postvoid dribbling
Bladder dysfunction:	
Urinary incontinence	
Difficulty voiding	
Bowel dysfunction	
Digital manipulation	
Stool incontinence/soiling	
Constipation	

endometrial assessment should be available before positioning the patient. Likewise, if a patient describes a vulvar lesion, the local anesthetic and biopsy instrument should be ready before the examination. Because of the changes associated with aging and possible long-term estrogen deprivation, the gynecologic examination of the older woman often requires special techniques and instruments and always requires awareness of the significance of findings compared with those of the examination of a premenopausal patient.

The care in positioning a postmenopausal or elderly woman for gynecologic examination is different from that of a younger woman. The older patient should be allowed to undress and gown privately, if she is able. If not, a nurse or family member should assist. Many gynecologic examining tables still require that the patient step up, turn around on the small step, and sit down. This maneuver should always be done with nursing assistance because of the risk of fall and injury. If the examining table is electronic and lowers to a level comfortable for the patient to sit on without climbing, the patient can do this without assistance. The patient should sit at the end of the table to avoid either having to swing her legs around to the end of the table or to get off the table and go to the end for the gynecologic examination. The initial breast examination should be done with the patient sitting. Any neurologic assessment of the lower extremities, which is important in women complaining of bowel or bladder dysfunction or prolapse, should be done at this time.

The patient should then be placed in the lithotomy position. The patient will be more comfortable if the back of the table can be inclined up for support before her feet are placed in the stirrups. Some offices use birthing chairs, which are easy for the patient to sit in, provide good back and leg support, and can be elevated and tilted for the examination. These chairs are especially useful for evaluating prolapse and bladder function. Special caution is necessary when positioning a patient with severe degenerative disease of the spine and osteoporosis to minimize the stress on spinal deformities. Women with severe osteoarthritis of the hips and knees may not be able to flex these joints for optimal examination. An assistant supporting and gently manipulating the lower extremities can maximize the exposure obtained. If the patient has extreme limitation of motion, she may not be able to be placed in the lithotomy position. Alternative positions include examination with the patient on her back in a modified and supported "frogleg" position or on her side with one leg raised and supported. Once the patient is positioned, the examination should be performed in a thorough, systematic, and expeditious manner. The essential components of the gynecologic and urologic examination are evaluation of the breasts, external genitalia (including Bartholin glands, Skene glands, and urethra),

vagina, cervix if present, uterine and vaginal support, uterus, adnexas (ovaries and tubes), and rectum.

Breast Examination

The breast examination of the older woman is not different from that for a younger woman. The patient should initially be sitting to allow the examiner to visually inspect the breasts for asymmetry, dimpling of the skin, and color or contour irregularities. Palpation of the breasts between the examiner's hands may then be performed. After the patient is in the supine position, four-quadrant or concentric circle evaluation may then be performed to detect deep masses in the chest wall. Gentle "milking" from the outer breast toward the nipple should be performed to express any discharge. Finally, all patients should be evaluated for lymphadenopathy, especially of the axillary and parasternal chains. If a patient has had a prior mastectomy, the scar of the chest wall should be palpated for nodules and masses. If a woman has had breast reconstruction, the tissue at the base of the implants should be palpated for nodularity or masses.

The consistency of the breasts of the older woman varies considerably. In many women, particularly those who are older and have not been on estrogen replacement therapy, the dense, firm fibroglandular tissue of the breast has been replaced by fat with resulting breast atrophy. However, fibrocystic breast changes and breast firmness may persist in women who have continued to have estrogen stimulation, either by replacement or their own sex steroid hormone production in peripheral tissues. As with younger women, the geriatric gynecology patient should be instructed in and perform monthly breast self-examinations. For women who are on cyclic progestogens as part of their hormonal replacement regimens, the breast self-examination should be performed the week following the last cyclic dose of the progestogen. The patient should also have annual breast exams by a health care provider.

Despite the importance of breast examinations, one cannot overemphasize the importance of annual mammograms for women over the age of 50. Annual mammograms are recommended by the American Cancer Society and the American College of Obstetricians and Gynecologists. Mammography remains the most sensitive diagnostic screening test available for the detection of breast malignancy. Faulk et al.⁶ reported the importance of mammography in women 65 and older, and showed that although women in this age group represented only 34% of women studied (140 women aged 50 or older), they accounted for 45% of all cancers. Medicare coverage for annual mammography should increase compliance in the geriatric age group. However, as discussed in the chapter on breast cancer, some believe that annual mammography is not necessary for older

women who have no history of abnormal mammograms or abnormalities on exam. As with younger women, all masses detected in the elderly woman must be evaluated with either ultrasound, aspiration, or biopsy as indicated.

External Genitalia

The external genitalia should be carefully inspected for any evidence of discoloration or mottling, raised or atrophic areas, excoriation or ulceration, or masses. If the patient has given a history of vulvar pruritis, this examination should be geared to identifying infectious, fungal, dystrophic, or malignant etiologies. Swabbings may be used for wet preps to test for fungal dermatoses (with KOH, if needed) and trichomoniasis, but scrapings may be needed to test for parasitic infection (scabies, pediculosis pubis, pediculosis corporis, or pinworms).

Any ulceration or raised lesion should be biopsied. As a general rule, the transition area of a lesion such as the edge of an ulcer rather than the necrotic center and the thickest area of a raised lesion should be sampled. The skin should be anesthetized with a 1% lidocaine with epinephrine subcutaneous injection using a 25 gauge needle. The biopsy itself may be obtained using either a punch biopsy instrument, cervical biopsy forceps, or a scalpel for wider excisions. Topical coagulating preparations such as silver nitrate or Monsel's solution generally will achieve hemostasis. Larger excisions may require interrupted stitches of a fine-gauge, absorbable suture.

Palpation of the Bartholin glands should be performed. Although malignancy of the Bartholin glands is rare, there may be delay in diagnosing it because it is asymptomatic in the early stages. The older patient is less likely to have infectious etiologies for changes in the Bartholin glands. If there is any indication of Bartholin enlargement or mass, aspiration or biopsy should be performed.

The Skene glands, or periurethral glands, are rarely visible or palpable unless there is infection. If this should occur, an area adjacent to the urethra and often proximal to the meatus may be swollen and tender. "Milking" these

glands may result in urethral discharge, but this maneuver may be difficult, for the patient may be unlikely to tolerate this maneuver. The urethra in the older woman may be normal in appearance, but it is not uncommon for an older, hypoestrogenic woman to have urethral mucosal prolapse, or caruncle, that appears as fleshy, erythematous tissue extruding from the urethral meatus. This tissue is usually tender and bleeds easily. If these urethral conditions are symptomatic, they often respond to estrogen therapy. If they do not, excision or biopsy under local anesthetic can be performed. Excessive bulging of the anterior vaginal wall below the urethra may indicate either a urethrocele or urethral diverticulum. One should have a higher index of suspicion for a diverticulum in a woman who has frequent urinary tract infections. Again, "milking" the bulge toward the meatus may result in urethral discharge, either urine or purulent.

Vaginal Examination

The purpose of the vaginal examination is to assess estrogenization or atrophy, assess caliber and depth, find any lesions, and assess genitourinary support. If the patient has severe vaginal atrophy with marked reduction in caliber and depth, the remainder of the examination may be extremely difficult. Before doing the speculum examination, it is worthwhile to look at the vaginal introitus. The introitus may be gaping at rest with obvious loss of support of the anterior and posterior vaginal walls to or beyond the introitus, or a woman may have a severe introital stricture as a result of estrogen deprivation and loss of coital function. For these reasons, it is important to have different specula available in the examining room. A Pederson speculum (Fig. 50.1) generally gives adequate exposure of the vagina and cervix. If the cervix has regressed apically, a long Pederson may be required. The advantage of the Pederson is the narrow blades, which are well suited for the narrowed vagina often seen in the older patient.

FIGURE 50.1. Pederson and pediatric specula. Note the varying width and length of the blades. The lack of splaying at the end of the blades is an advantage of these specula.

FIGURE 50.2. The Patton speculum allows retraction of the vaginal walls during the examination.

If the patient is severely atrophic, a narrow Pederson, a small pediatric speculum, or nasal speculum may be helpful. If the patient is obese or has vaginal redundancy because of prolapse, a regular or large Graves speculum may be necessary for visualization. If the lateral vaginal walls fold in and prevent cervical or apical visualization, a small examining glove with the fingers cut off can be placed around the blades of the speculum to act as a “dam” laterally, but a new speculum has been developed to enhance the examinations of these patients. It is called the Patton speculum (Fig. 50.2) and has four small blades that fan out to enhance cervical visualization. Finally, to evaluate for prolapse a Sims speculum (Fig. 50.3) is excellent because it is single bladed. However, the bottom half of a jointed speculum with the screw and top blade removed can be very functional when rotated anteriorly and posteriorly to assess prolapse while the patient performs a Valsalva maneuver.

The speculum is inserted into the vagina obliquely to use the length of the vaginal introitus for ease of insertion and to avoid passing the edges of the speculum blades along the urethra. Digital spreading of the posterior vaginal introitus with pressure downward will ease insertion. If a Pap smear is not to be obtained, a water-soluble lubricant should be used before insertion. If a Pap smear is needed, running the speculum under warm water

before inserting it will be helpful. The speculum should be inserted to the top of the vagina to visualize the cervix and vaginal cuff (if the patient has had a prior hysterectomy). If there is abnormal vaginal discharge, a swabbing should be taken and placed in a small amount (1 mL or less) of saline for wet prep evaluation after the examination. The speculum is then slowly removed with side-to-side rotation to allow visualization of the anterior, posterior, and lateral vaginal walls. If there is vaginal prolapse, as indicated by relaxation and redundancy of the vaginal mucosa, or frank descent of the pelvic structures (bladder, uterus, vaginal cuff, or rectum), further assessment is needed as described next. Vaginal lesions may be biopsied by cleansing, injecting local anesthetic submucosally, and using cervical biopsy forceps.

Uterus and Cervix

The cervix is assessed visually during the speculum examination. The Pap smear is obtained at that time using some form of notched spatula (many types are marketed) for a circumferential sampling of the ectocervix and a small brush (again, many types are available) for inserting into the cervical canal for endocervical sampling. Both samples should be spread thinly and evenly on slides, using all surfaces of the spatula and brush for

FIGURE 50.3. A Sims speculum is used for assessing prolapse.

adequate specimens. Pap smears, however, may be limited by the presence of atrophic vaginitis, resulting in a report of atypical squamous cells of undermined significance because of marked inflammation. Likewise, endocervical cells may be absent in the Pap smear because of cervical stenosis. In these settings, and if there is availability, the health care provider may choose to use the thin-layer Pap smear technique called AutoCyte PREP (TriPath Imaging, Burlington, NC). With this technique, the cells are obtained with a plastic spatula and transferred directly into a preserving solution. Tench⁷ reviewed 10,367 conventional Pap smears and compared them to 2231 thin-layer Pap smears and found a significant reduction in Pap smear reports read as “unsatisfactory” or “unsatisfactory but limited by.” There was also an improved rate of detecting squamous intraepithelial lesions.

The uterus is assessed with the bimanual examination. The uterus will not be palpable on the abdominal examination alone unless it is enlarged to at least the size of a 12- to 14-week pregnancy, when it can be palpated just above the pubis. For the bimanual examination, the examiner's two fingers (one, if there is a constricted vagina) are inserted in the vagina and used to elevate the uterus or vaginal cuff. The other hand is used to palpate the uterus, which should be small (approximately 6 cm), firm, and mobile. There may be residua from leiomyomata, which can be palpated as firm (very hard, if calcified), discrete round irregularities. It is helpful if the patient can give a history of having been told that she had fibroids in the past, but if this is a new finding, imaging may be necessary to confirm the appearance of leiomyomata. The uterus of the postmenopausal woman should not be soft or boggy, symmetrically enlarged, or tender. Because these findings are associated with infections, hematometria, pyometria, and malignancies, further evaluation with endometrial and uterine assessment by biopsy or imaging is essential.

Ovaries and Adnexa

The ovaries and adnexa are evaluated with the bimanual examination. For these assessments, the abdominal hand is used to sweep down from the lateral lower abdomen toward the vaginal hand midline to entrap ovaries, tubes, and possible masses between the examiner's two hands for palpation. As reported by Barber and Graber,⁸ the postmenopausal ovary should not be palpable, and the ability to palpate it correlates with risk of a neoplastic ovarian process. Miller et al.⁹ confirmed this with a neoplasm rate of 60% and a malignancy rate of 15% in 20 postmenopausal women who were asymptomatic with ovaries 5 cm in their greatest diameter. Therefore, palpable ovaries, particularly in geriatric postmenopausal patients, warrant further evaluation with ultrasound and

¹²⁵Ca. If these are normal, close follow-up and repeat testing should be done to document stability, as needed. Other masses can mimic ovarian neoplasm, such as bowel masses from malignancy or diverticular processes. Likewise, fallopian tube abnormalities such as residual hydrosalpinges or rare fallopian tube neoplasms may appear to be masses of ovarian origin.

Rectovaginal Examination

The rectovaginal examination should be performed after the bimanual examination. If the vaginal examining hand has been contaminated with blood, the glove should be changed, and a lubricant should be applied to the examining fingers. The rectovaginal exam is performed by placing the index finger of the dominant hand in the vagina and the middle finger in the rectum. The rectovaginal septum between the two fingers is palpated to detect masses, induration, fistulas, and tissue thinness on defects. The rectal finger examines the rectum in the usual fashion to assess for masses, hemorrhoids, and stool. The rectal finger is then used to palpate high in the adnexal area bilaterally and posterior to the uterus. Finally, a stool sample is obtained to test for occult blood.

The importance of the rectovaginal exam cannot be overemphasized. It can be especially useful for the assessment of the pelvis in the woman with severe atrophy and a contracted vagina that does not permit vaginal examination. The rectal finger can be used instead of the vaginal finger for bimanual examination, as already described.

Examining the Combative Patient

There will be times when an adequate gynecologic examination cannot be performed. The disoriented, delirious, or demented woman may be combative and not allow examination. When the patient resists the examination, she will be moving, attempting to hold her legs together, and contracting the pelvic muscles, and those actions will preclude examination even with assistants available for patient restraint. Furthermore, attempts by the patient to break away from restraints may cause injury. Establishing eye contact with and gently talking to the patient may allow a partial examination, but once the patient becomes combative, it is better to discontinue. If the examination is unsuccessful, the physician needs to decide what gynecologic information is essential. Abdominal ultrasonography of the pelvis can assess the cervix for masses; the uterus for size and contour; the endometrial cavity for abnormal endometrial thickening, irregularity from polyps or masses, or abnormal fluid collections; the tubes and ovaries for enlargement or masses; and abnormal fluid collection in the pelvis/abdomen. The combative patient may tolerate this imaging, but she may not

tolerate any of the preferred vaginal imaging approaches such as transvaginal ultrasonography, saline infusion hysteroscopy, or office hysteroscopy. If the patient has a specific problem that needs gynecologic evaluation such as postmenopausal bleeding, palpable abdominal mass, or abnormal vaginal discharge, referral to a gynecologist is indicated. Complete gynecologic evaluation may require examination under anesthesia with appropriate concomitant testing.

Common Urogynecologic Problems of the Older Woman

This section discusses common urogynecologic presenting symptoms and conditions in geriatric women, office evaluation techniques that can be performed by the primary care provider, diagnostic and therapeutic options, and indications for referral to gynecologists, urogynecologists, or urologists. Gynecologic malignancy, bladder function and urinary incontinence, and hormone replacement therapy are discussed in detail in other chapters in this book. The topics covered in this section are urogenital atrophy, recurrent urinary tract infections, vulvar disorders, postmenopausal bleeding, and pelvic organ prolapse.

Urogenital Atrophy

As discussed previously, estrogen deprivation has a profound effect on the vulva, vagina, cervix, urethra, and bladder. All women who are without estrogen supplementation postmenopausally will have some degree of urogenital atrophy. Endogenous peripheral production of estrogen may provide estrogenization and minimize vaginal and urethral atrophic changes. At least 20% of postmenopausal women with atrophic changes will report significant symptoms of urogenital atrophy, and the actual prevalence of symptomatology is probably higher because of underreporting. The specific presenting symptoms are related to the involved organ.

If significant vaginal atrophy has occurred, the most common presenting symptom is vaginal discharge, which is more irritative than pruritic. It may be malodorous, and there may be vaginal irritation with intercourse. The dyspareunia may be both superficial from the mucosal changes and deep from the changes in vaginal caliber and depth. The superficial dyspareunia is often described as “rawness” and “burning,” and the deep dyspareunia is more often described as “tearing,” particularly with intromission. Vaginal bleeding may occur in association with physical activity, vaginal manipulation such as douching, or coitus. One must not ascribe postmenopausal bleeding to atrophy, however, unless significant atrophy and vaginal friability are demonstrable on physical exam.

The atrophic vagina appears pale, smooth, dry, and telangectatic. Discharge, if present, is rarely copious, often appears yellowish and slightly purulent, and exhibits white blood cells and bacteria on wet prep. The wet prep should also be assessed for trichomoniasis and candida, although the latter is rare in the atrophic patient without diabetes. Vaginal atrophy responds extremely well to estrogen therapy. Systemic estrogen may be instituted, or administration of vaginal estrogen therapy will give a faster response because of direct effect on the vaginal mucosa. This method is particularly beneficial for the very elderly patient whose symptoms and expected benefits of therapy are related purely to those of urogenital atrophy.

The patient and the health care provider now have different therapeutic options for vaginal estrogen supplementation. In the past, vaginal estrogen cream, either conjugated estrogens or 17 β -estradiol, was the only possibility for vaginal treatment of atrophy. The creams tended to be messy and relatively expensive for regular use. The first new product for vaginal estrogenization was the Estring (Pharmacia & Upjohn, Uppsala, Sweden), a small silicone ring impregnated with 2 mg 17 β -estradiol for slow estrogen release. It is inserted high in the vagina and remains in place for 3 months before replacement. Intercourse is possible without removing the ring. Henriksson et al. reported a 1 year multicenter trial with Estring in 136 women.¹⁰ Only 8 of the patients withdrew from the study because of adverse events such as bleeding not associated with malignancy or endometrial proliferation or vaginal irritation/ulcers. The ring had high patient acceptability, induced a high vaginal maturation index, and corrected vaginal pH to premenopausal levels. Likewise, a 25- μ g 17 β -estradiol tablet (Vagifem) has been developed for insertion into the vagina once or twice weekly. Rioux et al. compared Vagifem with conjugated estrogen cream in 159 women treated for 24 weeks.¹¹ At the end of the study, there were fewer systemic effects as evidenced by lowered serum follicle-stimulating hormone (FSH) and increased higher serum estradiol levels, higher patient acceptability, and equal resolution of symptoms of atrophic vaginitis in the vaginal tablet group compared with the cream group.

The atrophic cervix rarely causes symptoms unless it has become very stenotic with resulting fluid collection in the uterus. The fluid collection may be blood in a patient with malignancy or one on hormonal replacement therapy who has stopped having withdrawal bleeding. If ascending infection has occurred, the fluid may represent purulence with associated endometritis. If these situations have occurred, the presenting symptoms include cyclic lower abdominal/pelvic pain in the patient who is on cyclic progestogen and has failed to have withdrawal bleeding, continuous pain in the patient with endometritis and a pyometrium, erratic bleeding sometimes associ-

ated with Valsalva maneuvers (i.e., blood is “squeezed” out of the uterus), or purulent discharge. If endometritis is severe, the patient may manifest fever or an elevated white blood cell count, but these symptoms are the exception rather than the expected. On exam, the cervix may appear atrophic but with a normal external os. The internal os, however, may be tightly stenotic. For the primary care physician, obtaining an abdominal or vaginal probe ultrasound to demonstrate endometrial pathology or intrauterine fluid collections may be selected as the first step in evaluation. If pathology is demonstrated, a referral to a gynecologist is indicated. Some primary care physicians, however, are skilled in cervical dilatation and endometrial biopsy and may prefer to attempt these before referral. This procedure should be done with extreme caution, however, because of the risk of cervical or uterine perforation in the presence of malignancy or infection with ensuing potential intraabdominal or vaginal uterine hemorrhage. These procedures should not be done if difficulty is encountered and emergency services including operating room accessibility are not readily available.

If the patient is found to have hematometrium without associated malignancy, the cervix should be dilated on a monthly basis until patency is established and persists. If the patient has a pyometrium (which should be cultured for aerobic and anaerobic bacteria and acid-fast bacteria at the time of endometrial sampling and cervical dilatation) without associated malignancy, she should be treated with antibiotics selected on the basis of the cultured organism’s sensitivities, and undergo repeat cervical dilatations as above. If cervical dilatation and patency cannot be accomplished in an office setting, the patient should be referred to a gynecologist for further evaluation and management.

Because the bladder and urethra have estrogen receptive mucosa, atrophic changes affect their function also. The most frequently described symptoms related to this atrophy are those of the urethral syndrome—pain on urination, frequency, and urgency. This syndrome is the classic triad of symptoms of a urinary tract infection. In fact, many postmenopausal women with vaginal atrophy undergo multiple courses of antibiotics for empiric treatment of urinary tract infection. Clean-catch urinalysis will be contaminated with the white and red cells of the vaginal discharge and may give false indices consistent with infection. Urinary tract infection should be documented with culture if antibiotics are to be instituted in the symptomatic patient with urogenital atrophy. Therapy should be based on urinalysis should be from a good catheterized sample with culture submitted.

Another frequently encountered symptom of the urogenital system and atrophy as related to bladder function is urinary incontinence. In past literature such as the report by Faber and Heidenreich¹² and the more recent

review by Elia and Bergman,¹³ beneficial effects of estrogen on urethral pressure and decrease in stress incontinence have been shown. More recently, other reports such as that of Fantl et al.¹⁴ have indicated no improvement in urethral function or significant decrease in incontinence, but they have shown that patients with estrogen supplementation had a trend to less urinary loss, a significantly decreased rate of nocturia, and a borderline positive effect on maximal bladder capacity. Their findings suggest that hypoestrogenism has its main effect on the bladder/urethral sensory threshold of incontinent postmenopausal women and leads to the symptomatology described above. Kok et al. confirmed the marked decrease in nocturia with a 65% cure 6 months after beginning a combined estrogen and progestogen regimen (2 mg 17 β -estradiol with varying doses of dehydrogestosterone). In addition, there was a 23% cure of incontinence.¹⁵ Jackson et al., however, reported the results of a 6-month, double blind, randomized, placebo-controlled trial in 67 women who were treated with either 2 mg estradiol valerate or placebo daily,¹⁶ and found no improvement in postmenopausal stress incontinence. Even more confounding, Grady et al. from the Heart and Estrogen/Progestin Replacement Study reported worsening urinary incontinence in postmenopausal women receiving 0.625 mg conjugated estrogens/2.5 mg medroxyprogesterone acetate for a mean of 4 years when compared to the placebo group.¹⁷ It would appear from the conflicting results of these studies that estrogen treats atrophy of the bladder and urethra and probably does provide some sensory threshold improvement that leads to decreased frequency and nocturia, but it may have little effect on stress incontinence overall.

Recurrent Urinary Tract Infections

The pitfalls of the diagnosis of a bladder infection in the woman with urogenital atrophy have been discussed. In the woman with culture-documented recurrent urinary tract infections, several potential etiologies must be assessed. The symptoms are generally those of urinary tract infection—dysuria, frequency, and urgency. The patient may have fever and persistent lower abdominal or flank pain, but these symptoms are more associated with upper tract infection. Incontinence, both stress and urge, can clearly be caused or worsened by urinary tract infection. The patient may also complain of gross hematuria. Abdominal examination may reveal lower abdominal tenderness, and bimanual examination may reveal focal bladder tenderness.

Hypoestrogenism is an etiologic factor in recurrent urinary tract infections in women. Parsons and Schmidt¹⁸ confirmed prior studies in showing that the atrophic vagina becomes more basic and is colonized by coliform bacteria in postmenopausal women, and they were able to

acidify the vagina, revert vaginal flora back to normal, and prevent recurrent urinary tract infections by treating the women with vaginal estradiol. Raz and Stamm confirmed this study in a controlled study also using intravaginal estriol in postmenopausal women with recurrent urinary tract infection.¹⁹ Eriksen added further support that estrogen therapy can prevent recurrent bladder infections in the postmenopausal woman in his multicenter, randomized, parallel group study of 108 postmenopausal women.²⁰ The Estring treatment group and the placebo group were followed for 36 weeks, and the treatment group had a 45% likelihood of remaining disease free compared to 20% in the placebo group. Therefore, the first line of therapy in the postmenopausal woman with urogenital atrophy and recurrent urinary tract infections is the institution of estrogen replacement therapy, and the vaginal route of administration is effective.

Another important potential contributing factor for recurrent urinary tract infections in the elderly woman is impaired bladder emptying. This problem may occur because of vaginal prolapse with a urethral kinking effect and incomplete emptying, anticholinergic medications, surgical overcorrection of urethral hypermobility or bladder prolapse, and decreased mobility, leading to repetitive overdistension of the bladder and resulting impaired bladder function. The patient may describe difficulty initiating her urinary stream, a vaginal bulge, digital vaginal manipulation necessary for voiding, prolonged voiding, a weak urinary stream, postvoid dribbling, and incontinence (consistent with overflow by history). Examination may reveal significant prolapse or a bladder neck and urethra elevated and fixed retropubically from prior surgery. A useful office test, however, is to have the patient void when she has a full bladder. She should be given a stopwatch (or the nurse or family member may assist) to start at the commencement of voiding and stop when completed. The amount voided should be recorded (the patient may void in a volumetric "hat" placed on the toilet), and then the patient should be immediately catheterized for postvoid residual (this sample should be sent for urinalysis and culture). This simple test will allow the calculation of flow rate (amount voided divided by the number of seconds taken), which should be at least 10 mL/s, and the efficiency of the voiding. The postvoid residual should be less than half the amount voided and, in general, less than 100 mL. If voiding dysfunction is documented, bladder function may be improved by the use of pessaries or surgery to reduce prolapse, and surgery to release prior overcorrection can be performed. If the voiding dysfunction is found to be secondary to medications, these should be changed when possible. Finally, if voiding dysfunction is diagnosed without obvious etiology or means of correction, the patient should have fluid intake monitoring to prevent excessive fluid intake and overdistension of the bladder,

timed voids every 2 h, and consideration for a catheterization regimen (either by the patient herself or nursing staff) with antibiotic suppression.

Perineal hygiene is an important aspect of preventing recurrent urinary tract infections; this is especially pertinent for the elderly patient with arthritic changes, one who has had a stroke with residual impaired movement, the demented patient, or the woman with fecal incontinence for whatever reason. These patients tend to be unable to clean themselves well after defecation. Examination may show fecal soiling of the perianal and perineal areas. Therapy should be aimed at enhancing cleansing, sometimes with the aid of nurses or family members. Another useful technique is to have the patient clean with a squirt bottle, aiming the stream away from the vagina, after defecation. This, however, may not be possible for the impaired patient.

Structural abnormalities of the urinary system should be suspected if there is no obvious cause for recurrent urinary tract infections. Urethral diverticula occur in 1.4% to 4.7% of women. These may be asymptomatic except for recurrent urinary tract infections, urinary incontinence, or dyspareunia. When the diverticulum becomes infected, there is vaginal swelling, erythema, and severe pain. Examination of the noninfected diverticulum may show only a suburethral bulge with egress of urine from the meatus when the diverticulum is "milked." Kidney and bladder stones may serve as a nidus for urinary tract infection. The patient may have the previously described irritative symptoms plus the sensation of passing gravel, colicky pain, and hematuria. Similar symptoms may be produced by bladder or renal malignancy. For this reason, referral to a urologist is indicated for complete evaluation and management.

Vulvar Disorders

The purpose of this section is to discuss conditions affecting the vulva in geriatric patients. Dermatoses such as dermatitis, folliculitis, sebaceous cysts, parasitic infections, and candidiasis are not discussed. Vulvar malignancies are discussed in Chapter 37. Nonneoplastic vulvar disorders (vulvar dystrophies), vulvodynia, abscesses, and cellulitis are presented.

Vulvar dystrophy or nonneoplastic vulvar disorders are general terms to describe a constellation of benign disorders of the vulvae. They are classified into three broad categories; (1) lichen sclerosus; (2) squamous cell hyperplasia not otherwise specified (such as resulting from candidiasis or condylomata); and (3) other dermatoses (e.g., lichen planus, psoriasis, seborrheic dermatitis). Lichen sclerosus and squamous cell hyperplasia may occur together to give a mixed picture of both atrophy and hyperplasia. These conditions affect all age groups and both genders and may affect nongenital skin.

Lichen Sclerosus

The woman with vulvar lichen sclerosus is rarely asymptomatic. Lorenz et al. reported the frequency of presenting symptoms (Table 50.2) of 81 women with biopsy-proven lichen sclerosus.²¹ Examination reveals whitened plaques progressing to parchment-like skin, distortion of vulvar architecture (adhesion and obliteration of the labia minora to the labia majora causing obliteration of identifiable labia minora, agglutination of the periclitoral tissues with subsequent burying of the clitoris, and sometimes complete introital contracture), and hematomas and telangectasia with a mottled pattern. Punch biopsy can confirm the diagnosis.

The etiology of lichen sclerosus is unclear. In a study by Scrimin et al., immunologic parameters were evaluated from the serum of 68 women with biopsy-proven lichen sclerosus and compared to serum from 53 matched controls.²² The changes in the seroimmunologic profiles of the patients showed no evidence of a T-cell-mediated cell response, viral etiology, or autoimmune pathogenesis. Carlson et al.²³ used immunohistochemical techniques to show that activated macrophages and lymphocytes were present, indicating persistent antigen-driven inflammation. Infectious etiologies have been proposed but have not been substantiated.

The goal of therapy is symptom remission and regression of lesions. Historically, testosterone cream or ointment has been used for topical treatment. However, not only has it been proved by Sideri et al.²⁴ that topical treatment with 2% testosterone in petrolatum is no more effective than treatment with petrolatum alone, but testosterone therapy has also been shown by Joura et al. to result in serum testosterone levels that exceeded the normal range in 8 of 10 women treated with topical testosterone for 4 weeks, that 4 of 10 had clinical symptoms of virilization.²⁵ In a study by Bracco et al.,²⁶ only patients treated with clobetasol, a potent topical steroid, had significant improvement in symptoms, gross appearance of lesions, and histology when compared to those

treated with testosterone and progesterone creams. In a follow-up study,²⁷ the same group found clobetasol propionate cream (0.05%) to be effective maintenance therapy for lichen sclerosus when compared to testosterone propionate (which again was shown to be no more effective than the vehicle alone). Clobetasol propionate cream 0.05% is applied twice a day for 4 weeks, once a day for 2 weeks, and twice a week for 12 weeks. Furthermore, Lewis proposed a maintenance treatment of clobetasol propionate once a week if symptom free.²⁸ He showed that 63% were able to use the weekly application for 6 months and remain symptom free. This therapy is begun in conjunction with meticulous perineal hygiene, including blow drying the perineum after bathing and modifications in lifestyle to diminish perineal moisture (cotton underpants, avoidance of slacks and jeans, and allowing free air flow by wearing loose-fitting garments without underpants when at home).

If a patient does not respond to the clobetasol therapy, Virgili et al. reported decreased symptoms and regression of lesions with topical 0.025% tretinoin once a day, 5 days a week, for a year.²⁹ Likewise, subcutaneous injections of triamcinolone suspension or absolute alcohol (with the patient under general anesthesia) will give relief from intractable pruritus as described by Kaufman.³⁰ Surgery for treatment of lichen sclerosus should be considered only when all other treatment modalities fail, because of the high rates of recurrence, as high as 50%, as described by Abramov et al.³¹

Because of the association of lichen sclerosus with increased risk of vulvar malignancy (2%–5%), patients with lichen sclerosus must be followed closely with biopsy of suspicious lesions. For cases of severe lichen sclerosus, referral to a gynecologic oncologist for evaluation and management is indicated.

Squamous Cell Hyperplasia

Squamous cell hyperplasia is a disorder characterized by epithelial thickening, as would be expected from the name. The most common presenting symptom is again pruritis. The vulvar and perianal distribution is similar to that seen in lichen sclerosus, but the marked vulvar architectural destruction is rare. The appearance of the skin may range from reddened in early lesions to raised, white plaques in more advanced lesions. As in lichen sclerosus, lichenification, excoriation, and fissures are common in the symptomatic patient. Biopsy is indicated to rule out malignancy. Treatment consists of topical corticosteroid creams, as previously described, and perineal hygiene. Clark et al. reported a study in which patients with lichen sclerosus, squamous cell hyperplasia, and mixed disease were treated twice a day in a 12-week treatment regimen of 4 weeks clobetasol propionate 0.05%, followed by betamethasone valerate 0.1%, and followed by hydro-

TABLE 50.2. Frequency of presenting symptoms of lichen sclerosus.

Symptom	Percent
Itching	98.8
Irritation	60.5
Burning	28.4
Dyspareunia	24.7
Tearing	14.8
Bleeding	9.9
Fissuring	8.8
Discharge	7.4

cortisone 1% with the same regimen.³² There was a trend for the squamous cell hyperplasia and the mixed disease groups to have a decreased lower cure/improvement rate. Again, severe cases or those not responding to therapy should be referred for evaluation and management to a gynecologic oncologist.

Mixed Vulvar Disorders

The mixed dystrophies are treated and evaluated as the individual components. The important aspect of mixed disorders is their higher rate of associated cellular atypia, reported to be 16% by Fu and Reagan.³³ Therefore, there needs to be increased surveillance for malignant transformation with biopsies of changing lesions.

Vulvodynia

Vulvodynia is a condition characterized by chronic vulvar symptoms of discomfort, burning, itching, and rawness caused by multiple etiologies. Although the symptoms are similar, the etiologies can be infectious (candidiasis, viral with human papilloma virus, etc.), nonneoplastic vulvar disorders as already discussed in detail, dermatoses (lichen planus, psoriasis, dermatitis, etc.), neurologic (postherpetic neuralgia, reflex sympathetic dystrophy, pudendal neuralgia, etc.), and psychologic (a diagnosis of exclusion). There is no mainstay of treatment. The most important aspect in the treatment of this condition is an accurate diagnosis based on detailed history and physical exam to permit the institution of appropriate therapy. Therapies range from antifungals, treatments for vestibular papillomatosis secondary to human papilloma virus (excisional surgery, intralesional interferon injections), low-dose antidepressants (30–50 mg amitriptyline daily), and either topical corticosteroids or discontinuation of these same agents. The primary caregiver needs to be aware that evaluation and treatment of vulvodynia requires time and patience because there are rarely easy diagnoses or rapid cures, as discussed by Jones and Lehr.³⁴ If the diagnosis is elusive and the therapeutic modalities unsuccessful, gynecologic referral is indicated and would be best if the consultant has a special interest in this complex problem.

Vulvar Cellulitis and Abscesses

These vulvar problems are not common in the elderly woman unless she is diabetic, hypertensive, or has extremely poor hygiene. However, when they do occur they may be life threatening. The patient may present complaining of vulvar pain, swelling, and fever. Examination frequently will reveal vulvar cellulitis with erythema, edema, induration, and tenderness. There may be no fluctuance suggestive of abscess formation. If the patient is diabetic, has symptoms of systemic sepsis (fever, elevated white blood cell count), or has involve-

ment of the Bartholin gland, referral to a gynecologist is indicated for evaluation and probable hospitalization for aggressive parenteral antibiotic therapy and possible surgical incision and drainage. In the absence of such conditions, the physician can mark the borders of the cellulitis with an indelible surgical marking pen, institute broad-spectrum oral antibiotic therapy, and have the patient use sitz baths alternating with warm compresses three to four times per day. CBC should be obtained, and the patient should be reexamined within 24 h. If the induration or borders of the cellulitis are expanding or the patient has developed an abscess or systemic illness, she should be referred to a gynecologist. The reason for this aggressive therapy and vigilance is the potential for the development of necrotizing fasciitis, a polymicrobial synergistic condition characterized by dissolution of the subcutaneous tissues and fascia with resultant severe sepsis and a high mortality. Delay in diagnosis and aggressive therapy, both antibiotic and surgical, increases both morbidity and mortality.

Postmenopausal Bleeding

Postmenopausal bleeding is defined as any bleeding that occurs in a woman with an elevated follicle-stimulating hormone (FSH) after 6 months of amenorrhea. For a postmenopausal woman on hormone replacement therapy, abnormal bleeding is defined by what is expected to occur according to the specific hormonal regimen that she is using. However, abnormal bleeding on hormonal therapy and postmenopausal bleeding are evaluated with the same techniques.

For the postmenopausal, older woman who is not on hormonal replacement therapy, any vaginal bleeding must be evaluated. The patient presents complaining of bleeding, generally painless. It is important to obtain a history of associated activity (physical exercise, coitus, Valsalva maneuvers), any bladder symptomatology, and any bowel symptoms (hemorrhoids, constipation, bloody stools, change in bowel habits, etc.). The importance of the detailed history is to try to differentiate the source of the bleeding. Often, a woman describes blood on the tissue when she wipes herself after urinating or defecating. Likewise, it is important to differentiate between staining, spotting, and actual flow of either blood-tinged discharge, old blood, or bright red blood. The examination should focus on the vagina to detect vulvar lesions (neoplasms, excoriations, or ulcerations), blood in the vagina, a friable atrophic vagina, or evidence of blood in the cervix. The rectal exam should be done with a clean glove to detect gross or occult blood. If genital or rectal blood is not found, a catheterized urine should be obtained to rule out hematuria.

If the bleeding does not appear to be of bowel or bladder source, it must be assumed to be of gynecologic

origin. If vulvar lesions are present and are believed to be the source, they should be biopsied. If vaginal bleeding is assumed to be secondary to vaginal mucosal atrophy with demonstrable friability, particularly in a posthysterectomized woman, estrogen therapy should be instituted, and the patient should return for reevaluation in 1 month. Finally, the bleeding may be of uterine or cervical source. The most common cause of postmenopausal uterine bleeding is endometrial polyps, which may be benign, hyperplastic, or malignant. Nonetheless, the patient must have a complete evaluation of the uterus and cervix to rule out malignancy.

Standard evaluation in the past has included Pap smear with colposcopy and directed cervical biopsies if the Pap smear is abnormal. The uterus and endometrium must be assessed. Endometrial assessment has traditionally been achieved with endometrial biopsy or complete fractional dilatation and curettage, and both of these have an 85% correlation with pathology. However, there are now multiple methods to evaluate the uterus and endometrium (Table 50.3). There is a growing trend to do the initial endometrial evaluation with ultrasonographic techniques. Garuti et al. concluded that if the endometrium was less than 4mm thick, further evaluation was unnecessary.³⁵ However, although transvaginal ultrasonography had a sensitivity of 95.1% and specificity of 54.8%,

hysteroscopy had a sensitivity of 96.5% and specificity of 93.6%, making it the more accurate test.

The most exciting new technique for endometrial cavity assessment is the development of saline infusion sonography. This technique involves infusing sterile saline into the uterine cavity to distend it and then passing a small ultrasound probe into the uterus. Laifer-Narin et al. reported 63 patients who underwent saline infusion sonography followed by either endometrial biopsy, hysteroscopy, or hysterectomy.³⁶ All the polyps and submucosal leiomyomata and endometrial hyperplasia were detected. Of the three endometrial cancers, two had an abnormal endometrial appearance. One could not be assessed because of inability to distend the endometrial canal, common to all three of the studies with malignancy. Hysteroscopy is the test that allows direct visualization of the endometrium and uterine cavity with the capacity for directed biopsies, polypectomies, and resection of submucosal fibroids. Office hysteroscopy was compared to transvaginal ultrasonography by Towbin,³⁷ who performed office hysteroscopy on 149 patients after transvaginal ultrasonography.

Sixty-five of the patients underwent operative hysteroscopy or hysterectomy after the procedures, and pathology was correlated. Office hysteroscopy had a sensitivity of 79% and specificity of 93% whereas transvaginal ultrasonography had a sensitivity of 54% and specificity of 90%. Although saline infusion sonography is diagnostically more accurate than transvaginal ultrasonography, De Vries et al. recommend that saline infusion sonography be reserved for women who have abnormal bleeding with an endometrial thickness greater than 5mm or endometrial irregularities.³⁸ If the postmenopausal woman with abnormal bleeding has a normal pelvic examination, endometrial biopsy, and transvaginal ultrasound showing an endometrial thickness less than 5mm and no contour irregularity, the health care provider can be reassured that it is highly unlikely that the patient has a malignancy or serious condition. However, the patient should be followed closely for recurrent abnormal bleeding or change in symptomatology. If this should occur, the patient needs referral for enhanced ultrasonographic evaluation or hysteroscopy.

Pelvic Organ Prolapse

Pelvic organ prolapse is a broad term describing the consequences of relaxation of the supporting structures of the pelvic organs, allowing descent and herniation of these organs. The causes are multiple. DeLancey³⁹ described the mechanisms of loss of support and possible contributing factors: aging (with decreases in both collagen content and striated muscle function in supporting structures), obesity, and childbirth injury. Other contributing factors are occupational or recreational

TABLE 50.3. Techniques for uterine/endometrial assessment.

Techniques	Advantages	Disadvantages
Endometrial biopsy	Performed in office Histologic diagnosis	Cervical stenosis may preclude
Dilatation and curettage	Histologic diagnosis	Performed in operating room
Hysteroscopy	Performed in some offices Direct visualization Histologic diagnosis	Cervical stenosis may preclude
Transabdominal ultrasonography	Does not require vaginal probe	Limited visualization Difficult with the obese patient Not correlated well with pathology No histologic diagnosis
Transvaginal ultrasonography	Improved urogenital imaging Excellent cervical imaging	No histologic diagnosis Severe vaginal atrophy may preclude
Saline infusion sonography	Best endometrial imaging	No histologic diagnosis Severe vaginal or cervical stenosis may preclude

TABLE 50.4. Compartmental approach to urogenital prolapse.

Compartment	Pathology	Symptoms
Anterior	Cystocele/urethrocele	Urinary incontinence (generally stress) Urgency Urinary retention if there is urethral kinking Pressure/protrusion if large
Middle	Uterine procidentia	Pressure Cervical bleeding if protrusion Discomfort with activity
	Vaginal vault prolapse	Pressure
	Enterocoele (anterior or posterior)	Vaginal irritation
Posterior	Rectocele	Constipation Pressure Digital manipulation for rectal evacuation Stool soiling

lifestyles that lead to increases in intraabdominal pressure, medical conditions (chronic lung disease, lower extremity weakness, etc.) that also increase intraabdominal pressure, and disorders of connective tissue (specifically collagen).

DeLancey⁴⁰ further correlated loss of specific support levels with pathology: loss of high support is associated with prolapse of the vaginal apex with uterine descent and/or enterocele formation, middle support with cystourethrocele and rectocele, and lower support with urethrocele or perineal body descent. A simple way to evaluate pelvic organ prolapse is by thinking of the vagina as having three compartments (Table 50.4). In some instances, generally in women who have had previous prolapse or anti-incontinence procedures, enteroceles may occur in either the anterior or posterior compartment instead of the middle compartment. Although a standard prolapse classification system exists, it was developed for use principally by gynecologists, urologists, and urogynecologists. A practical approach for the primary care provider is to think of prolapse as mild (first degree) with the leading edge of the prolapsing organ descending halfway to the vaginal introitus, moderate (second degree) with descent to the introitus, and severe (third degree) with prolapse beyond the introitus. Consistent conditions of grading are important. Most examiners do the grading with the patient in the lithotomy position doing a Valsalva, and although this is the most functional way for the routine office evaluation, it may not detect some prolapse and lead to the underestimation of the degree of prolapse.

Inspection of the introitus at rest may show a gaping introitus with anterior and posterior bulges to or beyond the introitus. The speculum is then inserted to the apex

and withdrawn slowly with the patient bearing down so that the examiner can assess apical support and possible descent of the cervix or vaginal vault. The top of the vagina may remain well supported despite significant prolapse at other sites. Half of a speculum or a Sims speculum is then inserted and traction is directed to the floor. Again, the patient is asked to perform a strong Valsalva, and the anterior wall support is assessed. The patient is then asked to cough, and the urethra is observed for loss of urine. The speculum blade is then rotated 180°, and the anterior vaginal wall is retracted upward to allow assessment of the posterior vagina while the patient repeats the bearing down. Bimanual examination is then performed with the patient intermittently bearing down so the examiner can palpate the prolapsing parts and better assess the small bowel prolapse in an enterocele. Rectovaginal examination permits better assessment of rectal bulging and rectovaginal septum thickness as well as a possible high enterocele component to a large rectocele.

There are, however, limitations to this examination. Most women will have their maximal prolapse after physical activity or at the end of the day, but her examination may be in the morning after reduction of the prolapse in the supine position overnight. If the patient gives a history consistent with prolapse, and very little is seen on examination with the patient in the lithotomy position, the patient should be allowed to stand up with one foot on a small stepping stool or the step of the examining table. The examiner should then observe, repeat the observation with the patient performing a Valsalva, and perform a bimanual followed by a rectovaginal examination with and without patient bearing down. A cough stress incontinence test will give a false negative if the patient has an empty bladder. Finally, some patients will have difficulty bearing down because of fear of urinary or fecal incontinence. Reassurance as to the need to assess these dysfunctions and having the patient lift her head off the table and give a strong cough may aid the examiner in eliciting a good patient Valsalva. Complex imaging can be used as a diagnostic tool, although it is rarely necessary. These techniques are not readily available or generally clinically useful for the primary care provider. If a patient's prolapse presents diagnostic difficulty, referral is indicated.

Sagittal sections of the female pelvis and anatomic relationships and prolapses are shown in Figures 50.4 through 50.9. With prolapses beyond the opening of the vagina, the prolapsed parts may ulcerate or incarcerate. It should be noted from the diagram that severe prolapse of the uterus also entails bladder and rectal prolapse. When the patient has a rectocele, it is important to differentiate between true constipation with hard stools versus inability to empty the rectum because of stool impaction in the rectocele. When questioned, the patient

FIGURE 50.4. Sagittal section of the female pelvis with normal anatomic relationships.

FIGURE 50.9. Second- to third-degree rectocele.

may admit to vaginal, perineal, or rectal digital manipulation for rectal evacuation. Likewise, the stool soiling may not be true stool incontinence of formed stool but rather a leakage of stool slurry from the rectocele.

If the patient has mild to moderate prolapse, therapy is indicated to attempt to prevent progression of prolapse. The patient should be encouraged to modify her lifestyle to avoid causes of stress to the pelvic floor—heavy lifting, high-impact aerobics, repetitive stooping, obesity, chronic coughing. She should also be taught Kegel exercises with both verbal instruction and assessment and written literature. These exercises involve tightening and relaxing the vaginal supporting muscles, particularly the pubococcygeus muscle, and are done both as fast flicks, which are rapid contractions and releases of the muscles, and gradual holds, which are gradual contractions of the muscles with maintaining the contraction for 3s initially with a goal of 10s as the muscles strengthen before gradual relaxation. The patient can tell if she is doing them correctly by starting and stopping her urinary stream with contractions and by feeling a tightening of the vagina when two or three fingers are inserted in the vagina and the exercise performed. The patient should understand that these need to be done twice daily to strengthen and maintain the pelvic supporting muscles, and that the benefits will be lost if she does not continue to do them. Another technique to improve pelvic muscle tone is the use of weighted vaginal cones, which come in a set with progressively increased weight. Starting with the lightest cone, the patient inserts it vaginally and maintains it in the vagina for as long as she can until she can keep it in for 15min several times per day. When she can keep the light cone in, she repeats the process with heavier cones. When the heaviest cone can be retained, the exercises should be continued as with Kegel's.

Patients with problematic urinary incontinence, either stress or urge, and prolapse may benefit from biofeedback or electrostimulation. Biofeedback consists of a computerized program in which a sensor (about the size of a tampon) is inserted in the vagina, the patient does the Kegel exercises, and the ability to sustain contractions of the correct pelvic muscles is shown graphically on a video monitor. The advantage is that the patient learns the correct way to do pelvic floor exercises and can see improvement in strength over the course of therapy. The disadvantages are that the patient must come to the clinic regularly for a variable amount of time, and referral to a urogynecologist or physical therapist for this program is necessary and but may not be widely available in some areas.

Electrostimulation has progressed from requiring clinic equipment to using a small, battery-powered individual unit that a patient can rent or purchase and use at home. The actual stimulator that must be purchased is about the size of a tampon and is inserted into the vagina (the rectum has been used but patients find vaginal insertion preferable). Varying levels and frequency of low-level shock can be set to allow progressively increased muscle stimulation. The advantages are that this can be used at home. The disadvantages are that it is expensive (but it is often covered by insurance).

Therapy to reduce prolapse in patients who have any protrusion beyond the vaginal introitus is essential to prevent the complications of severe prolapse—bleeding, ulceration and infection, pain, organ incarceration, and urinary retention with potential urosepsis. In addition, reducing a severe prolapse in a woman improves her quality of life. The options for correction are limited to surgery or pessary use.

Pessaries can be a useful therapy with good patient acceptance, as reported by Sulak et al.⁴¹ They found that 50 of 101 women who were treated with pessaries because they were awaiting surgery, did not want surgery, or were not surgical candidates, were continuing to use them at 2 years. The principal reasons for discontinuation in patients not having surgery were inconvenience/inadequate relief of symptoms (40%), difficulty removing (23%), and discomfort (13%). Only 6% had inability to retain a pessary and 5% could not urinate. This study is important because it shows that pessaries are an acceptable alternative to surgery for some women and are very useful in elderly, infirm women who are not candidates for surgery.

Primary care providers should become familiar with the types, indications for each type, fitting, and management of pessaries if they want to treat third-degree prolapse in geriatric women. Brubaker⁴² provided a comprehensive and practical review of pessary use, selection, and management. There are four commonly used pessaries (Fig. 50.10) for reduction of severe uterovaginal

FIGURE 50.10. Commonly used pessaries: doughnut, ring, Gellhorn, cube.

prolapse. Pessaries are made in silicone material and are more durable, softer, and better quality. There are a wide range of sizes, but the three middle sizes of each pessary type are generally useful for 85% of women with prolapse in a general practice. Women with severe prolapse require the large sizes, and women with introital contracture need the small sizes. The doughnut pessary is the one most familiar to practitioners. It is relatively easy to insert by squeezing the sides, well tolerated, and can often be inserted and removed by the patient. However, it is more often extruded in women who have vaginal vault prolapse without a uterus and who have poor perineal support (gaping introitus and small perineal distance between the anus and the posterior vagina). The ring pessary is excellent for uterine prolapse, easy to insert (the sides are jointed and fold the pessary in half), and is well tolerated. A modification has a fenestrated platform to give additional support.

The Gellhorn pessary has been found to be the most useful in patients with vaginal vault prolapse. These devices maintain support with sidewall apposition and a small amount of central suction due to the concavity of the platform. The flexible pessary is shown, but this type is also made out of rigid acrylic. The insertion is more difficult because the sides do not collapse. Patients can sometimes manage them on their own, but often family or nursing assistance is needed. Finally, the cube pessary is the most effective for reducing severe prolapse in the patient without any significant vaginal support. It works by suction attachment from the concavities of the walls. It is relatively easy to insert because of the softness of the construction material. Unfortunately, this pessary requires medical management because it is associated with vaginal infection, malodorous discharge, and ulceration. The pessary must be removed, cleaned, and

reinserted weekly with accompanying inspection of the vagina. However, it is excellent for short-term use in preparation for surgery.

Before pessary insertion, the patient must empty her bladder. She is placed in the lithotomy position, and the vagina is inspected for ulcerations. Ulcerations per se are not an absolute contraindication to pessary insertion because some will only heal when the prolapse is reduced. However, an actively infected or thin ulcer will require very close medical follow-up until it has healed. Hypoestrogenic patients will be at less risk of pessary complications if aggressive vaginal estrogen cream therapy is instituted for 2 weeks preceding pessary insertion. Vaginal estrogen therapy should always be a component of pessary therapy and should be used at least once a week to lubricate the pessary before reinsertion after cleansing, even in the woman on systemic estrogen replacement. The ability to insert the correct type and size of pessary comes with experience doing it. The patient needs to know that she may need different types or sizes of pessaries before the correct one is found. After the pessary is inserted, the patient should not feel the pessary unless it is too large. The patient should then perform a strong Valsalva. If the pessary is not extruded, the patient may then walk around, and if it continues to be retained and comfortable, she may be allowed to dress. If the patient has the time or she will be returning to a situation without easy access to medical care, she should be allowed to fill her bladder and show that she can void before leaving the clinic. I do not attempt to teach the patient or family member pessary removal, cleansing, or reinsertion at this visit.

Close follow-up is necessary, and the patient should return to the clinic in 1 week at the latest (earlier if the physician is following a preexisting vaginal ulcer). When

the patient returns, she is assessed for pessary comfort and retention, vaginal discharge, and bowel and bladder function. The pessary is changed to a different size or type if there are problems with any of these. If the pessary is well tolerated, it is removed, cleansed, and reinserted. At this time outpatient teaching as to pessary management with weekly cleaning, the importance of estrogenization, and the importance of regular follow-up is instituted. If the patient or family member can remove and reinsert the pessary, the patient may return in 1 month for reevaluation, or earlier if she has problems. For the community-dwelling patient or one who cannot manage the pessary, instructions are given to nursing home personnel or home health care nurses are enlisted. Again, the patient needs to return in a month if she does not have reassessment by a health care provider locally. Any retained and neglected pessary can become a nidus for infection, incarcerate, or, even worse, erode into the bladder, rectum, or abdominal cavity. The final issue regarding patient counseling is that the patient may not have any urinary incontinence maintained because of the urethral kinking associated with severe prolapse, and the patient may become incontinent because of underlying stress incontinence (with or without urethral weakness) or detrusor instability when the prolapse is reduced. This occurrence, failure to retain a pessary, or pessary complications are indications for referral to a gynecologist familiar with evaluation and management of pelvic prolapse, bladder function, and reconstructive pelvic surgery.

Surgical correction of pelvic organ prolapse and incontinence is rarely absolutely contraindicated in the elderly patient. Kaminski et al.⁴³ reported the good outcomes in 24 women with massive vaginal prolapse treated in a rural tertiary care center. Other literature confirms the safety and good results with surgical correction in the older patient. For these reasons and although pessary use is a valid option, referral to a gynecologist or urogynecologist experienced in surgery in the elderly patients with prolapse should always be considered and generally offered to the patient. There are many different surgical approaches including abdominal and vaginal techniques. The specific operation or complex of procedures performed is selected for the individual patient based on her lifestyle, activity level, general health, and desire for preservation of vaginal coital potential.

Conclusion

The gynecologic and urologic evaluation of the older woman is an important part of her medical evaluation. Increased availability of imaging can provide new diagnostic capabilities. Many conditions common in the older woman can be assessed and treated by the primary care provider without referral to specialists. These treatments

may successfully improve the quality of life for these women. The primary care provider, however, should have familiarity with these conditions and know the indications for referral.

Benign Prostatic Hyperplasia

Catherine E. DuBeau

The seventh and eighth decades bring many a man to an acute awareness of his prostate and its impact on his quality of life. Lower urinary tract symptoms (LUTS), particularly urgency and nocturia, begin to interrupt his days and, most annoyingly, his nights. After several months he is finally bothered enough to mention his symptoms to his doctor; a rectal exam is done, the news delivered that he has benign prostatic hyperplasia (BPH), and medication is prescribed to shrink his prostate or loosen the grasp of its smooth muscle on his urethra. His brother in a nursing home develops urinary retention; BPH is similarly blamed, but because of his frailty chronic catheterization is deemed the only possible treatment. Yet, although both these men are likely to have age-related proliferation of epithelial and stromal prostate tissue—the hallmark of BPH—it is not necessarily true that BPH is causing their symptoms, or that their prostate is enlarged, or that conventional treatment regimens are their only options.

Although the term BPH often is used synonymously for prostate enlargement, bladder outlet obstruction, and associated urinary tract symptoms, these terms are not equivalent. Histological BPH occurs nearly universally in older men, yet prostate enlargement results in only about half, and symptoms occur in only about half of men with enlargement.¹ Moreover, in older men “prostatism” symptoms often are caused by age-related physiologic lower urinary tract changes, comorbid conditions, or medications independent of any prostate disease²; indeed, similar “prostatism” symptoms occur in a significant proportion of older women.³ Even among symptomatic men with prostate enlargement, bladder outlet obstruction can be demonstrated urodynamically in only two-thirds.^{4,5} Thus, the prostate is not inevitably the cause of LUTS in older men, regardless of the presence of prostate enlargement. In this chapter, BPH refers only to the specific histology, as distinct from benign prostate enlargement (BPE) and bladder outlet obstruction (BOO). The term prostatism is abandoned for the more general term BPH-related LUTS.⁶

Epidemiology and Risk Factors

Benign prostatic hyperplasia changes significantly increase with age, occurring in nearly 80% of men by age 80.⁷ Population-based data indicate that 28% to 35% of older men without previous prostate surgery have moderate or more severe LUTS.^{8,9} Symptoms increase slowly over time, with the greatest rate during the seventh decade,¹⁰ such that nearly one in four men over age 80 receives treatment.¹¹ Besides advanced age, risk factors for BPH include no alcohol consumption (or, for moderate consumption versus none, 0.59; CI, 0.51–0.70) and smoking 35 or more cigarettes/day (or, compared with nonsmokers, 1.45; CI, 1.07–1.97).¹² LUTS (presumed to be BPH related in older men) also show significant associations with diabetes,¹³ cardiovascular disease,¹³ diuretics,¹³ nocturnal polyuria (excess urine production at night),¹⁴ and an age-related decrease in urine flow rate¹⁵ that is independent of any bladder outlet obstruction.¹⁶

Natural History of the Aging Prostate

BPH first develops in the third decade, and pathologic and ultrasound studies demonstrate significant increases in the volume of hyperplasia with age.^{6,17} In the seventh decade and beyond, however, BPH volume shows an inconsistent or negative relationship with age.^{6,17} In cross-sectional studies, the association of BPE with age is strongest in men less than 60 years of age. A small 7-year longitudinal ultrasound study¹⁸ found that prostate volume increased by more than 50% in only 3 of 16 men, with the increase occurring in the seventh decade; in the remaining men, prostate size changed –24% to +22%. In a larger 4-year study using MRI measures, mean prostate volume increased with time, but with wide variability (mean percent change, 14.1 ± 17.5).¹⁹ The strongest predictor of volume increase was not age but baseline prostate-specific antigen (PSA): nearly all men with PSA

greater than 2ng/ml had subsequent prostate growth, whereas 33% of men with PSA less than 2ng/ml had prostate shrinkage.

Clinical natural history studies and placebo arms of treatment trials demonstrate that symptomatic progression also is not inevitable, and that associated morbidity occurs only in a minority. Older studies of men on surgical waiting lists for transurethral resection of the prostate (TURP) found that LUTS progressed in only 15% to 20% over 5 years,²⁰⁻²² independent of initial symptom severity²² or radiographic evidence of BOO,²⁰ when LUTS decreased, symptom remission was durable up to 5 years. Controlled studies of medical therapy consistently show that BPH-related LUTS improve in at least one-third of patients on placebo.²³ In the Veterans Affairs randomized trial of TURP versus watchful waiting for moderately symptomatic BPH-related LUTS with BPE, men with watchful waiting had 38% mean decrease in mean symptom score over 4 years, and 3% developed urinary retention.²⁴ An observational study of 371 men with BPH-related LUTS surviving 4 years found that symptom progression requiring surgical treatment was related to baseline symptom severity (Table 51.1)²⁵; the risk of urinary retention was related to age, symptom severity, and use of anticholinergic drugs, but was low

overall (3% over 3.5 years). Symptom progression may also be related to baseline PSA: men with PSA less than 1.4ng/ml did not have symptom progression over 4 years.¹⁹

Pathogenesis and Pathophysiology

Hyperplasia occurs when prostate cell proliferation outpaces programmed cell death (apoptosis).¹ BPH may begin with either stimulation of cell growth, inhibition of apoptosis, or both. The mechanisms responsible for BPH are androgen dependent, complex, and incompletely understood. Sex hormones and aging are necessary to develop the characteristic combination of stromal and epithelial hyperplasia. The dominant prostate androgen is dihydrotestosterone, which is produced by 5 α -reduction of testosterone within the prostate. The increased incidence of TURP for BPH in men with shorter CAG repeat length in the androgen receptor gene suggests that cellular response to androgens, as well as androgen levels, play an important role.²⁶

The observation that castration causes less than complete prostate involution led to the discovery of additional androgen-independent factors supporting prostate

TABLE 51.1. Factors causing lower urinary tract symptoms (LUTS) in older men.

Pathophysiological mechanism	Etiologic factors	
	Outside urinary tract	Within urinary tract
Impaired bladder contractility	Medications: Anticholinergics Calcium channel blockers Narcotics Fecal impaction Neurologic disease: Lumbosacral spinal disease Neuropathy (alcoholism, diabetes, B ₁₂ deficiency) Pelvic surgery, radiation	Underactive bladder (idiopathic, age-related) Detrusor hyperactivity with impaired contractility (DHIC)
Increased outlet resistance	Medications: α -Adrenergic agonists (OTC "cold" medication)	Urethral obstruction Stricture Bladder sphincter dysynergia Urinary retention
Increased urine volume	Age-related shift to increased nocturnal urine excretion Diuretics: R _x , alcohol, caffeine Peripheral edema Endocrine: Diabetes Hypercalcemia Increased fluid intake	
Uninhibited contractions	Neurologic: Dementia Cervical spine disease Multiple sclerosis	Detrusor instability DHIC
Urethral obstruction Local inflammation		BOO, stricture Infection (urine, prostate) Cancer (prostate, bladder) Stone

OTC, over the counter; BOO, bladder outlet obstruction.

cell growth, including inflammatory infiltrates, autocrine cytokine growth factors, and neuroendocrine cell products.^{27,28} Some of these factors, especially stimulatory and inhibitory peptide growth factors, interact with androgens and estrogens to orchestrate some of the stromal–epithelial interactions that regulate prostate cell growth and proliferation.²⁹ The genetics of BPH are incompletely understood.

The divergence in prevalence between BPH, BPE, and LUTS reflects the variability in the pathophysiologic changes associated with BPH. Histologic diversity exists in the ratio of stromal and epithelial hyperplasia: stromal proliferation predominates in about half of men with BPH, glandular in one-quarter, and mixed in the remainder.³⁰ Stromal glands tend to be smaller, more symptomatic, and less likely to have good symptomatic response to prostatectomy.³⁰ BPH nodules occur predominantly in the central transitional and periurethral zones of the lateral prostate lobes, thereby predisposing to mechanical occlusion of the prostatic urethra, yet urethral compression and BOO are not universal with BPH.^{4,5} Some men develop significantly enlarged median lobes that compress the bladder base without causing BOO. BPH-related changes in the fibroelastic composition of the prostate capsule may alter prostate compliance and diminish urethral patency in the absence of mechanical blockage.³¹ BPH tissue contains an increased number of alpha-adrenergic receptors (primarily of the α_1C class) that mediate prostate smooth muscle contraction.³² The magnitude of the contractile responsiveness of these receptors is increased in symptomatic men with BPH, especially those with urinary retention.³³

BPH-related BOO is associated with several changes in bladder detrusor muscle structure and function: increased connective tissue infiltration; smooth muscle hypertrophy and disintegration; and decreased autonomic neuronal number and a conversion from predominantly β -adrenergic (inhibitory) to α -adrenergic (stimulatory) responsiveness.^{34,35} BOO also is associated with increased uninhibited contractions [detrusor instability (DI)], but the causality of this relationship is unclear, given that DI occurs in normal asymptomatic

elderly men and women.¹⁶ Detrusor instability (DI) disappears in up to two-thirds of men (mean age, 69) following transurethral prostatectomy,³⁶ yet it tends to persist in very elderly men (mean age, 80).³⁷

Clinical Presentation

The most common clinical manifestations of BPH are urgency, frequency, nocturia, hesitancy, weak urine flow, interrupted stream, postvoiding dribbling, and a sense of incomplete emptying. Many men are asymptomatic, even with BPE and BOO. Hematuria (from prostatic varices) and urinary retention can occur, but much less frequently. As noted, the descriptive term prostatism should be avoided, because it falsely implies a single prostatic etiology.⁶ LUTS itself is a misnomer, as these symptoms can result from a wide range of age-related physiologic changes, diseases, and medications, as well as lower urinary tract abnormalities other than BPH (Table 51.2; see also Chapter 63 on Urinary Incontinence). Furthermore, the separation of LUTS into “irritative” or “obstructive” groups is a false dichotomy. These groupings do not correlate with symptom bother or severity, urodynamic parameters, or response to medical therapy.³⁸ Irritative symptoms may result from obstructive pathophysiology (e.g., urinary frequency from severe BOO with overflow) and obstructive symptoms due to irritative pathophysiology (e.g., slowed urine flow rate caused by detrusor hyperactivity with impaired contractility).³⁹

BPH, BOO, and LUTS are not equivalent but overlapping concepts (Fig. 51.1).⁴⁰ The presence of BPH or BPE does not imply that coexistent LUTS are caused by benign prostate disease. Moreover, even if symptoms are related to BPH, they may not be due to BPE with BOO; up to one-third of symptomatic men with BPH referred to tertiary centers for TURP do not have urodynamic evidence of BOO.⁵ Conversely, men with severe BOO and partial or near-complete urinary retention may be entirely asymptomatic. Additionally, some symptomatic men have BOO without BPH (e.g., from urethral stricture) or neither BPH nor BOO.

FIGURE 51.1. Relationship between benign prostatic hyperplasia (BPH), bladder outlet obstruction (BOO), and lower urinary tract symptoms (LUTS). (After Hald with permission.⁴⁰)

Diagnosis and Differential Diagnosis

Symptoms and Their Impact

LUTS are the usual motivation for men to seek evaluation, especially when symptoms bother, worry, or embarrass them. LUTS are quantified using indices such as the American Urological Association (AUA) symptom score⁴¹ (Table 51.3) or the similar International Prostate Symptom Score (IPSS). Because LUTS are not specific for prostate disease, these indices should never be used for screening or diagnosis of BPH-related LUTS but only

to establish baseline symptom severity and to monitor symptoms over time. Changes in symptom score should be interpreted on the basis of expected intraindividual variation. Data from untreated men with symptomatic BPH who had AUA scores repeated 30 days apart suggest that changes greater than ± 4.9 points have at least an 80% probability of indicating a true clinical change.⁴² This point should be kept in mind when interpreting treatment studies in which smaller AUA or IPSS changes reach statistical significance because of study size. Any magnitude of change can be due to factors independent of BPH or its progression (see Table 51.2), which should be investigated before attributing symptom variation to prostate disease.

The effect of LUTS on quality of life is central, because for the majority of men the need for treatment depends on symptom bother alone. Bother may reflect interference with daily activities, work, sleep, or sexual function; worry or embarrassment; or physical discomfort.^{43,44} The bother from individual symptom(s) may be more important than overall symptom impact. Older men are bothered significantly more by nocturia, frequency, and urgency, independent of overall LUTS severity and the presence of BOO.⁴⁵

The initial step in evaluation always should be a full investigation of potential factors other than benign prostate disease that can cause these symptoms. Indeed, the evaluation of older men with LUTS closely parallels that of any older person with voiding dysfunction. For details of such an evaluation, see Chapter 63 on Urinary Incontinence; the additional points specific to benign prostate disease are emphasized here.

TABLE 51.3. The American Urological Association Symptom Index (score range, 0–35 points)

	Not at all	Less than one time in five	Less than half the time	About half the time	More than half the time	Almost always
1. Over the past month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. Over the past month or so, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5
3. Over the past month or so, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month or so, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month or so, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month or so, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the last month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning? ^a	0	1	2	3	4	5

AUA symptom score = sum of questions 1–7.

Mild symptoms: 0–7 points; moderate symptoms: 8–19 points; severe symptoms: 20–35 points.

The medical history and review of systems should inquire about additional urinary symptoms such as hematuria, pelvic pain, and previous episodes of urinary retention; cardiac symptoms (regarding possible congestive heart failure); bowel and sexual function (as clues to potential sacral and pelvic neuropathies); type and amount of fluid intake; and sleep disturbance. All medications (including nonprescription drugs) should be reviewed. In many cases, a 48-h voiding record will provide useful information about the possible role of fluids and urine volume in causing symptoms,² especially nocturnal polyuria.⁴⁶

Physical Examination

A complete physical exam is required to exclude nonurologic causes of LUTS, especially congestive heart failure, obstructive sleep apnea, and neurologic disease.

Digital rectal exam (DRE) is done to assess prostate nodularity and rectal tone and to exclude fecal impaction. Prostate sizing by DRE, however, is inaccurate and poorly reproducible, even when performed by specialists.⁴⁷ BPH adenomas may occur in the anterior prostate or median lobe, both inaccessible to rectal palpation. Importantly, prostate size or volume, as estimated by DRE, cystoscopy, MRI, or weight of tissue resected at TURP, is not a proxy for BOO.^{48,49} Large BPH adenomas may not obstruct the urethra, and small predominantly stromal glands may cause significant obstruction. Prostate size is important for choosing between transurethral and open surgical approaches (see following), but it is not predictive of surgical outcome,⁵⁰ with the exception that smaller glands are associated with more postoperative bladder neck contractures.³⁰

For men with moderate–severe symptoms, coexistent neurologic disease, or impaired renal function, or those taking bladder suppressant medications, the postvoiding residual volume (PVR) should be checked by urethral catheterization or ultrasound. Radiographic PVR estimates are only qualitative and may be correct only half the time.⁵¹ An elevated PVR may be secondary to detrusor underactivity (due to age, disease, or medication) rather than caused by BOO.^{39,52} Inability to pass a urethral catheter also is not diagnostic of BOO, as this is usually due to sphincter spasm from patient discomfort or anxiety.

Testing

Urine flow rates are commonly used to evaluate LUTS in men, yet are frequently misinterpreted. Urine flow rate depends on bladder contractility, outlet patency during voiding, and bladder volume; thus, low flow rates may result from impaired detrusor contractility, BOO, or low bladder volume, alone or in combination. Furthermore,

the prevalence of low flow rate increases with age in men and women independent of BOO.^{16,35} Therefore, flow rate is very sensitive for detecting BOO but is not specific. Consequently, a normal flow rate confirms the absence of BOO, but low flow rate is not diagnostic, a point emphasized by the repeated observation that low flow rate does not predict outcome from TURP.^{50,53–55} As a general rule, maximum flow rate greater than 12 mL/s for a void of 150 mL or more is normal and excludes BOO.⁵⁶

Maximum flow rate measurement requires an electronic uroflowmeter, whereas average flow rate can be calculated by dividing the volume voided (in milliliters) by the voiding time (in seconds). The dependence of flow on bladder volume can be adjusted for by using one of several nomograms.^{56,57} Unfortunately, the derivation populations for these nomograms included few older persons. Care should be taken to note whether the patient strains while voiding, which may falsely elevate the flow.

Voiding cystourethrography (VCUG) provides a dynamic evaluation of the urethral outlet during voiding and direct information regarding BOO. The sensitivity and specificity of VCUG for BOO have not been investigated. Radiographic evaluation of bladder morphology and upper urinary tracts are not required routinely in men with LUTS. Although radiographic observation of bladder base indentation or shadowing correlates well with BOO, their detection is inconsistent as a result of contrast dilution by urine, x-ray beam angulation, and prostate morphology.⁵¹ Radiographic evidence of bladder trabeculation correlates poorly with BOO, but more closely with detrusor instability—thus its frequent observation in elderly women.^{58,59} Routine screening for hydronephrosis is not necessary because it is uncommon in unselected patients (3%–10%) and mild hydronephrosis is occult in even fewer (1.8%).^{60,61} The relationship between elevated PVR and hydronephrosis in individual patients is unclear. Ultrasound is highly sensitive for detecting ureteral obstruction,⁶² but intravenous pyelography is necessary for the complete evaluation of upper and lower tracts when hematuria is present.

Cystoscopy is unreliable for assessing BOO because it evaluates the prostate at rest and not during micturition and should not be used diagnostically.²³ In men already selected for surgery, or with hematuria or pelvic pain, cystoscopy provides important information about potential intravesical pathology such as tumors, stones, or marked trabeculation, as well as prostate size, length, and median lobe enlargement.

Urodynamic tests for evaluating LUTS include cystometry (to determine detrusor stability, contractility, and compliance) and pressure–flow studies (to detect BOO and assess detrusor contractility). Voiding profilometry (simultaneous measurement of detrusor and urethral pressures) is comparable to pressure–flow studies in accuracy of BOO diagnosis and may be easier to perform

in frail patients.⁶³ Whether urodynamics are required to confirm BOO in all men with LUTS remains controversial.⁶⁴ Arguments for their use include these: obstructed men have better symptomatic outcomes from TURP than those without BOO²³; urodynamics are the most accurate method for diagnosing BOO⁶; and the causes of LUTS in older men are diverse, often multiple, and may not be distinguishable without physiologically based testing. Against routine urodynamic evaluation are the concerns that testing is invasive, expensive, and requires equipment and expertise that are not routinely available even in most urologic practices.⁶⁴ Additionally, the marginal difference in TURP outcome for obstructed versus unobstructed men is small in routine cases, making definitive diagnosis of BOO less pressing.⁶⁴ The Agency for Health Care Policy and Research (AHCPR)/Agency for Healthcare Research and Quality (AHRQ) Bureau of Primary Health (BPH) guideline designates urodynamics “optional” testing whose performance should be based on the physician’s judgment.²³

For geriatricians, there are two principal issues when considering urodynamic evaluation in older men with LUTS. First, if the man desires and would be a candidate for surgical treatment for BOO, then urodynamics should be strongly considered to exclude other forms of lower urinary tract dysfunction that do not require surgical treatment [e.g., detrusor hyperactivity with impaired contractility (DHIC)]. If he is not suitable for or would refuse surgery, then definitive urodynamic diagnosis is less pressing. Second, urodynamic evaluation should be considered when empiric treatment for BPH-related LUTS has failed, and when there is coexistent neurologic disease (especially spinal cord injury). These guidelines are intended to optimize treatment of older men, while recognizing that the majority of men who today undergo TURP and other invasive treatments for BPH in the United States do not receive preoperative urodynamic evaluation.

Screening for prostate cancer with prostate-specific antigen (PSA) should be considered in the evaluation of older men with LUTS, if the patient would be a candidate for curative treatment of localized cancer with radical prostatectomy or radiation therapy, or if a prostate cancer diagnosis would modify his management. Initial studies suggest that PSA level also may predict the progression of BPH-related LUTS¹⁹ (see earlier). For a full discussion of PSA screening, see Chapter 36.

Treatment

The Decision to Treat

BPH, BPE, and BOO have real but small risks of morbidity and cause variable subjective impact. Moreover, no current treatment prolongs life or abrogates the need

for future treatment. Therefore, all treatment decisions should be patient centered,²³ focusing on symptom severity and bother, patient preferences, and potential treatment effects and morbidity. Providers offer critical guidance by exploring these key issues, so that patients do not feel burdened by decision making, but rather supported toward the goal of tailoring treatment to their needs. Importantly, causes of LUTS other than BPH must be evaluated and treated before prostate-specific treatment is initiated. Because many men tolerate mild to moderate symptoms, and only a minority will experience rapid symptom progression or morbidity, care must be taken not to overtreat; many men are best managed with watchful waiting and lifestyle changes.⁶⁵

Symptom bother often drives the decision to initiate therapy. Indices such as the AUA symptom score can be used to quantify voiding symptom severity and overall bother. Asking men specifically which symptom is the most bothersome may be useful in tailoring treatment goals. For example, an older man with slow urinary flow, hesitancy, and nocturia is often most bothered by the latter⁴⁵; nocturia, however, generally responds poorly to BPE/BOO-specific medical and surgical therapies, and may be better addressed by decreasing evening fluid intake and eradicating pedal edema.⁴⁶ The specific nature of the bother also is important: for the man most bothered by worry, evaluation and reassurance alone may provide relief, whereas symptom eradication may be most important for the man predominantly bothered by interference with daily activities.

Patient preferences should be elicited regarding the immediacy and permanence of symptom relief, short- and long-term costs and morbidity, and ability to comply with long-term monitoring. As is common in geriatric medicine, decisions must balance individually the probability of desired treatment effect with the need to avoid specific side effects and interactions with comorbid disease. In frail institutionalized men, catheter removal may be the treatment goal, and side effects intolerable in younger men (such as impotence) may be less problematic. Impotence following TURP would not be problematic for an older man with diabetes-related erectile dysfunction, whereas orthostatic hypotension from alpha-blockers could result in a devastating fall for a man with Parkinson’s disease.

Time to treatment effect varies significantly among interventions (ranging from days with surgery to months with finasteride), as does duration of symptom relief and need for repeat or further treatment. Symptom palliation alone may or may not be an acceptable outcome short of cure. “Low-cost” medications can result in significant cost burden if treatment is long term, requires frequent monitoring, or results in side effects. The AHCPR Clinical Practice Guideline is a useful source for extensive materials comparing direct and indirect BPH treatment

TABLE 51.4. Probabilities of outcomes from treatment.

Treatment	Symptom improvement		Serious adverse events ^a		Retrograde ejaculation ^b		Five-year retreatment rate	
	Median	90% CI	Median	90% CI	Mean	90% CI	Median	90% CI
Placebo	45%	26%–65%	5%	4%–7%	0%	—	38%	15%–65%

outcomes.²³ A selective summary of this information regarding the major forms of treatment is provided in Table 51.4.

Lifestyle Changes

Behavioral approaches such as bladder retraining and unhurried voiding without straining to completely empty the bladder⁶⁶ can mitigate LUTS and their impact for some men. Other suggestions are avoidance of diuretic beverages with caffeine or alcohol and, for nocturia, decreasing evening fluid intake or possibly adding an afternoon diuretic for preemptive diuresis in men with a large shift to more nocturnal excretion of their daily fluid load.

Watchful Waiting

The natural history of BPH-related LUTS, along with the repeated observation of marked symptom response without specific therapy and to placebo treatment in trials, established watchful waiting (WW) as sound management. Men most appropriate for WW are those with mild to moderate symptoms who are comfortable with this approach, can be followed reliably, and have no evidence of bladder decompensation (e.g., elevated PVR). Watchful waiting is not, however, the absence of any intervention. Patients must be followed at least yearly to monitor symptoms, renal function, and possibly PVR and PSA level. They should be counseled to avoid medications that may precipitate urinary retention (e.g., over-the-counter “cold” tablets containing alpha-agonists) and monitored carefully if anticholinergic or calcium channel blocking drugs are prescribed.

Watchful waiting may not relieve symptoms, but significant morbidity is uncommon. In a randomized trial of

WW versus TURP involving 556 men with moderate symptoms, at 3 years symptom improvement was significantly greater after TURP, although still considerable with WW (mean symptom score decrease, 60% versus 38%).²⁴ Among WW men, 36% crossed over to TURP, yet the incidence of absolute treatment failures was low (urinary retention, 2.9%; PVR >350 mL, 5.8%; and high symptom score, 4.3%). TURP decreased symptom bother and improved activities of daily living significantly more than WW; there was no difference between treatments, however, regarding sexual performance, general well-being, and social activities. Bother from symptoms improved less in men who were less bothered at baseline, especially following TURP (as in earlier studies⁶⁷).

Medical Therapy

Alpha-Adrenergic Blockers

Smooth muscle contraction in BPH adenomas and the prostatic capsule is mediated by plentiful alpha-1-adrenergic receptors (primarily alpha-1A subtype). Alpha-adrenergic blockers may reduce BPH-related LUTS by decreasing capsule, tissue, and urethral contractility. Most commonly used are alpha-1-selective agents, such as prazosin (1–2 mg twice a day), the longer-acting terazosin (2–10 mg daily), and doxazosin (4–8 mg daily), and the alpha 1A-selective tamsulosin (0.4 mg daily). In general, alpha-adrenergic blockers reduce symptoms by 30% to 40% over placebo in 50% to 70% of moderately symptomatic men,^{23,68,69} and result in better disease-specific functional outcomes than placebo in men with moderate to severe symptoms.⁷⁰ No significant differences have been identified between the different agents.⁶⁹ Time to onset of action for alpha-blockers is 2 to 4 weeks, compared with 3 to 6 months for finasteride.⁷¹

Drug effectiveness appears to be durable, although all long-term (2–4 years) data come from “open label” trials (generally uncontrolled with small numbers of patients self-selected for treatment response).

Side effects of alpha-blockers include asthenia, headache, dizziness, lightheadedness, and orthostatic hypotension; withdrawal rates of 10% to 15% have occurred in published trials and may be higher in practice.⁷² The prevalence of dizziness related to terazosin was 19% in one Randomized Clinical Trial (RCT) and was not related to age (less than 65 years of age compared to 65 or older) or changes in blood pressure.⁷³ Significant blood pressure drops and orthostatic hypotension are more likely in persons with elevated blood pressure (whether treated or not).⁷⁴ Alpha-1A-selective agents do not appear to have fewer side effects.⁶⁹ Retrograde or delayed ejaculation occurs with tamsulosin in 4.5% to 14%.⁷⁵ Slow titration from minimal starting doses and nighttime dosing may mitigate first-dose hypotension. Although alpha-blockers may seem a reasonable and concise option in men with BPH-related LUTS and hypertension, alpha-blockers are not recommended as first-line antihypertensive treatment, especially given the increased risk for congestive heart failure observed with doxazosin in men with other cardiac risk factors in the ALLHAT trial.⁷⁶

5 α -Reductase Inhibitors

Finasteride causes prostate involution by blocking the 5 α -reduction of testosterone to dihydrotestosterone, the steroid sustaining prostate growth. Treatment with finasteride 5 mg daily decreases prostate volume by at least one-third in 27% of men by 6 months and in 36% at 12 months; symptom reduction of at least 25% occurs in 54% of men by 6 months and in 58% at 1 year.⁷⁷ Significant symptom improvement over placebo did not occur until 10 months.⁷⁷ Variability and delay in symptomatic response may reflect heterogeneity of BPH pathology present (with largest responses possibly in men with predominantly glandular rather than stromal tissue) and variable effects on obstructed voiding physiology.^{78,79} Combined data from six RCTs⁸⁰ and the PLESS trial (Proscar Long-term Efficacy and Safety Study)⁸¹ suggest that IPSS score improvement with finasteride is 55% greater in men with large prostates (>60 versus <20 g) and that prostate size accounts for 80% of the variability in outcome. Finasteride is less effective than terazosin in reducing symptoms⁸²; however, finasteride can reduce the risk of urinary retention by 57% and need for TURP by 55%.⁸³ (appropriate trials investigating the effect of alpha-blockers on such BPH complications have not been done). Sustained drug effect requires lifetime use because prostate growth resumes once finasteride is stopped. Cost-effectiveness studies suggest that, in men

with moderate symptoms, finasteride is less expensive and provides more Quality Adjusted Life Years (QALYs) than watchful waiting (for 3 years or less) and TURP (for 14 years or less)⁸⁰; over longer periods, the high cost of the drug is problematic.⁸⁴

Finasteride decreases PSA levels by up to 40% to 60% after 1 year in approximately one-third of men⁸⁵; this heterogeneity in response may make monitoring for prostate cancer difficult.⁸⁶ If PSA does not decline in a compliant patient on finasteride, he should be evaluated further with prostate biopsy. Despite maintained or increased testosterone levels, finasteride causes adverse sexual effects, including decreased libido (3%), decreased ejaculate volume (3%), and impotence (3%–4%)⁷⁷; gynecomastia is reported in 0.4% of patients.⁸³ Preliminary reports suggest that finasteride has little effect on serum lipids or bone density, although adequate long-term studies are lacking.⁸⁴

Phytotherapy

Plant-derived compounds are widely used as over-the-counter treatment for BPH. In general, studies of these agents suffer from short-term treatment (typically 4–24 weeks) and lack of standardized preparations, yet recent meta-analyses suggest these compounds are efficacious. Best studied is *Serenoa repens*, from the dwarf palm tree or saw palmetto. Meta-analyses demonstrate that, compared with placebo, *Serenoa repens* improves urinary symptoms (risk ratio, 1.75; 95% CI, 1.21, 2.54), decreases nocturia (weighted mean difference, –0.76 times a night; 95% CI, –1.22, –0.32), and increases flow rate (weighted mean difference, 1.93 mL/s; 95% CI, 0.72, 3.14 mL/s)^{87,88}; in two studies, improvements were similar to those seen with finasteride.^{87,88} In a systematic review, beta-sitosterols improved urinary symptoms (IPSS reduction weighted mean difference, –4.9 points; 95% CI, –6.3 to –3.5) and flow rate (weighted mean difference, 3.9 mL/s; 95% CI, 0.91–6.9 mL/s) compared with placebo.⁸⁹ Cernilton (pollen from the ryegrass *Secale cereale*) improves symptoms more than placebo (risk ratio, 2.40; 95% CI, 1.21, 4.75) but does not improve flow rate.⁹⁰ These agents have few to no reported side effects, but long-term data are lacking.

Antiandrogens

“Medical castration” and resultant prostate involution can be induced through luteinizing hormone-releasing hormone (LHRH) agonists or androgen receptor inhibitors.⁹¹ Small uncontrolled trials suggest that such agents may facilitate the removal of indwelling catheters in frail older men with BOO.⁹¹ A controlled trial of leuprolide demonstrated significant prostate shrinkage over placebo but no significant differences in symptoms until week 48.⁹² Similar to finasteride, these agents

decrease PSA levels and must be continued indefinitely to maintain prostate reduction. Side effects also include impotence, weight gain, and hot flashes (LHRH agonists and cyproterone acetate) and diarrhea and gynecomastia (flutamide).

Surgery

Transurethral Resection of Prostate (TURP)

Transurethral resection remains the standard against which other BPH treatments are compared because it has the highest rate of symptom improvement, generally 80% to 88%.²³ Despite the advent of alternative surgical treatments for BPH, many urologists continue to employ only TURP: the 1999 Gallup survey of urologists found that only 22% perform laser prostatectomy, 17% microwave thermotherapy, and 7% transurethral needle ablation.⁹³

The absolute indications for TURP are severe lower urinary tract obstruction, acute urinary retention, recurrent urinary infections, hydronephrosis, recurrent hematuria, and renal impairment (causes other than BOO excluded).⁹⁴ These indications account for nearly one-third of all surgeries; the rate is higher in studies in men over age 80 (48%–61%),^{95,96} although causes for retention other than BOO were not excluded. Several studies suggest that men with urodynamically confirmed BOO have better symptomatic outcomes.^{64,97}

The efficacy of TURP must be interpreted in light of several considerations. First, quality of life following TURP may be improved only in those with the most severe symptoms.⁶⁷ Second, improvement may not be durable: in one trial success rates declined from 87% at 3 months to 75% at 7 years among survivors.⁹⁸ Third, success rates tend to be lower in the elderly (less than 80%⁹⁶), often with a concomitant increase in associated morbidity (up to 71%).⁹⁴ Fourth, studies of TURP cost-effectiveness in the United States are complicated by marked geographic variability for charges and length of stay.⁹⁹ Fifth, although treatment options have expanded widely, there are few trials comparing these to TURP, and no long-term data. Finally, although a subset of men with BOO present initially with retention, bladder decompensation, and renal insufficiency, suggesting that earlier surgery might prevent such outcomes, the time course of decompensation and the true proportion of patients at risk are unknown. These concerns regarding selection for, outcome from, and alternatives to TURP have refocused attention on the indications for surgery in BPH and have fueled the controversy.^{6,64,100}

Sexual dysfunction following TURP is a concern for many men. Around 74% of men develop retrograde ejaculation after TURP,²³ which is of concern only if conception is desired. A small but significant proportion of men lose potency after TURP; estimates range as high as 40%,

yet the actual rate is closer to 14%, with higher rates in older men.^{23,101,102} Urinary incontinence occurs in approximately 5%.²³

The major complications of TURP are bleeding requiring transfusion, failure to void, and infection; rarer is “TURP syndrome,” severe hyponatremia due to systemic absorption of hypotonic bladder irrigation fluid used intraoperatively. Several studies suggest that compared to younger individuals men over age 80 have higher perioperative mortality (2%–3% versus <0.5%) and morbidity (up to 70% versus 18%–30% for major complications)^{96,103,104}; these comparisons, however, do not adjust for increased comorbidity in the oldest men. Indeed, in selected robust older men, TURP can be done as an outpatient procedure.¹⁰⁵ In frail patients with small prostates, general or spinal anesthesia can be avoided and TURP performed with sedation and local prostate anesthesia.¹⁰⁶

Open Prostatectomy

Larger prostates require longer transurethral resection times, with an increased risk of TURP syndrome and analgesia complications. Open prostatectomy by an abdominal or perineal approach generally is recommended for men with marked prostatic hypertrophy (>60 g). In practice, however, open procedures account for 5% or less of prostatectomies, because many surgeons prefer to perform an “incomplete” TURP rather than risk the greater morbidity of open surgery.¹⁰⁰ Retrospective studies suggest that TURP has higher reoperation rate and late mortality compared with open surgery,^{107,108} but these did not adequately control for increased age and comorbidity in TURP patients¹⁰⁹ or the secular trend of lower TURP mortality in older men.¹¹⁰ Unfortunately, a randomized trial under way to address this issue excludes patients with an indwelling catheter, that is, up to 40% of elderly men who undergo prostatectomy.^{95,96,104}

Prostate Incision

If the prostate is small (<30 g), prostatotomy or transurethral incision of the prostate (TUIP) may provide similar efficacy to TURP with a technically simpler procedure, shorter operation times, and the potential for using local anesthesia.¹¹¹ Randomized studies demonstrate similar symptomatic success rates for TUIP compared with TURP at 1 year; in a select case series with a 2-year mean follow-up, only 8% of patients required later TURP.¹¹² Additional advantages of TUIP include lower rates of bleeding complications and postoperative retrograde ejaculation. For the higher-risk older man with BOO and a small prostate for whom noninvasive management has failed or is not optimal, TUIP may be a safe and effective alternative to TURP,

especially in the hands of a surgeon familiar with the technique.

Laser Prostatectomy

Several different laser systems currently are used to cause prostate vaporization or coagulation necrosis. Randomized trials indicate that at 6 to 7.5 months TURP is superior to noncontact laser for symptom improvement, flow rate, and quality of life, but outcomes equalize at 1 year.¹¹³⁻¹¹⁵ TURP required longer hospital stay, more transfusions, and resulted in more urethral strictures, while laser therapy had longer catheterization and more infectious complications (including methicillin-resistant *Staphylococcus aureus*, MRSA¹¹⁶). The longest study has followed men for only 2 years.¹¹⁷ Different laser procedures yield results of variable consistency and success.¹¹⁸ Side effects also vary by method, but include impotence, retrograde ejaculation, increased urgency and frequency for several weeks, incontinence, and bladder neck stricture. Patients may require catheter drainage for several weeks until tissue sloughing is complete. Unlike TURP, laser procedures do not allow tissue examination for occult prostate cancer.

Microwave Hyperthermia

Controlled trials of transurethral microwave thermotherapy (TUMT) have shown variable results regarding symptom improvement, ranging from moderate to no difference from sham,^{119,120} and only a modest improvement in peak flow rate (2-4 mL/s).¹¹⁹ One-third of patients in a 3-year nonrandomized trial required further therapy for their symptoms.¹²¹ Compared with terazosin, TUMT provided less symptom relief at 2 weeks, but was better at 6 months (at least 50% decrease in symptoms; TUMT, 78% versus terazosin, 33%).¹²² There are no long-term treatment data.

Other Approaches

One randomized trial found transurethral needle ablation (TUNA) was less efficacious than TURP at 1 year for improving symptoms (decrease in IPSS, 13.6 versus 16 points), although TUNA resulted in no retrograde ejaculation and less bleeding (32% versus 100%).¹²³ Small, nonrandomized trials indicate that wire urethral stents, placed in the prostatic urethra under endoscopic or radiologic guidance, may restore spontaneous voiding in frail men with acute or chronic retention who are not surgical candidates or for whom indwelling catheters are undesirable. Stents consisting of a wire spiral have been complicated by encrustation, migration of the device, infection, urinary incontinence, and retention. Stents become covered by epithelium in 6 to 8 months, and have fewer infections, but are associated with a high rate of urgency and urge incontinence for up to 2 months.

Summary

BPH is nearly universal among older men, and the associated morbidity from related prostate enlargement, bladder outlet obstruction, and LUTS has a substantial impact on quality of life. The prevalence of BPH ensures a continuing need for geriatricians to be informed regarding issues in evaluation and treatment, while the established role of nonoperative therapy and the recognition of the importance of patient preferences have opened the way for expanded primary care involvement in management. Basic questions regarding the etiology of BPH and LUTS, the role of BOO in predicting treatment outcome, and the measurement of patient-weighted outcomes for invasive and noninvasive treatments await further study. In the interim, geriatricians can significantly help their male patients by understanding the large number of factors that can mimic prostate disease in older men; appreciating the often indolent natural history of BPH and related LUTS; understanding the clinical utility of current evaluation methods; and especially by assisting them in weighing risks and benefits of established and evolving therapies together with their own personal concerns and needs.

Sharon Anderson

The biologic price of aging includes progressive structural and functional deterioration of the kidney, and the changes in renal function during normal aging are among the most dramatic of any organ system. This chapter considers the functional and structural changes that occur with normal aging; more detailed reviews may be found in several recent publications.¹⁻⁶

Age-Related Changes in Renal Function and Structure

The glomerular filtration rate (GFR) is low at birth, approaches adult levels by the end of the second year of life, and is maintained at approximately 140 mL/min/1.73 m² until the fourth decade. Thereafter, GFR declines by about 8 mL/min/1.73 m² per decade.^{7,8} Acceleration of age-related loss of renal function has been noted in the setting of systemic hypertension,^{9,10} lead exposure,¹¹ smoking,¹²⁻¹⁴ and possibly male gender.¹⁵ Although clinically important in many elderly patients, it should be noted that there is wide variability among individuals in the age-related fall in GFR.^{9,16} The age-related reduction in creatinine clearance is accompanied by a reduction in the daily urinary creatinine excretion, due to reduced muscle mass.⁸ Accordingly, the relationship between serum creatinine (S_{Cr}) and creatinine clearance changes. The net effect is near-constancy of S_{Cr} while true GFR (and creatinine clearance) decline, and consequently, substantial reductions of GFR despite a relatively normal S_{Cr} level. The creatinine clearance in adult males may be estimated from the S_{Cr} with the following formula:

$$\begin{aligned} \text{Creatinine clearance} \\ = (140 - \text{age})(\text{weight in kg}) / (72 \times S_{Cr}) \end{aligned}$$

and, in females, by multiplying this value by 0.85.¹⁷

Similar changes in renal blood flow (RBF) occur, so that RBF is well maintained at about 600 mL/min until

approximately the fourth decade, and then declines by about 10% per decade.^{18,19} The reduction in RBF is not entirely due to loss of renal mass, as xenon-washout studies demonstrate a progressive reduction in blood flow per unit kidney mass with advancing age.¹⁹ The decrease in RBF is most profound in the renal cortex; redistribution of flow from cortex to medulla may explain the slight increase in filtration fraction seen in the elderly.^{18,19}

Studies in laboratory rats, whose age-related renal changes resemble an accelerated version of those in humans, suggest that another functional abnormality in aging is an increase in the glomerular basement membrane (GBM) permeability, leading to an increase in urinary excretion of protein, including both albumin and higher molecular weight proteins.²⁰ Studies in aging humans demonstrate decreased sulfation of the GBM glycosaminoglycans,²¹ which would be expected to render the GBM more permeable to macromolecules. Age-related changes in proteinuria in humans have not been extensively studied, but the incidence of microalbuminuria and proteinuria in the elderly may be slightly elevated.²²⁻²⁴

Renal mass increases from about 50 g at birth to more than 400 g during the fourth decade, after which it declines to less than 300 g by the ninth decade. The reduced kidney weight correlates well with the reduction in body surface area.²⁵⁻²⁷ Loss of renal mass is primarily cortical, with relative sparing of the medulla.^{27,28} Glomerular number decreases, but studies differ on the size of the remaining glomeruli.^{26,29,30} Glomerular shape changes as well,²⁹ with the spherical glomerulus in the fetal kidney developing lobular indentations as it matures. With aging, lobulation tends to diminish, and the length of the glomerular tuft perimeter decreases relative to total area. The GBM undergoes progressive folding and then thickening.^{31,32} This stage is accompanied by glomerular simplification, with the formation of free anastomoses between a reduced number of glomerular

capillary loops. Frequently, dilatation of the afferent arteriole near the hilum is seen at this stage. Eventually, the folded and thickened GBM condenses into hyaline material with glomerular tuft collapse. Degeneration of cortical glomeruli results in atrophy of both afferent and efferent arterioles, with global sclerosis. In the juxtamedullary glomeruli, glomerular tuft sclerosis is accompanied by the formation of direct channels between the afferent and efferent arterioles, resulting in aglomerular arterioles.^{32,33} These aglomerular arterioles, which presumably contribute to maintenance of medullary blood flow, are rarely seen in kidneys from healthy young persons; their frequency increases both in aging kidneys and in the presence of intrinsic renal disease.³³

The incidence of glomerular sclerosis increases with advancing age. Sclerotic glomeruli comprise fewer than 5% of the total under the age of 40; thereafter, the incidence increases so that sclerosis involves as much as 30% of the glomerular population by the eighth decade.³³⁻³⁵ Thus, both diminished glomerular lobulation and sclerosis of glomeruli tend to reduce the surface area available for filtration, and therefore contribute to the observed age-related decline in GFR.²⁹ In addition, age-related changes in cardiovascular hemodynamics, such as reduced cardiac output³⁶ and systemic hypertension,^{9,10} are likely to play a role in the reduced perfusion and filtration of aging.

Age-Related Alterations in Fluid and Electrolyte Homeostasis

Advancing age is not characterized by any specific changes in serum electrolyte or acid-base parameters in healthy subjects. A comprehensive study of serum electrolytes, enzymes, and other parameters in 327 healthy individuals ranging in age from 60 to over 100 years found that healthy aging subjects exhibit no change in serum sodium, potassium, chloride, or CO₂ levels; pH decreases only slightly. Values for blood urea nitrogen (BUN) increase significantly, while serum creatinine does not change.²³ However, the situation changes markedly when hospitalized or ill elderly subjects are considered. Such patients frequently exhibit elevated values for BUN and creatinine (which correlate with the degree of glomerular sclerosis),³⁷ while alterations in sodium and potassium levels are more prominent, as discussed next. These observations indicate ability of the aging kidney to maintain normal electrolyte homeostasis under steady-state conditions. However, the aging kidney demonstrates impaired ability to respond to perturbations of fluid and electrolyte balance, and therefore a number of these complications are frequently encountered in the presence of intercurrent illness. In concert with the loss of functioning glomeruli, evidence of tubular dysfunction is

found as well, with deterioration of several proximal tubular functions including maximum excretion of para-aminohippurate³⁸ and diodrast⁷ and maximal absorption of glucose.³⁹ These changes are proportional to changes in GFR, suggesting a constancy of the relationship between GFR and tubular function.² However, studies in experimental animals also indicate fewer energy-producing mitochondria,⁴⁰ lower enzyme concentrations,^{40,41} lower concentrations of total or sodium-potassium-activated adenosine triphosphatase (ATPase),⁴² decreased sodium extrusion and oxygen consumption,⁴³ and decreased brush border sodium-hydrogen exchange and sodium-dependent phosphate transport⁴⁴ in old versus younger kidneys. The most prominent abnormalities are found in renal handling of sodium and water, which probably relate to changes in innate tubular transport capacity, as well as to increasingly well-recognized alterations in renal responsiveness to hormonal stimuli.

Disorders of Sodium Balance

In the absence of acquired renal disease, the aging kidney is able to appropriately adjust sodium handling in the face of extracellular sodium deficiency or excess; however, the response time is impaired, and management of these disorders is accordingly complicated.⁴⁵⁻⁴⁸ The renal response to dietary sodium deprivation in the elderly is blunted. When challenged with an acute reduction in sodium intake (from 100 mEq/day to 10 mEq/day), elderly subjects are able to conserve sodium and achieve sodium balance, but at a slower rate than in younger subjects. An acute study of dietary sodium restriction found that the half-time for reduction in urinary sodium after salt restriction was 17.6 h in young persons but was prolonged to 30.9 h in older subjects.⁴⁵ In a more chronic state of sodium deprivation, administration of a 50 mEq/day sodium diet led to urinary sodium conservation and achievement of sodium balance after 5 days in younger subjects, whereas elderly patients did not return to sodium balance after 9 days despite a weight loss of 1.4 kg.⁴⁶ Studies in the segmental handling of sodium in elderly patients suggest that sodium handling is fairly normal in the proximal tubule, but that the capacity to reabsorb sodium in the ascending limb of the loop of Henle is markedly impaired.⁴⁷ The reduced loop capacity to reabsorb sodium has two important consequences: the amount of sodium delivered to the more distal segments increases, and the capacity to concentrate the medullary interstitium is reduced, therefore also contributing to inability to concentrate the urine.

Age-related abnormalities in several hormonal systems controlling sodium excretion are likely to play a role in this impaired ability to conserve sodium (Table 52.1). Plasma renin levels and blood and urinary aldosterone levels are significantly reduced in the elderly population,

TABLE 52.1. Age-related changes in sodium-modulating factors.

Reduced functioning nephron number
Decreased renin-angiotensin-aldosterone formation and effect
Decreased insulin secretion
Increased atrial natriuretic peptide levels with relatively reduced effect
Increased plasma norepinephrine levels
Decreased renal dopamine
Decreased kallikrein-kinin activity

and responses to appropriate stimuli such as sodium restriction are blunted.^{48,49} In addition, the tubular response to administration of aldosterone is reduced.⁴⁸ The mechanisms for suppression of the renin-angiotensin system are not yet well defined. Hall and coworkers have postulated that these age-related changes result from the loss of nephrons; compensatory hyperfiltration in the remaining nephrons leads to increased sodium chloride delivery to the macula densa, with suppression of renin synthesis and release, and therefore reduced formation of angiotensin II and aldosterone.⁵⁰ Studies in aging animals indicate that both renal renin synthesis and renin release in response to volume stimuli are reduced, and that both contribute to the observed fall in plasma renin concentration with aging.⁵¹

Other mechanisms, although not well studied, could play a role. Theoretically, the observed decrease in insulin secretion with aging⁵² could contribute, as insulin is antinatriuretic. In addition, the natriuretic response to head-out water immersion (a physiologic technique used to study redistribution of extracellular fluid) is enhanced in elderly subjects, possibly relating to the greater mean arterial pressure increments.⁵³ Whatever the mechanisms, the impaired response to sodium deprivation (or relative "salt-wasting") renders the elderly patient more susceptible to developing a cumulative sodium deficit and its attendant systemic complications.

Similarly, the renal response to a sodium load is sluggish in elderly patients.^{53,54} In a careful study of renal responses to an acute isotonic sodium load, the amount of sodium excreted acutely did not differ in older individuals. However, these individuals had higher baseline blood pressures, leading to the suggestion that the higher blood pressures in old versus young subjects serves to counteract this potential intrarenal defect.⁵⁵ Natriuresis is impaired by both the reduced GFR, leading to a reduced delivery of sodium to the nephron, and by abnormalities in tubular handling of sodium. Studies in aging animals indicate both a greater fall in renal perfusion^{56,57} and filtration⁵⁷ with angiotensin II administration, as well as impaired natriuresis and augmented kaliuresis with this maneuver.⁵⁷ Similarly, animal studies indicate impaired natriuretic responses to increased perfusion pressure, mediated in part by the renal nerves.⁵⁸

Other vasoactive mediators appear to be involved, as well. Plasma levels of norepinephrine increase with age,^{59,60} and therefore changes in sympathetic tone could contribute to a tendency to conserve sodium. Both clinical⁶¹⁻⁶³ and experimental⁶⁴ studies indicate that plasma levels of atrial natriuretic peptide (ANP) increase with age. Some investigators have found no differences in natriuretic responses to ANP infusion between young and elderly normal subjects,⁶⁵ but changes in fractional excretion of sodium were not measured, and the data indicate the possibility of a lesser augmentation of the fractional excretion of sodium in the older subjects. Most studies have noted similar natriuretic responses to ANP infusion in younger and older subjects,⁶⁵⁻⁶⁷ but the equivalent responses occur only with much higher increments in plasma ANP levels in older subjects,⁶⁶ or the effects in older subjects are more transient than in younger subjects.⁶⁷ Other studies have found diminished responses in the elderly.⁶⁸ Although indirect, these data are consistent with an altered ANP-sodium dose responsiveness in the older kidney. It has been postulated that several mechanisms underlie the age-related increase in plasma ANP levels: that elevated ANP is secondary to enhanced sensitivity of the atrial afferent system for ANP release, and also that end-organ resistance to ANP actions induces feedback stimulation of ANP release in the elderly.

Less well studied is another vasodilator, kallikrein; it has been reported that there is a negative correlation between age and urinary kallikrein excretion,⁶⁹ and that serum kininogen levels decrease with advancing age.⁷⁰ Moreover, urinary dopamine excretion declines with advancing age in humans.^{71,72} Studies in aging rats have indicated that these changes may be due to a reduction in DA₁ receptor number and subsequent G-protein activation,⁷³ and that the diminished natriuretic response to dopamine in aging rats is due to an impaired D₁-like receptor signaling pathway.⁷⁴ However, the natriuretic response to infusion of dopamine may be preserved in the elderly.⁷⁵ Together, altered levels of, or responsiveness to, various natriuretic stimuli most likely contribute to impaired sodium excretion in the elderly (see Table 52.1). Clinical aspects and therapy are discussed next.

Disorders of Water Balance

Renal concentrating and diluting abilities are also impaired in the aging kidney.^{76,77} In response to water deprivation, studies in healthy elderly patients indicate that the maximal decrease in urine volume and increase in urine osmolality are both significantly diminished as compared to responses in younger subjects and are not completely explained by the reduced GFR in the elderly.⁷⁸

The mechanisms that underlie the impaired concentrating capacity have been extensively explored. The

reduced number of functioning nephrons may contribute to an obligatory solute diuresis in the remaining intact nephrons, as occurs with chronic renal failure. In addition, the effect of age on the renal response to exogenous antidiuretic hormone (ADH) has been studied. Although age-related differences in response to submaximal ADH infusions were not found, such a defect in concentrating ability was found when higher doses of ADH were infused.⁷⁹ One explanation for these differences may relate to the relative sparing of medullary blood flow in the aging kidney; this might contribute to a "washout" of the medullary osmotic gradient necessary for urine concentration by the countercurrent multiplier system.

In addition to altered responsiveness to exogenous ADH, the release of endogenous ADH in response to appropriate stimuli is abnormal in elderly subjects. In some cases, there is a diminution in thirst perception to water deprivation⁸⁰⁻⁸³ or saline infusion,⁸⁴ so that stimuli such as volume depletion or hyperosmolality are less effective. Some studies have challenged this finding, in adults just over the age of 70.⁸⁵ Morphologic studies indicate no evidence of age-related degenerative changes in the supraoptic and paraventricular nuclei, the sites of ADH production.⁸⁶ The increase in plasma ADH levels after infusion of hypertonic saline (an osmolar stimulus) is greater in elderly than in younger subjects, indicating enhanced osmoreceptor sensitivity in the elderly.⁸⁷ In contrast to the response to an osmolar stimulus, however, the ADH response to volume-pressure stimuli (assumption of upright posture after overnight dehydration) is markedly impaired in some elderly subjects,⁸⁸ as is the fall in plasma ADH after drinking water.⁸² A portion of the afferent limb of the reflex arc involved in this response is the vasomotor center. In elderly subjects, plasma norepinephrine levels were comparable in those who did and who did not respond appropriately to the pressure-volume stimulus, suggesting that the defect in the afferent limb must exist between the vasomotor center and the hypothalamic area controlling ADH release. This reflex arc is inhibitory to ADH secretion, and a defect in this area would result in a lesser dampening of osmotically stimulated ADH release. These studies suggest that baroreflex input at the hypothalamic level during aging modulates osmotically mediated ADH release, and thus may alter water balance.

Plasma ADH levels under basal conditions do not change with advancing age,^{60,87,89} nor are there any differences in ADH pharmacokinetics following ADH administration after adaptation to high or low sodium diets between young and elderly subjects.⁹⁰ However, these studies found secondary increases in ADH that were enhanced in magnitude during low sodium intake and absent in elderly subjects. Taken together, these studies indicate that ADH is present in the elderly, and that provocative stimuli can both accentuate its release

and reduce its suppressibility; the mechanisms underlying these observations, as well as the consequences of attenuation of secondary ADH release, remain incompletely defined.

Similarly, the aging kidney demonstrates a modest inability to dilute urine appropriately, as determined by the maximal excretion of free water after water loading.^{91,92} This change is most likely due to the reduced GFR and renal perfusion, as well as to functional impairment in the diluting segment of the nephron.^{48,91} Recent studies in aging animals indicate that age-related polyuria is associated with downregulation of the aquaporin-2 and -3 receptors in the medullary collecting duct.⁹³

Hyponatremia

Serum sodium levels are generally within the normal range in healthy elderly individuals,²³ but the defective sodium and water homeostatic mechanisms render this population markedly susceptible to perturbations. Hyponatremia is the most common electrolyte disorder in the elderly, occurring in as many as one-quarter of all hospitalized or institutionalized elderly patients.^{46,94,95} In a survey of hospitalized elderly patients, 3.6% had serum sodium values below 130 mmol/L, even in the absence of drugs known to affect serum sodium.⁹⁶ Numerous mechanisms contribute to the susceptibility to hyponatremia and may generally be deduced after clinical evaluation. The most common underlying mechanisms of geriatric hyponatremia are (1) decreased ability to excrete water; (2) water intoxication in the setting of diuretic therapy; and (3) oversecretion of ADH.

As in patients of any age, evaluation of the hyponatremic patient begins with confirmation of true hyponatremia, a hypoosmolar state.^{77,97} Pseudohyponatremia may be found in the setting of marked hyperglycemia, hyperlipidemia, and hyperproteinemia. Measurement of plasma osmolality confirms this diagnosis, as plasma osmolality is normal in pseudohyponatremia but reduced in true hyponatremic states. Most clinical laboratories now use specific sodium electrodes, eliminating this form of false positive. Further evaluation requires estimation of extracellular fluid volume status, by physical examination and measurement of urinary sodium concentration. Hyponatremia may be associated with extracellular volume depletion (due to renal or extrarenal losses); with extracellular volume excess (due to cardiac failure, nephrotic syndrome, cirrhosis, or renal failure); or with normal to slightly increased extracellular volume excess in the absence of edema (endocrine disorders, drugs, and excess ADH secretion).

Elderly patients may suffer from any of these disorders, and in fact carry a disproportionate burden of illness associated with extracellular fluid volume deficit and excess.⁹⁷ Extracellular volume depletion is quite

common, particularly after administration of diuretics; in one series of 77 elderly patients, diuretic therapy accounted for two-thirds of all cases of hyponatremia.⁹⁸ In a survey of 631 hospitalized elderly patients, 11.8% of subjects on thiazides were hyponatremic, with the percentage being higher in elderly women.⁹⁶ Several age-related abnormalities are likely to contribute to this increased susceptibility: volume depletion, potassium depletion, and inhibition of urinary dilution. As compared to younger subjects, elderly patients challenged with a thiazide diuretic exhibit greater impairment of minimum urine osmolality and clearance of free water, possibly associated with lower prostaglandin production.⁹² Diuretic-induced hyponatremia occurs almost exclusively with thiazide diuretics, which interfere with urinary diluting but not concentrating ability and therefore may engender greater defects in free water excretion, particularly in the presence of ADH. Clinically significant hyponatremia tends to occur as early as the first few days of diuretic administration, and the frequency of life-threatening hyponatremia is increased in the elderly population.⁹⁹⁻¹⁰¹ It should also be noted that thiazide diuretics and nonsteroidal anti-inflammatory drugs may have an additive effect in causing hyponatremia in the elderly.⁹² Therapy consists of discontinuation of the drug(s) and restriction of water intake. In the setting of severe central nervous system symptomatology, administration of intravenous hypertonic saline is warranted.

Hypervolemic hyponatremia is also common in the elderly, with congestive heart failure being the most common etiology of this disorder. The reduction in renal perfusion, and thus GFR, that accompanies congestive heart failure at any age may be more destructive in the elderly, in whom values for GFR are only half those of younger persons when cardiac function is optimal. Congestive heart failure may be accompanied by increased plasma ADH levels, particularly in elderly patients.¹⁰² Therapy consists of water restriction, and treatment of congestive heart failure with loop diuretics (rather than thiazides) and other usual modalities.

Relatively isovolemic hyponatremia is also prominent in the elderly, who may exhibit elevations in plasma ADH levels in the absence of recognizable stimuli for ADH secretion.¹⁰³ The elderly seem to be particularly susceptible to hyponatremia in the setting of the syndrome of inappropriate ADH resulting from pulmonary disease, central nervous system disorders, paraneoplastic syndromes, pain, narcotics, and drugs that cause the syndrome. The presence of excessive levels of ADH, together with impaired ability to excrete free water, render the elderly particularly susceptible to hyponatremia in numerous clinical settings, and particularly in the postoperative setting in the presence of narcotic administration and large amounts of intravenous hypo-

tonic fluids. In one large series of elderly patients, excessive administration of hypotonic intravenous fluids was responsible for 14% of the cases of hyponatremia.⁹⁸ More recently, the incidence of hyponatremia due to antidepressant medication has been increasingly realized,^{104,105} as has the higher incidence of idiopathic hyponatremia in the elderly.^{106,107}

Hypertatremia

Hypertatremia is also particularly prominent in the elderly.¹⁰⁸ The major defense against hypertatremia is thirst, and so the populations at highest risk for hypertatremia are those with impaired access to water. A group at particularly high risk are institutionalized older patients with cognitive impairment, who manifest failure to recognize thirst or physical inability to obtain fluids. Additional evidence, although not entirely unequivocal, suggests that hypodipsia, or failure to recognize thirst despite substantial elevations in serum osmolality, may be more common in elderly patients.^{81,84,109} Cerebrovascular disease may also inhibit thirst, as well limiting physical ability to gain access to fluids. These problems, together with the inability of the aging kidney to maximally conserve water, render elderly patients at higher risk for the development of hypertatremia.

Hypertatremia may result from loss of sodium and water with predominant water loss and low total body sodium (renal and extrarenal losses); water losses with normal total body sodium (from nephrogenic and central diabetes insipidus, or inadequate water intake in the presence of normal water losses); and sodium addition with increased total body sodium (endocrine disorders, intravenous or oral sodium administration). Clinical evaluation and measurement of urinary sodium will usually disclose the cause. Therapy consists of administration of hypotonic saline in the setting of low total body sodium; water in the setting of normal total body sodium; and diuretics and water replacement in the setting of high total body sodium.

Alterations in Potassium Balance

Plasma potassium concentrations in the elderly remain within the normal range in the absence of abnormal stresses.²³ However, significant abnormalities in cellular and total body potassium occur with advancing age. Erythrocyte potassium concentration (a reflection of general intracellular potassium content) is decreased, and both total body potassium and total exchangeable body potassium are reduced by about 20% as compared to younger subjects.^{46,110-112} Several mechanisms for this reduction in total body potassium concentration have been proposed, including decreased muscle mass, alterations of cell membrane characteristics, nutritional

deficiencies, and inability of the kidney to conserve potassium.⁴⁶ Renal potassium excretion has been noted to be reduced in elderly subjects, but when corrected for the reduction in GFR, the fractional excretion of potassium may be higher than in younger subjects.⁴⁶

Hypokalemia

Hypokalemia is the most prominent potassium abnormality in the elderly population, and in one series was found in 11% of elderly patients visiting an emergency room, regardless of the reason for the visit.¹¹¹ The most prominent etiology of hypokalemia in the elderly population is probably diuretic therapy; aging patients appear to be more susceptible to the hypokalemic effects of these drugs.⁹⁸

Hyperkalemia

Hyperkalemia is relatively uncommon in elderly patients in the absence of renal disease or administration of potassium-sparing diuretics, despite evidence in aging experimental animals of impaired ability to excrete a potassium load.¹¹³ The reduction in total body potassium stores may serve to offset the reduced GFR, thus protecting against significant hyperkalemia. However, the reduced activity of the renin-angiotensin-aldosterone system in the elderly, and the predisposition to the syndrome of hyporeninemic hypoaldosteronism (type IV renal tubular acidosis) may serve to limit potassium excretion, thus enhancing the risk of hyperkalemia in the presence of excessive potassium loads or drugs that predispose to hyperkalemia.^{114,115} Elderly patients are less able to mount a sufficient aldosterone defense when faced with hyperkalemia.¹¹⁶ In fact, hyperkalemia is more prominent in elderly subjects than in younger individuals when administered potassium supplements and other drugs known to increase serum potassium levels, including nonsteroidal anti-inflammatory drugs and trimethoprim-sulfamethoxazole.¹¹⁷⁻¹¹⁹ Furthermore, the increasing use of angiotensin-converting enzyme inhibitors and spironolactone for treatment of congestive heart failure is likely to induce further hyperkalemia in elderly patients, in the setting of age-related reductions in renal function.

Disorders of Acid–Base Balance

Abnormalities in both pulmonary and renal acid–base mechanisms may contribute to disorders in elderly patients. Despite evidence for substantial deterioration in lung and kidney function with advancing age, acid–base balance is remarkably well maintained in the elderly, who are generally able to maintain normal values for serum pH, pCO₂, and bicarbonate concentrations.^{23,119-122} There

is a modest, significant decrease in bicarbonate levels (within the normal range) in the healthy elderly.¹²³ Although these systems adequately dispose of the normal daily acid load, studies of ammonium loading in elderly patients indicate a reduced ability to excrete an acute exogenous acid load. However, when corrected for the reduced values for GFR, the response of elderly subjects is similar to that in younger subjects, indicating that nephron loss rather than tubular dysfunction probably accounts for this difference.^{122,124} More chronic acid loading, however, may be associated with delayed restoration of normal serum pH and bicarbonate concentrations,¹²⁵ and the response to alkali loading may also be delayed in elderly subjects.¹²⁶ It seems possible that the numerous etiologies of acidosis and alkalosis (particularly those resulting from drugs) might result in more frequent, profound, and long-lasting acid–base disorders in this population.^{120,121} Although relatively few data are available addressing the clinical outcomes of various acid–base disorders in the elderly population, a recent study found that administration of potassium bicarbonate to postmenopausal women resulted in positive calcium and phosphate balance, decreased bone resorption, and increased bone formation.¹²⁷

Calcium/Phosphorus/Magnesium Disorders in Aging

Serum levels of total calcium, ionized calcium, phosphorus, magnesium, and parathyroid hormone (PTH) generally remain within the normal range in the elderly,²³ although some studies have found significant decreases in serum calcium, phosphorus, and vitamin D, and increases in PTH (with values remaining in the normal range), with advancing age.¹²⁸ In aging women, there is a sequence of an increase in serum calcium, followed by an increase in calcitriol and PTH.¹²⁹ However, calcium metabolism is substantially impaired with aging, due to age-related decreases in intestinal calcium absorption,^{130,131} decreased renal 1 α -hydroxylase activity and decreased 1,25(OH)₂D₃ activity,¹³²⁻¹³⁶ and decreased intestinal adaptation to dietary calcium restriction.¹³⁷ A decrease in vitamin D levels is frequently seen in elderly patients who are in poor health;^{138,139} contributing factors may include lack of exposure to sunlight, dietary deficiency, and impaired conversion to 1,25(OH)₂D₃. Other factors, including age-related changes in growth hormone and insulin-like growth factor 1,¹⁴⁰ have also been suggested to influence vitamin D levels in the elderly.¹²⁸ However, renal tubular absorption of calcium does not seem to be affected in aging,^{129,137} perhaps contributing to the observed constancy of serum calcium levels.

Phosphorus metabolism also changes with aging. The elderly exhibit decreased renal tubular reabsorption of

phosphate,¹⁴¹ and in experimental animals, decreased intestinal phosphate absorption,¹³⁰ and impaired renal tubular adaptation to dietary phosphate restriction.^{130,142,143} However, as with calcium, these defects do not appear to substantially influence serum levels.

Serum magnesium levels do not change with advancing age.²³ Erythrocyte magnesium content has been shown to increase in elderly women, possibly due to decreased estrogen effect,¹⁴⁴ but no clinical consequences have been identified.

Renal Disease in the Elderly

By itself, age-related loss of functioning nephrons poses little threat to well-being, because even 50% of the normal GFR is ample for sustaining renal excretory function. However, the gradual loss of renal function that accompanies normal aging may be greatly accelerated when surgical loss of renal mass or acquired intrinsic renal disease is superimposed on this process.

The incidence of primary renal disease in the elderly is not significantly different from that in young adults,^{1,145-147} although the preponderance of specific forms of glomerular injury varies in different age groups. Several large series of biopsies in elderly patients have indicated the relative incidence of the major forms of glomerular injury. Data from a survey of 12 published series from 1980 through 1993, representing patients with nephrotic syndrome, were recently tabulated by Cameron,¹⁴⁸ and are summarized in Table 52.2. For comparison, results of a large series of patients undergoing biopsy for various reasons, stratified by age, are depicted in Table 52.3.¹⁴⁹ Although differences in reporting classification make exact comparisons difficult, several general trends are apparent from the published studies. In each of these series, approximately two-thirds of the patients were found to have primary glomerular disease, with the remainder exhibiting glomerular disease secondary to systemic disease, or primary tubulointerstitial diseases. Of the primary glomerular diseases, membranous glomerulonephritis was the most frequent etiology,

followed in varying degrees by proliferative or rapidly progressive glomerulonephritis, and focal glomerular sclerosis. Of note, most of these series found a substantial proportion of minimal change disease. Although most frequently considered to be a disease of children, in whom it comprises the vast majority of glomerular disorders, this glomerular disease may be found in any age group, including the elderly. Other primary glomerular diseases were found relatively infrequently. Thus, the available data indicated that membranous glomerulonephritis is the most common etiology of nephrotic syndrome in the elderly, whereas rapidly progressive glomerulonephritis is the most common cause of an acute nephritic syndrome in the elderly population.

Although the incidence of primary glomerular diseases is not particularly enhanced in elderly patients, the incidence of renal disease secondary to systemic illness such as atherosclerosis, hypertension, cardiac failure, diabetes, and malignancy clearly increases with advancing age.¹⁴⁵ The etiologies of glomerular diseases secondary to systemic disease are also depicted in Table 52.3. Hypertensive nephrosclerosis, which was not listed as an independent category in all series, may be the most frequent etiology in this category. The next most common causes are vasculitis and amyloidosis, which are relatively infrequent in younger patients. Particularly prominent in the elderly are deposition diseases, including amyloidosis, light chain deposition disease, and fibrillary glomerulonephritis.

Acute Renal Failure in the Elderly

Elderly patients are susceptible to all the causes of acute renal failure seen in the general population, and suscep-

TABLE 52.4. Causes of acute renal failure.

Cause	Young patients (n = 67)	Elderly patients (n = 298)
Nephrotoxins	6.8	10.8

tibility to acute renal failure may be enhanced,¹ Presumably, the elderly may be at higher risk for prerenal causes of acute renal failure because of a tendency toward hypodipsia and reduced sodium intake, diuretic administration, and inability to conserve sodium, predisposing to dehydration and sodium depletion. A representative study of the etiology of acute renal failure in 67 young and 298 elderly patients is depicted in Table 52.4,¹⁵⁰ in which volume depletion was deemed primarily responsible in 23.4% of cases in elderly patients. Obviously, preexisting volume depletion would also enhance risk for acute renal failure after administration of contrast agents or nephrotoxic drugs. In addition, advancing age increases risk of acute renal failure associated with surgical complications, aminoglycoside nephrotoxicity, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitor therapy, radiocontrast, and postrenal (obstructive) causes.^{1,151} More recently, 4176 consecutive patients admitted to an acute care hospital were evaluated for the incidence and etiology of acute renal failure.¹⁵² Of these, 1.4% developed acute renal failure in the hospital. Contributing factors were nephrotoxic drugs (66%), sepsis and hypoperfusion (45.7% each), contrast media (16.9%), and postoperative acute renal failure (25.4%). Of these, contrast media, surgery, and drugs each predicted acute renal failure on their own. Mortality in the elderly with acute renal failure was significantly higher than in those without acute renal failure (25.4% versus 12.5%; $p = 0.03$). Sepsis (odds ratio, 43), oliguria (odds ratio, 64) and hypotension (odds ratio, 15) were independent predictors of poor patient outcome.¹⁵²

When the cause of acute renal insufficiency is not apparent, a renal biopsy may be required to make the diagnosis. Recently, the pathologic diagnoses in 1065 consecutive patients over the age of 60 who underwent renal biopsy were reviewed.¹⁵³ Of these 24.3% had a renal biopsy because of acute renal failure. Results of that survey are depicted in Table 52.5.¹⁵³ The most prominent diagnoses, pauci-immune glomerulonephritis and acute

interstitial nephritis, are more frequent in the elderly than in a younger population.

Whether advanced age is an independent risk factor for mortality associated with acute renal failure, dissociable from other systemic illnesses, is not entirely clear.¹⁵⁰ Certain causes of acute renal failure are certainly more frequent in the elderly; these include multiple myeloma; carcinoma leading to obstruction, humoral abnormalities, and risk of nephrotoxicity from chemotherapeutic interventions; polypharmacy with or without inappropriate drug dosing that fails to take into account the marked reduction in GFR in the elderly; obstructive uropathy due to prostatic disease; and atheroembolic renal disease.¹⁵⁰

End-Stage Renal Disease in the Elderly

The number and relative frequency of elderly patients entering end-stage renal disease (ESRD) programs, and the average age of dialysis patients, is increasing each year in the United States, reflecting the aging of the population in general. The average age of patients starting dialysis for ESRD in the United States is now 62 years. In 1998, the last year for which detailed data are available, there were more than 65,000 patients aged 65 to 74 (up from 13,000 in 1991), and more than 45,000 patients aged 75 or older (up from 8,000 in 1991), in ESRD treatment in the United States.¹⁵⁴ Moreover, the median age of hemodialysis patients is continually rising; some 35% of all ESRD patients are now 65 years of age or older, as are 45% of all hemodialysis patients.

Thus, elderly patients comprise an ever increasing percentage of the patients enrolled in treatment for ESRD. Indeed, while such interventions as improved hypertension control and smoking cessation have dramatically lowered the rates of stroke and fatal myocardial infarction, they have had no discernible impact on the incidence of ESRD. In addition to the direct burden of renal disease, the presence of this condition greatly increases

TABLE 52.5. Pathologic diagnoses in elderly patients with acute renal failure.

Diagnosis	Percent of biopsies
Pauci-immune crescentic GN	31.2
Acute interstitial nephritis	18.6
Acute tubular necrosis with nephrotic syndrome	7.5
Atheroemboli	7.1
Acute tubular necrosis alone	6.7
Light chain cast nephropathy	5.9
Postinfectious GN	5.5
Antiglomerular basement membrane antibody GN	4.0
IgA nephropathy or Henoch-Schonlein nephritis	3.6
Nondiagnostic for acute renal failure	9.9

Source: Adapted from Haas, Spargo, Wit et al., with permission.¹⁵³

cardiovascular risk; ESRD at age 75 confers a relative risk of death of just under 3, as compared with the population without renal disease.¹⁵⁵ All projections indicate that these trends will continue. The direct economic costs (\$17 billion in 1998), and the ancillary costs including hospitalization, drugs, disability, and increased cardiovascular risk, together pose a grave challenge for the health care team in the coming years.

Experimental Considerations and Implications for Further Research

The potential mechanisms associated with the normal age-related loss of renal function have been explored in experimental animals, which also exhibit age-related declines in renal blood flow and glomerular filtration rate in association with progressive glomerular sclerosis. The adaptive response to loss of functioning nephrons consists of increases in the glomerular capillary pressures and flows in the remaining functional nephrons, a compensation that serves to preserve total GFR. In the extreme case of extensive surgical removal of renal mass in the rat, the increased filtration in the surviving nephrons is accompanied by systemic hypertension, and progressive azotemia, proteinuria, and glomerular sclerosis. Recent studies using micropuncture techniques have indicated that, at least in some rat strains, development of age-related glomerular injury is associated with glomerular capillary hypertension,¹⁵⁶⁻¹⁵⁸ a hemodynamic abnormality common to many forms of renal disease. As in other diseases, angiotensin-converting enzyme inhibitor delays age-related nephropathy in the rat.¹⁵⁷

Observations in aging humans and experimental animals are highly reminiscent of changes observed in the setting of acquired renal disease, and lend support to the hypothesis that hemodynamic factors in the aging kidney operate in similar, albeit slower, fashion to injure and ultimately destroy the glomerular population. This formulation suggests that age- or disease-related reduction in functioning renal mass, systemic hypertension, conventionally treated diabetes, and ad libitum protein intake all lead to unrelenting vasodilatation. The resulting long-term elevations in glomerular pressures and flows promote hyperfiltration, impair the permselective properties of the glomerular wall, and injure the component cells of the glomerulus. The resulting glomerular sclerosis exerts a positive feedback stimulus to compensatory hyperfiltration in less affected glomeruli, contributing in turn to their eventual destruction. Numerous dietary, endocrine, and toxic factors that may accelerate nephron loss with normal aging or renal disease have been identified,^{1,5,6,159,160} and certain dietary manipulations (particularly dietary protein restriction and total food restriction),^{161,162} as well as angiotensin-converting

enzyme inhibitors¹⁵⁷ and angiotensin receptor antagonists,¹⁶³ have been demonstrated to retard the progression of age-related renal disease in laboratory animals. Given the vulnerability of the aging kidney to acceleration of renal insufficiency after acquired injury, it remains imperative to pay attention to those risk factors (volume depletion, nephrotoxic insults, uncontrolled hypertension, and dietary factors) that may contribute to loss of renal function. Although little information is available specifically addressing these interventions in the elderly population, it seems likely that these hemodynamically protective interventions will prove efficacious in this population as well. With the ever-increasing number of elderly patients entering ESRD programs, clinical studies evaluating these therapeutic interventions in this population at risk are certainly warranted.

Immunology of Aging

Edith A. Burns and James S. Goodwin

Immunologic function is one of the most intensively studied physiologic processes in gerontology, in part because of the explosive growth in all aspects of immunology research in the past several decades and the ease of obtaining immunocytes (lymphocytes, monocytes, and polymorphonuclear leukocytes) for study. There are more fundamental reasons, however, why the study of immunology is particularly relevant to gerontology. Immunologic function declines and becomes dysregulated with age, as do most physiologic functions. Concomitantly, there is a rise in the incidence of many infections and malignancies with age. There is greater morbidity and mortality associated with infections in adults over 65 years of age. Elderly persons respond less well to protective immunizations against common infections such as influenza and pneumococcal pneumonia. Also intriguing are early observations linking changes in immune function with changes in the life span of various animal species. An understanding of immunologic changes might be important not only in understanding the aging process, but also in developing potential strategies to prevent some of the morbidity and other changes that occur with age.^{1,2} This chapter describes changes in the immune system attributed to aging, and tries to give an overall sense of our understanding of aging and immune function at the beginning of the twenty-first century.

Organization of the Immune System

The immune system classically has been divided into the cellular and humoral components, with monocyte and granulocyte function treated separately. The cellular immune response, mediated primarily by T lymphocytes (or thymus-derived lymphocytes), rejects grafts of foreign tissues, kills virus-infected cells, protects against fungi

and some intracellular parasites and bacteria, modulates the immune response to prevent autoimmunity, and (possibly) defends against the growth of tumors (Fig. 53.1). The function of the humoral immune system is the production of antibodies (produced by differentiated B cells, or bone marrow-derived lymphocytes), which are the main defense against bacteria and other infectious agents that gain entry into an organism (Fig. 53.2). Cells of the monocyte-macrophage series, in addition to ingesting or killing foreign material that may or may not have been previously opsonized or coated with antibodies, also play an important regulatory role in both humoral and cellular immune responses.

The distinction between cellular and humoral immunity is in some ways artificial, because both B cells (bone marrow derived) and T cells (thymus derived) can participate in each reaction. For example, although T cells are the effectors of cellular immune responses, they are required for the great majority of humoral (antibody) responses. Although B cells evolve into antibody-producing plasma cells, culminating in the humoral response, they can act as antigen-presenting cells in cellular immune responses. Antibodies can be major participants in specific cytotoxic responses. Thus, the high incidence of anergy to delayed-type hypersensitivity skin testing seen in adults over 60 years of age³⁻⁵ could represent problems with antigen recognition, T-cell proliferation, lymphokine production, lymphocyte or monocyte chemotaxis, vascular responses to inflammatory mediators, or a multitude of other steps that are required to produce induration after an intradermal challenge with antigens. As details of age-related changes in immunity grow in quantity and diversity, it may be easier to broadly categorize them as qualitative or quantitative changes in cell populations and production of or response to macromolecules, rather than as changes in cellular versus humoral immunity.

FIGURE 53.1. Model of the cellular immune system. *Ag*, antigen; *CTL*, cytotoxic T lymphocyte; *IFN*, interferon; *IL*, interleukin; *IL-2R*, interleukin-2 receptor; *M*, macrophage/monocyte; *PGE₂*, prostaglandin E₂; *TH*, T-helper (CD4+) lymphocyte; *THM*, T-helper memory lymphocyte; *TS*, T-suppressor (CD8+) lymphocyte; *TSM*, T-suppressor memory lymphocyte; *TV*, virgin T lymphocyte; *TNF*, tumor necrosis factor.

Changes in Immune Function with Age: Lymphocytes

T Lymphocytes

There are varying reports on quantitative declines in different T-cell populations in aging humans and experimental animals. Studies using monoclonal antibodies to various receptors on T-lymphocyte membranes have shown a consistent decline in "virgin" or reactive T cells and an increase in "memory" or inert T cells in both helper and suppressor cell subpopulations.^{2,6-8} Memory T cells from aged individuals produce smaller amounts of interleukin 2 compared to young memory cells, whereas the smaller proportion of virgin T cells produce greater amounts of interleukin 2 than naïve cells from young animals.⁹ On a more fundamental level in both animals and humans, there seems to be a loss of stem cell potential to generate T cells.^{10,11}

One of the earliest changes reported in qualitative T-lymphocyte function was the decline in proliferative response to mitogens.^{3,12,13} In these assays, lymphocytes are isolated from peripheral blood and cultured in media with mitogens, such as phytohemagglutinin (PHA) or pokeweed mitogen, which nonspecifically activate most lymphocytes. The degree of the proliferative response is quantified by adding radiolabeled thymidine to the cultures, harvesting the cells, and measuring the amount of radioactivity incorporated into the lymphocyte DNA. The proliferative response of lymphocytes to specific antigens or nonspecific mitogens is thought to be the *in vitro* correlate of delayed-type hypersensitivity skin testing. Our study of 300 healthy elderly people showed a substantial decrease in response to phytohemagglutinin (PHA) with age.⁴ The mean response of the elderly subjects was significantly less than the mean response of the young control subjects to all mitogen doses. PHA responses were also measured in 24 chronically ill patients over 65 years of age who had a variety of life-threatening medical conditions and who were receiving a number of medications. The responses of this chronically ill group were not different from those of the healthy group. Thus, age *per se*, and not an accompanying illness, was the major determinant of depressed cellular immunity in this population.

Hyporesponsiveness to mitogens is the sum of several deficiencies.¹³ First, the number of mitogen-responsive cells is reduced in lymphocyte preparations from elderly persons. Second, the mitogen-responsive cells from elderly persons do not proliferate as vigorously after exposure to PHA as do lymphocytes from young persons. In old compared to young mice, a smaller percentage of T splenocytes respond to mitogenic stimulation by entering active phases of cell replication.¹⁴ This defect was noted for CD4+ T-helper cells and, to a lesser extent, for

CD8+ T-suppressor/cytotoxic cells. The smaller proportion of cells entering active phases of replication is regulated by a balance between genes that stimulate DNA replication and genes which inhibit DNA replication and lead to programmed cell death, or apoptosis.^{15,16} Lymphocytes from old donors have a deficit in expression of genes that stimulate DNA synthesis, coupled with decreased proliferative responses.^{17,18}

T-helper cells from old mice are less capable of generating cytotoxic effector cells to participate in delayed hypersensitivity reactions.¹⁹ More clinically relevant are studies showing a decreased cytotoxic response to influenza vaccination in old adults, with fewer T-cell subsets able to respond to influenza antigen.²⁰⁻²² Old mice are more likely than young mice to develop influenza pneumonia after intranasal inoculation, have impaired cytotoxic T-cell function, and generate ineffective antibody, even in the face of prevaccination.²³ Cytotoxic lymphocytes from aged mice are less able to bind targets, although they appear to be equally effective in destroying their targets.²⁴

The role of T-cell lymphocytes in supporting *in vitro* antibody production appears to change with increasing age. Lymphocytes from older subjects produce greater amounts of IgG and IgM when cultured with pokeweed mitogen than lymphocytes from young control subjects.²⁵ When lymphocytes are separated into T-cell and B-cell fractions and various combinations of old T cells are cultured with old B cells, old T cells with young B cells, and so on, the old T cells are more capable than the young T cells of supporting immunoglobulin production by either young or old B cells.^{26,27} This increased helper activity of the old T cells could result from an actual increase in helper activity or a decrease in suppressor activity. This question was addressed by studying the effects of irradiation of T cells, taking advantage of the fact that suppressor T cells are sensitive to low doses of irradiation whereas helper T cells are relatively radioreistant. Irradiation of T cells from elderly people resulted in smaller increases in immunoglobulin production in subsequent cultures than did irradiation of T cells from young people.²⁵ This finding suggests that the overall increase in T-cell helper function with age actually was, at least in part, caused by a failure of suppressor cell function.

Failure of tonic inhibition by suppressor T cells is a possible mechanism accounting for the increased incidence of autoimmune antibodies seen in aging. Healthy humans have circulating B cells that are programmed to differentiate into autoantibody-producing plasma cells (producing antinuclear, antithyroid, antimitochondrial, and other antibodies). Suppressor T cells are important in modulating these normal humoral immune responses and preventing the development of autoimmunity. Many investigators have reported an increase in the prevalence

of positive tests for various autoantibodies with age (antinuclear antibodies, rheumatoid factors, antithyroid antibodies, antismooth muscle antibodies, and anti-lymphocyte antibodies), with a steep rise in prevalence around 70 years of age.^{4,28} The rise in the presence of autoantibodies in elderly persons has been correlated to the decreased ability of T cells to proliferate in response to the mitogen PHA²⁹ (i.e., the higher the proliferation of T cells to mitogens, the lower was the level of autoantibodies). T-suppressor cells from old adults proliferate less and exert suppressor effects less effectively than those from young adults.^{25,30-32} In mice, declines in T-suppressor cell function with age have been associated with the development of oral tolerance.³³ Age-related changes in T lymphocytes are summarized in Table 53.1.

B Lymphocytes

Although the number of circulating B cells does not change appreciably with age,¹ there are alterations in the ratios of surface immunoglobulin and class II molecule expression on the cell surface.³⁴ Bone marrow precursor cells from old mice are impaired in their ability to generate B cells.³⁵⁻³⁷ Similar to studies in T cells, B cells from old individuals proliferate less efficiently, and fewer cells enter active phases of replication.^{38,39} Some of the early steps in cell activation are reduced in B cells from old humans⁴⁰ (see following).

The functional ability of B cells to mount appropriate antibody responses does change with age.⁴¹ The distinction between antibody responses to T-cell-dependent and T-cell-independent antigens (often made in mice, but less clear in humans) is made on the basis of whether there is an absolute requirement for T-cell help in the antibody response. In experimental animals, the decrease in T-dependent antibody responses is more obvious, with an 80% decrease in antibody-forming cells in older animals.^{2,3} The repertoire of B cells appears to change with aging, resulting in an altered ability to recognize

antigens.^{32,42} Compared to young animals, old mice develop much larger numbers of immunoglobulin-secreting cells that react with self-antigens after immunization with sheep red blood cells.⁴³ The accumulation of anti-idiotypes (antibodies directed against other antibodies) with increasing age may also interfere with the production of specific antibody.^{44,45}

The ability to respond to a specific antigenic challenge with specific antibody production is decreased in aging.^{41,46} Defects in the primary response to flagellin immunization were found in old subjects, who attained similar peak titers of IgG and IgM antibodies but failed to maintain the same levels of IgG antibody over time.⁴⁶ We studied a group of 77 healthy older adults not taking any medications who were participating in a larger study of emotions and health behavior. The older adults were less likely to show an *in vivo* response to immunization with the primary antigen, keyhole limpet hemocyanin, than a group of healthy young control subjects.⁴⁷ In contrast, old subjects meeting rigorous health inclusion criteria⁴⁸ developed similar numbers of antibody-producing cells after immunization with *Helix pomatia* hemocyanin as did young controls.⁴⁹

Following *in vivo* immunization, serum antibody levels are significantly lower in old than in young adults.⁵⁰⁻⁵² The antibody isotypes that are important in the agglutination response against influenza are lower in old adults after immunization.⁵¹ Kishimoto et al.⁵⁰ studied specific antitetanus toxoid antibody production and found evidence of declining B-cell function in adults over age 65 years.⁵⁰ Purified B cells from elderly or young subjects were cultured with T cells from a young individual who had been immunized with tetanus toxoid a week before. The B cells from the older subjects made significantly less antibody to tetanus toxoid than those from the younger subjects. We also have examined changes in tetanus toxoid-specific antibody production in elderly humans by stimulating lymphocytes from adults of different ages with tetanus toxoid *in vitro* and measuring the amount of antitetanus toxoid antibody produced.⁵² Regardless of the time elapsed since the last booster immunization, the old adults had significantly lower serum levels of antibody to tetanus toxoid. *In vitro*, old adults had fewer B cells that produced antitetanus toxoid antibody, and each cell produced significantly less antibody than the B cells from young adults. In these studies, the number of antitetanus toxoid precursor cells in the peripheral blood of the older subjects was more than a log magnitude lower than it was in the younger subjects. Thus, the lack of precursor cells with the ability to respond to a specific antigen was primarily responsible for the decreased specific antibody production against tetanus toxoid.⁵² Immunizing the subjects with tetanus toxoid led to an increase in the numbers of B cells producing antitetanus toxoid antibody for both age groups. However, the old adults still had sig-

TABLE 53.1. Changes in T lymphocytes with age.

TABLE 53.2. Changes in B cells with age.

Decreased surface MHC class II molecule expression
Decreased proportion of cells capable of clonal expansion
Decreased number of bone marrow precursors
Decreased number of T-cell-dependent antibody-forming cells
Decreased specific antibody production to primary and secondary antigens
Decreased potency
Decreased antigen recognition
Decreased affinity of antibody for targets
Increased anti-idiotypic antibody production

MHC, major histocompatibility complex.

nificantly fewer B cells producing specific antibody than did the young adults.⁵³ Booster immunizations did not alter the mean amount of antibody produced per B cell for either age group.

Although most investigators agree that the observed changes in antibody production are the result of declines in T-lymphocyte function, there is evidence for a decline in intrinsic B-cell function. Findings from our laboratory and others suggest a diminished ability of purified B cells to respond to isolated T-helper cells or to T-cell-derived helper factors.^{26,54,55} In old mice, some subsets of B cells function at a much lower level than the same cells from young mice.⁵⁶ Compared to young animals, old mice vaccinated with phosphorylcholine generate similar levels of antibody against *Streptococcus pneumoniae*, but the variable heavy portions of the antibody molecules are different.^{57,58} The antibodies produced have lower affinity for the target bacteria and confer less protection.^{58,59} Age-related changes in B-cell function are summarized in Table 53.2.

Macrophage Function

Macrophage function in aging has not been as well studied as other lymphocyte subpopulations. Early work suggested that they appear to produce similar levels of cytokines^{60,61} and that differences in immune function between age groups may be modulated through changes in T- and B-cell responses to these substances. More recent studies have challenged this concept, showing decreased interleukin 1 secretion with mitogen stimulation.⁶² Studies of cutaneous wound healing in old mice also suggest declines in macrophage function with age, as healing took twice as long in old as in young mice.⁶³ Adding peritoneal macrophages from young and old animals to wounds on old mice sped healing, but macrophages from young mice accelerated the healing process to a greater degree.⁶³ Studies of the bone marrow in senescence-accelerated mice give some evidence that stem cells are defective in their ability to generate granulocyte-macrophage precursor cells.⁶⁴

There appear to be defects in macrophage–T cell interactions in old animals and humans. Antigenically sensitized macrophages from old mice stimulate significantly lower levels of T-cell proliferation than young macrophages.⁶⁵ Dendritic cells (fixed macrophages) from old adults are significantly compromised in their ability to stimulate formation of germinal centers in lymph follicles where B-cell memory develops.⁶⁶ By replacing macrophages with other sources of activation, T cells from old adults are able to function at the same level as young T cells, suggesting that the defect may lay in macrophage–T cell communication.⁶⁷ Monocytes from old adults display lower cytotoxicity against some tumor cell lines and produce lower levels of reactive oxygen intermediates and lower levels of interleukin 1.^{62,68}

Natural Killer Cell Function

Natural killer cells (NK) are cytotoxic cells that are able to lyse targets without the need for antigenic sensitization, differentiating them from cytotoxic T cells. Lymphokine-activated killer cells (LAK cells) are thought to be highly activated NK, and are able to lyse certain cell lines that are resistant to NK. Murine NK show an age-related decline in their ability to lyse spleen cells.^{69,70} Most early studies showed little change in NK cytotoxic ability with age,⁷¹ in contrast to more recent work. The actual number of NK cells seems to increase with age, while cytotoxic activity decreases,^{72,73} probably due to increased expression of receptors that downregulate activity.⁷⁴ There may also be differential requirements for maximal activation of NK by interferon-alpha, with young cells showing maximal responses at lower concentrations of this cytokine.⁷⁵ Old adults with a deficiency of growth hormone have less active NK, which can be partially restored in vitro by exposing cells to the hormone's precursor protein.⁷⁶ The activity of LAK also may be reduced in aged compared to young humans.^{71,75}

Lymphocyte DNA

X chromosomes of T cells from old adults are more fragile than those from young adults,⁷⁷ and certain sites on the X chromosome have been shown to be more sensitive to chemical insults. Humans over age 55 exposed to radiation in vivo have lymphocytes that mount poor cellular responses as opposed to humans exposed to radiation when under the age of 15.⁷⁸ These results may reflect the increased susceptibility of the aging immune system to radiation. When examining the sensitivity of lymphocyte DNA to irradiation, there were actually fewer breaks in double-stranded DNA in lymphocytes from old adults, but the cells had a significantly reduced ability to repair

these breaks compared to lymphocytes from young donors.⁷⁹ Other investigators have looked at sister chromatid exchange, a measure of DNA damage, in healthy old individuals and newborns.⁸⁰ The basal frequency of sister chromatic exchange was 10 times greater in lymphocytes from the old subjects.

Cell Activation and Membrane Signal Transduction

The proliferative response of T cells to various stimuli results from a complex set of interactions involving T cells and macrophages or other accessory cells. Mitogens such as PHA bind to, cross-link with, and thereby activate the T-cell antigen receptor; this results in activation of phospholipase C, cleavage of membrane phosphatidylinositol phosphates, and liberation of inositol bisphosphate and diacylglycerol. Inositol bisphosphate and its metabolites, inositol triphosphate and tetra-kisphosphate, raise intracellular free calcium concentrations by releasing bound calcium from intracellular stores and by opening calcium channels.⁸¹⁻⁸³ Diacylglycerol binds to and activates protein kinase C, which is further activated by the increased free calcium concentration. At least two families of protein kinases, protein phosphate kinases and protein tyrosine kinases, play a role in cell activation.

Protein kinase activation stimulates transcription and subsequent translation of the gene coding for interleukin 2 (also known as T-cell growth factor) and also of recep-

tors for interleukin 2. Interleukin 2 is thus an autocrine growth factor, produced by the same cells that respond to it. Exposure of interleukin 2 receptor-bearing T cells to interleukin 2 results in proliferation. Monocytes assist T cells in producing and responding to interleukin 2 by presenting antigen that occupies and cross-links T-cell receptors. The antigen-presenting cells secrete a variety of cytokines that provide additional signals necessary for complete T-cell activation. A model of T-cell activation is shown in Figure 53.3.

Several laboratories have investigated whether the decreased proliferative response of lymphocytes from old animals and adults is due to impaired membrane signal transduction in response to various stimuli. Investigations using mouse T cells have found an association between decreased calcium metabolism and defective proliferation in some strains with old age.^{6,84} When T cells from old mice are stimulated with mitogens, the rise in intracellular calcium is generally lower than that seen in cells from young mice.⁸⁵ Although no change in inositol triphosphate levels was observed in these studies, it was reduced in a different assay system using human peripheral blood neutrophils.⁸⁶

Those T lymphocytes from old mice that retain the ability to proliferate to PHA have normal or enhanced mobilization of calcium compared to cells from young animals.⁸⁷ Work with human peripheral blood lymphocytes and isolated T cells has shown contrasting results, indicating that decreased calcium mobilization was a factor in some T-cell subpopulations but not others.^{2,33,88}

Compared to young donors, monocyte-depleted lymphocytes from old donors displayed decreased cell-cell binding, a calcium/magnesium-dependent interaction.⁸⁹

Other steps in the signal transduction cascade are altered with aging. Protein kinase activation by mitogens is significantly reduced in cells from old humans.⁹⁰ In particular, levels of protein kinase C- α are reduced,⁹¹ as well as the level of phosphorylation of the protein phosphokinases⁹² and protein tyrosine kinases.⁹³ The activation of protein kinase C and the protein tyrosine kinases also appears to be reduced in B cells from old humans.⁴⁰ The transcription of nuclear factors is also decreased, and correlates with reduced production of interleukin 2.⁹⁵

Production of and Response to Immunoregulatory Factors

Many of the changes in cell function already described may be secondary to age-related changes in sensitivity to a variety of other endogenously produced substances. For example, circulating trough cortisol levels appear to increase with age,⁹⁶ resulting in a flattening of the amplitude of diurnal variation of this hormone. Altered sensitivity to glucocorticoids may contribute to poor responses of aged mice to novel immunogens.⁹⁷

Prostaglandins

Arachidonic acid metabolites have been implicated in age-related changes in humoral immunity. Prostaglandin E₂ is a feedback inhibitor of T-cell proliferation in humans,⁹⁸ and T cells from adults over 70 years of age are much more sensitive to inhibition by prostaglandin E₂.^{99,100} Thus, prostaglandin E₂ may interfere with the expansion of antigen-specific T-cell helper clones. Recent studies have shown not only greater depression of proliferation and interleukin 2 production in T cells from old mice, but also age-related increases in production of prostaglandin E₂ by splenocytes from old mice compared to young mice.^{101,102} Old macrophages produce more cyclooxygenase, the enzyme that metabolizes arachidonic acid into prostaglandins.¹⁰³

Increased sensitivity to prostaglandin E₂ was the cause of an impaired primary antibody response of lymphocytes from older adults that were cultured with trinitrophenylated polyacrylamide beads.⁶⁰ Removing monocytes (the source of prostaglandin E₂ production) or adding drugs that blocked the production of prostaglandin E₂ partially reversed the depressed response of lymphocytes from older subjects.^{60,99} In contrast, other investigators have not found increased prostaglandin production by unstimulated or mitogen-stimulated lymphocytes from old versus young donors,

nor suppression of nonspecific antibody production by prostaglandin.¹⁰⁴

The increased sensitivity with age to prostaglandin E₂ would not appear to be part of a general increase in sensitivity to all immunomodulators. Lymphocytes from subjects over 70 years of age actually are less sensitive to inhibition by histamine and hydrocortisone than are lymphocytes from young control subjects.¹⁰⁰

Interleukins

Accessory cells such as monocytes help T cells produce and respond to interleukin 2 by cross-linking T-cell receptors. They secrete interleukin 1 and other monokines that provide additional signals necessary for complete activation of T cells (see Fig. 53.3). The response to interleukin 2 has been extensively studied as one mechanism underlying the age-related defect in cellular immunity. Several laboratories have demonstrated decreased production of interleukin 2 after mitogen stimulation and a decreased density of interleukin 2 receptor expression and decreased proliferation of these cells in response to interleukin 2.^{22,105-108} Additional experiments in rodents suggest that the picture might be more complex, with specific defects in production of or sensitivity to interleukin 2, depending on the immunologic stimulus.^{109,110} Other investigators have shown that lymphocytes from aged rats are defective in their ability to express messenger RNA for interleukin 2.¹¹¹ Some studies have found no differences in T-cell proliferation or interleukin 2 production when stimulating memory T cells from old and young donors.¹¹² Helper T cells from old mice accumulated similar levels of interleukin 2 transcripts, although they secreted lower levels of interleukin 2.¹¹³ Studies at the molecular level suggest that induction of interleukin 2 involves activation of a complex cascade of cell receptors and gene families.¹¹⁴ The somewhat conflicting results may be explained by the different systems and substances utilized by different investigators, resulting in differential activation at various steps in the activation pathway.

Interleukins 1 and 2 play a role in activation, recruitment, and proliferation of T lymphocytes. These activated T cells go on to produce a variety of cytokines including B-cell growth and differentiation factors such as interleukin 4, interleukin 6, and gamma-interferon. Experiments with rodents provide evidence that lymphocyte production and response to other cytokines, such as interleukin 1 and tumor necrosis factor, are also defective in aging.^{2,115} Monocytes from old adults secrete less interleukin 1 when stimulated with the mitogen lipopolysaccharide, although they produce comparable amounts of interleukin 1 precursor.⁶⁸ When lymphocytes from old adults are mixed with cells from other donors, they produce higher levels of interleukin 1, interleukin 2, and tumor necrosis factor- α (TNF- α) than cells from

young adults.¹¹⁶ In vivo circulating levels of interleukin 1 may increase with age.¹¹⁷

In some studies, lymphocytes from old animals display a lower stimulatory response than when interleukin 4 is added to lymphocytes from young mice,¹¹⁸ and B-cell proliferation to interleukin 4 and anti-IgM is significantly lower in old mice than in young mice.¹¹⁹ Memory T cells from old mice produce less interleukin 4 than memory cells from young mice.¹²⁰ We have shown that lymphocytes from old adults produce less interleukin 4 when stimulated by specific antigen than lymphocytes from young adults, and are less sensitive to inhibition of specific antibody production when interleukin 4 is added early in the course of stimulation with specific antigen.¹²¹ This finding is similar to findings in murine models.¹²² Again, seemingly contradictory findings have been reported in other systems, with either similar or increased production of interleukin 4 by aged cells^{117,123} and higher percentages of aged cells participating in production of interleukin 4.¹²⁴

Interferon-gamma (IFN- γ) can have a differential effect on NK activity, depending on the age of the donor.⁷⁵ NK cells from old adults secreted less IFN- γ than those from young adults.¹²⁵ Lymphocytes from old rats produced smaller amounts of IFN and interleukin 2 when stimulated with concanavalin A.¹²⁶ Others found no relationship between the degree of lymphocyte proliferation to mitogen and the production of IFN- γ .¹²⁷ In this system, cells from old donors were more sensitive to IFN- γ and interleukin 2. Several other investigators have reported increased IFN- γ mRNA¹²⁸ and IFN- γ production by old T cells and lymphocytes.¹²⁸⁻¹³⁰

Several investigators have described elevated in vivo blood levels of interleukin 6 in old mice, monkeys, and adults¹³¹⁻¹³³ whereas some found no differences.¹³⁴ In vitro, peritoneal macrophages from old mice stimulated with the mitogen lipopolysaccharide, and human B cells, produce higher levels of interleukin 6 than macrophages from young mice.¹³⁵ Interleukin 6 levels are elevated in 24-h, unstimulated culture supernates of lymphocytes from murine spleen and lymph nodes and in peripheral blood mononuclear cells from old humans compared to their young counterparts.¹³¹ Other investigators did not find differences in interleukin 6 production in vitro.¹²³ Newer investigations utilizing flow cytometry have detected greater intracellular increase in interleukin 6 in T cells from old versus young donors.^{117,136,137}

Production of interleukin 8 (neutrophil chemoattractant) by old lymphocytes may be decreased, although this unresponsiveness was observed primarily in cells from male donors.¹³⁸ Interleukin 5 has been little studied with aging, but at least one study has reported increased production by lymphocytes from old mice.¹³⁹

The balance between interleukins 10 and 12 is important in determining different patterns of cytokine

secretion, with interleukin 10 leading to production of cytokines stimulating B-cell differentiation and antibody production and interleukin 12 leading to production of cytokines stimulating cytotoxic T cells and a cellular immune response (see Fig. 53.3). Cells from old humans have been reported to produce greater levels of interleukin 10 than cells from young humans.^{117,140} The increased susceptibility of old mice to infection with *Mycobacterium tuberculosis* is associated with lower levels of interleukin 12 production in the lung.¹⁴¹ There appears to be a delay in the emergence of IFN- γ -secreting T cells, and these cells are slower in expressing surface adhesion markers that allow migration across endothelial linings to sites of active infection.¹⁴² Other cytokine alterations may contribute to increased spread of the disease in old animals.¹⁴³ T cells from young mice are able to protect old mice from infection, suggesting that old macrophages function adequately.^{144,145}

At this point, it is unclear which of the age-related changes in cytokine production is the most critical. The defects in interleukin 2 production may well account for some of the fundamental changes in lymphocyte function and have been linked to increased susceptibility to disease. It might be that changes in *patterns* of cytokine production are more important, as these patterns induce commitment to a TH 1 (cellular) response as opposed to a TH 2 (humoral) response. There continue to be conflicting reports as to which pathways are predominant in normal aging.^{146,147} Age-related changes in interleukins are summarized in Table 53.3.

Stress, Immunity, and Aging

It has long been known that stress affects the occurrence of disease. Investigators in the field of physiologic psychology have described complex and direct links between the perceptual capabilities of the central nervous system and the immune system. For example, it is possible to elicit specific immune responses in animals with sensory cues. Ader and Cohen have performed a series of elegant taste-aversion learning experiments in rats.¹⁴⁸ In one of these studies, a flavored substance, saccharin water, was administered to the animals along with a dose of cyclophosphamide. Several days later, the animals were injected with sheep red blood cells, with or without readministration of the saccharin solution. Animals given the saccharin had profound suppression of the hemagglutination response to the sheep red blood cells.

The neurohumorally mediated effects of stress on the immune system have been well demonstrated in carefully controlled experiments with animals.¹⁴⁹ In primates, levels of cortisol and complement factors are profoundly affected by a single stressful event.¹⁵⁰ Studies in humans have demonstrated similar effects, although it is impossi-

TABLE 53.3. Changes in interleukins with age.

Decreased	Increased or unchanged
Expression of IL-2 mRNA	In vivo levels of IL-6
Proportion of cells expressing IL-2R	Nonspecific stimulation of T-cell IL-4 and IL-6

ble to achieve the same degree of control as in the animal studies. Correlational studies have found that clusters of illness (from the common cold to cancer) occur around the time of major life changes.¹⁵¹ Others have found strong correlations between loneliness and decreased proliferative responses of lymphocytes to mitogens, decreased natural killer cell activity, and impaired DNA splicing and repair in lymphocytes.^{151,152} We found that healthy adults over the age of 60 years with a strong social support system (i.e., a close confidant) had significantly lower serum uric acid levels and cholesterol levels, greater total lymphocyte counts, and a stronger immune response (mitogen-induced proliferation of lymphocytes) than those without such a relationship.¹⁵³ Indeed, being married has been correlated with lower mortality from any cause, in contrast to being single, widowed, or divorced.¹⁵⁴

Quasi-experimental or “natural” experiments also have linked stress to depressed immune function and illness. Depressed lymphocyte proliferation in response to mitogens after bereavement has been described.¹⁵⁵ The stress of final examinations has been correlated with the recurrence of herpes simplex type 1 cold sores and rises in serum antibody titers against the virus¹⁵⁶ and with decreased proliferation of memory T cells.¹⁵⁷ Persons experiencing the stress of caring for a spouse with dementia have poorer antibody responses to influenza vaccination than age- and sex-matched controls.¹⁵⁸ Their lymphocytes make less interleukin 1-beta and interleukin 2 when exposed to influenza virus in vitro.¹⁵⁸ The caregivers also showed delayed wound healing after skin punch biopsy compared to controls.¹⁵⁹

Old age is associated with a greater frequency of major life changes, such as loss of spouse or close friends and changes in lifestyle resulting from retirement. Because of the decreased reserve in immune function with aging, elderly persons may be more sensitive to the effects of such stressful life events.

Immunologic Function, Morbidity, and Mortality

Despite vigorous investigation in the field of immunology, evidence that links depressed or disordered immune function in humans directly to subsequent morbidity or mortality is still scarce. There certainly is evidence that disruption of immune function can result in serious disease, of which the AIDS epidemic is a glaring example. The question of whether decreased immune responses contribute to morbidity and mortality in elderly persons has been addressed by looking for associations between abnormalities in a particular immune response and health status. Several studies have found an association between the response to delayed-type hypersensitivity skin tests and mortality. Elderly subjects who are anergic (responding poorly or not at all to a battery of antigens placed intradermally) have an increased risk of mortality compared to elderly subjects who respond well to one or more of these antigens.^{3,160} In our studies of healthy elderly individuals in New Mexico, approximately one-third were anergic at initial testing.⁴ The anergic group had about a twofold higher mortality rate and also a twofold higher incidence of pneumonia during 8 years of follow-up.¹⁶⁰

A similar study examined the in vitro correlate of delayed hypersensitivity skin testing, lymphocyte proliferation in response to mitogens, in a group of 403 adults over the age of 65 years.¹² In this group of community-living adults seen in an outpatient geriatric clinic, 18% had lymphocytes that did not respond to any of three mitogens. A 3-year follow-up found a significantly greater mortality rate among those with no response than among those with a positive response, 26% versus 13%. The increase in overall mortality was not due to an increase in one particular cause of death, such as infection or malignancy, and this increase remained significant after the

investigators controlled for medication use, an indirect indicator of health. Clarkson and Alexander demonstrated that vasectomies led to accelerated atherosclerosis in monkeys who were fed a high-fat diet.¹⁷⁴ Monkeys who were vasectomized and maintained on a very low fat, no-cholesterol diet still had an increased incidence of atherosclerosis at autopsy 9 to 14 years later compared with nonvasectomized control monkeys.¹⁷⁴ Thus, a very mild stimulus for autoantibody formation leads to accelerated atherosclerosis even without an atherogenic diet. This evidence provides a strong theoretic basis for proposing that autoantibodies and the resultant circulating immune complexes in humans, by causing a low level of chronic irritation in blood vessels, contribute to the development of atherosclerosis. Indeed, histologic examination of atherosclerotic blood vessels from humans reveals increased lymphocyte and cytokine infiltration in areas of plaque formation.¹⁷⁶

There are epidemiologic data supporting a link between autoimmunity and atherosclerosis in humans. Mackay and his colleagues found an association between the presence of autoantibodies and the presence of cardiovascular diseases in the adult population of Busselton, Australia.¹⁷⁷ The presence of autoantibodies in the same adults was associated with an increased risk of death due to vascular disease and cancer during 6 years of follow-up.¹⁷⁷

Reversal of Age-Related Immunodeficiency: Mechanistic Theories

Studies of substances that reverse age-related immunodeficiencies suggest mechanisms that might underlie these changes. One point to keep in mind is that different physiologic systems can display different levels of defect within a single individual and do not appear to be synchronized with each other.^{2,45} Immunomodulating substances may affect only some systems and not others. A few more recent studies have added weight to the association between age-related declines in immune measures and mortality.^{4,160-163}

As mentioned earlier, one function of the immune system may be to protect against the development of cancer. Early theories of "immune surveillance" proposed that the cellular arm of the immune system was constantly surveying for and eliminating malignancies and that the development of cancer represented a failure of this system.¹⁶⁴⁻¹⁶⁶ If this is indeed the case, elderly persons or those with depressed immune function should have a higher incidence of malignancy. Indeed, advanced age is one of the strongest risk factors for the development of cancer.^{167,168} However, the lack of a generalized increase in most malignancies among immunosuppressed

individuals has thrown this theory into relative disrepute.¹⁶¹ However, there continue to be observations in animal models of cancer that link age-related immune changes to malignant progress, particularly malignant transformation of B cells.¹⁶⁹⁻¹⁷¹ It is most likely that age-related changes in immune function influence the expression and progression of malignancy, rather than acting as a direct cause of cancer.

Other evidence that links disordered immune function to disease and death concerns the possible role of autoantibodies and circulating immune complexes in the etiology of atherosclerosis. It has been recognized for many years that circulating immune complexes produced by repeated injections of a foreign antigen can cause an acute arteritis. There is also evidence suggesting that the chronic atherosclerosis associated with the acute autoimmune arteritis is exacerbated by an atherogenic diet.^{172,173} The links between autoimmunity and atherosclerosis have been demonstrated in primates, as well as in rodents.^{174,175} Vasectomy is a mild stimulus for autoantibody and circulating immune complex formation, with antisperm antibodies developing in about 50% of all vasectomized human males and experimental animals.¹⁷⁵ Associated with declines in T-cell function, is the involution of the thymus with subsequent loss of thymic hormone influences.¹⁷⁸ Thymic lymphatic mass, particularly in the cortical area, decreases with age in humans and experimental animals, starting in adolescence. The thymic mass of aging humans and experimental animals is approximately 10% that of a younger thymus.¹⁷⁹ In spite of this involutinal process, the remaining thymic tissue from old animals maintains its ability to generate new T cells.¹⁸⁰

Associated with the loss of thymic mass is a decreased output of thymic hormones, such as thymosin.¹⁷⁹ Exposing lymphocytes of old individuals to thymic hormones either in vivo or in vitro has resulted in at least partial restoration of immunity on a temporary basis.¹⁸¹⁻¹⁸⁵ Administering thymopentin to aged mice increased their resistance to cutaneous *Leishmania* infection.¹⁸⁶

Several other hormonal substances whose in vivo production declines with age have been studied for their potential to reverse age-related immune dysfunction. Melatonin, a pineal hormone with free radical-scavenging, antioxidant properties, displays age-related declines in production.¹⁸⁷ Administration of melatonin to old mice increases antibody production, T-helper cell activity and interleukin 2 production.¹⁸⁸ Administering interleukin 2 and melatonin to humans before surgical treatment of gastrointestinal cancer resulted in increased numbers of lymphocytes, T cells, and T-helper cells after surgery.¹⁸⁹ Perhaps more clinically relevant, the combination of interleukin 2 and melatonin appeared to result in at least partial tumor regression and enhanced 1-year sur-

vival of patients with some metastatic solid tumors compared to supportive care alone.¹⁹⁰

Growth hormone and its precursor, insulin-like growth factor 1, have immunoenhancing effects, including stimulation of phagocytes and production of cytokines, which may help protect against bacterial infection.¹⁹¹ Old patients with growth hormone deficiency have lower NK activity, and this can be partially restored by exposing NK cells to the precursor protein *in vitro*.⁷⁶ By contrast, administering growth hormone to healthy old women for 6 months did not change proliferative responses of lymphocytes or the mean number of virgin T cells compared with untreated controls.¹⁹²

Dehydroepiandrosterone (DHEA), the most abundantly produced adrenal steroid, is another substance whose endogenous levels appear to decline with age. When DHEA is administered *in vivo*, it augments antibody production by upregulation of T-cell subsets associated with increased antibody production.¹⁹³ When aged mice are pretreated with DHEA, they display enhanced responses to vaccination with hepatitis B surface antigen and influenza vaccination, as well as increased resistance to infection with influenza.^{194,195} Old humans who received oral DHEA before influenza vaccination displayed a fourfold increase in hemagglutinin inhibition titers compared to untreated elderly individuals.¹⁹⁶

Often the most intriguing scientific discoveries are those that also are without an obvious practical consequence. An early example was the discovery by McCay and his colleagues in 1935 that caloric restriction of experimental animals markedly prolonged their life span.¹⁹⁷ Restricting total caloric intake to 50% to 60% of that which is required to maintain normal growth in adolescent mice, rats, and guinea pigs resulted in approximately 50% prolongation of the total life span of animals that survived the 6- to 12-month period of restriction. This interesting medical oddity received little attention over the next three decades until other investigators showed that the early starvation of experimental animals resulted in a preservation of normal immune function into old age.¹⁹⁸ Similar effects have been observed with lesser degrees of caloric restriction.^{199,200} In contrast to the studies on protein-calorie restriction in animals, nutritional deficiencies in humans are generally associated with poor immune responses.²⁰¹ In both nutritionally deficient and healthy elderly adults, caloric supplements and supplementation with vitamins and trace elements have been associated with enhanced immune responses, better responses to vaccines, and fewer days of infectious illness.^{202,203} Rasmussen et al. provided "reverse" support for the role of nutrition in immunocompromise by noting significant declines in NK activity in older men ingesting a diet high in polyunsaturated fatty acids.²⁰⁴

There has been a tremendous upsurge in interest in antioxidants as potential "antiaging" treatments. Much

of this interest is based on solid laboratory-based and epidemiologic and clinical evidence. Some of the most intriguing data involve the effects of vitamin E administration on immune function in old experimental animals and, more recently, in older men and women.^{205,206} Supplementation with 400 to 800 U of vitamin E in healthy elderly subjects results in improved immune parameters such as response to delayed-type hypersensitivity skin testing and increased production of interleukin 2 *in vitro*.^{207,208} Vitamin E may cause these effects via inhibition of suppressive factors such as prostaglandin E₂.²⁰⁵ The most dramatic demonstration of antioxidant effects was in a report by Chandra, who conducted a placebo-controlled, double-blinded trial of supplementation of healthy older men and women with a multiple vitamin containing the recommended daily allowance for most vitamins with the exception of vitamin E and beta carotene, which were at about four times the upper quartile of usual intakes.²⁰³ Supplementation was associated with marked increases in various parameters of immunity. More importantly, the supplemented group had only half the number of days with infection and 60% of days taking antibiotics during the 1-year trial.²⁰³ If these remarkable results can be reproduced in other populations, it will have major implications for recommendations on appropriate intake of the antioxidant vitamins. Although two large studies looking at antioxidant supplementation found a higher incidence of lung cancer in heavy smokers taking beta carotene, vitamin E supplementation was not related to an increased incidence of lung cancer.^{209,210}

Another potential means of reversing or improving age-related declines in immunity is by administering drugs that stimulate immune function in one way or another. Prostaglandin synthetase inhibitors, such as the nonsteroidal antiinflammatory drugs (NSAIDs), reduce production of the feedback inhibitor prostaglandin E₂ and stimulate immune responses both *in vitro* and *in vivo*.⁹⁸ For example, two of our patients with an adult-acquired immunodeficiency who were completely anergic became responsive to delayed-type hypersensitivity skin testing when they were treated with the cyclooxygenase inhibitor indomethacin.²¹¹ Aspirin administration enhanced specific antibody production to A/Beijing after influenza immunization in adults over the age of 75.²¹² Such therapeutic strategies might be especially relevant to elderly persons, whose T cells are more sensitive to inhibition by prostaglandin E₂.⁹⁹ Other evidence suggests that prostaglandin synthetase inhibitors can also stimulate the primary antibody response to novel antigens⁶⁰ and might reduce the increase in autoantibody production that occurs with age.²¹³

Investigations studying stress-induced suppression of immune function have explored the effects of psychological interventions on the same measures of immunity.

Writing about traumatic events, and simple relaxation exercises, have been associated with enhanced immune responses, although the duration of the benefit is unknown.^{214,215} The mechanisms underlying such associations are not fully understood.

Another theoretical explanation for age-related immune decline involves the role of cellular oncogenes and antioncogenes in aging. Over long periods of time, the activation of oncogenes, and loss of tumor suppressive genes, have been associated with the progression of malignant lesions.²¹⁶ These genes are thus postulated to play a role in the development of malignancies by their regulation of cell growth and differentiation. In vitro experiments in which hybrids are created between senescent cells and immortalized cell lines lead to finite life spans of the hybrids, a property thought to be controlled by antioncogenes.²¹⁷ Thus, antioncogenes may play a role in immune senescence by regulating programmed cell death.

The foregoing examples of immunostimulation are representative of the many therapies that have been proposed or tested to reverse age-related immune decline. Although it is difficult to justify medical intervention in a healthy individual with a disordered laboratory parameter (such as chronic nonsteroidal anti-inflammatory use in an individual with low PHA response or skin test anergy), the studies of nutrition and immunity, and stress and immunity, suggest the possibility of more benign interventions that may have a significant impact on the health status of elderly individuals.

Infectious Diseases

Thomas T. Yoshikawa

Epidemiology and Risk Factors

Mortality and Morbidity

Today, worldwide, infectious diseases account for one-third of all deaths. It has been estimated by the World Health Organization that approximately 50,000 people die each day throughout the world from an infectious disease.¹ In industrialized countries, such as the United States, infectious diseases were the major causes of death and disabilities until the mid-twentieth century.² Advances in sanitation, public health measures, antisepsis, antimicrobial drugs, and immunizations substantially reduced the mortality and morbidity caused by infections in developed nations during the past 50 years. The impact of the reduction in infections can be seen most strikingly in statistics on life expectancy in the United States. The average life expectancy at birth in 1900 in the United States was approximately 47 years (48 years for females and 46 years for males).³ In contrast, the present life expectancy at birth in the United States is approximately 75 years (80 years for females and 73 years for males).³ Although persons age 65 years and older constituted only 4% of the entire population in the United States in 1900, they currently represent 1300 of the total number of Americans.⁴ Thus the virtual eradication of many death-causing infectious diseases over the past century has resulted in the extraordinary growth in the number of people living to old age. Moreover, it is projected that the very old population (i.e., those persons age 80 years and older) will expand at an even greater rate over the next 50 years.

Unfortunately, the “benefits” of growing older have associated “costs,” and one of these is an increased susceptibility and mortality to infections. Although heart disease, cancer, and stroke are now the top three causes of death in the general and geriatric populations, pneumonia/influenza and sepsis are the fourth and ninth leading causes of death, respectively, in the elderly.⁵ Dia-

betes mellitus, which has a high incidence of infectious complications, is the sixth leading cause of death in those aged 65 years and older.⁵ Furthermore, older adults who have infections experience a higher mortality rate than younger adults with the same affliction. Table 54.1 illustrates as a ratio the comparative mortality rates of common infectious diseases in the elderly versus young adults. With the exception of urinary tract infection (UTI), most of the common infections are associated with at least a twofold higher death rate or more in the elderly population.⁶⁻¹³ Although earlier data suggested that bacteriuria and UTI was associated with a higher mortality rate in the elderly,¹⁴ more recent studies have refuted these findings.^{8,15}

In addition to a decreased survival rate, older patients who have infections suffer more complications related to the illness than do younger patients. In Table 54.2, select examples of infectious-related complications are listed along with the relative frequencies of these morbidities in the elderly in comparison with young adults.¹⁶⁻²⁰ For example, the incidence of bacteremia/sepsis in association with UTI (upper tract; pyelonephritis) was four to five times more common in elderly women than young women.¹⁶ Also, the debilitating complication of postherpetic neuralgia following herpes zoster infection (shingles) is essentially a morbid event confined to persons over the age of 60 years.²⁰

The higher rates of complications in the elderly translate into higher rates and longer duration of hospitalization, as well as greater risk for hospital-acquired infections. According to the National Nosocomial Infections Surveillance (NNIS) data between 1986 and 1990, 54% of nosocomial infections occurred in patients age 65 years and older.²¹ In another study of 4031 nosocomial infections in 2565 patients, the daily infection rates were 0.59% and 0.40% in patients 60 years and older and under 60 years, respectively.²² The mean length of hospitalization was 8.1 days for patients age 59 years and younger and 10.4 days for patients 60 years and older.²²

TABLE 54.1. Comparative mortality rates of infections in elderly and young adults.

Infection	Ratio mortality rates: elderly versus young
Pneumonia ^a	3
Tuberculosis ^b	10
Urinary tract infection ^c	1
Bacteremia/sepsis ^d	3
Cholecystitis	2–8
Appendicitis	15–20
Septic arthritis	2–3
Bacterial meningitis	3
Infective endocarditis ^e	2–3

^aCommunity acquired.

^bFrom 1979 to 1989.

^cBacteremic cases.

^dWith nonfatal and ultimately fatal underlying diseases.

^eMedically treated cases.

Risk Factors and Pathogenesis

The topic of age-associated changes of immune function is discussed in detail in Chapter 53 and thus is mentioned only briefly here. Infection is broadly defined as a host response to the presence of a microbial agent; these responses may include fever, systemic symptoms and signs, markers of inflammation (e.g., presence of neutrophils in tissue or leukocytosis in the blood; production of cytokines), or immune responses. In the elderly, changes in functional status, both physical and cognitive, should also be considered as a host response to microorganisms. In contrast, “colonization” is the presence of microorganisms without an associated host response. An example of colonization is the skin, which normally can be found to have bacteria (e.g., *Staphylococcus epidermidis*) on its surface with no evidence of disease or host reactions in healthy persons. Thus, the skin has a “normal flora.”

Whether infection develops or becomes established in a person is dependent on host–microorganism interaction. Three primary factors determine the outcome of a host–microorganism interaction: virulence, inoculum, and host resistance. For an organism to cause infection, it must be pathogenic or virulent to the host, that is, possess inherent properties to (a) gain access to the host (e.g., migrate, attach, and penetrate mucocutaneous surfaces); (b) replicate in the host environment; (c) avoid host defense processes; and (d) induce a host response. Inoculum refers to the number or quantity of microorganisms present at the time of introduction or entry into the host. Although a specific microorganism may have relatively low virulence when the host’s defense mechanisms are intact, if an enormous number of these organisms are introduced, the available host resistance processes may

be “overwhelmed” and be unable to mitigate the replication and subsequent tissue and organ injuries of these “pathogens.” For example, the large intestine is filled with billions of bacteria that normally cause little damage to or responses from the host (part of the normal bowel flora). However, if in the course of an elective, uncomplicated abdominal surgery, the colon is damaged with subsequent contamination of the peritoneum with normal flora, an infection is immediately established, that is, peritonitis.

The third major factor in the host–microorganism interaction is host resistance. Host resistance or host defenses include the mucocutaneous surfaces, phagocytic cells, complement, humoral immunity, and cellular immunity. Host resistance may also be termed immune responses, which can be divided into two interactive components: innate or natural immunity and acquired or adaptive immunity. Innate immunity is composed of a cellular component, macrophages, polymorphonuclear leukocytes (PMNLs), natural killer (NK) cells, and dendritic cells, and a noncellular component, complement, C-reactive protein, mannose-binding protein, and serum amyloid protein.²³ Compromises in the integrity and function of any or all components of the host’s defense mechanisms by age-related changes or underlying diseases or disorders place the elderly at greater risk for contracting an infection as well as experiencing a more severe illness.²⁴ The relationship of virulence, inoculum, and host resistance can be simply expressed in the following equation:

$$\text{Infection} \cong \frac{\text{virulence} \times \text{inoculum}}{\text{host resistance}}$$

Thus, the risk or severity of infection is directly proportional to the virulence of the microorganism and number of microorganisms and inversely proportional to host

TABLE 54.2. Morbidity from infections in elderly versus young adults.

Infectious complication	Elderly	Young adult
Urinary tract infection and bacteremia (%) ^a	50	11
Pneumococcal pneumonia bacteremia (per 100,000 population) ^b	15–25	1–9
Pneumococcal bacteremia without fever (%) ^c	29	11
Perforation of appendix (%) ^d	32	6
Postherpetic neuralgia (%) ^e	48	4

^aLess than 65 versus 65 years or older.

^b35–59 versus 60 years or older (frequency varies depending on study group and age cohorts (see also Ref. 144).

^c20–64 versus 65 years or older.

^dLess than 60 versus 60 years or older.

^eLess than 20 versus 70 years or older.

Source: Gleckman et al.¹⁶; Mufson et al.¹⁷; Finkelstein et al.¹⁸; Peltokallio et al.¹⁹; Demorgas et al.²⁰

resistance. Simply stated, susceptibility to infection is greater when the organism is virulent, there are a large number of microorganisms, or there is a reduction in the integrity of the host's defense mechanisms.

Clinical Patterns of Infection

Important Infections

Although there is an apparent increase in susceptibility to infections with aging, there are no data that indicate elderly persons are at greater risk or have a higher mortality rate to all infections. Rather, there is evidence that certain infectious diseases occur with greater incidence, have higher mortality rate, develop more severe complications, or present special or unique diagnostic and management challenges with aging. These important infections in the elderly are summarized in Table 54.3.^{25,26}

Intra-abdominal infections, particularly cholecystitis, diverticulitis, perforated appendicitis, and liver abscess, are seen with greater frequency in elderly persons and, as shown earlier (see Table 54.1), may be associated with high mortality.^{27,28} Because diabetes mellitus is a major health problem of aging adults, the infections associated with diabetes are a major complication for the elderly. Malignant otitis externa caused by *Pseudomonas aeruginosa*, and foot infections including osteomyelitis, are especially common in the geriatric diabetic patient and may result in serious complications including death.²⁹⁻³¹ Nearly 50% of the elderly have some form of joint disorder and many have prosthetic joints, which makes them highly vulnerable to septic arthritis. Older adults account for 40% of all nongonococcal joint infections, with most caused by bacteria.^{32,33}

TABLE 54.3. Important infections in the elderly.

Pneumonia
Influenza
Tuberculosis
Urinary tract infection
Chronic bacterial prostatitis
Skin and soft tissue infections
Herpes zoster

Infections by Setting or Environment

Elderly persons can be typically categorized as residing or temporarily staying in three broad types of settings, depending on their overall health status. These three settings include the home or community, acute care facility (hospital), and long-term care facility (e.g., nursing facility). Interactions between the environmental setting, functional status, and underlying disease(s) of the elderly person influence the types of infections often seen in the community, hospital, or long-term care facility.

In the home or community setting, the majority of elderly persons are ambulatory and functionally independent. The most common infections encountered (first diagnosed) under these circumstances include respiratory infections (bronchitis, pneumonia), UTI, gastroenteritis and intra-abdominal infections (cholecystitis, diverticulitis, appendicitis), cellulitis, septic arthritis, herpes zoster, and infective endocarditis.²⁵ However, depending on the severity of the illness, many of these infections may require hospital management.

If an elderly patient is in the hospital, there is a substantial risk for acquiring a nosocomial infection. These infections typically include UTI (often related to urinary bladder catheterization), aspiration pneumonia (including postendotracheal intubation), skin or soft tissue infections (infected pressure ulcers, wound infection), septic thrombophlebitis (line sepsis from intravenous catheters), gastroenteritis including antibiotic-associated (*Clostridium difficile*) diarrhea, and bacteremia/sepsis.^{21,22,34}

In a long-term care setting, most of the studies on infections have been in nursing facilities (nursing homes). Numerous investigations indicate that pneumonia, urinary tract infection, and skin/soft tissue infections (PUS) account for at least 75% of all infections in nursing facilities.³⁵ In addition, bacteremia/sepsis, viral respiratory infections, viral hepatitis, and *C. difficile* diarrhea/colitis are being reported with increasing frequency in long-term care facilities.³⁶⁻⁴¹

Multidrug-resistant bacteria, that is, penicillin-resistant pneumococci, drug-resistant gram-negative bacilli, methicillin-resistant *Staphylococcus aureus* (MRSA), and vancomycin-resistant enterococci (VRE), are being isolated from residents of long-term care facilities in greater numbers than expected.⁴² Approximately 30% of all penicillin-resistant invasive pneumococcal infections occurred in patients aged 65 or older. Strains of pneumococci that have a minimal inhibitory concentration (MIC) greater than 1.0 µg/mL are considered resistant. The majority of UTIs in long-term care facilities are caused by gram-negative bacteria. Resistance to a variety of antibiotics is occurring and has been seen for *Escherichia coli*, *Klebsiella*, and *Providencia*.

MRSA was first reported in nursing home residents in 1970, but since then it has appeared in a variety of long-

term care settings (LTCF) (community, Veterans Affairs, large, small, adult, pediatric, urban, and rural) throughout the United States. Currently approximately 40% of *Staphylococcus* species are resistant to methicillin. Risk factors for acquiring MRSA are age, Medical Intensive Care Unit (MICU) or prolonged hospital stay, and a history of invasive procedures. Colonization rates with MRSA are approximately 25% with infection rates of approximately 3%. Colonized individuals do not require antimicrobial therapy.

Risk factors for VRE include severe illness, advanced age, prolonged hospitalization, and previous exposure to antibiotics, especially vancomycin. VRE strains are found more frequently in *Enterococcus faecium* than in other species of enterococci. Most older patients with VRE in LTCF are simply colonized, and these patients do not require antibiotic therapy. However, those infected with VRE should receive antimicrobial therapy, preferably in an acute care facility. Therapeutic options are limited, and thus in vitro lab susceptibility testing of VRE as well as in vitro synergy tests of antibiotics should be used to determine appropriate antibiotic therapy. Combinations of penicillin (PCN), vancomycin, and gentamycin have been suggested if the organism is susceptible to gentamycin at an MIC less than 32 µg/mL, ciprofloxacin with ampicillin, novobiocin, or rifampin if the MIC to ciprofloxacin is less than 8 µg/mL.

Clinical Manifestations

Fever

The presence of fever has traditionally been viewed as a symptom or sign of an underlying infection, although other noninfectious diseases can cause a febrile response.⁴³ The pathogenesis of fever is a complex and dynamic process, and a detailed description of this process is beyond the scope of this chapter. It is only mentioned that eliciting an elevation of body temperature from infection involves a cascade of events from exogenous substances (e.g., microorganisms, microbial products), endogenous mediators [cytokines such as interleukin 1 (IL-1), IL-6 tumor necrosis factor, and interferon-gamma], the thermoregulatory center in the anterior hypothalamus, physiologic changes, and behavioral modifications.⁴³ Alterations along any aspect of this pathway could modify the host's capacity to mount a fever.

There has been accumulating evidence from a variety of human and animal studies that febrile responses may be blunted or abrogated with aging.⁴⁴ Approximately 25% of elderly patients who have serious infections, such as bacteremia, pneumonia, infective endocarditis, or meningitis, may not demonstrate a fever on initial pre-

sentation.⁴⁵⁻⁴⁸ Recent studies in frail nursing facility residents suggest that although febrile responses to infection may be diminished with aging, there are, nevertheless, elderly persons who mount an elevation of core body temperature with an infection but are recorded as being "afebrile." These individuals had low baseline core temperatures but responded with a rise in body temperature of at least 2.4°F (1.3°C) but failed to reach the traditional criterion of fever, that is, 100°F (37.8°C) or 101°F (38.3°C).^{49,50} Furthermore, nearly 90% of the nursing facility residents with infection had a temperature of 99°F (37.2°C) or higher. It has been suggested that the criteria for fever in frail elderly persons, especially those in long-term care facilities, be revised to the following: (1) an oral temperature of 99°F (37.2°C) or greater on repeated measurements; (2) a rectal temperature of 99.5°F (37.5°C) on repeated measurements; or (3) a persistent elevation of body temperature of at least 2°F (1.1°C), regardless of technique of measurement.⁵¹

Conversely, the presence of an elevated body temperature above normal in the elderly is a reliable and specific indicator of an underlying infectious disease process. Elderly patients manifesting robust fevers of at least 101°F (38.3°C) have been shown to be harboring serious bacterial (or viral in some cases) infections.⁵²⁻⁵⁴ Moreover, fever in the presence of leukocytosis and a "left shift" (increased percentage of band neutrophils and metamyelocytes) increases the positive predictive value for diagnosing a bacterial infection.⁵⁴ Alternatively, in the absence of any clinical evidence of infection or fever and with a normal leukocyte count and no left shift, the likelihood of a bacterial infection in the elderly is low.

Temperature measurements in incapacitated, debilitated, or cognitively impaired elderly persons may be difficult using oral or axillary thermometry. In addition, rectal temperature measurements may be problematic in persons with fecal incontinence or persistent diarrhea. An alternative approach to measuring body temperature is the use of infrared tympanic membrane thermometry.^{55,56} Although studies have been limited in elderly persons, it appears that tympanic thermometry may be a reliable method to measure body temperature and detect fever.^{57,58}

Other Symptoms and Signs

Although many older adults with a specific infectious disease manifest symptoms and signs typical for that infection (e.g., cough, fever, and dyspnea for pneumonia; frequency, urgency, and dysuria for UTI), a substantial number of the elderly may only exhibit nonspecific complaints or have confounding findings because of the changes of aging or coexisting chronic diseases.⁵⁹ These clinical manifestations may include delirium or other cognitive impairments, lethargy, anorexia, weakness, and

fatigue, as well as acute urinary incontinence, falls, and failure to thrive. Furthermore, the presence of an underlying chronic disorder may mask an acute infectious process; for example, a chronic degenerative osteoarthritis of the knee may delay the diagnosis of an active septic arthritis, or an elderly person with underlying Alzheimer's disease may be harboring a tuberculous meningitis but the symptoms are attributed to the dementing process.

Thus, in any elderly person who demonstrates a fever, or experiences a rapid onset of a change in functional capacity—physical or cognitive—or lack of well-being that cannot be explained by other health problems, an infectious disease should be considered as part of the initial differential diagnosis.

Diagnostic Approach and Treatment of Common or Life-Threatening Infections

Once infection is considered as part of the differential diagnosis, the diagnostic approach should be guided by the most likely source(s) or site(s) of infection based on the initial history and physical examination. Furthermore, determining the elderly person's environmental setting, whether community, hospital, or long-term care institution, can provide clues to the most likely primary causes of infection (see earlier discussion). In older patients who are suspected of harboring an infection but in whom no site or focus of infection can be determined on preliminary assessment, it is suggested that the following laboratory and radiologic studies be performed: complete blood count including differential count; urinalysis with urine culture; chest radiograph (posteroanterior and lateral views); renal function tests; and liver function tests. In elderly patients who are ill enough to require hospitalization, blood cultures should also be obtained.

The results of these preliminary studies and continued examination of the patient should allow the clinician to make decisions about additional laboratory, radiologic, or imaging studies. In some instances, older patients may develop prolonged fever and be considered to have a "fever of unknown origin" (FUO).⁴⁴ In contrast of younger adults with FUO, the cause can be identified in the majority of older patients with prolonged fever (more than 90% of cases versus 50% cases).⁶⁰ Moreover, infections (35%) are the leading cause of FUO in the elderly, followed by multisystem diseases (e.g., polymyalgia rheumatica) (28%).⁶⁰

The following discussions focus on the diagnosis and treatment in different settings of the more common and life-threatening infections encountered in the elderly.

Urinary Tract Infection

Diagnosis

Urinary tract infection (UTI) is the most common bacterial infection in older persons as well as the most frequent cause of bacteremia/sepsis, may be associated with indwelling bladder catheter, and, paradoxically, is most often asymptomatic.^{61–63} Chronic bacterial prostatitis may be a contributor to recurrent UTI in elderly men.⁶⁴

In an ambulatory setting, an elderly patient with suspected UTI should have a urinalysis and a confirmatory test for presence of bacteria. A clean-catch midstream urine specimen is the preferred method of urine collection for women; elderly men can provide a reliable specimen by a first-voided urine sample.⁶⁵ Besides being a screening test for bacteriuria, a urinalysis provides an estimate of pyuria, which has a high negative predictive value for absence of bacteriuria in the patients with low or absent white blood cells in the urine.^{66,67} Alternatively, a dipstick test for leukocyte esterase can be used to determine the presence of neutrophils in the urine.⁶⁸ The presence of bacteriuria can be screened by the nitrite (Greiss) test, a dip-strip that becomes positive (pink color) when bacteria convert nitrate to nitrite by the enzyme nitrate reductase.⁶⁸ However, the disadvantages of the nitrite test are that it has a sensitivity of only 65%, it fails to detect enterococci, and is best used for the first morning voided specimen (bacteria requires at least 4h incubation in the bladder to convert nitrate to nitrite; thus, random urine samples are less likely to be positive for bacteria). The dip-slide culture is a glass slide coated with nutrient agar on one side and differential agar to isolate gram-negative bacteria on the other side. An estimate of quantity of bacteria is made by comparison of density of bacteria on the slide to a standardized chart.⁶⁹ The correlation of the dip-slide culture method to standard culture method is greater than 95%. The dip-slide culture can be sent to a microbiology laboratory for incubation, or a small office incubator can be used. Any growth of organism on the slide can be subcultured for standard microbiologic processing and identification. The leukocyte esterase, nitrite, and dip-slide tests offer convenience, low cost, and a rapid means to screen for bacteriuria in an ambulatory setting.⁷⁰ The majority of ambulatory elderly patients with uncomplicated UTI (primarily cystitis; no sepsis, catheterization, underlying genitourinary abnormalities, or recurrence) harbor *Escherichia coli* (60%–70%), with *Proteus* spp. and *Klebsiella* spp. being isolated 20% to 30% of the time. Patients with more complicated infections will be infected with more diverse pathogens (e.g., *Enterobacter* spp., *Pseudomonas aeruginosa*, *Enterococcus* spp.).

For elderly patients who require hospitalization for managing their UTI, in addition to a urinalysis and urine

culture, blood cultures should be obtained. Urine should be obtained by standard voided methods as already described; however, in very sick or functionally incapacitated elderly, urinary bladder catheterization may be necessary to obtain a specimen as well as to monitor urine output. Hospitalized patients and those who have complicated infections (upper tract, recurrent, catheter-related) need assessment of renal function (blood urea nitrogen, serum creatinine), as well as evaluation of the genitourinary anatomy (ultrasonography; intravenous pyelography) and bladder function (residual urine volume). Some patients will warrant a cystoscopy, and male patients may require a careful examination of the prostate gland to exclude chronic bacterial prostatitis or prostatic hyperplasia.⁷¹ Uropathogens are similar to those found in ambulatory UTI patients.

In a long-term care setting (e.g., nursing facility), if the resident is clinically stable enough not to require hospitalization, a urinalysis and urine culture are sufficient for the initial evaluation of a UTI. Urine samples from incontinent men in nursing facilities can be collected with excellent accuracy by using an external catheter system.⁷² In incontinent women who do not have an indwelling bladder catheter, a straight in-and-out catheterization may be required to obtain an accurate (uncontaminated) urine sample. Residents with long-term bladder catheters should have their catheters changed before obtaining a urine specimen.⁷³ Catheters remaining in the bladder for prolonged periods become heavily colonized with numerous different species of microorganisms, which may invalidate the isolation of pathogens residing in the bladder. Institutionalized elderly appear to be infected more often with antibiotic-resistant bacteria such as *Citrobacter freundii*, *Pseudomonas aeruginosa*, and *Providencia stuartii*, especially those with chronic urinary catheters.⁷¹ Persons with chronic urinary catheters frequently have polymicrobial bacteriuria, with *Enterococcus* spp. occurring in about 25% of cases.

Treatment

For empiric therapy of elderly ambulatory patients with UTI, the most commonly recommended antimicrobial agent is trimethoprim-sulfamethoxazole.^{74,75} Although oral beta lactam agents previously were also prescribed as primary therapy for routine UTI (i.e., ampicillin, amoxicillin-clavulanate, cephalosporins), increasing antimicrobial resistance has reduced their efficacy. Oral fluoroquinolones are now preferred as an alternative to trimethoprim-sulfamethoxazole or as primary treatment in patients who are unable to tolerate trimethoprim or sulfonamides or fail on this regimen.^{76,77} Duration of therapy is at least 7 days, with more complicated cases requiring up to 14 days of treatment. Elderly men should generally be prescribed 14 days of antibiotics.

A repeat urine culture should be obtained approximately 7 to 10 days after completion of therapy for evidence of cure.

Older patients requiring hospitalization for UTI should be initially administered antibiotics until there is clinical improvement (afebrile for at least 24 h; improvement in other vital signs; able to eat and drink), at which time they may be switched to oral antibiotics based on culture and sensitivity data. Effective parenteral drugs for UTI (pyelonephritis, urosepsis) include fluoroquinolones, extended-spectrum cephalosporins, beta lactam-beta lactamase agents, and aminoglycosides.^{76,77} Aminoglycosides should be avoided in the elderly, whenever possible, because of the potential renal and eighth nerve toxicities of these drugs. If *Enterococcus* spp. is isolated or suspected, ampicillin-sulbactam is recommended. Most older patients with UTI in this setting should be treated with 10 to 14 days of antimicrobial therapy. A follow-up urine culture should be obtained 7 to 10 days after completion of treatment.

The management of UTI that requires treatment in the setting of a long-term care facility will be similar to managing UTI in an ambulatory setting. Most residents can be treated with oral antibiotics, that is, trimethoprim-sulfamethoxazole or fluoroquinolones; amoxicillin-clavulanate should be considered for patients with enterococci in the urine. Short-term parenteral therapy can be administered with intramuscular third-generation cephalosporin (e.g., ceftriaxone). Duration of antibiotics is similar to that prescribed for ambulatory UTI patients.

Respiratory Infections

Diagnosis

Pneumonia and influenza are particularly relevant in the elderly because of their associated high mortality rates and the high incidence of pneumonia with aging in both the community and institutional settings.⁷⁸⁻⁸¹

The most important respiratory infection is lower respiratory infection, which includes acute or chronic bronchitis and pneumonia. In the ambulatory setting, acute and chronic bronchitis is the dominant lower respiratory infection managed in an outpatient and home environment. Most acute bronchitis cases are caused by viruses and require no specific diagnostic evaluation. However, if the elderly patient appears to have more severe respiratory symptoms or fever, a chest radiograph may be warranted to exclude possible pneumonia. Chronic bronchitis is especially prevalent in older men, with as many as 40% of cases occurring in men age 65 years and older.⁸² Chronic bronchitis is defined as the presence of cough and sputum production on most days for at least 3

months per year for 2 consecutive years.⁸³ The disease often is a prelude to or is accompanied by airway obstruction, leading to chronic obstructive pulmonary disease (COPD). The most common pathogens found in chronic bronchitis are *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*. However, in more severe lung disease, as determined by the forced expiratory volume in 1 s (FEV₁) there appears to be a higher isolation rate of gram-negative bacteria (*Enterobacteriaceae* and *Pseudomonas* species) from sputum in patients with exacerbations of chronic bronchitis. With an FEV₁ less than 35%, 40% of chronic bronchitics had gram-negative bacteria isolated from purulent sputum in comparison with only 10% isolation rate for those with FEV₁ greater than 50%.⁸⁴ The evaluation of an elderly patient with chronic bronchitis should include a chest radiograph to exclude pneumonia or other respiratory complications; collection of expectorated sputum for microbiology is of limited value because of oropharyngeal contamination. Measurement of FEV₁ may be considered in those elderly patients with chronic bronchitis who fail to respond to standard therapy (see section on Treatment).

Most elderly patients (nearly two-thirds) with community-acquired pneumonia require hospitalization.⁸⁵ In one large study, 18% of outpatient-treated pneumonia cases were in the elderly, but 60% of the hospitalized patients with community-acquired pneumonia were 65 years and older.⁸⁶ More recently, the Pneumonia Patient Outcome Research Team (PORT) cohort study established objective criteria to predict prognosis (death) for patients with community-acquired pneumonia within 30 days of presentation.⁸⁷ Equally important, this study, by using clinical data and select laboratory/radiologic findings to develop a point scoring system, could infer which patients would most likely benefit from inpatient hospital care for their pneumonia. A total point of 91 or greater (class IV) predicted a poorer prognosis and thus justified hospitalization. With each year of a patient's age counted as 1 point, the elderly patient is more likely to achieve a point score of 91 or greater. Based on the PORT study, in addition to a chest radiograph, the following diagnostic studies are recommended on initial evaluation of an elderly patient with community-acquired pneumonia: arterial blood gas, hematocrit (complete blood count), blood urea nitrogen (BUN), serum sodium (electrolyte panel), and serum glucose. Microbiologic studies include blood cultures, sputum for Gram stain and culture, and tuberculin skin test if tuberculosis is part of the differential diagnosis. The most common reported cause of community-acquired pneumonia in the elderly is *S. pneumoniae* (40%–60%); however, *H. influenzae* (in COPD), gram-negative bacilli, and *Legionella* species may also be isolated.⁸⁸ If legionellosis is suspected, appropriate serologic and staining tests should be ordered.

Pneumonia acquired while in the hospital for another medical problem also occurs with greater frequency in elderly patients; the incidence is three times higher in the elderly compared with younger patients.⁸⁹ Hospital-acquired pneumonia in the elderly is caused by pathogens similar to those in younger adults, with nearly half of patients having more than one organism isolated; these are gram-negative bacilli (40%–50%), anaerobic bacteria (35%), *Staphylococcus aureus* (31%), and *Streptococcus pneumoniae* (26%).⁹⁰ The evaluation of hospital-acquired pneumonia would be similar to that of community-acquired pneumonia (see earlier discussion).

In residents of long-term care facilities who develop pneumonia, most studies are from nursing facilities (“nursing-home” acquired pneumonia).¹⁹ The PORT study predictive index for prognosis and severity of pneumonia has also been successfully applied to nursing facility residents with pneumonia.⁹¹ Whether nursing facility residents with pneumonia require hospitalization or can be treated within the long-term care setting remains unclear and controversial.^{92,93} The availability of appropriately trained staff and diagnostic and therapeutic support services in a long-term care facility, as well as the favorable pharmacokinetics of oral antibiotics, facilitate treatment of pneumonia in this setting.^{91,94,95} In recently developed practice guidelines endorsed by several geriatric/gerontology and infectious disease professional organizations, the diagnostic evaluation for suspected pneumonia in residents of long-term care facilities should be limited to the following tests: (1) chest radiograph; (2) pulse oximetry to determine oxygen saturation (diagnostic and prognostic value); and (3) respiratory secretions (expectorated sputum or nasopharyngeal aspirate) for assessing purulence (predominance of neutrophils), with subsequent analysis by Gram stain and culture and sensitivity if purulence is present.⁹⁶

Treatment

Acute bronchitis in an ambulatory setting should be managed symptomatically because most cases are caused by viruses. Hydration and nutrition are important in the frail elderly.⁷⁴ For severe cough, a mild antitussive agent should be prescribed, but more potent drugs (e.g., codeine) are not recommended for the elderly because of their side effects. If bronchospasm is present, an inhaled bronchodilator will be helpful. When a secondary bacterial infection occurs, empiric antibiotic treatment with such drugs as amoxicillin-clavulanic acid, cefuroxime axetil, azithromycin, clarithromycin, or erythromycin are recommended. Most patients will require only 5 to 7 days of treatment. Acute exacerbation of chronic bronchitis in the elderly generally requires antibiotic therapy.⁹⁷ In patients with repeated bouts of cough and purulent sputum, antibiotic therapy may be extended to 7 to 14

days. In elderly patients with FEV₁ less than 35% and failure on standard antibiotic regimens for bronchitis or patients with bronchiectasis, the likelihood of the presence of a gram-negative bacillary organism is high and treatment with an oral fluoroquinolone should be prescribed.⁷⁸ Immunization with influenza vaccine should be done on a yearly basis and at least one injection of pneumococcal vaccine should be administered (see section on Immunizations).

Community-acquired pneumonia requiring hospitalization should be managed with intravenous antibiotics until the patient clinically improves and is afebrile for at least 24 to 48 h, is able to eat and drink, the respiratory rate is less than 25/min, and pulse rate is less than 100/min.⁹⁸ Patients can be discharged if the preceding criteria are present plus the following conditions: (a) negative blood culture(s); (b) oxygen saturation on room air is above 90% (with COPD, arterial oxygen >60 mmHg and carbon dioxide <45 mmHg, or both values return to baseline); and (c) stable status of underlying diseases.⁹⁸ Antibiotic selection depends on severity of disease, suspected pathogens, and drug tolerance. Generally, an extended-spectrum cephalosporin (e.g., third-generation cephalosporin) or beta lactam-beta lactamase inhibitor (e.g., ampicillin-sulbactam, piperacillin-tazobactam) combined with a macrolide (i.e., azithromycin, clarithromycin, erythromycin) has been commonly recommended as initial empiric therapy until microbiologic data become available.⁹⁹ A fluoroquinolone (e.g., levofloxacin, moxifloxacin, gatifloxacin) alone is also acceptable. If aspiration is suspected, clindamycin should be included in the regimen. Patients suspected of harboring *Pseudomonas aeruginosa* should be treated with more than one antipseudomonal agent (e.g., piperacillin or piperacillin-tazobactam plus a fluoroquinolone).⁹⁹ Patients allergic to beta-lactam drugs should be treated with a fluoroquinolone plus clindamycin.

Residents who acquire pneumonia in a long-term care facility (e.g., nursing facility) may be treated in this setting or transferred to a hospital.⁹²⁻⁹⁵ The severity of disease, availability of 24-h/7-day per week appropriately trained nursing staff in the facility, physicians willing to follow patients at regular intervals (e.g., daily) in this setting, capacity to provide parenteral therapies and respiratory support treatment, quick and easy access to necessary laboratory and radiologic tests, advance directive or mutually agreed decision between patient/family and physician, and local institutional policies regarding transfer of residents will determine whether treatment occurs in the long-term care facility or hospital. A recent study, using a treatment guideline for nursing facility-acquired pneumonia based on community practices of geriatricians, demonstrated that 72% of residents could be initially treated in the nursing facility with 61% requiring only oral antibiotics.¹⁰⁰ The 30-day mortality rates

between those initially treated in the nursing facility (22%) and those treated in the hospital (31%) was not significant. Additionally, the mortality rates for residents treated in nursing homes with oral agents (21%) versus intramuscularly administered antibiotics (25%) was also similar.¹⁰⁰ A suggested guideline for treating pneumonia in a nursing facility was provided. Residents selected to be managed in the long-term care setting can be treated with a variety of antibiotics, with the route chosen determined by several factors mentioned earlier (i.e., severity of disease including ability to take oral medications, capacity to give intravenous or intramuscular medications, and availability of parenteral antibiotics). Appropriate intravenous antibiotics would be similar to those used to treat hospitalized elderly patients with pneumonia (see earlier discussion). Commonly used intramuscular antibiotics include certain third-generation cephalosporins such as ceftriaxone, cefotaxime, and cefoperazone.¹⁰⁰⁻¹⁰³ If oral administration of drugs is feasible,^{94,95,102} antibiotics such as amoxicillin-clavulanic acid, second- or third-generation cephalosporins (e.g., cefuroxime axetil, cefixime), or fluoroquinolones (with activity against *S. pneumoniae*, e.g., levofloxacin) would be primary choices. Clindamycin, macrolides (erythromycin, clarithromycin, azithromycin), or trimethoprim-sulfamethoxazole could be prescribed in select circumstances, such as aspiration (clindamycin), beta-lactam allergy (macrolides, clindamycin, trimethoprim-sulfamethoxazole), or possible legionellosis or mycoplasma (macrolides).

Skin and Soft Tissue Infections

Diagnosis

A variety of skin and soft tissue infections afflict older persons, but the most difficult to manage clinically are infected pressure ulcers, which occur most often in frail, debilitated elderly.^{104,105}

Cellulitis that is localized and without associated systemic symptoms requires no diagnostic evaluation. Most cellulitis cases are managed in an ambulatory setting. Most cases of cellulitis are caused by either group A streptococci or *Staphylococcus aureus*.¹⁰⁶ In older patients with skin infection associated with diabetes mellitus, the lesions may be ulcerated or at times gangrenous. The microbial agents in diabetic skin lesions are often mixed. In early diabetic cellulitis, the organisms are primarily staphylococci; lesions that are more chronic and ulcerated are generally composed of streptococci, gram-negative bacilli, and anaerobic bacteria.¹⁰⁶ Diabetic skin or soft tissue infections, especially in diabetic foot disease, should have a plain radiograph of the underlying bone to exclude a coexisting osteomyelitis.¹⁰⁷ If plain radiographs are negative and bone infection is still suspected, a bone

scan or magnetic resonance imaging (MRI) should be considered.

Another dermal infection occurring primarily in the elderly is herpes zoster (shingles) and its complication, postherpetic neuralgia.^{20,108} It is managed primarily in an outpatient setting. This infection is discussed separately in Chapter 71 and is not covered here.

In both hospital and long-term care facility settings, pressure ulcers that become secondarily infected pose major problems for the elderly, especially the frail and debilitated patient or resident. The topic of pressure ulcers is discussed in Chapter 66, and there are numerous excellent reviews on this clinical problem.¹⁰⁹⁻¹¹¹ The only comments to emphasize regarding infected pressure ulcers are (a) the microbiota of chronic lesions are generally a mixture of anaerobic and aerobic bacteria; (b) all wounds are always colonized with organisms and thus swab cultures of the surface of ulcers are not clinically useful; and (c) antimicrobial treatment should only be initiated if there are associated signs of purulence, cellulitis, or drainage of the wound or there is evidence of systemic toxicity or osteomyelitis.

Treatment

Cellulitis in ambulatory elderly patients can generally be effectively treated with oral cloxacillin or dicloxacillin for 7 to 10 days. Alternative drugs include oral cephalexin, clindamycin, and amoxicillin-clavulanic acid. Diabetic foot lesions with ulceration or those that are chronic may have anaerobic organisms as part of the flora; treatment with amoxicillin-clavulanic acid or a combination of clindamycin and an oral fluoroquinolone is recommended. If no bone infection is present, diabetic skin infection should be treated for approximately 2 weeks. Wound and foot care are also equally important for these infections.

The treatment of pressure ulcers is discussed in Chapter 66.

Tuberculosis

Diagnosis

Tuberculosis among persons without human immunodeficiency virus (HIV) infection occurs with the highest incidence rate in the geriatric population and poses some diagnostic challenges and a different therapeutic approach.¹¹²⁻¹¹³

Most cases of tuberculosis in the elderly (or any age group) are diagnosed in an ambulatory setting. The recommended screening test remains the tuberculin skin test, using a purified protein derivative (PPD) antigen in a strength of 5 units and applying the Mantoux technique.^{114,115} A two-step procedure for tuberculin test should be implemented in all elderly persons suspected

of tuberculosis because of the “booster effect.” In persons over age 55, the booster effect increases; that is, there is previous sensitization to mycobacteria primarily from earlier infection, the initial skin test application is negative, and a repeat test in 1 to 3 weeks becomes positive (10mm or greater of induration with at least 6mm increase from the first skin test). If a skin test is positive or if the elderly person has symptoms and signs suggestive of tuberculosis in the absence of a positive skin test, a chest radiograph should be performed.¹¹² An abnormal chest radiograph with findings consistent with tuberculosis (except old calcified granuloma as the only lesion) warrants sputum collection from the patient for acid-fast bacilli smear and culture for mycobacteria, specifically *Mycobacterium tuberculosis*. Approximately 75% of all tuberculosis in the elderly involves the lung.¹¹²

Disseminated tuberculosis and tuberculosis involving the pericardium and meninges (pericarditis, meningitis) generally require hospital care initially. The evaluation would be similar as in the ambulatory setting, but additional studies specific to the organ involved would be indicated (e.g., echocardiogram or pericardiocentesis for pericarditis; cerebrospinal fluid examination and imaging of the brain with meningitis).

Tuberculosis in a long-term care setting has been well described.^{113,116} The initial evaluation would be the same as described in the ambulatory setting. However, residents identified as having potential tuberculosis disease (active tuberculosis) based on abnormal chest radiograph or positive microbiologic studies require transfer to an acute care facility in which isolation procedures for tuberculosis are available unless (1) chemotherapy is promptly instituted at the time the diagnosis is suspected or confirmed; (2) recent and current contacts are evaluated and placed on appropriate therapy; and (3) new contacts can be prevented for a 1- to 2-week period.¹¹⁷

Treatment

The most recent recommendations for chemotherapy for tuberculosis were published in 1994;¹¹⁸ these are noted in Table 54.4. The recommendations are basically a four-drug regimen at the outset and are based on the assumption that resistance to isoniazid or rifampin may be prevalent.¹¹⁸ However, if isoniazid resistance is less than 4% in the community, a two- or three-drug regimen is acceptable. Because most elderly patients acquired their tuberculous infection before the usage of isoniazid, most *M. tuberculosis* infections acquired by older adults are drug sensitive to both isoniazid and rifampin.¹¹⁹ Most elderly patients with pulmonary tuberculosis disease (active infection), whether they are ambulatory, hospitalized, or institutionalized, may be treated with isoniazid and rifampin for 9 months or isoniazid, rifampin, and pyrazinamide for 2 months, followed by isoniazid and rifampin for another 4 months.¹¹⁹ For

TABLE 54.4. Treatment options for tuberculosis.

Drugs	Frequency
Option 1	
Isoniazid, rifampin, pyrazinamide and ethambutol or streptomycin for 8 weeks ^a ;	Daily
then isoniazid and rifampin for 16 weeks	Daily or two or three times weekly ^b
Option 2	
Isoniazid, rifampin, pyrazinamide and ethambutol or streptomycin for 2 weeks;	Daily
then same drugs for 6 weeks; then isoniazid and rifampin for 16 weeks	Twice weekly ^b
Option 3	
Isoniazid, rifampin, pyrazinamide and ethambutol or streptomycin for 24 weeks ^a	Three times weekly ^b

^aIf isoniazid resistance is less than 4% in a community, omit fourth drug; streptomycin is not recommended for the elderly because of potential ototoxicity.

^bIntermittent dosing should be directly observed.

Source: Bass et al.¹¹⁸

miliary or disseminated tuberculosis or tuberculous meningitis, osteomyelitis, and pericarditis, therapy should be extended to 12 months.

The indications for chemoprophylaxis (now called treatment of latent tuberculosis infection) for elderly patients or residents with positive tuberculin skin tests are the same as for younger adults.^{113,119} Previously, standard chemoprophylaxis was 6 months of isoniazid.¹¹⁸ More recently, the Centers for Disease Control and Prevention has revised its recommendations for chemoprophylaxis.¹²⁰ Isoniazid is now recommended for 9 months; 2 months of rifampin and pyrazinamide is also acceptable. Four months of rifampin alone is an alternative but less acceptable regimen.

Elderly patients may have a higher incidence of isoniazid-associated hepatitis, and thus careful clinical and laboratory monitoring of liver abnormalities is recommended. Baseline and follow-up liver function tests (serum aminotransferase; SGOT) are obtained every 1 to 2 months. Elevation of the SGOT to five times above normal or baseline or clinical signs of liver toxicity is an indication to discontinue isoniazid (and rifampin and pyrazinamide).¹¹³ After resolution of symptoms or abnormal liver function tests, the isoniazid (and other drugs) may be resumed at lower doses with gradual increasing dosages. Recurrence of liver abnormalities requires a trial of an alternative therapeutic regimen.

Infective Endocarditis

Diagnosis

As the American population ages and the incidence of childhood rheumatic heart disease has declined, the incidence of infective endocarditis has risen in the elderly;

nearly 50% of all cases of infective endocarditis in the United States occur in persons age 60 years and older.^{121,122}

Although the elderly patient with infective endocarditis may be initially seen in an office setting, all patients require diagnostic and therapeutic interventions performed in a hospital. Immediate obtaining of at least three sets of blood cultures at three different points in time and an echocardiogram are the most important tests for the diagnosis of infective endocarditis.¹²³ More recent criteria for diagnosing infective endocarditis incorporate findings of an echocardiogram.¹²⁴ The finding of persistent bacteremia with clinical findings of infective endocarditis (regurgitant murmur, evidence of septic emboli) or evidence of vegetation(s) on echocardiogram is sufficient to make the diagnosis. In general, patients with moderate to severe cardiac failure, prosthetic valve endocarditis, or failure on medical treatment should be evaluated by cardiac surgery (see Treatment section of Infective Endocarditis). The most common organisms causing infective endocarditis in the elderly are streptococci, including viridans group streptococci and occasionally *Streptococcus bovis*, *Enterococcus* spp., and *Staphylococcus aureus*.¹²⁵ In patients with prosthetic valve endocarditis, *S. aureus* and *S. epidermidis* are the dominant pathogens.

In a long-term care setting, if a resident is suspected of infective endocarditis, he or she should be transferred to an acute care facility for further diagnostic evaluation.

Treatment

Elderly patients with infective endocarditis require hospitalization. Ideally, if the patient is clinically stable, specific antimicrobial therapy should be initiated after identification of the organism from blood cultures. However, most patients with suspected infective endocarditis are empirically treated immediately after blood cultures are obtained, and antibiotics are then adjusted according to the pathogen(s) isolated. Empiric therapy for infective endocarditis in the elderly should be directed toward streptococci, enterococci, and staphylococci. A suggested regimen is intravenous ampicillin, nafcillin (or oxacillin), and an aminoglycoside (e.g., gentamicin) administered in high doses.¹²⁶ Patients allergic to beta-lactam antibiotics should be prescribed vancomycin plus an aminoglycoside. Duration of therapy varies depending on severity of illness, sensitivity of the organism(s) to the antibiotics, complications of endocarditis, valve involvement (e.g., aortic valve infection requires longer duration of antibiotics than tricuspid valve endocarditis), and clinical response. Antimicrobial therapy for infective endocarditis generally is for 4 to 6 weeks; prosthetic valve endocarditis requires at least 6 weeks of treatment.

Surgical intervention for infective endocarditis is indicated for the following: (1) refractory congestive heart failure; (2) more than one serious systemic embolic episode; (3) persistent infection despite appropriate antibiotics; (4) significant valve dysfunction as demonstrated by echocardiography; (5) unavailability of effective antimicrobial therapy (e.g., for fungal endocarditis); (6) resection of mycotic aneurysm; (7) antibiotic-resistant organism causing infection; and (8) local valvular or myocardial abscesses.¹²⁷ In addition, the American Heart Association has identified the following echocardiographic features as associated with increased potential for surgical intervention: (1) persistent vegetation after a major systemic embolic episode; (2) anterior mitral valve vegetation more than 1 cm in diameter; (3) increase in the size of vegetation after 4 weeks of antimicrobial therapy; (4) acute mitral valve insufficiency; (5) valve perforation or rupture; and (6) periannular extension of infection.¹²⁸

Recent data suggest that with early diagnosis of infective endocarditis using sensitive echocardiographic methods such as transesophageal echocardiography, the clinical outcome of elderly patients with valve infection is similar to that for younger patients.¹³ Antimicrobial chemoprophylaxis for preventing infective endocarditis is the same for elderly patients as for the general adult population, as has been published elsewhere.¹²⁹

Meningitis

Diagnosis

As previously mentioned (see Table 54.1), meningitis in the elderly has an especially high mortality rate;¹² in adults, the incidence of bacterial meningitis increases with advancing age.^{130,131}

Unless an office setting or outpatient clinic has the capacity for doing spinal punctures and immediate microbiologic studies (e.g., Gram stain), all elderly patients suspected of meningitis should be managed in a hospital. The sine qua non to making a specific diagnosis of meningitis requires examination of the cerebrospinal fluid. Most cases of meningitis in the elderly are caused by bacteria, primarily *Streptococcus pneumoniae*; *Listeria monocytogenes*, *Neisseria meningitidis*, and gram-negative bacilli (*E. coli*, *Proteus*, *Klebsiella*) are also important meningopathogens in elderly patients. An immediate Gram stain, immunologic studies for bacterial antigens, and culture of the cerebrospinal fluid are the most important initial tests; the cerebrospinal fluid glucose (with simultaneous serum glucose), white blood cell count with differential, and protein are also useful diagnostically. A low cerebrospinal fluid glucose (below 40 mg/dL or less than 30% of the simultaneously mea-

sured serum glucose), high white blood cell count (>500 cells/ μ L) with a differential of at least 80% neutrophils, and an elevated protein (>100 mg/dL) are consistent with bacterial meningitis.¹³² In patients who present with focal neurologic signs, seizures, coma, or suspicion of intracranial hypertension (e.g., papilledema), a brain imaging scan (e.g., computed tomography) should be performed before doing a lumbar spinal tap to exclude a coexisting mass lesion or shifts in brain structures. Under these conditions, the cerebrospinal fluid examination should be postponed to avoid potential herniation of the brain.

Treatment

Because most meningitis cases in the elderly are secondary to a bacterial infection, effective antimicrobial therapy is available for this life-threatening disease. In patients who are clinically stable without evidence of intracranial hypertension or mass lesion in the brain, empiric antimicrobial therapy may be withheld until blood cultures and lumbar spinal puncture are performed. Treatment then can be more specific and directed to a suspected etiologic pathogen based on findings on the initial examination of the cerebrospinal fluid (e.g., Gram stain). However, in elderly patients who are hypotensive, comatose, or having seizures or demonstrating rapid development of focal neurologic deficits (e.g., within 24 h) should receive the initial dose of antibiotics intravenously immediately after blood cultures are obtained and before any other tests are done (e.g., imaging scan of brain).¹³³ Under these circumstances, studies have shown that delays in antimicrobial therapy seriously affect the clinical outcome.¹³⁴ Earlier studies have indicated that prior antimicrobial therapy may affect the yield of organisms on Gram stain and culture, but that the microbiologic data retrieved after a few doses of antibiotics still remain substantial.¹³⁵

Empiric antibiotic treatment in elderly patients suspected of bacterial meningitis should be initiated with a third-generation cephalosporin, that is, cefotaxime or ceftriaxone, that penetrates well into the cerebrospinal fluid and has good antibacterial activity against *S. pneumoniae*, *N. meningitidis*, and gram-negative bacilli. Because *L. monocytogenes* is always a potential meningopathogen in the elderly, either penicillin G or ampicillin should also be added to the empiric therapeutic regimen (cephalosporins are relatively ineffective against this pathogen).¹³² In penicillin-allergic patients or if penicillin-resistant *S. pneumoniae* is suspected (e.g., because of a high incidence of this pathogen in the community), vancomycin should be prescribed in place of the cephalosporin for patients with beta-lactam allergy or added to the cephalosporin in penicillin-resistant *S. pneumoniae* cases. In addition, if methicillin-resistant *Staphylococcus aureus* is suspected or isolated, vancomycin would be the drug of choice;

otherwise, nafcillin or oxacillin should be administered for methicillin-sensitive *S. aureus* meningitis. All drugs should be administered intravenously during the entire period of therapy. For *Streptococcus pneumoniae* and *N. meningitidis* meningitis, most elderly patients should be treated for approximately 10 days, assuming there is a good clinical response. Meningitis caused by *L. monocytogenes* and gram-negative bacilli require at least 14 days and as long as 21 days of treatment.

With a good clinical response, repeat lumbar spinal punctures are not necessary at the completion of therapy. Measuring changes in cell counts, glucose, and protein in the cerebrospinal fluid are not better than clinical assessment (symptomatic improvement) in determining when to discontinue antibiotic therapy.¹³⁶ Although systemic corticosteroids have been recommended for children with acute bacterial meningitis,¹³³ data are lacking on their benefits for treatment of routine cases of bacterial meningitis in adults.¹³⁷ Nevertheless, in elderly patients with evidence of severely impaired mental status, intracranial hypertension, cranial nerve palsy, or cerebral edema, adjunctive corticosteroid therapy with dexamethasone may be beneficial even though supporting data for this are lacking.¹³³

Infectious Diarrhea

Infectious diarrhea has been recognized as a significant cause of morbidity and mortality in older adults in developed countries and is the fourth most common infectious disease in elderly patients confined to chronic care facilities. Acute diarrhea in the elderly is associated with the recovery of a specific diarrhea-inducing microorganism or toxin in the stools of 40% to 50% of patients.

Infectious causes generally result from two main pathophysiologic mechanisms: exudative (inflammatory or invasive) and secretory (noninflammatory or noninvasive). Exudative diarrhea is characterized by inflammation, necrosis, and sloughing of the intestinal mucosa and the presence of fecal leukocytes and occult or gross blood in the stool. Common diarrheal pathogens that operate predominantly by this method include *Salmonella*, *Shigella*, *Campylobacter*, and *Clostridium difficile* (*C. difficile*). Secretory diarrhea involves ion secretions that cause obligatory water loss. This diarrhea is unaffected by fasting and has been associated with viral infections (rotavirus, Norwalk virus), *Giardia lamblia*, and *Vibrio cholerae*.

Clostridium difficile infectious diarrhea following antibiotic use is more protracted and severe in the elderly because of repeated and prolonged use of these agents. It is managed by discontinuation of the offending antibiotic and treatment with oral metronidazole or vancomycin.

Immunizations

Influenza

Epidemics of influenza occur annually during the winter months and account for approximately 20,000 deaths each year in the United States.¹³⁸ Although the rates of influenza infection is the highest among children, the rates of serious morbidity and mortality are highest in the population age 65 years and older and in persons of any age with serious underlying medical conditions.¹³⁹ Influenza viruses that infect humans are primarily types A and B (there is a type C, but it is not clinically relevant), with influenza type A predominating in most epidemics. During the past three influenza seasons (1997–2000), influenza type A(H3N2) has been the dominant strain.¹⁴⁰

Vaccination is the primary method for the prevention of influenza and its complications (e.g., death, pneumonia). The primary target groups for immunization against influenza are those with the highest risk of experiencing complications from this infection, that is, all persons age 65 years and older and those persons under 65 years with chronic underlying medical conditions.⁸¹ In addition, individuals who are in contact with the high-risk influenza target groups should also receive immunization to prevent transmission of infection, such as health care personnel, staff of long-term care facilities, employees of assisted living and other residential settings housing high-risk groups, persons providing home to care to high-risk groups, and household members of persons in high-risk groups.⁸¹ Immunization with the influenza vaccine should be administered annually, usually from October through November. The influenza vaccine has a 30% to 40% effectiveness in preventing influenza in residents of long-term care facilities, and perhaps a slightly higher rate of protection in ambulatory elderly.⁸¹ Its greatest benefit is its effectiveness in reducing the severe complications of influenza. It is 50% to 60% effective in preventing hospitalization or pneumonia and 80% effective in preventing death in elderly residents in chronic care institutions.⁸¹

Use of antiviral agents against influenza is an important adjunct to influenza immunization in the control and prevention of this infection. Presently, amantadine and rimantadine are approved for both treatment and prophylaxis against influenza type A (neither drug is effective against influenza type B). Amantadine and rimantadine must be given within 48 h of onset of illness to be effective in reducing severity and duration of influenza. The standard dosage of 100 mg twice daily of amantadine should be reduced to 100 mg per day in the elderly; rimantadine, similarly, should be prescribed at a dosage of 100 mg/day for those age 65 years and older;⁸¹ further dose reduction is justified with renal impairment.

The drugs are given for 3 to 5 days or discontinued within 24 to 48 h after marked improvement of symptoms. Both drugs can be used as chemoprophylaxis against influenza type A infection during an outbreak but are not a substitute for immunization. It is recommended that chemoprophylaxis be prescribed for high-risk groups who have not been vaccinated, those who cannot be vaccinated (e.g., having allergy to vaccine), or individuals with diseases that are associated with inadequate antibody responses to immunization.⁸¹ In addition, during an outbreak chemoprophylaxis should be considered for all elderly residents in long-term care facilities, even those who have been appropriately vaccinated, because the vaccine has only a 30% to 40% effectiveness in preventing influenza. Duration of prophylaxis is not clear, but most would recommend prescribing the drug until the peak activity of influenza in the community resolves.

Recently, two newer antiviral agents have been approved for treatment of influenza types A and B, the neuraminidase inhibitors zanamivir and oseltamivir.¹⁴¹ The drugs are only recommended for persons with clinical symptoms of influenza for no more than 2 days (efficacy of drug after 48 h of symptoms has not been shown). Data are not available at the time of this writing showing whether either zanamivir or oseltamivir prevents the complications of influenza, but preliminary studies suggest their efficacy in reducing the incidence of influenza in previously vaccinated elderly.¹⁴² Zanamivir is administered via oral inhalation spray and oseltamivir is taken as an oral capsule: both drugs are prescribed for 5 days. Zanamivir and oseltamivir, at present, are not approved for chemoprophylaxis.

Pneumococcal Infection

Invasive *Streptococcus pneumoniae* (pneumococcal) disease in the United States increases with age. In one study, the annual incidence of bacteremia secondary to *S. pneumoniae* in the general population was 15 to 30 cases per 100,000 population; in persons age 65 years and older, the incidence was 50 to 83 cases per 100,000 population.¹⁴³ The majority (>60%) of pneumococcal bacteremia in adults is associated with pneumonia.¹⁴⁴ The incidence of pneumococcal meningitis in adults is also the highest in persons age 65 years and older.¹⁴⁵ Pneumococcal infection causes 40,000 deaths annually in the United States, with the case-fatality rates being the highest for bacteremia and meningitis; the highest mortality occurs in the elderly population and patients with serious underlying medical conditions.¹⁴⁵

Immunization against invasive disease caused by the most common serotypes of *S. pneumoniae* is the most effective means of prevention. In immunocompetent persons aged 65 years and older, the pneumococcal vaccine was shown to have an effectiveness of 75%.¹⁴⁶ A

single dose of the pneumococcal vaccine is indicated for all persons aged 65 years and older, including previously unvaccinated persons and persons who have not received the vaccine within 5 years and were less than age 65 years at the time of the vaccination.¹⁴⁵ Persons in whom their vaccination status is unknown should receive the vaccine. A repeat dose is presently not indicated except for immunocompromised persons. In immunocompromised persons (human immunodeficiency virus infection, leukemia, lymphoma, multiple myeloma, generalized malignancy, chronic renal failure or nephritic syndrome, status postorgan transplantation, and receiving immunosuppressive chemotherapy), a single revaccination is recommended after 5 or more years have lapsed since the first dose of pneumococcal vaccine.¹⁴⁵ The pneumococcal vaccine may be administered at the same time the influenza vaccine is given, provided they are injected at opposite sites.

Tetanus

Although the total number of cases of tetanus has continued to decline over the past 50 years, recent reports indicate that 35% of tetanus cases in the United States occurred in persons aged 60 years or older. The case-fatality rate also increased with age.¹⁴⁷

During 1995 to 1997, the average annual incidence of tetanus among persons age 60 years and older was 0.33 cases per 1 million population, which is a 2-fold increase compared with persons aged 20 to 59 years and a 12-fold increase compared with persons aged 1 to 19 years.¹⁴⁷ The case-fatality ratio was also highest in the older adult age group.¹⁴⁷ The primary explanation for the higher incidence and death rate from tetanus is the lack of adequate immunization.

The Advisory Committee on Immunization Practices (ACIP) recommends that immunization status be reviewed at age 50 and tetanus immunization be administered to all older adults.¹⁴⁸ However, there are no data on the cost-effectiveness of immunizing all persons age 50 and older (or 65 years and older) against tetanus in the United States, given the relatively few number of cases reported annually (average, 25 cases per year). In a Canadian study that examined the cost-effectiveness of implementing a primary tetanus vaccination program among the elderly for family physicians, the conclusion was that there was a questionable value of using health care resources for this program.¹⁴⁹ At that time (1984), in Canadian dollars, the cost of preventing one case of tetanus would be \$1.9 million. Some have recommended administering tetanus vaccine to all nursing home residents, which seems premature, given the lack of evidence for cost-effectiveness.¹⁵⁰ Immunization with tetanus vaccine should, perhaps, be considered for older adults who are at risk for wounds or injuries, and for institu-

tionalized elderly who are a significant risk for cutaneous ulcers.

Immunization for tetanus is administered using a combined tetanus-diphtheria toxoid preparation in adults. A primary series of three injections is given, followed by a booster vaccination every 10 years.¹⁴⁷

Hematologic Problems

Gerald Rothstein

The bone marrow and circulating blood cells make up the blood cell system. This system is a dynamic one where, in the nondiseased steady state, production and utilization of blood cells are equal. However, when there is an increased demand for blood cells, such as during anemia or infection, the marrow produces more cells to provide for the increased need. In young and middle-aged adults, the system functions appropriately, responding to physiologic needs and then returning to the steady state ready to respond to new demands. However, as aging proceeds, the response to increased demand for blood cells becomes disordered and a variety of factors combine to increase the prevalence of anemia and hematologic malignancy.

The Bone Marrow During Aging

The bone marrow is the site of production for circulating red blood cells, granulocytes, and platelets. As aging proceeds, the marrow becomes increasingly localized to the axial skeleton. However, in nondiseased elderly persons, the total number of marrow cells in the body is not decreased; it is similar to that of healthy young adults.¹ Consequently, clinical examination of the marrow (the myeloid: erythroid ratio, maturation of cell lines, karyotypic analysis, and presence and distribution of stainable iron) of older persons does not differ from that of normal young adults.

The Blood Cells and Their Laboratory Values During Aging

The concentrations of red cells, platelets, and leukocytes in the blood of healthy older persons do not differ from those of young adults. The normal ranges for hematocrit are expected to increase with altitude and are best interpreted in the context of locally generated means and

variances. The prevalence of anemia is increased in populations of community-dwelling, clinic-visiting, and hospitalized elderly. However, anemia is not a consequence of age. Indeed, the distribution of hematocrit values for elderly patients falls roughly into two populations: one that is in the anemic range, and another that overlaps with the distribution for normal young adults.² This finding supports the concept that older persons develop anemia because of underlying disease. Indeed, careful diagnostic testing of elderly anemic subjects reveals one or more identifiable causes for the anemia in at least 80% of cases.²

Substrates for Blood Cell Production

Critical substrates for blood cell production are iron, vitamin B₁₂, folic acid, dietary calories, and protein. Deficiencies in one or more of these substrates cause anemia, as well as other adverse consequences.

In the elderly, the body's iron is highly conserved. There is no excretory pathway for iron, and aged women are not affected by the iron loss of pregnancy or normal menstruation. Loss of iron from the body is only approximately 1 milligram (mg) per day, occurring as skin and gut cells are shed passively. In contrast to this slight daily insensible loss, total body iron is normally approximately 3g, distributed roughly equally between red cell hemoglobin and storage iron within reticuloendothelial cells.³ Consequently, storage iron alone is approximately 1500 times greater than the expected daily insensible loss. This extensive supply of stored iron provides a reserve with which to replace the iron of hemoglobin if blood were lost. Indeed, even if no dietary iron were ingested, more than 4 years would elapse before the iron stores were exhausted by insensible iron loss and anemia began to develop. Therefore, iron deficiency should never be considered to be a consequence of dietary deficiency of iron. *Iron deficiency should always be considered a*

consequence of blood loss, and should prompt a thorough search for a source of bleeding, such as occult colon carcinoma. Indeed, in more than 80% of cases of iron deficiency the reason for iron loss is identified, and, at least in a population of variously aged adults, almost always the cause is blood loss.⁴

Folic acid and vitamin B₁₂ have a critical role in cellular proliferation. Deficiencies in these vitamins lead to macrocytic anemia with characteristic morphologic alterations (megaloblastic changes) in the precursors of the marrow and circulating neutrophils. Vitamin B₁₂ is also important for maintenance of the integrity of the nervous system, and its deficiency leads to subacute combined degeneration of the nervous system with peripheral sensory manifestations and cognitive impairment. The megaloblastic anemia of either vitamin can be corrected by folic acid, so that administration of folic acid can mask the anemic manifestations of vitamin B₁₂ deficiency. The neurologic changes of B₁₂ deficiency are only inconsistently reversed by replacement therapy and may be irreversible if advanced.⁵

Regulation of Blood Cell Production During Aging

In steady state and during periods of increased demand, blood cell production is regulated by erythropoietin and a variety of cytokine stimulators, as well as being under the influence of endocrine hormones such as thyroxine, and corticosteroids. During aging, steady-state regulation of the marrow appears normal, as evidenced by normal numbers of marrow precursors.^{1,6-8} During periods of increased hematopoietic demand, the hematopoietic response of the elderly is dysregulated. For example, phlebotomized aged mice do not repair posthemorrhagic anemia as rapidly as young animals.⁶ The cause of this impaired regeneration of red cells is unclear and may be multifactorial. In elderly persons, deficiency of erythropoietin is a frequent contributing or causative factor, and the administration of recombinant erythropoietin is effective in reversing at least some of the anemias in elderly persons due to erythropoietin deficiency.⁹ Defects in leukocyte regeneration have also been demonstrated in aged animals, which do not replace utilized neutrophils as briskly as young adults.⁷ In fact, in bacterially infected aged mice, there is a *paradoxical reduction* in both the number and proliferative rate of neutrophil precursors.⁷ The marrow precursors of elderly persons show a similar defect, with paradoxical reductions in the concentrations of progenitor cells for granulocytes, as well as red cells.

A number of studies have shown that these hematopoietic defects may in part be explained by impaired production of cytokine stimulators such as granulocyte-macrophage colony-stimulating factor (GM-CSF).¹⁰

However, the disordered production of cytokines is not one of universal impairment; the production of other cytokines, such as interleukin 6 (IL-6) (a promoter of B-lymphocyte survival and growth) appears to be increased in the elderly.^{11,12} Consequently, factors that control the production of blood cells appear to be dysregulated during aging, thus impairing the ability of the marrow to appropriately respond to increased demand for blood cells. The age-associated paradoxical reduction in marrow cells during infection and anemia is not yet understood, but it can be speculated that the dysregulated production of cytokines, such as IL-10, which induce programmed cell death (apoptosis), may account for this.¹³ It can also be proposed that dysregulated production of cytokines that impair normal marrow growth or promote the growth of neoplastic clones may be factors in the increased prevalence of hematologic malignancies in the elderly. IL-6 is an example of an age-associated increase in cytokine production that can promote the emergence of a specific malignant disease, multiple myeloma. IL-6 is a promoter of the survival and growth of myeloma cells, and IL-6 also impairs the effectiveness of antimyeloma therapy with corticosteroids by blockading their mechanism of action: induction of programmed cell death.¹⁴

Anemia in the Elderly

Although anemia is more prevalent as aging proceeds, this cannot be assumed to be due to aging alone. In the elderly as in young adults, discrete and identifiable diseases cause anemia. However, elderly persons can be considered to be more susceptible to anemia-inducing events because of an age-associated impairment of the marrow's ability to appropriately increase red cell production.

Prevalence of Anemia in the Elderly

The prevalence of anemia in the elderly is greater than that of young adults, ranging from 5% to 51%, with the lowest prevalence in community-dwelling elderly who consider themselves healthy, intermediate values for prevalence among those enrolled in clinics for health care, and the greatest prevalence among the oldest old who are hospitalized.^{2,15-17} This correlation of age-associated anemia and health status supports the concept that anemia is a consequence of disease in the elderly and not due to age alone.

Clinical Presentation of Anemia

The clinical presentation of anemia depends on the degree of anemia, the underlying cause, and the presence of comorbid conditions. Often, anemia in the elderly is

TABLE 55.1. The kinetic categories of anemia: supportive laboratory tests and associated disorders.

Kinetic category of anemia	Laboratory tests	Corresponding disorders
Decreased red cell production	Reticulocyte count ^a (reduced) Marrow cellularity (reduced) Marrow myeloid: erythroid ratio (increased)	Iron deficiency, anemia of chronic disease, megaloblastic anemias, protein/calorie malnutrition, endocrine diseases, erythropoietin deficiency marrow infiltrative diseases, aplastic anemia, anemia secondary to chemotherapy
Increased red cell destruction	Indirect bilirubin ^a (increased) LDH (increased)	Hemolytic anemias, bleeding into closed body spaces, paroxysmal nocturnal hemoglobinuria
Loss of red cells	History of bleeding ^a Stool guaiac (positive) ^a	GI blood loss, surgical blood loss, bleeding diatheses
Ineffective erythropoiesis	Reticulocyte count ^a (reduced) Indirect bilirubin ^a (increased) LDH (increased) Marrow myeloid: erythroid ratio (increased)	Myelodysplastic syndromes, megaloblastic anemia

^aTests useful for screening purposes.

associated with such nonspecific symptoms as fatigue, functional decline, and weakness, and is only discovered by laboratory survey. Under these circumstances, the patient's perception of quality of life may be adversely affected, even when hemoglobin levels are as high as 11 g/dL. Importantly, the fatigue and poor quality of life associated with anemia respond to correction of the anemia even when serious underlying conditions such as malignancy are unresponsive to treatment. When anemia is a consequence of malignancy such as myeloma, the dominant presenting symptoms may be those associated with the underlying neoplasm, such as bone pain, symptoms of uremia, or even confusion due to hypercalcemia. When anemia is associated with newly developed postural hypotension, increasing dyspnea, or increasing angina, this may indicate that the anemia has developed acutely, is severe, or is associated with acute bleeding and intravascular volume loss. In such cases, aggressive interventions to restore intravascular volume and red cell mass are indicated.

Determining the Etiology of Anemia

The etiology of anemia should be established to identify the pathologic process responsible for the anemia, to determine the appropriate therapeutic approach for the anemia, and to provide prognostic information. The task of diagnosis is simplified by the consideration that anemia can be categorized kinetically as being due to decreased production of red cells, increased destruction of red cells, loss of red cells (bleeding), or ineffective erythropoiesis. The various laboratory tests that can be used to place anemia in one of these kinetic categories are shown in Table 55.1, as are disorders associated with each kinetic category. It can be seen that the decreased production category is primarily composed of deficiencies of molecular substrates for hematopoiesis, and by infiltrative diseases (e.g., hematopoietic malignancies,

metastases, myelofibrosis). The category of increased destruction is composed of the hemolytic anemias and by bleeding into closed body spaces, such as retroperitoneally. The category blood loss is a simple one, related to mechanical trauma, gastrointestinal lesions, or hemorrhagic diatheses. Ineffective erythropoiesis is associated with clonal hematoproliferative disorders and megaloblastic states.

In addition to the basic tests already listed, the complete blood count (CBC) should include a measure of the mean red cell volume, the MCV. In this way, the anemias may be characterized morphologically as normocytic, microcytic, or macrocytic. The morphologic categories of anemia are shown in Table 55.2, along with diseases associated with them. The need for the tests other than the CBC and MCV varies from example to example, and efficient and effective determination of etiologies is greatly

TABLE 55.2. Morphologic categories of anemia and selected corresponding disorders.

Morphologic category	Disorders
Microcytic	Iron deficiency Anemia of chronic disease Thalassemia, hemoglobin E disease Spherocytic hemolytic anemias
Macrocytic	Megaloblastic anemia (B ₁₂ and/or folate deficiency, antimetabolites) Liver disease with target cells Greatly increased numbers of reticulocytes
Normocytic	Renal failure Erythropoietin deficiency Endocrine disorders Anemia of chronic disease Protein-calorie malnutrition Infiltrative diseases of the marrow Aplastic anemia Anemia secondary to chemotherapy Polymyalgia rheumatica

enhanced by coupling tests of kinetic parameters with the morphologic information. However, results can sometimes be complex, such as is found in anemia resulting from ineffective erythropoiesis, where the corrected reticulocyte count is low (evidence of decreased production of red blood cells, RBC), the indirect bilirubin is elevated (increased destruction of RBC), and the bone marrow is hypercellular (increased RBC production). Also in hemolytic states, evidence of increased RBC destruction is frequently accompanied by an increased reticulocyte count. Effective use of the morphologic and kinetic information serves the essential process of progressively excluding disorders in the differential diagnosis until the correct cause is identified and confirmed.

Interpretation of Laboratory Tests for Anemia

The utilization of the various laboratory tests for the diagnosis of anemia requires an understanding of the strategies and pitfalls of their interpretation.

Laboratory reports for reticulocyte count are expressed as percent (%), or the number of reticulocytes (young red cells) per 100 red cells in the blood smear preparation. The normal range is from 0.8% to 2.5% in men and 0.8% to 4.1% in women if anemia is not present. However, anemia is expected to stimulate increased production of reticulocytes. In anemic subjects, an adjusted reticulocyte percentage should be calculated by multiplying a patient's raw laboratory reticulocyte percent by the ratio of the patient's hematocrit to an average normal hematocrit value, such as 45%.

Corrected reticulocyte %

$$= \text{uncorrected reticulocyte \%} \times \frac{\text{patient hematocrit (\%)}}{45}$$

Measurements of serum folate should be conducted before patients are fed in hospital because single feedings of foods rich in folic acid may raise folate levels into the normal range. Measurements of red cell folate content provide a better estimate of folate status for preceding months. Folic acid deficiency is most frequently caused by decreased dietary intake, although deficiency can also occur because of intestinal malabsorption and because of blockage of absorption by such drugs as anticonvulsants and sulfasalazine.

Serum levels of vitamin B₁₂ may also be difficult to interpret. Some reports have suggested that concentrations of less than 100 pg/mL are necessary for establishing the diagnosis of B₁₂-deficient anemia. However, more recent studies suggest that levels greater than 100 pg/mL are found in more than one-third subjects with pernicious anemia.² Other investigators suggest that even levels of B₁₂ in the low-normal range may be associated with the

central nervous system changes of B₁₂ deficiency, so that measurements of methylmalonic acid may be indicated when B₁₂ is in the low-normal range (200–300 pg/mL).^{2,18,19} Vitamin B₁₂ is plentiful in animal products and is stored in considerable quantity, so that strict vegetarian (vegan) diets appear necessary to cause deficiency states based on reduced dietary intake. More frequently, B₁₂ deficiency is based on defective absorption, either because of deficiency of gastric-produced intrinsic factor needed for B₁₂ absorption, or due to intestinal mucosal atrophy or removal of the jejunum. The Schilling test can be used to assess the mechanism of B₁₂ malabsorption but is relatively insensitive as a diagnostic tool for the deficiency state, so that normal Schilling test results do not exclude the diagnosis of B₁₂ deficiency.

Measurements of erythropoietin must be interpreted in light of the degree of anemia that is present. In the presence of anemia, erythropoietin production should be increased and circulating levels should rise. Unfortunately, the response of serum erythropoietin to varying degrees of anemia has not been clearly defined and varies among laboratories. However, serum erythropoietin is expected to rise to levels above those described as normal for nonanemic individuals, and many laboratories can supply at least partially complete data for relationship of erythropoietin levels to various degrees of anemia. If such data are not available, a practical approach would be to expect erythropoietin levels in patients with moderate or severe anemia to rise to at least fivefold of the upper limit of the laboratory's normal range.

Evaluation of Renal Function

For the purpose of assessing the role of renal function in anemia, one should use creatinine clearance. The "normal range" reported for serum creatinine by laboratories is derived from studies of young adults and assumptions that depend upon a phenotypically young body composition. During aging, lean body mass comprises a progressively smaller proportion of body weight, so that the source for creatinine diminishes; this change is magnified even further in elderly women. Consequently, reliance on serum creatinine measurements alone results in an overestimate of renal function in the elderly. To correct for the age-related change in body composition, the creatinine clearance can be estimated by the Cockcroft–Gault equation:

Creatinine clearance

$$= 72 \times \frac{140 - \text{age (years)} \times \text{weight (kg)}}{\text{serum creatinine concentration (mg/dL)}}$$

For women, the calculated creatinine clearance from this equation is multiplied by 0.85. Creatinine clearances of 30 mL/min can be expected to be associated with anemia,

and when creatinine clearance is 20 mL/min or less, the hematocrit is usually 30% or less.²⁰ In otherwise unexplained normocytic anemia, measurement of erythropoietin measurement may be useful even if calculated creatinine clearance is more than 40 mL/min because the Cockcroft–Gault formula only provides a rough estimate of creatinine clearance, and there may be uncoupling of erythropoietin secretion and renal function.²¹

Serum iron, total iron-binding capacity, transferrin saturation, and ferritin frequently are sufficient to assess iron stores.²² To avoid artifactual variation related to ingested iron or diurnal variation in iron concentration, the serum iron should be measured fasting and in the morning, and in the absence of medicinal iron supplementation. Normal values among laboratories vary highly and may range from 28 to 122 $\mu\text{moles/L}$; consequently, the normal values used should be those established for the laboratory performing the test. The total iron-binding capacity (TIBC) reflects the quantity of iron transport protein, transferrin, and ranges from 250 to 435 $\mu\text{moles/L}$. Elevated TIBC values are most often found in iron deficiency; low values are expected in the anemia of chronic disorders and in the presence of protein-calorie malnutrition. The transferrin saturation is calculated by dividing the serum iron \times 100 by the TIBC. The transferrin saturation is expected to be reduced to a mean value of 7% in iron deficiency, as compared with a mean of 15% in the anemia of chronic disease, and is between 20% and 45% in normal individuals. Saturations greater than 75% are found in sideroblastic anemia and iron overload conditions. Measurement of serum ferritin is a useful means of indirectly assessing the quantity of stored iron. Values greater than 300 micrograms per liter ($\mu\text{g/L}$) suggest iron overload, such as can occur with multiple transfusion or hemochromatosis.^{21–23} In studies of the elderly, serum ferritin measurements are informative in considering the diagnosis of iron deficiency. Concentrations greater than 100 $\mu\text{g/L}$ are associated with a probability of less than 10% of iron deficiency whereas values less than 18 $\mu\text{g/L}$ indicate a greater than 95% probability of iron deficiency.²⁴

Microscopic examination of the blood and marrow is also useful in identifying the etiology of anemia. Examination of the blood smear is highly dependent on the skill of the examiner, and should be carried out when the morphology of circulating RBC and white blood cells is critical to identifying the etiology of anemia. Variations in the size (anisocytosis) and shape (poikilocytosis) of red cells are prominent features of iron deficiency, and also are prominent with certain infiltrative diseases of the marrow, such as myelofibrosis and metastases to the marrow. Circulating nucleated red cells may also be found in the infiltrative diseases. In iron deficiency, the red cells are microcytic and their hemoglobin concentration (MCHC) is usually reduced (hypochromia) when the hematocrit is as low as 25%. Hypochromia is variably present or absent

when the hematocrit is greater than 30%.²⁵ Young red cells (reticulocytes) can be recognized by their large diameter, a bluish cast to the cytoplasm, and the presence of stippling, which is due to polyribosomes completing the synthesis of hemoglobin. Megaloblastic anemias are characterized by the presence of large, oval-shaped circulating red cells (macrocytes), and further examination usually reveals hypersegmented neutrophils with six or more nuclear lobes. The blood smear in megaloblastic anemia also may disclose a reduction in the numbers of leukocytes and platelets. In addition, examination of the blood smear can reveal leukemic white blood cells, myeloma cells, target cells (large red cells with a target-like distribution of hemoglobin), and a host of other abnormalities. Consequently, examination of the blood may aid substantially in identifying the cause of the anemia.

The marrow can be prepared by smearing cells on a slide, preparing pathologic sections of clotted aspirates, or preparing sections of biopsies obtained by cutting needle or surgical resection. Aspirates may theoretically be obtained from any bone bearing marrow, but most are obtained from the iliac crests. Occasionally, marrow is obtained by aspirate of the sternum, but this procedure is potentially hazardous because of the risk of pericardial or cardiac puncture in all patients; the risk is even greater in elderly persons with osteoporosis. Usually, both aspirated and biopsy specimens are obtained. Aspirated cells examined in smears are useful for morphologic evaluation of cellular maturation, examination for stainable storage iron, and determination of the myeloid: erythroid ratio. Aspirated cells can also be submitted for chromosomal analysis. In cases of megaloblastic anemia, examination of the marrow reveals typical changes characterized by red cell precursors whose nuclei appear younger than expected for the degree of hemoglobin synthesis in the cytoplasm. This “nuclear/cytoplasmic dissociation” is a hallmark of megaloblastic red cell production. Usually, the workup of anemia can be completed without marrow examination, and such examination is only carried out to definitively address issues such as iron status, infiltrative or malignant disease, megaloblastic processes, aplastic anemia, and sideroblastic anemia or myelodysplastic syndromes. The quantitative cellular content (cellularity) of the marrow can be estimated by examination of clot sections of aspirates and biopsies, but not by smears of aspirates.

The Basic Laboratory Approach to Anemia

A practical approach is to begin with the morphologic classification of the anemia and then proceed through additional selected tests to identify the etiology. Note that the values for mean corpuscular volume (MCV) may differ among laboratories, and values specific for each laboratory should be used.

Microcytic Anemias (MCV < 80 fL)

The most common diagnoses are iron deficiency, the anemia of chronic disorders and thalassemia. First, iron status should be defined.

Initial Laboratory Tests

Serum iron

Serum TIBC

% Transferrin saturation

Serum ferritin

Optional: Marrow for stainable iron if the serum tests do not clearly define iron status

Interpretation and Course of Action

This panel of tests defines iron status. Reduced serum iron, increased TIBC and greatly reduced % transferrin saturation establish the diagnosis of iron deficiency. When those results are ambiguous, staining of the marrow for iron represents the “gold standard” for evaluation of iron stores. When iron stores are depleted, stainable marrow iron is absent. The diagnosis of iron deficiency dictates an effort to identify the source of iron loss (bleeding) and to proceed with iron replacement therapy.

Reduced serum iron, decreased or normal TIBC, mildly decreased % transferrin saturation, normal or increased ferritin, the presence of stainable iron in the marrow, and the presence of an active inflammatory disease suggest the anemia of chronic disease. Approximately 30% of patients with the anemia of chronic disease have microcytic red cells, so the absence of microcytosis does not exclude this diagnosis.²⁵ The anemia of chronic disease may respond partially or completely to effective treatment of the underlying inflammatory condition²⁶ and, in some cases, erythropoietin administration may be indicated to improve quality of life, even if the underlying condition is not responsive to treatments directed against it.^{9,27}

Macrocytic Anemias (MCV > 100 fL)

In general, the diagnoses comprising this category can be divided into those caused by impaired DNA synthesis (megaloblastic anemias), increased reticulocytes, alterations of the RBC membrane due to liver disease, or, more rarely, hemoglobinopathy. The anemias of myelodysplastic disorders usually are also macrocytic. The etiology usually can be identified as follows.

Initial Laboratory Tests

Reticulocyte count

Indirect bilirubin

Interpretation and Course of Action

An increased reticulocyte count signifies increased RBC production in response to either blood loss or hemolytic anemia. In the absence of an elevated bilirubin, blood loss is most likely and the source of blood loss should be identified. If the bilirubin is also elevated, hemolytic anemia should be suspected.

If reticulocyte number is normal or reduced, proceed to examination of blood and bone marrow for megaloblastic changes.

Interpretation and Course of Action

If megaloblastic changes are found in the marrow, this confirms the diagnosis of megaloblastic anemia. Serum vitamin B₁₂ and folic acid concentrations should be measured. If a deficient value is found, therapy should be instituted to correct the deficiency. If antimetabolite therapy has been administered, this should be considered the cause of the anemia. If the marrow is not megaloblastic, the blood smear should be examined for the presence of target cells, which may signal the presence of liver disease, hypothyroidism, or, rarely, an inherited hemoglobinopathy such as hemoglobin C disease.

Normocytic Anemias (MCV 81–100 fL)

This morphologic category includes a wide variety of etiologies including posthemorrhagic anemias or hemolytic anemias without extensive reticulocytosis, conditions in which marrow cell production is impaired (e.g., aplastic anemia, infiltrative diseases of the marrow, anemia due to decreased erythropoietin production, the anemia of protein-calorie malnutrition, and most examples of the anemia of chronic disease). A useful initial procedure is to perform a reticulocyte count.

Initial Laboratory Test

Reticulocyte count

Interpretation and Course of Action

An increased reticulocyte count reflects an increase in RBC production and should prompt consideration of the diagnoses of hemolytic anemia or posthemorrhagic anemia. A history of blood loss should be sought, and tests that can reflect increased red cell destruction should be obtained (indirect bilirubin, LDH). If evidence of hemolysis is found, the differential diagnosis should include autoimmune causes with or without underlying malignancy or oxidant sensitivity due to glucose-6-phosphate dehydrogenase deficiency. It should also be noted that bleeding into closed body spaces, such as retroperitoneally, can yield kinetic and morphologic laboratory results that are indistinguishable from those of hemolytic anemia.

A normal or reduced reticulocyte count should prompt the consideration of hepatic or endocrine disorders. If these screening surveys are negative, an additional laboratory test should be preformed.

Microscopic Examination of the Peripheral Blood

Bone marrow aspirate and biopsy
Serum iron, TIBC, transferrin saturation, and ferritin

Interpretation and Course of Action

Examination of the blood and bone marrow is frequently sufficient to establish or exclude the diagnoses of leukemia, myeloma, myelofibrosis, myelodysplasia, or infiltration of the marrow with metastases. Submission of aspirated marrow cells for karyotypic analysis may be useful in differentiating certain of these causes. Iron studies that reveal a reduced serum iron, decreased TIBC, modest decrease in the % transferrin saturation, and normal or elevated ferritin are consistent with the diagnosis of the anemia of chronic disease, in which normocytic RBCs are found in approximately 70% of cases.²⁶

Treatment of Anemia

The goal in treating anemia is to increase or completely restore the circulating red cells to normal levels. The appropriate strategies for increasing the red cell mass should be specifically directed by the urgency of the need for treatment and the underlying cause of the anemia. Some remediable causes of anemia and their key laboratory findings and treatment, are displayed in Table 55.3.

Transfusion

Transfusion is associated with significant risks, such as volume overload, immunologic transfusion reactions, and the unintended infusion of infectious agents, such as transfusion-associated hepatitis, Epstein-Barr virus, and human immunodeficiency virus. Consequently, transfusion should not be given simply because a patient's hemoglobin or hematocrit has reached an arbitrary level. Indications for transfusion include acute blood loss with symptoms of hypovolemia, progressive symptoms of decreased oxygen delivery such as angina or increasing confusion, or symptomatic anemia that is refractory to nontransfusion therapy. When transfusion is used to treat refractory anemia without loss of blood volume, concentrated red cells should be used to avoid volume overload. However, even when restoration of blood volume is indicated, blood banks may only supply concentrated red cells rather than whole blood. In such cases, concentrated red cells may be given together with crystalloid or synthetic plasma volume expanders. The infusion of plasma or albumin appears unnecessary except when volume loss has exceeded 50% of total blood volume.²⁸ When blood transfusion is urgent, it should be given together with measures to ensure restoration of the blood volume.

Correction of Deficiencies of Substrates for Red Blood Cell Production

This strategy represents the ideal for management of anemia. A diagnostic process clearly identifies a deficiency of iron, folic acid, vitamin B₁₂, or protein/calories,

TABLE 55.3. Some remediable causes of anemia, their key laboratory results, and treatment.

Etiology	Laboratory results	Treatment and other interventions/studies
Iron deficiency	Microcytic RBC Reduced serum iron Increased TIBC Reduced Tf saturation Reticulocytes not increased	Identify source of iron loss and correct. Give oral iron 3 months, repeat iron studies. Intravenous iron only if iron cannot be given orally.
Anemia of chronic disease	Normo- or microcytic RBC Reduced serum iron Reduced TIBC Reduced Tf saturation Reticulocytes not increased	Identify underlying inflammatory disease. Apply remedy to underlying disease when available. May be responsive to erythropoietin administration.
B ₁₂ , folate-deficient anemia	Macrocytic RBC Hypersegmented PMN on blood smear Reduced B ₁₂ or folic acid Megaloblastic changes on bone marrow exam Reticulocytes not increased	Evaluate diet for sources of B ₁₂ , folic acid. Rule out malabsorption. Administer B ₁₂ or folate for replacement. Track response with reticulocyte counts, Hct/Hgb. B ₁₂ replacement must be for lifetime.
Protein-calorie-deficient anemia	Normocytic RBC Reduced lymphocyte count Reduced serum albumin Reduced serum transferrin	Restoration of protein-calorie nutrition restores the hematocrit to normal.

and administration of the appropriate substrate corrects the anemia. Usually, a response to therapy can be observed within 4 weeks of initiating therapy, and the anemia is repaired in 3 months or less. When iron therapy is needed, oral administration is the preferred route, and the gluconate, sulfate, or fumarate salts of iron are all effective. The iron should be administered with meals to avoid gastrointestinal side effects, and therapy is continued for 3 to 6 months after the anemia is resolved to assure replacement of iron stores.²⁹ If taken as directed, oral iron therapy is almost always effective in treating iron deficiency, although treatment failures may be encountered because patients may not comply with therapy. Parenteral iron therapy may be necessary in patients who are unable to tolerate oral iron, patients who are noncompliant with oral therapy, situations in which bleeding continues at a rate that exceeds the ability of oral iron to compensate for loss, patients with malabsorption of oral iron, dialysis patients unable to maintain adequate iron by oral intake, and in those who repeatedly and very frequently donate large amounts of blood. Iron-dextran is the preferred preparation for parenteral use and is usually administered intravenously because repeated intramuscular injections are painful and cause staining of the skin at the site of injection. It should be recognized that iron-dextran may cause hypersensitivity reactions.

Vitamin B₁₂ can be administered either intramuscularly, monthly at a dose of 1000 µg, or orally, in large doses of 1000 mg/day, even for treatment of pernicious anemia resulting from intrinsic factor deficiency.³⁰ Folic acid is also administered orally, and daily doses of 1 mg/day provide a generous excess above the minimum daily requirement of 50 to 100 µg/day. It should be noted, however, that large doses of folic acid are capable of reversing the anemia of B₁₂ deficiency while permitting the neurologic consequences of pernicious anemia to advance. Consequently, therapeutic trials with folic acid are potentially dangerous, and therapy should be directed in a focused manner only after the specific deficiency state has been identified. In some patients, the response to vitamin B₁₂ or folate may appear to fail before the anemia is repaired. In such cases, the explanation may be that existing iron stores have been exhausted by utilization for new red cell production. Iron status should therefore be evaluated and, if iron is deficient, its cause should be identified and replacement therapy instituted.

Treatment of Underlying Conditions

Some anemias are partially or completely resolved when therapy is directed toward underlying etiologic conditions. A noteworthy example is the anemia associated with polymyalgia rheumatica (PMR), which resolves when corticosteroid treatment of PMR is successful.

Similarly, replacement or thyroid hormone in hypothyroidism induces resolution of the associated anemia, unless it is due to the B₁₂ deficiency related to associated gastric autoimmunity.³¹ However, the response may be sluggish, requiring 3 to 12 months before the anemia resolves.³² The anemia associated with myeloma is also resolved by chemotherapeutic measures that induce remission of the malignancy, but may also respond to erythropoietin.

Growth Factors and Erythropoietin

An important characteristic of the hematopoietic progenitors of the elderly is the preservation of their responsiveness to hematopoietic stimulators. With the availability of recombinant growth factors and erythropoietin, an evolving strategy for the treatment of anemia is the use of these agents to directly drive erythropoiesis. For example, it is now clear that in myelodysplastic syndromes (MDS), prolonged administration of a combination of the hematopoietic stimulator, recombinant G-CSF, and erythropoietin can increase the hematocrits of individuals with these disorders.²⁷

Alterations of the White Blood Cells

Although the white blood cells (WBC) of the elderly exhibit in vitro changes in their function, the clinically observable function of WBC, laboratory values, and WBC morphology in the elderly are not different from those of young adults. However, some neoplastic disorders of the WBC such as chronic lymphocytic leukemia (CLL), polycythemia vera, atypical chronic myelocytic leukemia, and the myelodysplastic syndromes are particularly prevalent in the elderly.

Ageing and Physiologic Function of WBC

The WBC are a system that includes the neutrophils, monocytes, eosinophils, basophils, and lymphocytes. The neutrophils constitute a major physiologic barrier to microbial challenge; their function is based on their ability to migrate toward inflammatory attractants, engulf foreign particles, and kill bacteria via oxidant and enzymic mechanisms. Monocytes also possess migratory and microbial properties and appear particularly important in eradication of microbial organisms that could otherwise survive and proliferate intracellularly. Monocytes also possess the ability to detect and eradicate tumor cells and appear important for eliminating emerging neoplastic clones. Eosinophils participate in resistance to parasitic infections and in hypersensitivity reactions, whereas basophils are thought to serve as sources of histamine. Lymphocytes also participate in hypersensitivity reac-

tions, as well as in antibody synthesis. Both lymphocytes and monocytes synthesize and release a variety of cytokines, which modulate the function of a wide range of cells including blood cell progenitors. Regulation of the production of all the WBC is not completely understood. However, it is clear that neutrophil production can be driven *in vitro* and *in vivo* by recombinant growth factors such as G-CSF, and the progenitors of young adults and elderly persons appear to be equally responsive to such stimulation.³³ Proliferation of T lymphocytes is stimulated by interleukin 2, and the production of this cytokine is impaired during aging.³⁴ However, whether this is the cause of a predominance of naïve T cells that occurs in the elderly is not known.

Specific defects in the function of some types of WBC have been demonstrated in aged animals and man. For example, in *in vitro* studies, neutrophils from aged individuals do not generate antimicrobial oxidants as vigorously as the neutrophils of young adults.³⁵ However, this laboratory finding does not correlate with defective function of neutrophils *in vivo*. Monocytes from aged individuals also generate a reduced flux of antimicrobial oxidants *in vitro*, and this change may be a contributing factor in the increased susceptibility of aged rodents and man to infection with intracellular microbial agents, such as toxoplasma, legionella, and mycobacteria.³⁶ Despite observations in animals, which demonstrate impaired production of neutrophils after bacterial challenge,⁷ there is no evidence that elderly persons experience impaired neutrophil production during infection. Maldistribution of T cells is observed during aging, with the emergence of a predominance of naïve T cells. This change has been implicated in the reduced and shortened duration of antibody responses to antigen challenge in the elderly.³⁴

Laboratory Evaluation of the WBC

WBC are evaluated by numerical counting and morphologic examination. Blood usually is collected in tubes containing calcium chelators to prevent coagulation. The cells are counted electronically as they pass through an aperture and create the electrical resistance characteristic of nucleated cells. Thus, the laboratory “white blood count” is in reality a total nucleated cell count and not specific for WBC. Even so, the white blood count usually accurately reflects the number of leukocytes and not other cells. However, when large numbers of nucleated red cells are present in the circulation, the actual leukocyte count must be calculated by multiplying the WBC by the percentage of leukocytes as determined by differential counting.

Enumeration of the various types of WBC is carried out by performing a differential count, either electronically or by microscopic examination of smeared and stained blood. Laboratories ordinarily perform electronic differ-

TABLE 55.4. Laboratory values for the white blood cell count and absolute counts for specific leukocytes.

Cell type	Mean (10 ⁹ /L)	Range (10 ⁹ /L)
White cell count	6.6	3.5–9.8
Neutrophils	4.01	1.31–6.71
Lymphocytes	2.1	0.90–3.22
Monocytes	0.37	0.12–0.62
Eosinophils	0.13	0.00–0.30
Basophils	0.0	0.01–0.09

ential counts, which do not detect the “band” form, the less mature neutrophils that appear in the blood during infection. Consequently, when WBC are to be evaluated for signs of bacterial infection, microscopically determined differential counts should be ordered. Differential counting adds much to the evaluation of WBC, because this establishes the percentage of the total white blood count for each type of leukocyte. However, differential counting alone is insufficient to quantitatively assess each cell type. To quantify the various types of WBC, absolute cell counts should be calculated by multiplying the percentage for the cell type in question by the white blood count. For example, for a WBC of $8.4 \times 10^3/\mu\text{L}$ with 33% neutrophils, the absolute neutrophil count is $2.77 \times 10^3/\mu\text{L}$ ($8.4 \times 10^3/\mu\text{L} \times 0.33$). Values for the WBC and the various types of leukocytes are shown in Table 55.4.

Interpretation of Variations in the Leukocyte Counts

Decreased Leukocyte Counts

A decrease in the WBC (leukopenia) cannot be interpreted without a differential count and calculation of absolute counts.

The significance of neutropenia (neutrophil count $<1.4 \times 10^9/\text{L}$) depends on the distribution and kinetics of neutrophils in the blood and their subsequent delivery to sites of infection (Fig. 55.1). Neutrophils are produced in the marrow, and then released into the blood where they have a transit time ($T_{1/2}$) of 4 to 10 h.³⁷ Once they enter the circulation, they may be within a freely circulating pool of cells and available to the phlebotomy needle, or marginated along the walls of vessels where they cannot be obtained in a blood sample and therefore are not counted. Because the circulating and marginated neutrophils freely exchange, together they comprise the total pool of neutrophils available for function. Therefore, the neutrophil count alone does not always reflect the total pool of neutrophils. Indeed, when due to increased margination, even pronounced neutropenia is not associated with an increased risk for infection. The risk for infection

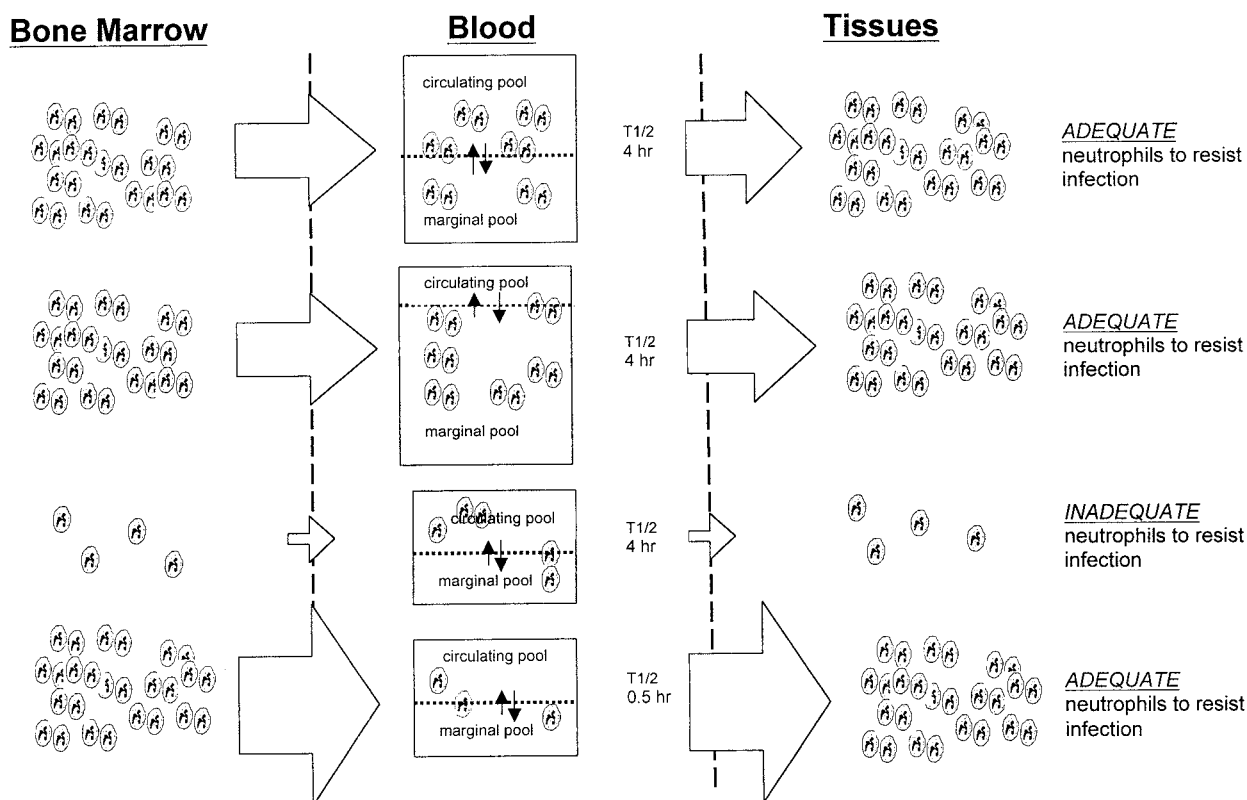

FIGURE 55.1 Distribution and kinetics of neutrophils in blood and tissues.

correlates best with the supply of neutrophils, and neutropenia can exist in circumstances where the total pool of neutrophils is decreased but the rate of production and use of neutrophils is increased, such as in Felty's syndrome. In this latter case, the supply of neutrophils is adequate and the risk for infection is not increased. When neutropenia reflects a reduced total neutrophil pool and production of neutrophils is reduced, the risk of infection increases (see Fig. 55.1). The risk of infection rises significantly with neutrophil counts less than $0.5 \times 10^9/L$.³⁸ Thus, it is neutropenia caused by hypoproduction, which must be differentiated from the neutropenias due to margination or rapid transit of neutrophils through the blood (see Fig. 55.1). The most definitive strategy for estimating the ability of the marrow to produce neutrophils is direct examination of a smear and biopsy of the marrow to determine cellularity, the myeloid : erythroid ratio, and cellular morphology/maturation. The marrow examination is also useful in recognizing the presence of myelodysplastic disorders, in which distinctive morphologic changes, increased numbers of immature blast cells, abnormal iron distribution, and chromosomal abnormalities confirm the diagnosis.

When neutropenia is due to margination or rapid transit of neutrophils in the blood, increased risk of infection is not expected. When neutropenia reflects severely

impaired production of neutrophils, fever and symptoms related to the site of infection and infectious organism are prominent. In addition, subjects with neutropenia may experience severe throat or oral pain (agranulocyte angina). Fever or other signs of infection in severely neutropenic patients should be approached as an urgent matter. A thorough workup should be initiated to identify the site and organism responsible for infection, and supportive/antibiotic therapy should either be instituted empirically or as dictated by the site and organisms that are found. In addition, the cause of neutropenia should be identified. Examination of the blood and marrow should be conducted, and a diagnosis of autoimmune disease should be considered. Medications should be reduced to a minimum and an exhaustive search conducted for any medicines that have previously been identified as offending agents.³⁹

Lymphopenia (lymphocyte count $<0.9 \times 10^9/L$) can be seen in a variety of conditions, such as following the administration of corticosteroids, in tuberculosis, and during AIDS. Lymphopenia is also a finding in subjects with protein-calorie malnutrition and can be considered as supporting evidence for malnutrition. A reduction in the eosinophil count is observed following corticosteroid administration, during some inflammatory processes, and during bacterial infection.

Increased Leukocyte Counts

The significance of leukocytosis cannot be determined without a differential count and calculation of absolute counts. An increase in the WBC can occur because of large numbers of nucleated red cells in the peripheral blood and may be due to the presence of neoplastic cells, such as leukemia cells. Neutrophilia is defined as a neutrophil count greater than $6.71 \times 10^9/L$. Neutrophilia can occur as a consequence of bacterial infection and, under those circumstances, is frequently associated with the appearance of band (nonsegmented) neutrophils in the blood. This appearance of band neutrophils in the blood is referred to as a "left shift." The left shift may also occur after corticosteroid administration. Neutrophilia also occurs as a consequence of movement of neutrophils from the marginal to the circulating pool of cells, without a change in the total circulating neutrophil pool. Neutrophilia due to demargination is not associated with a left shift and can be precipitated by stimuli such as exercise or epinephrine.³⁷ Lymphocytosis is defined as a lymphocyte count greater than $3.22 \times 10^9/L$.

Lymphocytosis occurs in hyperthyroidism, infectious hepatitis, and following blood transfusion when it can signal infection with cytomegalovirus. Unexplained sustained lymphocytosis is usually a reflection of chronic lymphocytic leukemia or, less frequently, lymphoma. Eosinophilia is defined as an eosinophil count greater than $0.7 \times 10^9/L$. Eosinophilia is frequently a signal of allergic conditions, such as asthma or allergy to medicines; it also occurs during parasitic infection, and during autoimmune diseases. Monocytosis may be seen in subjects with tuberculosis or during monocytic anemia, but frequently the explanation for it is obscure. Basophilia (basophil counts $>0.09 \times 10^9/L$) may be observed in chronic myelocytic leukemia, polycythemia vera, Hodgkin's disease, and systemic mastocytosis.

Disorders of Hemostasis

Hemostasis is a complex process that depends on vascular factors as well as the formation of an occlusive platelet plug and production of a stable insoluble fibrin clot.

The bleeding history is an indispensable element in evaluating hemostasis. Hemostasis itself is a tightly regulated process with focused hemostatic mechanisms that are intended to restrict the location and duration of the hemostatic process. During aging, chronic solar exposure as well as a reduction in cutaneous collagen and elastin leads to an increased prevalence of ecchymoses, particularly on the extensor surfaces of the forearms and dorsum of the hands. This finding does not signify a systemic disorder of hemostasis. Similar cutaneous ecchymoses are

also associated with hyperadrenalcorticism, in which case the clinical findings of Cushing's syndrome may be observed. Numerous unprovoked petechiae are symptoms of decreased platelet function or number, and generalized mucocutaneous bruising should raise the suspicion of a systemic hemostatic defect, particularly that associated with reduced number or function of platelets.

Spontaneous or easily provoked deep bleeding, such as into muscle, retroperitoneally, or into joints, is most likely to reflect a defect in the coagulation process, either due to deficiency of coagulation factors or because of the presence of an endogenously produced or medicinal circulating anticoagulant. The temporal occurrence of bleeding after trauma is also useful in identifying its underlying cause. Defects in platelet function or number are most likely to produce bleeding manifestations that occur within 1 h of procedures such as dental extraction; delay of bleeding until 4 to 6 h is more consistent with a defect in coagulation. Hereditary bleeding disorders are usually recognized and identified before patients reach old age, but a history of lifelong bleeding symptoms may occasionally disclose such disorders, even among the elderly.

Disorders of the restraint of hemostasis also produce distinctive symptoms. For example, unprovoked thrombosis at unusual sites, or even the new and repeated occurrence of deep vein thrombosis in the legs, may reflect a hypercoagulable state. Such events can be caused by deficiency of the naturally occurring endogenous anticoagulants and may be associated with malignancy or antiphospholipid antibody.

Laboratory Evaluation of Hemostasis

The investigation should include a careful history followed by laboratory studies. The basic panel of studies follows.

Initial Studies

Platelet count
 Prothrombin time (PT) and international normalized ratio (INR)
 Activated thromboplastin time (aPTT)

Interpretation

The platelet count is used to determine whether thrombocytopenia (platelets $<150 \times 10^9/L$) contributes to or causes the bleeding. Thrombocytopenia may be due to decreased production of platelets, increased removal of platelets from the circulation, or hemorrhage. A classification of thrombocytopenias is shown in Table 55.5. Bleeding usually is severe when the platelets are below

TABLE 55.5. Classification of the thrombocytopenias.

Decreased platelet production
Leukemia, other infiltrative diseases of the marrow
Megakaryocytic hypoplasia
Hereditary
Aplastic anemia
Viral infection
Increased removal of platelets from the circulation
Heparin-induced thrombocytopenia
Thrombotic thrombocytopenic purpura (TTP)/hemolytic uremic syndrome (HUS)
Disseminated intravascular coagulation (DIC)
Immune thrombocytopenic purpura (ITP)
Microangiopathic processes
Loss of platelets
Severe hemorrhage, replacement with platelet-poor bank blood
Sequestration of platelets
Splenic enlargement or infiltrative disease
Anesthesia coupled with hypothermia

10,000, variably present when platelets are 10,000 to $50,000 \times 10^9/L$, and hemostasis may appear clinically normal in those with counts above $50,000 \times 10^9/L$ unless trauma occurs.⁴⁰ The thrombocytopenia induced by heparin is due to an IgG antibody toward complexes of heparin and platelet factor 4.^{41,42} These antibody–heparin–platelet complexes can cause microvascular occlusive events that result in such consequences as stroke, myocardial infarction, and ischemia of extremities. Thrombotic thrombocytopenic purpura (TTP) is yet another cause of a reduced platelet count and is associated with hemolysis, thrombocytopenia, fever, and mental status changes. TTP represents an urgent condition requiring prompt intervention, such as with corticosteroids and plasma exchange.^{43,44}

In some instances, low platelet counts are not associated with clinical signs or symptoms of a bleeding diathesis; this can sometimes be ascribed to pseudothrombocytopenia, a laboratory artifact generated by *in vitro* clumping of platelets, which prevents their accurate electronic counting. Pseudothrombocytopenia can be recognized by examination of blood smears obtained directly from the fingertip and specially anticoagulated specimens.⁴⁵

Several laboratory tests can aid in defining the explanation for thrombocytopenia. The production of platelets is most definitively assessed by examination of a bone marrow biopsy. Assays for antiplatelet antibody may be useful in confirming an antibody-mediated mechanism for thrombocytopenia.^{46,47}

The clinical management of thrombocytopenia is dictated by symptoms, urgency of treatment, and etiology. Individuals with active bleeding may require platelet transfusion, although such treatment is not often effective in ITP. When heparin induces slight and asymptomatic reductions in the platelet count, the heparin need

not be discontinued. However pronounced or symptomatic heparin-induced thrombocytopenia should be managed by discontinuing the heparin and active management of the adverse consequences. The diagnosis of ITP dictates the use of steroid therapy or other immunosuppressive interventions. When thrombocytopenia occurs as manifestation of disseminated intravascular coagulation, therapy is directed toward the underlying cause and heparin may be indicated to retard pathologic coagulation, but replacement of platelets and consumed factors is also frequently necessary.

The PT/INR and aPTT are utilized to screen for coagulation disorders. The PT is carried out by activation of the extrinsic pathway of coagulation to generate fibrin (Fig. 55.2) and can only be accurately interpreted by expressing it as an international normalized ratio (INR), which standardizes the test for differing reagents used by various laboratories. The aPTT is performed by activation and fibrin formation via the intrinsic pathway (see Fig. 55.2). Prolongation of either of these tests can be due to (a) a deficiency of one or more coagulation factors or (b) inhibition of the coagulation. Deficiency states can be differentiated from the presence of inhibitors by mixing the patient's plasma with normal plasma, 1:1, and repeating the coagulation assay. In deficiency states, the addition of normal plasma corrects the test; when inhibitors are present, the test is not corrected. Deficiency states are partially clarified by the test that is abnormal: factor VII only functions in the PT, whereas factors VIII, IX, XI, and XII are restricted to the aPTT. Factors, I, II, V, and X function in the common pathway (see Fig. 55.2). Further refinement is obtained by consideration of the vitamin K-dependent factors (II, VII, IX, and X), and those consumed by the coagulation process (I, II, V, and VIII). Factor XIII is consumed with the hemostatic process; proteins S and C are vitamin K dependent, but none of these affect the PT/INR or aPTT.

Inhibitors of coagulation can be considered in two categories: medicinal inhibitors of coagulation, such as heparin, and endogenous inhibitors. Protein S and C, which are present normally, are not potential causes of abnormalities in the PT/INR or aPTT. Heparin preferentially prolongs the aPTT more than the PT, via its acceleration of the anticoagulant activity of antithrombin III. When the coagulation tests are prolonged and not corrected by the addition of normal plasma, the presence of pathologic anticoagulants should be sought. Of these perhaps the most frequently observed is an acquired inhibitor to Factor VIII which, in the elderly, may be found after Factor VIII treatment of classic hemophiles, in the presence of such disorders as rheumatologic disease or cancer, or as an isolated finding.⁴⁸ Factor VIII inhibitors are associated with prolongation of the aPTT but not the PT/INR and are usually associated with severe and intractable bleeding.⁴⁹ Another cause of

prolongation of the aPTT that is uncorrected by normal plasma is the presence of a phospholipid antibody. However, the phospholipid antibody is associated with hypercoagulability, not a hemorrhagic diathesis, and usually presents in subjects less than 60 years of age.⁵⁰ Prolongation of both the PT/INR and the aPTT should raise the question of deficiency of vitamin K, or consumption of coagulation factors such as occurs in disseminated intravascular coagulation (DIC). When the PT/INR is prolonged by the induction of vitamin K deficiency with warfarin it is corrected by the addition of normal plasma.

The presence of normal laboratory tests does not rule out a bleeding diathesis. Indeed, even if the complete blood count, PT/INR, and PTT are all normal, diagnoses such as von Willebrand's disease are not ruled out and should be pursued further with tests such as multimeric analysis of von Willebrand's factor (vWF), ristocetin-induced agglutination of platelets, and ristocetin cofactor analysis. In the past, the bleeding time has been con-

sidered as useful for the diagnosis of von Willebrand's disease and as a screening test for preoperative evaluation. However, because of the variability and relatively unreliable nature of the bleeding time, it is no longer recommended.⁵¹ Because of the variability of results for the various tests and their behavior as acute-phase reactants, even repeated sophisticated testing for von Willebrand's disease may be insufficient to definitively rule out this diagnosis.⁵²

Estimating the Risk for Bleeding at Surgery

Although routine laboratory tests are frequently ordered with the aim of predicting operative risk, the reliability of such testing is at least suspect, if not misleading, particularly when laboratory tests are normal. However, a history of possible systemic bleeding diathesis (e.g., mucocutaneous bleeding, history of deep hematomata or intra-articular hemorrhage, hemostatic problems with trauma or surgery, or excessive bleeding or rebleeding

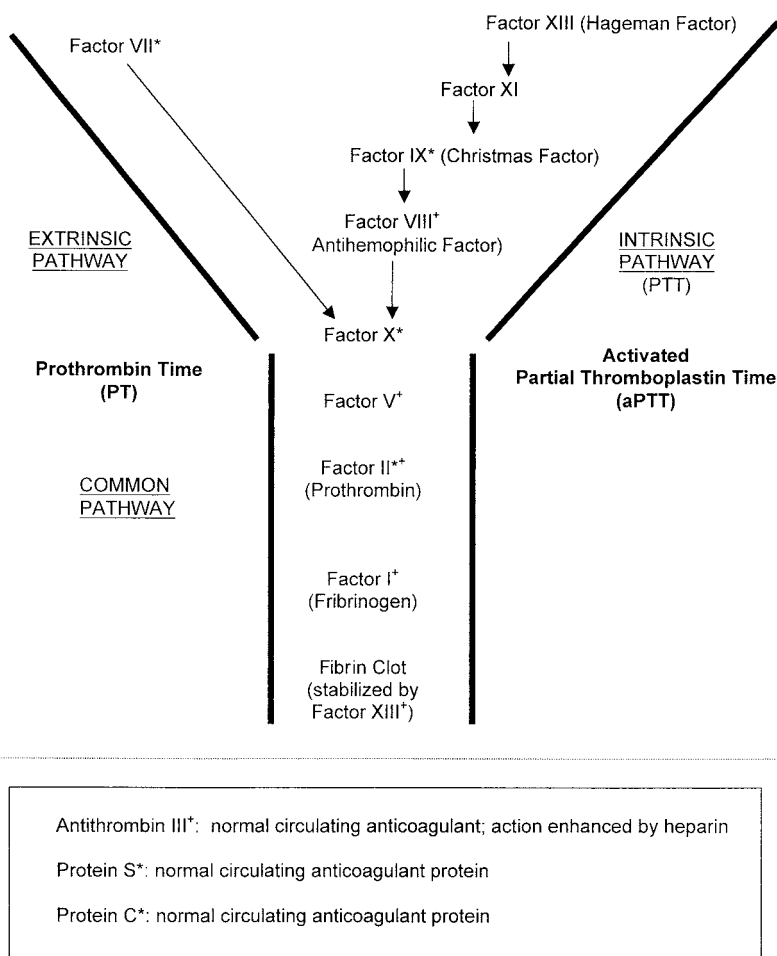

FIGURE 55.2 Pathways of coagulation.

after dental procedures) should prompt a thorough investigation of hemostatic status. In addition, laboratory screening should be performed on patients who are unduly susceptible to the consequences of even minor blood loss or who are to be subjected to surgery that itself carries a particular risk for major blood loss.

Hypercoagulable States

Hypercoagulable states are characterized by a history of excessive or inappropriate (usually venous) thrombotic events. The most common sites of thrombosis are in the lower extremities, although thromboses in unusual sites, such as superficial or deep veins in the arm or shoulder girdle, also occur. The hypercoagulable states may be either hereditary or acquired. Hereditary conditions that cause hypercoagulability usually are manifested in young adulthood, and the history provides the initial and necessary clue to their presence. The hereditary hypercoagulable states include deficiencies of antithrombin III, protein C, or protein S, and specific functional laboratory tests for these proteins are necessary to identify deficiencies of them. Protein S or C are dependent on vitamin K for their synthesis, and their deficiency underlies the phenomenon of warfarin-induced skin necrosis, which is actually a local manifestation of a hypercoagulable state initiated by vitamin K-deficient impairment of physiologic restraints of coagulation. Activated protein C resistance is another inherited cause of hypercoagulability, and is most commonly due to a point mutation in the factor V gene that results in the production of factor V Leiden. This mutation is very common in the Caucasian population (3%–7%) but almost absent among some black or Asian populations. A mutation in the gene for prothrombin (factor II) is also relatively common, and this mutation is found in 6% to 18% of patients with venous thromboembolism. Factor V Leiden and the prothrombin mutation must be diagnosed by specific laboratory testing or by DNA analysis.⁵³ Acquired hypercoagulable states may be associated with frank malignancy or with such diseases as the myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria. In addition, hypercoagulability may be associated with the antiphospholipid syndrome, although this condition usually presents before age 60.

The management of hypercoagulable states is dictated by management of acute thrombotic events and by preventive therapy with warfarin anticoagulation. Acute thromboses should be treated with either unfractionated or low molecular weight heparin. Patients with two or more spontaneous thromboses, a life-threatening thrombosis, a spontaneous thrombosis at an unusual site, or a thrombosis in the presence of more than one hypercoagulable state should receive anticoagulation for life.⁵³

Joanne A.P. Wilson

The function of the gastrointestinal tract remains relatively normal during the process of aging,¹⁻⁴ probably because of the apparent excess production of hormones and enzymes as well as redundancy in structure of the organ system. In the study of gastrointestinal function in the elderly, most of our studies have attempted to differentiate physiologic changes from pathologic changes that may be associated with systemic disorders. Early studies that did indicate significant physiologic changes appear not to have had essential age-specific controls and frequently represented comparisons of ill hospitalized elderly with younger normal controls. Most recent studies have shown few changes in gastrointestinal function with age.

One important factor in the elderly, however, is the increase in prevalence of certain disorders with age dramatically affecting the differential diagnosis in the elderly patient. For example, the incidence of *Helicobacter pylori* infection in certain populations as well as the incidence of gastric ulcers dramatically increases with age. The effect on the gastrointestinal tract of other disorders such as atherosclerotic vascular disease contributes to ischemic complications. Other vascular abnormalities associated with aging contribute to the development of angiodysplasias and other bleeding lesions within the gastrointestinal tract; these are generally not seen in younger populations. The incidence of other conditions such as cardiovascular dysfunction also contributes to modifications in the management of gastrointestinal problems in elderly patients, particularly with gastrointestinal bleeding and the hemodynamic compromise that may occur. The increased use of medications and the inherent effects of these drugs on the gastrointestinal tract also affect the spectrum of disease seen, which remains an important consideration in the evaluation of the elderly patient. Last, with age, there is an increase in gastrointestinal malignancies. (See Chapter 34, Colon Cancer and Other GI Malignancies.)

Disorders of Swallowing and the Esophagus

Age-related changes in esophageal function are common on careful manometric studies but generally not clinically significant. However, dysphagia and reflux esophagitis are two common problems for elderly patients.

Normal Swallowing

Normal swallowing is accomplished by a series of intricate and interrelated activities. After chewing, the tongue moves the bolus of food to the back of the oropharynx, where voluntary and involuntary muscle movements then occur. The upper esophageal sphincter and the upper third of the esophagus are composed of striated muscle, whereas the lower two-thirds of the esophagus is smooth muscle. Food in the back of the oropharynx initiates reflex progressive muscle contraction in a stripping action known as peristalsis. A voluntary swallow can also initiate peristalsis. As the peristaltic wave reaches the lower esophageal sphincter, reflex relaxation occurs, and food can enter the stomach. Resting pressure in the lower esophageal sphincter then keeps food and acid from refluxing back into the esophagus.

Physiologic Changes with Aging

Healthy older individuals do not have clinically significant evidence of aging when it comes to swallowing or esophageal function. There are, however, histologic and manometric evidence of changes that appear with aging which may predispose the elderly to be less tolerant to other stresses and illnesses. Some illnesses seem more frequently in the elderly may directly affect the ability to swallow.

Oropharyngeal Dysphagia

Age-related changes in the tongue with decrease in the muscle mass may have clinical significant impact on chewing and swallowing in the ill elderly. Age-related olfactory and taste discrimination losses may contribute to anorexia and dietary choices in the elderly as substantial decreases in these functions are noted by age 70 years. Medications may further impair these functions.⁴

Dysphagia

Dysphagia is the sensation that food is sticking or that there is difficulty with swallowing. The feeling of dysphagia is usually associated with the presence of an abnormal movement of food or liquids through the esophagus and should not be considered hysterical.

In general, dysphagia can be due to mechanical abnormalities or to abnormalities of function resulting in motility disturbances. A carefully taken history usually yields a very accurate diagnosis. Symptoms due to mechanical causes of dysphagia are usually consistent in presentation and are most frequently affected by eating solids, especially large solids. Progressive decrease in luminal size, as would be seen with a growing esophageal cancer, may present as progressive loss of ability to swallow meats, then potatoes, and eventually soups. Symptoms associated with motility disorders, on the other hand, are usually intermittent, with liquids playing a major role. Patients can frequently accurately point to the site of the dysphagia. Nonspecific points that represent nerve radiation and are therefore not specific include the sternal notch and the epigastrium. The most common causes of dysphagia can be found in Table 56.1. The reader is referred to a review by Mendez et al.⁵ for a more detailed approach to evaluating the patient with dysphagia, or to Sonies for a review of oropharyngeal dysphagia.⁶

Dysphagia is different from odynophagia, or pain on swallowing. Odynophagia usually implies mucosal ulcer-

ation, either from irritation (such as one might see from a pill lodged and eroding the mucosa of the esophagus), infection (such as candidial or herpes esophagitis), erosive (such as an esophageal ulcer from reflux esophagitis), or neoplastic.

Most disabling for patients and frustrating for health care practitioners is the problem of oropharyngeal dysphagia, most frequently associated with cricopharyngeal incoordination.⁷ Whether due to a large cerebrovascular accident (CVA) or to a point lesion in the swallowing center in the medulla, Parkinson's disease, myasthenia gravis, or myositis, patients with cricopharyngeal incoordination tend to have difficulty initiating swallowing and transferring food from the oropharynx to the upper esophagus and are at high risk of developing aspiration pneumonia. Recurrent coughing or aspiration during eating is the most frequent problem noted. Other symptoms include the sensation of food sticking in the neck or nasal regurgitation. Other evidence of neuromuscular weakness such as dysarthria may also be present. Gag reflex is a poor predictor of intact function.

Treatment usually involves a multidisciplinary approach, including evaluation by a speech therapist and dietary manipulation.⁶ In general, semisolids are better tolerated than liquids, as solids will initiate secondary peristalsis whereas liquids may sit in the back of the throat, waiting for the cricopharyngeus to eventually open. If opening does not occur before a breath is taken, then aspiration can occur. Positioning of the head and variation of food consistency may decrease the risk of aspiration. Rehabilitation has had some success after new strokes. For frail patients with recurrent aspiration pneumonia, avoidance of swallowing and tube feeding may be the only alternative.⁸ Nasogastric tubes are usually used only as a short-term solution and are not well tolerated by older patients with confusion. Percutaneous endoscopic gastric (PEGs) or duodenal feeding tubes are more permanent solutions.⁹

Some patients with oropharyngeal dysphagia may develop a Zenker's diverticulum, an outpouching through gaps in the muscles of the pharyngeal wall, immediately above the upper esophageal sphincter. These sacs collect food that becomes caught above the uncoordinated sphincter, slowly enlarging over time. They may enlarge enough to become a visible mass in the neck. Patients with Zenker's complain of coughing, gurgling in the neck, postprandial regurgitation, and aspiration. Diverticulectomy will reduce the danger of aspiration. Upper esophageal myotomy is done in some centers to improve the ease of swallowing.

Diabetes mellitus, a common problem in the elderly, can at times be associated with smooth muscle wasting,

TABLE 56.1. Common causes of dysphagia in the elderly.

Presbyesophagus
Mechanical disorders
Webs or rings
Carcinoma
Peptic ulceration or stricture
Extrinsic compression

Intermittent dysphagia to liquids and solids is the major complaint. With involvement of the lower esophageal sphincter, severe reflux esophagitis can also occur. Diagnosis is usually made by manometrically demonstrating loss of primary peristalsis in the body of the esophagus. Little therapeutic progress has been made in this frustrating problem. Having the patient sit upright while swallowing and until food has passed through the stomach may decrease symptoms.

Other problems presenting as motility disorders include scleroderma, especially in patients with Raynaud's phenomena; dermatomyositis; myasthenia gravis; amyotrophic lateral sclerosis; tabes; hyper- and hypothyroidism; and, occasionally, as a finding in patients with a distant carcinoma. The existence of presbyesophagus, the finding of decreased primary peristalsis and the development of spontaneous synchronous nonperistaltic contractions due to aging alone, has been a point of debate. Presbyesophagus, if it does occur, probably does not occur before age 90 unless other neuromuscular problems are present.¹⁰

Diffuse esophageal spasm (DES) is the development of synchronous, very high amplitude, prolonged nonperistaltic contractions. Known in the past as "nutcracker esophagus," the spasm of DES can produce crushing substernal chest pain that is indistinguishable from cardiac angina in location, character, or radiation. DES represents 10% to 30% of the noncardiac chest pain seen in emergency rooms. Patients with DES sometimes describe onset of pain or dysphagia with ingestion of cold liquids and have intermittent dysphagia for liquids and solids. Diagnosis of DES can be confirmed by barium swallow, where a "corkscrew esophagus" may be seen, or by esophageal manometry, where the multiple concentric nonperistaltic contractions may be shown. As the spasm of DES occurs intermittently, manometry or radiography may be falsely negative if the spasm is not occurring during the testing. Therapy of DES includes treatment of reflux esophagitis if it is present, administration of long-acting nitrates or calcium channel blockers, and occasionally esophageal dilatation or longitudinal myotomy for incapacitating cases with severe dysphagia and weight loss.^{7,11}

Achalasia is not frequent in the elderly, but does have a second prevalence peak in old age. Patients complain of a long history, with insidious onset, of intermittent dysphagia to liquids and solids and regurgitation of undigested foods or aspiration. Chest radiographs of patients with achalasia can show a widened mediastinum due to massive dilatation and tortuosity of the esophagus, often with an air-fluid level and evidence of retained secretions. Barium studies show the dilation of the esophagus with "bird beak" narrowing. Esophageal manom-

etry is diagnostic, revealing nonperistaltic contractions, poor relaxation of the lower sphincter, and very high pressure in this sphincter. Neither nitrates nor calcium channel blockers have proven beneficial. Recent studies have shown that botulinum toxin injection into the sphincter muscle is effective for up to 2 years but needs to be repeated.¹² Pneumatic dilatation or surgical myotomy can offer more permanent relief of many of the symptoms for those who can tolerate the procedure. Achalasia-like symptoms of shorter onset can also be seen in patients with carcinoma involving the lower esophageal sphincter. These patients tend to have a more significant weight loss associated with their dysphagia.¹³ Endoscopic evaluation is recommended for patients with achalasia.

Mechanical causes of dysphagia in the elderly include problems within the esophagus such as webs, rings, peptic strictures, and carcinoma. A lower esophageal web occurs with some frequency at the junction of the esophagus and the stomach. Known for the radiologist who first reported it, Schatzki rings are the cause of the so-called steakhouse syndrome. Elderly patients who do not chew their food well, especially if they have been drinking, may swallow a piece of steak or other hard food that is larger in diameter than their Schatzki ring. Rings larger than 13 mm in diameter are usually asymptomatic. Blockage of the bolus of food in the distal esophagus can result in significant substernal pressure or pain, and can be mistaken by the patient for cardiac pain. Endoscopic removal, dislodgment, or dissolution of the stuck food can usually be accomplished. A single bougienage with a large-diameter dilator is usually the only treatment that is necessary. Plummer and Vinson reported thin esophageal webs in the upper mid-esophagus in elderly Northern European women with iron deficiency; however, this kind of web is becoming a rare finding in the United States.

Medication-induced esophagitis ("pill esophagitis") and strictures are more likely in the elderly.¹⁴ Recumbency and structural and motility disorders are predisposing factors. Commonly seen medications are potassium chloride, iron compounds, tetracycline, doxycycline, and quinidine. Alendronate may cause a severe form of esophagitis. Pills and capsules can lodge in the esophagus near the aortic arch or in the distal esophagus, especially in patients who take their medication while lying in the supine position or patients with decreased primary peristalsis. Prolonged contact of the medication with the esophageal mucosa can result in local inflammation and ulceration. Change to liquid administration, if possible, and acid suppressive therapy is usually satisfactory in reducing the symptomatology if stricture formation has not occurred.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a common problem in the elderly, affecting at least 30%, and increasing in prevalence with aging.^{15,16} It plays a major role in the annual use of more than \$2 billion per year for antacids and other prescription and nonprescription remedies for dyspepsia. Heartburn is most frequent after meals and on reclining in bed; it is typically quickly relieved by ingestion of antacids or milk. Although many elderly present with only occasional mild heartburn, others may have disabling reflux, severe chest pain, bleeding or perforation due to ulceration, laryngeal stridor, asthma, or aspiration pneumonitis because of reflux, or eventually carcinoma if Barrett's esophagus develops. There is no good clinical correlation between the frequency or severity of heartburn and the endoscopic or pathologic evidence of esophagitis. Other symptoms of GERD include water brash, regurgitation, dysphagia, and anginal-like chest pain associated with diffuse spasm. Diagnosis of GERD can frequently be made by history alone. Endoscopy is indicated in patients with chronic reflux (>5 years), late onset, dysphagia, and/or severe pain.

For patients with symptoms that are not quickly responsive or in whom the diagnosis is in doubt, 24-h pH monitoring of the esophagus or barium swallow can demonstrate reflux. Gastroesophageal endoscopy will demonstrate if esophagitis is present and can demonstrate the presence of Barrett's esophagus, ulceration or stricture development, or other intraesophageal pathology.

Barrett's esophagus refers to the finding of one or more islands of gastric columnar epithelium with intestinal metaplasia within the lining of the esophagus, which is usually lined with squamous mucosa. These histologic changes develop after the squamous mucosa has been exposed to acid reflux for years. Barrett's esophagus is a premalignant condition associated with an increased risk of developing adenocarcinoma of the esophagus.¹⁷ The documentation of Barrett's mucosa mandates aggressive acid suppressive therapy with proton pump inhibitors and surveillance endoscopy with biopsy. If dysplasia develops, then ablative or surgical resection is recommended.

Empiric therapy includes elevation of the head of the bed, reduction in nocturnal meal size; avoidance of fat, caffeine, alcohol, and chocolate in the evening; and weight loss if overweight. Mild symptoms may respond to antacids or alginic acid (Gaviscon). Clearly, concerns regarding the administration of aluminum, magnesium, and sodium need to be considered in elderly patients with renal insufficiency or congestive heart failure. H₂ blockers are effective for patients with mild to moderate symptoms; these agents are not effective in patients with severe esophagitis or Barrett's esophagus.

Proton pump inhibitors are the most effective medications in the healing of reflux esophagus.¹⁸ Because reflux esophagitis tends to recur after cessation of therapy, long-term therapy with drugs should probably be considered.¹⁹ Theoretically, metaclopramide tightens the LES, opens the pylorus, and promotes gastric emptying, all of which should decrease reflux; it does not heal esophageal lesions unless taken along with H₂ blockers or other agents that decrease gastric acid production. CNS side effects such as drowsiness, insomnia, agitation, tremor, and dyskinesia may further reduce the usefulness of metaclopramide in the elderly. Elderly patients with significant or recurrent complications of reflux esophagitis should be evaluated for surgical intervention. Criteria for surgical intervention in esophageal disease do not change with age.²⁰ Laparoscopic Nissen fundoplication is an effective antireflux procedure without significant morbidity and is well tolerated in the elderly.²¹

Disorders of the Stomach and Duodenum

Gastric secretory and motor function has been studied extensively in the elderly during the past several years.²² Gastric acid secretion, both maximal (stimulated) and basal output, declines with age, probably because of the reduction in parietal cell mass.²³ Grossman et al. demonstrated decreases in basal and stimulated acid output after the age of 50, with the greatest decline in males.²⁴ Some of these changes were undoubtedly associated with gastric mucosal atrophy.²⁵ Recent studies have shown many elderly adults have normal gastric acidity.²⁶ Serum gastrin levels were shown to have increased with age in some studies; this, however, is probably secondary to the acid secretory changes.

Gastric emptying involves a complex interaction of numerous physiologic events. Several early studies have suggested that alterations in gastric emptying with age occur. However, most of these studies did not have adequate controls.²⁷ It is likely that underlying disease affected some of these findings. Later studies utilizing well-matched controls indicated that liquid emptying was delayed in the elderly whereas solid food emptying appeared to be unaffected.²⁸ These types of changes in gastric emptying may be an important cause of some age-related variations in drug absorption.²⁷

The organism *Helicobacter pylori* (*H. pylori*) has an important impact on gastric function in the elderly.²⁹⁻³¹ This spiral urease-producing organism is seen nestled in the narrow interface between the gastric epithelial cell surface and the overlying mucus layer in the infected patient. The organism has been highly correlated with antral gastritis and with the development of gastric and especially duodenal ulcers. Recent studies indicate that

the eradication of the organism effectively eliminates ulcer recurrence.³² Excellent epidemiologic studies in numerous populations indicate an increased carriage of the organism with age.³³ In the United States, an estimated 50% of adults by age 60 years are seropositive. The organism has been linked to antral gastritis of the type frequently associated with aging. It appears that *H. pylori*-induced gastritis is a pivotal event in development of peptic ulcer disease.

Nonsteroidal anti-inflammatory drugs are one of the most important factors in the development of gastrointestinal damage. This factor is particularly important in the elderly, who are heavy users of these medications.¹⁴ The elderly, especially elderly women, who have increased usage of nonsteroidal medications are at particularly high risk.³⁴⁻³⁶ Nonsteroidal use is associated with depletion of mucosal prostaglandins and decreased reparation with an increased risk of gastric and duodenal ulceration and bleeding; this difference may be as great as 50-fold for gastric ulcers and 8-fold for duodenal ulcers, with prevalence of 9% to 31% for gastric ulcers and 0% to 19% for duodenal ulcers. Patients with prior history of peptic ulcer disease and increased age are at particularly high risk.^{34,37,38} Newer NSAIDs, the Cox-2 inhibitor, have a significantly lowered risk of ulcerogenesis and although expensive are being used widely in the elderly.

Gastritis and gastric atrophy are two of the most commonly described gastric abnormalities in the elderly. Gastritis is associated with mucosal infiltration of inflammatory cells and with loss of secretory cells, both chief and parietal, from the mucosa. Depending on the type of gastritis, these changes may involve the body and fundus or antrum.²³ Acute forms of gastritis have been associated with alcohol and medication ingestion, in particular, nonsteroidal anti-inflammatory drugs. This type of inflammatory process is highly associated with gastrointestinal bleeding.³⁶

Classically, two types of atrophic gastritis have been described. Fundal gastritis (type A) is associated with an absence of fundal glands, which have been replaced by goblet cells, and the appearance of changes suggestive of intestinal metaplasia.³⁹ The loss of parietal cells is associated with a decrease in acid secretion, and consequently the antrum produces gastrin in response to the decline in acid secretion, resulting in high serum gastrin levels.⁴⁰ Antibodies to parietal cells as well as antibody to intrinsic factor are present resulting in vitamin B₁₂ malabsorption and the classic picture of pernicious anemia. Other autoantibodies have been described in this clinical situation.

Antral gastritis or type B gastritis is more commonly seen and is probably associated with *H. pylori* infection.⁴¹ This process may be associated with a decrease in serum gastrin levels. Parietal cell antibodies and other serologic abnormalities are not present. Antral mucosa may be

variably affected with acute and chronic cellular infiltrates and metaplastic glandular changes. Type B gastritis has been associated with gastric ulcer and gastric cancer.^{42,43}

Low-grade and some high-grade gastric lymphomas may be seen in the elderly in association with *H. pylori* infection. These lesions show mucosal infiltration by small lymphocytes and plasma cells, with the appearance of mucosa-associated lymphoid tissue (MALT). These lymphomas have been called B-cell lymphoma of MALT, MALT lymphoma, or MALToma. More than 90% of low-grade MALT lymphomas are positive for *H. pylori* infection. In addition, eradication of *Helicobacter* infection has resulted in resolution of low-grade MALT lymphomas.⁴¹

Pernicious anemia is an important diagnosis that is usually made secondary to hematologic abnormalities, as GI symptoms are unusual. There is a three- to fivefold increase in the incidence of gastric cancer in patients with pernicious anemia. However, specific screening strategies have not been widely accepted.⁴⁴

Hypertrophic gastropathy (Menetrier's disease) is an uncommon disorder of the stomach presenting with enlarged gastric rugae and is frequently associated with protein loss across the gastric mucosa.⁴⁵ Though it is not particularly increased in the elderly, it becomes an important consideration in the differentiation from neoplastic gastric lesions (i.e., lymphoma and carcinoma).

Peptic Ulcer Disease

The clinical picture of the patient with peptic ulcer disease has changed dramatically in the past decade. With the widespread use of nonsteroidal anti-inflammatory drugs (NSAIDs), the incidence of gastric ulcer disease has increased, particularly in the elderly.^{38,46} The availability of these drugs as over-the-counter preparations has been associated with markedly increased use. Elderly patients taking these medications frequently present with severe hemorrhage, perforation, and obstruction, often without abdominal pain.^{47,48} In addition, the widespread acceptance of *H. pylori* infection as an important factor in the pathogenesis of peptic ulcer disease (especially duodenal ulcer) has significantly changed the therapeutic approach to peptic ulcer disease in all patients.

The incidence of gastric ulcers and gastric erosive disease increases with age, as noted earlier.^{37,38,46} This factor is particularly important in those patients using nonsteroidal anti-inflammatory drugs. Gastric ulcers are usually located along the lesser curvature at the junction of body and antral mucosa transition; however, this junction frequently migrates proximally with advancing age.⁴² Giant gastric ulcers have been demonstrated frequently in the elderly and are associated with the high rate of complications and mortality.⁴⁹ These ulcers are also asso-

ciated with a greater likelihood of malignancy. Although the incidence of malignancy is low, as many as 6% of apparently benign ulcers may be malignant. It is clinically important to realize that the concurrence of duodenal ulcerations reduces the likelihood of malignancy.⁴⁹ Occasionally gastric ulcers, particularly those high in the fundus, may present with atypical symptoms such as chest pain.

Duodenal Ulcers

Duodenal ulcers are likewise common, particularly in elderly men,^{38,46} but these do not have as high an association with nonsteroidal anti-inflammatory drug use. The incidence of complications with peptic ulcer disease increases with age. Giant duodenal ulcers are seen more commonly in elderly patients. These ulcers (greater than 2 cm in diameter) may be associated with severe pain and bleeding as well as gastric outlet obstruction.⁵⁰ Symptoms and findings on imaging studies (CT scanning) may mimic tumor arising from the pancreas.

The diagnosis of peptic ulcer disease is highly dependent on the use of endoscopic modalities in the elderly. Numerous studies in the elderly have demonstrated excellent tolerance for routine diagnostic endoscopy.^{38,51} With monitoring of oxygen saturation and blood pressure as is routinely done for conscious sedation, patients tolerate routine sedation using diazepam and meperidine. The use of midazolam was not recommended for patients over the age of 60 years; however, there are numerous articles discussing its safety for older patients with appropriate titration of the medication.⁵² Endoscopy is important in documentation of the presence of active ulceration as well as obtaining tissue biopsy and cytology for histologic examination to determine if malignancy is present.⁵¹ Follow-up endoscopy may be indicated to determine complete healing of gastric ulcers and complicated duodenal ulcers (associated with bleeding or partial obstruction). In patients unable to tolerate endoscopy as a result of severe respiratory compromise or other medical conditions, barium studies may be useful in the diagnosis; however, these cannot determine definitely if malignancy is present.

Once a peptic ulcer is documented, the determination of *H. pylori* infection is important. A recent NIH consensus panel on *H. pylori* recommended that if *Helicobacter* is present in a patient with documented peptic ulcer disease, then the organism should be eradicated by antibiotic therapy.³¹ Numerous methods for documentation of *H. pylori* infection are available. Invasive tests include endoscopy with gastric tissue biopsy and detection of urease activity in the tissue. Histologic evaluation and urea fermentation are more sensitive than culture. Noninvasive tests include breath test of urease activity after oral ingestion of ¹⁴C or ¹³C labeled urea;

these methods have a 90% accuracy.⁵³ Serologic studies with serology for immunoglobulin G antibodies to *H. pylori* antigens are most useful in the documentation of prior infection as clearance of the antibody is variable.

Treatment

The treatment of peptic ulcer disease includes the use of antacids, H₂ receptor antagonists, proton pump inhibitors, sucralfate, misoprostol, and antibiotic programs (to eradicate *H. pylori*).^{38,54} Antacids have been used for the treatment of peptic ulcer disease for a number of years; they are most effective in relatively high doses. These doses may be associated with sodium overload, increased magnesium levels (important in patients with a renal dysfunction), and diarrhea or constipation. Antacids may also be associated with altered absorption of certain medications, including antibiotics and quinidine.^{54,55}

The H₂ receptor antagonists such as cimetidine, ranitidine, famotidine, and nizatidine remain important drugs in the treatment of peptic ulcer disease. These medications are available over the counter and are widely used. They are generally well tolerated in the elderly, although mental confusion has been described with cimetidine, particularly in high dose and with parenteral use.^{54,55} Cimetidine and ranitidine have been associated with altered metabolism of certain medications, such as warfarin, theophylline, and phenytoin. Cimetidine significantly inhibits the cytochrome P-450 system, whereas the other H₂ antagonists have a clinically insignificant effect.

Sucralfate is not absorbed and is effective in healing peptic ulcers. However, it may cause constipation and may bind certain medications.^{56,57}

The proton pump inhibitors (PPIs) are an important group of medications, particularly when ulcerogenic medication needs to be continued. These potent inhibitors of the H⁺/K⁺-ATPase enzyme of the gastric parietal cell result in almost complete suppression of acid secretion, both basal and stimulated. Initially omeprazole was the only available proton pump inhibitor; however, several others are available: lansoprazole, pantoprazole, rabeprazole, and esomeprazole. All appear equally effective. These agents are very effective in treating peptic ulcers, particularly large gastric and duodenal ulcers. PPIs have also been combined with amoxicillin in the treatment of patients with *H. pylori*-associated ulcers. Recent reports suggest that it is effective in treatment of peptic ulcers where continuation of nonsteroidal medications is necessary.^{38,58} PPIs may interact with drugs metabolized by the cytochrome P-450 system. They are associated with hypergastrinemia due to persistent gastric acid suppression; however, long-term treatment has been safe.³⁸

Misoprostol, a prostaglandin analogue and cytoprotective agent, has been shown to heal peptic ulcers even when NSAIDs must be continued. This medication has

also been used to prevent NSAID-associated ulcers in patients with a history of peptic ulcer disease and is particularly useful in the elderly patient as it has few drug interactions. Diarrhea is its major complication.⁵⁷

Eradication of *Helicobacter pylori* infection results in more rapid healing of ulcers and reduction in recurrence rates.^{59,60} Although the organism is sensitive to a number of antibiotics including ampicillin, amoxicillin, metronidazole, cephalosporins, tetracycline quinolones, and macrolides, single-agent treatments have low rates of eradication. The combination therapies including antibiotics and an acid suppressive agent are effective, as sensitivity is dependent on an alkaline environment. Simultaneous administration of bismuth appears to diminish development of resistance in some cases. Triple therapies including PPIs (omeprazole and lansoprazole) and two antibiotics, clarithromycin and amoxicillin or metronidazole, for 1- to 2-week periods are well tolerated and are 80% to 90% effective in eradication of the organism. Bismuth salts in combination with metronidazole and amoxicillin or tetracycline are similarly effective. Ranitidine, bismuth citrate in combination with clarithromycin for 2 weeks is likewise effective and well tolerated, although ranitidine must be continued for 4 weeks. After successful eradication, most patients remain free of *Helicobacter* infection and have duodenal ulcer relapse rates of less than 5% per year.^{32,38,59,60}

Other Less Common Gastric Lesions

Gastric bezoar and volvulus are two relatively uncommon lesions that may be seen more frequently in the elderly. Bezoars are frequently seen in patients who have a history of vagotomy or subtotal gastrectomy. Metabolic disorders that are associated with decreased gastric emptying may also be associated with bezoars. Patients with diabetes mellitus and autonomic dysfunction are especially at risk.^{61,62} Patients generally present with early satiety, weight loss, or unexplained nausea and emesis. Symptoms may mimic those suggestive of gastric neoplasia. Although either barium contrast studies or endoscopy will diagnose the lesion, endoscopy has also been shown to be effective in disruption of the mass of undigested fibrous material by biopsy or jet water spray.⁶² Prokinetic agents, such as metoclopramide and cisapride (now withdrawn), are effective in emptying the stomach of residual fragments.⁶² Chronic use of enzyme preparations may not be effective because of their low cellulase content.

Volvulus of the stomach may be seen in the elderly and is associated with chronic nausea and emesis or a more acute presentation with abdominal pain and acute abdomen. There are two types of volvulus, the more common being an organoaxial volvulus with rotation of the stomach on its longitudinal axis from cardia to

pylorus and, less commonly seen, a mesenteroaxial volvulus with rotation along the vertical axis. Acute volvulus may require emergency surgery for reasons of compromise in blood supply to the stomach. Chronic forms of the former may require no intervention.⁶¹

Gastrointestinal Bleeding

Gastrointestinal (GI) bleeding is a major problem in the elderly and is associated with high mortality (10%–25%).^{63,64} Underlying medical problems such as pulmonary and cardiovascular disease in addition to the use of medications (in particular NSAIDs) may contribute to this increased morbidity and mortality.^{65,66} It is important, when treating patients with gastrointestinal bleeding, to determine the initial severity of bleeding and to institute appropriate intervention as early as possible. When one is presented with compromised cardiac and renal reserves, rapid and focused approach to initial intervention is essential. The patient with acute gastrointestinal bleeding may present with hematemesis, melena (dark tarry stools), or hematochezia. Hematochezia is usually associated with lower gastrointestinal bleeding; however, it may occur with massive upper GI hemorrhage with rapid transit of blood through the bowel. The patient with massive gastrointestinal bleeding may present with syncope and/or shock. The elderly person with cardiac disease may present with angina, shortness of breath, or weakness associated with decreased cardiac output and anemia.^{66,67}

The initial evaluation and resuscitation of the patient is undertaken in rapid succession. It is important particularly in the elderly to determine whether there is a history of peptic ulcer disease and NSAID or other medication use. The initial clinical evaluation focuses on determination of hemodynamic status with careful monitoring of the blood pressure and pulse. Stigmata of underlying liver disease are important, because management may be altered. Initial laboratory studies should include hematocrit with platelet count, coagulation parameters, blood urea nitrogen (BUN), and creatinine. It is helpful to compare these to prior studies, noting that hematocrit may not reflect blood loss for 24 to 48h. In upper gastrointestinal bleeding, the BUN to creatinine ratio may be elevated, reflecting the absorption of blood from the gut; however, this may also occur with hypovolemia. Large-bore intravenous line placement for fluid repletion is imperative. The need to carefully monitor the responses to therapy in the elderly patient with cardiopulmonary compromise may necessitate early central venous pressure measurement. Oxygen support may be necessary in patients with severe anemia, particularly if there is underlying cardiac and pulmonary disease.⁶⁷

Nasogastric lavage is important in the initial evaluation and treatment of bleeding. If the nasogastric lavage is positive for gross blood, this suggests upper GI bleeding, although there is a false-negative rate of approximately 10%.⁶⁷⁻⁶⁹ Nasogastric lavage with room temperature water may be effective in clearing the stomach of blood, thereby decreasing emesis and facilitating endoscopy.

If an upper GI site is suspected, then upper endoscopy provides important diagnostic and prognostic information as well as therapeutic potential. The elderly patient tolerates endoscopy well, and there is no evidence of increased morbidity. If an active bleeding lesion is seen and treated successfully, studies have demonstrated a decrease in hospital stay and transfusion requirement.^{64,66,70} Endoscopy allows the identification of lesions that are associated with poor prognosis and increased incidence of rebleeding: actively bleeding ulcers, the presence of a visible vessel in an active ulcer crater, or stigmata of recent bleeding have up to a 50% chance of rebleeding. Lesions in these patients warrant endoscopic treatment.⁷⁰

Several endoscopic therapeutic modalities are available, including injection with saline and/or epinephrine, thermal coagulation, and laser therapy. The first two are more widely used due to availability and portability and have been shown to be effective.^{64,66,71}

Arteriography may be useful as both a diagnostic and a therapeutic modality. The radiologist can examine the celiac and superior mesenteric arteries and selectively embolize arteries with an absorbable gel sponge (gelfoam) or autologous clot. If the initial NG aspirate has been negative and a lower GI source is suspected, angiography can determine a lower GI site with initial examination of the superior mesenteric artery and subsequently the inferior mesenteric artery supply. Infusion of vasopressin is used to control bleeding in lower GI lesions.^{63,64,66,72-74}

In patients with suspected small bowel bleeding and colonic bleeding of unclear site, radioactive tagged red blood cell scanning may be effective. Red blood cells are labeled with technetium-99m and injected into the patient. Scanning may occur up to a 30-h period.⁷⁵ In cases of lower GI bleeding in which the patient has stopped bleeding or bleeding has slowed, the patient can be prepared for colonoscopy, which can be done in an emergent situation. The preparation with a Golytely purgation may be accomplished in approximately 4 h,⁷⁶ especially with delivery by nasogastric tube.

Medical Therapy

H₂ antagonists and proton pump inhibitors are commonly given to patients in initial management of their gastrointestinal bleeding. Recent studies have demonstrated a benefit of acid-controlling agents in decreasing recurrent

bleeding; it is certainly associated with the decrease in the incidence of stress ulceration in the intensive care unit setting.^{67,77} These agents are typically administered intravenously in bolus or in continuous infusion. Continuous infusion is associated with more consistent lowering of gastric acid. In the United States, proton pump inhibitors have not been available for parenteral use.⁷⁸ However, the early use of these agents orally is associated decrease in recurrence of bleeding. Sucralfate has been used as an agent with a lower risk of nosocomial pneumonia than H₂ antagonist therapy in intubated ICU patients.⁷⁹

Peptic ulcers remain the most common causes of upper GI bleeding. In some studies, 33% of the patients presenting with peptic ulcers are over the age of 65; of these, approximately 40% have been reported to have gastrointestinal bleeding.^{46,64} Rebleeding rates tend to be higher in the elderly,^{64,66,80} which would suggest that elderly patients may frequently need to be monitored for longer periods of time in the hospital than younger patients. Additionally, the mortality rate in gastric ulcers is higher, and these predominate in elderly patients. Giant duodenal and gastric ulcers are also a potential site of bleeding. Dieulafoy's lesion has been reported in the endoscopic literature as a cause of gastric bleeding. This lesion is the result of an arterial bleed from a small mucosal defect that may be difficult to detect unless actively bleeding.^{64,76} These lesions respond to endoscopic injection therapy. Vascular ectasia may be noted in the stomach; these are similar to those seen in the distal small bowel and colon.⁸¹

Surgical Intervention
