Surgical intervention may be necessary in patients, especially those requiring massive transfusions (>6 units).^{64,70,76} The mortality may be high but depends on underlying medical problems and duration of bleeding. Surgical therapy is mandated when less invasive procedures (therapeutic endoscopy and arteriography) have failed to control hemorrhage. It is important to exercise teamwork in the management of patients with gastrointestinal bleeding, in particular the elderly patient, by combining the primary provider (internist or family practitioner), gastroenterologist, radiologist, and surgeon.⁶⁶

Small Intestine Diseases

Age-related changes in small bowel anatomy and physiology in both animal and human studies have been reported in several studies. Although small intestine motility is maintained throughout the process of aging,⁸² studies have demonstrated a decrease in the surface area of villi with shortening and clubbing of villi.^{2,83,84} Potential small bowel absorptive deficiency may occur under

physiologic stress. Carbohydrate absorption has been demonstrated to be impaired when challenged. More sophisticated studies have demonstrated delayed disaccharidase expression, with a decrease in disaccharidase activities, probably contributing to acquired lactose intolerance.^{83,85} In the elderly, calcium absorption is impaired on low-calcium diets. Decreased tissue levels of zinc possibly related to impaired absorption have also been reported. Other investigators have reported vitamin absorption deficiencies. Idiopathic bacterial overgrowth has been demonstrated in some patients and appears to be associated with a decrease in postprandial motility.¹

Gluten-sensitive enteropathy or celiac sprue has been reported in the elderly, who may represent up to 25% of new cases.^{2,83} Patients usually present with classic symptoms of malabsorption, that is, anemia, steatorrhea, and osteomalacia. However, in elderly patients the latter may be confused with osteoporosis. Evidence of folate deficiency may predominate and must be differentiated from primary nutritional deficiency. Management is similar to that in younger patients, with institution of a gluten-free diet and vitamin and mineral supplementation.

Diverticulosis of the small bowel is a common age-associated small bowel lesion. Bacterial overgrowth and malabsorption with diarrhea, abdominal distension, steatorrhea, and weight loss are common presentations. Management includes antibiotic therapy, in conjunction with prokinetic agents such as metoclopramide.

Ischemic Bowel Disease

The superior mesenteric, inferior mesenteric, and hypogastric arteries supply the small bowel and colon. There is extensive collateralization between these arterial supplies, and ischemic disease only occurs when there is significant compromise of two of the three main arterial trunks. This compromise may arise from intrinsic arterial disease or from embolization, both of which are more common in the elderly. Acute occlusion of the superior mesenteric artery with inadequate collateralization may result in infarction of the small bowel⁸⁶; this is frequently a catastrophic event and presents with severe abdominal pain, typically out of proportion to the physical findings.

The patient may initially have an ileus with or without rectal bleeding. Physical findings are associated with transmural infarction and peritoneal irritation. This type of ischemia may frequently go unnoticed in patients in intensive care units with other medical problems.^{86,87} One should have a high level of suspicion when caring for the critically ill patient. Diagnostic findings are fairly nonspecific, with elevated white blood cell count and fever. Plain films of the abdomen may show an ileus or thumbprinting in the small bowel and in some instances

portal venous air. When the diagnosis is suspected, angiography is indicated to confirm the diagnosis and to direct surgery.

Chronic occlusion may be associated with "abdominal angina," or abdominal pain worsened by eating. Diarrhea, steatorrhea, and progressive weight loss result. Arteriography followed by revascularization of affected bowel is indicated.⁸⁷

Ischemic colitis is one of the most common causes of lower GI bleeding.^{63,64} Patients typically present with rectal bleeding and lower abdominal cramping. Physical examination may be unremarkable if there is no transmural infarction. Ischemia is common in "watershed" areas where two arterial supplies meet, in particular, the sigmoid colon, splenic flexure of the colon, and proximal transverse colon. Less commonly, the ascending colon and cecal areas may also be involved. Plain film of the abdomen may show thumbprinting and narrowing of the affected areas. Initial evaluation is as outlined for the treatment of lower GI bleeding with initial anoscopic and sigmoidoscopic evaluation. Urgent colonoscopy after appropriate bowel cleansing has been very effective in making this diagnosis. Barium enema should be avoided if bleeding has continued and, in particular, if angiographic or endoscopic studies are anticipated. Most patients resolve spontaneously with cessation of bleeding. With deep mucosal injury or transmural injury, resulting strictures may develop. Some patients may present with colonic strictures as a result of ischemic bowel without an acute history.^{16,88}

Vascular Ectasias

Vascular ectasias, also called angiodysplasias or arteriovenous malformations, are commonly encountered in the cecum and ascending colon of the elderly. Vascular lesions may also be seen in the small bowel (jejunum, ileum, and duodenum).⁸¹ These lesions are degenerative lesions that form from previously normal vessels. These ectatic, distorted veins and capillaries are thin-walled vessels lined with endothelium. The lesion is characterized in its earliest form by dilated submucosal veins with a progressively enlarged array of dilated and distorted vessels extending into the mucosa.

Boley and colleagues⁸⁶ have studied these lesions extensively by angiography and by silicone rubber injection of resected specimens. They have proposed that vascular ectasias develop as a result of intermittent distention of the cecum and right colon with resultant obstruction of venous outflow. According to this hypothesis, cecal location is caused by the large diameter of the cecum and relatively high wall pressures.^{56,63,80,89} This theory would not explain small bowel lesions, however.

Vascular ectasias of the colon occur predominantly in the elderly, with two-thirds of the patients over the age

of 70 years with equal sex distribution. Bleeding is usually recurrent and subacute, although 15% present with severe hemorrhage. The spectrum of presentation varies between patients and episodes in the same patient. Fifty percent of patients with bleeding have cardiac disease; about one-half of these have been reported to have aortic stenosis. Bleeding can be controlled successfully with endoscopic therapeutic modalities: heater probe, electrocoagulation, laser, or injection. Angiographic infusion of vasopressin is successful in treatment of active bleeding when demonstrated.^{64,81,89} If bleeding continues or is recurrent, surgery may be required.

Telangiectasias of the bowel wall may be associated with multiple causes and may be the site of acute and chronic blood loss in elderly patients. Hereditary hemorrhagic telangiectasias (or Osler–Weber–Rendu) may cause bleeding in the elderly. At younger ages, nasal (epistaxis) and oral lesions may be significant. Gastric duodenal and small bowel lesions may be treated endoscopically. Enteroscopy is now available and may diagnose lesions in 15% to 38% of patients studied. Endoscopic therapeutic modalities, as already outlined, can be effective in reduction of bleeding and transfusion requirements.⁸⁹

Hepatobiliary Disorders

The liver changes only slightly with age. Of particular interest is the decrease in the entire weight of the liver and its respective lobules with an overall decrease in the number of hepatocytes. Importantly, the ability of the aged liver to regenerate after injury or resection appears to be somewhat diminished. Liver chemistries and liver function remain normal. However, due to circulatory changes and some metabolic enzyme changes, metabolism of some drugs may be altered and is thus an important concern in the stressed elderly.^{90,91}

Cholestatic jaundice occurs more frequently in the elderly in association with an increase in both malignant and benign obstruction (choledocholithiasis). Drug-induced liver disease is an important problem in the elderly, presumably secondary to the increased drug use and drug sensitivity. Jaundice in the elderly may be drug induced in up to 20% of patients.^{92,93} The following are some of the commonly used drugs that are offenders: oral hypoglycemics, antibiotics, hormones, nonsteroidals, and anesthetics. Injury may present as primarily hepatocellular, cholestatic, or mixed hepatocellular and cholestatic. The type of injury will determine the pattern of enzyme abnormality in the older patient similar to that seen in younger patients. In most cases, withdrawal of the offending agent will lead to a resolution of biochemical abnormalities. In some cases, however, cholestasis may last for several months, as has been reported with phenothiazines

and imipramine. Several other drugs have been associated with chronic hepatitis.⁹⁴

Alcoholic liver disease may be seen in the elderly, although alcoholic hepatitis is unusual. Patients are more likely to present with cirrhosis in this age group. The anorexia, nausea, abdominal pain, and weight loss seen in alcoholic hepatitis are not dissimilar from viral hepatitis. However, with alcoholic hepatitis, transaminases are typically 300 or less. In severe cases, patients may have fever and leukocytosis. It is important to rule out acetaminophen toxicity as toxicity can occur without overdose and with therapeutic doses of the medication in alcoholic patients.^{95,96} Rapid determination of acetaminophen blood levels and therapy with acetylcysteine can be lifesaving.

Acute viral hepatitis is less common in the elderly. The acute course of hepatitis B, in the elderly, is typically very severe secondary due to age-related poor hepatic reserves and regenerative capabilities.^{97–99} Hepatitis C, which is frequently transfusion acquired, can be a major problem in the elderly. In particular, about 30% to 50% of patients develop chronic hepatitis after an initial infection, with a rapid progression to cirrhosis. Liver biopsy documentation of progressive liver disease is important in these cases.^{100–102}

Ischemic liver injury may occur in patients with circulatory failure, as the result of passive congestion of the liver or decreased blood flow to the liver. Patients with decreased cardiac output may present with a picture similar to acute hepatitis. One may see mild injury or the patient may have dramatically elevated transaminases and LDH.¹⁰³

Congestive failure with severe right heart failure may be associated with jaundice. Typically, patients have an elevation in bilirubin and alkaline phosphatase. In severe cases the liver may be pulsatile. In severe cases, associated passive congestion of the bowel can lead to diarrhea.

Cholelithiasis

Cholelithiasis and choledocholithiasis are common in the elderly. Gallstones may be associated with elevation in cholesterol as well as hemolysis with the formation of pigment stones.¹⁰⁴ When gallstones are asymptomatic, the general approach has been not to recommend surgery, on the basis of studies by Gracie and Ransohoff^{105,106} that revealed the probability of developing biliary colic to be 10% after 5 years, 15% after 10 years, and 18% by 15 to 20 years. However, biliary symptomatic cholelithiasis may present itself in the elderly patient as pain and jaundice, pain alone, or jaundice alone. Studies have suggested that the development of choledocholithiasis may be associated with a periampullary duodenal diverticulum. These diverticula increase with age.¹⁰⁷ Choledocholithiasis may be managed nonsurgically with

endoscopic sphincterotomy. Elderly patients tolerate endoscopic retrograde pancreatography and endoscopic sphincterotomy well; this may be followed by laparoscopic cholecystectomy, although in some fragile elderly, the gallbladder has been left in situ.¹⁰⁸

Acute cholecystitis is a serious complication of gallstone disease. Morbidity and mortality associated with acute cholecystitis may be high in the elderly, with one series reporting mortality of 9.8%.¹⁰⁹ With stabilization, some patients may be able to undergo laparoscopic cholecystectomy, which is associated with lower morbidity and mortality.¹⁰⁴

Pancreatic Disorders

Pancreatic function does not change significantly with age; however, some morphologic changes in the pancreas with age have been noted. The frequency of ductal dilatation of the main pancreatic duct increases by 8% per decade.¹¹⁰

Gallstone pancreatitis is a major concern in the elderly. The mortality from acute pancreatitis in the elderly patients has been reportedly as high as 80% as compared to 9% in younger patients.^{111,112} Recent studies suggest that early endoscopic retrograde cholangiopancreatography (ERCP) with stone removal may significantly decrease morbidity and possibly mortality.^{112,113}

Chronic pancreatitis may manifest in the elderly patient after a long history of alcohol abuse. Pancreatic insufficiency represents one of the major causes of steatorrhea in patients over the age of 65 years. In the setting of weight loss, abdominal pain, and steatorrhea, the differential diagnosis certainly includes pancreatic carcinoma and becomes one of the major diagnoses to be excluded. Pancreatic insufficiency may be difficult to diagnose; 72-h fecal fat collection is imperative to document malabsorption and maldigestion. Pancreatic enzyme replacement effectively treats insufficiency; microencapsulated preparations with high concentrations of pancreatic enzymes are very effective. Use of acid suppressive therapy is not necessary.

Disorders of the Colon

Almost half the gastrointestinal complaints that bring elderly patients to the physician revolve around constipation and irritable bowel syndrome. Other common colonic problems in the elderly include diverticulitis, fecal incontinence, inflammatory bowel disease, ischemic colitis, and appendicitis. Detailed understanding of the relationship between colonic structure, physiology, and clinical symptoms leaves much to be explored.

With aging, some minor changes in the colon do occur that can contribute to some of the problems seen in the elderly. These changes include decreased mucosal secretion, which can decrease the degree of lubrication of the colon; increased connective tissue and atrophy of the muscle layers, which can lead potentially to less effective muscle function; and weakness in the abdominal wall muscles, which can make defecation more difficult.

Studies in healthy active elderly, however, have shown little difference in colonic transit time¹¹⁴ or in the amplitude or duration of contractions during fasting or after the gastrocolic reflex in the sigmoid, rectosigmoid, or rectum compared to healthy subjects 40 years younger.¹¹⁵ There is conflicting information on various other measurements of defecation parameters with aging. With disabled elderly who have decreased mobility, transit time may be greatly prolonged.¹¹⁶

Constipation

There is a major difference between the medical definition of constipation and a person's perception of their need for laxatives. In general, most authors cite the definition of constipation as having bowel movements of decreased frequency and volume. Normal frequency of bowel movements is between three defecations per day and three per week, regardless of age. Sixty percent to 70% of healthy community-living elderly have a daily bowel movement, yet recurring studies show that 15% to 30% of elderly take laxatives on a regular basis,^{117,118} resulting in hundreds of millions of dollars spent yearly on laxatives.

The most frequent reasons for constipation in healthy elderly are chronic suppression of the gastrocolic reflex and poor intake of dietary fiber. Medical conditions that may contribute to constipation in the elderly include immobility, depression, hypothyroidism, and hypercalcemia. Medications that may contribute to constipation are shown in Table 56.3. Chronic use of certain irritant laxatives has been shown to be associated with myoneural degeneration, leading to chronic constipation,¹¹⁹ however, most cases today are not so associated.

For the patient who is not chronically constipated, many of the over-the-counter preparations, such as saline

Anticonvulsants

laxatives and mild stimulants (senna and bisacodyl), will work adequately for the acute incident if obstipation or impaction has not occurred. If impaction is present, then manual disimpaction should occur as soon as the diagnosis is made. Enemas may then be used to evacuate the feces above the rectal vault. Oral laxatives can be used for a time-limited episode of expected constipation, such as the patient acutely immobilized during hospitalization; these agents include milk of magnesia, lactulose, sorbitol, and anthroquinones. The bowel preparation Golytely has also been used in small amounts as an oral laxative in elderly patients.¹²⁰ Mineral oil, because it may predispose to aspiration pneumonitis in people with swallowing problems, is usually avoided in the elderly.

Most complaints of constipation can be eliminated or at least reduced by the following: patient education, reduction or elimination of offending medications, addition of fiber through dietary manipulation or supplements, increased physical activity, and bowel stimulation. Dietary fiber in the range of 15 to 20 g per day is recommended to increase fecal water content and maintain soft stool of adequate volume. Sources for fiber include whole wheat bread, bran, and shredded wheat cereals; fruit such as apples, bananas, and strawberries; nuts such as peanuts; vegetables such as broccoli, carrots, beans, peas; and bran additives. For patients who cannot or will not increase their dietary bran adequately, fiber supplement with psyllium or methylcellulose supplements are usually more effective than traditional "stool softeners" such as bisacodyl ducosate. Adequate fluid intake needs to be encouraged in patients taking fiber supplements. Addition of dietary fiber has been shown to reduce the need for laxatives even in elderly institutionalized patients.¹²¹ Table 56.4 presents some of the management approaches in the elderly.

Increased water intake has been suggested by some, especially for those elderly with blunted thirst responses and those on diuretics. Increased physical activity has been shown to decrease the need for laxatives in healthy elderly. Even minor increases in physical activity in institutionalized elderly can play a role in decreasing the need for laxatives.

Bowel training is a method of overcoming inhibition of the gastrocolic reflex and includes providing the opportunity to have a bowel movement immediately following the first meal of the day. If a bowel movement does not occur, then a suppository or enema is given to effect the bowel movement. This behavioral training is continued on a daily basis. Usually, by the third to fifth day of reinforcement of the gastrocolic reflex, defecation occurs without the need for a rectal stimulant. Even in institutionalized elderly with neurologic deficits, bowel training has been shown to be effective in more than 85% by day 8.¹²²

The complications most frequently associated with constipation include the development of megacolon and

overflow fecal incontinence. Fecal incontinence is a frequent reason for institutionalization, accounting in various studies for 10% to 60% of institutionalized elderly, especially female patients; this is a complication of severe constipation in debilitated patients, where it presents as overflow incontinence, and is a major hygienic and health care issue in patients with depressed cerebral function.¹²³ Treatment is similar to that described for constipation. Make sure that fecal impaction is not present, and then make sure that it does not recur. Bowel training, increased physical activity, biofeedback, and pelvic floor exercises have also been suggested.¹²⁴ For patients with neuromuscular causes of fecal incontinence, thickening of stool with bulking agents such as psyllium and cautious use of constipating drugs such as Imodium may be tried.

Irritable bowel syndrome is used to refer to a combination of symptoms including constipation with or without diarrhea, left lower quadrant discomfort, abdominal distension, excessive flatus, and incomplete evacuation. Unlike pathologic conditions that cause constipation, irritable bowel syndrome is never associated with blood in the stool, does not awaken the patient at night, and is not associated with change in appetite or weight loss. Although frequently presenting in middle age, it may not become a significant complaint until the sixth or seventh decade.¹²⁵ Treatment is similar to that for constipation and includes increase of fiber content, physical activity, and bowel training. Stress management and behavior modification (biofeedback) have also been successful at times.

Diverticulosis and Diverticulitis

The prevalence of diverticulosis (the presence of numerous colonic diverticula) increases with advancing age and is equally prevalent in men and women. Diverticulosis, which is present in one-third to two-thirds of the American population over the age of 60,¹²⁶ represents outpouchings in the colon at sites of insertion of penetrating blood vessels that are most frequently present in the descending colon and sigmoid. Diverticula themselves are usually asymptomatic, unless perforation, infection, or bleeding occurs. Most people who have recurring low-grade discomfort in the left lower quadrant probably have irritable bowel syndrome, even if diverticulosis is present.

Occasionally obstruction of the opening of the diverticulum by a fecalith is associated with microperforation, and diverticulitis occurs. Increased incidence of diverticulitis may also be seen in patients taking nonsteroidal anti-inflammatory drugs.¹²⁷ The inflammatory state of acute diverticulitis is classically associated with significant left lower quadrant pain, a left lower quadrant tender inflammatory mass, and fever, with or without chills. Pain increasing with time, anorexia, nausea, and dysuria or abdominal pain aggravated by micturition may also be seen. A left lower quadrant mass with tenderness and local rebound is classically found. In the elderly, many of the classic findings may be diminished, so that pain may be minimal, and tenderness or even the finding of a mass may be absent. Generalized peritoneal findings are unusual. Although fecal occult blood may be found, evidence of gross bleeding is very rare during an attack of acute diverticulitis. Leukocytosis with a shift to the left is classic, but may be blunted in the elderly or in those on steroids. Where there is a suspicion for diverticulitis, absence of a classic finding should not rule out the process. Rather, close observation should be undertaken to ensure that deterioration is not occurring. Evidence of inflammatory cells in the urine may indicate bladder or ureteral involvement. Because presentation of diverticulitis can be so similar to ischemic and inflammatory bowel disease in the elderly, early sigmoidoscopy without bowel preparation is sometimes recommended. Due to risk of perforation, enemas should be avoided if compromise in bowel wall is suspected.

Treatment of suspected acute diverticulitis requires hospitalization for observation, especially for the frail elderly. Bowel rest, fluid replacement, and broad-spectrum antibiotics usually result in defervescence of the inflammatory findings in 3 to 10 days. Radiologic or colonoscopic evaluation of the colon 6 to 8 weeks after an attack is usually recommended to assure that stricture formation has not occurred and that the presenting problem was indeed due to diverticulitis and not to penetrating colon carcinoma.¹²⁸

Decreased recurrence of symptoms and reduced development of additional diverticula has been suggested with the use of a high-fiber diet or bulking agents.¹²⁹ Recurrent attacks occur in fewer than 25% of patients.¹²⁸

Acute surgery is necessary in less than 20%, usually in those patients with signs of worsening inflammation or failure to respond despite conservative management. Fistula formation from the perforated diverticulum to urinary bladder, vagina, small bowel, or skin may occur and be another reason to consider surgery.

Diverticula in the right colon are less frequent but, if present, may be a source for major hemorrhage, if erosion of the mucosa underlying the perforating artery occurs. Bleeding from diverticula is said to be the most common cause of major lower intestinal hemorrhage in the elderly, occurring in 10% to 25% of patients with diverticular disease. Diverticular bleeding can be massive, with the patient presenting with mahogany stools or frankly bloody diarrhea. Unlike the pulse and vital sign changes classic for upper gastrointestinal bleeding, older patients with lower gastrointestinal bleeding can experience large volume losses without development of appreciable tachycardia or orthostasis, further complicating diagnosis. Diagnosis can be made by emergency colonoscopy, arteriography, or tagged red cells. Most patients with diverticular bleeding spontaneously resolve bleeding; however, a second bleed is seen in 20%.

Inflammatory Bowel Disease

Both Crohn's disease and ulcerative colitis are now recognized to have a bimodal age presentation, with the second peak between 60 and 75 years of age. Older patients are frequently women and are more likely to have left-sided involvement. Presentation of Crohn's can be very similar to diverticulitis, with acute presentation of left lower quadrant abdominal pain, tender abdominal mass, and fistula development. Ulcerative colitis on the other hand is more likely to present as chronic diarrhea. For more extensive review of the differences and similarities between Crohn's disease and ulcerative colitis, the reader is referred to an excellent review by Lennard-Jones et al.¹³¹⁻¹³³

Evaluation includes plain film of the abdomen and examination of the stool for fecal leukocytes, blood, and parasites, as well as flexible sigmoidoscopy to rule out ischemic colitis, pseudomembranous colitis, and neoplasm.

There is growing evidence that presentation in late life is associated with fewer relapses and a milder overall course if the first episode is tolerated.¹³³ Treatment options for Crohn's colitis and ulcerative colitis include sulfasalazine, 5-aminosalicylic acid agents, and steroids. Systemic steroids are more likely to be necessary in the first attack of late-onset ulcerative colitis than in attacks

presenting earlier. Azathioprine and 6-mercaptopurine immunosuppressive agents and infliximab (tumor necrosis factor antibody) are well tolerated in the elderly. Treatment considerations in the elderly include the need to be careful with the use of opiate-containing drugs for diarrhea, with concern for oversedation leading to mental confusion and falls. Loperamide may be better tolerated because of decreased central effects. Anticholinergics should also be used sparingly in the elderly to avoid potential cardiac and neurologic complications.

A severe complication is the development of toxic megacolon, which may be precipitated by anticholinergic drugs and which may progress to colonic perforation. The appearance of acute toxic megacolon is an indication for emergency surgery.

Risk of colon carcinoma is increased with long-standing inflammatory bowel disease, highest in those with active ulcerative colitis for over 10 years.

Pseudomembranous Colitis

Antibiotic-associated colitis, *C. difficile* colitis, is caused by toxins produced by the overgrowth of *Clostridium difficile*. Its name comes from the frequent finding of a necrotic epithelium with an overlying, easily removed yellowish membrane. Alteration of gut flora associated with exposure to broad-spectrum antibiotics and, in some cases, chemotherapy is responsible for colonization and then overgrowth of the pathogenic bacteria.

Person-to-person nosocomial spread has been demonstrated, and several epidemics of pseudomembranous colitis occurring in institutionalized elderly have been reported.¹³⁴ Cases occur up to 8 weeks after receiving broad-spectrum antibiotics. Fever, abdominal pain, tenesmus, and blood-streaked diarrhea are common. Diagnosis is confirmed by the isolation of *C. difficile* or its toxin from the stool or characteristic findings on mucosal biopsy.

Withdrawal of the antibiotic and correction of fluid and electrolytes are important. Metronidazole or vancomycin is usually effective in treatment; however, relapses may occur. In the latter case, prolonged treatment course with these agents is indicated. Dehydration and shock may occur. Mortality is high among the elderly so afflicted.

Conclusion

Physiologic changes with aging are usually not clinically significant but predispose the elderly to less ably withstand disease processes. Common problems such as relationship of dysphagia to aspiration, role of NSAIDs and *Helicobacter pylori* in the increased frequency and severity of peptic ulcer disease in the elderly, role of laparoscopic treatment of gallstones, approach to GI bleeding,

constipation, and diverticulitis are reviewed. Decreases in mortality have come from heightened awareness of presentations in the elderly, early intervention, and development of effective, less invasive treatment approaches.

Pulmonary Disease

James R. Webster, Jr.

Evaluation of the Elderly Patient with Pulmonary Disease

In many ways, pulmonary problems in the elderly can be considered classic examples of geriatric medicine. (1) For example, normal lung aging is a benign process with minimal clinical implications.¹ A decline in physiologic reserve is the only truly consistent finding in healthy adults; this results in some mild decrements in vital capacity and peak flow expiratory measurements but does not affect usual activities of daily living and, compared to cardiovascular aging, has only minor effects on exercise capabilities in the elderly. (2) Lifestyle issues, especially relating to cigarette smoking, nutrition, and preventive measures such as immunization, are crucially important in preserving lung health. (3) As usual, in geriatric practice, atypical clinical presentations of pulmonary disease are quite common. (4) Unfortunately, therapeutic nihilism is present with respect to such issues as using bronchodilators in obstructive lung disease, intensive care unit (ICU) admission policies, or recommending pulmonary rehabilitation for older adults.

The effects of repeated environmental exposures, concurrent illness, deconditioning, and especially cigarette abuse can be difficult to assess while evaluating any single individual who presents with dyspnea or other pulmonary symptoms, but these factors are generally more important than any anticipated changes of “normal” aging. Further complicating the issue of normal lung aging is the fact that many studies of lung function in elderly subjects have been cross-sectional and of small size. If a primary lung disease is not present, predictable lung changes due to age in healthy adults below age 85 are relatively mild and should be considered without clinical significance; these include anatomically a decrease in airway size with some qualitative alterations in supporting elastic tissue, gradual increases in chest wall stiffness, and a loss of approximately 20% of intercostal muscle strength beginning after age 50.

As a result of these factors, lung elastic recoil and inspiratory muscle strength (including especially the diaphragm) decrease.² With respect to blood gas findings, the arterial–alveolar oxygen gradient widens with a decline in arterial oxygen levels of approximately 1 mmHg per year from ages 60 to 75, after which the levels remain constant in healthy individuals, probably due to cohort survival. There is also a decrease in the sensitivity of the respiratory centers to neurochemical stimuli, in particular hypercapnia. The associated age-related changes in measurable lung functions include increases in residual volume, closing volume, and functional residual capacity. There are also mild decreases in the expiratory flow rate, the total vital capacity, and the 1-s vital capacity (Table 57.1).

Changes occur in the pharyngeal component of swallowing, with slowing of transit times and reduced pharyngeal sensation, which, if neurologic disease supervenes, can set the stage for aspiration. Wide oscillations in upper airway resistance during supine sleep are often present in healthy older persons and may portend problems with sleep disordered breathing. All these changes can combine to contribute to the reduced physiologic reserves and, if an acute insult occurs (for example, an infection or pulmonary embolism), this lack of reserve may be unmasked and both patient and physician may be caught unawares by the steep spiral of disaster that may follow. Finally, the inherited level of lung volume, gender, cigarette smoking, and childhood infections are much more important in determining lung function in older adults than is chronologic age.³

It should be noted that pulmonary problems are becoming increasingly recognized as an elderly women’s health issue.⁴ For example, there is now evidence that women are more susceptible than men to the effects of cigarette smoking, leading to the recently noted disproportionate increase of lung cancer in women (the most common cause of cancer death for women) and the rising incidence of chronic obstructive pulmonary disease

TABLE 57.1. Clinical and functional aspects of age-related lung changes.

Structural	Functional
Increased chest wall stiffness	Increase in elastic work of breathing (+ ? dyspnea)
Muscle loss	Decrease in MVV ^a
Increased anteroposterior diameter	(? increase in dyspnea)
Enlargement of terminal lung units	Decrease in surface area of lung (+ lower PaO ₂ ^b)
Reduced elasticity	Decrease in VC, ^c flow rates
Rearrangement in collagen	Increase in RV ^d (? Increase in dyspnea)
Decrease in ciliary function	Decrease in cough effectiveness

^aMVV, maximum voluntary ventilation; average decrease, 25% between ages 20 and 80.

^bArterial pressure of oxygen; average decrease, 1 mmHg/year after age 60.

^cVital capacity; average decrease, 18% between ages 20 and 80.

^dResidual volume.

(COPD) in women. Currently, the number of women older than 65 years of age who die of COPD is almost the same as men;⁵ this is not surprising, given that women have smaller lungs than men and have more hyperresponsive airways and lower elastic recoil at any given lung volume than men.

Atypical presentations of lung disease are not unusual, as with other geriatric situations. Often, this is due to poor patient perception of their symptoms. For example, elderly individuals, even those without lung disease, underestimate dyspnea, presumably because of attenuated upper airway responses, peripheral sensory misinterpretations, and a reduced central nervous system responsiveness to increased mechanical loads.⁶ They also have less robust cough responses to irritative stimuli; therefore, they may not appreciate the effects of acute or chronic bronchial obstruction.⁷ The use of questionnaires that are specifically designed for elderly patients may provide reliable data.⁸ Confusion, especially in cognitively impaired older individuals, may be the presenting syndrome for many pulmonary illnesses, making it difficult to obtain an accurate, coherent, or complete history. There are often associated blunted signs as well; for example, a reduced febrile response to infection.

All this makes it a challenge to see such patients but also offers outstanding opportunities to improve their functional status by applying simple medical strategies for acute or chronic pulmonary problems. These measures include exercise programs, bronchodilators, antibiotics, anticoagulants, nutritional interventions, and smoking cessation. In addition, there is the professionally satisfying opportunity to bring all the high-tech wonders of modern medicine to assist in diagnosis and treatment of functionally young older adults. In summary,

the care of these patients is what being a physician is all about.

COPD in the Elderly

Chronic obstructive pulmonary disease (COPD) is a common, underappreciated, underdiagnosed, and therefore undertreated disease that causes significant morbidity and mortality and excess health care utilization in the elderly. It is the most common lung disease causing dyspnea in the older patient.⁹ When faced with a patient complaining of shortness of breath, it is of course important that the clinician exclude the myriad nonpulmonary causes of dyspnea, such as anemia, congestive heart failure, and chronic aspiration. With its subcategories of asthma, chronic bronchitis, and emphysema, COPD is the fourth leading cause of death in the elderly in the United States for both men and women.⁵ Compared with the general population, patients with COPD are twice as likely to rate their health as fair or poor and to report limitations in ADL and IADL activities. They have a higher incidence of depression than most other chronic diseases, they visit physicians for medical care more frequently than their peers, and they have an increased likelihood of hospitalization and ICU admission. There is virtually a 1:1 male:female prevalence of COPD after age 68. Although men have a slightly higher mortality rate, their rate is stabilizing, while the death rate of women is rising. As discussed in the introduction of this chapter, COPD is becoming a women's health issue.⁴ Prognosis of COPD patients is variable; the most important determinants of survival are the presence of comorbidities and the severity and reversibility of the airflow obstruction.

In terms of differentiating the various syndromes of COPD, the diagnosis of "late-onset asthma" in older individuals with its inflammation of conducting airways and its separation from pulmonary emphysema (a disease of inflamed and destroyed alveoli) with a reversible component can be difficult, although from a practical standpoint these two entities can generally be considered to have an anatomic and functional continuum.¹⁰ Classic asthma is a disorder manifested by episodic, reversible airways obstruction, and hyperresponsive airways with a return to normal lung function between attacks. In the elderly asthmatic, however, a complete return to normal baseline is unlikely because most of these patients have a component of permanent lung damage.¹¹ Usually the symptoms of coughing and wheezing are precipitated or made worse by viral respiratory tract infections, gastroesophageal reflux disease (GERD), or chronic sinus disease, and a history of allergies is often lacking. To further complicate the picture, there may be a remote history of cigarette use. Longitudinal studies of such

patients simply are not available at this time, but there is abundant evidence that older patients with asthma are underdiagnosed and undertreated.¹²

In contrast to asthma, classic pulmonary emphysema is manifested anatomically by permanent lung destruction, primarily seen in the terminal lung units, accompanied by irreversible airflow obstruction on testing. It has been described as “a gross exaggeration of what happens to the lung with advancing years.”¹³ Both chronic bronchitis, with its airways inflammation, mucous production, and peribronchial fibrosis, and asthma, with its bronchospasm, edema and peribronchial fibrosis, and airways remodeling, are susceptible to effective treatment of their somewhat different inflammatory components.

The largest percentage of elderly patients with COPD present with a mixed picture in which maximizing reversibility of airflow obstruction should be a major therapeutic objective. If using the word asthma increases the efforts in this regard, so be it. The American Thoracic Society criteria for reversibility are improvement in forced expiratory volume at 1 s (FEV_{1.0}) of at least 15% and an increase of more than 200 mL. Such patients present an outstanding opportunity to improve both functional status and quality of life.

In terms of diagnosis, because the elderly have a decreased perception of dyspnea imposed by mechanical loads or irritative stimuli and the responses to hypoxia and hypercapnea are diminished with age, health professionals need to have a high sensitivity to the possibility of this disease. The diagnosis of COPD can be reliably suggested by the history of smoking and findings on examination of lung hyperinflation with an associated decrease in breath sounds and a prolonged expiratory time, with or without a wheeze, on forced expiration. Cough and breathlessness have a low specificity in older patients with COPD, who often simply complain of fatigue and reduced mobility and ADLs.⁸ Recent studies demonstrate that COPD does not impair cognition, although depression is common in these patients, especially in advanced disease when isolation is common.

Confirmation of a diagnosis of COPD can best be made by pulmonary function testing, a simple forced vital capacity (FVC) demonstrating limitation of airflow (less than 70% of predicted FEV_{1.0}) being adequate for initial diagnosis and following the effects of therapy.¹⁴ If the results of testing are abnormal, the FEV_{1.0} should be repeated following administration of an inhaled beta-agonist bronchodilator to look for a reversible “hidden asthmatic” component. An arterial blood gas measurement may be obtained, especially in moderate to severe COPD, because the ability of physicians to estimate hypoxia or hypercapnia is notoriously poor. In the patient with unexplained dyspnea, full pulmonary function studies are most often required to help achieve a diagnosis.

There is good evidence that morbidity (i.e., days of illness or hospitalization) can be reduced by treatment of the COPD patient, who will most likely experience a significantly improved quality of life. Therapy of COPD in the elderly should focus on relief of symptoms, reduction of breathlessness, and improvement of functional status. Smoking cessation, specific medications, and adjunctive therapies form the cornerstones of effective management.^{14,15}

Smoking cessation is vital to successful management of COPD in any age group, including the elderly. Physicians can play a key role because a direct recommendation to stop can result in a 5% to 10% long-term quit rate. After such advice, a firm quit date should be set. Survey results of older smokers show that they are far less likely than younger persons to believe data about the adverse health effects of smoking and may well view it as a beneficial coping and weight control tactic. Thus clear, specific messages about the risks and the benefits of cessation must be given. “Hard-core” smokers who quit even after the age of 60 have improved pulmonary function, a slower rate of airflow decline, and a decrease in cardiovascular and all-cause mortality compared to those who continue to smoke.¹⁶ Pulmonary benefits include reduction of cough and sputum production, decreased airway irritability, and improved ciliary and macrophage function with subsequent reduction in the frequency and severity of respiratory infections. Ex-smokers have higher levels of physical function, improved appetite and nutrition, and better quality of life than smokers, due in part to fewer cardiovascular problems or strokes.

Management of smoking cessation requires both behavioral and pharmacologic intervention, which include provision of written self-help material, enrollment in formal cessation programs conducted by the Lung and Heart Associations, the use of nicotine gum or patches or bupropion hydrochloride for patients who have significant addiction (smoke one or more packs per day or smoke their first cigarette upon awakening). The use of pharmacologic measures has not been specifically studied in the elderly, but expert opinion recommends their use. Nicotine patch or gum use is contraindicated in patients who have recent myocardial infarction, angina, or serious cardiac arrhythmias. When smokers do quit, the chance of relapse is a strong reality, most occurring within the first 2 to 4 weeks. Follow-up counseling, calls, letters, or visits during this period are important components of success, and patients who relapse should be encouraged to try again with clear discussion of the circumstances of the relapse. Smoking cessation is often an evolving process requiring physician advice and encouragement, patient motivation, and persistence.

Inhaled aerosols are a major component of long-term treatment of COPD. No matter which aerosol is used, metered dose inhaler (MDI) techniques are crucial. In

TABLE 57.2. Proper technique for metered dose inhaler (MDI) use.

Remove the cap. Attach spacer if one is being used.
Shake the canister. Breathe out completely.
Place the mouthpiece fully into your mouth.
Trigger the canister and simultaneously breathe in slowly and deeply.
Hold your breath for as long as you can, at least 10 s.
If more inhalations are prescribed, wait 1 to 5 min and repeat.
When finished, replace the cap on the MDI unit.

terms of outcome, results of using handheld MDIs are equivalent to nebulizer treatments if proper technique is used. Unfortunately, 40% of elderly patients do not use MDIs correctly due to poor hand/breathing coordination or associated illness such as arthritis or cerebral vascular disease.¹⁷ The use of a spacer with the MDI allows for more reliable delivery of medication by slowing the velocity of the aerosol particles, enhancing distal medication deposition in the lungs, and decreasing deposition in the oropharyngeal and laryngeal areas, thus avoiding systemic side effects such as tachycardia or tremors. MDIs that are breath activated have been developed to overcome the hand/breathing coordination problem, but the patient must still develop a rapid inhalation technique. Proper use of a MDI is reviewed in Table 57.2.

Generally, physicians should begin treatment of mild to moderate COPD with inhaled ipratropium, which has been shown to slow the progression of COPD in cohorts of all ages.¹⁸ Cholinergic receptors located in large airways are involved in controlling bronchomotor tone, especially in COPD patients who predominantly have emphysema. The bronchodilatation following inhalation is a local, site-specific effect, not a systemic one. Anticholinergics administered by MDI act locally and therefore do not cause the serious adverse reactions seen if this class of drug is administered to the elderly by oral or parenteral routes; they have a slower onset of action but a longer duration of effect than beta agonists. Tiotropium is an emerging site-specific agent that only affects the anti-muscarinic M₁ and M₃ receptors. It is still under investigation.

Inhaled selective beta-2 agonists may be short acting for “rescue” (e.g., albuterol) or long acting (e.g., salmeterol) and are particularly useful for symptomatic relief of episodic dyspnea in patients with COPD. These drugs initiate relaxation of bronchial smooth muscle and decrease mucosal edema; they also facilitate mucociliary clearance and decrease goblet cell hypertrophy. They are especially effective in patients with a large component of “asthma”; however, unlike ipratropium, there is no evidence that they slow the progression of disease. There are now combinations of long-acting beta-agonists and ipratropium that are useful in improving compliance and are especially useful in patients with nocturnal symptoms. Inhaled corticosteroids are sometimes used in patients

with a large reversible “asthmatic” component because they suppress inflammation and reduce airways hyper-responsiveness. They work by interfering with arachnoidic acid metabolism, reducing vascular leaks, and enhancing responsiveness of beta-adrenergic receptors. Patients should follow the package insert recommendations to prevent oral candidiasis. Systemic side effects are negligible although osteoporosis is a long-term concern, particularly at high dose ranges. They have long-term benefits in younger patients with chronic asthma, and their use in the elderly is based on the data generated from these younger populations, with the hypothesis that inflammation of small airways is instrumental in the progression of COPD. Inhaled steroids are most commonly used as an adjunct for patients in whom the disease is difficult to control.

Oral corticosteroids are possibly useful for some moderate to severe COPD exacerbations.¹⁹ An empiric trial of 40 to 60 milligrams (mg) prednisone per day can help return the patient to baseline lung function, shortening the duration of morbidity on average by a few days. Doses are conventionally tapered over 7 to 14 days. The use of oral corticosteroids in the stable phase of COPD is at best very controversial and frequently results in osteoporosis, loss of muscle strength, hyperglycemia, and hypogonadism.

Methyxanthines are considered an archaic third-line agent of treatment. Theophylline preparations can provide consistent but modest bronchodilation and decrease the severity of breathlessness by improving respiratory muscle strength in an occasional patient, but they have a narrow therapeutic window with many side effects (i.e., anorexia, nausea, vomiting, CNS stimulation, and cardiac arrhythmias). The elderly are at greater risk for major toxicity (hypotension, serious arrhythmias, seizures, and death from overmedication) than younger patients.²⁰ This severely limits their usefulness, and obtaining blood levels is mandatory in patients who are using this group of drugs on a short- or long-term basis. Serum levels of 5 to 10 µg/ml are appropriate. It should also be noted that adverse drug reactions occur with macrolides and fluoroquinolones. Leukotriene inhibitors have not been systematically studied in the elderly. If they are used, ipratropium should be discontinued because adverse drug interactions may occur. Patient and physician should also be aware that the international normalized ratio (INR) may be increased by the interaction of leukotriene inhibitors with warfarin.

Oral antibiotics are beneficial in selected COPD patients who have recurrent episodes of bacterial infection.²¹ Most commonly these follow a viral upper respiratory illness, and antibiotics can reduce the inflammatory response within the airways. Patients with impaired mucociliary clearance are at risk for a recurrent cycle of infection, tracheobronchial mucosal destruction,

and worsening mucociliary clearance. The use of a 2-week course of antibiotics in patients with severe chronic bronchitis and bronchiectasis can break the cycle and provide relief. The most common pathogens associated with such exacerbations are *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae*. Ampicillin is frequently used but is ineffective against betalactamase-producing organisms, so that the treating physician must be aware of local sensitivity and resistance patterns. Trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, and third-generation cephalosporins or macrolides may provide broad coverage and can be very effective in treatment of exacerbations. Cost issues are, of course, also a consideration in the choice of antibiotic therapy. The use of long-term antibiotics to prevent exacerbations in patients with COPD is of unproven value, although some interesting new immunostimulating vaccines may prove helpful in reducing such events.

Long-term home oxygen therapy (LOT) for 15 to 24 h per day is useful in hypoxemic patients. Raising the arterial oxygen level has been shown to reduce mortality by decreasing pulmonary hypertension in patients with cor pulmonale, as it decreases pulmonary vascular resistance and right ventricular diastolic pressure.²² In the hypoxemic patient, oxygen therapy also improves neuropsychiatric function, decreases secondary polycythemia, and relieves breathlessness, all of which can improve mobility, functional status, and independence in selected elderly COPD patients. Those patients who are stable on optimal bronchodilator treatment with an arterial oxygen level of less than 55 mmHg (or 55–59 mmHg with concomitant polycythemia, pulmonary hypertension, or right heart failure) are appropriate for treatment and eligible for Medicare reimbursement (Table 57.3). Patients started on oxygen therapy often incorrectly assume that this represents the end of a useful and independent existence. They need to be clearly counseled about benefits of oxygen supplementation and told that therapy will most likely improve overall status and the quality as well as the length of their life.

Oxygen supply systems are of three types: stationary, portable, and ambulatory. Stationary systems refer to any

large reservoir of oxygen or oxygen-producing device that cannot easily be moved, including compressed gas cylinders (H or K size), liquid oxygen reservoirs, and oxygen concentrators. Portable oxygen equipment can be moved or transported by the patient. This equipment usually weighs more than 10 lb, involving smaller (E size) compressed oxygen cylinders with a regulator, which is carried on wheels, a cart, or stroller. Ambulatory oxygen can be carried by most adults on their person during activities of daily living; these are small liquid oxygen canisters or lightweight high-pressure cylinders, with a regulator. The liquid oxygen reservoir for home use with an ambulatory liquid system offers an ideal arrangement for the ambulatory patient requiring continuous oxygen rather than the minimum of 15 to 16 h/day. The reservoir will provide a 1-month supply of oxygen and serves as a source to refill the portable ambulatory system, which weighs 5 to 7 lb and provides about 4 h of oxygen. The use of a control valve that delivers oxygen only when the patient inhales can conserve oxygen in patients using ambulatory systems.

The oxygen concentrators that are used for homebound patients take advantage of a differential separation principle based on the molecular weights of nitrogen and oxygen to concentrate oxygen from room air. Patients using these systems can be active and ambulatory in the home with use of extended tubing. A supply of smaller cylinders is necessary for out-of-home use. These can be pulled on a cart by the patient or carried in a wheelchair but are cumbersome and are a potential cause of falls. Careful evaluation of the patient and knowledge of the patient's activity level and concerns about oxygen therapy will help determine the appropriate system.

As with most older patients (Chapter 21), the perioperative period becomes a time of great hazard for patients with COPD.²³ The frequency of postoperative complications increases with age, particularly if these patients undergo thoracic or upper abdominal procedures. Perioperative evaluation is crucial, with educational interventions stressing the use of effective cough maneuvers, incentive spirometry, and early ambulation. Specific risk factors for an adverse outcome include a PaCO₂ level greater than 45 mmHg, poor nutritional status with recent weight loss, current cigarette smoking, and emergency surgery. Careful preoperative evaluation with pulmonary function and arterial blood gas measurements is crucial, and judicious use of analgesics postoperatively to avoid respiratory depression, delirium, and oversedation are important strategies. Recent studies do indicate that elderly postoperative patients in the ICU who need intubation and mechanical ventilation (MV) under any circumstances do as well as younger patients in terms of outcome, although if they have been nutritionally depleted, weaning from MV can be a problem.²⁴

TABLE 57.3. Medicare criteria for long-term oxygen therapy indications.

P _a O ₂ ≤ 55 mmHg (on room air)
Oxygen saturation ≤ 88% (on room air)
P _a O ₂ ≤ 59 mm with at least one of these four findings:
Secondary polycythemia (hematocrit > 55%)
Clinical cor pulmonale
Established right ventricular hypertrophy
Pulmonary hypertension
Optimal medical management established

P_aO₂, partial pressure of arterial oxygen.

Therefore, age alone should never be used to deny older patients either surgery or ICU admission, even though many prognostic rating formulas (e.g., Acute Physiology and Chronic Health Evaluation, APACHE III) list age as an adverse prognostic marker.

Pulmonary rehabilitation can be an important component of successful treatment in patients with moderate to severe COPD.²⁵ The primary goal is to attain the highest possible functional level using multiple modalities. The rehabilitation model focuses on not only reversing the chronic progressive disease process but on reversing the patient's disability from the disease. Comprehensive patient and family education, breathing retraining, bronchial hygiene, exercise reconditioning, work simplification and energy conservation training, and psychosocial support are all part of pulmonary rehabilitation, which in randomized control trials has been shown to improve functional status and decrease hospitalization rates.²⁶

The role of adequate nutrition is also to be stressed, because malnutrition is a common problem among COPD patients. Decreased muscle mass (including muscles of respiration) and impairment of immune function are seen with protein-calorie malnutrition. A body weight of less than 90% of ideal is associated with an increased mortality rate regardless of the severity of COPD. The weight loss may be due to such things as early satiety associated with dyspnea of deglutition or depression, and, according to some recent evidence, tumor necrosis factor (TNF) is increased in these patients.²⁷ In underweight COPD patients, the increased ventilation requirements during activity require a disproportionately greater increase in energy requirements for respiratory muscle activities compared to well-nourished COPD patients or controls.²⁸ Malnourished patients also have increased rates of infection, which appear to be partially due to decreased functioning of T cells, complement, and humoral immunity. Treating the malnourished COPD patient requires a comprehensive assessment with an exclusion of treatable causes of weight loss other than pulmonary disease. An assessment (using calorie counts) of the patient's current intake habits and limiting factors (whether physical, environmental, or economic) is important and requires evaluation by dietitians and social workers. Fatigue or dyspnea associated with eating may be reduced by using bronchodilators before meals, assistance with meal preparation, or rests before meal times. Patients can also be encouraged to eat multiple smaller meals and to add liquid protein supplements to their diets. Studies indicated that in severely compromised patients a high percentage of calories from lipids instead of carbohydrates reduces excessive carbon dioxide production and the subsequent increase in minute ventilation at rest.

Immunization against influenza and *S. pneumoniae* plays a significant role in prevention of pneumonia in the

elderly COPD patient. Influenza vaccine has been shown to decrease hospitalization, morbidity and mortality, and medical costs and should be given every autumn. In patients who are immunosuppressed or have severely debilitating cardiovascular, pulmonary, renal, or hepatic disease, or diabetes mellitus, the antibody titers from pneumococcal vaccine may not be sustained; therefore, clinicians should consider revaccination after 6 years, although convincing data regarding the effectiveness of such a program in the elderly are currently not available. The pneumococcal vaccine is cost-effective in both community-living and institutionalized older patients.

Because adequate lung or heart/lung donor specimens are very difficult to obtain, most lung transplant programs exclude those applicants over age 60, citing frequent comorbidities (diagnosed or subclinical) as the reason. Some lung transplant programs are still collecting experience as to efficacy for various disease states, but it is not currently an option for the elderly.

In summary, COPD is a common and serious condition often overlooked in the elderly. Clinical suspicion, with confirmative pulmonary function testing, will establish the diagnosis. Successful treatment involves simple, well-established measures that improve functional status and result in significant improvement in the quality of life for these patients.

Pulmonary Embolism in the Elderly

The entities of deep venous thrombosis (DVT) and pulmonary embolism (PE) present a continuum of venous thromboembolic disease (VTE), which is of crucial importance for elderly patients, and offer constant diagnostic and therapeutic challenges to physicians caring for patients of any age. For multiple reasons, the incidence of both DVT and PE increase with age.²⁹ First, there is often a decrease in the leg muscle mass, setting the stage for stasis. There are increased thrombotic tendencies in the elderly,³⁰ beginning around age 60, which may involve up to 20% of those over age 85; these include impaired vascular wall fibrinolysis and hypercoagulable states, especially with respect to products of factor X_a activity, Leiden factor V,³¹ and likely increased activity of other clotting factors,³² notably prothrombin. In addition, there may be a decrease in antithrombin III and other antithrombotic components, such as proteins C and S. There is also a dramatic increase in the frequency of triggering risk factors, such as surgery, with its immobility and temporary hypercoagulable state, congestive heart failure, malignancies, lower extremity fractures, and hip and knee joint replacements. This is not only a common problem but a serious one: the in-hospital mortality of elderly patients over the age of 65 with documented pulmonary embolism was 21% in the Prospective Investigation of Pulmonary

Embolism Diagnosis (PIOPED) Study, and the 1-year mortality was 39%.³³ Recent data suggest these numbers may be even higher.³⁴ Such grim statistics demand optimal vigilance, treatment, and, ideally, prevention.

The diagnosis of VTE in the elderly is difficult, although the presentation is usually quite similar to that seen in younger patient groups. The most common presenting symptom of PE is some complaint of chest discomfort or pain, seen in approximately 35% of patients in most series, usually without hemoptysis. Dyspnea and tachypnea occur frequently. Although circulatory collapse occurs in a relatively small proportion of the elderly, these latter patients are much more likely to have sustained massive pulmonary emboli and often have evidence of neurologic deficits and findings of pulmonary hypertension. Although virtually all younger patients present with one of these syndromes, about 10% of the elderly do not, and in the setting of respiratory distress this minority may show only confusion or atypical new radiographic findings. The major diagnostic strategy³⁵ required is one of constant suspicion and concern and a consideration that, in any older hospitalized patient who is "failing to thrive," to ask whether this could be due to pulmonary embolism, because both the symptoms and standard laboratory findings are nonspecific and the diagnosis is too often made postmortem. The classic triad of hemoptysis, pleuritic chest pain, and clinically apparent thrombophlebitis is infrequently seen, in less than 10% of elderly patients with VTE.

The first step in making the diagnosis is a careful physical examination to evaluate alternative diagnoses, for example, congestive heart failure, coronary artery disease, malignancy, and infections that are all frequent in the elderly and may on occasion be confused with pulmonary embolism. Studies demonstrate that when clinicians have a high (>90%) certainty of pulmonary embolism, they are most often correct; similarly, when they believe that there is a small (<20%) likelihood, they are also usually correct.^{33,35} The problem is the large group of "in-between" patients for whom neither certainty exists.

The most common and serious major error is one of omission, when the diagnosis simply is not considered clinically and is confirmed only at autopsy. The diagnosis should be approached with urgency, once it is considered and diagnostic algorithms are well established.³⁵ Unfortunately, routine chest roentgenograms are of only limited value at best, to exclude other disorders such as pneumonia or pneumothorax. Most frequently they are unremarkable or demonstrate only scattered areas of atelectasis. Pleural changes and possibly some local asymmetric changes in vascularity may be detected if the film is keenly studied; however, the most common finding is that of an essentially normal chest roentgenogram in a very sick patient. Electrocardiograms are likewise useful in excluding acute myocardial infarction but are not

generally helpful in making the diagnosis of PE, because tachycardia and nonspecific ST segment abnormalities are by far the most likely alterations. Recent studies utilizing echocardiography in patients with PE have shown an unexpectedly high incidence of pulmonary hypertension and right ventricular strain.³⁶ The echocardiogram is, however, not a proven sensitive or specific test for PE. Arterial blood gases generally show mild hyperventilation and hypoxemia ($\text{PaO}_2 < 60 \text{ mmHg}$ on room air), but again, this is a nonspecific finding.

Ventilation-perfusion lung scans are helpful, particularly when there are segmental mismatches with areas that are well ventilated and not perfused. Lung scans are interpreted as high probability, intermediate probability, low probability, or normal. The PIOPED³³ study demonstrated that combining a high clinical probability and a high-probability lung scan virtually confirmed the diagnosis (>96% certainty). The combination of a low clinical suspicion and low-probability lung scan was associated with low frequency of significant pulmonary embolism (<6%). In patients in whom the lung scan pattern was high probability and clinical suspicion was intermediate, the frequency of pulmonary embolism fell but was still relatively high (86%). The most frequent problem is a high-risk patient with an "intermediate probability" lung scan. Because of the unfortunate lack of specificity of such scans, their utility remains problematic, and with the hazard of "clinical judgment" in such a precarious setting, physicians must often proceed with further studies, either helical computerized tomography (HCT) or pulmonary angiography.

The understanding of the place of HCT in the diagnosis of PE is still an evolving concept. Due to improvements in the technology, and its general availability and safety, the procedure has great appeal. In addition, there is reasonable interobserver reliability in most studies. Unfortunately, it still suffers in published studies from a lack of sensitivity (53%–100%) with specificities of 81% to 100%, and thus is not an ideal test to exclude the diagnosis of PE, especially in the "high clinical suspicion" patient.³⁷ HCT may be helpful in establishing a diagnosis of pulmonary embolism in selected patients with a nondiagnostic lung scan. It appears to be more accurate in evaluating the central pulmonary arteries (sensitivity, 83%–100%; specificity, 92%–100%) than in the subsegmental vessels (sensitivity, 29%).³⁸ Future prospective studies of HCT are needed to evaluate its role in the diagnostic algorithm for VTE. These investigations should settle issues of overall specificity, sensitivity, and cost-effectiveness.³⁹

Pulmonary angiography is still the gold standard for diagnosis of PE.⁴⁰ A positive angiogram requires either a cutoff vessel or clear evidence of an intravascular filling defect, which is typical of a clot. Multiple recent studies indicate that, contrary to some opinions, pulmonary

angiography is quite safe in the elderly patient. There is a somewhat increased incidence of postangiogram renal failure in the elderly (1%–2%), but this can be managed quite satisfactorily when identified and is often preventable using hydration and diuretics. One last caveat in the elderly; a small embolus that would not present a serious burden for a younger patient may result in dramatic pulmonary hypertension and significantly impaired cardiovascular status in an elderly patient with underlying heart or lung disease and therefore marginal physiologic reserves. Such patients have been shown to be clinically improved following treatment for PE.

The identification and diagnosis of DVT, the source of PE, may also be difficult. It is well demonstrated that for this entity, clinical signs are notoriously unreliable. Virchow's triad (stasis, hypercoagulability, and vessel wall injury) is still the physiologic basis of DVT, which forms the continuum with PE. Elderly patients who have "idiopathic" thrombophlebitis most likely have an acquired hypercoagulable state, most commonly due to Leiden factor V or a prothrombin mutation. In the absence of an obvious precipitating cause or clotting problem, a clinically focused search for a malignancy is appropriate based on a history and physical exam with routine screening studies. One review⁴¹ reported a standardized incidence ratio of 1.5 for malignancies in such patients. Recent data suggest that cancers diagnosed concurrently with or within a year of an episode of VTE are associated with an advanced stage and have a poor prognosis.⁴² Tumors of pancreas, lung, ovary, and brain were the most common sites.

Noninvasive studies of veins in the lower extremities (the site of more than 95% of emboli) are now widely available and have been demonstrated to have good specificity and sensitivity. B-mode ultrasonography with flow Doppler is the most commonly used diagnostic method because it avoids some of the confounding false positives of the impedance plethysmography methods [e.g., congestive heart failure (CHF), extrinsic obstruction]. Contrast venography is the gold standard for the diagnosis, but it is usually reserved for extremely serious and equivocal situations. Approximately 70% of patients with demonstrated PE have positive noninvasive lower extremity studies. Presumptive explanations for the "30%" are either that the clot has migrated, leaving no demonstrable residue, or possibly that clots were coming from elsewhere in the venous system, particularly the pelvic veins or the right ventricle. This finding means that although a positive study is a call to therapy, a single negative study does not completely exclude the diagnosis; serial investigations are appropriate⁴³ if suspicion is high and a decision is made not to begin anticoagulant therapy.

The use of D-dimers as a secondary strategy to exclude the diagnosis of VTE has been recommended because

the test has a high sensitivity, although a low specificity. False positives may occur in patients with recent trauma or surgery, malignancy, pregnancy, severe infections, and liver disease. It is somewhat dependent on the specific methods used, and most series show that a normal plasma level (e.g., <500 µg/ml by immunosorbent assay) is useful in conjunction with other strategies to exclude the diagnosis of VTE, although false negatives up to 3%–5% are reported.⁴⁴

The treatment of VTE has been revolutionized by the emergence of low molecular weight heparins (LMWH), which have been demonstrated to be effective for both DVT and PE.⁴⁵ They are given on a weight-adjusted schedule, often only once a day, and the treating physician should be familiar with the specifics of the preparation being used. They are easier to use than older treatment protocols because they do not require frequent partial thromboplastin time testing to adjust dose schedules, as is required for the intravenous unfractionated heparins.

The thrombocytopenias that were occasionally (3%–6%) a problem with the unfractionated preparations are seen in less than 1% of patients treated with LMWH. Studies indicate that they are safe in terms of bleeding complications and can even be given on an outpatient basis to compliant patients with uncomplicated DVT. It is usually recommended that warfarin be started concurrently and, after a 4- to 7-day crossover, that the warfarin be continued, maintaining an international normalized ratio (INR) of approximately 2:3. Bleeding complications of warfarin therapy are more frequent in the elderly, particularly in older women, and increase with duration of therapy; however, with careful clinical and laboratory monitoring in formalized programs, bleeding should not become a major problem in most cases.

The question of how long to continue warfarin therapy is always a difficult clinical judgment. In general, it is recommended that therapy be sustained for 3 to 4 months in patients for whom the initial risk factor can be controlled or eliminated. Patients may need long-term therapy if they are considered to remain at high risk, and recent studies show that recurrences can be cut to 6% by maintaining anticoagulation for 1 year. Current recommendations for "idiopathic" VTE are for up to 2 years of therapy for the first episode and that a second episode requires lifelong anticoagulation, possibly with INRs of 3 to 3.5.⁴⁶ Thrombolytic therapy, particularly tissue plasminogen activator (TPA), is occasionally used in the elderly patient with massive PE and circulatory collapse but is generally not required.⁴⁷

Although the experience is relatively small, there seems to be an increased incidence of bleeding in the elderly, especially intracranial hemorrhages, with even a single administration. Supportive therapy, such as oxygen, fluids, and vasopressors for hypotension and

TABLE 57.4. Prevention of venous thromboembolism (VTE)

Risk	Recommended Rx
High	
Bed confined with:	Low molecular weight heparin (LMWH)
Congestive heart failure	? Intermittent pneumatic compression
Active malignancy	
Postoperative: lower extremity, orthopedic, extensive abdominal, or pelvic surgery	
Previous diagnosis of DVT or PE	
Moderate	LMWH or warfarin
Medical illness with:	
Immobilization, e.g., stroke, COPD	
Less extensive surgery, of shorter duration	

For patients who cannot be anticoagulated (e.g., postoperative neurologic surgery), pneumatic compression boots or graduated pressure stockings provide some proven effectiveness.

Source: From Ref. 49, with permission.

hypovolemia, and pain control, are of course standard treatments that must be used in the critically ill patient. Vena caval interruption, for example, use of the Greenfield filter, may be needed in patients with PE who cannot immediately be anticoagulated. Chronic venous complications are common with use of these devices, and such patients, if possible, should have lifelong anticoagulation as studies show that they are at risk of proximal clot formation above the filter.⁴⁸ Pulmonary embolectomy is not recommended in the elderly because it has a very low success rate and medical therapy is generally quite effective.

Preventive guidelines are fairly straightforward at this time. Patients who are at risk due to bed rest, postoperative status, congestive heart failure, or malignancies are best treated according to the measures listed in Table 57.4. Intermittent pneumatic compression boots have been demonstrated to be useful for prophylaxis in patients who are at high risk of critical local wound hemorrhage (for example, following neurosurgical procedures) but who cannot be immediately anticoagulated. Graded compression antiembolic stockings also have some limited effectiveness in prevention. Low-dose warfarin with an INR adjusted to 1.5 to 2 units, or subcutaneous LMWH, appear to be the preventive treatments of choice. Studies demonstrate that, for unknown reasons, such preventive strategies are not used on a regular basis by physicians, probably because of the mistaken opinions that pulmonary embolism is not a common or serious problem, that preventive strategies do not work, or that such anticoagulation protocols are actually dangerous. None of these beliefs is true. Particularly in the elderly, for whom an ounce of prevention is worth more than a pound of cure, these procedures should regularly be found in the armamentarium of geriatricians.⁴⁹

In conclusion, the continuum of DVT and PE in the elderly is quite similar to that of the younger patient. Constant consideration of the diagnosis and application of standard diagnostic and therapeutic strategies will

benefit patients and also enhance the mental equanimity and professional satisfaction of physicians caring for the elderly.

Interstitial Lung Disease

The term interstitial lung disease covers a heterogeneous group of disorders that are lumped together as a result of common radiographic and clinical findings which are nonspecific and not related to etiology (Table 57.5).⁵⁰ The conventional wisdom on the pathogenesis of interstitial lung disease postulates an etiologic insult resulting in alveolitis, followed by an abnormal, hyperexuberant repair process that causes excess connective tissue generation, fibrosis, and ultimately a “honeycomb” appearance of a scarred, destroyed lung, both on biopsy and radiographically. The presentation is usually one of cough, dyspnea, and frequent associated systemic symptoms such as fatigue and arthralgias. The astute geriatrician will focus on the clinical history, seeking drug exposures, disorders of swallowing leading to chronic

TABLE 57.5. Disorders associated with interstitial lung disease in the elderly.

Common
Recurrent gastric aspiration
Drugs
Infection
Acute: viral, bacterial
Chronic: granulomatosis, especially TB
Atypical congestive heart failure
Environmental/occupational exposures
Lymphangitic spread of malignancies
Idiopathic
Less common
Sarcoidosis
Eosinophilic and lymphocytic infiltrative disorders
Collagen vascular disease

aspiration with lower lobe infiltrates, often without classic symptoms of gastroesophageal reflux,⁵¹ classic rheumatologic symptoms (which would suggest rheumatoid arthritis or vasculitis), and environmental exposures during previous employment or at home (e.g., to humidifiers, hobbies, or pets) as possible etiologic clues. There are few data on the incidence or outcomes of these diseases in elderly patients.

The laboratory findings are often nonspecific, but useful findings may occasionally be elicited. For example, abnormal liver function tests suggest the possibility of metastatic malignancy, and hematuria or impaired renal function suggests Wegner's granulomatosis or Goodpasture's syndrome. The chest radiograph usually shows an increase in interstitial markings and on serial films an associated progressive decrease in lung volume. Diagnostic inferences may be made by correlating pleural changes or adenopathy. The various specific syndromes relating to radiographic findings are beyond the scope of this text; contemporary review articles are available.⁵⁰ High-resolution computerized tomography (CT) of the lung is of considerable value in determining the extent and severity of these interstitial disorders, although, like roentgenograms, it does not give an etiologic diagnosis—that is the job of the clinician. Gallium scans are nonspecific, have serious problems of interobserver variability, and are totally useless in evaluating these entities. Pulmonary function studies, on the other hand, may be clinically helpful in diagnosis and for following the results of therapy, demonstrating classic restrictive changes, that is, a decrease in lung volumes, diffusing capacity, compliance, and, frequently, a low PaO₂.

If diagnosis cannot be achieved on the basis of a careful history, physical examination, and consideration of the patient's overall medical diagnoses, and if it appears that lung biopsy will likely be useful in terms of management, this invasive intervention can be performed. Transbronchial biopsy with a fiberoptic bronchoscope (FOB) may be helpful and is safe in older patients, although the tissue sample size is usually quite limited and the ability to achieve a firm diagnosis is disappointingly small in most series. Open lung biopsy with sampling of several sites gives a higher probability of a definitive diagnosis, although it carries a small (approximately 1%) risk of mortality and a 5% to 10% incidence of complications. In more than 50% of patients, the diagnosis is idiopathic pulmonary fibrosis (IPF), leaving both the patient and physician unsatisfied. Prognosis is related to the specific etiology. IPF, which occurs on average at age 61, has an especially poor prognosis, with a 50% mortality in 2 years.

Therapy is often difficult, disappointing, and limited to supportive measures. Corticosteroids or cytotoxic agent treatments have significant side effects, and if they are used, short therapeutic trials of 3 to 4 months with objective PFT and CT measurements for follow-up and prog-

nosis should be the strategy utilized. Colchicine has been recommended and is safer than steroids or immunosuppression, but long-term results show no difference from untreated patients. Recent data suggest that interferon gamma-1b may provide a better outcome than steroids in patients with IPF.⁵² Advanced patient age, even with a diagnosis of IPF, should not deter physicians from offering nondrug treatments that may improve physical and social functional status and even survival (e.g., pulmonary rehabilitation). Portable oxygen can improve exercise capacity and quality of life in these patients.

Sleep Disordered Breathing

Sleep complaints increase in the elderly, partly because of changes in central nervous system control of breathing during sleep. The sensitivity of brainstem receptors to carbon dioxide and oxygen levels decreases with aging to as much as one-half of the awake response. The resultant reduction in ventilation can combine with an increase in upper airway resistance and lead to rises in the blood levels of carbon dioxide (PaCO₂) and decreases in oxygen (PaO₂) during sleep. These changes all help to explain the increase in sleep disordered breathing that occurs with aging, with increasingly frequent apneic or hypopneic events being more common in older men than women.⁵³ (See Chapter 70 for details.)

Perioperative Care of the Elderly

Pulmonary complications in the postoperative period occur with increased frequency in older as compared to younger patients, especially in those undergoing thoracic or upper abdominal procedures.^{23,54} Proper preoperative evaluation, patient education, and postoperative management will decrease the risk of pulmonary complications such as atelectasis, impaired gas exchange, and infection. The elderly are at higher risk of complications, not because of age, but as a result of decreased pulmonary and cardiovascular reserves associated with aging and an increased number of accompanying comorbidities. Congestive atelectasis is the predominant pulmonary complication seen in the immediate postoperative period. Following thoracic or upper abdominal procedures, it may take to 2 to 3 weeks for pulmonary function capability to return to a baseline. These procedures cause impaired diaphragmatic and intercostal muscle function, and this impairment results in a decreased functional residual capacity (FRC) with an associated increase in residual volume (RV) and a closing capacity (CC), which rises into the tidal volume (TV). This change means that some alveoli remain unventilated throughout the entire respiratory cycle, primarily because

of an increase in lung recoil and decrease in chest wall compliance. In recumbency, the decrease in FRG is approximately 500 mL, or 20% of the awake value, so that bed rest exacerbates this problem.

Postoperative patients generally show a significant restrictive pattern of breathing, with a decrease in forced vital capacity (FVC), TV, FRC, and peak expiratory flow rate. They demonstrate a shallow breathing pattern without the deep breaths that are needed to replete surfactant and prevent atelectasis. The work of breathing is also increased, and cough effectiveness is reduced.²³ Patients with underlying pulmonary disorders and minimal pulmonary reserve due to cigarettes are at particularly high risk of postoperative atelectasis. Thorough preoperative evaluation and patient education will identify these patients and guide postoperative management to reduce complications. A careful history and physical examination with special focus on cardiopulmonary symptoms and findings, smoking history, and functional status is at the center of this endeavor. The use of additional testing is often necessary to clarify the evaluation of pulmonary function and to guide pre- and postoperative treatment.

The routine use of preoperative pulmonary function testing is controversial because many of the frequently cited studies in this area were conducted 20 to 30 years ago when different surgical, anesthetic, and perioperative management practices prevailed. However, patients who are to have abdominal or thoracic surgery, and who have a history of smoking or signs or symptoms of pulmonary disease identified preoperatively, will benefit from spirometry measurements before and after bronchodilators.⁵⁵ The pulmonary function testing assists in making a specific pulmonary diagnosis, assessing the degree of impairment and risk, and identifying appropriate maximal pre- and postoperative therapy. An increase in perioperative complications and mortality is seen in patients with an elevated PaCO₂ (>45), which makes the arterial blood gas measurement an important component of a complete preoperative evaluation of the high-risk patient.⁵⁴ High-risk warning signs include emergency surgery, poor nutritional status, and continued cigarette use.^{23,54} The use of pancuronium during surgery has been associated with a 3.2 increase in relative risk of postoperative pulmonary complications.²³

Preoperative patient education is essential to reduce the risk of postoperative pulmonary complications. The use of incentive spirometry has been shown to decrease atelectasis and other postoperative pulmonary complications and is equivalent to chest physiotherapy.⁵⁶ The use of intermittent positive pressure breathing (IPPB) is much more expensive, has more complications, and offers no advantage over incentive spirometry. The objective of incentive spirometry is to increase the low postoperative FRC. The teaching and implementation of incentive

spirometry preoperatively has been shown to improve its effective use after surgery. Patients should use the device for at least 5 min every waking hour. The preoperative teaching of the effective cough at the end of a deep inspiration is also an important strategy. The high alveolar and airway pressures obtained during the periods of glottic closure are beneficial in clearing secretions and expanding atelectatic portions of the lung. The patient should hold a pillow or other "splint" over the incisional area, take a breath to total lung capacity, hold for 4 to 6 s, then cough repeatedly throughout exhalation, and finish by expectorating the mobilized secretions.

Counseling patients preoperatively to cease smoking is essential. The benefit of stopping smoking can be dramatic in improving overall prognosis. Cigarette smoking is associated with a fourfold increase in postoperative pulmonary complications. Smoking cessation 4 to 8 weeks before surgery is accompanied by a demonstrated decrease in postoperative pulmonary complications, predominantly due to improved tracheobronchial clearance, with a decrease in cough and sputum and an increase in vital capacity and PaO₂.²³ Smoking cessation even the day before surgery theoretically can be beneficial due to a decrease in carboxyhemoglobin concentration (CO-HgB). The half-life of CO-HgB is 6 h, and a decreased level of CO-HgB will improve oxygen delivery to tissues. The patient should be counseled to continue smoking abstinence in the postoperative period and beyond.

Pain control measures in the postoperative period can both cause or prevent postoperative complications. Elderly patients are at very high risk for oversedation and postoperative delirium from narcotic pain medications. The education in and use of patient-controlled analgesia (PCA) is often the best option for pain relief.⁵⁷ When compared with intermittent intramuscular opiate injections in a population of frail elderly in the postoperative period, PCA is easier to use, provides better analgesia, is associated with less frequent pulmonary complications or postoperative confusion, and shows less variability in serum morphine levels.⁵⁷ Avoiding oversedation is critical in preventing a complicated prolonged postoperative course. In the patient with a thoracic or abdominal procedure, proper pain control improves cough effectiveness. The use of epidural anesthesia or intercostal nerve block also can be used to provide effective pain control in the postoperative period.²³

In conclusion, there is a rationale for the routine use of pulmonary function tests and arterial blood gas measurements in the perioperative assessment of elderly patients with a history of smoking or previous pulmonary disease. It is especially crucial in those patients undergoing thoracic or upper abdominal operations. Comprehensive education regarding incentive spirometry, effective coughing, and smoking cessation is critical to

prevent postoperative pulmonary complications. The judicious use of analgesia is likewise of benefit. Recent studies have demonstrated that even the oldest-old (those over 85 years of age) can safely undergo operations.⁵⁸ Thus, age alone should never be a criteria for denying a patient the benefits of surgery.

Critical Care Issues

Elderly persons are more frequently admitted to ICUs than are those in younger cohorts and currently represent 25% to 45% of days of ICU occupancy.⁵⁹ This rate no doubt reflects the generally high rate of hospitalization of elderly and their multiple interacting acute and chronic diseases. Age, per se, is not a reason for exclusion from ICUs, as functional status and comorbidities have been shown to be much more important initial prognostic factors than chronologic age, both for survival and for return to a meaningful life following an ICU stay.²⁴ However, critically ill elderly patients are more likely to develop respiratory failure requiring mechanical ventilation (MV) than are younger individuals; this is due to their decrease in pulmonary reserve, with declines in FEV_{1.0}, and PaO₂, blunted respiratory responses to stimuli such as hypercapnia and hypoxemia, decreased muscle strength and endurance with reduced ability to generate inspiratory and expiratory pressures, a reduced cardiac reserve, and, finally, an increased likelihood of sepsis. Specific management of the elderly while on MV and strategies for “weaning” from support are not covered here, although they are of crucial importance in day-to-day management and have been the focus of several recent reviews.⁶⁰ Specific adverse prognostic factors for recovery and survival in the elderly, some of which are apparent at time of admission for an acute illness, are the following:

- A diagnosis of pneumonia
- A diagnosis of COPD
- Poor prior functional status
- Severity of illness (APACHE III score >30)
- Difficulty maintaining oxygenation (e.g., PaO₂ < 55 mmHg, FIO₂ > 60%)
- Advanced age (greater than 90 years old) plus 24 or more h of ventilation
- Prolonged mechanical ventilation requirements (more than 3 days)

The issue of ICU costs (totaling more than \$60 billion per year in the United States), which are proportionally higher for the elderly, and the relation of these costs to outcomes is a topic under intense study at this time by health economists and physicians.⁶¹ Firm conclusions are hampered by the fact that, although mortality is an easy endpoint to evaluate, quality of life following survival is crucial and much more difficult to evaluate.

Terminal Care: Palliative Care Issues

An especially vexing problem is that of the patient dying of respiratory failure who seemingly cannot be effectively treated, with dyspnea as a devastating symptom. This range includes both patients on mechanical ventilation (MV) in a hospital setting and those patients cared for outside the hospital who are dying of respiratory insufficiency, most often with severe COPD. In counseling such patients and their families, a strategy of open communication is essential, so that after exploration of the patient's life values advance directives can be implemented. This plan is enhanced if there has been a prior physician-patient relationship and is an area where the primary care physician (geriatrician) can provide a crucial service as he or she takes over management from the intensivist staff.

Palliative care of patients who are clearly dying in the end stages of respiratory insufficiency and who have no reversible aspects is a difficult but extremely important undertaking; this can be a gratifying professional experience and of true value for patient, family, and the care team. First, it is important to share the knowledge that death, although unpredictable (due to well-documented physician inability to render accurate prognosis in this situation), is coming soon and that in the absence of a clear acute reversible complication, MV or CPR with prolongation of dying would not be in the best interests of the patient.⁶² Data show that survival, much less a return to a meaningful quality of life, in such situations is nil. At this time, previous advance directives should be reviewed. Most often patients are well aware of their status and are relieved by the knowledge that such frank discussions can be held and that their physician will not abandon them at this time. Palliative care interventions and what to expect and how they will die can then be discussed with emphasis on effective control of dyspnea, cough, mental or physical suffering, and pain. This discussion should focus on support of activities of daily living, symptomatic treatment of infection, and the aggressive use of medical measures for comfort (as in the previous discussion of COPD) to reduce symptoms. These support measures can be arranged at home, as well as in the inpatient hospice setting.

Special attention must be given to help with emotional needs. Depression and panic are common problems at this time, and, in addition to sensitive communication and counseling interventions, patients may respond to serotonin reuptake inhibitors, benzodiazapines, or even low-dose opiates, which can reduce dyspnea without significantly altering respiratory rate or oxygenation. The provision of sleep and a dignified transition should be assured. A détente with death can usually be achieved with supportive discussions and judicious pharmacologic interventions, with the focus concentrated on comfort and symptom control. Frequently, with CO₂ retention,

supplemental oxygen is all that is required for tranquility in the patient who is within hours of dying with severe COPD. Sedation can be achieved with diazepam, lorazepam, or most effectively with an intravenous morphine sulfate drip that can be titrated to control terminal restlessness, *not* for euthanasia, but as an excellent way to provide continuous relief of dyspnea. Intravenous haloperidol is also useful with a rapid onset of action in the dyspneic agitated patient, and it does not suppress respiratory drive. The use of alcohol, or sedatives, if previously utilized by the patient, is appropriate, even if by secondary effect they hasten the moment of death. Cutaneous scopolamine patches may be used to control troublesome secretions.

Management of withdrawal of MV must be done using “best practices” to avoid excess suffering, and guidelines are available.^{63,64} Discontinuation of MV in the ICU in the comatose patient is relatively straightforward. The ventilator is disconnected, 100% oxygen at atmospheric pressure is maintained, and a quiet and peaceful death occurs. The endotracheal tube can be left in place to prevent disturbing upper airway obstructive phenomena (“gurgling,” etc.). Sedatives and anticholinergics for control of secretions can be utilized as needed. In the patient in whom ventilatory support is to be terminated and where mental status is perhaps more a stupor than coma, once all good-byes have been said and the course has been set (most easily done when explicit discussions and advance directives have been previously completed), adequate sedation must be assured. Intravenous opiates with or without an optional benzodiazepine should be instituted until the patient is comfortable and has spontaneous respirations but is clearly fully sedated and comfortable. Muscle relaxants should never be used to give an appearance of comfort. Then and only then should the ventilator be disconnected and 100% oxygen at atmospheric pressure be given. With an endotracheal tube in place, no “struggle” should occur.

The staff should be aware that as many as 10% of patients may survive for up to a day or longer following withdrawal of MV. Frequently it is beneficial for the family to be present at the bedside at this time so that they can be part of the process, which should be similar to a tranquil sleep leading to apnea and death. Colleagues involved in palliative care hospice and critical care programs and hospital ethics committees are useful consultants in all these difficult situations.⁶³

Dermatologic Diseases and Problems

Amy Krupnick Freeman and Marsha Gordon

Structure and Physiology of Aging Skin

Epidermis

Overall, the epidermis thins with advancing age. The stratum corneum loses its basket-weave pattern and becomes thin and compact, providing a less effective barrier. Keratinocytes exhibit some nuclear irregularity, especially in sun-exposed areas. Melanocyte density decreases by 10% to 20% each decade, but the exact decrease varies according to anatomic site. There is loss of cellular immunity with aging, as demonstrated by a nearly 50% decrease in the bone marrow-derived dendritic Langerhans' cells.¹

Dermis

With aging, the dermis loses roughly 20% of its thickness secondary to the loss of proteoglycan as well as collagen. Collagen fibers become more cross-linked. Elastic fibers decrease and fragment, particularly in sun-exposed skin. In addition to decreased cellularity, the dermis becomes less vascular, as demonstrated by the loss of capillary loops. These vascular alterations may lead to pallor and contribute to decreased inflammation, a decreased rate of healing after injury, and delayed clearance of foreign materials.²

Subcutaneous Fat

The underlying subcutaneous fat also undergoes atrophy with age. These changes predispose the elderly to the effects of trauma and cold. The loss of subcutaneous fat in the face contributes to what we interpret as an aged appearance.¹

Appendages

Age-related changes of the hair include most notably loss and graying of the hair. The loss of hair is determined by

both androgenetic and involutional alopecia. The former begins before age 40 and is dependent upon male sex hormones and genetics. It is marked by bitemporal recession and hair loss on the vertex and frontal areas of the scalp in men, and by hair loss just posterior to the frontal rim in women, as the hair changes from thick to fine vellus-like hairs. Involutional alopecia, seen after the age of 40, is a process where there is a decrease in the hair shaft diameter and a decrease in the number of hair units, resulting in diffuse hair thinning. This phenomenon poses a cosmetic issue for some people. Therapy is available for androgenetic alopecia. Topical minoxidil, 2% solution 1.0 mL twice daily, has been shown to significantly increase hair counts. Oral finasteride at a dose of 1 mg daily has also been proven to increase hair counts and improve scalp coverage in men. There is also the option of scalp reduction and hair transplants to restore hair.³

Hair graying, often synonymous with aging, is a hereditary loss of functional melanocytes in the hair bulb. By age 50, roughly half of all body hairs become gray.⁴

Nail plate thickness and linear growth rate also decrease with age. Nails become thinner, more brittle, and may develop longitudinal ridges. This fragility may be improved with the application of lactic acid 12% lotion or a creamy moisturizer massaged daily into unpolished nails.

Sebaceous glands undergo hypertrophy with age, although sebum production decreases with age, partly due to a decline in androgen levels.⁵ Apocrine and eccrine sweat glands decrease in density as they accumulate lipofuscin, an aging pigment of unknown significance. These glandular changes contribute to decreased thermoregulatory abilities, making the elderly person more susceptible to hyperthermia.¹

Changes in Aging Skin from Physical Elements

In addition to the intrinsic process of senescence, there is the extrinsic component of skin aging that results from photodamage, smoking, and diet. The cutaneous changes of chronic ultraviolet (UV) damage manifest as wrinkling, solar lentigines (“liver spots”), telangiectasias, mottled pigmentation, and, most significantly, premalignant and malignant neoplasms.⁵ Therefore, it is very important to take appropriate measures to protect the skin from these environmental effects.

Sun Exposure

Dermatoheliosis

The sun is the most damaging physical element to the skin. The cumulative effects of chronic sun damage on the skin is called dermatoheliosis. Appropriate lifelong use of sunscreens, protective clothing (hats and long-sleeved shirts), and avoiding sunlight between 10 A.M. and 3 P.M. may significantly reduce the cutaneous effects of photoaging. It is now known that both ultraviolet A (320–400 nm) and ultraviolet B (290–320 nm) light are responsible for chronic damage from the sun.⁶ Therefore, the ideal photoprotectant agent shields against both UVB and UVA radiation and has a sun protection factor rating of 15 or more.

The epidermal changes that occur with chronic sun exposure range from benign hyperplasia to epidermal dysplasia and neoplasia. There is thinning of the epidermis with a predominance of atypical keratinocytes. Melanocyte hyperplasia and uneven melanin distribution lead to the blotchy pigmentation characteristic of photodamage. With solar damage, there is deposition of abnormal clumps of elastin within the dermis, called elastosis.² Actinically damaged skin, which is thicker than intrinsically aged skin, has smaller and fewer collagen fibers. Clinically, elastosis leads to wrinkling. Wrinkling is determined by solar damage as well as genetics. Facial movements play a role in those wrinkles formed at the nasolabial fold, forehead, and periorbital areas. Cosmetic treatment of aging skin is discussed in detail at the end of this chapter.

The American Academy of Dermatology consensus conference estimated that most of the UV-induced photoaging occurs within the first 20 years of life.² Thus, early preventive measures play a key role in the defense against solar radiation. By age 70, the number of melanocytes per unit area decreases by 40%. Fair-skinned persons inherently have less photoprotectant melanin pigment, so they are far more susceptible to sun damage than others with greater pigmentation.

Cutis Rhomboidalis Nuchae

This condition is characterized by thickened, furrowed skin that forms a rhomboid pattern at the back of the neck.⁷ It is most often seen in men. Treatment is not necessary, unless it poses an aesthetic problem for the patient.

Nodular Elastoidosis with Cysts and Comedones (Favre–Racouchot Syndrome)

Cysts and comedones develop most commonly at the temporal and periorbital areas in patients with advanced actinic damage. Clinically, they appear as either a blackhead (filled with a greasy blue-black plug) or a whitehead with no apparent opening (miliun).⁷ Like cutis rhomboidalis nuchae, this condition does not require medical intervention, unless it is cosmetically bothersome to the patient.

Colloid Milium

Clinically, colloid milium is an entity in which numerous, translucent papules, approximately 2 mm in diameter, form on the dorsal hands and face. Histologically, the dermis is expanded by discrete lobules of homogeneous, eosinophilic material called colloid, formed after years of overexposure to sunlight.⁷

Senile/Solar Purpura (Bateman’s Purpura)

This term refers to the transient red-purple patches on the forearms and dorsal hands in older persons (Fig. 58.1).⁸ The elastotic dermis does not provide adequate structural support for the blood vessels. Therefore, even minor trauma to the aging skin can cause small vessels to rupture and form purpuric lesions.

Stellate Pseudoscars

These white, atrophic, irregularly shaped scars form after minor trauma.⁸ They are commonly found on the fore-

FIGURE 58.1. Senile purpura on the dorsal hands. (See color plate)

arms. Chronic sun exposure leading to solar purpura and atrophy with subsequent shearing from minor trauma and poor reparative abilities may be responsible for this clinical entity.

Heat

Erythema Ab Igne

Erythema ab igne is a condition caused by chronic exposure to heat.⁹ This problem often occurs in elderly people who warm themselves by a fire, or a space heater, or with a heating blanket. They develop a reticulated brown pigmentation in the heat-exposed areas that may become keratotic and rarely develops into squamous cell carcinoma.

Cold

Cold is also poorly tolerated by older adults. Winter weather causes the aging skin, with less eccrine and sebaceous gland function, to become dry and pruritic. The loss of subcutaneous fat and reduced vascularity makes aging skin more susceptible to frostbite. Thus, extreme weather conditions can be damaging to the elderly.

Inflammatory Dermatoses in Aging Skin

Xerosis and Asteatotic Eczema

Xerosis or dryness is frequently seen in the elderly, particularly during the wintertime with the low humidity of heated rooms.¹⁰ The decrease in eccrine and sebaceous gland function as well as an increase in transepidermal water loss due to impaired barrier function of the stratum corneum all likely play an etiologic role. Xerosis, seen most commonly on the extremities and trunk, is dry, scaly, and oftentimes pruritic. It may progress to asteatotic eczema, which in turn may progress to fissured, cracked, inflamed skin called eczema craquelé (Fig. 58.2).

During the winter months, xerosis can be reduced by limiting the amount of bathing and avoiding hot bath water and soap. The daily use of a topical emollient, preferably an ointment, can further prevent drying of the skin. It may be necessary to use a daily topical application of an alpha-hydroxy acid, such as lactic acid 12% lotion. For inflammatory changes, a low-dose topical corticosteroid ointment, such as 1% to 2.5% hydrocortisone, may be used twice daily, but with caution in thin, aging skin. To control pruritus, a low-dose systemic antihistamine at bedtime may be useful.¹¹

Nummular Eczema

This eczema is characterized by scattered oval patches with scaly erythema and sometimes crusted papulovesi-

FIGURE 58.2. Eczema craquelé, characterized by fissured and inflamed skin, located on bilateral lower extremities. (See color plate)

cles on the trunk and extremities of people with dry skin. Nummular eczema may be treated with emollients and low-dose topical corticosteroids.

Lichen Simplex Chronicus

This is an eczematous eruption that results from chronic scratching or rubbing.¹² Pruritus precedes the scratching, which causes lichenification and further itching, resulting in a perpetual cycle. The lesion is usually a thick plaque with enhanced skin markings, and perhaps erythema and excoriations. It commonly involves the dorsum of the feet and ankles, the back of the neck, and the wrists. Potent topical corticosteroids, menthol-containing preparations, or topical doxepin may be helpful. Lichen simplex chronicus resolves when scratching or rubbing ceases.

Pruritus

Pruritus is a common complaint in the geriatric population, yet remains a challenge for physicians. It may be caused by a primary skin disease, or by an underlying systemic disease, or be idiopathic. First, the clinician should look for a skin condition, such as xerosis, scabies, urticaria, contact dermatitis, dermatitis herpetiformis, or eczema. If a skin disease is not evident, a systemic cause may be present. Systemic disorders include renal failure, liver disease, cancer (especially myeloproliferative disorders), thyrotoxicosis, diabetes, and psychiatric and neurologic disorders. Treatment is aimed at the underlying disease. Oftentimes, there is no apparent etiology for the pruritus and the patient must be treated symptomatically. Emollients and topical antipruritic agents with 0.5% menthol may be helpful. The use of low-dose oral antihistamines and topical corticosteroids can also be useful. Doxepin 5% cream applied every 3 to 4 h has proven to be successful, but should be limited to 8 days of use and to no more than 10% of the body surface.¹¹

Angular Cheilitis

This inflammatory condition is characterized by erythema and fissuring at the corners of the mouth.¹³ It is frequently seen in elderly people who do not have teeth. In this situation, the cheek loses support and the angles of the mouth overlap trapping saliva. As a result, maceration and sometimes secondary *Candida* infections develop. Properly fit dentures and nightly application of petrolatum are measures that can prevent this condition. Topical antifungals can treat the secondary candidal infection and low-dose topical corticosteroids can minimize the inflammation.

Seborrheic Dermatitis

This is an extremely common chronic eczematous condition affecting more than 20% of the geriatric population. It affects the hairy regions of the body, where there is an abundance of sebaceous glands, such as the scalp, eyebrows, nasolabial creases, ears, chest, and intertriginous areas. Clinically, it appears as erythematous patches and plaques with yellowish, greasy scale. The etiology is unclear but is thought to be, in part, caused by an inflammatory reaction against the resident skin yeast, *Pityrosporum ovale*. In light of this, therapy can include a topical antifungal agent, such as ketoconazole 2% cream or shampoo applied to nonhair-bearing areas or the scalp, respectively. There is only symptomatic treatment for this chronic condition. For the scalp, one can use either selenium sulfide, tar-based, or as mentioned before, ketoconazole shampoo, applied twice weekly. In addition to ketoconazole cream, a low-dose topical corticosteroid may be helpful. Seborrheic dermatitis has a wide differential diagnosis that includes atopic dermatitis, candidiasis, dermatophytosis, histiocytosis X, psoriasis vulgaris, rosacea, systemic lupus erythematosus, tinea capitis, tinea versicolor, and vitamin deficiency.¹⁴

Rosacea

Rosacea, also known as "adult acne," tends to occur on the face of those with fair hair and skin. Facial flushing is thought to be one of the causative factors in rosacea, eventually leading to persistent erythema and telangiectasias, which then progress to inflammatory papules, pustules, and nodules. In a minority with long-standing rosacea, the sebaceous glands and connective and vascular tissue of the nose proliferate, causing a bulbous hypertrophy of the nose, called rhinophyma. Rosacea may cause ocular problems such as blepharitis and conjunctivitis. Avoidance of factors that trigger flushing is central to the management of rosacea. These provocative factors include exposure to extreme temperature changes (especially heat), consumption of hot or spicy foods, alcohol (especially red wine), sunlight, and stress. The mainstay of

treatment has been topical metronidazole 0.75% gel twice daily with or without an oral antibiotic, such as erythromycin or a tetracycline. For the rare patient with resistant disease, systemic isotretinoin may be necessary, but its use is limited by side effects. Therapy for telangiectasias and rhinophyma is surgical. New approaches include use of a tunable dye laser for vascular lesions and dermabrasion, excision and skin grafting, scalpel shaving, cryosurgery, electrosurgery, or laser for cases of rhinophyma.¹⁵

Grover's Disease

Grover's disease, also known as transient acantholytic dermatosis, is a self-limited, pruritic, papulovesicular eruption primarily on the central trunk. Its classic presentation is an erythematous, scaling, papular eruption after an extreme environmental stress such as heavy exercise/sweating, excessive sun exposure, or high fever in a middle-aged male, although there are many cases reported in female patients. The characteristic histologic finding is acantholysis, or separation of epidermal cells and formation of an intraepidermal vesicle. Treatment may prove frustrating. However, the disease may resolve spontaneously or with topical corticosteroids. Treatment should also be aimed at avoiding the precipitating factors, such as excessive heat or exercise or extreme environmental stresses such as dryness. Soothing baths, emollients, or topical antipruritics may relieve the pruritus. If the eruption is severely pruritic, persistent, or extensive, systemic therapy may be necessary.¹⁶

Psoriasis

Psoriasis is a condition that most often appears in young adulthood, but increases in prevalence with age.¹⁷ Therefore, it affects a significant proportion of the geriatric population. Psoriasis is an inflammatory rash with increased epidermal proliferation of unclear etiology. Its characteristic lesions are sharply demarcated, oval or round erythematous plaques surmounted by silvery scales, typically located on the scalp and extensor aspects of the elbows and knees. There are four main clinical forms of psoriasis, plaque type being the most common, which include guttate (eruptive), inverse (flexural), erythrodermic, and pustular. Inverse psoriasis is mainly observed in the elderly population. Approximately 7% of psoriatic patients, usually those with severe disease or with nail involvement, develop arthritis. Because there is no cure for psoriasis, the goal of treatment is remission and prevention of recurrence. Topical therapies include coal tar preparations, dithranol, topical corticosteroids, tazarotene, calcipotriol (a vitamin D₃ analogue), and ultraviolet light. Systemic treatment is indicated in those with severe disease or in patients who are resistant to topical agents. The elderly person may be at particular

risk for the adverse side effects of systemic therapy, and therefore it is important to carefully evaluate the risks and benefits in this age group. The various systemic agents are psoralen with long-wave ultraviolet light (PUVA), methotrexate, and etretinate (an oral retinoid), recently replaced by its metabolite acitretin. Cyclosporin is effective, but its use in the elderly is limited by the adverse effects of nephrotoxicity and hypertension. The major concerns with methotrexate are liver toxicity and myelosuppression. The retinoids have numerous side effects, but myalgias, arthralgias, xerosis, and headache are particularly common in older people.

Contact Dermatitis

Contact dermatitis is an inflammatory reaction to either an irritant or allergen. The typical acute lesions are erythematous macules, papules, and vesicles with exudation and crusting. Elderly people may present with milder clinical disease because of depressed inflammatory responses. Instead, older individuals may present with severe itching, associated with mild erythema, scaling, or early hyperpigmentation, and lichenification rather than vesiculation and inflammation.¹⁰ Therefore, contact dermatitis can be a difficult diagnosis. Common causative agents in older persons include neomycin, parabens (a common preservative in medications), lanolin, ethylenediamines, nitrofurazone, and acrylate adhesives in transdermal medications. Plants, nickel, and rubber compounds commonly cause allergic contact dermatitis. The key to treatment is removal of the offending agent. Topical corticosteroids of moderate to high potency and antihistamines are also mainstays of therapy.

Drug Eruptions

Elderly patients are particularly susceptible to drug eruptions because of their numerous comorbidities and the increased likelihood of polypharmacy in this age group. Approximately 2% of medical inpatients have cutaneous drug reactions, and this rate is significantly higher in those receiving eight or more medications.¹⁸ There are myriad clinical presentations including erythematous, lichenoid, eczematous, acneiform, urticarial, bullous, fixed drug, exfoliative, nodular, photosensitive, and purpuric. However, morbilliform (erythematous macules and papules) represents nearly 75% of the eruptions. The penicillins, cephalosporins, and sulfonamides have high reaction rates. Once the offending agent is discontinued, the rash clears within 1 to 2 weeks.

Bullous Pemphigoid

This is the most common blistering disorder in older persons, occurring in the sixth, seventh, and eighth

FIGURE 58.3. Bullous pemphigoid on the upper aspect of the arm. (See color plate)

decades.¹⁰ The bullae are large, tense, and nonscarring and may contain clear or hemorrhagic fluid (Fig. 58.3). They occur on normal or urticarial skin over flexural surfaces of the extremities and abdomen. Approximately one-third of patients may have oral involvement. Diagnosis is made by skin biopsy. The bullae are subepidermal according to light microscopy. Immunofluorescence reveals linear deposits of immunoglobulin G and C3 along the basement membrane.¹⁹ Typically, the disease subsides after months to years, but relapses do occur. Debilitated patients with widespread blistering have died of this condition. Initial therapy is prednisone (0.5–1 mg/kg/day) to suppress blister formation. Steroids should be tapered as soon as clinically feasible. Azathioprine, gold, methotrexate, or cyclophosphamide may be used for their steroid-sparing effects. When prescribing a systemic corticosteroid in an older person, it is important to also start vitamin D and calcium to counteract the adverse side effects of osteoporosis. For mild disease, dapsone or treatment with tetracycline with or without niacinamide may be used. Local care with compresses, topical corticosteroids, and, sometimes, topical antibiotics is helpful.

Pemphigus vulgaris is a blistering disease predominant in middle-aged people. The bullae are flaccid, fragile, and intraepidermal. Therapy consists of systemic corticosteroids and immunosuppressive agents. Untreated pemphigus is fatal.

Anogenital Disease in Aging Skin

Pruritus Ani

This is a common frustrating problem in the elderly population. Fecal soiling and moisture accumulation in the anal region cause irritation, which starts the vicious cycle of itching, rubbing with subsequent development of lichenification, and further pruritus.²⁰ Major causative

factors may be incomplete cleansing after defecation and fecal incontinence. Or, there may be a primary condition as the etiology, such as hemorrhoids, candidiasis, and psoriasis. Treatment always includes education on proper hygiene (cleansing, baths) and, in cases of incontinence, application of barrier preparations. Hydrocortisone cream may alleviate the pruritus.

Senile Vulvar Atrophy

Postmenopausal women frequently experience vulvar atrophy.⁸ Specifically, there is atrophy of the labia majora, labia minora, and clitoris and the vaginal mucosa becomes dry. This condition may be pruritic. A topical emollient or topical estrogen preparation may be very helpful.

Lichen Sclerosus et Atrophicus, Balanitis Xerotica Obliterans

Lichen sclerosus et atrophicus commonly occurs in menopausal women, but can also affect children. Clinically, it appears as ivory-white, well-defined atrophic plaques that often form a “figure-of-eight” arrangement on the vulva and anus.²⁰ Patients may experience pruritus, dyspareunia, or discomfort. There is a waxing and waning course, with roughly 50% of people developing leukoplakia. Squamous cell carcinoma rarely develops, but surveillance for it necessitates follow-up every 12 months. Treatment options include the application of bland emollients and topical corticosteroids for pruritus and inflammation. Topical testosterone, once the mainstay of therapy, has fallen out of favor because of minimal results and masculinizing side effects.

Balanitis xerotica obliterans is the male equivalent.²⁰ The white atrophic lesions occur on the glans and prepuce. Urethral stricture and phimosis may occur.

Angiokeratomas of Fordyce

This entity is characterized by dilated venules that appear as dark red to purple lesions with minimal hyperkeratosis.²¹ These benign lesions are located on the scrotum and are asymptomatic, making removal unnecessary.

Infections in Aging Skin

Herpes Zoster

Herpes zoster (shingles) is a vesicular dermatomal disease caused by the varicella virus (chicken pox).²² (See Chapter 72 for a detailed discussion on herpes zoster.) It can be severe and debilitating in the elderly. After the primary infection, the varicella-zoster virus remains dormant in the dorsal root ganglion. Herpes zoster

develops after reactivation of the latent virus, perhaps precipitated by trauma, radiotherapy, immunosuppression, or stress. People with neoplastic disease and those on immunosuppressive therapy are also at increased risk.

A prodrome of pain and paresthesia precedes the eruption of unilaterally grouped vesicles on an erythematous base (Fig. 58.4). The lesions are situated in a dermatomal distribution. Any dermatome may be involved, but the thoracic and trigeminal nerves are the most common. Disseminated disease is more common in patients with lymphoreticular disease or in immunosuppressed individuals; this can be life threatening. Postherpetic neuralgia is a complication that increases in incidence with age. Elderly people also have increased recurrence of herpes zoster infection.

Diagnosis can quickly be made by demonstration of multinucleated giant cells on Tzanck smear. Analgesics and topical compresses to dry the vesicles are helpful. Secondary infection may be controlled with oral antibiotics that provide staphylococcal and streptococcal coverage.

Ongoing pain after the acute infection has subsided is called postherpetic neuralgia and can be a debilitating condition.²² Topical capsaicin or various oral psychoactive medications for pain have been useful for this condition.

Dermatophytes and Candida

Dermatophyte infection of the toenail plate, called tinea unguium or onychomycosis, is a common disorder, especially in elderly people.²³ The involved nail becomes thick and yellow, with subungual accumulation of debris (Fig. 58.5). Often the nail changes cannot clinically be distinguished from nail dystrophy of aging, psoriasis, or trauma. Onychomycosis is usually associated with tinea pedis and can be diagnosed by demonstration of hyphae on KOH

FIGURE 58.4. Herpes zoster of the back, with grouped vesicles in a dermatomal distribution. (See color plate)

FIGURE 58.5. Onychomycosis of toenails with distal subungual hyperkeratosis and onycholysis. (See color plate)

preparation, histologic preparation of a nail clipping, or fungal culture.²⁴ Oral antifungals are considerably more effective than topical preparations. In the past, a 1- to 2-year course of griseofulvin with monitoring of renal, hepatic, and hematopoietic functions was the treatment of choice. Newer antifungals, including terbinafine or itraconazole, require only 3 months of treatment.²⁵ However, close monitoring of hepatic function and blood counts is still necessary. After successful treatment of onychomycosis, interdigital application of a topical antifungal preparation may be necessary to prevent the recurrence of tinea pedis, from which a future case of onychomycosis may develop. Additionally, it is important to be aware that the interdigital scale of tinea pedis can act as the portal of entry for bacteria, which may lead to cellulitis of the lower extremity.

Older people, particularly those who are obese or bedridden, can develop candidiasis in the moist areas of the groin, axilla, and submammary region. This infection appears as a “beefy-red” rash with satellite papules and pustules. Drying moist areas thoroughly and frequent turning of bedridden patients are important preventive measures. Candidiasis may be treated with topical antifungal agents such as nystatin or ketoconazole cream applied twice a day.

Benign and Malignant Skin Tumors in Aging Skin

Elderly patients frequently develop various benign, premalignant, or malignant skin tumors, which can be of epidermal, melanocytic, or dermal origin.

Seborrheic Keratosis

This extremely common benign epidermal growth may occur anywhere on the body. The keratoses are crusty,

greasy appearing, “pasted-on” papules or plaques that are sharply margined. The color ranges from tan to black, and the occasional dark lesion may require biopsy to distinguish from malignant melanoma. The elderly may develop stucco keratosis, a variant form marked by white, keratotic papules on the extremities. Treatment is not necessary for these benign lesions unless they are cosmetically unacceptable, inflamed, or atypical in appearance.²⁶ Curettage and liquid nitrogen cryosurgery are two simple treatment options. Of note is the rare paraneoplastic sign of Leser–Trelat, which is the rapid increase in size and number of these lesions.²⁷ This development signifies an internal malignancy, usually adenocarcinoma of the gastrointestinal tract.

Skin Tags (Acrochordons)

These are benign, fleshy, pedunculated papules that are frequently acquired in adult life.²⁰ The lesions have a predilection for the axilla, neck, eyelids, and flexural areas. Removal is not necessary but can easily be performed by scissor excision or light electrodesiccation.

Sebaceous Hyperplasia

This benign clinical entity often occurs on the face in the elderly patient.²⁸ It appears as one or multiple, yellowish dome-shaped papules with central umbilication. The lesions range in size from 1 to 3 mm in diameter and may be mistaken for a basal cell carcinoma. Therefore, a biopsy is sometimes necessary. Lesions can be removed with light electrodesiccation.

Cherry Angiomas

These extremely common benign lesions appear as bright-red, dome-shaped vascular lesions. They are principally found on the trunk. They first appear at about age 30 then tend to become more numerous and larger with age. If cosmetically problematic, then electrodesiccation or excision for larger lesions can be used.

Venous Lakes

Venous lakes are dilated venules characterized by a blue to black soft papule. They occur on the face, lips, and ears of people over the age of 50 years. The etiology is unknown but may be secondary to solar exposure. The differential diagnosis includes malignant melanoma and blue nevus. Treatment is cosmetic and can be performed with electrodesiccation or excision.

Spider Veins

This common complaint in older women is often a frustrating cosmetic problem. Spider veins are dilated purple

veins, approximately 1 to 2 mm in diameter, on the lower extremities that result from elevated venous pressure over time. Treatment, called sclerotherapy, involves injection of 23.4% hypertonic saline or an alternative sclerosing agent into the vessel lumen.²⁹

Solar Lentigos (Senile Lentigos)

Solar lentiginos, also called “liver spots” or “age spots,” are commonly seen on sun-exposed areas in Caucasians over 60 years of age.⁶ They appear as uniformly colored tan to dark brown macules that vary in size. Biopsy may be required to distinguish the lesion from lentigo maligna. Treatment is not necessary for these benign lesions, but can be accomplished with liquid nitrogen cryotherapy, trichloroacetic acid, or laser modalities. Additionally, tretinoin cream with 4% hydroquinone cream applied twice daily for 6 to 8 weeks can fade solar lentiginos.

Actinic Keratosis

Actinic, or solar, keratosis is a premalignant lesion caused by exposure to ultraviolet light.³⁰ Therefore, actinic keratoses are most commonly found on sun-exposed areas, such as the face and dorsal hands, in fair-skinned, middle-aged to elderly people. Clinically, the lesions are pink macules or papules with dry adherent scale. They are often more easily felt than seen secondary to their rough nature.

A small percentage of actinic keratoses develop into squamous cell carcinoma, necessitating removal of these lesions.³¹ With fewer lesions, options of removal are cryosurgery, curettage, or application of 30% to 50% trichloroacetic acid. Topical 5-fluorouracil cream (efudex) applied twice daily for 3 to 6 weeks is an effective means of treating multiple lesions. This antimitabolite selectively destroys the pathologic cell, leaving normal skin relatively unharmed, but may cause much discomfort and inflammation. Once therapy is stopped, the inflamed skin resolves. In cases where large areas are involved, dermabrasion or chemical peeling may be useful.³² Prevention by avoidance of excessive sun exposure is the best approach.

Bowen's Disease

Bowen's disease, or squamous cell carcinoma in situ, is an intraepidermal tumor.⁶ It is differentiated from actinic keratoses in that it is not found on sun-exposed skin.³³ The lesion of Bowen's disease is a slowly enlarging, sharply defined erythematous plaque with scale, which may be clinically confused with psoriasis or eczema. Biopsy will differentiate these entities. Electrodesiccation and curettage, cryosurgery, excision, ionizing radia-

tion, and Mohs' surgery can all be used to remove the lesion. Close follow-up is essential.

When this lesion occurs on the glans penis in uncircumcised men, it appears as a red, moist, or velvety, well-circumscribed oval to round patch and is known as erythroplasia of Queyrat.²⁰ This entity is histologically identical to Bowen's disease, but metastasizes more frequently. Therefore, it is important to identify these lesions immediately so treatment can be initiated.

Squamous Cell Carcinoma

Squamous cell carcinoma often appears on sun-exposed areas in fair-skinned patients.³⁴ It may arise from an actinic keratosis or de novo. Clinically, the lesion is an erythematous, scaly nodule that may become ulcerated, crusted, or verrucous as it enlarges (Fig. 58.6). Squamous cell carcinoma arising in sun-damaged skin rarely metastasizes and is typically only locally destructive. Lesions arising on mucous membranes, however, such as the lip, vulva, or penis, or lesions arising from a chronic skin ulcer, all have a greater tendency to metastasize. Complete eradication of the lesion can be accomplished with excision or Mohs' surgery. Other treatment modalities are curettage and electrodesiccation, useful in early lesions, and ionizing radiation, useful in older people.

Keratoacanthoma

Keratoacanthoma is a rapidly growing, benign tumor that clinically and histologically resembles squamous cell carcinoma.³⁵ It commonly occurs in older light-skinned individuals on sun-exposed, hair-bearing sites. Clinically, the lesion is a solitary, firm, dome-shaped nodule with a central keratinous plug. It may suddenly grow over 4 to 6 weeks, stabilize, and then regress, leaving a scar. Surgical excision or curettage with electrodesiccation are the

FIGURE 58.6. Squamous cell carcinoma of the scalp with thick keratotic scale. (See color plate)

FIGURE 58.7. Basal cell carcinoma, appearing as a nodule with irregular borders and a scarlike quality. (See color plate)

best treatment modalities, as they allow for histologic confirmation of diagnosis.

Basal Cell Carcinoma

Basal cell carcinoma is the most common malignant tumor.³⁶ Chronic exposure to UV light is strongly associated with these slow-growing lesions on sun-exposed areas of older, fair-skinned individuals. Metastasis is extremely rare, but basal cell cancers may become very large and be locally destructive.

There are several clinical presentations of basal cell carcinoma ranging from nodular to flat in nature. The most common is the nodular ulcerative type, characterized by a pearly, translucent papule or nodule with a central depression, rolled borders, and telangiectasias. These lesions may ulcerate, become crusted, or bleed (Fig. 58.7). Superficial basal cell carcinoma usually appears on the trunk and is characterized by a slowly growing, erythematous slightly scaling plaque. It may be clinically similar to a patch of eczema. Sclerosing basal cell carcinoma has a flat scarlike quality and often has a poorly defined border. Pigmented basal cell carcinomas contain brown pigment and may be clinically indistinguishable from melanomas. In all types, histologic examination confirms the diagnosis.

Treatment options include curettage and electrodesiccation (usually reserved for small lesions and nonsclerosing basal cell carcinomas) or excision with a possible skin graft or flap in large lesions. Ionizing radiation may be used in elderly patients. However, in middle-aged or younger patients, concerns about future radiation dermatitis severely limits its use. Mohs' surgery, a microscopically controlled technique in which a lesion's perimeter is histologically examined to ensure tumor-free margins, has the highest cure rate.³⁷ It is employed when treating lesions that abut a functional structure such as the eye, or in lesions from areas with high risk of recur-

rence, such as the nasolabial fold near the nose. It is also the treatment of choice for recurrent basal cell carcinoma and for very large lesions. Evolving therapies include intralesional injection of interferon and prophylactic oral retinoid therapy. Long-term follow-up is necessary because of the possibility of recurrence and the high risk for developing new lesions.³⁸

Lentigo Maligna and Lentigo Maligna Melanoma

Lentigo maligna is a slowly enlarging pigmented macular lesion found on sun-exposed skin in older people.³⁹ It can reach a size of several centimeters. There is often variation in color within the same lesion. Lentigo maligna is a form of melanoma in situ. It may have a horizontal growth phase of many years before dermal invasion, at which time it is called lentigo maligna melanoma. In fact, many elderly patients succumb to other conditions before lentigo maligna transforms into lentigo maligna melanoma. However, because of the concern of invasion, treatment is complete surgical excision.

The A, B, C, D, Es of melanoma recognition are valuable for clinicians and for patient education: Asymmetry, Border irregularities, Color variegation, Diameter greater than 6 mm, Enlargement (Fig. 58.8). Excisional biopsy is the diagnostic procedure of choice for clinically suspicious lesions. It is important to completely excise the lesion, providing a full-thickness specimen extending to the subcutaneous fat, as tumor thickness, measured from the granular layer of the epidermis to the deepest area of involvement, determines prognosis of the disease.^{40,41} Accurate staging involves complete examination of the skin, lymph nodes, liver, and spleen, along with a review of systems. Surgical excision is the treatment of choice for melanoma. Current recommendations are based on the histologic depth of the melanoma and no longer rely on the principle of "deep and wide" excisions that predominated in previous years. For

FIGURE 58.8. Malignant melanoma with characteristic features. (See color plate)

in situ melanomas, a margin of 0.5 cm of normal skin is recommended and, for melanomas less than 1 mm thick, a margin of 1 cm is accepted. The benefit of lymph node dissection remains controversial.⁴² Patients with lesions greater than 4 mm thick are at high risk for metastatic disease. Interferon alpha-2b has been approved for the treatment of metastatic melanoma.⁴³ Chemotherapy and radiation therapy are, unfortunately, of minimal help in most cases of melanoma, as most melanomas are relatively resistant to these modalities. Vaccines and gene therapies are experimental treatment options.^{44,45} Of course, reducing risk by using a broad-spectrum sunscreen with both UVA and UVB coverage of at least spf 15, wearing sun-protecting clothing, and avoiding midday sun is strongly recommended.

Paget's Disease

Paget's disease is an intraepidermal carcinoma of glandular origin with two forms, mammary⁴⁶ and extramammary.⁴⁷ In mammary Paget's disease, the carcinoma involves the nipple and areola, stimulating a sharply marginated, eczematous plaque. It is associated with underlying intraductal carcinoma of the breast. Management consists of surgery, radiotherapy, or chemotherapy. Extramammary Paget's disease, clinically and histologically similar to Paget's disease of the breast, involves the anogenital and axillary skin. It is often associated with an underlying adenocarcinoma of the secretory glands, lower gastrointestinal, urinary, or female genital tracts. Treatment involves surgical excision and examination for a possible underlying malignancy. Paget's disease clinically resembles eczema, so any treatment-resistant dermatitis should be biopsied.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is a malignant, vascular tumor characterized by purple macules, papules, or nodule, usually on the lower legs.⁴⁸ This malignancy is typically seen in three settings. Classic Kaposi's occurs in elderly men of Eastern European or Jewish descent and progresses very slowly; or, it is an endemic disease in Africa, presenting as an aggressive lymphadenopathic tumor that is often fatal; and last, Kaposi's sarcoma is found in association with the acquired immunodeficiency syndrome (AIDS), particularly in homosexual patients. It is more extensive and has a poorer prognosis in these individuals than in the elderly. Approximately 95% of KS lesions have been found to be infected with Kaposi's sarcoma-associated herpesvirus (also known as human herpesvirus 8). Therapy often depends on the extent and form of the disease. Kaposi's sarcoma may respond to radiotherapy or chemotherapy, such as vinblastine. Palliative destruction of individual lesions by cryosurgery or excision may also be helpful.

Angiosarcoma

Angiosarcoma is a rare, aggressive vascular tumor that occurs typically on the head of the elderly. It appears as reddish-purple nodules or plaques that are asymptomatic. Because the lesions often metastasize early, treatment is usually unsuccessful.

Cutaneous Metastases

Metastatic cancer to the skin is characterized by solitary or multiple hard nodules, often intradermal.²⁰ Approximately 4% of internal malignancies eventually spread to the skin by hematogenous, lymphatic, or direct extension. The most common sites of primary tumor are breast, lung, gastrointestinal tract, and kidney. The average survival after detection of cutaneous metastases is only 3 months, with the exception of breast cancer. The lesions may be treated with excision or systemic therapy.

Ulcerations in Aging Skin

Further discussion of these conditions can be found in Chapter 66.

Stasis Dermatitis and Venous Ulceration

Stasis dermatitis is caused by elevated venous pressures secondary to either valvular incompetence or obstruction.¹⁰ It is an eczematous eruption of the lower extremities with brown hemosiderin-derived pigmentation and, sometimes, petechiae, often preceded by edema and swelling. The predominant site of involvement is the medial malleolus. Predisposing factors include a history of thrombophlebitis, a positive family history, obesity, or multiple pregnancies. Low-dose topical corticosteroids and reduction of edema, by such measures as leg elevation and compression stockings, are the mainstays of treatment.⁴⁹

The most common cause of ulcerations in older people is venous ulcers, which may arise spontaneously or from a superficial injury in the setting of chronic venous insufficiency. The ulcer is usually surrounded by brown-red pigmentation, located at the medial malleolus, and has irregular borders. There may be surrounding edema and pigmentation. Cellulitis may complicate venous ulcers. Ulcerations often recur unless the underlying risk factors are corrected. Leg elevation and use of elastic support stockings can alleviate the venous hypertension.^{50,51} Dressings can facilitate healing by maintaining a moist environment that promotes reepithelialization.⁵² Options include wet or dry nonadherent dressings, occlusive dressings (such as OpSite and DuoDerm), or zinc paste-impregnated bandages (known as the Unna boot). An

associated eczematous dermatitis can be treated with moist compresses, if needed, and corticosteroid ointment. If a secondary bacterial infection develops, a systemic antibiotic may be used.

Arterial Ulceration

Arterial ulcers are caused by atherosclerosis-induced ischemia of the skin.⁵³ Arterial ulcers are clinically different from venous ulcers. These lesions are gray-black, sharply demarcated ulcers, located at the pretibial area or on the toes. The ulcer is often painful and is associated with other ischemic findings, such as loss of hair and cold, atrophic skin. Pulses may be diminished or absent. Control or elimination of risk factors, such as smoking, hypertension, diabetes, obesity, and high cholesterol, are important in management. Local therapy includes moist saline dressings, changed frequently, although healing is slow. Analgesics for pain may be necessary.

Diabetic Ulceration

Leg ulcers in diabetics are multifactorial, resulting from complications of small and large vessel disease and neuropathy.⁴⁹ Diabetes mellitus causes proliferation of endothelial cells and thickening of the basement membrane in small vessels, which leads to decreased blood flow through the vessel lumen. Furthermore, patients with diabetes are at increased risk for atherosclerosis of medium- and large-sized vessels. Therefore, arterial ulcerations commonly develop in these patients.

Long-standing diabetes can also cause peripheral and autonomic neuropathy. Patients eventually lose sensation in their feet and, as a result, cannot perceive trauma, pressure, or chronic friction. Mal perforans refers to the neurotrophic ulcer that develops in these patients. The diabetic foot is typically numb, warm, and dry. The ulcer is gray to black, surrounded by hyperkeratotic skin, and located at points of pressure or trauma, such as the heel, sole, metatarsal head, and great toe. These ulcers may evolve into cellulitis, osteomyelitis, or gangrene, which requires amputation. This diabetic complication can be prevented by daily inspection of the feet for early signs of trauma, properly fitted shoes, and avoidance of trauma and going barefoot. Surrounding callus may need debridement, and associated infections may require antibiotic therapy. Also see Chapter 66 for further detail on this condition.

Nutritional Deficiencies and Aging Skin

Many elderly people, particularly those who live alone, have a fixed income, or suffer from chronic disease, suffer from malnutrition.⁵⁴ The skin is a rapidly dividing tissue

and, therefore, is particularly sensitive to nutritional deficiencies. Skin desquamation and alopecia often result from malnutrition. Certain vitamin deficiencies are marked by specific cutaneous changes. Vitamin A deficiency leads to generalized scaling with hyperkeratosis and dry eyes. Pellagra (vitamin B complex deficiency) causes cheilitis and dermatitis. Patients who lack vitamin C suffer from perifollicular hemorrhage with coiled hairs, impaired wound healing, and swollen, bleeding gums (scurvy).

Cosmetic Treatment of Aging Skin

With society's emphasis on physical appearance, elderly people are becoming increasingly interested in cosmetic options to improve aging skin. When elderly patients feel physically attractive, their mental well-being also improves. Therefore, it is important to provide options for these patients seeking advice on the use of cosmetics for wrinkling, mottled pigmentation, or rough skin.

Tretinoin (all-*trans* retinoic acid) is a topical cream effective in improving fine wrinkling, rough skin, hyperpigmentation, and lentigines, when used daily.⁵⁵ A pea-sized drop should be applied nightly to clean, dry skin approximately 20 to 30 min after washing the face. In the morning, the face should be washed and a broad-spectrum sunscreen (blocking UVA and UVB) should be applied, as well as a moisturizer, if needed. Side effects include redness, scaling, burning, and irritation; these often improve with time or with a reduction in dosing strength or frequency. The alpha-hydroxy acids, especially glycolic acid, have recently been used to improve sun-damaged skin and wrinkling.⁵⁶ Lower concentrations in a cream or lotion formulation (5%–10%) can be used twice daily at home, alternating with use of higher concentrations applied as a peel. The latter is typically used at the physician's office, or now in beauty salons, at a concentration up to 70% for 2 to 6 min every 1 to 6 weeks. Each of the topical approaches exfoliates the skin and, therefore, may cause irritation in sensitive individuals. With patience, however, a regimen can be found for nearly everyone.

In cases of more severe sun damage, other procedures have been used. Injections of augmenting agents into the nasolabial fold, perioral, chin areas, and, less often, the forehead, may improve wrinkles. Several materials such as collagen, hyaluronic acid, and silicone have been used, but at the present time, collagen is a popular choice. These injections, which place collagen into the dermis underneath a wrinkle, plump up the depressed furrow of the wrinkle and therefore smooth the appearance of the skin. Several products and formulations are available. The choice of material used is dictated by the location and depth of the wrinkle, as well as by the experience of the

physician. The effects are temporary, and patients often require touch-up injections every 3 to 6 months. Chemical peels, using either trichloroacetic acid or phenol, dermabrasion, and laser resurfacing have been used to treat wrinkles and lentigines. In experienced hands, trichloroacetic acid is a safe way to induce a medium-depth peel that may decrease the appearance of some wrinkles and even out skin tone. It is important to note that even a relatively safe peeling material such as 30% trichloroacetic acid may cause scarring as well as other complications. Therefore, it should be used only by experienced physicians. Phenol penetrates deeper, but it can cause hypopigmentation and cardiac arrhythmias, necessitating cardiac monitoring. An infrequent side effect of dermabrasion may be hypertrophic scarring. Laser may leave persistent erythema and, rarely, scarring. Botulinum A exotoxin has also been used to minimize those lines and wrinkles caused by muscular movement (i.e., "kinetic" wrinkles).⁵⁷ It is safest and most effective on crow's feet and glabellar and forehead lines. The toxin produces reversible paralysis of striated muscle. A facelift and eye surgery are other options for improving wrinkles and sagging skin.

Changes and Diseases of the Aging Eye

Bruce P. Rosenthal

The eye is a complex dynamic structure that undergoes physiologic and functional changes as well as significant pathological changes with age. In addition, vision may be affected by systemic conditions that are more prevalent after the age of 50, such as hypertension and diabetes. Visual performance, however, is not limited only to changes in the eye itself but may also be affected by changes to the surrounding structures, such as the eyelids, orbit, and internal and external muscles, as well as the visual pathways.¹⁻⁶

There are other common functional as well as physiologic changes that take place in the aging visual system, including a decrease in visual acuity, accommodation, visual field, contrast sensitivity function, color vision, and recovery from a glare source. Bullimore et al.⁷ found that the functional losses may ultimately affect the most basic of activities of daily living, including reading, and driving performance, as well as the ability to recognize faces.

Ginsberg⁸ and Ginsberg et al.⁹ found that contrast sensitivity function (CSF) is one of the most important measures of functional visual performance. Rubin et al.¹⁰ found that contrast sensitivity function decreases from the early sixties to the nineties. It is especially important in the detection of changes of aging and ocular pathology in the visual system. Contrast sensitivity function is the eye's ability to detect the whiteness to the blackness of a target or the blackness to the whiteness of a target. Contrast sensitivity testing gives some indication of how a person sees under nonideal conditions and may give a more realistic indication of how a person sees. Rubin¹¹ also found that glare sensitivity and recovery from a bright light source are changes that may take place in the visual system with age. Glare recovery is a measure of the speed with which the visual system regains function following exposure to bright light.

Prevalence Studies

The Lighthouse National Survey on Vision Loss¹² revealed that the prevalence of vision impairment substantially increases with age. In fact, 15% of Americans aged 45 to 64 years (representing 7.2 million persons) self-report some form of vision impairment. This number increases to 17% of Americans aged 65 to 74 years and older (representing 3.1 million persons) and to 26% of Americans (3.5 million persons) aged 75 years and older.

Moderate and significant vision impairment can result in an inability to continue to perform activities of daily living (ADLs), such as reading, driving, watching television, or writing a check.^{13,14} Horowitz and Reinhardt¹⁵ and Kleinschmidt et al.¹⁶ found that this could result in a loss of independence and social integration, as well as depression.

Demographics, Epidemiology, and Risk Factors

Definitions related to vision loss are important in a discussion on the demographics and epidemiology of the aging eye. Colenbrander¹⁷ and Bailey¹⁸ have categorized vision impairment as a condition that encompasses the continuum from near-normal vision with a slight deficit in the visual acuity or visual field to low vision with significantly reduced vision to profound vision loss and blindness (no light perception). About 7 million, or 21% of persons age 65 and over, report some form of visual impairment. This number will dramatically increase to 8.3 million in the year 2010, 11.2 million in 2020, and 15 million in 2030.¹⁹ Blindness is defined as no usable vision with the exception of light perception. It is estimated by

the American Foundation for the Blind that there are about 220,000 persons nationally in this category.²⁰ Only 1% of the functionally blind population at Lighthouse International are from the 45 to 64 age group; 5% are from the 65 to 84 age group and 0.6% are from the 85-plus age group.²¹

Legal blindness is another term that is important to define in determining disability, state, and social security benefits. Legal blindness is defined as a visual acuity of 20/200 or less in the better eye or a visual field of 20° or less in the better eye in the widest meridian.²² Approximately 1.1 million Americans were in this category in 1992.²³

Ocular Anatomy and Surrounding Structures

The eye and its surrounding structures are unique, often dependent structures that work in concert for optimum visual performance. The major anatomic ocular structures include (anterior to posterior in the eye) the eyelids, eyelashes, the cornea and its overriding tear film, conjunctiva, sclera, aqueous fluid, the canal of Schlemm and the trabecular meshwork (the aqueous fluid drainage complex), pupil, the lens and the zonules of Zinn (supporting “wires” for the lens), ciliary body, vitreous, retina, choroid, and optic nerve.²⁴

The photons of light energy entering the eye are converted into chemical energy when the image falls on the retina. This image is then transferred via the optic nerve of the right and the left eye to the brain. Some of the fibers from the optic nerve of the right and the left eye cross over to the other side of the brain at the optic chiasm while some fibers remain uncrossed. Some of the visual information from the right nasal visual field is transmitted to the left visual cortex and some left nasal visual field information is transmitted to the right visual cortex. The visual information is processed and integrated in the brain with sensations such as form, texture, size, and taste. A cerebral vascular accident, however, may disrupt transmission and result in the loss of vision on one side (hemianopia) as well as visual neglect contralateral to the involved side.

In addition, two internal muscles and six external muscles are associated with each eye. The internal muscles, known as the dilator and constrictor, control the pupil's ability to constrict or dilate in response to ambient light. The six external muscles associated with each eye include the superior, inferior, internal, and external recti as well as the superior and inferior obliques. These muscles enable the eyes to work as a yoked “binocular” team for horizontal, vertical, and oblique movements as well as enable the eyes to converge to a point focus when reading.²⁵

Sites of Care

Eyelids

The lids, which are not only protective in nature but also help to spread the tear film and prevent desiccation of the cornea, are predisposed to aging changes. They thin out with age, while the dermis²⁶ becomes dehydrated and loses its vascularity. The loss in tonicity is often associated with a condition such as myasthenia gravis²⁷ and results in a lid droop (ptosis) that may obscure the pupil. Non-surgical prosthesis, such as the ptosis crutch, which holds up the drooping lid, as well as surgical techniques may be indicated if the pupillary aperture is either partially or fully obscured.^{28,29}

Dermatochalasis is another condition that may occur normally with aging. This condition is characterized by thin, loose redundant skin of the eyelids that may be severe enough to restrict peripheral vision.³⁰

Another normal consequence of aging is ectropion or eversion of the lower lid. The eyelids lose tonicity and droop, which may result in exposure of the protective inner lining of the eyelids, the conjunctiva. Ectropion results not only in chronic conjunctival inflammation but in a thickening of the lid margins, excess tearing (epiphora), exposure keratitis (inflammation of the cornea),³¹ and chronic dry eye. The latter is caused by the inability of the tears to reach the drainage canal of the lid (puncta).

Entropion, which is an involution of the eyelid (it may also be cicatricial or paralytic, i.e., cranial nerve VII palsy),³² may result in the eyelashes rubbing up against and scratching the delicate epidermis of the cornea. Epilation (removal of the eyelashes) or surgical intervention may be required if the condition persists.

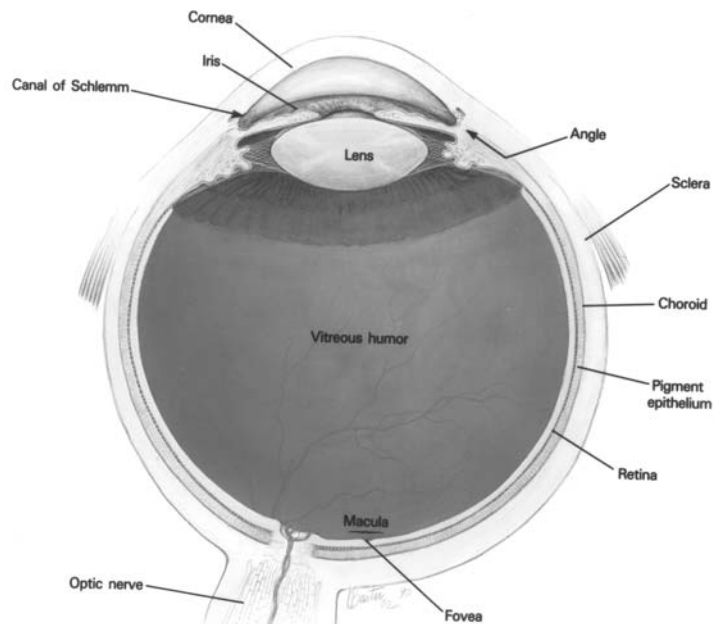

The eyelids may also be the sites of neoplasms, such as the most common malignant eyelid tumor, basal cell carcinoma, as well as squamous cell carcinoma.³³

Tear Layer

The layer of tears produced by the lacrimal glands protects the cornea, as well as the inner surface of the lids, to keep them from drying out. DeRoethth,³⁴ Paschides et al.,³⁵ and others found that tear production begins to decrease markedly after age 40. By age 50, an individual produces half the tears produced at age 20 and by age 80 this is reduced to one-quarter in males and females. This decreased supply of tears may cause erosion of the cornea, dry spots, neovascularization, and scarring. Tear production is also decreased in the meibomian and goblet cells (contributors to the makeup of the tears); this may result in a thinning of the tear film that, in turn, reduces the stability of the tear layer.³⁶

Talal³⁷ and Preston and Buchanan³⁸ have also found that systemic conditions, such as rheumatoid arthritis and

FIGURE 59.1. Cross section of the eye. (Courtesy of the National Eye Institute.)

Sjögren's syndrome (over 90% are women, with the age of onset between 40 and 60) may also affect the supply of the tears to the eyes.

Conjunctiva

The conjunctiva is a transparent mucous membrane that overlies the sclera and lines the inside of the eyelids. It protects the eye from infection and injury. The conjunctiva is subject to infectious, allergic, metabolic, degenerative, vascular, and neoplastic changes in the elderly.

Cornea

The cornea is a multilayered transparent window of the eye that is composed of five distinct layers. It is one of the two major refracting structures of the eye (the other being the lens) that enable light to reach the retina. It is affected by pathologic and degenerative changes, becomes yellower with age, loses some of its transparency, and becomes more astigmatic in shape³⁹ (Fig. 59.1).

Corneal disease, in the elderly, may be the result of infections, metabolic changes, viruses, fungi, a decrease in the tear film, trigeminal nerve involvement, degenerations, and neoplasms.

Fuch's dystrophy is one of the common corneal conditions associated with aging and is found after the fifth decade. Kachmer et al.⁴⁰ have described it as an autosomal dominant disease that is 2.5 times more prevalent in women.⁴¹ The condition, which may result in severe pain as well as a loss in transparency of the cornea, may be medically managed. However, transplantation of the

cornea may be necessary to restore vision as well as to relieve pain.

Dry eye may also contribute to the changes in the integrity of the corneal structure. If left untreated, dry eye can result in severe visual disability. Remedies include insertion of small plugs (inserted into the drainage canal on the lid, the puncta) to increase tear supply, as well as supplementation with artificial tears.

Aqueous Fluid, Canal of Schlemm, and Glaucoma

The aqueous fluid, which is produced by the ciliary body, helps to maintain the intraocular pressure of the eye and is eventually drained through a structure known as Schlemm's canal and into the venous system.

Any change in the outflow of aqueous through Schlemm's canal can result in an elevation of the intraocular eye pressure. This elevation in pressure, known as glaucoma, in turn can result in damage to the optic nerve as well as the retina.

Glaucoma

Glaucoma is a group of diseases rather than a simple disease. It is generally classified into open- and closed-angle types. It is estimated that between 2 and 4 million people 40 and older have glaucoma.^{42,43} The Baltimore Eye Study and the Barbados Eye study revealed an incidence of glaucoma of 6% in the African-American population and persons of West African ancestry in the Caribbean region.^{44,45} Kahn and Milton⁴⁶ found a preva-

lence of glaucoma in 1.2% to 2% of the Caucasian population in the Framingham Eye Study.

Quigley and Vitale^{47,48} estimated, from glaucoma prevalence studies, that there would be 2.43 million cases of open-angle glaucoma in the year 2000 in the United States and 67 million cases worldwide. There are no comparable statistics for closed angle.

There is no agreement that changes in the anterior chamber structures of the aging eye, including the trabecular meshwork and Schlemm's canal, are associated with glaucoma.⁴⁹ Grierson and Calthorpe,⁵⁰ however, believe that a change in resistance to outflow appears to be a primary causative agent in glaucoma that is associated with the normal aging changes. The aging changes include a loss of cells, increase in pigment in the endothelial cells of the trabecular meshwork, increase in thickening of the meshwork, and deposition of plaque in key areas⁵¹ (Fig. 59.2).

The diagnosis of glaucoma⁵² is generally made on the basis of elevated intraocular pressure, changes in the visual field, changes in the appearance of the optic nerve and optic disk, changes in the nerve fiber layer, and family history.

The symptoms of glaucoma, may include halos around lights, difficulty with mobility, difficulty in seeing under low levels of illumination, and difficulty with contrast. Glaucoma, if left untreated, will result in significant changes in the ganglion cell layer of the retina, optic nerve, and visual field.

Tonometry, the measurement of eye pressure, has traditionally been one of the tests to diagnose as well as manage glaucoma. However, damage may take place in the optic nerve even with "normal" eye pressures for that individual. Visual field testing (perimetry) is another measure used to determine the extent of vision loss in

glaucoma. The newer types of automated perimeters help to precisely measure the damage of the visual field in decibels and are very analogous to a hearing test; this technique will enable the examiner to measure the effect of the various treatments used to preserve the remaining visual field.

The diagnosis and evaluation of the optic nerve head has changed dramatically with the introduction of retinal color photography, automated stereoscopic evaluation, digital optic nerve head analysis, scanning laser ophthalmoscopes, and nerve fiber layer analyzers.

Traditional treatment for glaucoma has included the instillation of eyedrops as well as surgery. However, there are numerous new medications that work on different mechanisms in the eye to reduce the eye pressure. Some beta-blockers are used to inhibit production by blocking beta receptors in the ciliary body. There are also carbonic anhydrase inhibitors that similarly reduce the production of aqueous, whereas epinephrine reduces aqueous production and to a less extent increases outflow of the fluid. In addition, there are adrenergic agonists, pilocarpine, and prostaglandin analogues that also increase aqueous outflow. Unfortunately, laser surgery or other filtering procedures may be indicated if damage continues.

Pupil

The pupil is basically an opening in the iris through which the aqueous fluid flows. Its size may vary in response to light, medication, emotional states, disease, or trauma as well as surgical procedures. The pupil functions in much the same manner as a diaphragm in a camera. It dilates under conditions of dim illumination and constricts when the illumination is increased.

Lowenfeld⁵³ found that the pupillary aperture decreases by about 2.5mm between the age of 20 and 80 due to the loss in muscle tonus. This resultant decrease in the ambient light reaching the photosensitive layer, the retina, in turn may affect mobility as well as reading performance.⁵⁴

Morgan⁵⁵ found that the pupillary response to ambient light diminishes with age and results in a smaller pupillary diameter. He found that the pupillary diameter diminishes from about 6 to 7mm in the 20-year-old to 4mm and less in the 75-year-old person.

Lens: Normal Aging Changes

The lens is commonly known as the crystalline lens, because of its impressive regularity, precise organization, and clarity in the early years of life.⁵⁶ It is avascular (no blood vessels) and is biconvex in shape. Positioned just behind the pupillary aperture, the lens is supported in place by tiny "guy wires" known as the zonules of Zinn.

FIGURE 59.2. Aqueous outflow. (Courtesy of the National Eye Institute.)

Its construction is very similar to that of an onion or peach pit, having a cortex, nucleus, and capsule.

Weale⁵⁷ found that aging changes affect the transmission of light through the lens in the visible and the ultraviolet regions of the spectrum. In addition, there is a yellowing of the crystalline lens due to the slow growth of the lens throughout life. These factors result in a significant decrease of light reaching the retina with advancing age. In fact, Weale⁵⁸ found that only one-third of the amount of light reaches the retina of a 60-year-old compared to the retina of a 20-year-old.

Lens: Presbyopia

The most common of these “normal” aging changes, known as presbyopia, begins in the fourth decade. Beers and van der Hiejde,⁵⁹ Hamasaki et al.,⁶⁰ Ramsdale and Charman,⁶¹ and Wagstaff⁶² defined presbyopia as a natural age-related condition that is the result of a gradual decrease in accommodative amplitude, from about 15 diopters (D) in early childhood to 1D before the age of 60 years.

Presbyopia is basically the inability to focus clearly on close objects or to see print clearly. The lens, which is a flexible structure that can change its shape into a more or less convex structure, begins to lose its elasticity in the third and fourth decade. Reading is not generally affected, however, until the early or mid-forties.

Pointer,⁶³ Patorgis,⁶⁴ and Jain et al.⁶⁵ found that the major risk factors for presbyopia are age, short stature, the occurrence of certain systemic diseases such as diabetes and cardiovascular disease, medications, trauma, hyperopia (farsightedness), and side effects of drugs. However, there are still major unanswered questions on the influence of genetics, caloric intake, hypertension, ethnic and racial factors, and environmental influences.

There has been a paradigm shift in the treatment for most eye conditions. Presbyopia was traditionally treated with reading lenses, contact lenses, bifocals, or trifocals. The latest optical designs include bifocal contact lenses as well as optical systems that allow the viewer to see simultaneously at distance and near. One of the more recent changes in the treatment of presbyopia, known as monovision, involves correction of the dominant eye for distance vision. Patients may either wear a contact lens or, more recently, have corrective surgery on the cornea to correct for near vision, which is done by inserting an intraocular lens (lens placed in the eye) to correct for close vision. One of the newest surgical advances includes a foldable silicone multifocal intraocular lens that allows the viewer to see more clearly at different distances.

The future will see intraocular lenses that will eventually be able to focus and reproduce the same effect as the normal lens does before the age of 40, as well as surgical procedures to reverse the effect of presbyopia.⁶⁶

Lens: Cataracts

Leske, in The National Health and Nutritional Examination Survey (NHANES),⁶⁷ Taylor et al. in the Waterman Eye Study,⁶⁸ and Klein et al. in the Framingham Study⁶⁹ showed that there is also a significant increase in the prevalence of cataract with age. Podgor et al. showed, in The Framingham Eye Study,⁷⁰ that the prevalence of cataract was 5% in the 52 to 64 age group, 18% in the 65 to 74 group, and 46% of persons aged 75 to 85 years.

There is a steady increase in cataracts with age according to Kahn et al.⁷¹: 45.5% in individuals 52 to 64 years of age; 18.0% in individuals 65 to 74 years of age, and 45.9% in individuals 75 to 85 years of age. The Framingham Eye, NHANES, Punjab, and the Tibet Eye studies also showed a higher prevalence in females.⁷²

Some of the risk factors for cataract development include excessive exposure to sunlight (UVB), age (as already noted), cigarette smoking,⁷³ high cholesterol and triglycerides, diabetes mellitus, cortisone medication, and eye injury.⁷⁴

Surgical procedures have dramatically shifted to a procedure known as extracapsular cataract extraction.⁷⁵ Ophthalmic treatment for cataract has also evolved rapidly over the past 25 years from the prescription of thick heavy glass and plastic lenses to contact lenses to the posterior chamber-placed intraocular implant (IOL).⁷⁶ The IOL is the treatment of choice for more than 95% of persons undergoing cataract surgery in the Western world.

Vitreous

The vitreous is an avascular and acellular transparent jelly-like substance that occupies the central cavity of the eye and helps to maintain its shape. The vitreous is generally transparent throughout life but may contract, liquefy, shrink, and possibly detach in the aging eyes.

Vitreous hemorrhage, often a complication of proliferative diabetic retinopathy, results in a clouding of the vitreous. Charles⁷⁷ and Machemer⁷⁸ were instrumental in developing a procedure to remove the vitreous, known as a vitrectomy. The vitreous is often removed and replaced when delicate surgery is performed on the retina and the macular region.

Retina

The posterior lining of the eye, the retina, is a multi-layered structure that contains the light-sensitive photoreceptors known as the rods and cones (Fig. 59.3). The cones, which respond to color, are tightly packed into the central area of the eye, known as the macula. The rods, which occupy the majority of the peripheral retina, respond to black and white and to low levels of illumi-

FIGURE 59.3. Normal retina: macula is pigmented area at the center. (Courtesy of the National Eye Institute.)

nation and are important in mobility. The central as well as the peripheral retina may be significantly affected by pathologic changes later in life from conditions such as macular degeneration, diabetic retinopathy, retinal detachment, central and branch artery and vein occlusions, and hemorrhagic disease.

The value of the macula far outweighs its size in relation to the rest of the retina. It is the area that contains the sharpest vision. Everyday tasks such as reading print and seeing facial features, television, and street signs are dependent upon an intact macula.

The choroid is the pigmented, heavy vascular layer lying between the retina and the sclera. It is a layer that is prone to the growth of new fragile leaky blood vessels in the “wet” form of macular degeneration.

Macular Degeneration

More than 13.2 million Americans (15%) have signs of age-related macular degeneration. That number climbs to 1 in 3 over the age of 75.⁷⁹ It is estimated that as the population ages, more people will become legally blind from macular degeneration than from glaucoma and diabetic retinopathy combined.⁸⁰

Age-related macular degeneration, formerly known as senile macular degeneration, is primarily found in the Caucasian population. Known risk factors include smoking, light-colored irises, women over 60, familial history, and postmenopausal women who have not undergone hormonal replacement therapy, individuals taking antihypertensive drug therapy, and those having a high serum cholesterol level.⁸¹

Visual function may be dramatically affected in macular degeneration. Age-related macular degeneration might also be manifested by blurred vision, with difficulty

in seeing words, letters, faces, or street signs, as well as difficulty in differentiating colors.

There are primarily two types of age-related macular degeneration (AMD). The dry (atrophic) type, for which there is no treatment at this time, accounts for 90% of the new cases diagnosed. The wet type, also known as choroidal neovascularization or exudative maculopathy, accounts for the remaining 10% of the cases. The wet AMD is generally characterized by a more profound loss of visual function. However, despite the profound vision loss, there is usually enough peripheral vision to be able to function and travel safely.

Remediation includes traditional “thermal” laser as well as nonthermal photodynamic therapy for the wet AMD. The latter treatment may arrest the progressive loss of vision but never results in complete restoration of visual function. Additional research on AMD is being done with low-dose radiation, submacular surgery, cell transplantation, macular translocation, blood filtration, and vasogenic factors that stimulate the growth of new blood vessels.

Diabetic Retinopathy

Diabetic retinopathy is a microvascular complication of chronic diabetes mellitus.⁸² Forty percent or 4.8 million of the estimated 12.7 million people over the age of 40 have diabetic retinopathy,⁸³ the majority having the more common background diabetic retinopathy. However, there are 700,000 people who have the proliferative, more destructive type of the disease. It is also estimated that 12,000 to 24,000 persons lose their sight from diabetic retinopathy.⁸⁴

In addition to ongoing medical care, the diabetic may need laser photocoagulation and cataract extraction as the disease progresses. Vision rehabilitation is often indicated for the diabetic, especially those with advanced vision loss.

Optic Nerve

The optic nerve contains the retinal nerve fibers and consists of ganglion cell axons. It transmits the images falling on the retina to the visual pathway and eventually to the visual cortex. The optic nerve is also synonymous with the blind spot of the eye and contains no light-sensitive receptors where it exits the eye. The optic nerve may be affected by a number of disease processes including glaucoma, multiple sclerosis, and brain tumors.

Visual Field Loss

The etiology of visual field loss is generally glaucoma, stroke, or brain tumor. The vast majority (92%) of all strokes occur in patients aged 50 and older.⁸⁵ The inci-

dence doubles with each successive decade.⁸⁶ The ocular consequences of stroke are often serious and may include transient vision loss as well as the loss of the right or the left side of vision (hemianopia) in both eyes or partial field loss. Hemianopia can also be the result of brain tumors that affect the older individual between 50 and 70 years.⁸⁷ Depending upon the location of the visual field loss, reading, as well as mobility, may be affected.

Individuals with hemianopia often read the entire eyechart to the 20/20 line because of macular sparing. However, there may still be an absolute or relative loss in the visual field. Many people are unaware that the vision is actually lost and can injure themselves unless instructed on the management of using the residual vision.

Stroke rehabilitation often requires a team approach and usually includes a variety of professionals for re-education in the areas of vision, mobility, speech, and cognitive functioning. The low-vision specialist may recommend techniques, and optical and nonoptical devices, as well as special lens systems to enhance visual performance.

Low Vision and Vision Rehabilitation

Vision rehabilitation may be an essential component in the management of the person with a visual impairment from macular degeneration, inoperable cataracts, glaucoma, diabetic retinopathy, or visual field loss from a stroke or tumor. Vision rehabilitation may involve many other professionals, including the eyecare professionals specializing in low vision, the optometrist (O.D.) or ophthalmologist (M.D.), as well as vision rehabilitation teachers, an orientation and mobility instructor, social workers, and an occupational therapist. The low-vision specialist will prescribe specialized optical, nonoptical, and electronic low-vision devices for distance and near tasks. A rehabilitation teacher may be called upon to teach how to safely manage one's kitchen and personal affairs, and an orientation or mobility instructor may be involved to teach safe independent cane travel.

Low-Vision Evaluation and Low-Vision Devices

A low-vision evaluation is an eye examination that may be ordered when the vision is not corrected with ordinary glasses, contact lenses, or medical treatment including surgery. The examiner will use specialized eyecharts to test visual acuity function at distance and near to determine the visual potential. Various researchers⁸⁸⁻⁹¹ have outlined specialized tests of visual function, including a

contrast sensitivity test, evaluation of the macular function with the Amsler grid, visual field tests, color vision analysis, and photostress tests, that may be indicated.

Rosenthal and Williams⁹² have demonstrated the value of the prescription of specialized low-vision devices for persons with a visual impairment ranging from mild to profound. These low-vision devices would be especially valuable with persons having a visual acuity ranging from 20/40 to 20/800, as well as for individuals with visual field and loss in contrast sensitivity function.

These specialized low-vision devices include high-powered reading lenses (microscopic lenses), hand and stand magnifiers, handheld and head-borne telescopic systems, absorptive and tinted lenses, closed-circuit television, and systems for persons with visual field defects. In addition, there are numerous nonoptical devices including lighting and illumination systems, reading stands, and talking devices, as well as high-contrast devices, that will help to improve visual performance.

Otologic Changes and Disorders

George A. Gates and Thomas S. Rees

Age-related hearing loss is one of the most frequent health problems encountered in geriatric medicine. It is the third most prevalent major chronic disability in the over-65-year-old age group. Unfortunately, hearing loss is a disorder that is frequently unrecognized, frequently misunderstood, and all too frequently neglected, both by the affected themselves as well as by health care providers.

Presbycusis, literally meaning “elder hearing,” is the generic term applied to age-related hearing loss and is used to signify the sum of all the processes that affect hearing with the passage of time. The prevalence of self-reported hearing problems among the elderly is 30%.¹ The prevalence increases substantially with age, with a 10-dB reduction in hearing sensitivity per decade of life after age 60. Although only slightly more than 1% of people under the age of 17 have hearing loss, the prevalence rises to 12% between the ages of 45 and 64, to 24% between the ages of 65 and 74, and up to 39% for those over 75 years. In the Framingham Heart Study Cohort (ages 63–95), the prevalence of hearing loss for the speech frequencies was 42%.² It is predicted that, by the year 2030, older adults will comprise 32% of the population, and as many as 60% to 75% of the elderly will suffer hearing loss, approximately 21 million persons.

Hearing loss impairs communication, subtly at first, and increasingly so as the magnitude of the hearing loss increases. Impairment in the ability to hear and understand speech leads older adults to withdraw from life’s activities, resulting in social isolation and depression.^{3,4} Significant social, emotional, and communication difficulties have been associated with hearing loss in the elderly. Social and emotional handicaps are present even in those with only mild to moderate hearing loss. Bess and associates analyzed the impact of hearing impairment in elderly patients by using the Sickness Impact Profile (SIP) to measure functional and psychosocial impairment.³ Poor hearing was associated with higher SIP scores (greater impairment) and increased dysfunction.

Even mild amounts of hearing loss were related to poorer function. Hearing loss has also been implicated as a cofactor in senile dementia.⁵ Although measures for hearing loss identification and remediation are widely available, they are frequently underutilized.

Symptoms of Presbycusis

Age-related hearing loss is manifested by deterioration in each of the two critical dimensions of hearing: reduction in threshold sensitivity and reduction in the ability to understand speech. The loss in threshold sensitivity is insidious in onset, beginning in the highest frequencies (8000 Hz) and slowly progressing to involve those frequencies important in speech understanding (1000–3000 Hz range). The most common complaint of presbycusis patients is not that “I can’t hear”; rather, it is “I can’t understand.” The high frequency hearing impairment causes the voiceless consonants (t, p, k, f, s, and ch) to be rendered unintelligible. For example, people confuse “mash, math, map, and mat,” or “Sunday” with “someday.” Seniors often complain that others “mumble” and they cannot participate in conversations because bits and pieces of speech are missing. As the hearing loss worsens to affect the lower frequencies with advancing years, the older person requires greater volume for speech detection and often needs repetition or confuses what is said. Everyday sounds, such as beepers, turn signals, and escaping steam are not heard, which places the hearing-impaired at greater risk of injury and makes them more isolated from the everyday world.

Whenever the speech message is degraded, the older listener’s understanding difficulties increase dramatically. Rapid speech, foreign accents, and speech through poor transmitting equipment (i.e., airport intercoms) are often not understood. In addition, speech understanding in poor acoustic environments, such as noisy restaurants and large reverberant rooms, presents substantial difficulties

for the hearing-impaired senior. Older adults typically have greater difficulties in speech understanding and processing than do younger persons with comparable hearing loss.⁶ It has been postulated that some of these difficulties are due to a central integrative and synthesizing hearing disability that reflects a progressive deterioration within the central auditory pathways.⁷

Pathogenesis of Presbycusis

The major components of presbycusis are noise toxicity and aging.⁸ Other factors are genetic susceptibility, age-related diseases, and ototoxic medications. Damage to the hearing is cumulative from the effects of these various factors. Much of our knowledge about presbycusis comes from cross-sectional studies of large cohorts. While it is generally possible to sort out the components of presbycusis in individuals, it is difficult to do so with group data. Therefore, presbycusis is best used as an inclusive term to signify all the processes that affect hearing with the passage of time, rather than limiting its meaning to aging per se.

The aging process has three distinct components: physiologic degeneration, extrinsic insults, and intrinsic insults. These factors are superimposed on a genetic substrate and possibly overshadowed by age-related susceptibility to disease. In the auditory system, the extrinsic component (nosocosis) includes hearing loss due to otologic disease, hazardous noise exposure, acoustic trauma, and ototoxic agents. The intrinsic component (sociocosis) indicates the wear-and-tear effects of exposure to the everyday sounds of normal living.⁹ People who live in nonindustrialized regions avoid both nosocosis and sociocosis and demonstrate excellent hearing into old age.¹⁰

Although hearing steadily worsens with age, the rate of change is not linear, is highly variable, and is only weakly associated with chronologic age. For example, in comparing the change in hearing thresholds of the Framingham subjects over the 6-year interval between examinations 15 and 18, less than 10% of the variance is accounted for solely by age.¹¹ This finding suggests that other factors affect hearing more than age alone. In our industrialized society, it is difficult to escape from noise pollution. It is likely that much of the variance in levels of presbycusis is due to unmeasured effects of noise damage, which is the most common form of ototoxicity. The effects of systemic disease on hearing are still incompletely understood but may contribute as well. For example, older people with prior cardiovascular disease (CVD) events have poorer hearing than do those without CVD.¹²

Four types of presbycusis have been described, based on audiograms and postmortem histopathologic findings.¹³ Sensory presbycusis involves loss of cochlear hair

cells in the basal end of the cochlea and secondary degeneration of associated neurons. It usually begins in middle age and is characterized by steeply sloping high-frequency hearing loss and proportional reduction in word recognition. Neural presbycusis involves primary degeneration of cochlear neurons and central auditory pathways. The most significant clinical finding is disproportionately severe loss of word recognition ability, much poorer than would be expected from pure tone findings. Metabolic presbycusis is characterized by a flat pure tone audiogram with excellent word recognition and is due to atrophy of the stria vascularis in the cochlea. Mechanical (cochlear conductive) presbycusis is thought to result from stiffening of the basilar membrane and is reflected by a gradually sloping audiogram and word recognition that is correspondingly affected to a greater degree. In clinical practice, the majority of cases of age-related hearing loss appear as a mixture of types. The data of the Framingham Cohort showed most patients fell into the sensory category, and pure neural types were infrequent.¹⁴

Hearing Loss Types

Hearing loss is traditionally classified as conductive, sensorineural, and central. These types are based on the site of structural damage or blockage in the auditory system. Conductive hearing loss arises from obstruction of sound transfer through the external or middle ear space or both. Cerumen impaction represents the most common external ear cause of conductive hearing loss and is a frequently overlooked problem in elderly people whose ear canals often "collapse" with age. Cerumen impaction is commonly the result of misguided attempts by people to clean their ear canals with Q-tips. Other types of conductive loss, such as otitis media and otosclerosis, seldom arise primarily in the senior years. Unilateral middle ear effusion can be a sign of nasopharyngeal cancer but is more commonly the result of an ear infection.

A sensorineural hearing loss involves damage to the cochlea or fibers of the eighth cranial nerve. "Nerve deafness" and "perceptive deafness" are obsolete terms for sensorineural hearing loss that are occasionally encountered. Sensorineural hearing loss may be sensory only (cochlear hair cell loss), may involve the auditory nerve or brainstem (neural), or both. Newer diagnostic methods permit finer distinctions between sensory and neural losses. Now, by measuring otoacoustic emissions (OAEs) the status of the outer hair cells in the cochlea can be determined quickly and objectively. OAEs are very soft sounds produced by the contraction of the outer hair cells either spontaneously or in response to sound input into the ear. Sensorineural hearing loss due to presbycusis affects both ears equally and generally begins in

the higher frequencies. Unilateral sensorineural hearing loss may be caused by a neoplasm (acoustic neuroma), acoustic trauma (blast injury), or a viral infection or vascular event (sudden sensorineural hearing loss). Sudden sensorineural hearing loss may be accompanied by vestibular symptoms of vertigo, dizziness, and nystagmus. Idiopathic sudden sensorineural hearing loss often recovers with prompt corticosteroid therapy. Therefore, immediate otologic referral is indicated for evaluation and treatment. Metabolic causes of hearing impairment are seen in endocrine diseases—thyroid, pancreatic, and adrenal, and in renal disease, diabetes mellitus, and hypertension.

Central auditory dysfunction is far less common and is seen in conditions such as stroke and Alzheimer's disease, neoplasm, multiple sclerosis, and degenerative disorders.¹⁵

Clinical Evaluation of Hearing Loss

The History and Physical Examination

The otologic examination is preceded by a carefully taken patient history. In the case of hearing loss, the time of onset, whether the loss was gradual or sudden, and the presence or absence of associated symptoms, especially vertigo, tinnitus, discharge, or pain, should be noted. Family history, noise exposure history, previous ear or head trauma, and use of ototoxic drugs should also be included. People with substantial exposure to workplace noise, recreational noise, and firearm use are more likely to have irreversible high-frequency hearing loss. Medication history should be explored to determine possible ototoxicity. Aminoglycoside antimicrobials, *cis*-platinum, loop diuretics, and anti-inflammatory agents may contribute to hearing loss. Metabolic evaluation is indicated if the patient has not had a recent health examination. Diabetes, hypertension, and hyperlipidemia should be excluded as cofactors. Patients receiving renal dialysis often have poorer hearing than would be expected from age alone. Hearing loss does cluster in families, particularly the strial form of presbycusis.

The physical examination of the ear canal and tympanic membrane is typically normal in most seniors, with the exception of cerumen accumulation in some. Cerumen removal with either ear canal irrigation, often preceded by use of cerumen-dissolving drops (10% sodium bicarbonate is the most effective), or manual (instrumental) removal is necessary. Although the removal of occluding cerumen can result in hearing improvement for some individuals, most often the locus of the hearing loss is in the sensorineural system. Itching and dryness of the external canal is a common complaint among seniors. The itching is often temporarily relieved

TABLE 60.1. Medical referral guidelines.

Visible congenital or traumatic deformity of the ear, including perforation of the eardrum
History of, or active, drainage from the ear within the previous 90 days
History of sudden or rapidly progressive hearing loss within the previous 90 days
Acute or chronic dizziness
Any unilateral hearing loss
Visible evidence of significant cerumen accumulation or foreign body in the ear canal
Pain or discomfort in the ear

by their Q-tip use, but this habit inevitably worsens the dryness and itching due to trauma of the canal. Aging causes atrophy of the canal epithelium and underlying sebaceous and cerumen glands, which results in decreased hydration of the canal skin and increased susceptibility to Q-tip abrasion. Patients should avoid putting anything in their canals. Canal itching can be controlled with steroid-based creams as needed.

Examination of the tympanic membrane should be accompanied by pneumatic otoscopy to assess tympanic membrane mobility. In people with middle ear effusion, the drum does not move or moves very little. Relying on the “color” of the tympanic membrane to diagnose effusion may be misleading. Commonly seen is opacification of the normally translucent tympanic membrane (tympanosclerosis); this has no effect on conduction of sound energy into the inner ear and is simply a manifestation of age.

Imaging studies are not indicated except where the loss is unilateral or significantly asymmetric, or where tinnitus is unexplained by the audiogram. Screening MRI examinations using the T₂ fast spin echo technique provide superb visualization of the eighth nerve and brainstem and can detect tumors in the millimeter range, even before hearing is affected.¹⁶ Table 60.1 lists several “warning signs” associated with the history and physical examination that should prompt referral to an otolaryngologist for complete evaluation and treatment.

Screening Audiometry

Although it would seem prudent for health care providers to screen for one of the most prevalent chronic conditions affecting the elderly, this is unfortunately not the practice with hearing loss identification.⁴ Moreover, even when elderly patients have discussed their hearing difficulties with their primary care providers, they are often told that their hearing loss is minor or that it cannot be improved with a hearing aid.¹⁷ When one considers the adverse effects of hearing loss on quality of life and that such effects are reversible with hearing aids, it is surprising that in-office hearing loss screening is not common practice.

TABLE 60.2. Audiometric screening chart.

Intensity	Frequency		
	1000Hz	2000Hz	3000Hz
25 dB (normal)			
40 dB (borderline)			
60 dB (fail)			

25 dB, normal hearing; 40 dB, borderline (referral dependent upon patient's self-perceived handicap); 60 dB, fail; 0, right ear; X, left ear.

Tuning forks, whispered/spoken voice, or finger friction test, which are used by many practitioners, are not effective and reliable approaches to hearing loss identification. The use of screening audiometry is the tool of choice in the identification of hearing loss. Screening audiometry can be quickly and easily administered by a trained office nurse or medical assistant. The equipment needed for screening audiometry is lightweight and low cost. There are portable, battery-operated audiometers and even specially developed otoscopes with audiometric capabilities available for the practitioner.¹⁸ A portable audiometer can be used to screen hearing at 1000, 2000, and 3000 Hz at intensity levels of 25 dB (normal), 40 dB (borderline), and 60 dB HL. Failure at any one frequency at 25 dB for younger adults or 40 dB for older adults suggests the need for referral for a complete audiologic evaluation.¹⁹ A sample form for recording audiometric screening results is shown in Table 60.2.

Self-Assessment

The simplest self-assessment screening method is to ask patients if they think they have a hearing problem. This single question is more sensitive than multi-item questionnaires, which are more specific. A number of self-

assessment inventories have been developed as a means of evaluating hearing handicap. These scales quantify hearing handicap by including questions about the self-perceived situational and psychosocial effects of decreased hearing on various aspects of daily function. One of these scales, the Hearing Handicap Inventory for the Elderly—Screening Version (HHIE-S), is specifically designed for use with noninstitutionalized elderly (Table 60.3).²⁰ It has been shown to be a reliable and valid method for delineating handicapping hearing impairment among aging persons and is a good screening tool for primary care practices.²¹ The HHIE-S can be completed by patients in about 10 min while they are waiting for their appointment or may be verbally administered by the practitioner or assistant. The inventory consists of 10 questions about circumstances related to hearing. Patients simply circle whether or not they have a problem in that situation. A “yes” response scores 4 points, a “sometimes” scores 2 points, and a “no” scores 0. Total scores range from 0 to 40, with a score of 40 representing the maximum self-perceived hearing handicap. Scores of 0 to 10 are unlikely to occur in people with significant hearing loss; scores of 26 to 40 should prompt referral for otologic/audiologic evaluation. Intermediate scores are ambiguous. The person with a score of 12 to 24 who notes having a hearing problem should be referred for testing, but a similar score in one who denies having a problem should not be a cause for action.

Patients who fail audiometric screening tests, or have a high self-perceived hearing handicap, should be referred for formal audiologic and otologic assessment. This evaluation will delineate the pattern and degree of loss, indicate the likely site of loss, and predict the suitability of otologic treatment or amplification for rehabilitation. Central auditory tests are widely available and should be considered when the possibility of early dementia exists. People with clinical Alzheimer's disease have poor central auditory function. We have recently shown that poor performance on a standard central auditory test (Synthetic Sentence Identification with

TABLE 60.3. Hearing Handicap Inventory for the Elderly—Screening Version (HHIE-S).

Please answer the following questions by circling the appropriate letter: **Y** = yes, **N** = no, **S** = sometimes.

1. Does a hearing problem cause you to feel embarrassed when meeting new people?	Y	N	S
2. Does a hearing problem cause you to feel frustrated when talking to members of your family?	Y	N	S
3. Do you have difficulty hearing when someone speaks in a whisper?	Y	N	S
4. Do you feel handicapped by a hearing problem?	Y	N	S
5. Does a hearing problem cause you difficulty when visiting friends, relatives, or neighbors?	Y	N	S
6. Does a hearing problem cause you to attend religious services less often than you would like?	Y	N	S
7. Does a hearing problem cause you to have arguments with family members?	Y	N	S
8. Does a hearing problem cause you difficulty when listening to TV or radio?	Y	N	S
9. Do you feel that any difficulty with your hearing limits or hampers your personal or social life?	Y	N	S
10. Does a hearing problem cause you difficulty when in a restaurant with relatives and friends?	Y	N	S

“Yes” = 4 points; “Sometimes” = 2 points; “No” = 0 points; total possible = 40.

Contralateral Competing Message) precedes the clinical onset of dementia by many years.²² With the possibility of treatments to forestall the progression of Alzheimer's disease, early identification may be of great importance.

Hearing Loss Rehabilitation

Medical–Surgical Treatment

Hearing loss caused by conductive deficits (e.g., otosclerosis, otitis media, eardrum perforations, etc.) can most often be successfully treated with medical or surgical intervention by an otolaryngologist. Eardrum perforations can be surgically repaired (myringoplasty), middle ear fluid can be removed and the middle ear aerated (myringotomy with placement of a pressure equalization tube), a nonmobile stapes can be removed and replaced with a prosthesis (stapedectomy), and an absent or disarticulated ossicle can be replaced with a prosthesis (ossicular chain reconstruction). These procedures generally can eliminate the conductive hearing loss and return hearing to normal or near-normal levels.

Once thought to be untreatable, some cochlear lesions are now responding to medical therapy. About one-third of people with sudden hearing loss recover hearing. For example, the majority of people with autoimmune hearing loss recover substantial amounts of hearing with corticosteroid and other anti-immune treatment, such as methotrexate and plasmapheresis. However, for the vast majority of people with presbycusis, definitive treatment must await the results of our ongoing research programs in hair cell regeneration. This section will undoubtedly be expanded in the next decade or two.

Hearing Aid Amplification

The most common site of age-related hearing loss is dysfunction in the cochlea or associated neural structures. Of all patients with sensorineural hearing loss, less than 5% can be helped medically. Consequently, hearing aid amplification is the principal resource for improving communication and reducing hearing handicaps in persons with sensorineural hearing loss. Unfortunately, only 10% of people who might benefit from an aid actually own one, which indicates a substantial underservice. Current hearing aids include devices that fit behind the ear, in the canal, and, most recently, completely in the canal. Those seniors with dexterity problems or vision impairments are often unable to insert and adjust the smaller aids properly and are better served with larger hearing aids. The audiologist reviews such issues with the hearing-impaired individual during the prefitting session.

Today's hearing aids have evolved from simple devices to remarkably sophisticated technologically advanced

instruments. In just the past few years, more advances in hearing aid technology have been made than throughout history. Hearing aids no longer merely provide linear amplification but may include compression circuitry to reduce the amplification for loud sounds. There are also hearing aids that include several programs for use at the listener's discretion, because a single amplification paradigm may not be of benefit for all listening situations. One may choose a wide frequency band amplification for quiet environments, another program that reduces low frequencies for noisier situations, and a program specifically suited for telephone use. These hearing aids are digitally programmed by an external programmer or computer through a microchip within the hearing aid itself. Customized programming of the hearing aid enables the dispenser to make significant electroacoustic modifications to an individual's needs and to change the hearing aid parameters if the hearing loss should change in future years.

Conventional hearing aids typically use omnidirectional microphones, which pick up sounds from all directions. These microphones are helpful in quiet situations, but persons often complain of amplification of background noise in restaurants and groups. Directional and dual microphones are now available in hearing aids that attenuate sounds from the back or side and focus on sounds from the front of the listener. The hearing aid user can choose either the directional microphone or omnidirectional microphone to suit the listening situation.

The most recent introduction in hearing aid technology is the fully digital instrument. These aids offer complex sound processing, fitting flexibility, precision in signal manipulation, multiple memories, multiple channels, and automatic feedback reduction capabilities, which are not available in conventional devices. Although digital aids are considerably more expensive than conventional aids, the benefits may be justified by many hearing-impaired persons. One must consider the acoustic and communicative needs of an individual patient and determine the appropriate level of hearing aid technology. If the patient does not participate in social activities and has few demands placed on their hearing, a digital hearing aid is inappropriate. If, on the other hand, the patient is socially active and encounters a variety of listening environments and high hearing demands, digital hearing aids with multiple memories and dual microphone technology are highly beneficial and worth the added cost.

The choice of hearing aid depends on the type of hearing loss, cosmetic concerns, and manual ability to insert/remove and care for the device. A telephone coil (T coil) should be available to optimize telephone use. Dispensing audiologists provide sophisticated evaluations to select and program the optimal device, and also provide training and long-term rehabilitative services.

These audiologists may practice in an otology office, a speech and hearing clinic, or independently. Some hearing aid dealers are relatively skilled in the fitting of hearing aids, but others possess only minimal training or are more oriented to sales. Many states, in fact, require that a hearing aid dealer meet only the minimum requirements of being 18 years old and passing a state licensing examination; there are typically no educational requirements. The clinical audiologist, on the other hand, holds at least a master's degree in the evaluation and rehabilitation of hearing loss. The audiologist is uniquely qualified to provide a full range of auditory assessment and rehabilitative services to elderly persons.

The industry standard of practice is to provide the user with at least a 30-day trial period with amplification and to refund the cost of the hearing aid if it is returned. The new amplification systems are considerably more expensive than conventional hearing aids. Currently, digital in-the-canal aids cost approximately \$2500 per aid, and binaural aids are typically most beneficial. Neither Medicare nor most insurance carriers provide financial coverage for hearing aids. The specific hearing needs, lifestyle, and adaptability of the hearing aid wearer must be taken into account during the prefitting process.

Assistive Listening Devices

Although substantial improvements have been achieved in hearing aid design and application, few of the hearing-impaired can ever come close to achieving "normal" auditory function with the use of hearing aids alone. The inherent physiologic restrictions imposed by age-related hearing loss, coupled with the electronic constraints of hearing aids, render "normal hearing" impossible, especially considering the levels of noise and background interference found in most public places. The amplification of unwanted sounds (e.g., multiple speakers in groups, background noise, ventilation) by hearing aids often causes the desired message to be rendered unintelligible.

Assistive listening devices (ALDs) constitute a growing number of situation-specific amplification systems designed for use in difficult listening environments. ALDs commonly use a microphone placed close to the desired sound source (e.g., a television, theater stage, or speaker's lectern), and sound is directly transmitted to the listener. Several transmission methods include infrared, audio loop, FM radio, or direct audio input. Desired sounds are enhanced while competing extraneous noises are decreased, thus permitting improved understanding. These ALDs are becoming more available in churches, theaters, and classrooms, enabling hearing-impaired seniors to avoid the isolation imposed by the inability to hear a sermon, play, or public address.

Other assistive listening devices, such as small portable pocket amplifiers, are very helpful in medical situations.

These amplifiers are particularly well suited for health care professionals' communication with the hearing-impaired elderly. Often it is in the setting of acute health care delivery that older patients have misplaced or forgotten their own hearing aids. Portable amplifiers can save the voice and patience of the health care provider and allow respectful and private interactions to take place. Amplified telephones, low-frequency doorbells, amplified ringers, and closed-captioned TV decoders are just a few examples of the number of devices currently available for the hearing-impaired for everyday use. Flashing alarm clocks, alarm bed vibrators, and flashing smoke detectors provide valuable help for severely hearing-impaired individuals. Audiologists can provide such devices for their patients.

Implantable Hearing Aids

Surgically implantable hearing systems are in field testing in the United States and Europe. These systems avoid the discomfort many people experience with ear molds and they eliminate the telltale "squeal" or acoustic feedback that is so common when the ear mold does not fit tightly. It is likely that some of these systems will be available commercially in the very near future.

Cochlear Implants

Cochlear implants are used frequently for older deafened adults with excellent results. The cochlear implant is a neural stimulator with an electrode array that is surgically placed inside the cochlea. Speech sounds are extracted and encoded via an external speech processor, and transmitted to the electrodes through a transcutaneous radio coil. For patients whose hearing loss is so severe that amplification is of little or no benefit, the cochlear implant is a standard, safe, and effective method of auditory rehabilitation. Most insurance plans now include cochlear implantation as a benefit. There are approximately 25,000 implantees in the United States and 35,000 worldwide.

Audiologic Rehabilitation

While the hearing aid serves as the nucleus of audiologic rehabilitation, other avenues of hearing loss management are becoming increasingly more important. Audiologic rehabilitation can include speech reading (lipreading) training, auditory training, and hearing loss counseling. Speech reading training teaches the use of visual cues to help in understanding speech. Cues include the use of lip movement, facial expression, body gestures, and context. Auditory training teaches strategies to improve listening skills and encourages the acceptance of amplified sound. Informational counseling sessions address numerous issues including implications of hearing loss on everyday

life, coping mechanisms, speech conservation, and other specific concerns of the patient. Patients can find support through self-help groups and hearing loss informational materials, such as those offered by SHHH (Self Help for Hard of Hearing People, Inc.). SHHH has local chapters throughout the country and provides a valuable resource for hearing-impaired seniors.

Effective Communication with the Hearing-Impaired

Communication with the hearing-impaired adult can be frustrating at times, both for the affected individual and for those who communicate with them. The hearing-impaired person may confuse words, give inappropriate answers, ask for repetition, or just not hear and respond to questions or comments. These difficulties are even greater in background noise or group environments. Some persons unfortunately avoid communicating with a hearing-impaired person or show displeasure or irritation when asked for repetition. Others talk around the person by talking with their spouse or companion and ignoring the hearing-impaired person. Health care practitioners may at times talk with the spouse or caregiver about the patient's symptoms or medical treatment options while treating the hearing-impaired patient as if their cognitive abilities were affected. This obviously causes much frustration and isolation to the patient.

The practitioner should be aware of the communicative difficulties associated with hearing loss and use techniques to enhance communication. A quiet office environment without distracting noises is an ideal setting for the hearing-impaired patient. The examination door should be closed to reduce the noise from other rooms, and there should not be competing music or equipment noise. The patient should be spoken to face to face in a slower than usual voice. Table 60.4 lists several ways to enhance communication with hearing-impaired persons. These "guidelines" can be very helpful for improved communication in the practitioner-patient relationship.

TABLE 60.4. Guidelines for communicating with the hearing-impaired.

1. Get listener's attention before speaking.
2. Face listener directly to give visual cues.
3. Do not cover mouth while talking or turn away.
4. Try to reduce background noise: turn down TV, radio, etc.
5. Use facial expressions and gestures.
6. Speak slowly and clearly with more pauses than usual.
7. Speak only slightly louder than normal: do not shout.
8. Rephrase if listener does not understand rather than repeating word for word.
9. Alert listener to changes in topic before proceeding.
10. Do not turn and walk away while talking.
11. Use written notes if necessary.

Hearing-impaired persons most often remove their hearing aids when sleeping, so it is important that their aids are in place before talking with them; this is especially true with nursing home patients or those in health care facilities. Once the hearing aids are inserted, a simple question such as "Can you hear me now?" is helpful before conversing with the patient. Patients with hearing loss will appreciate such efforts in establishing effective communication with the health care provider.

Quality of Life and Amplification

The "treatment" of hearing impairments with hearing aid amplification, assistive listening devices, or aural rehabilitation therapy does not "cure" the impairment or restore hearing and communicative efficiency to normal, but such approaches do represent the best treatments to date. They will improve the ability of most older persons to communicate and reduce the handicapping consequences of hearing loss.

Numerous studies have shown that hearing aids do improve the quality of life for older persons with hearing loss. Successful hearing aid users have been found to show an advantage in self-perceived communication effectiveness, assertiveness in managing difficult listening situations, and an increased ability to accept their hearing loss as opposed to nonhearing aid users. Malinoff and Weinstein reported dramatic reductions in hearing handicap following only 3 weeks of hearing aid use that was sustainable after 1 year of use.²³ Mulrow and colleagues reported statistically significant improvements in cognitive and mental status scores and on a geriatric depression scale for hearing aid users compared to a nonhearing aid user control group.²⁴

There is mounting evidence to suggest that the psychosocial implications of hearing handicap can be reduced with hearing aids and that these positive outcomes can be sustained over time. Studies using self-report methods to assess hearing aid benefit are providing overwhelming evidence of the efficacy of hearing aids. Unfortunately, only 10% of the people who might benefit from amplification actually have hearing aids.

Tinnitus Management

Tinnitus is a common consequence of presbycusis, noise-induced hearing loss, and, indeed, of most types of hearing loss. Tinnitus sensations are probably generated central to the cochlea; tinnitus has been noted to worsen in some cases after section of the cochlear nerve (e.g., as with tumor surgery). Given that spontaneous neural activity is typical of normal auditory nerve fibers, the absence of such activity may be a code for silence and

may trigger the central generation of tinnitus sensations. However, the exact mechanism for tinnitus remains poorly defined.

Most patients with tinnitus adapt to the new sensation without difficulty and accept it as part of their existence. A small percentage, 5% or less, are unduly bothered by the unwanted sound. High proportions of these tinnitus sufferers are clinically depressed. Many are also bothered by loud sounds (hyperacusis). It is important to recognize that the characteristics of the tinnitus (as determined psychoacoustically) are no different in sufferers and nonsufferers. Rather, it is the psychological status of the sufferer that is the focal point.

Management of the tinnitus sufferer may require amplification (which masks much of the unwanted sound) and antidepressive therapy, in addition to education about the nature of tinnitus. Cognitive psychotherapy may be useful in difficult cases. Drug therapy of the tinnitus, per se, is futile.

Summary

Hearing loss is a normal accompaniment of old age. Many specific steps can be taken to overcome the potentially devastating effects on the individual. The geriatrician should be alert to the signs of hearing impairment and assist the patient in obtaining and using appropriate rehabilitation.

Aging and the Oral Cavity

Gretchen Gibson and Linda C. Niessen

Many myths surround aging and the oral cavity. The stereotype of your grandmother going to bed with her teeth in a cup on the nightstand will fade rapidly as the baby boomers, those Americans born between 1946 and 1964, reach older adulthood in the twenty-first century.

The key roles of the oral cavity include initiation of alimentation and production of speech. Any discussion of the age-related and disease-related changes that occur in the oral cavity must address the effect of the changes on these functions. The oral cavity has developed specialized tissues to speak and to process food. The teeth and their supporting structures, called the periodontium, and the muscles of mastication, including the tongue, participate in preparing food for swallowing. The secretions of the salivary glands participate in digestion but also lubricate and protect the oral tissues.

The goal of this chapter is to provide clinicians with a better understanding of the effects of aging on the oral cavity in the hope of preventing as many disease-related changes as possible.

Oral Changes Associated with Aging

Tooth loss is the most common oral change associated with aging. However, no one ever lost a tooth because they celebrated a 75th birthday. Adults lose teeth because of disease, primarily dental caries or periodontal disease.

Although tooth loss does increase with age in cross-sectional and longitudinal studies, the percent of adults who have lost all their teeth (i.e., are completely edentulous) has decreased from the 1960s through the 1990s.¹⁻⁴ Figure 61.1 shows the percent of edentulous adults aged 65 to 74 years for 1960 to 1962, 1971 to 1974, 1985 to 1986, and 1993. The trend is a quite dramatic decrease in the rate of edentulousness from the high in the 1960s of 49.4% to the current low in the 1990s of 25% for this age group.

The tooth consists of enamel and cementum, which cover the outer surfaces of the crown and root, respectively (Fig. 61.2). Enamel is the hardest substance in the body, composed of more than 90% mineralized tissue. Dentin is the layer beneath both the enamel and cementum. Both dentin and cementum are softer than enamel, consisting of only 50% mineralized tissue. Dental caries (tooth decay) can affect enamel, dentin, or cementum surfaces. The dental pulp in the center of the tooth is composed of soft tissue where the nerve, blood, and lymphatic supply are located.

The supporting structures of the teeth (i.e., the periodontium) are those tissues that support the teeth in the jawbones. The periodontium consists of soft tissues [the gingiva (gums) and periodontal ligament (a ligament that attaches cementum to alveolar bone)] and mineralized tissues (cementum and bone support). Gingivitis occurs when the gingival tissues are inflamed. Periodontal disease or chronic periodontitis occurs when inflammation of the attachment tissues results in loss of bony support for the teeth.

Changes in the teeth do occur with aging. Teeth appear to darken with age. It is not clear what accounts for this change. It is hypothesized that wearing away of the enamel layers allows for the yellow dentin color to become more predominant. Clinically, some of the age-related oral changes have led to an increased interest in esthetic or cosmetic dentistry among senior patients. The ability to smile confidently and improve self-esteem is fueling the esthetic dentistry movement among older adults. Affluent older adults who are contemplating plastic surgery are also exploring a smile makeover, such as tooth whitening to eliminate darkened teeth and crowns or veneers to correct shortened, elongated, or even crooked teeth.

The dental pulp decreases in size as a result of aging. The clinical implications of a decreased dental pulp are not clear. Enamel and cementum surfaces continue to absorb fluoride, thus promoting remineralization of early

FIGURE 61.1. Edentulous rates for seniors, age 65–74 years. (From References 1–4, with permission.)

carious lesions, which contributes significantly to the theoretical basis for fluoride use in adults to prevent dental caries.

At one time, salivary flow was thought to decrease with aging. However, much of the research conducted on aging and salivary flow often compared healthy young adults with medically compromised older adults. Failure to draw appropriate samples and characterize the sample populations according to medical conditions and medication use resulted in the erroneous conclusion that salivary flow decreased as a result of aging.

More recent studies have shown that, in healthy adults, decreased salivary flow is not a normal consequence of aging.^{5,6} Although histologic changes in salivary glands are noted with aging, it is thought that the glands contain

sufficient reserve capacity to offset these morphologic changes. Thus, a patient's complaint of oral dryness should not be attributed to aging. The differential diagnosis for salivary dysfunction is discussed later in this chapter.

Disease-Related Changes of the Mouth

Disease-related changes of the mouth appear to play a larger role in poor oral health than the currently known age-related changes. Most diseases of the oral cavity are either treatable or, more importantly, preventable.

Infectious Diseases of the Oral Cavity

The oral cavity, as a part of the gastrointestinal complex, is not only accessible to bacterial colonization from the environment but is a natural host to many species. Both dental caries and periodontal disease, the two most common diseases of the dentition, are the results of chronic bacterial infections.

Caries and periodontal disease occur when there is a shift in the oral environment and normal bacterial balance. This shift allows pathogenic organisms to flourish. The *Candida* species of fungus is also found in the oral cavity and other parts of the body of most healthy adults.

FIGURE 61.2. Anatomy of tooth and supporting structures.

Patients with dental caries or periodontal disease may or may not experience pain. Patients with root surface caries may be unaware of its presence until the caries has progressed circumferentially around the tooth and broken off the crown of the tooth. Patients may be unaware of the presence of periodontal disease until they wake up one morning and notice that their teeth are loose. Periodontal disease, like dental caries, requires dental intervention to stop disease progression.

Factors that affect the body's immune potential, or the natural colonization of the oral cavity, can lead to opportunistic infection of yeast, such as an overgrowth of *Candida albicans*.⁷ Oropharyngeal colonization of gram-negative bacteria is the most common route of acquiring gram-negative pneumonia.^{8,9} It has been hypothesized that bacterial infections, such as those found in periodontal disease, may play a role in aspiration pneumonia.¹⁰ For these reasons, it is important to maintain good oral hygiene, even for nonresponsive patients who are parenterally fed.

Dental Caries

Dental caries is often thought of as a disease of childhood. Currently, an increasing number of older adults are afflicted with this infectious condition. In fact, caries has been shown to be a major cause of tooth loss in adults.¹¹ With the rate of edentulism continuing to decline, there will be an increase in the number of people with natural teeth who are at risk for caries.¹² Thus, the preventive dental methods that have contributed to declining tooth decay rates in children will need to be applied to a growing older population.

Caries is identified by the surface of the tooth on which the lesion is found. Caries attacking enamel surface is classified as coronal (the crown portion of the tooth). Caries attacking cementum, which covers the tooth root, is classified as root surface caries. Most current epidemiologic studies report coronal and root caries as two separate diseases.

The etiology of caries is threefold. It requires (1) a predominance of cariogenic bacteria; (2) a food source for the bacteria, such as fermentable carbohydrates; and (3) an acidic environment for continued bacterial growth. Because caries can be site specific in the oral cavity, the bacterial environment can vary from tooth to tooth within the same mouth and surface to surface on the same tooth. The bacteria most commonly associated with both coronal and root caries are *Streptococcus mutans*, a gram-positive coccus, and to a lesser degree, *Lactobacillus*, a gram-positive rod, and *Actinomyces*.¹³⁻¹⁵

Risk factors for caries among older adults are similar to those for all adults. Unfortunately, these risk factors are often enhanced by local and systemic diseases that are more prevalent in old age. Poor oral hygiene allows

both an acidic environment and prolonged access to food sources for bacterial proliferation. Poor oral hygiene can be exacerbated by decreased dexterity, as occurs in arthritic or stroke victims. As a general rule, persons who have difficulty with their activities of daily living, particularly feeding, will have difficulty with daily oral care and are at greater risk for dental caries.

Dietary choices made by older adults can greatly affect their caries activity. A decreased ability to chew and poor economic status among older adults have been shown to contribute to a diet that is higher in fermentable carbohydrates, softer, and therefore more cariogenic.^{16,17}

Periodontal disease also acts as a risk factor specific for root caries. Chronic periodontal disease often leads to recession of gingival tissue with resulting tooth root exposure. Once the root surface or cementum of a tooth is exposed to the oral environment, it can be quickly demineralized when exposed to the acidic by-products of bacteria.

Decreases in salivary flow contribute significantly to increased caries activity. Patients who have a significantly decreased flow rate secondary to radiation therapy to the head or neck, which affects the salivary glands, have demonstrated a significant increase in caries activity.¹⁸ Medication use and primary salivary gland disease can also cause low salivary flow, as is discussed later in this chapter.

Periodontal Diseases

The periodontal diseases consist of various disease processes, including gingivitis and periodontitis. Gingivitis is an inflammatory response of the gingival tissue to the metabolic products of bacteria found in oral plaque. Plaque-associated gingivitis most commonly presents as erythematous, edematous tissue that halos the teeth (Fig. 61.3). The gingiva bleed easily on tissue manipulation, such as during an examination or routine tooth brushing.

The primary risk factor for gingivitis is poor oral hygiene. Removal of the plaque eliminates the inflammatory response and, in most cases, the gingivitis will heal. Some research has shown that although gingivitis forms more quickly in older adults, healing is not impaired.¹⁹

Medications can also alter the gingival tissue. Steroid-induced gingivitis has been associated with postmenopausal women receiving hormone replacement therapy.²⁰ Gingival overgrowth can be induced by certain medications, such as cyclosporins, nifedipine, and phenytoin. Poor oral hygiene increases the risk of gingival hyperplasia when taking any of these medications.^{21,22} This overgrowth further decreases a person's ability to maintain good oral hygiene. To eliminate the overgrowth, oral hygiene must be improved and any plaque or calculus removed from beneath the gingival tissue. If the tissue does not satisfactorily resolve after a dental scaling

FIGURE 61.3. Gingivitis. Dark halo (indicated by arrows) on gingival tissue surrounds gold crowns, which are covered with plaque.

(cleaning), the overgrown tissue can be surgically removed.

Periodontitis is the destruction of the supporting structure of the tooth. If a sufficiently large amount of supporting bone is lost, clinically a patient may present with a chief complaint of tooth migration or movement, loose teeth, and tooth loss.

Periodontal disease in older adults is commonly referred to as chronic periodontitis (Fig. 61.4). Chronic periodontitis (referred to as periodontitis in this discussion) is now believed to be composed of short bursts of disease activity or destruction and longer periods of quiescence.^{23,24} Because periodontitis is a chronic disease, much of the ravages of the disease we see in older adults results from an accumulation of the disease over time. Research has shown that the advanced stages of periodontitis are less prevalent than the moderate stages in the elderly population.^{3,25} It is theorized that many of the sites of advanced periodontal disease have resulted in tooth loss earlier in life, suggesting that older age is not a risk factor for periodontal disease.²⁰

As with caries, bacteria-containing plaque is the primary risk factor for periodontal disease. An altered immune response can exacerbate the inflammatory reaction in periodontal disease. Certain nutritional deficiencies, such as vitamin C, calcium, and zinc, may all play a role in the susceptibility and progression of periodontitis.^{26,27} People who smoke are at greater risk for periodontal disease.²⁸ Smoking has been shown to be as important as bacterial destruction in the formation of this oral disease.^{29,30}

Recently, strong evidence has begun to suggest a link between periodontal disease and the severity and progression of diabetes. Diabetic patients are at risk for a more severe form of periodontal disease, when compared

to healthy adults. More recently, preliminary data have suggested that controlling the gram-negative chronic infection of periodontal disease can have a positive impact on the control of diabetes.³¹

The evidence for the relationship between periodontal disease and coronary atherosclerosis is still somewhat controversial. Multiple studies have shown periodontal disease to have an independent association with coronary atherosclerosis, even after adjustment for other obvious and known risk factors, whereas others show no evidence of causal association between periodontal disease and coronary heart disease.^{32,33} Theoretical causes include similar inflammatory mediators for both periodontitis and atherosclerosis,³² increased platelet aggregation, and possible formation of an embolus due to an oral plaque organism.³⁴ Finally, there is recent evidence from a national prospective study that found periodontal disease to be a risk factor for nonhemorrhagic stroke.³⁵

Yeast

As part of the gastrointestinal tract, the oral cavity is a natural host to many species of microorganisms. Yeast is one of these microorganisms. Most healthy adults who are cultured may at various times have a low yeast count. *Candida albicans* is the primary cause of pathogenic yeast infection in the oral cavity. Overproliferation of the organism and infiltration into the mucosal layers result in a pathogenic infection. The causes can be both local and systemic, and the infection is collectively termed candidiasis. The various types of candidiasis are classified by their onset and appearance.

Oral candidiasis can be classified as acute or chronic. The acute form can present as pseudomembranous or

FIGURE 61.4. Periodontal disease. Note the bone loss and the elongated appearance of the lower teeth, as well as puffy or inflamed gums. Also note verrucous appearance of tissue below the gums due to smokeless tobacco.

atrophic. Chronic candidiasis can present as atrophic or hyperplastic. In older adults, the two most common types of candidiasis are acute pseudomembranous (traditionally called thrush) and chronic atrophic.

Thrush is characterized by white plaques described as having a curdlike appearance. Patients with *Candida* often complain of a burning mouth. Thrush can be found on any soft tissue in the oral cavity and pharynx, including the tongue. For diagnostic purposes, the white lesions can be wiped away with gauze, leaving an erythematous area under the white lesion. For clinical laboratory verification, a smear of the white lesion can be placed on a slide with 20% potassium hydroxide and viewed for hyphae. The presence of budding yeast and hyphae will confirm the presence of *Candida*.

Any condition compromising a patient's immune system or altering normal flora can be considered a risk factor for candidiasis. Oral candidiasis can occur with long-term use of medications such as antibiotics, steroid therapies, or chemotherapy. Diabetes mellitus, human immunodeficiency virus (HIV) disease, and head and neck radiation are risk factors for thrush.

Candidiasis located under a denture can be either atrophic or hyperplastic. It occurs as an erythematous area under a maxillary denture that vividly outlines the tissue covered by the prosthesis (Fig. 61.5). An ill-fitting upper denture is the most commonly cited risk factor. There is a decrease in the pH of the salivary film between denture and oral tissue from breakdown of carbohydrates (food debris) under a poorly fitting denture. This acidic atmosphere may be part of the etiology of the candidal overgrowth.³⁶ In patients without a prosthesis, chronic atrophic candidiasis may present as a generalized redness or even generalized burning of the mouth.

Because of the difficulty of identifying an area of tissue to scrape for a smear in this type of candidiasis, the

FIGURE 61.5. Chronic atrophic candidiasis. Note the dark outline of maxillary (*top*) denture on the palate.

FIGURE 61.6. Angular cheilitis caused by *Candida albicans* in the commissures of the mouth.

patient may also swish with sterile saline for 1 min. The saline is subsequently cultured for the *Candida* species and read as the number of microorganisms per milliliter.³⁷ Patients showing more than 75 to 100 organisms per milliliter should be considered for treatment.

Chronic atrophic candidiasis associated with denture use is usually accompanied by poor oral hygiene of both the oral tissue and the prosthesis. Many patients wear their prosthesis 24 h per day and therefore do not allow the tissue to heal from the fungal infection. Xerostomia, or dry mouth, can also predispose a patient to this type of *Candida* infection, which causes a burning sensation in the oral cavity.

When chronic atrophic candidiasis manifests itself in the creases or commissures of the lips, it is called angular cheilitis (Fig. 61.6); this occurs when a patient has a tendency to pool saliva around the corners of the mouth or, in some cases, constantly lick the lips. It presents as a red-dened or raw area in the commissures on either one or both sides.

Treatment for Oral Candidiasis

The treatment for all types of candidiasis includes an antifungal medication. Topical (nystatin, chlortrimazole troches) or systemic (ketoconazole, fluconazole) medications are available. Topical medications should be used for at least 14 days to assure total eradication of the fungus. If the infection is more widespread than just the oral cavity or does not subside within 3 to 6 weeks of topical treatment, then systemic medication may be necessary. Fluconazole is a good drug of choice because of its once-daily dosing regimen and minimal drug interactions compared with other systemic antifungals, but is also costly in comparison. Table 61.1 lists the various medications that are indicated for treating candidiasis, as well as prescription information and comments.

TABLE 61.1. Medications for treatment of oral candidiasis.

Medication	Prescription	Comments and cautions
Nystatin oral suspension 100,000 U/ml	Disp: 240 ml Sig: Rinse w/5 ml and expectorate qid × 14 days	*50% sucrose, which can be highly cariogenic in patients with natural teeth *Patient may swallow if candidiasis extends in GI tract beyond oral cavity
Nystatin powder	Disp: 1 billion units Sig: Mix 1/8 t to 1/2 cup water, swish for 1 min and expectorate qid × 14 days	*Can be mixed with sugar-free, noncarbonated drink *Sugar substitute may be added to water to improve taste *May be difficult to find in pharmacy
Nystatin ointment 100,000 U/g	Disp: 15 g Sig: Apply thin coat to inner surface of denture qid OR apply to corners of mouth qid × 14 days	*Used for denture stomatitis or angular cheilitis
Nystatin pastille	Disp: 28 pastilles Sig: Dissolve in mouth qid × 14 days	*Denture must be out when using pastilles or troches for medication to reach areas affected by denture stomatitis *May be hard to dissolve if patient has xerostomia
Chlortrimazole troches	Disp: 50 tabs Sig: Dissolve one tab in mouth 5 ×/day for 10–14 days	*Can also use OTC vaginal chlortrimazole troches: dissolve 1/2 troche in mouth bid × 14 days
0.12% Chlorhexidine gluconate	Disp: 1 bottle Sig: Swish with 1 capful for 1 min and expectorate bid × 14 days	*Can also be swabbed on affected areas *Can cause taste alterations and staining *Contains 12% alcohol, which may cause discomfort in xerostomic patients
Ketoconazole 100 mg	Disp: 14 tabs Sig: Take 1 tab/day × 14 days	Multiple drug interactions that must be assessed before prescribing
Fluconazole 100 mg	Disp: 15 tabs Sig: Take 2 tabs on day 1, and 1 tab each day for 13 days	Medication is expensive compared to other treatments mentioned
Soaking solutions for infected dentures	*1 teaspoon sodium hypochlorite to 1 C water *1/2 capful 0.12% chlorhexidine gluconate added to soaking liquid *Full solution mouthrinse containing cetylpyridinium chloride (Cepacol or Gum)	*Dentures must be soaked every night while treating oral cavity for denture stomatitis *Solution must be changed each evening before soaking

Both nystatin and 0.12% chlorhexidine gluconate are effective antifungal agents. However, if both are prescribed, they must be taken at different times of the day because, when taken together, the overall efficacy is decreased. The decreased efficacy may be the result of a precipitation reaction that renders both medications much less effective when used together.³⁸

Salivary Gland Pathology

Saliva has numerous functions in the maintenance of overall health and oral health. Saliva starts the digestive process by mediating taste acuity and combining food for further digestion. Saliva also lubricates and repairs the oral tissues to allow comfortable oral function and speech. It aids in maintaining the oral pH balance by buffering acids produced by oral bacteria, contains minerals that remineralize teeth, and provides mechanical cleansing and antimicrobial and antifungal activities.

For various reasons, salivary flow may be reduced. The subjective feeling of dry mouth is termed xerostomia. Table 61.2 provides a differential diagnosis for oral dryness. Xerostomia may be reversible or irreversible. Some xerostomic patients have salivary flow when stimulated (i.e., during eating), whereas others with glandular damage, such as Sjögren’s syndrome, have a greatly

reduced flow, even when stimulated. It is imperative to diagnose the cause of the oral dryness to appropriately select treatment.

Oral dryness can adversely affect oral tissues, both mineralized and soft tissues. Oral dryness can cause an increase in caries activity, alterations in taste and smell, or a decrease in the ability to comfortably speak, chew, or swallow. Patients with dry mouth are at increased risk for oral *Candida* infections. If the patient wears a removable prosthesis, lack of adequate saliva for lubrication can make the denture uncomfortable or sometimes impossible to wear without damaging the underlying soft tissue.

Medication Use and Xerostomia

Medication use is the most common cause of oral dryness. More than 400 medications currently prescribed have xerostomia as an adverse drug effect. The actual mechanism of xerostomia resulting from medication use is varied and often is not completely understood. Some, such as anticholinergics, have been linked to actual salivary reduction. Others may dehydrate the tissue, causing the feeling of oral dryness. It is important to note that, in most cases of drug-induced xerostomia, stimulation of the glands does produce adequate salivary flow, which is an important distinction between drug-induced xerostomia and xerostomia attributed to gland destruction caused by disease or radiation.

The effects of drug-induced xerostomia are also reversible. If the patient discontinues the medication or if their dosage is altered, salivary flow returns to the previous normal rates.³⁹ Methods to stimulate the salivary flow will help ease the patient's symptoms.

Treatment of oral dryness is dependent on the cause. In the case of medication-induced xerostomia, an evaluation of the causative drugs and possible dose or medication changes should be considered. Also, consider the dosing schedule so that the primary time of dryness is at night, during sleep, or close to mealtime when the patient will have more salivary stimulation to overcome the dryness.

Because medication-induced oral dryness is not the result of a destructive process within the gland, treatment directed at salivary stimulation will be helpful, including the use of sugarless chewing gums, sugarless candies, and flavored drinks that do not contain sugar or caffeine. Patients must also be advised to drink adequate amounts of water daily to avoid dehydration and to provide the major component of saliva, that is, water.

Salivary substitutes serve as a palliative measure. Most of these products do not stimulate salivary flow but do provide relief from the discomforts of xerostomia. An oral gel, such as Oralbalance (Laclede, Gardena, CA, USA), will help coat and protect the oral tissues, especially during the night. A gel can also be used daily under dentures to provide moisture and reduce friction.

Alcohol-free mouthwashes should be recommended for xerostomic patients to avoid oral tissue irritation. Caffeine and alcohol are both known to increase oral dryness and should be avoided by xerostomic patients. Because dry oral tissue may be both more sensitive and more fragile, a toothpaste with mild flavoring agents (avoid a strong peppermint or cinnamon flavoring) may provide relief from burning. A children's toothpaste may contain less of the flavorings associated with burning.

Most toothpastes contain fluoride (1100 ppm F⁻). For the patient with severe oral dryness and natural teeth, an additional at-home fluoride gel (5000 ppm F⁻) or high-fluoride toothpaste (5000 ppm F⁻) should be prescribed to prevent the severe tooth decay seen in these patients. Proper oral hygiene care is also essential to avoid the rapid carious breakdown that can occur without the adequate antibacterial protection of saliva.

Sjögren's Syndrome

Sjögren's syndrome is an autoimmune disorder characterized by an immune infiltrate of the exocrine glands, such as the salivary and lacrimal glands, that occurs primarily in middle-aged and older women. Individuals with the disease complain of both dry mouth and dry eyes. A diagnosis of Sjögren's syndrome with only dry eyes and dry mouth as symptoms is termed primary. If, however, there is an associated connective tissue disorder with these symptoms, such as systemic lupus erythematosus or scleroderma, it is termed secondary Sjögren's syndrome.⁴⁰

The inflammatory damage of this disease on salivary glands is irreversible. Many patients, however, do have some remaining residual gland function. For this reason, treatment for these patients should focus both on ways to stimulate their remaining gland function and on palliative measures to increase their comfort. Treatment options for stimulation and palliative relief already mentioned are also applicable for Sjögren's syndrome patients. Five milligrams of oral pilocarpine given four times daily has shown positive results in increasing salivary flow and decreasing xerostomic symptoms in Sjögren's syndrome patients.⁴¹ Contraindications for this medication include narrow-angle glaucoma and patients who suffer from respiratory problems. Because 5% to 10% of Sjögren's patients will progress to a systemic lymphoproliferation that may become malignant,⁴² it is important to monitor these patients for any suspicious changes. At increased risk of rampant caries, these patients should be seen regularly by a dental professional and encouraged to practice good daily oral hygiene care.

Bacterial Infection of Salivary Glands

Reduced salivary flow can sometimes lead to a bacterial infiltrate and subsequent infection within the salivary

FIGURE 61.7. Exudate caused by a bacterial infection expressed from the parotid gland duct.

gland and duct. Patients may present with pain within the gland, swelling of the gland, possible headache and fever, or a purulent exudate upon milking the salivary gland. The patient will complain of the pain worsening during mealtime (Fig. 61.7).

If not in the acute phase, this problem can be diagnosed using a sialogram. Infection is noted by the classic dilated duct with segmental strictures within the gland.⁴³ Bacterial infections are seen primarily within the parotid glands. If the gland is still functional, antibiotics may also be utilized in treatment. However, often antibiotics may not reach the duct where the bacteria are residing, and hydration and salivary stimulation are the only means of treatment to help flush the duct as much as possible.

Sialolith

Sialoliths are radiopaque stones seen primarily within the submandibular glands and are composed mostly of calcium salts that can form anywhere within the gland. Symptoms include swelling or pain in the gland. The swelling is often associated with salivary stimulation occurring at mealtime and during eating. Sialoliths may cause glandular blockage, which may require surgical removal of either the sialolith or the gland itself. Soft tissue radiographs in the area of glandular blockage may aid in diagnosing the sialolith.

Salivary Gland Tumors

Tumors can occur in salivary glands as in other parts of the oral cavity. The percentage of malignant salivary tumors varies according to the type of salivary gland; 90% of parotid tumors and 50% of submandibular tumors are benign, whereas only 10% of sublingual tumors are benign.^{44,45}

As with most oral cancers, pain is usually not present with salivary gland tumors. Indications of a salivary

tumor include nerve damage and paresthesia, rapid growth, fixation of the gland, and telangiectatic vessels over the tumor site.⁴⁶

Early diagnosis is an important factor in treatment outcomes. Most tumors of the salivary glands require excision of the gland with or without radiation therapy.

Mucocele

A mucocele is a surface swelling of the salivary gland due to trauma, a severed duct, or ductal blockage. These lesions occur primarily in the lower lip but may be seen wherever minor salivary glands are located, such as the palate, floor of the mouth, and tongue. They appear as a bluish or translucent swelling in the affected area. Deeper mucoceles may appear as nondescript swellings of normal color. These lesions may appear when the salivary gland is stimulated and not recede until the mucinous saliva is absorbed. Because the lesion often is traumatized before it has receded, causing the patient discomfort, the minor salivary gland is often removed to prevent further trauma in the area.

Radiation-Induced Xerostomia

If salivary glands are included in the radiation field for head and neck cancer, the result is most often destruction of much of the salivary gland, leading to radiation-induced xerostomia. Whole saliva (saliva collected from the oral cavity, which includes flow from all major and minor salivary glands) is usually measurably reduced at 2000cGy of radiation.⁴⁷ Along with all the negative sequelae of xerostomia described earlier, the altered oral environment can lead to rampant caries and loss of teeth.

Loss of glandular function from radiation is irreversible. The patient must learn to function with whatever salivary flow is remaining after therapy. Current research includes investigating materials that will block the radiation in the specific areas of the salivary glands, leaving some function intact.

Oral pilocarpine has been recommended both during and following radiation treatment, which includes that of the salivary glands. Research found that patients who received a 5-mg dose of pilocarpine three times per day had the best outcomes in terms of increased salivary production and relief of symptoms with minimal adverse reactions.⁴⁸ Another study proposed the use of 5 mg pilocarpine four times daily during and for a time following radiation treatment to decrease the damage and flow loss of salivary glands.⁴⁹

Disease Processes of the Temporomandibular Joint

The temporomandibular joint (TMJ) is a ball-and-socket joint with a cartilaginous disk between the skull and

mandible to aid in movement within the joint. Although complications with the TMJ decrease with increasing age, they are still present within the older population.⁵⁰ Many older adults exhibit sounds described as clicking, popping, or crepitus on joint manipulation. However, treatment is usually not initiated unless discomfort or pain is involved.

Symptoms of temporomandibular disorder (TMD) include pain in the area of the joint and inability to fully open the mouth. Symptoms range from vague or non-specific, such as diffuse pain of the head and neck, to vertigo, tinnitus, paresthesia, visual, and hearing disturbances.⁵¹

Loss of occlusal function may predispose a person to TMD pain. It has been shown that persons with missing teeth are more likely to have pain and clicking on the side with the missing teeth.⁵² Persons wearing dentures are also susceptible to TMD and should be evaluated if symptoms of the disorder are reported by the patient; however, edentulous patients without prostheses rarely report temporomandibular joint pain.⁵³

Acute and life-threatening causes of temporomandibular pain, such as malignancies or infectious processes, should always be considered in the initial differential diagnosis. Malignancies in this area are rare. The clinical signs would be similar to those listed for a parotid gland tumor. Infections of the TMJ are also rare and include pain and swelling in the area that has been distinguished from a parotid swelling, which is much more common as the result of Sjögren's syndrome or parotid gland infection. Due to the threat of intracranial spreading, aggressive treatment is advised for this type of infection.

Both osteoarthritis and rheumatoid arthritis affect the TMJ. Although osteoarthritis is the most common type noted in the TMJ, many patients do not exhibit pain or symptoms with this type of arthritis. Rheumatoid arthritis of the TMJ is seen primarily in younger women and usually occurs in conjunction with inflammatory responses in other joints. Common complaints with this type of TMD include stiffness, crepitus, tenderness, swelling, masticatory pain, hypomobility of the mandible, and, in severe cases, mandibular fixation.⁵¹ One study linked severe degradation of the TMJ from rheumatoid arthritis to upper airway obstruction in 70% of the cases with severe rheumatoid arthritis⁵⁴; this was hypothesized to result from an induced micrognathia-causing tongue retrusion that blocks the airway. During acute exacerbation of rheumatoid arthritis, the patient may benefit from decreased mandibular movement and a soft diet, along with pharmacologic therapy for rheumatoid arthritis.

Oral Cancer

Oral cancer refers to lesions of the lips, tongue, pharynx, and all other hard and soft tissue within the oral cavity.

Oral cancer accounts for 3% of all diagnosed cancers. The average age of diagnosis of oral cancer is 60 to 63 years. Men account for the majority of oral cancers, with 20,200 cases estimated in the year 2000, and 10,000 new cases estimated in women in the same year. Oral cavity and pharyngeal cancer are among the 10 leading sites for men, but not for women.⁵⁵ Although oral cancer has traditionally been considered a disease of older men, recent data have shown an increase in oral cancer rates in women, with the gender ratio of 6:1 (male to female) in 1950 changing to 2:1 (male to female) in 1980.⁵⁶

Unlike many other cancers, there has been little improvement in the mortality rate of oral cancer through the years. Even if mortality is avoided, the morbidity of this disease and the treatment can be very disfiguring.⁵⁷ Many patients suffer from decreased self-esteem due to altered appearance from radical surgery, a decrease in the ability to speak and masticate, and a severe decrease in saliva secondary to surgery or radiation therapy or both.

Use of alcohol and of tobacco are the primary risk factors for oral cancer. Sunlight is a risk factor for lip cancer. The combination of alcohol and tobacco use has been shown to have a multiplicative effect on the incidence of oral cancer, accounting for 75% of all oral cancers in the United States.⁵⁸

Oral cancer is primarily squamous cell carcinoma. (For the purpose of this discussion, oral cancer and squamous cell carcinoma are used synonymously.) The most common sites in men are the floor of the mouth (under the tongue) and the retromolar area (just behind the last molar teeth in the mandible). For women, the most common area is the gingiva. Other common sites include the lateral borders of the tongue and the soft palate area.⁵⁹

Oral cancer can present as a red or white lesion that does not heal. When performing an oral examination, the health professional should note anything that appears unusual. Oral cancer is rarely associated with pain. When a patient does present with pain or paresthesia associated with a cancerous lesion, it usually suggests invasive disease.

Although white lesions, or leukoplakia, are common in older adults, their cause should always be diagnosed. If there is no obvious cause for the leukoplakia, such as friction or trauma, then the lesion should be biopsied if it has not resolved within 1 to 2 weeks.

Red lesions (erythroplakia), red and white mixed lesions, and ulcerations without pain should be held as highly suspicious. Again, if resolution of the lesion is not noted within 1 to 2 weeks, a biopsy should be performed to confirm or rule out oral cancer.

Oral Examination

Currently, early detection is the most effective way to reduce the mortality and morbidity associated with oral

cancer. Because the mouth is easily accessible, physicians and nurses should include a routine oral cancer screening as part of the physical examination for all older adults.

To efficiently perform an oral examination, a focused source of light, a tongue blade, and gauze are all that are required. These instruments are readily available in most examination rooms. The examiner should always wear gloves when conducting an oral examination.

As any other part of the physical examination, an oral examination should proceed in a systematic and consistent manner. Emphasis should be placed on the areas where oral cancer most often occurs, which are the areas where saliva would pool. These areas include the floor of the mouth, lateral borders of the tongue, retromolar area (area behind the last molar tooth on the bottom arch), and soft palate. The examiner should first examine the buccal mucosa for red, white, and ulcerative lesions or any swellings that cannot be readily explained. From the buccal mucosa, the examiner should proceed to the hard and soft palate. The tongue blade should be used to manipulate the tissue, as well as to hold the tongue to adequately view the soft palate. The examiner should be sure to fully visualize the soft palate and oropharynx by asking the patient to stick out the tongue and say "ah," while depressing the tongue with the tongue blade. The examiner should also view the floor of the mouth, retromolar area, and lateral borders of the tongue. The lateral borders of the tongue can be best seen by asking the patient to stick out the tongue. The examiner then holds the tongue with a gauze and moves the tongue from side to side so that the most posterior lateral borders can be visualized (Fig. 61.8).

Just as patient self-examination has become an important part of other cancer prevention campaigns, oral cancer prevention may also benefit from teaching

patients the warning signs of oral cancer and how to examine their mouth during daily oral hygiene care.

Soft Tissue Lesions Common in Older Adults

Soft tissue lesions are common in older adults, most with identifiable causative factors. The most common lesions noted in older adults are ulcerations, white or leukoplakic areas, and maculopapular lesions (to be discussed with ill-fitting prostheses).⁶⁰

Oral Ulcerations

Ulcerations are most often associated with trauma, and patients usually present with a complaint of pain. The most common sites for oral ulcerations include the tongue, lips, buccal mucosa, and gingiva.⁶⁰ Many ulcerative lesions in older adults are associated with an ill-fitting or broken prosthesis (denture). Risk factors that make a patient more susceptible to ulcerations under a prosthesis include diabetes, xerostomia, and a compromised immune complex. Patients who have received radiation therapy encompassing either the mandible or maxilla are at high risk for oral ulcerations that may lead to osteoradionecrosis. For this reason, a dentist may choose to wait up to 1 year after radiation therapy before making removable prostheses. Fractured teeth may also cause ulcerations, and patients should be referred to a dentist for treatment.

As stated earlier, an ulceration that is painless or does not heal within 1 to 2 weeks should be biopsied to rule out cancer. Painful lesions will usually cease being painful in 3 to 4 days and completely heal within 7 to 10 days following removal of the source of irritation. Any treatment is usually palliative, consisting of an emollient with a topical anesthetic.

If no source of trauma is noted and the lesion is located on unattached tissue (tissue not directly attached to bone), the diagnosis may be recurrent aphthous ulcerations. Patients will give a history of recurrence of these lesions. The exact etiology is unknown, but stress plays an important factor in reoccurrence. The lesions are small and self-limiting, healing in 7 to 10 days. Treatment, if necessary, is usually palliative. On rare occasions these ulcerations may become quite large (major aphthous ulcerations) and require systemic steroids or surgery for proper healing.

Lichen planus is a chronic inflammatory mucocutaneous disease that has been suggested to be an autoimmune disorder. It may be initiated by stress, drug hypersensitivity, bacterial or viral infection, or a genetic predisposition.⁶¹ Biopsy of a lesion is required for definitive diagnosis of the disease. The lesions often appear as eroded or ulcerative areas surrounded by white lines radiating from the ulcerations in a lacelike pattern. These

FIGURE 61.8. Correct retraction of tongue to assure complete observation of posterior lateral tongue reveals an oral cancer lesion.

FIGURE 61.9. Lichen planus. *White arrow* indicates white stria (Wickham's stria), which radiate from a red central lesion (*black arrow*) in a lacelike pattern on the buccal mucosa.

white lines, called Wickham's striae, are characteristic of this disorder (Fig. 61.9).

Lesions are seen primarily in the buccal mucosa, gingiva, and tongue and less frequently on the lips and hard and soft palate. Erosive painful lesions are noted during exacerbations of the disease, often from a source of local or systemic stress. Secondary *Candida* infection may occur during exacerbations.

Treatment during exacerbations is a topical steroid applied to the lesions after they have been gently dried. Three topical medications of choice include fluocononide gel 0.05%, triamcinolon acetonide in gel base 0.1%, and clobetasol propionate ointment 0.05%. All these should be applied three times daily and at bedtime. Various topical antihistamines and topical anesthetics have also been suggested to help ease the symptoms. If the symptoms worsen, or are not responding to topical treatment, systemic steroids may be used.⁶² Diagnosis and treatment of oral candidal infections should be done regularly for patients suffering with lichen planus.

Leukoplakia

Leukoplakia, a white plaque on the oral tissue, is most often attributable to chronic friction resulting in a hyperkeratotic lesion. It is often seen under a denture or on the lateral borders of the tongue. Again, oral cancer should be ruled out. If the cause of the lesion is known, treatment of the lesion consists of removing the source of trauma or friction. If the lesion is raised and causing discomfort for the patient, its excision may be necessary.

Burning Mouth

Burning mouth or burning tongue is primarily seen in middle-aged and older women. The exact etiology is

unknown and may be varied or multifactorial. The primary symptom, as the name describes, is a burning sensation in the oral cavity. It may manifest as a diffuse burning within the mouth or a localized burning, often specific to the tongue.

The most common cause of a burning mouth is an oral *Candida* infection. Oral *Candida* should be ruled out before considering other causes. Burning mouth has also been associated with chronic or severe xerostomia, vitamin B deficiency, diabetes mellitus, hematologic deficiencies such as iron, nonfunctional oral habits, allergies, and peri- and postmenopause.⁶³

Treatment is based primarily on proper evaluation of etiology. Treatments include antifungal medications, vitamin or iron supplements, and improved oral hygiene of both natural and prosthetic dentition. Treatment for the xerostomia, which is described elsewhere in this chapter, may help decrease the burning or discomfort. A dentist should be consulted.

Treatment as simple as smoothing roughened tooth surfaces or fabricating a splint to protect the tongue from rubbing on the teeth, may help ease the discomfort. A patient's oral hygiene regimen should always be evaluated to look for products to which the patient may be sensitive. Possibilities include products with cinnamon, tartar control toothpaste, or even strong flavorings. It is sometimes helpful to have the patient switch to a milder flavored children's toothpaste that still contains fluoride. Some postmenopausal women suffering from burning mouth and with no other noted etiology have found relief after implementation of estrogen replacement therapy.⁶⁴

Oral Lesions Associated with Protheses (Dentures)

For this discussion, protheses refers to removable dentures, either full or partial, made to replace natural teeth and enhance oral function. A full or complete denture replaces all the teeth in an arch. A partial denture replaces some teeth, and the remaining teeth help to retain the partial denture.

Most oral problems attributed to protheses are due to an ill-fitting prosthesis. Natural teeth serve as the main stabilizing factor in maintaining mandibular and maxillary osseous ridges. When teeth are removed, most persons lose some alveolar bone when functional stress is placed on the ridge. This loss of bony support is a primary factor for an ill-fitting prosthesis. Other factors that may cause oral lesions include need for adjustment after placing a new prosthesis and poor oral hygiene causing a *Candida* infection.

Ulcerative lesions caused by trauma from ill-fitting protheses and their treatment were discussed earlier in this chapter. (See Ulcerative Lesions.) When a prosthesis does not fit in the border areas (the edge of the denture),

fibrous connective tissue can form to protect the area from chronic trauma. This overgrowth of tissue is termed *epulis fissuratum* or chronic fibrous hyperplasia. It usually appears as an overgrowth of tissue where the denture fits in the mouth. There may or may not be an associated ulcer, depending on the duration of the lesion. The lesion may shrink with removal of the overextended border of the denture, but it usually does not completely resolve. Before a new denture is made, this lesion should be removed to ensure a properly fitting prosthesis.

Papillary hyperplasia is a lesion described as multiple papillary nodules primarily covering the palate vault. It is usually erythematous or red in color, painless, and not associated with dysplasia. It is a reactive lesion caused by an ill-fitting prosthesis and is sometimes linked to candidiasis. Treatment includes having the patient remove the prosthesis for at least 6h each day or night, proper hygiene of the prosthesis and underlying soft tissue, and treatment of candidiasis, if present. The patient should be counseled on the need for a new prosthesis.

Oral Manifestations of Systemic Disease

In addition to the previously described primary oral diseases, many systemic disease can present oral manifestations.

Arthritis

Arthritis is currently the most prevalent chronic condition in older adults in the United States. Arthritis can have temporomandibular manifestations, as described earlier in this chapter. A more common oral problem is decreased oral hygiene abilities. Patients with hands deformed from rheumatoid arthritis may be unable to grip or maneuver a toothbrush or floss. For patients with such problems, devices are available to assist with brushing and flossing. Referrals or consultations with dental professionals will assist physicians and nurses in preventing the patient's arthritis from causing additional oral disease.

Stroke

Stroke is the third leading cause of death in the United States.⁴ Paralysis of extremities and speech impairments, two of the residual effects of strokes, are among the most common chronic impairments of the older adult population. Both dentate and edentulous persons are at risk for oral sequela of stroke. These risks include swallowing disorders, a decrease in oral motor function, decreased oral hygiene abilities, oral numbness or sensitivity, an alteration in the ability to wear a prosthesis, and altered bite or occlusion.

Decreased swallowing ability can lead to aspiration and the possibility of an aspiration-type pneumonia.

Eighty-five percent of patients surviving a stroke have been found to have swallowing abnormalities of either the oral or pharyngeal stage.⁶⁵ Dental professionals should be advised of a patient's swallowing disorder to avoid the risk of aspiration of fluids during dental treatment.

The residual hemiparesis associated with a stroke can result in decreased oral hygiene abilities. The guiding principle in dentistry is if a patient can be taught to feed themselves then the patient can be retaught oral hygiene skills. A patient may need some assistance from a caregiver during the rehabilitation period. The patient should be evaluated for competence in providing oral hygiene and be referred to a dental professional, if necessary.

Poststroke patients will sometimes present with very poor oral hygiene or food packing on the affected side. Although patients may report brushing or caring for their mouth, they seem unaware of this food buildup. Loss of sensation on the affected side may account for this condition (Fig. 61.10). Oral hygiene should be monitored after a stroke and the patient informed if this problem is noted. The patient or a caregiver may need to visually check this area after the patient brushes or eats to ensure that the food has been removed. Because poststroke patients may also have increased pain sensitivity or numbness in the oral cavity, it is important to have periodic oral examinations to rule out infections or oral lesions.

Current recommendations suggest delaying elective dental treatment for 6 months poststroke. The time varies according to an individual's rehabilitation progress. It is optimal for the patient to have regained the maximum amount of oral motor function before denture fabrication to achieve a properly fitting prosthesis.

FIGURE 61.10. Denture with one-half covered with food debris on the affected side in a poststroke patient.

FIGURE 61.11. Dried oral secretions in the palate (roof of the mouth) of a patient who breathes through his mouth and is fed parenterally.

Often after a stroke, an edentulous patient with full removable prostheses will complain that the prosthesis no longer fits. The patient may have lost weight during an extended hospital stay, causing a decrease in the adipose pads of the maxilla, leading to a loose maxillary prosthesis. More often, however, the muscles that once accommodated a slightly ill fitting prosthesis before the stroke are no longer compensating for the poor fit after the stroke. The treatment in either case requires the dentist to temporarily reline the denture by adding a soft material to the tissue side of the denture until the patient is able to undergo more definitive treatment.

Good oral care should be maintained as well for patients who are nonresponsive or using parenteral nutrition. Because many are at high risk for aspiration of secretions, the oral flora should be reduced as much as possible. If a patient is unable to brush their teeth, the caregiver may swab an antimicrobial in the oral cavity daily to reduce the aspiration risk.

Another oral problem occurring in patients with difficulty swallowing and who are mouth breathers is drying oral tissues and secretions (Fig. 61.11). Dried oral secretions should be removed at least two times per day with a wet gauze. After the secretions are removed, the caregiver may swab the tissues with a small amount of a lubricating gel or a water-soluble lubricant.

Dementia

Oral health should not decline simultaneously with cognitive function.⁶⁶ Unfortunately, a large percentage of patients suffering with dementia also suffer from various oral diseases. Because of the increasing cognitive decline expected as the disease progresses, physicians and nurses must assist caregivers in reminding them to provide daily oral care as part of their 36-h day. This plan may begin

with a referral to the dentist to obtain needed dental care early in the course of the disease. The caregiver can provide daily reminders to the patient to perform daily oral hygiene. During the latter stages of the disease, the caregiver must provide total oral care for the patient.

Food packing in the buccal pouches of the maxilla often occurs in dementia patients, causing an increase in caries and an increase in the susceptibility to oral infections. Research suggests that dementia patients may have an increased craving for sweets, also increasing their risk for dental caries.⁶⁷ The increase in caries risk, coupled with decreased oral hygiene abilities, suggests the need for an aggressive preventive dental plan.⁶⁶ This plan can include daily oral hygiene care and use of a prescribed at-home fluoride gel or high-fluoride toothpaste and chlorhexidine mouth rinse.

Many patients with later stages of dementia may not communicate pain effectively to caregivers and subtle signs must be investigated. For all these reasons, scheduled oral exams should be performed for these patients, at a minimum of once per year.

Because of the progressive nature of this disease, early intervention and planning are key to maintaining oral health. Dental treatment in the early stages should be aggressive, knowing that treatment may not be possible in the later stages. If removable prostheses are made, two sets may be fabricated in case of loss in later stages of the disease. Prostheses should be labeled with the patient's name in case the patient misplaces the dentures. In the later stages of dementia, it may be necessary to remove the prosthesis if the patient no longer tolerates it. A removable partial denture may become a danger to the oral cavity if the patient can no longer place it in their mouth properly as it may puncture the lip or other soft tissue with the metal projections or clasps. Some patients, however, feel comfortable wearing their prosthesis until very late in the disease; this should always be evaluated on an individual basis. Often it is difficult for family members to see the patient without the prosthesis.

Nutritional Deficiencies and Oral Health

Nutritional deficiencies can cause oral symptoms, and poor oral health can lead to decreased nutritional intake.¹⁶ For example, malnutrition and zinc deficiency may result in increasing susceptibility to periodontal disease. Poor food choices, such as softer foods that may be easier to chew with compromised dentition, may also be more cariogenic.

Changes in the tongue, such as reddening, balding, and burning are associated with deficiencies in B₁₂ and iron. Mucosal pallor may be due to anemia. Hyperkeratosis of soft tissue may be seen with a deficiency of vitamin A, and gingival inflammation, such as acute gingivitis, may be associated with vitamin C deficiency.

Systemic Sequelae Requiring Antibiotic Prophylaxis

The American Heart Association (AHA) periodically reviews and publishes standardized guidelines for antibiotic prophylaxis for the prevention of bacterial endocarditis.⁶⁸ These guidelines speak specifically about dental procedures and prophylaxis needs. Table 61.3 lists specifics of the latest recommendations.

Although a 91% efficacy has been shown for endocarditis prophylaxis in patients with prosthetic heart valves,⁶⁹ the AHA guidelines are not always followed. Researchers from one study found that only 22% of the cases identified as needing antibiotic premedication before invasive procedures were premedicated according to the guidelines.⁷⁰ This issue is still somewhat controversial. Strom et al., in 1998, through a population-based, case-control study, concluded that even with 100% effectiveness of antibiotic prophylaxis preceding invasive dental care, few cases of infective endocarditis would be prevented.⁷¹ However, at this time the standard of care is still the AHA recommendations (see Table 61.3).

Of even greater controversy is the issue of antibiotic premedication before dental care for patients with prosthetic joints. The evidence that links dental procedures with the failure of prosthetic joints is highly debatable. Most infections around a joint prosthesis are staphylococcal organisms, yet most transient bacteremias secondary to dental manipulation are streptococcal in nature. Even the choice of antibiotic is questioned, because although a penicillin would be the choice for a dentally

induced bacteremia, a first-generation cephalosporin is the choice of most physicians.

In 1997 the American Dental Association and the American Academy of Orthopedic Surgeons produced an advisory statement that was published in the *Journal of the American Dental Association*.⁷² Both organizations recognized the fact that not all patients with a prosthetic joint share the same high risk for failure. The joint statement recognized that patients with such systemic complications as immunosuppression, poorly controlled diabetes, history of previous joint failure, malnourishment, hemophilia, and a joint placed as recently as 2 years earlier all increase the possibility of joint failure. Their recommendation for a drug regimen is the same as the AHA guidelines for premedication for bacterial endocarditis because of the nature of the bacteremias most often seen from a dental procedure.

Oral Problems Resulting from Medical Treatment

Oral Adverse Drug Reactions

With the increase in the number of older adults with chronic diseases in the United States, medication use by older adults will continue to increase. As a result, adverse drug reactions or oral complications of medication use may also increase. An assessment of the top 22 medications in the United States shows that 79% have oral adverse drug reactions listed. The three most common

TABLE 61.3. Antibiotic prophylaxis (AP) for prevention of infective endocarditis (IE): conditions and regimens.

	AP recommended	AP not recommended
Cardiac conditions	<ul style="list-style-type: none"> • Prosthetic cardiac valves • Previous IE • Most congenital cardiac malformations • Surgically constructed systemic pulmonary shunts and conduits • Acquired valvular dysfunction (ex. rheumatic heart dx) • Hypertrophic cardiomyopathy • Mitral valve prolapse with valve; regurgitation or thickened leaflets 	<ul style="list-style-type: none"> • Isolated secundum atrial septal defect • Surgical repair of atrial septal or ventricular septal defects or patent ductal arteriosus • Previous coronary artery bypass graft surgery • Mitral valve prolapse without valvular regurgitation • Physiologic, functional or innocent murmurs • Previous Kawasaki dx without valvular dysfunction • Previous rheumatic heart dx without valvular dysfunction • Cardiac pacemaker and defibrillators
Dental procedures	<ul style="list-style-type: none"> • Tooth extraction • Periodontal procedures • Dental implant placement • Root canal • Intraligamentary local anesthetic injections • Dental prophylaxis 	<ul style="list-style-type: none"> • Fillings not near the gingival • All other local anesthesia injections • Suture removal • Prosthesis fabrication steps • Fluoride treatment • Taking radiographs

Recommended oral regimens: Amoxicillin, adult dose 2.0g 1h before dental procedure; for patients allergic to penicillin, clindamycin, adult dose 600mg 1h before dental procedure; cephalixin, adult dose 2.0g 1h before dental procedure; azithromycin or clarithromycin, adult dose 500mg 1h before dental procedure.

oral side effects are xerostomia, taste alteration, and stomatitis.⁷³

Tardive dyskinesia, an oral movement disorder, results from neuroleptics, lithium, antipsychotics, and antiparkinson agents. Tardive dyskinesia, unlike most oral adverse drug reactions, is usually irreversible. Gingival overgrowth can result from the use of calcium channel blockers, phenytoin, and cyclosporins. For these patients, good oral hygiene is imperative to reduce the risk of severe periodontal disease and caries.

Patients on anticoagulation therapy may be at risk for excessive bleeding during surgical dental procedures. If the patient's international normalized ratio (INR) is below 3.0 and the surgery is limited to a single tooth extraction or deep scaling or cleaning of only one-quarter or one-half of the mouth, the treatment is most likely feasible without alteration of the anticoagulation therapy. If however, the oral surgery consists of more than one tooth extraction, periodontal surgery, or implant surgery or the patient has further risk factors for excessive bleeding, cessation of the anticoagulation therapy for at least 3 days may be required. If the patient is unstable and stopping anticoagulation is not feasible, consideration should be given to hospitalizing the patient to switch therapy to heparin, which has a shorter half-life and can be stopped for the minimal amount of time during the dental procedure and immediately postoperatively. Over-the-counter medications, such as aspirin and nonsteroidal anti-inflammatories, can also cause an increased bleeding time that can pose problems during dental treatment.

The systemic effects of chemotherapy for malignant lesions include oral manifestations due to the myelosuppressive and cytotoxic effects, which include mucositis, or inflamed and tender oral tissues, primarily resulting from the high mitotic rate of the oral epithelium and its sensitivity to the chemotherapy. Oral infections, including fungal infections, and bleeding are increased because of bone marrow suppression and overall immunosuppression. Fifty percent of patients undergoing chemotherapy for leukemia experience oral complications, and the percentage for patients undergoing chemotherapy for lymphomas and carcinomas is 33% and 12%, respectively.^{74,75}

Good oral health before the chemotherapy begins will help prevent many oral infections. If dental treatment is required during chemotherapy, it is essential to treat either immediately before or after an episode of chemotherapy, when the immunosuppression effect is at its lowest.

Research has shown that placing patients on a 0.12% chlorhexidine gluconate rinse during chemotherapy can both reduce the severity of the mucositis and help resolve the mucositis more rapidly.⁷⁶ Palliative treatment for stomatitis include rinses such as 1/2t salt, 1/2t soda, and 1 quart of water; a 50:50 mixture of diphenhydramine and kaolin-pectate; and for existing ulcerative lesions,

sucralfate suspension. If oral hemorrhagic oozing occurs easily, the patient may be required to use a very soft toothbrush or to swab the teeth with chlorhexidine to avoid bleeding from brushing but still remove oral bacteria.

Oral adverse effects from head and neck radiation include osteoradionecrosis of osseous tissue, xerostomia, rampant caries, mucositis, trismus, altered taste, and an increased susceptibility to oral infections. Osteoradionecrosis, the sloughing of injured or dying bone, can affect large areas of the jaw due to suppressed osteoblastic activity and a decrease in the bony vascularity caused by hyalinization of the vessels and endarteritis. The mandible is the most susceptible oral osseous structure because of its density. Risks for osteoradionecrosis include extractions, trauma, or even ulcerations from wearing a prosthesis. Signs and symptoms include pain, exposure sloughing, and suppuration of the osseous tissue.

Before initiating radiation therapy to the head and neck, a thorough dental evaluation is essential. All sources of oral infection should be treated aggressively. Xerostomia and mucositis may be treated as listed in other sections of this chapter, although the therapeutic benefit of 0.12% chlorhexidine to prevent mucositis from radiation therapy has been questioned.⁷⁶ Patients who have had teeth removed before head and neck radiation therapy are usually required to wait 1 year after therapy to help decrease the risk of severe bone destruction due to osteoradionecrosis from ulcerations that often occur while wearing a new prosthesis. Good oral hygiene must be a lifetime commitment for the postradiation patient with remaining teeth to avoid the rampant tooth decay and risk of osteoradionecrosis that will always be present.

With the addition of the baby boomer seniors, who are retaining their natural teeth longer, there will most likely come an increase in the prevalence of oral disease and infection seen in geriatric patients. It is imperative that all health care providers understand the symbiotic nature of good oral health and good systemic health. The good news is that, unlike many of the chronic conditions faced in later years, oral disease is preventable and in most cases curable.

Dietary Supplements for Geriatric Patients

Cynthia X. Pan and Charles Mobbs

Information about the safety and efficacy of nutritional supplements is increasingly important to the geriatrician because these supplements are widely used by elderly patients, often without the knowledge of their physicians, yet the use of such supplements can have deleterious effects, including interference with prescribed drugs. Recent studies indicate that adults are increasingly using nutritional supplements such as herbal therapy¹ and other forms of complementary/alternative medicine (CAM) in the United States.²⁻⁴ Several epidemiologic studies spanning different nations suggest that older individuals of both sexes use such therapies.^{2,5-7} In a study of more than 1000 patients who complained of "arthritis," one-third had received treatment from a nonorthodox medical practitioner.⁸ Risberg et al. noted that 20% of a population of hospitalized cancer patients used alternative medicine.⁹ A 1995 study of 101 primary caregivers of dementia patients found that 55% of caregivers attending support groups had tried at least one type of alternative therapy in an attempt to improve the memory of the demented individual for whom they were caring.¹⁰ A Canadian telephone survey of 115 caregivers and patients (with dementia) found that 9.6% of the patients were using complementary medicine as a treatment to help with their memory or thinking problems.¹¹

More recent data reveal CAM use patterns in older adults. In a cross-sectional survey examining patterns of complementary therapy use in urban multiethnic populations, 421 older participants were interviewed at two sites: an academic geriatrics primary care practice and a veterans medical clinic.¹² Fifty-eight percent (58%) of all subjects surveyed used some form of CAM, almost 75% at the academic practice alone. In a national survey of Californians enrolled in a Medicare risk product that offers coverage for acupuncture and chiropractic care, surveys were sent to 1597 members and responses received from 728 (51% response rate). Forty-one percent of seniors reported use of CAM. Herbs (24%), chiropractic (20%), massage (15%), and acupuncture

(14%) were the most frequently cited therapies. Respondents also expressed considerable interest in receiving third-party coverage for CAM. Although 80% reported that they had received substantial benefit from their use of CAM, the majority (58%) did not discuss the use of these therapies with their medical doctor.¹³

The widespread use of nutritional supplements in elderly patients was corroborated by a study of one of the authors (Pan), who conducted a multisite survey of 503 patients aged 65 and older.¹⁴ This survey included a diverse population whose mean age was 77 years; 50% were white, 34% African-American, and 13% Hispanic-American. Approximately 57% of respondents used some form of complementary therapy within 12 months of being surveyed, of which 35% consisted of dietary supplements and another 35% was herbal supplements. The most common herbal supplements used were garlic, ginkgo, fish oils, ginger, and ginseng, and the most common vitamin supplements used were vitamin E, vitamin C, the B vitamins, and carotenes/vitamin A. Physicians increasingly may be called upon by patients to advise them about the use of nutritional supplements. Physicians also need to be aware of potentially hazardous interactions between supplements and drugs and when appropriate should ask patients specifically about the use of such supplements. Nevertheless, despite the widespread use of herbal treatments, a recent survey indicated that only about half of responding physicians reported discussing complementary, including herbal, therapies with their patients.¹⁵ Another study compared results of a convenience sample survey of older adults with documentation in medical charts.¹⁶ Authors measured the proportion of CAM supplements and herbs (CAMsh) reported by patients *also* documented in patients' charts: only 35% of all self-reported supplements were documented in the charts. Of 182 patients, 46% reported taking CAM with anticoagulant properties: of these, 52% took a prescribed anticoagulant (per chart). This lack of knowledge of patient use of herbal and dietary sup-

TABLE 62.1. Internet (Google) searches: January 2001.

	Health	Cholesterol	Cancer	Memory	Fatigue
Garlic	181,000	91,000	60,800	45,000	28,200
<i>Ginkgo biloba</i>	12,600	2,900	4,600	3,000	2,490
Fish oils	99,100	17,000	29,000	7,000	10,000
Ginseng	102,000	32,000	39,700	33,000	35,000

^aMany discussed how St. John's wort can interfere with cholesterol-lowering drugs.

plements can have potentially serious and lethal consequences.

Garlic (*Allium sativum*)

Garlic (*Allium sativum*) is a common folk remedy for many conditions, as well as a ubiquitous component in food preparation. One index of popular interest of supplements is a simple search on the Internet of the supplement combined with various health concerns such as "health," "cholesterol," "cancer," "memory," and "fatigue" (Table 62.1). Of the supplements we searched, garlic was one of the most popular, particularly in connection with cholesterol.

Although garlic has been reported to improve certain cardiovascular risk factors, especially cholesterol, there is currently no evidence that these effects translate into reduction of morbidity or mortality. A recent meta-analysis concluded that garlic preparations may reduce plasma cholesterol, a finding not seen in some small well-designed studies. Therefore, the cholesterol-lowering effect of garlic is likely to be weak and requires a highly powered study to demonstrate a significantly positive effect.¹⁷ Conversely, another report indicated that although the trial failed to demonstrate an effect of garlic powder on plasma cholesterol levels,¹⁸ meta-analysis of previous data supported that garlic probably can have a beneficial effect. Another well-designed double-blind placebo study did find a significant effect of a garlic preparation on reducing total serum cholesterol as well as low-density lipoprotein and blood pressure.¹⁹ Similarly, an uncontrolled study indicated that daily consumption of a fresh garlic clove for 16 weeks reduced serum cholesterol

by 20%, but also reduced serum thromboxane a remarkable 80%.²⁰

Earlier meta-analyses had reported that garlic reduced cholesterol by about 12%²¹ or 9%.²² However, observing effects on potential risk factors may not predict clinical outcomes [such as coronary artery disease (CAD), myocardial infarction (MI), and mortality]. For example, a meta-analysis in the Cochrane review series has concluded that the use of garlic has no significant effect on at least one cardiovascular outcome, peripheral occlusive arterial disease.²³ In terms of garlic for cancer, a recent meta-analysis of epidemiologic evidence concluded that the evidence supports that high intake of both raw and cooked garlic may protect against stomach and colorectal cancer.²⁴ However, there have been no clinical trials to study this conclusion. All these data should be framed in the context of a 1998 ruling²⁵ that the U.S. Food and Drug Administration (FDA) issued prohibiting the use on foods of a claim relating to the relationship between garlic, decreased serum cholesterol, and the risk in adults of cardiovascular disease.

The use of garlic provides a good example of the issues faced by practitioners on the subject of nutritional supplements. First, garlic represents the most commonly used nutritional supplement, probably because it is a common component of cooking. For this reason, garlic is perceived as safer than most herbal nutritional supplements. Second, there is a literature substantiating that the use of garlic as a nutritional supplement (specifically entailing the consumption of fresh garlic or garlic powder at levels far exceeding levels normally consumed in food) produces clinically desirable effects, especially on plasma cholesterol, although similar controlled trials on cancer prevention have not yet been undertaken. Thus, when a patient asks about the advisability of consuming garlic, the answer is not clear-cut. In general, relatively high-level consumption of garlic is unlikely to cause harm and may marginally reduce plasma cholesterol. In patients with clinically significant hypercholesterolemia, numerous treatments, including weight loss and pharmacologic intervention with statins, are far more likely to produce clinically significant effects. The main concern of the clinician is that the use of garlic as a nutritional supplement may produce a false sense of security in some patients and undermine their compliance with clinically more efficacious treatments. Clinicians also need to advise patients about garlic halitosis, expense issues, and potential drug-herb interactions, such as with warfarin.²⁶

Ginkgo biloba

Extracts from the leaves of the ginkgo biloba tree have been used in traditional Chinese medicine to treat a variety of ailments associated with "cerebral insuffi-

ciency.” In comparison with most of the other supplements reviewed here, which average around 100,000 hits when searched with the word “health,” ginkgo appears to be of much less popular interest, at least as reflected in Web pages. Ginkgo use does hold a special place in geriatric medicine, however, because of its positive effects in treating cognitive impairment associated with dementia.

For more than a decade the effectiveness of ginkgo extracts to improve cognitive function in dementia has been extensively studied, and such extracts have even been approved for the treatment of dementia in Germany.²⁷ A meta-analysis of these studies concluded that ginkgo extracts do improve cognitive symptoms in dementia, although the effects are modest.²⁸ Consistent with that analysis, a later study also concluded that ginkgo in the form of the EGB761 extract produces effects in patients with Alzheimer’s disease, as measured by the Alzheimer’s Disease Assessment Scale–Cognitive subscale (ADAS-Cog) scale, that are comparable to those produced by cholinesterase inhibitors including tacrine,²⁹ furthermore, EGB761 use resulted in a lower dropout rate than tacrine.²⁹ A recent large trial reached a similar conclusion.³⁰ This trial was a double-blind, placebo-controlled, parallel group, and multicenter study on mildly to severely demented patients with either Alzheimer’s disease or vascular dementia. The patients’ mean age was 69 years, and their Mini-Mental Status score ranged from 9 to 26. The extract EGB761 was used at 120mg/day in three divided doses and given for 26 weeks. The extract stabilized and modestly improved patients’ cognitive performance and social functioning. The findings were documented objectively by ADAS-Cog and noticed by caregivers. The study’s conclusions are valid mostly for Alzheimer’s disease patients with mild to moderate cognitive impairment. However, another study found no effect of treatment with higher doses of the same extract given for 12 weeks.³¹ Thus, one may need to take ginkgo for a long period of time (e.g., 26 weeks) to observe an effect. In terms of ginkgo extracts for fatigue, no randomized, placebo-controlled double-blind trials exist to date.

In conclusion, the EGB761 preparation of ginkgo produces real but modest improvements in cognitive function in individuals with mild moderate cognitive impairment, probably comparable to that produced by tacrine or other cholinesterase inhibitors. Ginkgo extracts may be better tolerated by some patients than cholinesterase inhibitors, so in those patients it may be the treatment of choice. It is essential to emphasize, however, that no current treatment, including Aricept and other prescription drugs, produces more than a slight delay in the deterioration of cognitive function in Alzheimer’s disease or other dementias.

Fish Oils (3-Omega Fatty Acids)

Interest in fish oils, especially omega-3 fatty acids (including eicosapentaenoic acid and docosahexaenoic acid), was stimulated by epidemiologic findings that indigenous Inuit people in Greenland were often obese but suffered lower than expected levels of cardiovascular complications, apparently due to a diet consisting mainly of fish.^{32,33} The highest ranked of our Internet searches reviewed published data reporting beneficial effects of omega-3 fatty acids on a rather large variety of clinical conditions, especially related to cardiovascular function and cancer. It is interesting that although the Web pages exhibit greater popular interest in the use of fish oils to prevent or reduce cancer, there are far more scientific data to support a role in cardiovascular disease risk reduction.

Recent meta-analyses of controlled clinical trials confirm that use of omega-3 fatty acids up to 3g/day for 3 to 24 weeks produced clinically significant reductions in blood pressure.^{34,35} Similarly, a recent meta-analysis concluded that consumption of omega-3 fatty acids, especially eicosapentaenoic acid and docosahexaenoic acid, produced clinically significant reduction of triglycerides in diabetic patients.^{36,37} Despite these data, the position of the FDA, as of 1998, was typically cautious, and prohibited a claim by commercial vendors that consumption of omega-3 fatty acids would produce cardiovascular benefits.³⁸ Nevertheless, while the literature supports that consumption of omega-3 fatty acids up to 3g/day leads to reduction of some risk factors for cardiovascular disease, there has not yet been definitive proof that reduction in these risk factors will lead to reduction in actual cardiovascular events.

Ginseng (from Root of *Panax ginseng*)

Ginseng is one of the most popular herbal and nutritional supplements and is a major mainstay of the traditional Chinese medicine pharmacopeia. In contrast to the substantial data supporting statistically significant, if modest, effects of other nutritional supplements including garlic, ginkgo, and St. John’s wort, there is relatively little objective evidence that ginseng produces significant clinical effects. For example, an extensive systematic review³⁹ searched the computerized literature for double-blind, randomized, placebo-controlled trials of ginseng root extract for any indication. Sixteen trials met the inclusion criteria and were reviewed. These trials looked at physical performance, psychomotor performance and cognitive function, immunomodulation, diabetes mellitus, and herpes simplex type 2 infections. The authors concluded that efficacy of ginseng was not firmly established for any

of those indications. There are several reports in the literature, however, that ginseng may produce subjective improvements that many patients may consider valuable. For example, in a randomized, double-blind placebo-controlled study of symptomatic perimenopausal women,⁴⁰ ginseng was found to produce significant improvements in self-rated assessments of depression, well-being, and health. Similarly, a randomized, double-blind study assessed effects of a ginseng plus vitamin preparation on responses to a quality of life questionnaire in 625 patients, compared to a vitamin regimen.⁴¹ The ginseng preparation did not produce a significant improvement in every item assessed, whereas the vitamin preparation was reported not to produce an improvement in any item. Although subjective outcomes are difficult to measure and more subject to bias, they are patient centered and should not be dismissed. Also, ginseng may have pharmacologic activity for which we have not yet found the appropriate objective measures.

Ginger (*Zingiber officinale*)

The main interest in ginger appears to be its effects on nausea: a search on “ginger” and “nausea” produced 2900 hits. Indeed, this indication of ginger is the only one for which clinical trials exist. A recent meta-analysis of randomized clinical trials concluded that the six trials that met the criterion of the analysis suggested that ginger reduces nausea more than placebo and may in fact be as effective as metoclopramide for postoperative nausea.⁴² As with garlic, the use of ginger may be effective, and is probably not as likely to produce iatrogenic effects as some pharmaceuticals.

Vitamins

There is tremendous interest in vitamin supplements, which are widely used. A search on the Internet (Google) on “vitamin” and “health” in January 2001 resulted in almost 500,000 hits. There is however surprisingly little support for a clinically significant effect of vitamin supplementation, at least in well-nourished Western populations. Two recent meta-analyses concluded that although epidemiologic evidence clearly suggests that higher intake of antioxidant vitamins C and E are protective against cardiovascular disease, controlled clinical trials, examining high doses up to 400IU per day, have not convincingly demonstrated this effect.^{43–45} While current studies are continuing to assess this question in more detail, it is instructive that vitamin supplementation is far more common than other supplements described in the review, but there is actually less evidence supporting the

value of their use than there is for most of the other supplements. However, they are also not likely to be harmful.

Wine

The observation that incidence of coronary heart disease is relatively low in France, despite high levels of dietary fat, led to the hypothesis that the relatively high levels of wine consumed in France may produce a protective effect against heart disease.^{46–48} Like garlic, drinking wine is a common component of dining habits in many societies, and there is intense popular interest in the health consequences of drinking wine. A search on the Internet (Google) on “wine” and “health” in January 2001 resulted in almost 800,000 hits, “wine” and “cholesterol” generated about 60,000 hits, “wine” and “cancer” generated about 189,000 hits, “wine” and “memory” generated about 283,000 hits, and “wine” and “fatigue” generated about 33,000 hits.

Extensive epidemiologic data have demonstrated a J-shaped relationship between consumption of alcohol, especially red wine, and reduction of mortality resulting from cardiovascular disease.^{49–52} However, such data do not address the effects of alcohol consumption specifically in the elderly. Furthermore, clinical trials to assess the effects of alcohol consumption on any health parameter have not actually been undertaken, and as with vitamins, it remains possible that the epidemiologic data may be misleading. It is plausible that consumption of wine reduces the development of cardiovascular impairments but does not reverse them. For both pharmacokinetic and pharmacodynamic reasons, older adults have a greater response to the same amount of wine they were able to tolerate when younger. Considering the increased risk of falls and other potential major injuries that might be exacerbated by alcohol in the elderly, it may be that the optimal use of alcohol is to consume it during the middle-age years and abstain during older adulthood. Currently, these precise relationships remain unclear. Therefore, the current thinking is that if moderate drinking of wine has been part of the normal lifestyle of an elderly individual, there is no reason to recommend a marked change in habit, but the evidence also does not support a recommendation to begin consumption of wine in elderly individuals who would otherwise abstain.

St. John's Wort (*Hypericum perforatum*): Potential for Lethal Drug Interactions

There is much evidence supporting extracts of St. John's wort, or *Hypericum perforatum*, as an effective treatment for depression. A search on the Internet (Google)

on “St. John’s wort” and “health” in January 2001 resulted in about 67,800 hits, while “St. John’s wort” and “cholesterol” generated about 22,000 hits (many of which discussed how St. John’s wort can interfere with cholesterol-lowering drugs). Recent studies have demonstrated an unexpected danger in the use of these extracts, however, especially in elderly patients who are more likely to be under treatment with several medications simultaneously.

Hypericum extracts are now commonly used by patients to treat depressive symptoms, often without consultation with medical professionals;⁵³ a high percentage of such patients report positive effects of the treatment, although some patients cease using the extracts because of side effects, including symptoms of serotonin syndrome.⁵³ Several meta-studies have concluded that hypericum extracts are more effective than placebo to reduce depressive symptoms⁵⁴⁻⁵⁶ and may be as effective as prescription pharmacologic treatments of depression⁵⁷ although a recent large study failed to show a benefit.^{57a} Hypericum extracts have been reported to be as effective as imipramine in reducing depressive symptoms, with fewer iatrogenic effects than imipramine.⁵⁸ Similarly, hypericum extracts were reported to be as effective as sertraline⁵⁹ and fluoxetine^{60,61} in reducing symptoms of mild depression. Hypericum extracts were also found to reduce obsessive-compulsive symptoms.⁶² At least one report specifically suggests that hypericum extracts may be a particularly useful treatment for even severe depression in the elderly, because these extracts are both efficacious and may be better tolerated than tricyclic antidepressants.⁶³

Hypericum extracts appear to exert their antidepressant activity by enhancing serotonin tone, as is the case with many antidepressants, but the mechanism by which this occurs may be different from the mechanisms engaged by classic serotonin uptake inhibitors,⁶⁴ including an effect to stimulate dopamine release,⁶⁵ inhibit norepinephrine synthesis,⁶⁶ and reduce reuptake of glutamate and GABA.⁶⁷ Interestingly, some compounds extracted from hypericum may interact directly with receptors for corticotropin-releasing factor,⁶⁸ a system known to influence anxiety. As is typically the case with herbal extracts, the specific chemical constituents that mediate the antidepressant effects of hypericum extracts remain to be determined. In the case of hypericum extract, the main candidates are hypericin and hyperforin, but the role of these and other constituents are unclear.⁶⁹

As with any drug, hypericum extracts can have iatrogenic effects, including inducing reversible mania in some patients.^{70,71} On the whole, such iatrogenic effects are thought to be less problematic for hypericum extracts than for prescription drugs. Several recent reports have indicated that hypericum extracts can dramatically reduce the bioavailability of cyclosporin A in liver trans-

plant patients, leading to almost fatal rejection of the transplanted liver.⁷² After cessation of ingestion of hypericum, cyclosporin A levels returned to normal, as did liver function.⁷² Similar observations were made in patients with kidney transplantations^{73,74} and with heart transplantations.⁷⁵ Part of the mechanism by which hypericum extracts reduce drug bioavailability is through the activation of the pregnane X orphan steroid receptor,^{76,77} which in turn activates the hepatocyte cytochrome P-450 A34 (CYPA34) enzyme that is involved in the oxidative inactivation of more than 50% of all drugs.^{77,78} Because activation of CYPA34 may enhance inactivation of many drugs, the effect of hypericum extracts to activate CYPA34 may be particularly dangerous in elderly patients who are more likely to be treated with several drugs simultaneously. Thus, the wide use of hypericum extracts constitutes a particularly clear example of the need for physicians to obtain a complete appraisal of the use of nutritional supplements that their patients are consuming, as well as a renewed effort to monitor medications that are metabolized by the P-450 cytochrome system.

Glucosamine and Chondroitin

Glucosamine and chondroitin sulfate have become increasingly popular nutritional supplements to treat symptoms of osteoarthritis.⁷⁹ A search on the Internet (Google) on “glucosamine” and “arthritis” generated about 46,000 hits, and “chondroitin” and “arthritis” generated about 20,000 hits. In a recent meta-analysis⁷⁹ assessing the efficacy of glucosamine in treating symptoms of osteoarthritis, 13 randomized clinical trials compared glucosamine to placebo; glucosamine was found to be superior in all except 1, using a variety of outcomes including patient reports of pain and mobility. In the four randomized clinical trials in which glucosamine was compared to a nonsteroid anti-inflammatory drug, glucosamine was superior in two, and equivalent in two, again using the same outcomes. However, the present data are considered preliminary by the American College of Rheumatology because of the small number of patients examined so far. A large NIH-sponsored trial is under way to more definitively assess the efficacy of glucosamine and chondroitin in osteoarthritis and to include some objective outcomes in addition to patients’ subjective reports.⁸⁰

DHEA (Dehydroepiandrosterone)

Plasma levels of dehydroepiandrosterone (DHEA) and its more abundant sulfated form, DHEA-S, decrease more markedly during aging (maximum levels observed in the early twenties) than levels of any other hormone

in humans, with the exception of the decrease of estradiol in postmenopausal women.^{81,82} The most recent meta-analysis of trials assessing effects of DHEA concluded that DHEA replacement produced no significant objective benefit, although it may produce subjective benefit.⁸³ To date the most complete study published that addresses the effects of DHEA supplementation in aging humans has been by Morales et al.⁸⁴ This randomized, double-blind, placebo-controlled crossover trial involved nightly oral DHEA administration (producing pharmacologic levels of the hormone) or placebo over 6 months in a group of healthy men and women 40 to 70 years of age, a regimen that restored plasma DHEA and DHEA-S to youthful levels. This study examined a wide variety of outcomes, including concentration of androgens, lipids, apolipoproteins, insulin-like growth factor 1 (IGF-1), IGF-binding protein 1 (IGFB-1), IGFB-3, insulin sensitivity, percent body fat, libido, and sense of well-being. In a subgroup, blood was taken every 20 min over 24 h for measurement of growth hormone. Of all these parameters, the only objective measurements that were significantly influenced by DHEA replacement were an increase in IGF-1 (20% in men and 12% in women) and a decrease in IGFB-1 (29% in men, 23% in women). The significance of these isolated effects remains unclear.

Despite the rather impressive lack of effect of DHEA supplementation in the study by Morales et al.⁸⁴ on objective parameters, the increase in perceived physical and psychologic well-being was dramatic. Although fewer than 10% of the subjects on placebo reported an improvement in sense of well-being, 82% of women and 67% of men given the DHEA replacement reported an improvement in sense of well-being. Specific statements included improved quality of sleep, increased sense of relaxation, and increased sense of energy. Furthermore, several subjects given DHEA self-reported marked improvements of preexisting joint pains and mobility. Because this study was double blinded, these subjective improvements were impressive despite the paucity of objective measurements that showed any improvement. It is plausible that DHEA replacement may produce physiologic effects, which we have not yet been able to measure, that lead to improvements in the sense of well-being. Nevertheless, as with any steroid hormone, the use of DHEA can be potentially dangerous (high levels are associated with increased risk of some cancers and reduced HDL levels⁸⁵), and there is currently little basis to recommend the use of DHEA.

Growth Hormone

Similar to that of DHEA, growth hormone secretion decreases during aging.⁸⁶ Growth hormone (GH) is not a nutritional supplement; it is available only by injection.

Reports by Rudman et al.^{87,88} that treatment of elderly hyposomatotropic men with growth hormone significantly increased muscle mass and partially reversed other age-related impairments greatly stimulated interest in this treatment during aging. Replacement of growth hormone has even been touted as an antiaging regimen.⁸⁹ However, this possibility must be approached with considerable caution, because acromegalic humans with elevated growth hormone secretion exhibit shortened life span.⁹⁰ Similarly, it was observed that transgenic mice expressing elevated levels of growth hormone, like acromegalic humans, actually exhibit a reduced life span compared with wild-type mice.^{91,92} Even more surprisingly, it has recently been observed that mice with growth hormone secretion or receptors genetically ablated actually live longer than wild-type controls.^{93,94} Thus the concept of using growth hormone replacement as an antiaging regimen must be considered to be highly suspect.

Discussion

The nutritional supplements and “antiaging” medicines discussed in this review are available commercially (except for GH) and are widely popularized on the Internet and other sources. Several studies document that older adults use these supplements, often without the knowledge of the health care provider. Because nutritional supplements are increasingly popular, the clinician is increasingly called upon to address the use of these supplements in several capacities: to recommend whether or not the patient should begin or continue using a supplement, to compare a supplement with a medication to decide which one to try first, and to advise about potential drug-herb interactions. When advising patients about nutritional supplements, we must consider the following. First, many people seek nutritional/dietary supplements because they think they are “natural” and therefore safe. We must advise our patients that natural does not automatically mean safe, especially because supplements are not regulated by the FDA, are not required to follow strict manufacturing standards, and can potentially contain contaminants such as lead or other compounds. Second, when recommending the use of a supplement that has been tested in a clinical trial, it is probably safest to recommend that the patient buy the brand that was used in that trial, thus ensuring the patient receives as standardized a dose as possible. Third, evidence for efficacy of supplements is derived from different sources: anecdotal evidence, epidemiologic evidence, uncontrolled studies, and controlled clinical trials. Thus, all supplements are not created equal. Although clinical trial evidence would support using glucosamine for osteoarthritis, it would not support using GH to reverse the aging process. Finally, we should educate patients

about dosing their supplements. The maxim, “The difference between a drug and poison is dose” may be helpful for some patients to understand why in vitro effects may not predict therapeutic value.

Urinary Incontinence

Neil M. Resnick

Urinary incontinence poses a major problem for the elderly. Afflicting 15% to 30% of older people living at home, one-third of those in acute care settings, and at least half of those in nursing homes,¹ it predisposes to rashes, pressure ulcers, urinary tract infections, urosepsis, falls, and fractures.¹⁻³ It is also associated with embarrassment, stigmatization, isolation, depression, and risk of institutionalization,¹ as well as caregiver burden and depression.⁴ Finally, it cost more than \$26 billion to manage in America in 1995,⁵ exceeding the amount devoted to dialysis and coronary artery bypass surgery combined.

Although both providers and older patients often neglect incontinence or dismiss it as a normal part of growing older,^{6,7} it is abnormal at any age.^{1,8} Although its prevalence increases with age, at no age does incontinence affect the majority of individuals, even above age 85.⁹ Moreover, the reason for its increased prevalence in the elderly is likely the diseases and functional impairments that become more common with age rather than age itself.⁸⁻¹⁰ Regardless, incontinence is usually treatable and often curable at all ages, even in frail elderly,¹¹⁻¹⁴ but the approach must differ significantly from that used in younger patients.

Lower Urinary Tract Anatomy and Physiology

Details of the anatomy and physiology of normal micturition remain controversial. For present purposes, however, both can be simplified. The lower urinary tract includes the bladder (detrusor), the urethra, and two urethral sphincters. The internal sphincter lies in the proximal urethra, at the bladder neck and is composed predominantly of smooth muscle. The external sphincter lies distally, at the level of the urogenital diaphragm, and is composed of striated muscle.

Innervation of the lower urinary tract is derived from the parasympathetic (S2–S4), sympathetic (T10–L2), and somatic (voluntary) nervous systems (S2–S4). The parasympathetic nervous system innervates the detrusor; increased cholinergic activity increases the force and frequency of detrusor contraction, while reduced activity has the opposite effect. The sympathetic nervous system innervates both the bladder and the urethra, with its effect determined by local receptors. Adrenergic receptors are sparse in the bladder body, but those normally present are beta receptors; their stimulation relaxes the bladder. Receptors in the bladder base and proximal urethra are alpha receptors; their stimulation contracts the internal sphincter. Thus, activation of the sympathetic nervous system facilitates storage of urine in a coordinated manner. The somatic nervous system is the primary source of innervation for the urogenital diaphragm and the external sphincter. The central nervous system integrates control of the urinary tract; the pontine micturition center mediates synchronous detrusor contraction and sphincter relaxation, while higher centers in the frontal lobe, basal ganglia, and cerebellum (among others) exert inhibitory and facilitatory effects.

Storage of urine is mediated by detrusor relaxation and closure of the sphincters. Detrusor relaxation is accomplished by central nervous system inhibition of parasympathetic tone, while sphincter closure is mediated by a reflex increase in the activity of the alpha-adrenergic and somatic nervous systems. Voiding occurs when detrusor contraction, stimulated by the parasympathetic nervous system, is coordinated with sphincter relaxation.

The Impact of Age on Incontinence

At any age, continence depends on not only the integrity of urinary tract function and innervation, but also the presence of adequate mentation, mobility, motivation,

and manual dexterity. Although incontinence in younger patients is rarely associated with deficits outside the urinary tract, such deficits are found commonly in older patients. It is crucial to detect them, both because they exacerbate and occasionally even cause incontinence in the elderly and because design of an efficacious intervention requires that they be addressed.

In addition, the lower urinary tract changes with age, even in the absence of disease. Data from continent elderly are sparse, and longitudinal data virtually nonexistent, but bladder contractility and capacity, as well as the ability to postpone voiding, appear to decline in both sexes. Urethral length and closure pressure, as well as striated sphincter muscle cells, probably decline with age in women.¹⁵⁻¹⁸ The prostate enlarges in most men and appears to cause urodynamic obstruction in half.¹⁷ In both sexes, the prevalence of involuntary detrusor contractions increases while the postvoiding residual volume (PVR) probably increases, but to no more than 50 to 100 mL.¹⁵⁻¹⁷ In addition, the elderly often excrete most of their fluid intake at night, even in the absence of venous insufficiency, renal disease, heart failure, or prostatism.^{19,20} This fact, coupled with the age-associated increase in sleep disorders, leads to one to two episodes of nocturia in the majority of healthy elderly.^{19,20} Finally, at the cellular level, detrusor smooth muscle develops a “dense band pattern” characterized by dense sarcolemmal bands with depleted caveolae.^{21,22} This depletion may mediate the age-related decline in bladder contractility. In addition, an “incomplete dysjunction pattern” develops, characterized by scattered protrusion junctions, albeit not in chains; these changes likely underlie the high prevalence of involuntary detrusor contractions.^{17,23}

None of these age-related changes causes incontinence, but they do predispose to it. This predisposition, coupled with the increased likelihood that an older person will encounter an additional pathologic, physiologic, or pharmacologic insult, explains why the elderly are so likely to become incontinent. The implications are equally important. The onset or exacerbation of incontinence in an older person is likely to be caused by precipitant(s) *outside* the lower urinary tract that are amenable to medical intervention. Furthermore, *treatment of the precipitant(s) alone may be sufficient to restore continence, even if there is coexistent urinary tract dysfunction.* For instance, flare of hip arthritis in a woman with age-related detrusor overactivity may be sufficient to convert her urinary urgency into incontinence. Treatment of the arthritis—rather than the involuntary detrusor contractions—will not only restore continence but also lessen pain and improve mobility. These principles, depicted in Figures 63.1 and 63.2, provide the rationale in the older patient for adding, to the established lower urinary tract causes of incontinence, a set of transient causes. Because of their frequency, ready reversibil-

FIGURE 63.1. Incontinence results when the ability to compensate for bladder dysfunction is inadequate. For instance, in the intact older person, detrusor overactivity or sphincter weakness may not cause leakage if the patient is more attuned to bladder fullness, drinks less, voids more often, eliminates precipitants such as coughing, and stays close to a toilet. This behavior explains how older patients may remain continent despite such abnormalities and also suggests alternate therapeutic approaches independent of the urinary tract. (Modified from Resnick NM. *JAMA*. 1996;276:1832-1840, with permission.)

ity, and association with morbidity beyond incontinence, the transient causes are discussed first.

Causes of Transient Incontinence

Incontinence is transient in up to one-third of community-dwelling elderly and up to half of acutely hospitalized patients.^{8,15} Although most of the transient causes of incontinence in the elderly lie outside the lower urinary tract, three points are worth emphasizing. First, the risk of incontinence developing from a transient cause is increased if, in addition to physiologic changes of the lower urinary tract, the older person also suffers from pathologic changes. Anticholinergic agents are more likely to cause overflow incontinence in individuals with a weak or obstructed bladder, whereas excess urine output is more likely to cause urge incontinence in people with detrusor overactivity and/or impaired mobility.^{24,25} Second, although termed “transient,” these causes of incontinence may persist if left untreated and cannot be dismissed merely because incontinence is long-standing. Third, similar to the situation for established causes (see following), identification of “the most common cause” is of little value. The likelihood of each cause depends on the individual, the clinical setting (community, acute hospital, nursing home), and the referral pattern. Moreover, geriatric incontinence is rarely the result of a single etiology.

The causes of transient incontinence can be recalled easily using the mnemonic “DIAPERS” (Table 63.1). In the setting of *delirium*, incontinence is merely an associated symptom that abates once the underlying cause of confusion is identified and treated. The patient needs medical rather than bladder management.¹⁵

Symptomatic urinary tract *infection* (UTI) causes transient incontinence when dysuria and urgency are so prominent that the older person is unable to reach the toilet before voiding. Asymptomatic bacteriuria, which is much more common in the elderly, does not cause incontinence.^{15,26–28} Because illness can present atypically in older patients, however, incontinence is occasionally the only atypical symptom of a UTI. Thus, if otherwise asymptomatic bacteriuria is found on the initial evaluation, it should be treated and the result recorded in the patient's record to prevent future futile therapy.

Atrophic urethritis/vaginitis frequently causes lower urinary tract symptoms, including incontinence. As many as 80% of elderly women attending an incontinence clinic have atrophic vaginitis, characterized by vaginal mucosal atrophy, friability, erosions, and punctate hemorrhages.²⁹ Incontinence associated with this entity usually is associated with urgency and occasionally a sense of “scalding” dysuria, mimicking a urinary tract infection, but both symptoms may be unimpressive. In demented individuals, atrophic vaginitis may present as agitation. Atrophic vaginitis also can exacerbate or even cause stress incontinence.

Atrophic vaginitis is important to recognize because it responds to low-dose estrogen (e.g., 0.3–0.6 mg con-

jugated estrogen/day, orally or vaginally).¹ Moreover, as for the other causes of transient incontinence, treatment has other benefits; in this case, treatment ameliorates dyspareunia and reduces the frequency of recurrent cystitis.^{15,30,31} Recently, estrogen has been given transcutaneously, but studies of its impact on atrophic vaginitis are not yet available. The transcutaneous route seems promising, however, because it requires application only twice weekly and preliminary data suggest that it may have beneficial effects on lipids without adverse hepatic effects. Whichever route is chosen, symptoms remit in a few days to several weeks, but the intracellular response takes longer.³²

The duration of therapy has not been well established.³³ One approach is to administer a low dose of estrogen daily for 1 to 2 months and then taper it. Most patients probably can be weaned to a dose given as infrequently as two to four times per month. After 6 months, it can be discontinued entirely in some patients, but recrudescence is common. Because the estrogen dose is low and given briefly, its carcinogenic effect is likely slight, if any. However, if long-term treatment is required, a progestin probably should be added if the patient has a uterus. Hormone treatment is contraindicated for women with a history of breast cancer. For those without such a history, mammography should be performed before initiating therapy. There may be a small increased risk of breast cancer among women using estrogen daily for more than 5 years, but fortunately, such high-dose, frequent, and long-term therapy is rarely required. Of note, the estrogen dose for atrophic vaginitis is lower than the more typically used daily dose of 0.625 mg.

Pharmaceuticals are one of the most common causes of geriatric incontinence, and they precipitate leakage by a variety of mechanisms (Table 63.2). Experts often cite dosages and serum levels below which side effects are uncommon. Unfortunately, such rules are of limited use in the elderly because they are generally derived from studies of younger people who have no other diseases and take no other medications. Of note, many of these agents also are used in the treatment of incontinence, underscoring the fact that most medications are “double-edged swords” for the elderly.

Incontinence: Young vs Old

FIGURE 63.2. This cartoon shows why treatment of urinary incontinence (UI) in older adults has to differ and is often easier to treat than in younger adults. Both these patients with detrusor overactivity (DO) have the same frequency of leakage. However, in the younger patient with intact compensatory mechanisms, such leakage reflects solely the contribution of the DO. In the older adult, other comorbid conditions make it more difficult to appreciate bladder fullness, adjust fluid output, and reach the bathroom. Such conditions magnify the impact of DO and will be unaffected by bladder relaxant therapy. However, addressing them will result in a marked improvement in the UI even without treatment of the DO and will make bladder relaxant therapy, if still required, more effective. (Modified from Resnick NM, Marcantonio ER. *Lancet*. 1997;350:1157–1158, with permission.)

TABLE 63.2. Commonly used medications that may affect continence.

Type of medication	Examples	Potential effects on continence
Sedatives/hypnotics	Long-acting benzodiazepines (e.g., diazepam, flurazepam)	Sedation, delirium, immobility
Alcohol		Polyuria, frequency, urgency, sedation, delirium, immobility
Anticholinergics	Dicyclomine, disopyramide, antihistamines (sedating)	Urinary retention, overflow incontinence, delirium, impaction
Antipsychotics	Thioridazine, haloperidol	Anticholinergic actions, sedation, rigidity, immobility
Antidepressants (tricyclics)	Amitriptyline, desipramine	Anticholinergic actions, sedation
Anti-Parkinsonians	Trihexyphenidyl, bethanechol	Anticholinergic actions, sedation
Narcotic analgesics	Opiates	Urinary retention, fecal impaction, sedation, delirium
α -Adrenergic antagonists	Prazosin, terazosin, doxazosin	Urethral relaxation may precipitate stress incontinence in women
α -Adrenergic agonists	Nasal decongestants	Urinary retention in men
Calcium channel blockers	All dihydropyridines ^a	Urinary retention; nocturnal diuresis due to fluid retention
Potent diuretics	Furosemide, bumetanide	Polyuria, frequency, urgency
Angiotensin-converting enzyme (ACE) inhibitors	Captopril, enalapril, lisinopril	Drug-induced cough can precipitate stress incontinence in women and in some men with prior prostatectomy
Vincristine		Urinary retention caused by neuropathy

^aExamples include nifedipine, nicardipine, isradipine, felodipine, nimodipine.

Source: Adapted from Resnick NM. Geriatric medicine. In: Isselbacher KJ, Braunwald E, Wilson JD, Martin JB, Fauci AS, Kasper DJ, eds. *Harrison's Principles of Internal Medicine*. New York: McGraw-Hill; 1994:34, with permission.

Anticholinergic agents are used often by older people, even when not prescribed (e.g., sedating antihistamines used for allergies, coryza, and insomnia). These substances are particularly important to ask about because they cause or contribute to incontinence in several ways. In addition to provoking overt urinary retention, they often induce subclinical retention. The resultant decrease in functional bladder capacity allows bladder capacity to be reached more quickly, exacerbating incontinence from detrusor overactivity as well as that caused by functional impairment. By increasing residual volume, anticholinergic agents also can aggravate leakage due to stress incontinence. Additionally, many of these drugs decrease mobility (e.g., antipsychotics that induce extrapyramidal stiffness) and precipitate confusion. Finally, several agents intensify the dry mouth that is already so common in the elderly; the resultant increased fluid intake contributes to incontinence. Attempts should be made to discontinue anticholinergic agents, or to substitute those with less anticholinergic effect. Bethanechol may be useful for nonobstructed patients whose urinary retention is associated with use of an anticholinergic that cannot be discontinued.³⁴

Because the proximal urethra, prostate, and prostatic capsule all contain alpha-adrenergic receptors, urethral tone can be increased by alpha-adrenergic agonists and decreased by alpha antagonists. In men with otherwise asymptomatic prostatic obstruction, alpha-adrenergic agonists can provoke acute retention. Particularly problematic are nonprescription decongestants, because they also often contain an (anticholinergic) anti-

histamine and are taken with a nonprescription (sedating antihistamine) hypnotic as well. In other words, both agents can come together (e.g., Contac) or separately (e.g., Sudafed, Benadryl). Because older individuals often fail to mention nonprescription agents to a physician, urinary retention due to use of a decongestant, nose drops, and a hypnotic may result in premature or even unnecessary prostatectomy. In older women, in whom urethral length and sphincter strength decline with age, alpha-adrenergic antagonists (many antihypertensives) may induce stress incontinence by blocking receptors at the bladder neck.³⁵ Before considering other interventions, one should substitute an alternative agent and reevaluate.

Calcium channel blockers also can cause incontinence. As smooth muscle relaxants, they may increase residual volume and occasionally even provoke overflow incontinence, particularly in obstructed men with coexisting detrusor weakness. The dihydropyridine class of these agents (e.g., nifedipine, nicardipine, isradipine, nimodipine) also can cause peripheral edema, which may exacerbate nocturia and nocturnal incontinence.

Angiotensin-converting enzyme inhibitors (ACEI) can induce a chronic cough. Because the risk of this side effect increases with age, these agents may exacerbate what otherwise would be minimal stress incontinence in older women.

Excess urine output commonly contributes to or even causes geriatric incontinence. Causes include excessive fluid intake, diuretics, metabolic abnormalities, and disorders associated with fluid retention. Excess output is a

likely contributor when incontinence is associated with nocturia (Table 63.3).

Restricted mobility commonly contributes to geriatric incontinence. It can result from numerous treatable conditions including arthritis, hip deformity, deconditioning, postural or postprandial hypotension, claudication, spinal stenosis, heart failure, poor eyesight, fear of falling, stroke, foot problems, drug-induced disequilibrium or confusion, or being restrained in a bed or chair.³⁶ A careful search will often identify these or other correctable causes. If not, a urinal or bedside commode may still improve or resolve the incontinence.

Finally, *stool impaction* is implicated as a cause of urinary incontinence in up to 10% of older patients admitted to acute care hospitals or referred to incontinence clinics¹⁵; the mechanism may involve stimulation of opioid receptors.³⁷ Patients usually present with either urge or overflow incontinence and typically have associated fecal incontinence as well. Disimpaction restores continence.

These seven reversible causes of incontinence should be assiduously sought in every older patient. In one series of hospitalized elderly, when these causes were identified, continence was regained by most of those who became incontinent in the context of acute illness.¹⁵ Regardless of their frequency, however, their identification is important in all settings because they are easily treatable and contribute to morbidity beyond incontinence.

Established Incontinence

Causes Unrelated to the Lower Urinary Tract (“Functional” Incontinence)

In contrast with transient causes, the established causes of geriatric incontinence generally lie *within* the urinary tract. The exception is “functional incontinence,” a type of incontinence attributed to deficits of cognition and mobility. However, this concept is problematic for several reasons.³⁸ First, “functional incontinence” implies that urinary tract function is normal, but studies of both institutionalized and ambulatory elderly reveal that normal urinary tract function is the exception even in continent subjects and is rarely observed in incontinent elderly patients.^{15,17,39,40} Second, incontinence is not inevitable with either dementia or immobility. For instance, we found that 17% of the most severely demented institutionalized residents (mean age, 89) were continent; more impressive, if they could merely transfer from a bed to a chair, nearly *half* were *continent*.¹⁰ Third, because functionally impaired individuals are the most likely to suffer from factors causing transient incontinence,^{10,41-43} a diagnosis of functional incontinence may result in failure to detect reversible causes of incontinence. Finally, functionally impaired individuals may still have obstruction or stress incontinence and benefit from targeted therapy.^{15,40,41}

Nonetheless, the importance of functional impairment as a factor *contributing* to incontinence should not be underestimated, because incontinence is also affected by environmental demands, mentation, mobility, manual dexterity, medical factors, and motivation. Although lower urinary tract function is rarely normal in such individuals, these factors are important to keep in mind because small improvements in each may markedly ameliorate both incontinence and functional status. In fact, once one has excluded causes of transient incontinence and serious underlying lesions, dealing with functional impairment often obviates the need for further investigation.

Lower Urinary Tract Causes

If incontinence persists after transient and functional causes have been addressed, the urinary tract causes of incontinence should be considered. The lower urinary tract can malfunction in only four ways. Two involve the bladder and two involve the outlet: the bladder either contracts when it should not (detrusor overactivity) or fails to contract when or as well as it should (detrusor underactivity); alternatively, outlet resistance is high when it should be low (obstruction) or low when it should be high (outlet incompetence). Because incontinence in

older individuals is frequently due to a cause other than the classic types of “neurogenic bladder,” it is better to think of the causes of incontinence in terms of these four pathophysiologic mechanisms and to realize that each mechanism can be caused by “neurogenic” as well as “nonneurogenic” conditions (Table 63.4). This section provides an overview of the four basic mechanisms and their causes; a later section provides treatment strategies for each.

Detrusor overactivity (DO), characterized by involuntary bladder contractions, is the most common form of urinary tract dysfunction in incontinent elderly of either sex.^{15,40} DO is associated with increased spontaneous activity of detrusor smooth muscle. Recently, we found that it is also associated with unique changes at the cellular level. Termed the “complete dysjunction pattern,” these changes include widening of the intercellular space and replacement of normal (intermediate) muscle cell junctions by novel “protrusion” junctions and ultraclose abutments connecting cells together in chains. These junctions and abutments may mediate a change in cell coupling from a mechanical to an electrical mechanism, which could facilitate propagation of heightened smooth muscle activity and provide the “final common pathway” by which such spontaneous cellular contractions result in involuntary contraction of the entire bladder.^{23,44–46}

A distinction is generally made between detrusor overactivity that is associated with a CNS lesion (detrusor hyperreflexia) and that which is not (detrusor instability). In the latter situation, the etiology of the DO may be in the urinary tract itself, where a source of irritation—such as cystitis (interstitial, or radiation- or chemotherapy-

induced), bladder tumor, or stone—overwhelms the brain's ability to inhibit bladder contraction. Two other important local causes are prostate obstruction and stress incontinence, each of which may lead to secondary detrusor overactivity. However, in older patients the distinction is often unclear because many of these causes may be present concomitantly, even in a patient with Alzheimer's disease. Unfortunately, there is still no reliable way to determine the source of such contractions, which obviously complicates treatment decisions. It also suggests that DO coexisting with urethral obstruction or stress incontinence may be less likely to resolve post-operatively than in younger individuals without other reasons for detrusor overactivity.^{15,47}

Traditionally, detrusor overactivity has been thought to be the primary urinary tract cause of incontinence in demented patients. While this is true, it is also the most common cause in nondemented patients, and the three studies that have examined it failed to find an association between cognitive status and DO.^{40,48,49} This lack of association likely reflects the fact that in the elderly there are multiple causes of DO unrelated to dementia, including cervical disk disease or spondylosis, Parkinson's disease, stroke, subclinical urethral obstruction or sphincter incompetence, and age itself. Moreover, demented patients also may be incontinent due to the transient or functional causes already discussed. Thus, it is not tenable to ascribe incontinence in demented individuals a priori to detrusor overactivity.

Detrusor overactivity in the elderly exists as two physiologic subsets, one in which contractile function is preserved and one in which it is impaired.⁵⁰ The latter

condition is called detrusor hyperactivity with impaired contractility (DHIC), and it has proved to be the most common form of DO found in the elderly.^{40,44} Evidence suggests that DHIC may represent the coexistence of DO and bladder weakness, rather than a separate physiologic entity.⁴⁴ Nonetheless, DHIC has several implications. First, because the bladder is weak, urinary retention develops commonly in these patients, and DHIC must be added to outlet obstruction and detrusor underactivity as a cause of retention. Second, even in the absence of retention, DHIC mimics virtually every other lower urinary tract cause of incontinence. For instance, if the involuntary detrusor contraction is triggered by or occurs coincident with a stress maneuver and the weak contraction (often only 2–6 cmH₂O) is not detected, DHIC will be misdiagnosed as stress incontinence or urethral instability.⁵¹ Alternatively, because DHIC is associated with urinary urgency, frequency, weak flow rate, elevated residual urine, and bladder trabeculation, in men it may mimic urethral obstruction.⁵² Third, bladder weakness often frustrates anticholinergic therapy of DHIC because urinary retention is induced so easily. Thus, alternative therapeutic approaches are often required (see Therapy, following).

Regardless of etiology or bladder strength, DO is characterized by frequent and precipitant voiding. Leakage is usually moderate to large, nocturnal frequency and incontinence are common, sacral sensation and reflexes are preserved, voluntary control of the anal sphincter is intact, and postvoiding residual volume is generally low. A residual volume in excess of 50 mL in a

patient with detrusor overactivity suggests outlet obstruction (although there may be no residual in early obstruction), DHIC, or pooling of urine in a woman with a cystocele. It is also found in patients with Parkinson's disease or spinal cord injury.

Stress incontinence is the second most common cause of incontinence in older women. As in younger women, it is usually a result of pelvic muscle laxity; this results in "urethral hypermobility," which allows the proximal urethra and bladder neck to "herniate" through the urogenital diaphragm when abdominal pressure increases. Such herniation may result in unequal transmission of abdominal pressure to the bladder and urethra and consequent stress incontinence (Fig. 63.3). The defect is thus one of urethral support, rather than sphincter strength. Leakage due to urethral hypermobility is characterized by daytime loss of small to moderate amounts of urine, infrequent nocturnal incontinence, and low postvoiding residual volume (in the absence of urine pooling in a large cystocele). The hallmark of the diagnosis is leakage that, in the absence of bladder distension, occurs coincident with the stress maneuver.

A much less common cause of stress incontinence is intrinsic sphincter deficiency (ISD) or "type 3 stress incontinence,"^{53,54} in which the sphincter is intrinsically weak. Afflicted women usually leak with even trivial stress maneuvers (e.g., walking) and may even note continuous seepage when standing quietly. The prevalence of ISD may be lower than thought, however, because the diagnosis is often based solely on documenting a very low urethral "leak point" or "closure pressure" during

FIGURE 63.3. Pathophysiology of stress incontinence (SUI) caused by urethral hypermobility. Normally, resting urethral pressure is greater than bladder pressure. With a stress maneuver (such as coughing, straining, laughing, or bending over), the increase in abdominal pressure is transmitted equally to the bladder and the outlet, and the individual remains dry. In a woman with urethral hypermobility, however, the proximal

urethra "herniates" through the urogenital diaphragm (UGD) into the pelvis with a stress maneuver. Because abdominal pressure is no longer transmitted equally, instantaneous leakage occurs but stops coincident with the drop in intra-abdominal pressure. (From Resnick NM. Urinary incontinence—a treatable disorder. In: Rowe JW, Besdine RW, eds. *Geriatric Medicine*, 2nd Ed. Boston: Little, Brown; 1988, with permission.)

urodynamic testing. Because pressure declines with age and low pressures are seen commonly in older women without stress incontinence, this finding does not establish the presence of ISD. Moreover, because urethral pressure falls reflexly with detrusor contraction, leakage coinciding with low urethral pressure can be seen in patients with DHIC in whom the low-pressure contraction is missed.

When it occurs, ISD is usually due to operative trauma. However, a milder form also occurs in older women, resulting only from urethral atrophy superimposed on the age-related decline in urethral pressure. Instead of leaking with any bladder volume, such women often leak only at higher amounts (e.g., >200 ml); many become dry if bladder volume is kept below this level.

A rare cause of stress incontinence in older women is urethral instability, in which the sphincter paradoxically relaxes in the absence of apparent detrusor contraction.⁵⁵ However, most older women thought to have this condition actually have DHIC.⁵¹

In men, stress incontinence is uncommon and usually caused by sphincter damage following prostatectomy. In both sexes, stress-associated leakage also can occur in association with urinary retention, but in this situation leakage is not due to outlet incompetence.

Outlet obstruction is the second most common cause of incontinence in older men, although most obstructed men are not incontinent. If caused by neurologic disease, obstruction is invariably associated with a spinal cord lesion. In this situation, pathways are interrupted to the pontine micturition center, where outlet relaxation is coordinated with bladder contraction. Rather than relaxing when the bladder contracts, the outlet contracts simultaneously, leading to severe outlet obstruction, a "Christmas tree bladder," hydronephrosis, and renal failure—a condition termed detrusor-sphincter dyssynergia.

Much more commonly, obstruction results from prostatic enlargement, prostate carcinoma, or urethral stricture. Such men present with postvoid dribbling, urge incontinence (because detrusor overactivity coexists in two-thirds of cases), or, less commonly, overflow incontinence due to urinary retention. Because symptoms, ease of catheterization, and palpated prostate size correlate poorly with obstruction, and PVR is insufficiently specific, obstruction is difficult to exclude without further testing.⁵⁶

Anatomic obstruction is rare in women. With age, urethral elasticity decreases in most women. In a small proportion of them, in whom it may be compounded by fibrotic changes associated with atrophic vaginitis, moderate urethral stenosis may occur. Frank outlet obstruction, however, is usually caused not by stricture but by kinking associated with a large cystocele or obstruction following bladder neck suspension. Rarely, bladder neck obstruction or a bladder calculus is the cause.

Detrusor underactivity, which causes 5% to 10% of incontinence in older persons, may be caused by mechanical injury to the nerves supplying the bladder (e.g., disk compression or tumor involvement) or by the autonomic neuropathy of diabetes, B₁₂ deficiency, Parkinson's disease, alcoholism, vincristine therapy, or tabes dorsalis. Alternatively, the detrusor may be replaced by fibrosis and connective tissue, as occurs in men with chronic outlet obstruction, so that even when the obstruction is removed, the bladder fails to empty normally. Detrusor weakness in women is generally idiopathic; instead of fibrosis, the detrusor displays degeneration of both muscle cells and axons, without accompanying regeneration.²²

A mild degree of bladder weakness occurs commonly in older individuals. Although insufficient to cause incontinence, it can complicate treatment of other causes (see Therapy). However, when severe enough to cause leakage, detrusor underactivity is associated with overflow incontinence.^{15,16,40} Leakage of small amounts occurs frequently throughout the day and night. The patient also may notice hesitancy, diminished and interrupted flow, incomplete emptying, and a need to strain to void. If the problem is neurologically mediated, perineal sensation, sacral reflexes, and anal sphincter control are frequently impaired.

Diagnostic Approach

Evaluation

The evaluation should identify transient and established causes of incontinence, assess the patient's environment and available support, and detect uncommon but serious conditions that may underlie incontinence, including lesions of the brain and spinal cord, carcinoma of the bladder or prostate, hydronephrosis, bladder calculi, detrusor-sphincter dyssynergia, and decreased bladder compliance. Assessment must be tailored to the individual's clinical status and goals and be tempered by the realization that not all detected conditions can be cured, that simple interventions may be effective even in the absence of a diagnosis, and that for many elderly persons, diagnostic tests are themselves often interventions. Because the evaluation generally requires a comprehensive approach, it should be conducted over several visits to ease the burden and to obviate further testing in those who respond to simple measures.

History

After assessing functional status, one elicits a detailed description of the incontinence, focusing on its onset, frequency, severity, pattern, precipitants, palliating features,

TABLE 63.5. Evaluation of the incontinent elderly patient.

History
Type (urge, reflex, stress, overflow, or mixed)
Frequency, severity, duration
Pattern (diurnal, nocturnal, or both; also after taking medications, for example)
Associated symptoms (straining to void, incomplete emptying, dysuria, hematuria, suprapubic/perineal discomfort)
Alteration in bowel habit/sexual function
Other relevant factors (cancer, diabetes, acute illness, neurologic disease, urinary tract infections, and pelvic or lower urinary tract surgery or radiation therapy)
Medications, including nonprescription agents
Functional assessment (mobility, manual dexterity, mentation, motivation)
Physical examination
Identify other medical conditions (e.g., orthostatic hypotension, CHF, peripheral edema)
Test for stress-induced leakage when bladder is full, but not during abrupt urgency
Observe/listen to void for force, continuity, straining
Palpate for bladder distension after voiding
Pelvic examination (atrophic vaginitis or urethritis; pelvic muscle laxity; pelvic mass)
Rectal examination (skin irritation; resting tone and voluntary control of anal sphincter; prostate nodules; fecal impaction. <i>Note:</i> ease of catheterization and prostate size correlate poorly with presence or absence of urethral obstruction)
Neurologic examination (mental status and affect, mobility, and elemental examination, including sacral reflexes and perineal sensation)
Laboratory investigation
Voiding record (incontinence chart)
Metabolic survey (measurement of electrolytes, calcium, glucose, and urea nitrogen) ^a
Measurement of postvoiding residual volume (PVR) by catheterization or portable ultrasound
Urinalysis and culture
Renal ultrasound for men whose residual urine exceeds 100–200 ml ^a
Urine cytology for patients with sterile hematuria, suprapubic/perineal pain, or unexplained new onset or worsening of incontinence ^a
Uroflowmetry for men in whom urethral obstruction is suspected ^a
Cystoscopy for patients with hematuria, suspected lower urinary tract pathology (e.g., bladder fistula, stone, or tumor; urethral diverticulum), or need for surgery
Urodynamic evaluation when the risk of empiric therapy exceeds the benefit, when empiric therapy has failed or might be improved by more precise assessment, or when surgery would be clinically appropriate if a correctable condition were found ^a

^aTests indicated only for selected individuals, as described.

and associated symptoms and conditions (Table 63.5). It is also helpful to know if the patient leaks at night. Generally, individuals with detrusor overactivity gush intermittently both day and night, whereas those with pure stress incontinence are usually dry at night because they are in the supine position and not straining. However, individuals with intrinsic sphincter deficiency, especially those who also have a poorly compliant bladder, may leak only at night if they allow their bladder to fill to a volume greater than their weakened outlet can withstand. Such individuals also have the almost continuous seepage mentioned earlier.

Although the clinical type of incontinence most often associated with detrusor overactivity (DO) is urge incontinence, “urge” is neither a sensitive nor specific symptom; it is absent in 20% of older patients with detrusor overactivity, and the figure is higher in demented patients.⁴⁰ “Urge” is also reported commonly by patients with stress incontinence, outlet obstruction, and overflow incontinence.

A more useful term for the symptom associated with DO is “precipitancy,” which can be defined in two ways. For patients with no warning of imminent urination

(“reflex” or “unconscious” incontinence), the abrupt gush of urine in the absence of a stress maneuver can be termed precipitant leakage, and it is almost invariably due to DO. For those who do sense a warning, it is of less value to focus on the leakage, because the presence and volume of leakage in this situation depend on bladder volume, amount of warning, toilet accessibility, the patient’s mobility, and whether the individual can overcome the relative sphincter relaxation that normally accompanies detrusor contraction.⁵⁷ Instead, precipitancy should be defined as the *abrupt sensation* that urination is imminent, *whatever the interval or amount of leakage that follows*; defined in these two ways, precipitancy is both a sensitive and specific symptom.⁵⁸

Similar to the situation for urgency, other symptoms ascribed to DO also can be misleading unless explored carefully. Urinary frequency (more than seven diurnal voids) is common,^{15,26,59} and may result from voiding habit, preemptive urination to avoid leakage, overflow incontinence, sensory urgency, a stable but poorly compliant bladder, excessive urine production, depression, anxiety, or social reasons.⁵⁸ Conversely, incontinent individuals may severely restrict their fluid intake so that

Date	Time	Volume voided (mL)	Are you wet or dry?	Approximate volume of incontinence	Comments

FIGURE 63.4. Sample voiding record. Voiding diary of an incontinent 75-year-old man. Urodynamic evaluation excluded urethral obstruction and confirmed a diagnosis of detrusor hyperactivity with impaired contractility (DHIC). However, note the 24-h urine output of nearly 3L due to the belief that drinking 10 glasses of fluid/day was “good for my health.” (Patient did not mention this until queried about the voiding record.) Given the typical voided volume of 150–250mL and a measured postvoiding residual (PVR) of 150mL, excess fluid intake was overwhelming his usual bladder capacity of 400ml

(150 + 250ml). Although uninhibited bladder contractions were present, the easily reversible volume component of the problem—coupled with the risk of precipitating urinary retention with an anticholinergic agent—prompted treatment with volume restriction alone. After daily urinary output dropped to 1500mL, frequency abated and incontinence resolved. (Adapted from DuBeau CE, Resnick NM. Evaluation of the causes and severity of geriatric incontinence: a critical appraisal. *Urol Clin North Am.* 1991;18:243–256, with permission.)

even in the presence of DO they do not void frequently. Thus, the significance of urinary frequency—or its absence—can be determined only in the context of more information.

Nocturia also can be misleading unless it is first defined (e.g., two episodes may be normal for the individual who sleeps 10h but not for one who sleeps 4h) and then approached systematically (see Table 63.3). There are three general reasons for nocturia: excessive urine output, sleep-related difficulties, and urinary tract dysfunction. These causes can be differentiated by careful questioning and examination of a voiding diary that includes voided volumes (Fig. 63.4). One inspects the record of voided volumes to determine the functional bladder capacity (the largest single voided volume) and compares the capacity to the volume of each nighttime void. For instance, if the functional bladder capacity is 400mL and each of three nightly voids is approximately 400mL, the nocturia is due to excessive production of urine at night. If the volume of most nightly voids is much smaller than bladder capacity, nocturia is due to either (1) a sleep-related problem (the patient voids because she is awake anyway) or (2) a problem with the lower urinary tract. Like excess urine output, sleep-related nocturia may also be due to treatable causes, including age-related sleep disorders, pain (e.g., bursitis, arthritis), dyspnea,

depression, caffeine, or a short-acting hypnotic (e.g., triazolam). Bladder-related causes of nocturia are displayed in Table 63.3. Whatever the cause, the nocturnal component of incontinence is generally remediable.

Prostatism is another symptom complex that warrants comment. Regardless of whether the patient has “irritative” or “obstructive” symptoms, the physician can be easily misled. Most investigators have found that one-third of middle-aged patients referred for prostatectomy are not obstructed. Usually, the problem is an overactive detrusor, which, if unaccompanied by outlet obstruction, may be exacerbated by operative intervention. In older men, the specificity of “prostatism” for obstruction is even lower, owing to the high prevalence of medication use, altered fluid excretion,⁶⁰ constipation, and DHIC, as well as the impairment of bladder contractility that accompanies aging. Thus, symptoms of prostatism are a clue to the diagnosis but are alone insufficiently specific to confirm it.⁶¹

When asking women about leakage with stress maneuvers, it is important to ensure that the absence of such leakage is not due simply to the lack of coughing or sneezing. For those without such precipitants, it is useful to inquire about leakage that occurs instantaneously with lifting or bending over to put on a shoe or stockings.

Finally, patients or their caregivers should be asked which voiding symptom is most bothersome. For example, although a woman may have both stress and urge incontinence, the urge component may be her worst problem and should become the focus of evaluation and treatment. A man with “prostatism” may be most bothered by nocturia,⁶² which may be remedied without any consideration of his prostate (see Fig. 63.4). Failure to address symptom bother can lead to frustration for patient and provider alike.

Voiding Record

One of the most helpful components of the history is the voiding diary. Kept by the patient or caregiver for 48 to 72 h, the diary records the time of each void and incontinent episode. No attempt is made to alter voiding pattern or fluid intake. Many formats have been proposed; a sample is shown in Figure 63.4.

To record voided volumes at home, individuals use a measuring cup, coffee can, pickle jar, or other large-mouth container. Information regarding the volume voided provides an index of functional bladder capacity and, together with the pattern of voiding and leakage, can suggest the cause of leakage. For example, incontinence occurring only between 8 A.M. and noon may be caused by a morning diuretic. Incontinence that occurs at night in a demented man with congestive heart failure, but not during a 4-h nap in his wheelchair, is likely due to neither dementia nor prostatic obstruction but to postural diuresis associated with his heart failure. A woman with volume-dependent stress incontinence may leak only on the way to void after a full night’s sleep, when her bladder contains more than 400 mL, more than it ever does during her continent waking hours. A patient may also void frequently because of polyuria.

The voiding record should also guide therapy. For instance, in a patient with DO or prostatic obstruction, excess nocturnal fluid excretion may result in nocturnal incontinence that is more severe and troublesome than daytime leakage; successful therapy must address the excess excretion. In contrast, another patient with the same urinary dysfunction and excretion, but able to hold more urine when asleep, might be bothered more by daytime leakage. Shifting his excess nocturnal excretion to the daytime will *exacerbate* the problem.

The information gathered from the history and voiding record permits symptomatic characterization of the incontinence as *urge*, in which precipitant leakage of a large volume is preceded by a brief warning of seconds to minutes; *reflex*, in which precipitant leakage is not preceded by a warning; *stress*, in which leakage occurs coincident with, and only in association with, increases in abdominal pressure; *overflow*, in which continual drib-

bling occurs; and *mixed*, which is usually a combination of urge and stress. Each of these types correlates fairly well with the pathophysiologic mechanisms already mentioned: urge and reflex with detrusor overactivity; stress with urethral incompetence (owing to either urethral hypermobility or ISD); overflow with urethral obstruction or detrusor underactivity; and mixed with both an overactive detrusor and an incompetent outlet.

Targeted Physical Examination

Similar to the history, the physical examination is essential to detect transient causes, comorbid disease, and functional impairment. One should check for signs of neurologic disease, such as delirium, dementia, stroke, Parkinson’s disease, cord compression, and neuropathy (autonomic or peripheral), as well as for atrophic vaginitis and general medical illnesses such as heart failure and peripheral edema. One also should check for bladder distension and for spinal column deformities suggestive of vertebral anomalies that may impinge on the spinal cord.

The rectal exam checks for fecal impaction, masses, and prostate nodularity and consistency. Prostate size is less important to assess because, as determined by palpation, it correlates poorly with the presence or absence of outlet obstruction.⁵⁶ The remainder of the rectal exam is actually a detailed neurourologic examination because the same sacral roots (S2–S4) innervate both the external urethral and the anal sphincters. Gluteal fold symmetry should be assessed. Then, with the finger in the rectum, one assesses motor innervation by asking the patient to voluntarily contract and relax the anal sphincter. Because abdominal straining may mimic sphincter contraction, it is useful to place one’s other hand on the patient’s abdomen to check for this. Many neurologically unimpaired elderly patients are unable to voluntarily contract their sphincter, but if they can, it is evidence against a cord lesion. When the perineum is relaxed, one can assess motor innervation further by testing the anal wink (S4–S5) and bulbocavernosus reflexes (S2–S4). In an older person, however, the absence of these reflexes is not necessarily pathologic, nor does their presence exclude an underactive detrusor (due to a diabetic neuropathy, for example). Finally, afferent supply is assessed by testing perineal sensation.

In women, one can check for pelvic muscle laxity (cystocele, rectocele, enterocele, uterine prolapse). After removing one blade of the vaginal speculum (or using a “tongue blade”), one sequentially places the remaining blade on the anterior and posterior vaginal walls and asks the patient to cough. If bulging of the anterior wall is detected when the posterior wall is stabilized, a cystocele is present; conversely, if bulging of the posterior wall is

detected, a rectocele or enterocele is present. While the extent of pelvic muscle laxity may be underestimated if one checks in only the supine position, the presence of laxity can usually be determined in any position. It is important to realize, however, that the presence or absence of pelvic muscle laxity reveals little about the cause of an individual's leakage. Detrusor overactivity may exist in addition to a cystocele, and stress incontinence may exist in the absence of a cystocele. Thus, knowledge of pelvic muscle laxity is useful primarily in informing the surgeon's choice of operation. The one exception occurs in the woman with a large cystocele: descent of the cystocele may kink the urethra and cause obstruction.

Stress Testing and PVR Measurement

Stress testing is important for incontinent women. Optimally, it is performed when the bladder is full and she is relaxed (check gluteal folds to corroborate) and in as close to the upright position as possible. The cough or strain should be vigorous and *single*, so that one can determine whether leakage coincides with the increase in abdominal pressure or follows it. Stress-related leakage can be missed if any of these conditions is not met. Delayed leakage, typical of stress-induced DO, should be differentiated from leakage typical of stress incontinence, which is instantaneous and ceases as abdominal pressure declines. *To be useful diagnostically, leakage must replicate the symptom for which help is sought*, because many older women have incidental but not bothersome leakage of a few drops. The test should not be performed if the patient has an abrupt urge to void, because this is usually due to an involuntary detrusor contraction that will lead to a falsely positive stress test. Falsely negative tests occur when the patient fails to cough vigorously or fails to relax the perineal muscles, the bladder is not full, or the test is performed in the upright position in a woman with a large cystocele (which kinks the urethra). If performed correctly, the stress test is reasonably sensitive and quite specific (>90%).⁶³⁻⁶⁵

Following the stress test, the patient is asked to void into a receptacle and the PVR is measured. If the stress test was negative but the history suggests stress incontinence *and* the combined volume of the void and PVR is less than 200 mL, the bladder should be filled with sterile fluid so that the stress test can be repeated at an adequate volume. There is no need to repeat a well-performed positive stress test or to repeat it in a woman whose history is negative for stress-related leakage; the sensitivity of the history for stress incontinence, unlike its specificity, exceeds 90%,^{66,67} making the likelihood of stress incontinence remote in this situation.

Optimally, the PVR is measured within 5 min of voiding. Measuring it after an intentional void is better

than after an incontinent episode, because many patients are able to partially suppress the involuntary contraction during the episode and more than the true PVR remains. In cognitively impaired patients this may not be possible; however, as the resulting artifact will lead to a falsely elevated PVR, a low value is still useful. The PVR will also be spuriously high if measurement is delayed (especially if the patient's fluid intake was high or included caffeine), the patient was inhibited during voiding, or there is discomfort due to urethral inflammation or infection. It will be spuriously low if the patient augmented voiding by straining (most important in women), if the catheter is withdrawn too quickly, and if the woman has a cystocele that allows urine to "puddle" beneath the catheter's reach. Of note, relying on the ease of catheterization to establish the presence of obstruction can be misleading, because difficult catheter passage may be caused by urethral tortuosity, a "false passage," or catheter-induced spasm of the distal sphincter, whereas catheter passage may be easy in even obstructed men.⁶⁸

Two other tests should be mentioned. Because pelvic muscle laxity may be present regardless of the cause of incontinence in an older woman, the "Q-tip test" used to detect such laxity is of little value.⁶¹ The Bonney (or Marshall) test assesses whether leakage that coincides with increased abdominal pressure can be prevented by stabilizing (not occluding) the bladder base and thereby preventing its herniation through the urogenital diaphragm. The test is performed by placing a finger in each lateral vaginal fornix and asking the patient to cough again. Stress incontinence owing to urethral hypermobility is considered present if leakage is prevented. The value of this test is limited in elderly women because vaginal stenosis is common and may lead to a false-positive result by precluding accurate finger placement; if one's fingers are not placed far enough laterally, they may occlude the bladder outlet rather than stabilizing it and prevent leakage even in a patient with detrusor instability. Furthermore, even if the test is performed correctly, a false-positive result may occur if the first episode of leakage was due to a cough-induced detrusor contraction, which, having emptied the bladder, does not recur during bladder base elevation.

Laboratory Investigation

One should check the blood urea nitrogen (BUN), creatinine, urinalysis, and PVR in all patients.^{1,61,69,70} Urine culture should be obtained in those with dysuria or an abnormal urinalysis. Serum sodium, glucose, and calcium should be measured in patients with confusion. If the voiding record suggests polyuria, serum glucose and calcium should be determined. Sterile hematuria suggests partially or recently treated bacteriuria, malignancy, calculus, or tuberculosis.

Empiric Diagnostic Categorization

After transient and serious causes have been addressed, the optimal diagnostic strategy for persistent incontinence is unknown.^{1,70,71} “Bedside” cystometry has been proposed, but its utility is limited because it misses low-pressure contractions of DHIC; its feasibility and accuracy are low in frail elderly⁷²; and detected DO may be either incidental and unrelated to leakage or due to urethral obstruction or incompetence and warrant different therapy. The following approach,¹¹ although still unproved, is relatively noninvasive, accurate, cost-effective, and easily tolerated. A similar approach forms the basis for the AHCPR Clinical Practice Guideline,¹ as well as the Minimum Data Set/Resident Assessment Instrument that we designed and validated for use in all American nursing homes.⁷³

The first step is to identify the 5% to 10% of individuals with overflow incontinence (e.g., PVR >450 mL). Because its causes (obstruction and underactive detrusor) cannot be differentiated clinically,⁷³⁻⁷⁵ further assessment is warranted for those in whom it would affect therapy, and catheterization should be used for the rest.

For the remaining patients, the next step depends on their sex. In women, obstruction is rare. Thus, in the absence of previous bladder neck suspension or prolapsing cystocele, the differential diagnosis is generally between stress incontinence and DO. If the contemplated intervention is nonoperative, this distinction usually can be made on clinical grounds alone, informed by the caveats mentioned earlier.

In men, stress incontinence is uncommon and presents with a characteristic drip (similar to a “leaky faucet”) that is exacerbated by standing or straining. Thus, the usual problem in men is differentiating DO from obstruction. Figure 63.5 summarizes the approach. Uroflowmetry is helpful, but only if peak flow is normal (e.g., >12 mL/s for voided volume of 200 mL); the age-related decrease in bladder contractility means that a normal unstrained flow rate, together with PVR less than 100 mL, effectively excludes clinically significant obstruction in an older man.⁷⁴ The next step is to search for hydronephrosis in men whose PVR exceeds 200 mL and to decompress those in whom it is found.⁵⁶ Further evaluation is also reasonable for men without hydronephrosis who would be amenable to surgery if obstructed. For the rest, it seems

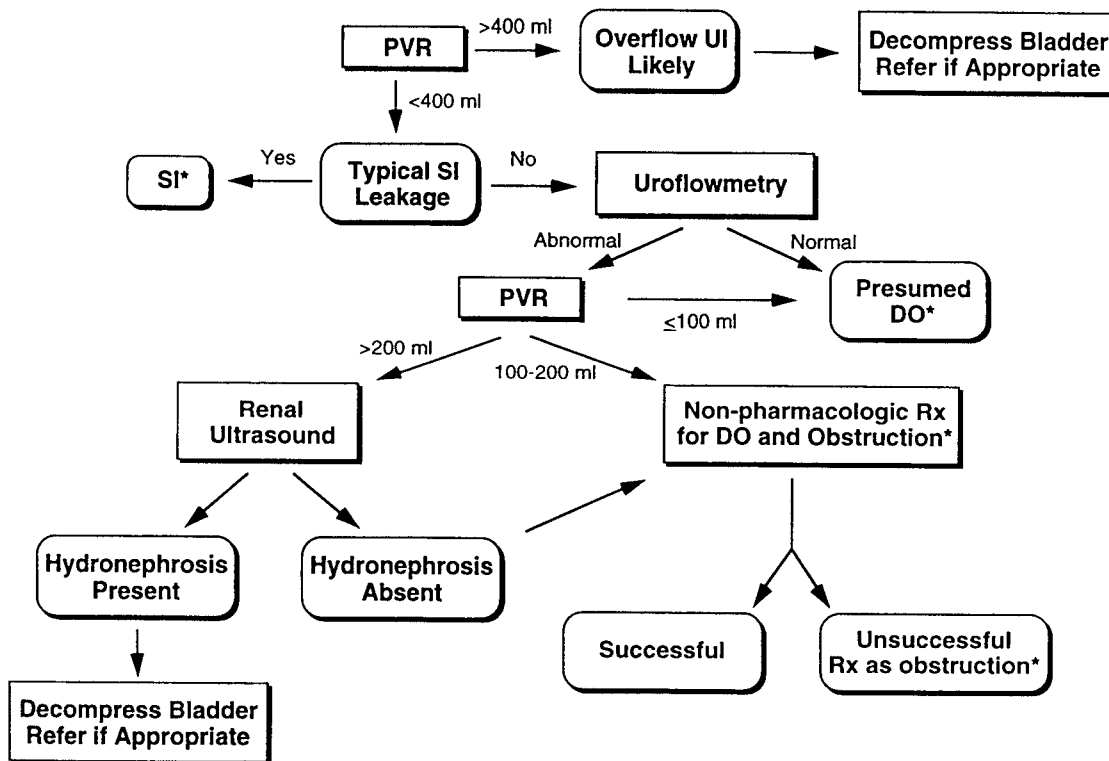

FIGURE 63.5. Stepwise evaluation of incontinent men. Assumes transient (DIAPERS) causes have been excluded. Cutoffs for postvoiding residual urine volumes are intended as guidelines rather than absolute values, which are not available; see text for further details and caveats. Rectangles, denote tests/actions;

rounded boxes, findings/diagnoses; UI, urinary incontinence; PVR, postvoiding residual volume; SI, stress incontinence; DO, detrusor overactivity. (See Table 63.6 for management suggestions.)

sensible to treat those with urge incontinence for presumed DO, provided they are compliant and can be taught signs of incipient urinary retention; bladder relaxants should be avoided in those with significantly elevated PVR (e.g., >150mL). A similar approach is advocated for cognitively impaired men who can be closely observed (e.g., institutionalized residents).^{73,76} Men without urge incontinence, those who fail empiric therapy, and those who are cognitively impaired and less supervised should be evaluated further if findings would affect therapy.

Urodynamic Testing

Although its precise role in the elderly is unclear, multi-channel urodynamic evaluation is probably warranted when diagnostic uncertainty may affect therapy and when empiric therapy has failed and other approaches would be tried. Because conditions that closely mimic obstruction and stress incontinence are so common in the elderly—including altered fluid excretion,⁶⁰ medication use, Detrusor Hyperactivity (DH), and DHIC^{51,52}—urodynamic corroboration of the diagnosis is strongly recommended if surgery will be performed.^{1,51,73,76} Whatever its role, however, urodynamic evaluation of elderly patients is reproducible, safe, and feasible to perform, even in frail and debilitated individuals.^{40,77}

Urodynamic evaluation consists of a battery of tests that characterize bladder and urethral function during both the filling and voiding phases of the micturition cycle. Optimally, bladder, urethral, and rectal pressures are measured simultaneously and during both phases of the cycle. Concurrent fluoroscopic monitoring is extremely helpful for the elderly patient, because pressure monitoring alone may miss involuntary contractions, obstruction, and stress incontinence. Some of the more commonly used tests are described next.

Cystometry

Cystometry (CMG) assesses only the bladder, not the outlet, and only during filling, not voiding. Therefore, it yields only part of the information needed to establish a diagnosis. It is performed by inserting a catheter into the bladder, filling it with gas or fluid, and observing the bladder's pressure response to increasing volume. In addition to providing information about bladder proprioception (sensation), compliance, and capacity, cystometry detects involuntary detrusor contractions (detrusor overactivity), which generally appear as phasic increases in bladder pressure. However, if the contraction amplitude is low (as in DHIC) or if the patient talks, coughs, or moves during the contraction, these contractions may be missed.^{51,52} Furthermore, artifacts are common, especially when investigating the elderly. These artifacts can be

minimized by having the test performed by a knowledgeable physician (not a technician), by infusing fluid rather than gas, by using moderate infusion rates (<100mL/min) rather than rapid ones, by using fluoroscopy, and—most importantly—by measuring abdominal and bladder pressures simultaneously to differentiate rises in bladder pressure from rises in abdominal pressure.

Finally, because involuntary contractions may occur in the elderly as an incidental finding rather than as the cause of incontinence or since they may be merely secondary to primary urethral pathology (e.g., stress incontinence or obstruction), their significance is difficult to discern without further testing. Such differentiation is important to avoid misdirected therapy; for instance, anticholinergic therapy of DO in a man in whom the DO is incidental to obstruction could precipitate painful urinary retention.

Urethral Profilometry (During Filling and Voiding)

There are two types of profilometry, depending on whether urethral pressure is measured when the bladder is at rest or contracting. The first is called urethral closure pressure profilometry (UCPP) and the second micturitional urethral pressure profilometry (MUPP). UCPP is performed by inserting a catheter into the bladder, slowly withdrawing it through the urethra, and plotting urethral pressure at each point. The diagnostic value of UCPP is limited. In women with known stress incontinence, however, very low urethral pressures suggest that leakage may reflect intrinsic sphincter deficiency (ISD) rather than urethral hypermobility; in the former, urethral pressure is consistently low (e.g., <10cmH₂O), while in the latter it is normal. Determining “leak point pressure,” the pressure at which the sphincter becomes incompetent during coughing or straining, is another way to identify ISD. Urethral profilometry is also used to exclude detrusor-sphincter dyssynergia. Generally, only evaluation of the distal urethral sphincter is required; this sphincter should relax just before, or coincident with, detrusor contraction.

MUPP is useful for evaluating men.⁷⁸ It is performed by simultaneously measuring pressure in the bladder and along the urethra as the patient voids. With urethral obstruction, the pressure distal to the obstruction is lower than bladder pressure. If obstruction is detected, fluoroscopy can localize the site. MUPP is more accurate than cystoscopy for determining the presence of an obstruction and judging its severity.⁵⁶

Uroflowmetry

Uroflowmetry is often used to screen men for urethral obstructions.⁷⁴ The flow rate depends not only upon the

presence of obstruction, however, but also upon the strength of detrusor contraction. To interpret the test, one must know the voided volume, residual volume, whether the void was augmented by abdominal straining, the peak and mean flow rates, and the configuration of the accompanying trace. Interrupted and oscillatory patterns are suggestive of abdominal straining, bladder weakness, or outlet obstruction. Although age-related norms have been devised to facilitate interpretation of the test, the studies on which they are based are flawed and included few patients over age 70. Moreover, although the sensitivity of the test likely increases with age, its specificity almost certainly declines.⁷⁴ Thus, the utility of isolated uroflowmetry in elderly males remains undefined. One can, however, derive some information from it. In the older man with symptoms of prostatism, a normal flow rate and PVR less than 100 mL exclude clinically significant obstruction.

Electromyography

Electromyography (EMG) evaluates the distal urethral sphincter by determining the integrity of its innervation, testing its response to reflex stimuli [such as bladder filling (guarding reflex) and bulbocavernosus stimulation], and characterizing its behavior during voiding. Several techniques are available for EMG, depending on whether one employs surface or needle electrodes, records the response of single or multiple nerve fibers, and evaluates the nerve supply to the urethral sphincter or the pelvic floor musculature (through vaginal, anal, or perineal probes). The most accurate technique is to insert a needle electrode directly into the distal urethral sphincter. Although most elderly patients can tolerate this, the results can be difficult to interpret, the equipment is expensive, and, if urodynamic testing is performed as already detailed, EMG adds little. If fluoroscopically monitored multichannel urodynamic capability is not available, however, EMG is useful. Unfortunately, in these situations, only surface or anal EMG is usually performed. As these techniques are fraught with artifact, they should be interpreted with caution.

Radiographic Evaluation

Optimally, the radiographic and urodynamic evaluations are performed simultaneously, allowing correlation of visual and manometric information. If this is not feasible, substantial information can still be gleaned from cystography. A full evaluation includes posteroanterior and oblique (or lateral) views of the bladder, at rest and during straining and voiding. These films check for bladder trabeculation, diverticula, masses, bladder neck competence, and ureteral reflux. Although the urethrovesical angle and axis are also often measured, their reliability and relevance are limited. The *voiding* films

allow one to check for outlet obstruction. Postvoiding residual volume also can be assessed radiographically, but there are pitfalls. Elderly patients are frequently rushed through busy radiography departments and may feel too inhibited to void to completion; the radiologist, who may have been absent during the exam, may then erroneously conclude that the residual volume is elevated. Conversely, a low volume does not exclude a weak bladder if the patient augmented voiding by straining or by multiple voids before the film was obtained. Therefore, the radiographer should be viewed as a partner in the evaluation, rather than being asked to read films blindly after the examination is completed.

Therapy

Like the diagnostic approach, treatment must be individualized because factors outside the lower urinary tract so often affect feasibility and efficacy. For instance, although both may have detrusor overactivity that can be managed successfully, a patient with impaired cognition and mobility must be treated differently from one who is ambulatory and cognitively intact. This section and Table 63.6 outline several treatments for each condition and provide guidance for their use. It is assumed that serious underlying conditions, transient causes of incontinence, and functional impairments have already been addressed. It cannot be overemphasized that successful treatment of established incontinence, especially in the elderly, is usually multifactorial and requires addressing factors beyond the urinary tract, as well.

Detrusor Overactivity

The initial approach to detrusor overactivity is to identify and treat its reversible causes. Unfortunately, many of its causes are not amenable to specific therapy or a cause may not be found, so treatment usually must be symptomatic. Simple measures, such as adjusting the timing or amount of fluid excretion (see Fig. 63.4) or providing a bedside commode or urinal are often successful. If not, the cornerstone of treatment is behavioral therapy. If the patient can cooperate, bladder training regimens will extend the voiding interval.^{79–82} For instance, if the voiding record documents incontinence when the interval exceeds 3 h, the patient is instructed to void every 2 h and to suppress urgency in between. Once dry, the patient can extend the interval by half an hour and repeat the process until a satisfactory result or continence is achieved. Patients need not follow this regimen at night, because nighttime improvement parallels daytime success. Biofeedback may be added,^{80,81,83,84} but its marginal benefit is unclear.^{82,85}

TABLE 63.6. Stepwise approach to treatment.^a

Condition	Clinical type of incontinence ^b	Treatment
Detrusor overactivity with normal contractility (DO)	Urge	<ol style="list-style-type: none"> 1. Bladder retraining or prompted voiding regimens 2. ±Bladder relaxant medication (anticholinergic, smooth muscle relaxant, calcium channel blocker), if needed and not contraindicated 3. Indwelling catheterization alone is often unhelpful because detrusor “spasms” often increase, leading to leakage around the catheter 4. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization^f
Detrusor hyperactivity with impaired contractility (DHIC)	Urge ^c	<ol style="list-style-type: none"> 1. If bladder empties adequately with straining, behavioral methods (as above) ±bladder relaxant medication (low doses; especially feasible if sphincter incompetence coexists) 2. If residual urine >150 ml, augmented voiding techniques^d or intermittent catheterization (±bladder relaxant medication); if neither feasible, undergarment or indwelling catheter
Stress incontinence	Stress	<ol style="list-style-type: none"> 1. Conservative methods [weight loss if obese; treatment of cough or atrophic vaginitis; physical maneuvers to prevent leakage (e.g., tighten pelvic muscles, cross legs); occasionally, use of tampon or pessary is useful] 2. If leakage threshold ≥150 ml identified, adjust fluid excretion and voiding intervals 3. Pelvic muscle exercises ±biofeedback/weighted intravaginal “cones” 4. Imipramine (or doxepin) or alpha-adrenergic agonists, ±estrogen, if not contraindicated 5. Surgery [urethral suspension, or compression (“sling”), periurethral bulking injections, artificial sphincter]
Urethral obstruction	Urge/overflow ^e	<ol style="list-style-type: none"> 1. Conservative methods (including adjustment of fluid excretion, bladder retraining/prompted voiding) if hydronephrosis, elevated residual urine, recurrent symptomatic UTI, and gross hematuria have been excluded 2. Bladder relaxants if DO coexists, PVR is small, and surgery is not desired or feasible 3. Alpha-adrenergic antagonists, finasteride, antiandrogens, and/or LHRH analogues if not contraindicated and the patient either prefers them or is not a surgical candidate 4. Surgery (incision, prostatectomy)
Underactive detrusor	Overflow	<ol style="list-style-type: none"> 1. If duration unknown, decompress for several weeks and perform a voiding trial 2. If cannot void, PVR remains large, or retention is chronic, try augmented voiding techniques^d ±alpha-adrenergic antagonist, but only if some voiding possible; bethanechol rarely useful unless bladder weakness due to an anticholinergic agent that cannot be discontinued 3. If fails, or voiding is not possible, intermittent or indwelling catheterization^f

UTI, urinary tract infection; PVR, postvoiding residual volume.

^aThese treatments should be initiated only after adequate toilet access has been ensured, contributing conditions have been treated (e.g., atrophic vaginitis, heart failure), fluid management has been optimized, and unnecessary or exacerbating medications have been stopped. For additional details, recommendations, and drug doses, see text.

^b*Urge*: Leakage in the absence of stress maneuvers and urinary retention, usually preceded by *abrupt* onset of need to void.

Stress: Leakage that coincides *instantaneously* with stress maneuvers, in the absence of urinary retention or detrusor contraction.

Overflow: Frequent leakage of small amounts associated with urinary retention.

^cMay also mimic stress or overflow incontinence.

^dAugmented voiding techniques include Crede (application of suprapubic pressure) and Valsalva (straining) maneuvers, and “double” voiding. They should be performed only *after* voiding has begun.

^eAlso can cause postvoid “dribbling” alone, which is treated conservatively (e.g., by sitting to void and allowing more time, “double voiding,” and by gently “milking” the urethra after voiding).

^fUTI prophylaxis can be used for recurrent symptomatic UTIs, but only if catheter is not indwelling.

Source: Adapted from Resnick NM. Voiding dysfunction and urinary incontinence. In: Beck JC, ed. *Geriatric Review Syllabus*. New York: American Geriatrics Society; 1991:141–154, with permission.

For cognitively impaired patients, “prompted voiding” is used.^{12,86} Asked every 2 h whether they need to void, patients are escorted to the toilet if the response is affirmative. Positive verbal reinforcement is employed and negative comments are avoided. Prompted voiding reduces incontinence frequency in nursing homes by roughly 50%, and leakage can be virtually eliminated during daytime hours in one-third of residents.^{87–89} The

latter group can be identified within 3 days. When prompted *hourly* to void during the daytime, they urinate into a toilet or commode more than two-thirds of the time that they indicate the need to do so, or they become continent on more than 80% of checks. Response is maintained when the prompting interval is increased to 2 h. Half the remaining patients also improve with prompting, but they remain wet more than once during

the daytime. For the quarter of patients who do not respond to prompting at baseline, little benefit is obtained by further prompting. Importantly, response does not correlate with the degree of dementia. In addition, these results were obtained without drugs, and urodynamic evaluations were not performed.^{89,90} Tailoring the regimen to the cause and pattern of incontinence should further improve outcome.

The voiding record also can be helpful if it reveals that nocturnal incontinence correlates with nocturnal diuresis. If caused by systolic congestive heart failure, it should improve with diuretic therapy. If due to peripheral edema in the absence of heart failure and hypoalbuminemia (i.e., venous insufficiency), it should respond to pressure gradient stockings. If it is not associated with peripheral edema, it may respond to alteration of the pattern of fluid intake or administration of a rapidly acting diuretic in the early evening.^{60,91} For patients with DHIC whose voiding record and PVR suggest that involuntary detrusor contractions are provoked only at high bladder volumes, catheterization at bedtime will remove the residual urine, thereby increasing functional bladder capacity and restoring both continence and sleep.

Drugs augment behavioral intervention but do not supplant it because they generally do not abolish involuntary contractions. Timed toileting or bladder retraining, in conjunction with a bladder relaxant, is thus especially useful for older adults who have little warning before detrusor contraction.¹³ Table 63.7 provides infor-

mation on drugs used to treat DO. There are few data on comparative efficacy or toxicity of standard drugs in the elderly, but available studies show similar efficacy for most agents, except flavoxate, which fares poorly in controlled trials¹; no controlled data are available for hyoscyamine in the elderly.

Both oxybutynin and tolterodine have proved effective in well-conducted trials that included older adults,^{13,92,93} and healthy elderly participants appeared to respond as well as younger patients. Fewer data are available for extended-release oxybutynin in the elderly,^{1,13,94} but our randomized and controlled data, in which low-dose immediate-release oxybutynin was given three or four times daily, suggest that the more constant serum concentrations achieved with extended release oxybutynin should yield similar results to the immediate-release form given frequently. For instance, in our trial of community-dwelling patients, two-thirds of patients (mean age, 73 years) became continent, including 71% whose bladder had normal contractility and 47% of those with DHIC, as compared with 17% on placebo.⁹⁵ Immediate-release oxybutynin, which has a short half-life, can be employed prophylactically if incontinence occurs at predictable times. Intravesical instillation of several agents is also effective in younger patients,⁹² but the need for self-catheterization makes this strategy less useful in the elderly.

Unlike tolterodine or extended-release oxybutynin, immediate-release oral oxybutynin has been assessed in

TABLE 63.7. Bladder relaxant medications used to treat urge incontinence.^a

Medication class, name, and dosage	Comments
Smooth muscle relaxant	
Flavoxate 300–800 mg daily (100–200 mg po tid-qid) ^b	Has not proved effective in placebo-controlled trials
Calcium channel blocker	
Diltiazem 90–270 mg daily (30–90 mg po qd-tid)	No controlled trial data; most useful for the patient with another indication
Nifedipine 30–90 mg daily (10–30 mg po qd-tid)	for the drug (e.g., hypertension, angina pectoris, or abnormalities of cardiac diastolic relaxation)
Combination smooth muscle relaxant and anticholinergic	
Oxybutynin IR 7.5–20 mg daily (2.5–5 mg po tid-qid) ^c	Both oxybutynin and tolterodine have proved effective in rigorous controlled trials when used continuously; fewer controlled data are available for dicyclomine but efficacy appears to be similar; because immediate release oxybutynin and dicyclomine have a rapid onset of action, they can be tried prophylactically if incontinence occurs at predictable times
Oxybutynin XL 5–30 mg daily (given once daily)	
Tolterodine 2 mg twice daily	
Dicyclomine 30–90 mg daily (10–30 mg po tid)	
Tricyclic antidepressants ^d	
Doxepin 25–75 mg daily (10–25 mg po qd-tid)	May be particularly helpful in women with coexistent stress incontinence; orthostatic hypotension often precludes their use, but a tricyclic antidepressant may be preferred for a depressed incontinent patient without orthostatic hypotension
Imipramine 25–100 mg daily (10–25 mg po qd-qid)	

IR, immediate release; XL, extended release.

^aAll drugs should be started at the lowest dose and increased slowly until encountering maximum benefit or intolerable side effects. All are given in divided doses, except the antidepressants and long-acting forms of oxybutynin and tolterodine, which may be given as a single daily dose.

^bSome uncontrolled reports suggest that doses up to 1200 mg/day may be effective with tolerable side effects; efficacy has not been supported by randomized controlled trials at any dose.

^cMay also be applied intravesically in patients who can use intermittent catheterization.

^dMay give as single daily dose of 25–100 mg after determining the optimal dose.

Source: Adapted from Resnick NM. Urinary incontinence. *Lancet*. 1995;346:94–99, with permission.

nursing home patients. In a randomized controlled trial, 2.5 mg qid proved well tolerated and effective, albeit less so than in more independent people. On this dose, 10% of these frail patients (mean age, 89 years) became completely continent, and incontinence frequency decreased by at least half in 27% and by at least one-third in 54% (Resnick et al., unpublished data).

For depressed patients, imipramine may be tried,¹ but only if the depression has not already remitted and there is no evidence of orthostatic hypotension. Other tricyclic agents should work similarly, but efficacy data are available only for imipramine and doxepin.⁹²

Regardless of which bladder relaxant is used, urinary retention may develop. PVR and urine output should be monitored, especially in DHIC in which the detrusor is already weak. Subclinical urinary retention also may develop, reducing functional bladder capacity and attenuating or even reversing the drug's benefit. Thus, if incontinence worsens as the dose is increased, PVR should be remeasured. Another reason for drug failure is excess fluid ingestion engendered by anticholinergic-induced xerostomia. For patients whose incontinence defies other remedies (such as those with DHIC), inducing urinary retention and using intermittent catheterization may be viable if catheterization is feasible. Other remedies for urge incontinence, including electrical stimulation⁹⁶⁻⁹⁸ and selective nerve blocks,⁹⁹ are successful in selected situations but have not been studied adequately in the elderly.

Vasopressin has little efficacy for geriatric incontinence,¹⁰⁰⁻¹⁰² and the high prevalence of contraindications to its use [e.g., renal insufficiency, heart failure (even subclinical)], the risk of inducing serious hyponatremia and fluid retention,¹⁰² and the considerable expense suggest that use of desmopressin acetate (DDAVP) in the elderly should await results of further studies. These caveats are underscored by recent data that suggest that nocturnal polyuria may reflect more of a disordered release of atrial natriuretic hormone (ANH) than of vasopressin.¹⁰³ If corroborated, such increased ANH release could result in a natriuresis that would underlie the older patient's predisposition to hyponatremia when treated with vasopressin.

Adjunctive measures, such as pads and special undergarments, are invaluable if incontinence proves refractory. Many types are now available, allowing the recommendation to be tailored to the individual's problem.¹⁰⁴⁻¹⁰⁷ [Most are included in an illustrated catalog (NAFC, P.O. Box 8310, Spartanburg, SC 29305; www.nafc.org)]. For bedridden individuals, a launderable bedpad may be preferable, whereas for those with a stroke, a diaper or pant that can be opened using the good hand may be preferred. For ambulatory patients with large gushes of incontinence, wood pulp-containing products are usually superior to those containing polymer gel because the gel generally cannot absorb the large amount

and rapid flow, whereas the wood pulp product can easily be doubled up if necessary. Optimal products for men and women differ because of the location of the "target zone" of the urinary loss. Finally, the choice will be influenced by the presence of fecal incontinence.

Condom catheters are helpful for men, but they are associated with skin breakdown, bacteriuria, and decreased motivation to become dry^{12,86,108,109}; these also are not feasible for the older man with a small or retracted penis. External collecting devices have been devised for institutionalized women¹¹⁰; whether they will adhere adequately in more active women remains to be determined. Indwelling urethral catheters are not recommended for detrusor overactivity because they usually exacerbate it. If they must be used (e.g., to allow healing of a pressure sore), a small catheter with a small balloon is preferable to avoid leakage around the catheter; such leakage almost invariably results from bladder contractions rather than a catheter that is too small. Increasing catheter and balloon size only aggravates the problem and may result in urethral erosion and sphincter incompetence. If spasms persist, drugs such as oxybutynin can be tried. More potent anticholinergic agents, such as belladonna suppositories, should be avoided in the elderly.

Stress Incontinence

Urethral hypermobility, the most common cause of stress incontinence in older women, may be improved by weight loss if the patient is obese, by postural maneuvers,¹¹¹ by therapy of precipitating conditions such as atrophic vaginitis or cough (e.g., due to an angiotensin-converting enzyme inhibitor), and (rarely) by insertion of a pessary.^{112,113} If the voiding diary reveals that leakage is volume dependent, it may be improved by adjusting fluid excretion and voiding intervals to keep bladder volume below this threshold. However, if the threshold is less than 150 to 200 ml, this strategy generally is not alone sufficient.

Pelvic muscle (Kegel) exercises can decrease incontinence substantially, especially if the patient also contracts her pelvic muscles at the time of stress. The exercises are performed by "drawing in" the perianal and perivaginal muscles while relaxing the abdominal, gluteal, and thigh muscles. The patient should place her hand on her abdomen to ensure that it remains relaxed. Another method is to interrupt voiding midstream by contracting the sphincter, again ensuring that nearby muscles remain relaxed. The exercise can be taught during the examination; for patients who need more help, an inexpensive audiotape is available from NAFC (National Association for Continence, at the above address). Once she identifies the correct muscles, the patient should try to increase the number and duration of contractions, exercising at any time and during any activity. The optimal regimen

remains to be determined, but proven regimens involve 30 to 200 contractions/day for up to 10s at a time.^{1,114–117} Unfortunately, these exercises must be pursued indefinitely, efficacy is limited for severe incontinence, only 10% to 25% of women become fully continent, and many older women are unable or unmotivated to follow such regimens. Adding vaginal cones, biofeedback, or electrical stimulation likely enhances efficacy, but their marginal benefit is unclear.^{1,115,117,118} Urethral plugs are still under development.

If not contraindicated by other conditions, treatment with an alpha-adrenergic agonist, such as phenylpropanolamine (PPA) or pseudoephedrine, may be added and is often beneficial for women, especially when administered with estrogen.^{1,92,116} Pseudoephedrine and estrogen may also work for women with sphincter deficiency. Unfortunately, PPA, the agent for which most data are available, was recently withdrawn from the American market, owing to reports of a very small risk of stroke.¹¹⁹ Pseudoephedrine remains available, inexpensive, and obtainable without a prescription. As it is also contained in nonprescribed remedies for coryza and allergy, however, the physician should prescribe the dose and guide the choice of preparation, because some capsules also contain agents such as chlorpheniramine in doses that can be troublesome for elderly patients. The physician should also closely supervise its use in patients with hypertension, if it is used at all. Imipramine, with beneficial effects on the bladder and the outlet, is a reasonable alternative for patients with evidence of both stress and urge incontinence, but it should be used only if symptoms as well as signs of postural hypotension have been excluded.

If these methods fail or are unacceptable, further evaluation of the urinary tract may be warranted. If urethral hypermobility is confirmed, surgical correction is successful in the majority of selected elderly patients.^{15,120–122} If sphincter incompetence is diagnosed instead, it can be corrected with a different procedure (pubovaginal sling),¹²³ but the morbidity is higher and precipitation of chronic retention is more likely than with correction of urethral hypermobility. The influence of coincident DO on outcome in older women has been inadequately investigated for either type of stress incontinence. Other treatments for sphincter incompetence include periurethral bulking injections (e.g., bovine collagen) and insertion of an artificial sphincter.¹²⁴ Each is effective in selected cases, but reported experience with these approaches in individuals over age 75 is still limited, and so is long-term follow-up.¹²⁵ Many devices other than pessaries have been developed to contain the leakage. Most are applied as a “cap” over the urethral meatus. Unfortunately, most are available for only a brief period, and few objective data have yet been accrued on any, especially in older women for whom atrophic mucosa makes application of such devices more problematic.

For men in whom these interventions fail, prostheses such as condom catheters or penile clamps may be useful, but most require substantial cognitive capacity and manual dexterity and are often poorly tolerated. Penile sheaths (e.g., McGuire prosthesis or adhesive underwear liners) are an alternative. As already discussed, pads and undergarments are used as adjunctive measures. However, in these cases, polymer gel pads are frequently successful because the gel can more readily absorb the smaller amount of leakage. Some products can be flushed down the toilet, a convenient feature for ambulatory individuals.

Outlet Obstruction

For older men, conservative management often suffices. In the absence of urinary retention, modification of fluid excretion and voiding habits may be effective. If not, alpha-adrenergic antagonists are useful and generally well tolerated, except for men with diastolic dysfunction or significant aortic stenosis, in whom these agents should be used with more caution. Tamsulosin may be better tolerated than less specific alpha-blocking agents, but definitive clinical data are still not available.¹²⁶ Finasteride, a 5 α -reductase inhibitor, is another alternative, but fewer men appear to benefit, the effect is more modest, and the benefit is more delayed.¹²⁷ Devices and surgical approaches are discussed elsewhere. Of note, DO probably resolves less often following removal of obstruction in older persons than in younger ones; however, incontinence may still improve, even in cognitively impaired individuals.^{47,128} In addition, less extensive resection often suffices for frail elderly men, in whom recurrence of symptoms with adenoma regrowth years later is often not an issue. This fact, coupled with surgical techniques that now permit resection under local anesthesia, has made surgery increasingly feasible for this population. More detailed discussion of these and other options is provided in Chapter 52.

In women, if a large cystocele is the problem, surgical correction is usually required and should include bladder neck suspension if urethral hypermobility is also present. Prior urodynamic evaluation is helpful as well: if intrinsic sphincter deficiency is identified, a different surgical approach is required to avoid converting incontinence due to obstruction into incontinence due to sphincter incompetence. Bladder neck obstruction is also corrected easily, in even the frailest patient. Distal urethral stenosis can be dilated and treated with estrogen. If meatal stenosis is present, more extensive intervention may be necessary; alternatively, dilation can be repeated at fairly frequent intervals. It should be noted that most women who undergo dilation do not have urethral stenosis but rather an underactive detrusor; for these women, dilation is usually unhelpful and may be harmful.

Underactive Detrusor

Management of detrusor underactivity is directed at reducing the residual volume, eliminating hydronephrosis (if present), and preventing urosepsis. The first step is to use indwelling or intermittent catheterization to decompress the bladder for up to a month (at least 7–14 days), while reversing potential contributors to impaired detrusor function (fecal impaction and medications). If an indwelling catheter has been inserted, it then should be withdrawn (Table 63.8). If decompression does not fully restore bladder function, augmented voiding techniques [such as double voiding and implementation of the Credé (application of suprapubic pressure during voiding) or Valsalva maneuver] may help if the patient is able to initiate a detrusor contraction or if there is coexistent stress incontinence, especially in a woman. Bethanechol (40–200 mg/day in divided doses) is occasionally useful in a patient whose bladder contracts poorly because of treatment with anticholinergic agents that cannot be discontinued (e.g., tricyclic antidepressant).³⁴ In other patients, bethanechol may decrease the PVR if sphincter function and local innervation are normal, but evidence for its efficacy is equivocal at best, and residual volume should be monitored to assess its effect.^{129,130}

On the other hand, if after decompression the detrusor is acontractile, these interventions are apt to be fruitless,

and the patient should be started on intermittent or indwelling catheterization; a condom catheter is contraindicated in the setting of retention. For individuals at home, intermittent self-catheterization is preferable and requires only clean, rather than sterile, catheter insertion. The patient can purchase two or three of these catheters inexpensively. One or two are used during the day and another is kept at home. Men can carry their catheter in a coat pocket, and women can carry theirs in a purse (the catheter used for females is only a few inches long). Catheters are cleaned daily, allowed to air dry at night, sterilized periodically, and may be reused repeatedly. Antibiotic or methenamine prophylaxis against urinary tract infection is probably warranted if the individual gets more than an occasional symptomatic infection or has an abnormal heart valve.^{131,132} Intermittent catheterization in this setting is generally painless, safe, inexpensive, and effective, and allows individuals to carry on with their usual daily activities. For debilitated patients, however, intermittent catheterization is usually less feasible, although sometimes possible.^{107,133} If used in an institutional setting, sterile rather than clean technique should be employed until studies document the safety of the latter.

Unfortunately, despite the benefits and proven feasibility of intermittent catheterization,^{134,135} most elderly individuals choose indwelling catheterization instead.

TABLE 63.8. Removing an indwelling urethral catheter.

Ensure that bladder has been decompressed for at least several days, and 7–21 days if possible; the higher the residual volume, the longer the bladder should be decompressed.

Correct reversible causes of urinary retention: fecal impaction; pelvic/perineal pain; and use of anticholinergic, alpha-adrenergic agonist, or calcium channel blocker medications. If an anticholinergic antidepressant/antipsychotic agent cannot be stopped, consider switching to one with fewer or no anticholinergic side effects, or consider adding bethanechol. Addition of an alpha-adrenoceptor antagonist may be helpful, but is unproven in women.

Treat delirium, depression, atrophic vaginitis, or urinary tract infection, if present.

Record urinary output at intervals of 6–8 h for 2 days to establish a pattern of baseline urine excretion.

Remove the catheter at a time that permits accurate recording of urine output and allows for postvoiding recatheterization; clamping the catheter before removal is not necessary and can be dangerous.

Reinsert the catheter *only*:

- After the patient voids, to determine PVR volume; or
- After the expected bladder *volume* (based on records of urine output)—not the time since the catheter was removed—exceeds a preset limit (e.g., 600–800 ml); or
- If the patient is uncomfortable and unable to void despite ensured privacy and maneuvers performed to encourage voiding (e.g., running water, tapping suprapubic area, or stroking inner thigh).

If the patient voids and the PVR volume is:

- Greater than 400 ml—reinsert the catheter and evaluate further, if appropriate.^a
- 100–400 ml—watch for delayed retention and evaluate further, if appropriate.^a
- Less than 100 ml—watch for delayed retention.

If the patient is unable to void, evaluate further if appropriate. If not, resident requires permanent catheterization.^a

PVR, postvoiding residual.

^aFurther evaluation is appropriate when the patient and physician feel that if a surgically correctable condition were found (e.g., urethral obstruction), an operation would be preferable to chronic catheterization or the other options described in the text.

Source: Modified from Resnick NM. Incontinence. In: Beck JC, ed. *Geriatric Review Syllabus*. New York: American Geriatrics Society; 1991:141–154, with permission.

TABLE 63.9. Principles of indwelling catheter care.

Maintain sterile, closed-gravity drainage system:

- Secure the catheter to upper thigh or abdomen to avoid urethral irritation and contamination. Rotate the site of attachment every few days.
- Empty the bag every 8h.
- Do not routinely irrigate the catheter.
- Do not clamp or kink the drainage tubing, and keep the collection bag below bladder level at all times.
- Avoid frequent cleaning of the urethral meatus; washing with soap and water once daily is sufficient; periurethral application of antimicrobial creams is ineffective.

If “bypassing” occurs in the absence of obstruction, it is likely caused by a bladder spasm, which can be minimized by using the smallest balloon that will keep the catheter in place and by treating with a bladder relaxant medication if necessary.

Infection prophylaxis, as well as treatment of asymptomatic bacteriuria, is fruitless and usually leads to the emergence of resistant organisms. Surveillance cultures are unnecessary and potentially misleading because bacteriuria is universal, frequently changing, and often polymicrobial. If symptomatic urinary tract infection (UTI) develops, change the catheter before obtaining a culture specimen, because cultures obtained through the old catheter may reflect organisms colonizing encrustations rather than the infecting organism. Pending culture results, antibiotic treatment should include coverage of common uropathogens, as well as uncommon ones such as *Providencia stuartii* and *Morganella morganii*.

If catheter obstruction occurs frequently, and urine cultures reveal *Providencia stuartii* or *Proteus mirabilis*, antibiotic treatment may reduce the frequency of obstruction but induces emergence of resistant organisms. In the absence of urea-splitting organisms, consider urine acidification if urine output is normal (at low output, acidification may increase blockage due to uric acid crystals). If frequent blockage persists, consider using a silicon catheter.

In the absence of obstruction and symptomatic UTI, there is no consensus on the best time to change the catheter. Some persons form material that frequently clogs the lumen; their catheter probably should be changed often enough to reduce such obstruction. Other individuals can use the same catheter for years, but it is customary to change it every 1–2 months. For patients who are difficult to catheterize, the catheter can be changed less frequently if it remains patent and complication free.

Source: Adapted from: Resnick NM. Voiding dysfunction and urinary incontinence. In: Beck JC, ed. *Geriatric Review Syllabus*. New York: American Geriatrics Society; 1991;141–154, with permission.

As in younger individuals, complications of chronic indwelling catheterization include renal inflammation and chronic pyelonephritis,¹³⁶ bladder and urethral erosions, bladder stones and cancer, as well as urosepsis.¹³² Principles of catheter care are summarized in Table 63.9.

When indicated, indwelling catheters can be extremely effective, but their use should be restricted. They are indicated in the acutely ill patient to monitor fluid balance, in the patient with a nonhealing pressure ulcer, for temporary bladder decompression in patients with acute urinary retention, and in the patient with overflow incontinence refractory to other measures. Even in long-term care facilities, they are probably indicated for only 1% to 2% of patients. However, patient preference and values are also important. Thus, an indwelling catheter may also be justified for a cognitively intact patient who is willing to accept the risk in return for the security and convenience the catheter can provide.

Summary

Regardless of age, mobility, mentation, or institutionalization, incontinence is never normal. By attenuating physiologic reserve, aging increases the likelihood of becoming incontinent in the setting of additional physiologic, pharmacologic, or pathologic insults. Because many of these problems lie outside the urinary tract, so too must the diagnostic and therapeutic focus. However, such

a strategy—coupled with a multifactorial, creative, persistent, and optimistic approach—will increase the chances of a successful outcome and generally reward patient and physician alike.

Syncope in the Elderly

Wishwa N. Kapoor

Syncope is defined as a sudden transient loss of consciousness associated with loss of postural tone from which the patient recovers spontaneously. Syncope has a large differential diagnosis, ranging from common benign problems to severe life-threatening disorders. As a result, the approach to this symptom frequently results in hospital admission and performance of many diagnostic tests. Although evaluation is often focused on explaining the symptom by a single disease process, this approach may not apply to the elderly because multiple physiologic processes and age-related changes may contribute to syncope. This chapter briefly reviews the pathophysiology and etiologies of syncope and provides a practical and directed evaluation of syncope in the elderly.

Pathophysiology

Syncope is caused by a sudden decrease in cerebral blood flow to those areas of the brain that are responsible for consciousness (reticular activating system and both hemispheres). Elderly patients often have multiple comorbid conditions that interact with age-related physiologic derangement, leading to a reduction in cerebral blood flow when even mild acute processes are superimposed. Elderly patients with hypertension and atherosclerotic vascular disease have baseline decreased cerebral blood flow, which may be further reduced by multiple comorbid conditions. Additionally, elderly patients are often taking multiple medications, which may further reduce cerebral blood flow by altering vascular tone or volume.

Physiologic changes related to aging may diminish the ability to adapt to a sudden drop in blood pressure.¹ These changes include the following events.

Age-Related Cardiovascular Changes

Baroreflex sensitivity diminishes with aging, manifesting as a reduction in vascular response to hypotensive stimuli; this may be due to a blunting of beta-adrenergic-mediated

vasodilation. Additionally, there is an increase in plasma norepinephrine and a greater norepinephrine response to acute hypotension in the elderly, suggesting impaired end-organ responsiveness to adrenergic stimulation with normal central and afferent components of the baroreflex circuit. As a result of decreased baroreceptor reflex sensitivity, elderly persons may not be able to maintain cerebral blood flow by increasing heart rate and vascular tone in the setting of hypotension. Thus, the elderly are more sensitive to the effects of vasodilators and other hypotensive drugs and are more likely to have exaggerated hypotension from volume loss, hemorrhage, and upright posture.

Systolic hypertension, prevalent in more than 30% of persons over age 75, also leads to diminished baroreflex sensitivity and decreased vascular and ventricular compliance. Hypertension may also increase the threshold for cerebral autoregulation, which can lead to a decrease in cerebral blood flow with modest acute decreases in blood pressure to levels within the normotensive ranges.¹ Thus, the age-related physiologic changes just described may be worsened by the presence of systolic hypertension.

Decreased Ability to Maintain Extracellular Volume

With aging, kidneys develop impairment of sodium conservation when salt intake is restricted. Basal plasma levels of renin and aldosterone are also decreased. These changes may increase the susceptibility of the elderly to orthostatic hypotension and syncope. As a result, the effects of diuretics, salt restriction, and upright posture may be more pronounced in the elderly.

Clinical Classification

Although syncope has a large differential diagnosis, the etiologies can be classified into four major categories (Table 64.1).

TABLE 64.1. Etiologies of syncope.

Neurally mediated syndromes
Vasovagal
Situational
Micturition
Cough
Swallow
Defecation
Carotid sinus syncope
Neuralgias
High altitude
Psychiatric disorders
Others (exercise, selected drugs)
Orthostatic hypotension
Neurologic diseases
Migraines
TIAs
Seizures
Decreased cardiac output
Obstruction to flow
Obstruction to LV outflow or inflow
Aortic stenosis, IHSS
Mitral stenosis, myxoma
Obstruction to RV outflow or inflow
Pulmonic stenosis
PE, pulmonary hypertension
Myxoma
Other heart disease
Pump failure
MI, CAD, coronary spasm
Tamponade, aortic dissection
Arrhythmias
Bradyarrhythmias
Sinus node disease
Second- and third-degree
atrioventricular block
Pacemaker malfunction
Drug-induced bradyarrhythmias
Tachyarrhythmias
Ventricular tachycardia
Torsades de pointes (e.g., associated with congenital long QT
syndromes or acquired QT prolongation)
Supraventricular tachycardia

TIA, transient ischemic attack; LV, left ventricular; IHSS, idiopathic hypertrophic subaortic stenosis; RV, right ventricular; PE, pulmonary embolism; MI, myocardial infarction; CAD, coronary artery disease.

Neurally Mediated Syndromes

Neurally mediated or neurocardiogenic syncope are terms used synonymously that refer to syncope resulting from reflex mechanisms associated with inappropriate vasodilatation and/or bradycardia.^{2,3} These terms encompass more specific syndromes such as vasovagal, vasodepressor, situational, or carotid sinus syncope.

The mechanism of neurally mediated syncope is poorly understood, but receptors that respond to pain, mechanical stimuli, and temperature are widely believed to be important in the pathophysiology of these spells. These receptors appear to serve as the origins of the afferent

signals triggering the various neurally mediated syncopal syndromes.^{2,3} For example, in carotid sinus hypersensitivity, carotid artery baroreceptors, and vasovagal syncope, left ventricular baroreceptors (mechanoreceptors) serve as triggers. Similar receptors in the aortic arch, carotid arteries, atrial and ventricular myocardium, respiratory tree, bladder, and the gastrointestinal tract may trigger various other neurally mediated syndromes.² The afferent pathway consists of neural fibers that transmit signals to the central nervous system sites (in the medulla, particularly the nucleus tractus solitarius). The efferent outflow results in vasodilatation and bradycardia. The effect of higher CNS centers is not fully understood.

Vasovagal syncope is a common etiology of syncope in the elderly. Vasovagal syncope is commonly associated with pallor, nausea, vomiting, and sweating but may occur without associated symptoms. It is often a response to fear or injury. Examples of precipitating factors include fatigue, prolonged standing, venipuncture, blood donation, heat, dental surgery, and eye surgery.

Syncope in the elderly may be associated with a wide variety of daily situations (termed situational syncope). In a study of institutionalized elderly, syncope in association with micturition, defecation, postural change, and meals was found in 20% of patients.⁴ Other situations include coughing, laughing, and swallowing. Mechanisms of syncope in these circumstances may be similar to vasovagal syncope with activation of inhibitory reflexes mediated by these activities. In the elderly, impaired homeostasis and orthostatic hypotension may facilitate situational syncope.

Postprandial hypotension can be associated with syncope during or after a meal. In a nursing home elderly population, up to 36% may have a systolic blood pressure decline of more than 20 mmHg after a meal (generally at 45–60 min).⁵ However, acute symptoms are rare. In institutionalized elderly patients with syncope, 8% of patients had postprandial syncope.⁴ The mechanism of postprandial hypotension is not well understood. Impaired compensation for the pooling of blood in the splanchnic blood vessels, insufficient increase in cardiac output, impaired baroreflex function, poor peripheral vasoconstriction, and other factors may contribute to postprandial hypotension.⁶

Carotid sinus hypersensitivity results from the stimulation of baroreceptors located just above the bifurcation of the common carotid artery. Carotid sinus hypersensitivity may be cardioinhibitory (asystole ≥ 3 s), vasodepressor (a systolic blood pressure decline ≥ 50 mmHg in the absence of significant bradycardia), or mixed (combination of cardioinhibitory and vasodepressor response). Spontaneous loss of consciousness, termed carotid sinus syncope, is reported in 5% to 20% of individuals with carotid sinus hypersensitivity. Attacks may

be precipitated by a tight collar, shaving, or sudden turning. This disorder occurs primarily in the elderly, and the majority of patients have coronary artery disease and hypertension. Other factors leading to carotid sinus hypersensitivity include neck pathology such as enlarged lymph nodes, tissue scars, carotid body tumors, parotid, thyroid, head, and neck tumors, and drugs such as digitalis, alpha-methyl dopa, and propranolol.

Stress and psychiatric illnesses such as generalized anxiety disorder, panic disorder, and major depression probably cause syncope by precipitating vasovagal reactions. A neurally mediated mechanism is also implicated for syncope in association with exercise, especially immediately postexercise in individuals without structural heart disease, where mild volume depletion and shifts of blood flow to dissipate heat may precipitate neurally mediated syncope. Neurally mediated syncope may also occur with drugs that decrease venous return to the heart in an upright position, such as nitroglycerine. Syncope with aortic stenosis, hypertrophic cardiomyopathy, supraventricular tachycardias, paroxysmal atrial fibrillation, and related to pacemakers (i.e., pacemaker syndrome) appear to be consistent with neurally mediated syndrome.

Orthostatic Hypotension

Blood pressure is maintained by homeostatic adjustments in the brain and reflexes in the systemic circulation. Upon standing, pooling of blood in the lower extremities and the splanchnic circulation results in reduced venous return to the heart and a decrease in cardiac output, leading to stimulation of aortic, carotid, and cardiopulmonary baroreceptors. An increase in sympathetic outflow and a decrease in parasympathetic activity result, leading to an increase in heart rate and vascular resistance to maintain systemic blood pressure. A number of pathophysiologic processes, disease states, and medications may alter blood pressure homeostasis, leading to orthostatic hypotension (Table 64.2).

Age-related physiologic changes and systolic hypertension contribute significantly to the development of orthostatic hypotension in the elderly. Volume depletion is another major cause of orthostatic hypotension because salt and water homeostasis is impaired in the elderly. Thus, the elderly can readily develop volume depletion with the use of even low-dose mild diuretics or during acute illnesses that increase insensible water losses. This state is further exacerbated because the elderly experience less thirst than younger people in the setting of hyperosmolality. Medications are also a common cause of orthostatic hypotension in the elderly and often in the usual therapeutic doses rather than in toxic amounts (see Table 64.2).

TABLE 64.2. Causes of orthostatic hypotension.

Primary
Autonomic failure with multiple system atrophy (Shy-Drager syndrome)
Secondary
General medical disorders: diabetes; amyloid; alcoholism
Autoimmune disease: Guillain-Barré syndrome; mixed connective tissue disease; rheumatoid arthritis; Eaton-Lambert syndrome; systemic lupus erythematosus
Metabolic disease: vitamin B ₁₂ deficiency; porphyria; Fabry's disease; Tangier disease
Hereditary sensory neuropathies, dominant or recessive
Central brain lesions: vascular lesion or tumors involving the hypothalamus and midbrain, for example, craniopharyngioma; multiple sclerosis; Wernicke's encephalopathy
Spinal cord lesions
Familial dysautonomia
Aging
Drugs
Tranquilizers: phenothiazines; barbiturates
Antidepressants: tricyclics; monoamine oxidase inhibitors
Vasodilators: prazosin; hydralazine; calcium channel blockers
Centrally acting hypotensive drugs: methyl dopa; clonidine
Adrenergic neuron-blocking drugs: guanethidine
α-Adrenergic blocking drugs: phenoxybenzamine; labetalol
Ganglion-blocking drugs: hexamethonium; mecamlamine
Angiotensin-converting enzyme inhibitors: captopril; enalapril; lisinopril

Source: Adapted from Bannister SR, ed. *Autonomic Failure*, 4th Ed. New York: Oxford University Press, 1999, with permission.

A wide variety of diseases affecting the autonomic nervous system may cause chronic orthostatic hypotension (Table 64.2). Idiopathic orthostatic hypotension is a rare illness that affects men five times more than women. Its manifestations may include sphincter disturbances, impotence, impaired erection and ejaculation, and impaired sweating. Supine basal plasma norepinephrine levels are markedly low and remain unchanged on standing, suggesting a peripheral dysfunction with depletion of norepinephrine from sympathetic nerve endings. Shy-Drager syndrome consists of autonomic failure and involvement of the corticospinal, extrapyramidal, and cerebellar tracts, including a Parkinson-like syndrome. Basal norepinephrine levels are normal at rest but do not increase substantially on standing, suggesting an inability to stimulate normally functioning peripheral neurons.

Neurologic Diseases

Neurologic disorders are infrequent causes of syncope. Approximately 6% of persons with ischemic stroke or transient cerebral ischemia have associated syncope. In 483 syncope patients seen in an emergency room, 7.7% had transient ischemic attacks.⁷ All patients had concurrent neurologic symptoms, most frequently vertigo, ataxia, and paraesthesia. Almost all patients had verte-

brobasilar transient ischemic attacks (TIAs).⁷ Migraines may lead to a vasovagal reaction secondary to pain, although they are unusual in the elderly.

Less than 2% of patients presenting with syncope are diagnosed as having a seizure disorder as a cause of their loss of consciousness.⁸ These events may include atonic seizures and sudden falls associated with temporal lobe epilepsy (termed temporal lobe syncope). Unwitnessed grand mal seizures may also be mistaken as syncope if the patient cannot provide detailed information.

Cardiac Syncope

Obstruction to Flow

Obstruction to outflow may result from structural lesions of either the left or right side of the heart (see Table 64.1). Exertional syncope is a common manifestation of all types of heart disease in which cardiac output is fixed and does not rise with exercise. The most likely mechanism of exertional syncope is ventricular baroreceptor-mediated hypotension and bradycardia. Exercise leads to a marked increase in left ventricular systolic pressure, which may result in excessive stimulation of left ventricular mechanoreceptors that leads to inhibition of sympathetic and activation of parasympathetic tone through cardiac vagal afferent fibers. Syncope in hypertrophic cardiomyopathy may also be due to neurally mediated syndrome or ventricular tachycardia, which is commonly found in these patients.

Syncope, which may occasionally occur with exertion, is reported in 10% to 15% of patients with pulmonary embolism and is more likely with massive embolism. The mechanism may be acute right ventricular failure with decreased cardiac output and hypotension or activation of cardiopulmonary mechanoreceptors leading to neurally mediated syncope.

Other Organic Heart Disease

Syncope may be the presenting symptom in 5% to 12% of elderly patients with acute myocardial infarction because of (1) sudden pump failure producing a decrease in perfusion pressure of the brain, (2) rhythm disturbance that may include ventricular tachycardia or bradyarrhythmias, and (3) vasovagal reactions resulting from stimulation of left ventricular baroreceptors during acute inferior infarction or ischemia involving the right coronary artery.

Arrhythmias

Bradyarrhythmias and tachyarrhythmias may cause a sudden decrease in cardiac output and syncope. The elderly are less able to compensate for sudden decrease in cardiac output caused by arrhythmias. Physiologic

impairments with aging and the effects of multiple medications and comorbidity may predispose elderly to syncope in the setting of brief arrhythmias whereas such arrhythmias may not lead to symptoms in the young.

Sick sinus syndrome and ventricular tachycardia were the most common arrhythmic causes of syncope in the elderly, occurring in 22% of this group. Syncope is a central manifestation of sick sinus syndrome, reported in 25% to 70% of these patients. Electrocardiographic findings include sinus bradycardia, pauses, arrest, or exit block. These bradyarrhythmias may be associated with supraventricular tachycardia or atrial fibrillation (tachycardia-bradycardia syndrome).

Ventricular tachycardia commonly occurs in the setting of known organic heart disease. Torsades de pointes and syncope in the elderly occur in the setting of acquired long QT syndromes associated with drugs, electrolyte abnormalities, and central nervous system disorders. Antiarrhythmic drugs such as quinidine (quinidine syncope), procainamide, disopyramide, flecainide, and encainide are the most common causes of torsades de pointes.

Multiple Abnormalities

The evaluation of the elderly should initially focus on a single disease as explaining the loss of consciousness. If a single disease is found (such as severe aortic stenosis, symptomatic bradycardia, or symptomatic orthostatic hypotension), treatment of that disease can be planned. However, a single disease as the cause of syncope is often not apparent. In these patients, inability to compensate for common situational stresses in the setting of multiple medical problems, medications, and physiologic impairments may be responsible for the loss of consciousness. Once these potential processes are identified, treatment should be directed to correcting these factors. As an example, consider an elderly patient presenting with syncope, who has taken enalapril 10mg/day, has anemia (hemoglobin 9.0), mild orthostatic hypotension, and a recent upper respiratory tract infection. In this patient, if no other etiology of syncope is apparent based on clinical findings and selective use of laboratory tests, volume repletion, treatment of anemia, and adjustment or change of antihypertensive medication may help prevent further episodes of syncope.

Diagnostic Evaluation

The most important elements in the evaluation of syncope in the elderly are (1) determining whether the patient had syncope; (2) risk stratification; and (3) selective use of diagnostic tests to define the etiology of loss of consciousness.

Determining Whether the Patient Had Syncope

A history from the patient and the witness, if present, is needed to separate syncope from other entities such as dizziness, vertigo, drop attacks, coma, and seizure. A particularly important issue is the distinction between syncope and seizure, as videometric analysis of syncope has shown myoclonic activity in 90%, predominantly consisting of multifocal arrhythmic jerks in both proximal and distal muscles.⁹ Historical features are often sufficient to distinguish syncope from seizures. Seizures are associated with blue face (or not pale), frothing at the mouth, tongue biting, disorientation, aching muscles, sleepiness after the event, and duration of unconsciousness of more than 5 min. On the other hand, symptoms associated with syncope are sweating or nausea before the event and being oriented after the event. The best discriminatory symptom is disorientation after the episode, which often signifies a seizure.¹⁰

Risk Stratification

Risk stratification is important for initial management decisions such as admission to the hospital and the use of invasive testing such as electrophysiologic studies. The issues include prediction of risk of sudden death and likelihood of cardiac syncope. In the assessment of risk, the cause of syncope, presence of underlying cardiac disease, and abnormalities on ECG are important.^{11–13}

Previous studies have consistently shown increased mortality and sudden death rates in patients with cardiac causes of syncope, thus identifying patients with cardiac causes as a high-risk subset.^{8,14} Examples include aortic stenosis, pulmonary hypertension, and arrhythmic syncope. Arrhythmias are primarily of concern in patients with heart disease or abnormal ECG. Thus, the presence of heart disease and certain abnormalities on ECG help stratify patients into low- and high-risk groups.¹¹ Congestive heart failure, valvular heart disease, hypertrophic cardiomyopathy and other types of organic heart disease constitute a high risk group. AV block, old myocardial infarction, and Wolf–Parkinson–White syndrome (WPW) are examples of high-risk findings on ECG. If the presence or absence of heart disease cannot be determined clinically, specific tests such as echocardiogram, stress test, and ventricular function studies may be needed for risk stratification.

Selective Use of Diagnostic Tests

The evaluation of syncope is best approached by using the history and physical examination, ECG, and risk stratification to guide further diagnostic tests.

History, Physical Examination, and Baseline Laboratory Tests

A detailed account of syncope, the events leading to loss of consciousness, and symptoms following the episode are crucial to diagnosing specific entities. Table 64.3 shows

TABLE 64.3. Clinical features suggestive of specific causes.

Symptom of finding	Diagnostic consideration
After sudden unexpected pain, fear, unpleasant sight, sound, or smell	Vasovagal
Prolonged standing at attention	Vasovagal
Well-trained athlete after exertion (without heart disease)	Vasovagal
During or immediately after micturition, cough, swallow, or defecation	Situational syncope
Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)	Neurally mediated syncope with neuralgia
With head rotation, pressure on carotid sinus (as in tumors, shaving, tight collars)	Carotid sinus syncope
Immediately upon standing	Orthostatic hypotension
Medications that may lead to long QT or orthostasis/bradycardia	Drug induced
Associated with headaches	Migraines, seizures
Associated with vertigo, dysarthria, diplopia	TIA, subclavian steal, basilar migraine
With arm exercise	Subclavian steal
Confusion after spell or loss of consciousness more than 5 min	Seizure
Differences in BP or pulse in two arms	Subclavian steal or aortic dissection
Syncope and murmur with changing position (from sitting to lying, bending, turning over in bed)	Atrial myxoma or thrombus
Syncope with exertion	Aortic stenosis, pulmonary hypertension mitral stenosis, hypertrophic cardiomyopathy, coronary artery disease
Family history of sudden death	Long QT syndrome, Brugada syndrome
Brief loss of consciousness, no prodrome, with heart disease	Arrhythmias
Frequent syncope, somatic complaints, no heart disease	Psychiatric illness

clinical presentations that may suggest specific entities. Physical examination is used to diagnose specific entities and exclude others. Orthostatic hypotension, cardiovascular findings, and neurologic examination are critical in this regard.

Orthostatic hypotension is generally defined as a decline of 20 mmHg or more in systolic pressure on assuming an upright position. However, this finding is reported in up to 24% of the elderly and is frequently not associated with symptoms. Thus, the clinical diagnosis of orthostatic hypotension should incorporate the presence of symptoms (e.g., dizziness and syncope) in association with a decrease in systolic blood pressure.

In detection of orthostatic hypotension, supine blood pressure and heart rate should be measured after the patient has been lying down for at least 5 min. Standing measurements should be obtained immediately and for at least 3 min. Sitting blood pressures are not reliable for detection of orthostatic hypotension.

Several cardiovascular findings are crucial diagnostically. Differences in the pulse intensity and blood pressure (generally >20 mmHg) in the two arms are suggestive of aortic dissection or subclavian steal syndrome. Special focus on cardiovascular examination for aortic stenosis, idiopathic hypertrophic subaortic stenosis, pulmonary hypertension, myxomas, and aortic dissection may uncover clues to these entities.

In a study of syncope in the elderly, a history and physical examination led to 40% of the diagnoses that could be assigned.¹⁴ Furthermore, in an additional 15%, a diagnosis was suggested by history and physical examination and confirmed by specific tests (e.g., echocardiogram or catheterization for aortic stenosis).¹⁴ In comparing elderly to young, arrhythmias are more often diagnosed as the etiology in the elderly, and several entities were primarily found in the elderly including aortic stenosis, TIAs, and carotid sinus syncope.¹⁴

Initial laboratory blood tests rarely yield diagnostically helpful information. Hypoglycemia, hyponatremia, hypocalcemia, or renal failure are found in 2% to 3% of patients, but most of these conditions appear to result in seizures rather than syncope.^{15,16} These tests are often confirmatory of clinical suspicion of these laboratory abnormalities. In the elderly patients in whom a cause of syncope is not established by the initial history and physical examination, further evaluation should focus on the following issues: (1) arrhythmia detection, (2) tilt testing, and (3) multiple abnormalities causing symptoms.

Arrhythmia Detection

In diagnosing arrhythmias, every attempt should be made to attain symptomatic correlation. When this is not possible, uncertainty may remain regarding the cause of syncope because at the current time there are no vali-

dated criteria for attributing syncope to most arrhythmias by the use of electrocardiographic or electrophysiologic abnormalities during asymptomatic periods.

Arrhythmias are evaluated by prolonged electrocardiographic monitoring or electrophysiologic studies, although rarely (in 2%–9%) the initial electrocardiogram or a rhythm strip may show an arrhythmia.^{8,14,15,16} In one study of the elderly, ECG led to a diagnosis in 9% of patients as compared to 4% of the young group.¹⁴ Exercise ECG can be used to evaluate syncope with exercise for the diagnosis of ischemia, exercise-induced tachyarrhythmias or bradyarrhythmias after abrupt termination of exercise. However, the yield of this test for arrhythmias is very low.

Prolonged Electrocardiographic Monitoring

One method of assessing the impact of ambulatory monitoring in syncope is to determine the presence or absence of arrhythmias in patients who develop symptoms during monitoring. In studies that evaluated syncope or presyncope with monitoring and reported on symptoms, only 4% of patients had symptomatic correlation with arrhythmias.¹⁷ In approximately 17% of patients, symptoms were not associated with arrhythmias, thus potentially excluding rhythm disturbance as an etiology for syncope.¹⁷ In approximately 80% of patients, no symptoms occurred but arrhythmias were often found. The causal relation between these arrhythmias and syncope therefore is uncertain. Furthermore, finding brief or no arrhythmias (without symptoms) on monitoring does not exclude arrhythmic syncope because of the episodic nature of arrhythmias. In patients with high pretest likelihood of arrhythmias, further evaluation for arrhythmias needs to be pursued by event monitoring or electrophysiologic studies. Extending the duration of monitoring to 72 h may increase the yield of arrhythmias detected but not the yield for arrhythmias associated with symptoms.¹⁸

Long-term monitoring (weeks to months) is possible with patient-activated intermittent external loop recorders that can capture the rhythm during syncope after the patient has regained consciousness because several minutes of retrograde electrocardiographic recording can be obtained. Loop monitoring is most useful in patients with a history of recurrent unexplained syncope because their probability of recurrence is higher, making it more likely for arrhythmias to be captured during an event. Recently, long-term monitoring (up to 24 months) has become possible with subcutaneously inserted loop monitors. This device, roughly the size of a pacemaker, is usually inserted in the left pectoral or inframammary region, and can record an episode from 6 to 40 min before activation and 1 to 2 min afterward. Although this is an invasive test, it may be useful in

patients with brief episodic arrhythmias not captured by other means who have infrequent episodes. In one study of 85 patients with recurrent syncope, a positive yield of 27% was found that included tachycardias and bradycardias (5 of 18 patients with bradycardias were considered to have neurally mediated syncope).¹⁹

Electrophysiologic Studies

Electrophysiologic studies are more likely to be “positive” in patients with known heart disease, abnormal ventricular function, or abnormalities on electrocardiogram or ambulatory monitoring. Predictors of ventricular tachycardia by electrophysiologic studies include organic heart disease, premature ventricular contractions (PVCs) by ECG, and nonsustained ventricular tachycardia by Holter monitoring. Sinus bradycardia, first-degree AV block, and bundle branch block by ECG predict bradyarrhythmic outcome.

Predictors of a negative electrophysiologic study in patients with syncope include the absence of heart disease; an ejection fraction greater than 40%; normal electrocardiogram and Holter monitoring; absence of injury during syncope; and multiple or prolonged (>5 min) episodes of syncope.

Electrophysiologic studies are abnormal in approximately 50% of patients undergoing this test. The most common finding is inducible ventricular tachycardia. In the elderly, a study of 75 patients who were 75 years old or older showed electrophysiologic testing to be abnormal in 68%.²⁰ The abnormalities were mostly conduction disturbances, such as sinus node disease in 55% and His bundle conduction abnormalities in 39%. Inducible ventricular tachycardia was found in 14% of the patients.²⁰

The limitations of electrophysiologic testing for syncope are similar to the problems with prolonged monitoring. Symptomatic correlation is often not possible, and the criteria for significant abnormalities are controversial. For example, criteria for significantly abnormal HV interval have ranged from greater than 55 ms to greater than 100 ms. Furthermore, some of the abnormalities such as polymorphic ventricular tachycardia have poor specificity.

Electrophysiologic studies identify a group of patients who are at high risk of mortality. Mortality rates as high as 61% and sudden death rates of 48% have been reported at 3 years in patients with abnormal studies as compared to 15% and 9% in the negative group.²¹ These differences are probably largely due to the higher prevalence of cardiac comorbidity in patients with positive findings. A low rate of mortality and sudden death in patients with negative studies can also be reassuring because this defines a low-risk group of syncope patients.

Patients with abnormal electrophysiologic studies generally have lower rates of recurrence of syncope in

follow-up as compared to patients with normal findings. At a mean of 26 months, recurrence of syncope in the elderly with positive electrophysiologic studies was 16% as compared to 25% in the negative group.²¹ These studies have been observational and not controlled. Because of differences in the prevalence of heart disease in patients with normal and abnormal electrophysiologic testing, it is difficult to be sure that the outcome differences are a result of this procedure.

Tilt Testing

The pathophysiologic mechanism of inducing syncope by upright tilt testing is poorly understood. One postulated mechanism centers around the stimulation of cardiac mechanoreceptors. Upright posture leads to pooling of blood in the lower limbs, resulting in decreased venous return. Normal compensatory response to standing upright is reflex tachycardia, more forceful contraction of the ventricles, and vasoconstriction. However, in individuals susceptible to vasovagal syncope, this forceful ventricular contraction in the setting of a relatively empty ventricle may excessively stimulate the cardiac sensory nerves (mechanoreceptors). Afferent impulses are relayed to the medulla, resulting in a decrease in sympathetic and increase in parasympathetic tone. Catecholamine release (as may occur with anxiety, fear, and panic), by increasing ventricular contraction, may also activate the nerve endings responsible for triggering this reflex. The role of higher cortical centers is controversial.

The American College of Cardiology Expert Consensus has recommended tilt testing methods and indications.²² Tilt testing methods generally involve the use of provocative agents such as isoproterenol or nitroglycerine because rates of positive responses without chemical stimulation appear to be low.^{22–24} In patients with unexplained syncope, positive responses occur in approximately 66% with isoproterenol protocols.^{24,25} The results with the use of nitroglycerine appear to be similar.^{26,27} The specificity of most currently used tilt testing approaches 90% with chemical stimulation.^{24,25}

Studies of upright tilt testing in syncope of unknown origin in the elderly (studies of patients with a mean age of 60 years or older or specified as elderly) mostly have used passive protocols. The overall percent positive response is 54% (range, 26%–90%).^{24,25} The rate of positive response in elderly control subjects without syncope is approximately 11% with a range of 0% to 100%.²⁴ Isoproterenol should be avoided in the elderly whenever possible. Protocols with the use of nitroglycerine may be more suitable for testing in the elderly.

Other Tests

Skull films, lumbar puncture, radionuclide brain scan, and cerebral angiography have not yielded diagnostic infor-

mation for a cause of syncope in the absence of clinical findings suggestive of a specific neurologic process.⁸ EEG shows an epileptiform abnormality in 1%, but almost all these are suspected clinically. Head CT scans are needed if subdural bleed due to head injury is suspected or in patients suspected to have a seizure as a cause of loss of consciousness, but the yield is low when used in a nondirected fashion.⁸

Approach to Evaluation

The majority of the causes of syncope are identified by a careful history and physical examination. Additionally, history and physical examination may suggest specific entities as possible causes (e.g., findings of aortic stenosis or neurologic signs and symptoms suggestive of a seizure disorder). These entities can then be approached in a directed fashion by performing further noninvasive or invasive tests for establishing a diagnosis and initiating treatment. An electrocardiogram is generally needed for the initial evaluation of patients with syncope. Although the diagnostic yield of electrocardiogram for arrhythmias or suspicion of myocardial infarction is low, abnormalities can be acted upon quickly if found.

In patients with a negative history, physical examination, and ECG, further testing can be approached by stratifying patients into those with and without heart disease.

Patients with heart disease (e.g., coronary artery disease, congestive heart failure, valvular heart disease, obstructive cardiomyopathy, and ECG abnormalities such as bundle branch block) have a higher likelihood of arrhythmic syncope. In elderly patients without clinical heart disease and unexplained syncope, cardiac assessment with stress testing or echocardiogram may be needed to define the presence of occult heart disease. Prolonged electrocardiographic monitoring provides an initial step in the evaluation of patients with syncope and heart disease or when arrhythmias are suspected based on clinical presentation. If prolonged monitoring is nondiagnostic, these patients may be candidates for electrophysiologic studies. Because in the elderly, diseases may present in an atypical fashion or multiple abnormalities may be important in causing syncope, the clinical assessment should be particularly focused on these issues. If multiple abnormalities are found that could have led to loss of consciousness, a trial of empiric treatment of those factors is warranted before considering an invasive workup with electrophysiologic tests. Carotid sinus syncope is a disorder of the older individuals. Carotid sinus massage is recommended in all elderly patients.

The prognosis of patients with negative electrophysiologic studies is favorable. Upright tilt testing may define a potential etiology in these patients, but therapy is only

recommended for patients with recurrent or disabling symptoms as the effectiveness of therapy has not been established, especially in patients with single or rare episodes. In the elderly patients without heart disease and with a normal electrocardiogram, the likelihood of arrhythmias is low. A large proportion of these patients may also have vasovagal syncope. If there is a clinical suspicion of arrhythmias, ambulatory monitoring or loop monitoring (when there is recurrent syncope) may help define an etiology. Because the yield of electrophysiologic studies is low in this group, these studies should generally be avoided in these patients.

Management Issues in the Elderly

Management issues include hospitalization decision, treatment selection, and patient instructions and education.

Hospital Admission

There are no studies evaluating the need for hospital admission in syncope. Table 64.4 lists reasons for admis-

TABLE 64.4. Reasons for hospital admission.

Admission for diagnostic evaluation:
Structural heart disease
Known coronary artery disease
Congestive heart failure
Valvular or congenital heart disease
History of ventricular arrhythmias
Physical findings of heart disease (e.g., findings of aortic stenosis)
Symptoms suggestive of arrhythmias or ischemia
Associated with palpitations
Chest pain suggestive of coronary disease
Exertional syncope
Electrocardiographic abnormalities
Ischemia
Conduction system disease (e.g., bundle branch block, first-degree atrioventricular block)
Unsustained ventricular or supraventricular tachycardia
Prolonged QT
Accessory pathway
Right bundle branch block with ST elevation in V1–V3
Pacemaker malfunction
Neurologic disease
New stroke or focal neurologic findings
Admission for treatments:
Structural heart disease
Acute myocardial infarction, pulmonary embolism, other cardiac diseases diagnosed as causing syncope
Orthostatic hypotension
Acute severe volume loss (e.g., dehydration, gastrointestinal bleeding)
Moderate to severe chronic orthostatic hypotension
Treatment of multiple coexisting abnormalities
Discontinuation or dose modification of offending drug
Drugs causing torsades de pointes and long QT
Drug reaction such as anaphylaxis, orthostasis, bradyarrhythmias

sion. Generally patients are admitted if a rapid diagnostic evaluation is needed because of concerns about serious arrhythmias, sudden death, newly diagnosed serious cardiac disease (e.g., aortic stenosis, myocardial infarction), and new onset of seizure or stroke. Admission may also be needed for treatment when etiology is clear (e.g., management of dehydration). In the large group of patients with unexplained syncope after initial history, physical examination, and ECG, risk stratification for arrhythmias and sudden death should guide the admission decision.

Treatment Selection

Because the treatment largely depends on the cause of syncope, a discussion of the treatment of all the causes is beyond the scope of this review. General management issues and treatments of neurally mediated syncope that have recently received considerable attention are reviewed here.

Neurally Mediated Syncope

Because of potential side effects, treatment should be reserved for elderly patients with frequent or disabling symptoms. As psychiatric illnesses (especially depression and anxiety) probably lead to vasovagal reactions, screening for the psychiatric illnesses noted here should be performed. Treatment of the psychiatric illness often results in resolution of recurrent syncope.

Various drugs and pacemakers have been tried for patients with vasovagal syncope, and a decrease in recurrence of syncope or resolution of symptoms have been reported in almost every uncontrolled study. There are very few controlled studies of drug therapy for neurally mediated syncope. The drugs most commonly used are beta-blockers²⁸ (e.g., metoprolol 50–200 mg/day, atenolol 25–200 mg/day, propranolol 40–160 mg/day), which may inhibit the activation of cardiac mechanoreceptors by decreasing cardiac contractility. Other drugs include anticholinergic drugs, such as transdermal scopolamine (one patch every 2–3 days), disopyramide (200–600 mg/day), paroxetine (20–40 mg/day),²⁹ or theophylline (6–12 mg/kg/day), and measures to expand volume (increased salt intake, custom-fitted counterpressure support garments from ankle to waist, and fludrocortisone acetate at 0.1–1 mg per day). Dual-chamber atrioventricular pacing with rate drop response has been reported to decrease recurrence in patients with frequent recurrent neurally mediated syncope associated with bradycardia and can be considered when medications are ineffective.^{30,31}

Orthostatic Hypotension

The initial approach to treatment of orthostatic hypotension is to ensure adequate salt and volume intake and to

discontinue drugs that cause orthostatic hypotension. Patients with orthostatic hypotension should be advised to raise the head of the bed at night, to rise from bed or chair slowly, and to avoid prolonged standing. Compression stockings applied up to thigh level may help decrease venous pooling. Frequent small feedings may be helpful in patients with marked postprandial hypotension.

Pharmacologic agents of potential benefit include fludrocortisone (0.1–1 mg/day), in conjunction with increased salt intake. Various agents have been used including midodrine, ephedrine, and phenylephrine.

Patient Instruction and Education

Issues in patient education include instruction in prevention of syncope, nonpharmacologic treatment, and restriction of activities. Many patients with vasovagal syncope have precipitating factors or situations that should be identified and the patient instructed to avoid these situations. Common triggers include prolonged standing, venipuncture, large meals, and heat (such as hot baths or sunbathing). Additionally, fasting, lack of sleep, and alcohol intake may predispose to vasovagal syncope and should be avoided. Postexercise vasovagal syncope may occasionally be related to chronic inadequate salt and fluid replacement. Syncope may be prevented with the use of electrolyte-containing solutions and water in such instances. In other patients, exercise may have to be curtailed.

Although 84% of states in the United States have specific regulations for driving restriction for seizures, only 26 states (52%) have regulations that limit driving after an episode of loss of consciousness other than seizure³² (e.g., vasovagal syncope, arrhythmias, diabetic coma). In nonseizure loss of consciousness, the average mandated duration of driving restriction is 4.3 months. In addition to adhering to state regulations on driving, the likelihood of recurrent episodes and the probability of treatment efficacy should be considered in restricting driving.³²

Management of Chronic Wounds

David R. Thomas

Sites of Care

Chronic wounds, including pressure ulcers, diabetic ulcers, and venous stasis ulcers, occur across the spectrum of care. In 1997, among 265 acute care hospitals the overall prevalence of pressure ulcers was 10.1% (range, 1.4%–36.4%), with the sacrum and heels the most common sites. Seventy-four percent of pressure ulcers were superficial (i.e., stages I and II).¹ A 1995 analysis of the Minimum Data Set data for 2011 nursing home residents aged 60 or older who lived in 270 facilities from 10 states found a prevalence of 11.2% for stage II through IV lesions and a 6-month incidence of 6.2%. Logistic regression analysis determined that dependence in transfer or mobility, being bedfast, having diabetes mellitus, and having had a pressure ulcer in the past were significantly associated with a stage II through IV pressure ulcer.² Among persons with diabetes, 15% develop a foot ulcer, and 14% to 24% of these will require amputation.³ Venous stasis ulcers affect 0.2% to 1.3% of the adult population.⁴

Diagnosis and Differential Diagnosis

The differential diagnosis of chronic ulcers is imperative because the management of each wound type differs substantially. Pressure ulcers are the visible evidence of pathologic changes in dermal blood flow caused by pressure. The most common sites of occurrence are found on the sacrum, posterior heels, and trochanteric areas. Diabetic ulcers are often caused by recurrent pressure in neuropathic extremities and may be complicated by diminished blood flow in small and larger vessels. These ulcers frequently occur at sites on the foot subjected to pressure, especially over the plantar aspect of the foot and metatarsal heads. Diabetic ulcers often coexist with arterial ischemic ulcers due to macrovascular and

microvascular complications of the diabetic state. Arterial ischemic ulcers usually occur in areas not necessarily subjected to pressure and result from decreased blood flow to that area.

Most often the diagnosis of ulcer type is made by wound location, wound appearance, and the presence of pain. Ischemic ulcers typically occur distally to the impaired blood supply and frequently are painful, particularly with leg elevation. Microemboli from infection or cholesterol plaques can cause the sudden onset of pain and discoloration in the distal extremity.^{5,6} Venous stasis ulcers develop in the lower extremities as a result of incompetent valves in the veins. Edema may or may not be present, but hyperpigmentation changes are usually present when the condition is chronic. Typically, venous stasis ulcers occur on the lateral aspect of the calf. The sites of occurrence among these various wounds overlap, but careful history and physical examination usually establishes the correct etiology. Adequate tissue perfusion with blood is important for healing of all types of wounds, particularly on the extremities. Examination of pulses and an ankle–brachial blood pressure index can assess healing adequacy. An ankle–brachial index below 0.7 is abnormal, and an index below 0.4 is associated with a poor likelihood of healing.

Course of Illness

Chronic wounds fail to proceed through an orderly and timely process to produce anatomic or functional integrity.⁷ Normally, fibroblasts and epithelial cells grow rapidly in skin tissue cultures, covering 80% of in vitro surfaces within the first 3 days. In contrast, biopsy specimens from pressure ulcers usually do not grow until much later, covering only 70% of surfaces by 14 days.⁸ The lack of hemorrhage in chronic wounds interferes with bringing wound-healing factors into contact with tissue. Platelet release and fibrinolytic activity are diminished.

Finally, these wounds contain complex polymicrobial colonizations that are poorly understood.⁹

The result is slow healing. Eight weeks were required to heal 75% of stage II pressure ulcers while only 17% of stage III or IV pressure ulcers healed in that time.¹⁰ In a similar study, 23% of stage II pressure ulcers and 48% of stage IV pressure ulcers remained unhealed at 1 year. At 2 years, 8% of stage II pressure ulcers, 29% of stage III, and 38% of stage IV remained unhealed.¹¹ An estimated 76% of diabetic wounds remain unhealed at 12 weeks of follow-up and 69% remain unhealed at 20 weeks.¹² Thus, treatment of these chronic wounds extends over months to years.

Pressure ulcers have been associated with more than a fourfold increase in mortality rates in both acute and long-term care settings. Death has been reported to occur during acute hospitalization in 67% of patients who develop a pressure ulcer compared to 15% of at-risk patients without pressure ulcers.¹³ Patients who develop a new pressure ulcer within 6 weeks after hospitalization are three times as likely to die as patients not developing a pressure ulcer.¹⁴ In long-term care settings, development of a pressure ulcer within 3 months among newly admitted patients was associated with a 92% mortality rate, compared to a mortality rate of 4% among residents who did not subsequently develop a pressure ulcer.¹⁵ Residents in a skilled nursing facility who had pressure ulcers experienced a 6-month mortality rate of 77.3% whereas patients without pressure ulcers had a mortality rate of 18.3%.¹¹ Interestingly, patients whose pressure ulcers healed within 6 months had a significantly lower mortality rate (11% versus 64%) than patients whose pressure ulcers did not heal.¹⁶

Despite this association with death rates, it is not clear if pressure ulcers contribute to increased mortality or are mainly a marker for increased frailty. The severity of the pressure ulcer has not correlated with an increased mortality risk. Patients with stage II pressure ulcers have been equally as likely to die as patients with stage IV pressure ulcers.¹⁴ In the absence of complications, it is difficult to imagine how stage I or II pressure ulcers contribute to death. Evidence suggesting that the association with mortality may result from their occurrence in otherwise frail, sick patients comes from a prospective study of residents of 51 nursing homes, where pressure ulcers were associated with an increased rate of mortality but not with the rate of acute hospitalization.¹⁴ Additionally, a correction for the presence and severity of coexistent conditions can eliminate the association of pressure ulcers with death. In a prospective study of high-risk patients in an acute hospital setting, the development of a new pressure ulcer predicted death within 1 year. Independent risk factors for mortality in this study included weight loss reported in the 6 months before admission relative risk (RR 2.4), the admitting physician's estimate

of life expectancy of less than 5 years (RR 2.1), and the Co-morbidity Damage Index score (RR 1.1). When adjusted for measures of disease severity, comorbidity, and a history of weight loss, the development of a pressure ulcer was no longer a predictor of mortality at 1 year.¹⁷

The incidence of bacteremia from pressure ulcers is about 1.7 per 10,000 hospital discharges.¹⁸ However, sepsis is a serious complication of pressure ulcers and a frequent cause of death. In a study of 21 patients with sepsis syndrome attributed to pressure ulcers, 76% had bacteremia that originated from the pressure ulcer. Overall, mortality was 48% and all patients over age 60 died despite empiric antibiotic treatment. In 5 patients, bacteremia persisted despite antibiotic treatment and resolved only after local debridement.¹⁹ The bacteremia occurring with pressure ulcers is likely to be polymicrobial.¹⁸

Osteomyelitis is a frequent complication of pressure ulcers and diabetic ulcers, reported in 38% of patients who have infected pressure ulcers²⁰ and in 59 of 96 (61%) of foot infections in diabetic patients.²¹ Diagnosis of contiguous osteomyelitis in pressure ulcers is difficult. Plain radiographs are unable to differentiate true osteomyelitis from pressure changes to bone.²² Radionuclide studies, including technetium-99m and gallium-67, are sensitive but have a false-positive rate of 41%.²⁰ Computed tomography may be more useful, with a specificity of 90%, although the sensitivity is only 10%.²³ A needle biopsy of bone is the most useful single test, with a sensitivity of 73% and a specificity of 96%,²⁴ and should be used whenever osteomyelitis must be excluded.

Infection occurs in up to 25% of diabetic foot ulcers.^{25,26} Similar problems with the diagnosis of osteomyelitis occur in diabetic ulcers. Gentle probing of the wound with a steel probe to detect palpable bone demonstrated a 66% sensitivity and specificity of 89% with a positive predictive value of 89% and negative predictive value of 56%. Thus, a positive probe test was accurate in detecting osteomyelitis, but a negative probe does not exclude osteomyelitis.²⁷

An estimated 8000 foot amputations are performed annually on patients with diabetes in the United States.²⁸ More than 70% of these amputations are due to complicated foot ulcers.²⁹ The higher risk factors for lower extremity amputation include a transcutaneous oxygen of 50mmHg or less, insensitivity to monofilament testing, and a lower extremity ulcer.³⁰ Peripheral vascular disease is the major cause of morbidity associated with diabetic foot ulcers in older patients. Peripheral vascular disease and peripheral neuropathy, occurring in 11% and 42% of diabetic patients respectively,³¹ may further predispose patients with diabetes to develop foot ulcers. The presence of peripheral vascular disease results in delaying ulcer healing and has been shown to associate significantly with the incidence of amputation.³²

Treatment and Management

Pain Management

A primary goal of wound assessment should be to relieve pain. Except in neurologically impaired patients, chronic ulcers may be painful. Relief of pressure results in pain relief. Unfortunately, persons who develop pressure ulcers often are unable to report pain due to cognitive deficits and persons with diabetic neuropathy often cannot feel pain due to neuropathies. A decrease in wound pain with occlusive dressings has been noted in donor sites and venous stasis ulcers,^{33,34} but studies in pressure ulcers have been limited. Analgesics should be used when pain assessment reveals discomfort. Principles of pain therapy are discussed in Chapter 28 and elsewhere³⁵ and should be incorporated into management of chronic wounds.

Nutrition

One of the most important reversible host factors contributing to wound healing is nutritional status. Several studies suggest that dietary intake, especially of protein, is important in healing pressure ulcers. Greater healing of pressure ulcers has been reported with a higher protein intake irrespective of positive nitrogen balance.³⁶ Breslow et al. evaluated 48 patients with stage II through IV pressure ulcers in a dietary intervention trial. Malnutrition was defined as a serum albumin below 3.5 mg/dL or body weight more than 10% below the midpoint of the age-specific weight range. The results suggested that patients fed a 24% protein diet healed their pressure ulcers at a greater rate than those fed a 14% protein standard diet. However, changes in body weight or in biochemical parameters of nutritional status did not occur between groups. The study was limited by a small sample size (only 28 patients completed the study), nonrandom assignment to treatment groups, confounding effects of air-fluidized beds, and the use of two different feeding routes.³⁷ Chernoff et al. randomized 12 enterally fed patients to formulas containing 17% versus 25% of calories as protein. The group that received 1.8 g/kg of protein had a 73% improvement in pressure ulcer surface area compared to a 42% improvement in surface area in the group receiving 1.2 g/kg of protein, despite the fact that the group that received the higher protein level began the study with larger surface area pressure ulcers (22.6 cm² versus 9.1 cm²). Serum albumin did not appear to be a predictor of the development of pressure ulcers or their healing rate, although values were not given.³⁶

An optimum dietary protein intake in patients with pressure ulcers is unknown, but may be much higher than current adult recommendations of 0.8 g/kg/day. Half of chronically ill elderly persons are unable to maintain

nitrogen balance at this level.³⁸ Increasing protein intake beyond 1.5 g/kg/day may not increase protein synthesis and may cause dehydration.³⁹ A reasonable protein requirement is therefore between 1.2 and 1.5 g/kg/day.

The deficiency of several vitamins and minerals has significant effects on wound healing. However, supplementation to accelerate wound healing is controversial. High doses of vitamin C have not been shown to accelerate wound healing.⁴⁰ In a 12-week study of 88 patients who received either 10 or 500 mg of ascorbic acid twice daily, the healing rate and the healing velocity of their pressure ulcers were not different in the higher-dose group.⁴¹ No evidence of benefit from topical or oral zinc sulfate in patients with chronic leg ulcers has been shown. Oral zinc sulfate may be beneficial in the treatment of patients with leg ulcers who have a low serum zinc level, but evidence of benefit is lacking in patients who are not zinc deficient.^{42,43} High serum zinc levels interfere with healing, and supplementation above 150 mg/day may interfere with copper metabolism.^{44,45}

Nutritional therapy in diabetic ulcers is aimed at control of hyperglycemia and hyperlipidemia. The risk for a lower extremity amputation increases 25% with each 1% rise in glycosylated hemoglobin above normal.⁴⁶ Whether tight diabetic control can reduce this risk is not known. Proper glycemic control is also essential for ulcer healing.⁴⁷ Hyperglycemia interferes with immune function.^{48,49} Glucose levels greater than 216 mg/dl are associated with a lower phagocytosis index of leukocytes.⁵⁰ Correction of hyperglycemia has been shown to normalize leukocyte function.

Local wound treatment is directed to providing an optimum wound environment and improving host factors.

Dressings

Moist wound healing allows experimentally induced wounds to resurface up to 40% faster than air-exposed wounds.⁵¹⁻⁵³ The concept of a moist wound environment led to development of occlusive dressings. The term "occlusive" describes the lessened ability of a dressing to transmit moisture vapor from a wound to the external atmosphere. The degree to which dressings dry the wound can be measured by the moisture vapor transmission rate (MVTR). An MVTR of less than 35 g of water vapor per square meter per hour is required to maintain a moist wound environment. Woven gauze has an MVTR of 68 g/m²/h and impregnated gauze has an MVTR of 57 g/m²/h. In comparison, hydrocolloid dressings have an MVTR of 8 g/m²/h.⁵⁴ In chronic wounds, occlusion has been shown to reduce wound pain,^{55,56} enhance autolytic debridement,^{57,58} and prevent bacterial contamination.^{59,60}

Wound exudate in chronic ulcers has been found to be an excellent medium for fibroblast stimulation.⁶¹ Removal of this medium by aggressive scrubbing or drying has been shown to be detrimental. Wound fluid is thought to contain a variety of growth factors such as interleukin-1, epidermal growth factor, and platelet-derived growth factor-beta, which may enhance healing.⁶² A moist environment may maintain a normal electrical voltage gradient across the wound necessary for epithelial migration.⁶³ Wound fluid under occlusive dressings may also increase bacterial overgrowth, stimulating epidermal migration.⁵⁰

Because of the appreciation of the importance of wound fluid, dressings that preserve this environment have become important. Any therapy that dehydrates the wound, such as dry gauze, heat lamps, air exposure, or liquid antacids, is detrimental to chronic wound healing.⁶⁴⁻⁶⁷ Several types of topical wound treatments can promote more rapid epidermal resurfacing. Results of controlled trials for several agents are shown in Table 65.1.⁶⁸ The range of acceleration in healing varies from 18% to 36%. Note that most of these agents, or their vehicles, are occlusive. Whether the benefit is independent of the occlusive vehicle is not known. Certain antiseptic agents are cytotoxic to human fibroblasts, including povidone iodine (Betadine), Hibicles, pHisoHex, benzalkonium chloride, and Granulex.⁶⁹⁻⁷² In animal models, povidone-iodine 1%, acetic acid 3%, and sodium hypochlorite 0.5% adversely affected wound healing.⁷³ In human pressure ulcers, Dakins solution 0.05% was clearly inferior to a hydrocolloid dressing⁶⁰ (Table 65.2).

Hydrocolloid dressings under a compression system have been shown to heal 62% to 82% of venous stasis ulcers at 12 weeks^{74,75} and to be superior to an Unna's boot alone.⁷⁶ Topical cadexomer iodine produced a mean reduction in venous ulcer size of 62% versus 41% and 24% for hydrocolloid and paraffin gauze (ns).⁷⁷ Use of

pentoxifylline and compression produces a 30% increase in complete healing compared to compression alone.⁷⁸

Occlusive dressings can be divided into broad categories of polymer films, polymer foams, hydrogels, hydrocolloids, alginates, and biomembranes. Each has several advantages and disadvantages; no single agent is perfect. The choice of a particular agent depends on the clinical circumstances. The available agents differ in their properties of permeability to water vapor and wound protection. Understanding these differences is the key to planning for wound management in a particular patient.

Comparative qualities among available agents are shown in Table 65.3.^{79,80} All the occlusive dressings offer pain relief. Only absorbing granules or polymers fail to reduce pain. Polymer films are impermeable to liquid but permeable to both gas and moisture vapor. Because of low permeability to water vapor, these dressings are not dehydrating to the wound. Nonpermeable polymers such as polyvinylidene and polyethylene can be macerating to normal skin. Polymer films are not absorptive and may leak, particularly when the wound is highly exudative. Most films have an adhesive backing that may remove epithelial cells when the dressing is changed. Polymer films do not eliminate deadspace and do not absorb exudate.

Hydrogels are three-layer hydrophilic polymers that are insoluble in water but absorb aqueous solutions. They are poor bacterial barriers and are nonadherent to the wound. Because of their high specific heat, these dressings are cooling to the skin, aiding in pain control and reducing inflammation. Most of these dressings require a secondary dressing to secure them to the wound.

Hydrocolloid dressings are complex dressings similar to ostomy barrier products. They are impermeable to moisture vapor and gases and are highly adherent to the skin. Their adhesiveness to surrounding skin is higher than that of some surgical tapes, but they are nonadherent to wound tissue and do not damage epithelialization of the wound. The adhesive barrier is frequently overcome in highly exudative wounds. Hydrocolloid dressings

cannot be used over tendons or on wounds with eschar formation. Several of these dressings include a foam padding layer that may reduce pressure to the wound.

Alginates are complex polysaccharide dressings that are highly absorbent in exudative wounds. This high absorbency is particularly suited to exudative wounds. Alginates are nonadherent to the wound, but if the wound is allowed to dry, damage to the epithelial tissue may occur with removal.

Only the hydrocolloid and biomembranes offer bacterial resistance. The biomembranes are very expensive and not readily available. Hydrocolloid dressings theoretically have a disadvantage because of impermeability to oxygen. These dressings could be problematic in wounds contaminated by anaerobes, but this effect has not been demonstrated clinically.

The agents differ in the ease of application. This difference is important in pressure ulcers in unusual locations, or when considering for home care. Dressings should be left in place until wound fluid is leaking from the sides, a period ranging from days to 3 weeks.

Saline-soaked gauze that is not allowed to dry is an effective wound dressing. When moist saline gauze has been compared to occlusive-type dressings, healing of pressure ulcers has been similar with both dressings.⁸¹⁻⁸³ The use of occlusive-type dressings has been shown to be more cost-effective than traditional dressings, primarily due to decrease in nursing time required for dressing changes.^{82,83}

The optimal dressing choice for diabetic wounds remains controversial.⁸⁶ No differences in healing were seen comparing cadexomer iodine, vaseline gauze, gentamicin solution, or streptodornase/streptokinase treatments in 25 diabetic patients over a 12-week period.⁸⁷ Moist saline gauze remains the standard dressing for diabetic ulcers. Use of cultured human dermis tissue weekly for 8 weeks demonstrated a higher healed rate compared to standard treatment (50% versus 8%).⁸⁸

Partial-thickness skin grafts for venous stasis ulcers have resulted in healing rates of 52% to 70%, with recur-

rence rates of 22% to 30%.^{89,90} Bioengineered skin tissue grafting resulted in healing of 61% of venous ulcers compared to 44% of control ulcers.⁹¹ Complete wound healing occurred by 12 weeks in 60% of diabetic wounds treated with a culture human dermis compared to 8% of controls.⁸⁸

Debridement

Necrotic debris increases the possibility of bacterial infection and delays wound healing.⁹² The preferred method of debriding the pressure ulcers remains controversial. Options include mechanical debridement with gauze dressings, sharp surgical debridement, autolytic debridement with occlusive dressings, or application of exogenous enzymes. Surgical sharp debridement produces the most rapid removal of necrotic debris and is indicated in the presence of clinical wound infection. Mechanical debridement can be easily accomplished by letting the saline gauze dressing dry before removal. Remoistening of gauze dressings in an attempt to reduce pain can defeat the debridement effect. Aggressive surgical or mechanical debridement can damage healthy tissue or fail to completely clean the wound.

Thin portions of eschar can be removed by occlusion under a semipermeable dressing. Both autolytic and enzymatic debridement requires periods of several days to several weeks to achieve results. Enzymatic debridement can dissolve necrotic debris, but whether it harms healthy tissue is debated. Penetration of enzymatic agents is limited in eschar and requires either softening by autolysis or cross-hatching by sharp incision before application.

Enzymatic debridement evaluated in pressure ulcer trials include streptokinase/streptodornase (SK/SD) combination, collagenase, trypsin, and papain. Debridement with SK/SD combination was equivalent to zinc oxide/gauze at 8 weeks,⁹³ and worse than dextranomer granules at 7 days.⁹⁴ Collagenase reduced necrosis, pus, and odor, compared to inactivated control ointment,⁹⁵

and produced debridement in 82% of pressure ulcers at 4 weeks compared to petrolatum.⁹⁶ Papain produced measurable debridement in 4 days compared to the control vehicle ointment.⁹⁷ Trypsin in balsam of Peru and castor oil was not better than mechanical gauze debridement.⁹⁸ Three enzyme preparations are currently marketed in the United States for debridement: collagenase, papain/urea, and a papain/urea–chlorophyll combination. A trial in 21 patients with pressure ulcers found a greater reduction in necrotic tissue using papain/urea (95.4%) compared to collagenase (35.8%) at 4 weeks, but the rate of complete healing was not different between groups.⁹⁹

Diabetic ulcers require extensive debridement to remove callous formation and nonviable tissue. Removal of necrotic debris has been reported to be the chief factor associated with healing in diabetic ulcers.¹⁰⁰ Frequent sharp debridement has been shown to heal diabetic neuropathic wounds more rapidly.

Growth Factors

Acute wound healing proceeds in a carefully regulated fashion that is reproducible from wound to wound. A number of growth factors have been demonstrated to mediate the healing process. The factors described include transforming growth factor- α and - β , epidermal growth factor, platelet-derived growth factor, fibroblast growth factor, interleukin-1 and -2, and tumor necrosis factor- α . Accelerating healing in chronic wounds by using these acute wound factors is attractive. The development of wound healing factors is still in infancy but shows great promise. Several of these factors have been favorable in animal models; however, they have not been as successful in human trials.

In pressure ulcers, recombinant human platelet-derived growth factor (rhPDGF-BB) failed to improve the rate of complete healing,¹⁰¹ although a 15% difference in percentage of initial volume of ulcers was shown with PDGF-BB in another study.¹⁰² Another report showed that more subjects had greater than 70% wound closure with basic fibroblast growth factor at 100 $\mu\text{g}/\text{mL}$ ($p = 0.05$).¹⁰³

The topical use of rhPDGF-BB has been shown to accelerate wound healing in diabetic ulcers. In ulcers present for at least 8 weeks, the addition of 30 μg rhPDGF-BB to moist saline dressings resulted in complete closure of 48% of ulcers compared to 25% of ulcers treated with placebo gel. However, in another trial, 10 μg rhPDGF-BB was superior to 30 μg and placebo (complete closure 50% versus 36% versus 35%, respectively). Using 10 μg rhPDGF-BB, placebo gel, and moist saline gauze alone, the rate of complete closure at 20 weeks was 44% versus 36% versus 22%, respectively. Finally, in

another trial of 10 μg rhPDGF-BB compared to moist saline alone, there was no difference in rate of closure at 20 weeks (36% versus 32%; $n = 250$).¹⁰⁴

A small study of basic fibroblast growth factor (bFGF) in diabetic neurotrophic foot ulcers showed 63% of ulcers completely healed at 12 weeks in the placebo group compared to 33% using bFGF,¹⁰⁵ suggesting a detrimental effect on healing.

Infection

Quantitative microbiology alone is a poor predictor of clinical infection in chronic wounds.¹⁰⁶ Although normal skin flora in numbers greater than 10^5 organisms/mL produce local disease in intact skin¹⁰⁷ and skin grafts and flaps show poor healing when greater than 10^5 organisms of certain species of bacteria are present,¹⁰⁸ chronic wounds do not appear to follow these rules. Greater than 10^5 organisms may persist for months or years in chronic wounds without apparent clinical effect. Colonization with bacteria is common and unavoidable. All chronic wounds become colonized, initially with skin organisms, followed in 48 h by gram-negative bacteria.

The diagnosis of infection in chronic wounds must be based on clinical signs—erythema, edema, odor, fever, or purulent exudate. A foul odor is a particularly important clinical sign, usually signifying anaerobic organisms.⁸⁴ However, wounds with a reported foul odor are not always infected. When there is evidence of clinical infection, topical or systemic antimicrobials or antibiotics are required. Reduction of colony-forming units (CFUs) has been used as the endpoint in evaluating antimicrobial efficacy in acute wounds. Several antimicrobial or antibiotic agents reduce CFUs without damaging the wound, including silver sulfadiazine 1% cream, combination antibiotic ointments, and propylene glycol.⁸⁵ Topical gentamicin and silver sulfadiazine have been shown to improve clinical appearance of infected wounds and may improve healing.^{109,110} Iodine and thimerosal have been noted to increase pain and delay healing.¹¹¹ Infections with anaerobes may respond to topical metronidazole.¹¹² Systemic antibiotics are indicated when the clinical condition suggests spread of the infection to bone or to the bloodstream.

In worsening pressure ulcers, *Pseudomonas aeruginosa* and *Providencia* species were found in 88% and 34% of ulcers, compared to 0% of stationary wounds and 7% of rapidly healing ulcers. Peptococci, *Bacteroides* species, or *Clostridia* were found in more than half of worsening or stationary ulcers but were absent in healing pressure ulcers. Staphylococci and enterococci were frequently isolated from rapidly healing ulcers.^{113,114} Based on these findings, *Pseudomonas aeruginosa* and *Providencia* species should not be regarded as simple colonization.

Similar principles apply to diabetic ulcers. Systemic antimicrobial therapy is clearly indicated in the presence of systemic signs of infection or underlying osteomyelitis. Mild to moderate infections without systemic signs may respond to oral agents.¹¹⁵ Topical antiseptics may have a role in this setting.

Despite an increase in numbers of bacteria, occlusive dressings used to treat chronic wounds very rarely cause a clinical infection. Hutchinson and McGuckin reviewed 36 studies comparing infection rates under occlusive dressings to gauze or impregnated gauze. Infection rates were 2.6% for occlusive dressings and 7.1% for nonocclusive gauze.¹¹⁶

Pressure-Relieving Devices

Pressure-relieving devices have a therapeutic role in treating pressure ulcers. This therapy is successful in the acute hospital and in some nursing home studies but is very expensive. When patients with pressure ulcers in an acute hospital setting were randomized to air-fluidized therapy or a vinyl alternating air mattress, patients treated on air-fluidized beds had a decrease in ulcer size over a mean of 15 days. However, there was no difference in the number of ulcers showing a size reduction of at least 50%. The cost was estimated at an additional \$80 per day.¹¹⁷

In 95 nursing home patients with severe pressure ulcers treated on air-fluidized beds, 14% of pressure ulcers healed in a mean of 79 days; 44% of patients had greater than 50% reduction in surface area of the index ulcer. Very few patients had a reduction in ulcer surface area after 1 month of treatment on the specialized bed. The median length of time to healing was 119 days and of time to improvement was 127 days. The additional cost for the bed was \$50 to \$100 per day.¹¹⁸ Low-air-loss beds have produced substantial improvement in ulcer size (9.0 versus 2.5 mm² per day) compared to a 10-cm convoluted foam mattress in nursing home patients.¹⁰

Repetitive mechanical trauma is the most common cause of foot ulcers in diabetic individuals.¹¹⁹ Mechanical trauma resulting in foot ulceration may be the result of abnormal foot mechanics, abnormal foot structure, or ill-fitting shoes or socks.¹²⁰ Chronic sensorimotor neuropathy may contribute to the development of foot deformity that results from the denervation of foot muscles.¹²¹ Accompanying autonomic neuropathy may also result in dry skin as well as cutaneous arteriovenous shunting that further predisposes the skin to damage.¹²²

In the presence of diabetic sensory neuropathy, trauma to soft tissue from foot deformity (e.g., hammertoes, or bunions) or ill-fitting footwear may remain undetected

and result in foot ulceration. Removal of recurrent pressure, particularly in the presence of bony deformity, is critical to prevent recurrence.¹²³ When therapeutic shoes were prescribed, the recurrence rate has been reduced to 17% compared to an 83% recurrence rate in regular shoes.¹²⁴

Although pressure relief is required for pressure ulcers and diabetic ulcers, the critical component of healing of venous stasis ulcers is compression therapy.¹²⁵ Compression can be achieved with a rigid boot or external multi-layered elastic compression.¹²⁶

Surgical Management

Pressure Ulcers

Nowhere does the difference in pressure ulcers among younger spinal cord injury patients and elderly patients become so pronounced as in discussing surgical management. Surgical closure of pressure ulcers results in a more rapid resolution of the wound. The chief problems are the frequent recurrence of ulcers and the inability of the frail patient to tolerate the procedure.

The efficacy of surgical repair of pressure ulcers is high in the short term. The efficacy for long-term management has been questioned, even in younger patients.¹²⁷ In a series of 40 patients selected for surgical closure of pressure ulcers, patients were divided into three subgroups. In nontraumatic, nonparaplegic elderly patients with a mean age of 73, 84% of surgically treated pressure ulcers were healed at discharge. Twelve percent of surgically treated patients had another pressure ulcer at discharge. Within 7.7 months, 40% of surgically treated pressure ulcers recurred and 69% of the patients had a pressure ulcer at a different site. In patients with traumatic paraplegia, 74% of operated pressure ulcers were healed at discharge and 76% of patients were free of pressure ulcers. Within 10.9 months, 79% of operated ulcers recurred, and 79% of patients had additional pressure ulcers. Only 21% of traumatic paraplegics and 31% of nontraumatic nonparaplegic elderly patients remained healed after muscle-flap coverage for pressure ulcers.¹²⁸ After 10 years of follow-up in 16 surgically treated patients, only 1 patient remained alive and free of pressure ulcers.¹²⁹

A decision analysis demonstrated that myocutaneous flap procedures for stage III pressure ulcers was favorable unless the success rate for surgery was less than 30% or the healing rate with medical therapy was less than 40%. The added cost for the procedure was estimated at \$17,000 per treatment episode compared to medical therapy.¹³⁰

Diabetic Ulcers

Indications for revascularization in diabetic ischemic ulcers include rest pain, impending gangrene, and failure to progress toward healing. An ankle-brachial pressure index (determined by dividing the systolic pressure in the foot arteries by that of the brachial artery) value greater than 0.45 has been shown to predict healing in diabetic foot ulcers (10).¹³¹ Distal arterial reconstruction can result in lower rates of amputation in diabetic patients.¹³²

Venous Stasis Ulcers

Surgical graft techniques have been used for venous stasis ulcers. In 51 venous ulcers in older patients who had not responded to conservative treatment, split skin grafts resulted in an 88% healing rate after a mean of 15 days. However, 49% of the healed venous ulcers recurred after a mean of 4 months. After a mean of 4 years, 18 of the patients were dead and 10 had had the leg in question amputated. Of the 34 patients still alive who had not had amputations, 7 patients had open leg ulcers. The mean cost for treating one leg ulcer by skin grafting was estimated at \$11,125.¹³³ Pinch grafting demonstrated a healing rate after 12 weeks for venous ulcers of 45%.¹³⁴

Summary

Chronic wounds represent complex clinical problems for which no gold standard for prevention or treatment has yet been established. In practice guidelines for the treatment of pressure ulcers published by the Agency for Health Care Policy and Research, approximately 85 specific recommendations were made based on a careful literature review.¹³⁵ Only four level A recommendations and 10 level B recommendations were made. The remaining recommendations were made using expert opinion. In those areas where supporting data are insufficient, local and national consensus determines management.

Falls

David C. Thomas, Helen K. Edelberg, and Mary E. Tinetti

Until the 1940s, falls and fall-related injuries were considered accidents, that is, “acts of God,” random or chance events without observable or understandable explanations.¹ Since the early studies by Droller,² Sheldon,³ and Fine,⁴ falls have gained appreciation, first as predictable, then as preventable health problems worthy of careful evaluation and preventive efforts. Up through the early 1990s, risk factors were identified in various settings, that is, community and nursing home. Simultaneously, the notion of falls as multifactorial events was established as the norm. Over the past decade, studies have focused more on the prevention and treatment of falls as well as on identifying subgroups of patients who would benefit most from preventive interventions.

Falling is an important clinical marker of frailty, as evidenced by its association with other functional problems, such as incontinence, and with a high mortality rate that is not directly attributable to fall-related injuries.⁵ As a consequence of its associated morbidity, falling is also an important health problem in its own right among frail as well as healthier older persons.

As discussed here, although some falls have a single intrinsic (disease- or impairment-related) or extrinsic (environmental) cause, many falls by elderly persons are multifactorial in origin, resulting from an interaction between stability-impairing characteristics of the individual and the hazards and demands of the environment. As recent evidence indicates that individual interventions may play a key role in fall prevention and treatment, these are also presented. We address nonsyncopal rather than syncopal falls, that is, those events that are not associated with a loss of consciousness, stroke, or epileptic seizure nor related to sustaining a violent blow.⁶

Prevalence and Morbidity

Community

Each year, approximately one-third of community-living adults over age 65 years and 50% of persons over age 80

years sustain a fall.⁷⁻⁹ Half of these individuals experience multiple falls. Among individuals under age 75, women fall more frequently than men do. This gender difference in prevalence lessens, however, among adults over age 75.¹⁰

Unintentional injury is the sixth leading cause of death in persons over the age of 65 years; the majority of these deaths are attributed to falls and their complications, especially among persons 85 years of age and older.¹¹ Although women are about twice as likely to suffer a serious injury during a fall,^{12,13} the rates for fall-related deaths are consistently higher among men, who are 22% more likely than women to sustain a fatal fall.¹⁴

About 7% of persons over 75 years visit emergency rooms for a fall injury event each year; more than 40% of these visits result in hospitalizations.¹⁵ As many as 10% of falls in this age group are complicated by serious injury, such as a fracture, joint dislocation, or severe head trauma.¹⁶ An estimated 5% of falls by community-living elderly persons result in a fracture, fewer than 1% in a hip fracture.¹⁵ In persons over age 75, fractures of the lower extremity are about twice as common as fractures of the upper extremity. An additional 5% of falls result in serious soft tissue injuries requiring medical attention.^{9,11} These injuries include hemarthroses, joint dislocations, sprains, and hematomas. Subdural hematomas and cervical fractures are devastating, but rare. About 30% to 50% of falls by elderly persons result in minor injuries such as bruises, lacerations, and abrasions.

Being unable to get up after a fall is a potentially hazardous consequence of falling that can occur with or without serious injury. Community-based studies have reported that 50% of older fallers are unable to get up without help after at least one fall.^{10,13} Factors associated with the inability to get up without assistance include age over 80 years, decreased upper and lower extremity strength, poor balance, arthritis, and greater dependency in activities of daily living (ADL).^{10,13} Older individuals who are unable to get up after a fall are at risk for com-

plications such as dehydration, pressure sores, rhabdomyolysis, and pneumonia.

Fear of falling is common among community-living older adults, particularly among older women. Many older women express concern over the loss of independence and quality of life resulting from a fall and hip fracture.¹⁷ One in four fallers reports that they avoid activities because of fear of falling.^{9,18} As a result of this fear, patients report a poorer quality of life with a loss of function and independence.¹⁹ Fear of falling has been independently associated with requiring assistance to climb stairs, poor vision, restriction in instrumental activities of daily living (IADL), poor self-related health, and poor performance on tests of balance.^{20,21} The concept of self-efficacy or confidence in the ability to perform specific activities in specific situations has been applied to fear of falling to understand the relationship between fear and function.⁶ Self-efficacy shows a stronger association with functioning in basic and instrumental activities of daily living and higher-level physical and social activities than does self-reported fear of falling.²²

Limitation of functioning and activity, whether because of physical impairment from injury or fear of future falls, is a common adverse consequence of falling. In a national survey, falls and their sequelae accounted for 18% of restricted activity days among elderly persons, the highest proportion for any health condition.²³ In a prospective study, more than 40% of fallers restricted their activities at least temporarily after a fall.²⁴ Pain or limitation of activity after a fall was present 8 weeks later in 40% of fallers treated in an emergency room; almost half these persons had not yet fully recovered by 8 months.²⁴

Falling has been associated with an increased likelihood of hospitalization, nursing home placement, and death.²⁵⁻²⁷ Much of this relationship, however, may be accounted for by older age, chronic conditions, and ADL disabilities.²⁷ Noninjurious as well as injurious falls have been found to be independent predictors of nursing home placement, after adjusting for other known risk factors, and falls with serious injury were twice as likely as noninjurious falls to result in nursing home placement.²⁸

Nursing Home

More than half of ambulatory nursing home residents fall each year.²⁹ The annual incidence of falling among nursing home residents is 1.5 falls per bed per year. About 4% of falls within nursing homes result in fractures and 11% in other serious injuries such as head trauma, soft tissue injuries, and severe lacerations. Each year, about 1800 fatal falls occur in nursing homes. Among persons 85 years and older, 1 of 5 fatal falls occurs in a nursing home. The contribution of falls to fear and

functioning has been less studied among nursing home than among community residents.

The use of physical restraints in nursing homes to prevent high-risk persons from falling has been associated with an increased frequency of serious injury, as well as increased agitation, depression, and immobility.³⁰ Immobilization by physical restraint may result in vasomotor instability and decreased muscle mass, strength, and joint flexibility, all of which can contribute to falls and injuries.³¹ Although some restraint reduction programs have resulted in an increase in falls and minor injuries, the discontinuation of physical restraints has not led to an increase in serious fall injuries.^{32,33}

Pathogenesis

Community

Nonsyncopal falls occur when environmental hazards or demands exceed the individual's ability to maintain postural stability. Specific diseases such as Parkinson's syndrome, normal pressure hydrocephalus, white matter disease, and high cervical myelopathy may result in severe postural instability. Some authors also describe a gait disturbance of unknown central nervous system etiology, referred to as senile or essential gait disorder. Overall, these central nervous system diseases account for a relatively small percentage of falls by older persons.

Immediate Causes

Investigators have attempted, through a careful review of fall circumstances, to identify the most likely immediate cause of falls. Summarizing the results of several studies, Rubenstein et al. reported that an environmentally related factor was the most likely cause of 41% (range, 23%–53%) of falls, gait or balance disturbance or weakness of 13% (2%–29%), drop attack of 13% (0%–25%), dizziness or vertigo of 8% (0%–19%), confusion of 2% (0%–7%), and postural hypotension of 1% (0%–6%), while visual disorder, syncope, acute illness, drugs, and other factors accounted for an additional 17% of falls.²⁹ The cause was unknown for 6% (0%–16%) of falls. The relative frequency of the various causes varied widely among the studies.

Classification Schemes

Several classification schemes have been developed to explain the pathogenesis of falls. One approach has been to classify balance and gait dysfunctions based on anatomy and physiology. One such scheme, described by Nutt et al.,³⁴ proposed four categories of balance and gait disorders: (1) lower-level disorders, due to problems with sensory systems (proprioceptive, vestibular, or visual) or

strength; (2) middle-level disorders, involving the spinal cord or brainstem; (3) higher-level disorders, concerning the cerebellum, basal ganglia, or corticospinal tracts; and (4) highest-level gait disorders, relating to the frontal cortex.³⁴ Although this classification system has helped advance research into postural instability and falls, many older persons with the presumed anatomic or physiologic lesions do not fall and many fallers do not possess a readily identifiable single lesion within the sensory or neuromuscular systems. Another classification system, used in a large prospective community study, divided falls into four broad categories: (1) falls related to extrinsic factors, slips, trips, or displaced center of gravity (55%); (2) falls related to intrinsic factors, such as poor mobility, balance, cognitive, or sensory impairments (39%); (3) falls from a nonbipedal stance, such as falling out of bed or while using an assistive device (8%); and (4) unclassified falls (7%).³⁵ Although investigators have used such classification schemes to identify differences in types of falls by age, gender, and other factors, these schemes fail to account for the multifactorial etiology of most falls.

Multifactorial Etiology

The epidemiologic model of host, activity, and environmental factors addresses the multifactorial etiology of most falls. Under this model, there is a reciprocal relationship among host, activity, and environmental factors. The importance of these three categories of factors varies with individual falls. Host factors contributing to falls can best be understood by considering that postural stability requires input from sensory, central integrative, and effector neuromuscular components in a highly integrated manner.³⁶ These components are overlapping and compensatory. Cardiac, circulatory, respiratory, metabolic, and other conditions may further influence the functioning of these three primary components. Postural instability and predisposition to falling may not be evident until several contributing components are impaired.

A related and clinically useful method for explaining fall etiology is to consider both predisposing as well as situational factors. Predisposing risk factors are those intrinsic characteristics of the individual that chronically impair stability and render the individual vulnerable to new insults. Situational factors are those host, activity, and environmental factors that are present at the time of the fall (Tables 66.1 and 66.2).

Predisposing Risk Factors

As noted, stability depends on the intricate functioning of sensory, central integrative, and musculoskeletal effec-

TABLE 66.1. Results of univariate analysis of most common risk factors for falls identified in 16 studies that examined risk factors.^a

Risk factor	Significant/total ^b	RR-OR ^c	Range
Muscle weakness	10/11	4.4	1.5–10.3
History of falls	12/13	3.0	1.7–7.0
Gait deficit	10/12	2.9	1.3–5.6

tor components. Accumulated impairments and diseases affecting these components, superimposed on age-related physiologic changes or lifestyle factors (e.g., past physical activity), result in a predisposition to falling.³⁷

The major sensory modalities responsible for orienting the individual in space and identifying hazards include the visual, auditory, vestibular, and proprioceptive systems. These modalities have multiple interconnections with one another. Age-related visual changes include decreased visual acuity, contrast sensitivity, dark adaptation, and accommodation. In addition, ocular diseases that are common in older persons, such as macular degeneration, glaucoma, and cataracts, may adversely affect visual functioning. Visual acuity, contrast sensitivity, and

depth perception, a visual function involved in spatial orientation, have been shown to be especially relevant to postural stability and falling.³⁸⁻⁴⁰

An age-related decline in vestibular function has been suggested as an explanation for increased postural sway as well as dizziness and perhaps falling in elderly persons.⁴¹ The vestibular system contributes to spatial orientation at rest as well as during acceleration and is responsible for visual fixation during head and body movements. An age-related decline in vestibular function has been attributed to changes in the otoconia. Predisposing factors include past aminoglycoside use as well as present use of aspirin, furosemide, quinine, quinidine, and perhaps tobacco and alcohol. Head trauma, mastoid or ear surgery, and middle ear infections are other possible predisposing factors. Elderly persons with vestibular problems complain of worsening stability in the dark because of increased reliance on visual input.

Hearing contributes directly to stability through the detection and interpretation of auditory stimuli, which help localize and orient the individual in space, particularly when other sensory modalities are impaired. More than 50% of elderly persons have some hearing loss.⁴²

The proprioceptive system provides spatial orientation during position changes, while walking on uneven ground, or when other modalities are impaired.³⁶ The proprioceptive system includes peripheral nerves, apophyseal joint mechanoreceptors, and the posterior columns, as well as multiple central nervous system connections. It is unclear whether age-related changes occur in peripheral nerves. Nevertheless, peripheral neuropathy from a variety of different causes is common among elderly persons. The contribution of cervical mechanoreceptors to proprioception is not well appreciated.⁴³ Predisposing factors for cervical disorders include whiplash injuries and cervical degenerative diseases such as rheumatoid arthritis or spondylosis. Older adults with proprioceptive problems complain of worsening difficulties in the dark or on uneven ground. They may complain of true vertigo. Gait often improves in these individuals with even minimal support.

The central nervous system channels inputs from the sensory modalities to the appropriate efferent components of the musculoskeletal system. Given the multiple connections and their complexity, virtually any central nervous system disorder can contribute to instability and falling. Specific diseases such as Parkinson's disease, normal pressure hydrocephalus, and stroke are associated with an increased risk of falling. Central nervous system processes that adversely affect cognition further impede stability because problem solving and judgment are needed to interpret and respond appropriately to environmental stimuli. Individuals with impaired mental status or dementia have consistently been found to have an increased incidence of falling, even in the absence of

a clinical gait disorder. Additional studies have demonstrated the relationship between white matter disease, even in the absence of cognitive impairment, and gait disorders.⁴⁴

Any impairment within the musculoskeletal system, including joints, muscles, and bones, will decrease stability and increase fall risk. Arthritis, myopathies, and hemiparesis are all associated with falling. Arthritis likely increases the risk of falling through several mechanisms including pain, periarticular muscle weakness, and compromised proprioception due to deterioration of joint mechanoreceptors. Hip, knee, and ankle weakness have all been found to significantly increase risk of falling.⁴⁵ Reciprocal flexion and extension of lower extremity muscles appears essential to postural stability. Ankle dorsiflexion weakness may explain the tendency of some elderly persons to fall backward with even minimal displacement. Alternatively, the predisposition to falling backward may result from a smaller posterior than anterior base of support. Foot abnormalities such as calluses, bunions, and deformed toes and nail abnormalities may provide incorrect proprioceptive information and adversely affect gait patterns.

Systemic diseases may contribute to instability by impairing sensory, neurologic, or musculoskeletal functioning or by causing a reduction in cerebral oxygenation or perfusion, fatigue, or confusion. Common examples include anemia, electrolyte disturbances, hypoglycemia or hyperglycemia, acid-base disturbances, or hypothyroidism.

Postural hypotension may result in instability by compromising cerebral blood flow.⁴⁶ The prevalence of postural hypotension ranges from 10% to 30% in community-dwelling persons over 65 years of age. As is falling, postural hypotension is frequently multifactorial. Contributing factors include age-related autonomic changes, decreased baroreceptor sensitivity, decreased renin-angiotensin response to upright position, decreased venous and lymphatic return, and salt and water depletion. The effects of diseases such as diabetes or Parkinson's disease and of medications such as antidepressants, neuroleptics, antihypertensives, nitrates, and diuretics are further contributing factors. Postural hypotension should be considered if the fall occurred while moving from a lying or sitting to a standing position, after prolonged standing, or during exertion. Another abnormality in blood pressure homeostasis is postprandial hypotension.⁴⁶ The mechanisms and mediators of postprandial hypotension remain unknown, although inability to compensate for splanchnic blood pooling after the meal has been postulated as a possible etiology.

Medications may contribute to gait instability through a variety of mechanisms, including impairment of cognitive functioning, postural hypotension, dehydration, impaired balance, fatigue, or electrolyte disturbance.

(Table 66.2) Centrally acting medications, including sedative-hypnotics, tranquilizers, antidepressants, and neuroleptics have repeatedly been associated with an increased risk of falls and injuries.^{47,48} Both selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants have been implicated in falls and hip fractures.⁴⁹ Other classes of medications associated with falls in older adults include diuretics, type 1A antiarrhythmics, and digoxin.⁵⁰ In addition to specific medications, recent changes in dose and the total number of medications have been associated with an increased risk of falling.⁵¹ Conversely, evidence suggests that postural instability, as manifested by impaired balance, dizziness, and falling, is one of the most frequent presentations of adverse drug effect in an older population.^{52,53}

Situational Factors

Falling is well recognized as a nonspecific presentation of acute illness in older adults. Acute febrile illnesses (e.g., pneumonia or urinary tract infections) and chronic disease exacerbations (e.g., congestive heart failure or diabetes mellitus) likely precipitate falls by temporarily impairing stability.⁹ Some cardiac dysrhythmias cause a decrease in cerebral blood flow and loss of consciousness, resulting in a fall.⁵³ Carotid baroreceptor hypersensitivity may contribute to syncopal, as well as nonsyncopal, falls.

One type of fall, mentioned most frequently in the British literature, is the drop attack.³ This term refers to a sudden loss of postural tone without loss of consciousness. Drop attacks may occur while walking, while turning the neck, while looking up, or without an obvious precipitating movement. Some individuals note that their knees buckled or “just gave out.” It is likely that at least some of those who report their knees buckling have impaired mechanoreceptors secondary to arthritic joint changes. Difficulty getting up is often reported. The etiology and frequency of drop attacks are unknown. Although reported in up to 25% of falls in the earlier literature,³ more recently “just going down” without any obvious intrinsic or environmental cause is reported in less than 5% of falls.^{9,29}

The majority of falls by community-living elderly persons occur during the course of usual, relatively non-hazardous activities such as walking, changing position, or performing basic activities of daily living. Only a small percentage of falls occur during clearly hazardous activities such as climbing on chairs or ladders or participating in sports activities.⁹

Although major environmental hazards account for few falls, environmental factors probably contribute to the majority of falls by community-dwelling older adults. The precise role of environmental factors is difficult to ascertain because studies lack control data on nonfallers or fallers at times other than their fall. Over 70% of

falls by community-dwelling older adults occur at home. About 10% of falls occur on stairs, well out of proportion to time spent on them, with descending being more hazardous than ascending.^{9,54} The most commonly mentioned environmental hazards include carrying heavy or bulky objects, and negotiating obstacles that can be tripped over, slippery floors, and poor lighting.⁵⁵ Slippery or improperly fitting shoes are another potential hazard. Finally, patterns on floors or walls, depending on their quality, may either distort or improve visual perception.⁵⁶

Nursing Homes

Immediate Causes and Predisposing Factors

As in community-based studies, investigators have attempted to identify the “most likely cause” of individual falls by nursing home residents.⁵⁷ Studies of nursing home residents have found a higher incidence of falls caused by gait, balance, or strength disorders (25%; range, 20%–39%), by dizziness (25%; range, 0%–30%) and by confusion (10%; range, 0%–14%).²⁹ Only 16% (range, 6%–27%) of falls are primarily attributed to an environmental factor.²⁹ Visual disorders (4%; range, 0%–5%), postural hypotension (2%; range, 0%–16%), and drop attacks (0.3%; range, 0%–3%) are other less frequently cited causes. Other causes such as acute illness, drugs, and pain were believed to account for 12% of falls among nursing home residents. Although investigators have attempted to identify the “most likely cause of individual falls,” falling among nursing home residents, as among community-living residents, most often results from the accumulated effect of multiple specific impairments and diseases.^{51,58} The predisposing impairments are the same as those cited for community-dwelling older adults. The prevalence of the impairments is higher among nursing home than among community residents, which may partially explain the higher frequency of falling.²⁹ Similar to community studies, studies of nursing home residents have identified an increased risk of falling with an increased number of impairments and diseases possessed.^{51,58}

Situational Factors

Host factors such as acute illness, postural hypotension, dizziness, or medications have been described. Environmental factors are thought to be less important among institutionalized than community-dwelling older adults. The greater frailty and larger number of impairments predispose institutionalized elderly persons to fall in situations where healthier persons would not. Also, by and large, institutions are safer environments than the community because many potential hazards have been

removed. Further, institutionalized elderly persons have fewer opportunities to engage in such hazardous activities as climbing stairs, walking on ice, or climbing on ladders. Even so, environmental factors do contribute to falls among institutionalized older adults.²⁹ Examples include ill-fitting shoes, untied shoelaces, long pants, or slippery floors.⁵⁹ Furniture may be hazardous; beds that are either too high or too low, bed rails that can be climbed over, and chairs that are too low or soft may also be dangerous. Walking aids are an unappreciated fall hazard. Canes and footrests can be tripped over, and the added weight of a walker may displace an individual backward. Many residents are able to remove their restraints. In addition, restrained persons may take their wheelchairs or chairs over with them in a fall. As one study points out, falls are a possible, but not inevitable, outcome in the nursing home setting. Through the implementation of a standardized and structured safety program, the impact of these falls can be minimized.⁶⁰

Risk Factors for Serious Fall Injury

Recent interest has focused on factors that increase the risk of serious injury, particularly fractures, during a fall. The likelihood of suffering a serious injury during a fall has been postulated to depend on factors such as the velocity of the fall, the energy-absorbing capacity of the surface landed on, the protective responses of the faller, the injury threshold of the tissue, and the direction and location of impact.^{61,62} Characteristics of fallers shown to be independently associated with serious injury include older age, female gender, white race, decreased bone mineral density, decreased body mass index, cognitive impairment, the use of certain medications, abnormal neuromuscular findings such as decreased reaction time and balance disturbance, poor visual acuity, history of previous falls and fall injuries, and the presence of specific chronic diseases, such as diabetes, and stroke.^{12,18,63-74} Increased physical activity level has been associated with both an increased and a decreased risk of suffering a serious fall injury event.^{12,72} Circumstances of the fall that increase likelihood of serious injuries such as fractures include the direction and impact of the fall, the height of the fall, and the hardness of the landing surface, as well as low body mass index (BMI).⁷³⁻⁷⁵ A discussion of the risk factors and medical aspects of hip fracture management are covered in Chapter 45.

Evaluation and Management

The goal of a fall evaluation and prevention strategy is to minimize the risk of falling without compromising mobil-

ity or functional independence. Given the inherent trade-offs between safety and independence, this goal may be difficult to achieve in some individuals. Perhaps a better goal, rather than to prevent all falls, would be to prevent relevant fall-related morbidities such as serious injury, fear, and the inability to get up. As the ability to identify the subset of fallers at risk for these fall sequelae improves, evaluative and preventive efforts can be better targeted. A recent report by an expert panel provides an evidence-based approach to the management and prevention of falls: *The Quality Indicators for Assessing Care of the Elderly (ACOVE)* project.⁷⁵⁻⁷⁷

As already described, the etiology and risk factors for falls are similar in nursing home and community residents, but the relative frequency and modifiability of contributing risk factors may differ in these two populations. Therefore, the recommended evaluation and preventive strategies are discussed separately for community and nursing home residents. The American Geriatrics Society and British Geriatrics Society Panel on Falls in Older Persons has published the most up-to-date guidelines for the prevention of falls in older persons, and the reader is referred there for a discussion of these guidelines.⁷⁸

Community

The first step in evaluating individuals who have experienced a fall or who are at risk for falling is to identify possible contributing factors.^{79,80} The following components of the evaluation provide complementary information: (1) a thorough assessment of predisposing risk factors and diseases; (2) a balance and gait assessment; and (3) a review of previous fall situations.

Predisposing Risk Factor Assessment

History and Examination

The risk assessment begins with a careful history and physical examination aimed at identifying all predisposing risk factors. It is important to bear in mind that the multiple diseases and disabilities suffered by many older individuals may render the signs and symptoms of specific conditions obscure, vague, or nonspecific. For example, nonvestibular disorders may present with vertigo, whereas individuals with vestibular dysfunction may complain only of vague dizziness or unsteadiness. Therefore, a thorough systematic assessment of all possible contributing factors is essential. The governing concept in fall assessment is that it may be possible to decrease fall risk by ameliorating as many contributing factors as possible.

The neurologic diseases that predispose to falls can be diagnosed from a thorough neurologic history and exam-

ination. Although most neurologic diseases associated with falling result in postural instability and pathologic gait patterns, these findings are not disease specific. Common features of gait seen in persons with central neurologic diseases include flexed posture, step-to-step variability, path deviation, decreased step height that results in shuffling if severe, instability on turning, and easy displacement backward.^{36,81} Many of these findings, however, can also be seen in individuals with sensory abnormalities and may represent compensatory, rather than primary, changes. Thus, in diagnosing neurologic diseases, gait findings must be considered in association with findings from other components of the neurologic examination including cranial nerve findings, sensation, tone, muscle strength, and coordination. The neurologic examination is helpful not only in diagnosing specific diseases but also in identifying other contributing factors to fall risk such as decreased sensation or muscle weakness.

Other important components of the risk assessment are included in Table 66.3. Simple screening tests such as the Snellen chart can be used to measure near and distant visual acuity. If there are any questions concerning visual function, the individual should be referred to an ophthalmologist or optometrist for a full evaluation. Portable audiometry or the Whisper Test⁸² can be used to screen for hearing problems. Although vestibular dysfunction is difficult to diagnose from simple clinical tests, a vestibular contribution to instability should be suspected if the individual complains of vertigo, worsening stability in the dark or with specific head positions, or provides a history of predisposing factors including past aminoglycoside use, use of aspirin, furosemide, quinine, or quinidine, or has a past history of head trauma, mastoid or ear surgery, or middle ear infections. If vestibular problems are suspected, attempts should be made to provoke vertigo with the Dix–Hillpike maneuver (see Chapter 67). Selected patients should be referred to audiology for a complete hearing evaluation or to otolaryngology for full vestibular testing.

Individuals with proprioceptive impairments complain of worsening stability in the dark, on uneven ground, on inclines, or on thick rugs. Decreased position and vibration sense are noted on examination. During gait testing, individuals with decreased proprioception may markedly improve their gait pattern simply by holding on to the examiner's finger or using a straight cane. If a cervical disorder is the cause of the proprioceptive problem, the complaints will be similar to those for peripheral neuropathy, but the individual will also complain of worsening symptoms with head turning or true vertigo. In some cases, the examination may reveal signs of radiculopathy or myelopathy; there may be clumsiness with fine motor tasks and even mild spastic quadriparesis. Many elderly individuals will, on examination of neck range of motion while standing, exhibit decreased neck range of motion

and complaints ranging from vague dizziness to marked instability. It may be difficult to determine whether these individuals suffer from a mechanoreceptor-related cervical disorder or whether the decreased neck range of motion is secondary to vestibular dysfunction and inadvertent avoidance of neck movements that precipitate the symptoms. It is important to distinguish between the two because a decrease in neck movements will exacerbate the underlying vestibular disorder by impeding compensation by the central nervous system. The musculoskeletal examination may reveal various patterns of muscle weakness.

As noted earlier, all of hip, knee, and ankle strength and range of motion are essential to postural stability and the response to perturbations. Thus, any arthritic or musculoskeletal process may contribute to fall risk. Individuals with knee arthritis may complain of falls because their “knee gave out.” Individuals with proximal muscle weakness may report difficulty getting in and out of chairs, in and out of the bathtub, and climbing stairs, whereas individuals with distal weakness will complain of frequent tripping. The contribution of upper extremity arm movements to postural stability and response to perturbation is unappreciated and needs to be considered. Foot problems, including bunions, calluses, and deformity, can affect gait patterns and decrease proprioception and thus should be identified.

Although postural hypotension has not been identified as a frequent risk factor for falls among community-dwelling elderly persons, this is likely because it is not feasible to assess blood pressure change at the time of a fall. Blood pressure change with position change should be part of the risk factor assessment. Individuals may complain of lightheadedness or other vague sensations on position change, prolonged standing, or walking, although many individuals with significant postural hypotension may be asymptomatic and thus unaware of the blood pressure drop. Many, but not all, of these individuals may have concomitant diseases such as Parkinson's syndrome or diabetes. In addition, as noted next, many medications can contribute to the risk of falling by causing postural hypotension. Particularly important medications to ask about include nitrates, antihypertensives, and antidepressants.

The screen for depressive symptoms may reveal vegetative complaints, poor concentration, or apathy. Finally, a careful medication review is an essential component of a fall risk assessment. The assessment should involve the direct recording of all prescription medications from the original containers and verification of the dose and timing of each medication. Over-the-counter medications, particularly sedative-hypnotics, cold preparations, and nonsteroidal anti-inflammatory agents, must be ascertained as well. In addition, possible medication side effects including confusion, lightheadedness, fatigue,

TABLE 66.3. Predisposing and situational factors associated with risk of falling.

Predisposing factors with contribution to falling	Possible interventions
Sensory	
Vision: acuity, perception Impaired hazard recognition; distorted environmental signals; spatial disorientation	Medical: refraction; cataract extraction Rehabilitative: balance and gait training Environmental: good lighting; home safety assessment; architectural design that minimizes distortions and illusions
Hearing Spatial disorientation; balance impairment; distorted environmental signals (auditory)	Medical: cerumen removal; audiologic evaluation with hearing aid if appropriate Rehabilitative: training in hearing aid use Environmental: decrease background noise
Vestibular dysfunction Spatial disorientation at rest; impaired visual fixation; balance impairment especially with head or body turning	Medical: avoid vestibulotoxic drugs; surgical ablation Rehabilitative: habituation exercises Environmental: good lighting (increased reliance on visual input); architectural design that minimizes distortions and illusions
Proprioceptive: cervical disorders; peripheral neuropathy Spatial disorientation during position changes or while walking on uneven surfaces or in dark	Medical: diagnose and treat specific disease (e.g., spondylosis, B ₁₂ deficiency) Rehabilitative: balance exercises; correct walking aid Environmental: good lighting (increased reliance on visual input); appropriate footwear; home safety assessment
Central neurologic	
Central nervous system diseases Impaired problem solving, strength, sensation, balance, gait, tone, or coordination	Medical: diagnose and treat specific diseases (e.g. Parkinson's syndrome, Normal Pressure hydrocephalus) Rehabilitative: physical therapy; balance and gait training; correct walking aid Environmental: home safety assessment; appropriate adaptations (e.g. high, firm chairs, raised toilet seats, grab bars in bathroom)
Dementia/cognitive impairment Impaired problem solving, impaired gait	Medical: minimize sedating or centrally acting drugs Rehabilitative: supervised exercise and ambulation Environmental: safe, structure, supervised environment
Musculoskeletal	
Muscle weakness: upper and lower extremity, Impaired postural stability	Medical: diagnose and treat specific diseases Rehabilitative: balance and gait training; Tai Chi, muscle-strengthening exercises; back exercises; correct walking aid; correct footwear; good foot care (nails, bunions)
Arthritides Impaired postural stability	
Feet Impaired proprioception; impaired postural instability; altered gait pattern	Environmental: home safety assessment; appropriate adaptations
Back Impaired ability to regain stability	
Other	
Postural hypotension Impaired cerebral blood flow leading to fatigue, weakness, postural instability; syncope if severe	Medical: diagnose and treat specific disease; avoid offending drugs; rehydrate; replenish salt Rehabilitative: tilt table if severe; reconditioning if component of deconditioning; graded pressure stockings; dorsiflexion and hand flexion exercises before arising Environmental: elevate head of bed
Depression ? accident-proneness; ? poor concentration	Medical: ?antidepressants associated with increased risk of falling; ? select least anticholinergic
Medications: especially sedatives, phenothiazines, antidepressants; total number and dose of medications Impaired alertness; postural hypotension; postural instability; fatigue	Medical: lowest effective dose of essential medications; readjust or discontinue when possible
Situational factors	Possible interventions
Acute host factors	
Acute illness; new or increased medications Transiently impaired alertness; postural hypotension; fatigue	Medical: diagnose and treat specific diseases; start medications low and increase slowly Environmental: increase supervision during illnesses or with new medication
Displacing activity	
Increased opportunity to fall	Rehabilitative: recommend avoiding only clearly hazardous and unnecessary activities (e.g., climbing on chairs); balance and gait training
Environmental hazards	
Slipping or tripping hazards (e.g., loose rugs, wet floors, ice, small objects) stairs, lighting, and furniture Nursing home: movable tables; inappropriate bed or chair height; ill-fitting shoes or pants; restraints	Environmental: home safety assessment with appropriate adaptive or structural changes (see Ref. 7)

weakness, or postural hypotension should be elicited from the patient.

Carotid hypersensitivity should be suspected if the individual gives a history of “just going down” or falling with head turning or with looking up. Carotid sinus massage should be performed if carotid sinus syndrome is suspected, if there is no evidence of cerebrovascular disease or cardiac conduction abnormality, and if the procedure is judged safe in the individual patient. The carotid sinus syndrome is defined as greater than a 3-s sinus pause or more than a 5 mmHg drop in systolic blood pressure.

Laboratory Evaluation

All elderly persons who have experienced falls should undergo routine laboratory screening including a complete blood count, thyroid function tests, electrolytes, including blood urea nitrogen (BUN) and creatinine, and serum glucose, as well as a determination of vitamin B₁₂ levels. These tests are warranted to screen for anemia, thyroid dysfunction, electrolyte abnormalities, dehydration, hyperglycemia or hypoglycemia, and B₁₂ deficiency because of the prevalence, nonspecific presentation, and potential for modification of underlying diseases by these diagnoses. Drug levels, for example, should be measured in individuals taking anticonvulsants, tricyclic antidepressants, antiarrhythmics, and high-dose aspirin. History and examination should guide other laboratory investigations.

As already noted, in approximately 10% of cases falls by community-dwelling older adults are a nonspecific manifestation of an acute illness. In these situations the laboratory and diagnostic evaluation in these situations should be dictated by the suspected etiology. Examples of potentially useful tests include the electrocardiogram, cardiac enzymes, chest x-ray, urine analysis and culture, and blood cultures.

Brain imaging with computed tomography or magnetic resonance imaging is indicated only when focal abnormalities are noted on the neurologic examination. Cervical spine films may be helpful in individuals with impaired gait, lower extremity spasticity, and hyperreflexia suggestive of cervical spondylosis. A lateral dimension of the spinal canal of less than 12mm is suggestive of a significant encroachment on the cervical cord. Magnetic resonance imaging should be pursued to confirm this finding only if the individual is deemed a candidate for neurosurgery.

A 24 h ambulatory cardiac monitor (Holter) is not warranted for the routine evaluation of nonsyncopal falls. The yield of ambulatory electrocardiographic monitoring is very low in these individuals. In addition, the results may be difficult to interpret because of the high prevalence of asymptomatic arrhythmias in older adults.

Balance and Gait Evaluation

Balance and gait represent end products of the accumulated effects of disease, age-related and lifestyle changes, and impairments in sensory, neurologic, and musculoskeletal functioning. Therefore, a careful assessment of balance and gait is an essential component of the fall evaluation. There is strong epidemiologic evidence to support balance and gait assessment as the single best means of identifying individuals at increased risk of falling.^{9,10,13,18,83,84} Simple but reliable methods for observing an individual's balance and gait performance are available for use in clinical practice.^{58,85}

Tests of balance and gait typically reproduce the position changes, postural responses, and gait maneuvers used during daily activities. The “Get Up and Go” test and the Performance-oriented Assessment of Mobility are two examples of clinical observation tests of balance and gait that have been used extensively in clinical practice.^{58,85} Both assessments involve observing the individual perform various combinations of maneuvers such as getting up from a chair, reaching up, turning, bending over, assuming various narrowed stances, walking at a usual and rapid pace, and sitting in a chair. The examiner watches for instability or difficulty with performing each maneuver. Components of a simple balance and gait assessment are included in Table 66.4. The assessment may help to identify not only individuals at risk for falling but the circumstances in which falls are most likely to occur. As discussed next, combinations of medical, rehabilitative, and environmental interventions can be recommended based on the simple observations of balance and gait.

The role of computerized posturography in the clinical evaluation and treatment of balance and falling disorders remains to be determined. Posturography may be helpful in determining the relative contribution of visual, vestibular, and proprioceptive abnormalities to postural instability.⁸³ Posturography may further reveal the method by which the individual responds to postural perturbations. Although still under investigation, preliminary studies suggest that these findings may help in the development of effective rehabilitative interventions.⁸⁶

Review of Fall Situations

The fourth component of the fall evaluation is a careful review of recent fall situations. In determining the contribution of possible intrinsic factors, the clinician should obtain information on premonitions; feelings of lightheadedness, vertigo, or unsteadiness; recent medications, particularly focusing on recent changes; preceding alcohol consumption; or symptoms of acute illness, postural hypotension, or dysrhythmias. A precise description of activity at the time of the fall is important as well.⁸⁷ Was the individual standing still, performing a simple

TABLE 66.4. Position changes, balance maneuvers, and gait components included in performance-oriented mobility assessment.

Position change or balance maneuver	Observation: fall risk if
Getting up from chair ^a	Does not get up with single movement; pushes up with arms or moves forward in chair first; unsteady on first standing
Sitting down in chair	Plops in chair; does not land in center
Withstanding nudge on sternum or pull at waist	Moves feet; begins to fall backward; grabs object for support; feet not touching side by side
Side by side standing with eyes open and shut	Same as above; eyes closed tests patient's reliance on visual input for balance
Neck turning	Moves feet; grabs object for support; feet not touching side by side; complains of vertigo, dizziness, or unsteadiness
Bending over	Unable to bend over to pick up small object (e.g., pen) from floor; grabs object to pull up on; requires multiple attempts to arise
Gait component or maneuver	Observation: fall risk if
Initiation ^b	Hesitates; stumbles; grabs object for support
Step height (raising feet with stepping)	Does not clear floor consistently (scrapes or shuffles); raises foot too high (more than 2 in.)
Step continuity	After first few steps, does not consistently begin raising one foot as other foot touches floor
Step symmetry	Step length not equal (pathologic side usually has longer step length; problem may be in hip, knee, ankle, or surrounding muscles)
Path deviation	Does not walk in straight line; weaves side to side
Turning	Stops before initiating turn, staggers; sways; grabs object for support

^aUse hard, armless chair. Other more difficult balance maneuvers include tandem, semitandem, and one-leg standing.

^bPatient walks down hallway at "usual pace," turns and comes back using usual walking aid. Repeat at "rapid pace." Examiner observes single component of gait at a time (analogous to heart examination). Other gait observations include heel-toe sequencing; armswing; trunk sway; stepping over objects.

activity of daily living such as getting dressed, or walking? If walking, on what type of surface? Was the individual getting up or sitting down, arising from a lying position, going up or down stairs or curbs? If the fall occurred during routine and relatively nonhazardous activities, the goal of intervention will be to improve the safety and effectiveness of the maneuver during which the fall occurred. If, on the other hand, the fall occurred while performing more hazardous activities such as climbing on chairs or ladders, substitution of safer activities or avoidance should be recommended.

Environmental details that should be ascertained include obstacles in the immediate area of the fall; the volume and intensity of lighting; the floor or ground surface; objects being carried; footwear, including the fit, heel height, and type of sole; and walking aids used at the time of the fall. A home safety evaluation as well as careful review of specific fall situations may reveal remedial environmental hazards. While common sense dictates eliminating obvious hazards such as throw rugs and obstacles, these have not been shown to be independent risk factors. Still, a recent Cochrane review supports interventions to reduce home hazards, particularly by a trained professional for patients in the immediate posthospitalization period.^{88,90}

Prevention and Therapy

The appropriate intervention strategy depends on the health status and fall history of the individual. For

healthy individuals who have not suffered falls, the treatment goal is to maintain or improve balance, gait, flexibility, and endurance to decrease the risk of falls and to maintain mobility and functional independence. Recent clinical trials suggest that strength and balance training are effective in increasing lower extremity strength in healthier, more vigorous elderly persons.⁹¹ In a case-control study, older persons who perform vigorous physical activity at least three times per week and have no limitations in their ADLs may be at a lower risk for fall-related fractures.⁹² Recent evidence suggests that older adults who participate in a program of resistance exercise training once or twice weekly demonstrate improved neuromuscular performance and achieve muscle strength gains similar to those training 3 days per week.⁹³

Further studies are needed to define the long-term effectiveness, optimal combination of exercise components, and minimal intensity required. In a recent randomized controlled trial, a low-cost multifactorial intervention based at a community organization was shown to be effective in reducing slips by 61%, trips by 56%, and falls by 29% in a group of healthy older adults during 1 year.⁹⁴ Evidence is emerging that among "healthier," less-impaired persons, exercise seems to have as strong an effect on falls as does the multifactorial approach in the less healthy.⁹⁵ The aim of treatment in older individuals who have already experienced falls or who suffer from chronic diseases and impairments is to reduce the rate of subsequent falls and decrease the incidence of fall-related morbidity such as injury, fear,

inability to get up, functional decline, and immobility. The treatment strategy should be guided by the results of the assessment.⁹⁶⁻⁹⁸ The governing concept should be that it is possible to reduce the risk of falls and fall sequelae by eliminating or modifying as many contributing factors as possible. Because of the overlapping, compensatory nature of the systems affecting stability as described earlier, simple interventions may result in major improvements, even if the interventions are not targeted at the systems believed to be most impaired.

As most of the factors contributing to fall risk are chronic diseases or impairments that may be modifiable, but only rarely curable, the treatment strategy should combine appropriate combinations of medical, surgical, rehabilitative, and environmental interventions. These interventions are summarized in Table 66.3. Similarly, the balance and gait assessment is useful not only for identifying individuals at risk for falling and the situations under which falls are likely to occur but can also be used to determine rehabilitative and environmental interventions that may decrease risk. Examples of using the results of balance and gait examination to guide treatment are outlined in Table 66.4. Rather than targeting one area of risk, an individualized, interdisciplinary, multifactorial approach to modifying all risk factors was shown to be most beneficial in reducing falls in older adults.⁹⁰ The withdrawal of psychotropic medications in association with a home-based exercise program had a relative hazard for falls of 0.34 (95% CI, 0.16–0.74) compared with maintaining the psychoactive medications and the exercise program.⁹⁹

As can be seen from reviewing Tables 66.3 and 66.4, physical therapy is an integral part of any fall assessment and treatment program.⁹⁷ A home safety evaluation with recommendations for modification and adaptation, prescription of and training in the appropriate use of assistive devices, transfer and gait training, and instruction in muscle-strengthening and balance exercises are examples of fall preventive interventions carried out by a trained physical therapist.⁹⁷ The physical therapist may also help in treating the consequences of falls by teaching strategies for how to fall, or for getting up from the floor after a fall, and by encouraging confidence in performance of activities of daily living without falling. Recent evidence suggests that a home exercise program may reduce falls, but further evidence is needed to determine the long-term effects of this intervention.¹⁰⁰

A randomized controlled trial of thrice-weekly progressive resistance exercises, walking, and balance training in a group of high-risk community-dwelling male fallers resulted in improved endurance and lower extremity strength and decreased fall rates.¹⁰¹ A pre-planned meta-analysis of the seven federally funded Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT) Trials showed a 10% reduction in

the adjusted fall incidence ratio for studies that included endurance, resistance, and flexibility exercise programs and a 17% reduction for those that only used balance.¹⁰² After adjusting for fall risk factors, a moderate Tai Chi training program was found to reduce the risk of multiple falls by 48%.¹⁰³

Promising treatment modalities for the prevention of fall-related fractures include treatment of osteoporosis, discussed in Chapter 43. Additionally, an assessment of falls is recommended for those patients who have already sustained a hip fracture.¹⁰⁴ Providing extra padding, through the use of various types of hip protectors, appears to be a promising approach for the prevention of hip fractures, one of the most serious consequences of falls among elderly persons.¹⁰⁵ These devices were recently shown to improve self-efficacy in high-risk community-dwelling older adults and to reduce the risk of hip fracture in a group of frail ambulatory elderly.¹⁰⁶

Nursing Home

The first step to developing and implementing a fall evaluation and prevention program for institutionalized older adults is to establish appropriate goals. Not only are institutionalized older adults more likely than their community-dwelling counterparts to be frail, they are also more likely to have readily available alternatives to walking as a means of mobility. It is important to carefully assess the trade-offs of safety versus functional independence and mobility in institutionalized older adults, as an increase in physical activity may increase the risk of injury. Although the components of a fall evaluation are the same in nursing home and community-dwelling older adults, the relative contribution of chronic or situational risk factors may differ.

Predisposing Risk Factor Assessment

A thorough clinical evaluation aimed at identifying all contributing risk factors is the cornerstone of the evaluation among nursing home residents.¹⁰⁷ As with community-living elderly persons, the risk of falling increases with the number of impairments, suggesting again that ameliorating or eliminating as many risk factors as possible may decrease risk.^{51,58,108} A careful examination of the risk factors noted in Table 66.3 is essential as the number and severity of impairments and diseases is greater among nursing home than community residents, and nonspecific and vague presentations, particularly among the large number of nursing home residents with cognitive impairment, render the clinical history less reliable.¹⁰⁹

Laboratory Evaluation

As among community-living elderly persons, routine laboratory testing should be targeted toward conditions

that are common and treatable. Additional testing should be considered on an individual resident basis, guided by the history and examination. There is no role for routine ambulatory cardiac monitoring for nonsyncopal falls among nursing home residents.

Balance and Gait Evaluation

Balance and gait assessment plays the same role in nursing home as in community residents. Reliable and validated assessments have been developed specifically for use among frail nursing home residents and hospital patients.¹¹⁰

Review of Fall Situations

Although many falls among nursing home residents are unwitnessed, there is greater opportunity to identify acute intrinsic and environmental contributors to falling among nursing home residents compared with community residents.^{29,57} Symptoms experienced near the time of the fall such as dizziness may suggest postural hypotension, hypoglycemia, dysrhythmia, or a medication side effect. Chest pain may suggest angina or myocardial infarction. The immediate postfall physical examination should include a careful evaluation of postural blood pressure and pulse changes at both 1 and 3 min, focal neurologic signs, and signs of any acute illnesses that may present as a fall.

Environmental factors that are particularly relevant to nursing home residents include the presence of side rails, inappropriate use of walking aids such as walkers or wheelchairs, and the presence and application of vest, belt, or other restraints. Among nonambulatory nursing home residents, injurious falls are more likely to occur while seated or during transfers from the chair or bed level and to involve ill-fitting or poorly maintained equipment such as wheelchairs, shower chairs, or commodes.¹¹¹

Prevention and Therapy

Although earlier studies demonstrated that careful assessment and intervention among nursing home residents who fall reduces the risk of hospitalization, there was little evidence that it prevents subsequent falls.¹¹² A recent randomized controlled trial of a nursing home consultation service demonstrated a reduction in the proportion of nursing home residents who were recurrent fallers, especially among those who adhered to the recommendations. These interventions included targeting environmental and personal safety issues, wheelchair use, transferring, and ambulation, along with psychotropic drug use.⁶⁰ The specific role of physical therapy in fall prevention among nursing home residents remains to be determined. Although on the one hand studies have not found physical therapy interventions to be effective,

other studies have shown that intense strength training results in increased strength, balance, and gait in even very frail elderly nursing home residents.^{113,114} These seemingly conflicting results suggest that the optimal cost-effective strategy is to identify and treat those elderly persons most likely to benefit from a multifactorial intervention to prevent falls. At the very least, a physical therapy evaluation is warranted to prescribe and ensure the correct use of assistive devices, including walkers, canes, crutches, orthotics, and shoe modification.

Although researchers have failed to establish a causal link between medications and falls by nursing home residents, the strong association between medications and falling and the contribution of polypharmacy to other adverse events warrants frequent medication review and adjustment. The goal should be to reduce the total number and dosage of medications taken by nursing home residents. On the strength of the current evidence it is suggested that efforts to prevent falls in nursing homes should focus on decreasing the use of psychoactive medications, training staff members to perform safe transfers, and repairing broken equipment such as wheelchairs.

Environmental Assessment

In addition to assessing the environment at the time of a fall, ongoing environmental assessment aimed at removing potential hazards and modifying the environment to improve mobility and safety should be an ongoing practice in nursing homes. The provision of adequate lighting without glare; dry, nonslippery floors that are free of obstacles; high, firm chairs with arms; beds at appropriate heights for individual residents (feet should touch the floor with the knees bent at 90°); beds without upper side rails; and raised toilet seats with arms are preventive measures that should be implemented for all nursing home residents. Movable bed trays, which are often used by residents for support, should be considered a serious fall hazard. Footwear should be scrutinized; shoes that are ill fitting, have worn soles or heels, or are left untied are unsafe for nursing home residents. Slippers without backs, with soles that are either too slippery or have too high friction, or which provide little foot and ankle support are particularly hazardous, as is wearing stockings without shoes.

Restraints

Recent efforts, guided by federal regulations as well as by the results of several studies, have aimed at reducing the use of physical restraints. Although controlled studies are lacking, observational evidence suggests that physical restraints may contribute to falls, injuries, and death through strangulation as well as to other adverse outcomes such as withdrawal and depression.^{30,115,116} One

prospective study showed a 25% to 40% reduction in restraint use in a nursing home with restraint education with consultation compared to restraint education or control alone.¹¹⁷ Increasingly, nursing homes are implementing alternative measures such as increased nurse-to-resident ratio, alternative seating, lowered side rails and bed heights for residents who climb out of bed, and alarms that are activated when residents try to get out of bed or move unassisted.²⁹ Although the effectiveness of these various techniques and devices remains to be determined, restraint reduction does appear to decrease the injury rate in those who fall.³³

As noted for community-living elderly persons, injury prevention alternatives such as hip protectors are currently being tested.^{105,118} It has been proven that hip protectors can be particularly effective in preventing hip fractures. At this point, however, patients complain about the discomfort and practicality of the device, thereby resulting in only a small percentage of at-risk patients wearing them. As a result, nursing home patients should be encouraged to use hip protectors to prevent injury from falls.¹¹⁹

Summary

Falling is a common event among community and nursing home residents. These falls may result in considerable morbidity, ranging from self-imposed activity restriction to serious injury and death. Until methods are available for accurately identifying those falls or fallers at risk for serious morbidity, all fallers should be assumed to be at risk. A small percent of falls result from a single, overwhelming intrinsic event such as a stroke, from the effects of a single disease process such as Parkinson's disease, or from overwhelming environmental hazards. The majority of falls are multifactorial, resulting from various combinations of intrinsic, activity-related, and environmental factors. Recent studies suggest that careful assessment and interventions aimed at identified risk factors and well-designed exercise programs may decrease the risk of falling. Most often, the goal of fall prevention programs should be to minimize the risk of falls and injuries without compromising function or mobility. As with all older individuals, however, the goals and priorities may be different for individual persons.

Chronic Dizziness and Vertigo

Aman Nanda and Mary E. Tinetti

Dizziness is a subjective sensation of postural instability or of illusory motion. It is a nonspecific term that includes vertigo, disequilibrium, lightheadedness, spinning, giddiness, faintness, floating, feeling woozy, and many other sensations. As the etiologies differ, dizziness is often classified on the basis of duration as acute (present for less than 1–2 months) or chronic (present for more than 1–2 months). Because the causes of acute dizziness are usually identical for patients of all ages, this chapter is therefore limited to a discussion of chronic dizziness.

Prevalence and Morbidity

Dizziness is one of the most common presenting complaints in primary care practice for persons aged 65 years and older.¹ The prevalence of dizziness ranges from 4% to 30% in this age group.^{2–4} Dizziness increases with age, with a 10% increase every 5 years. After adjusting for age, women are 30% more likely than men to report dizziness.³

Chronic dizziness has been associated with an increased risk of falls, syncope, functional disability, and, in some studies, strokes and death.^{4–12} It is strongly associated with fear of falling and reduced confidence in performing daily activities.¹³ In one study, 47% of patients with dizziness expressed a fear of falling compared to only 3% of the controls.¹⁴ It has also been associated with worsening of depressive symptoms, self-rated health, and participation in social activities.¹⁵

Types of Dizziness

There is no universally accepted classification of dizziness. Dizziness has been categorized by either duration (acute/chronic) or types of sensations. Drachman and Hart¹⁶ categorized dizziness into four subtypes based on sensations: vertigo, presyncope, disequilibrium, and other.

Vertigo is a spinning or rotational sensation, either of the patient with respect to the environment (subjective vertigo) or of the environment with respect to the patient (objective vertigo). The key element is the perception of motion. Vertigo often begins instantaneously, is episodic, and when severe may be associated with nausea, vomiting, and a staggering gait. Vertigo is considered to result from a disturbance within the vestibular system or its connections. However, the lack of a spinning sensation may not be used to exclude vestibular diseases, as patients with vestibular problems can describe dizziness as an imbalance, disequilibrium, or other sensation. Also, etiologies outside the vestibular system (e.g., cervical causes of dizziness) may result in vertigo.

Presyncope is a feeling of lightheadedness or impending faintness or a feeling that one is about to pass out. It is usually considered to result from a hypoperfusion of the brain. A number of cardiovascular conditions may cause presyncope and syncope.

Disequilibrium is a feeling of imbalance or unsteadiness usually not associated with any abnormal head sensations. The patient feels as if he or she is going to fall. Disequilibrium usually results from abnormalities in the proprioceptive system.

The category “other” is defined as a vague feeling other than vertigo, presyncope, or disequilibrium. The patient may describe “floating,” “wooziness,” “spaciness,” “whirling,” and other nonspecific sensations.

A person may have a combination of two or more of these four types of dizziness; this is the most common type of dizziness reported by older persons^{17,18} and is believed to result from systemic disorders such as anemia, electrolyte imbalances, diabetes, and hypothyroidism, or from the presence of combinations of diseases affecting the vestibular, central nervous, visual, or proprioceptive system.

These sensations as noted here have diagnostic specificity among persons of all ages with acute dizziness and among younger persons with chronic dizziness. Among

older persons with chronic dizziness, however, there is a less consistent correlation between the type of sensation and specific organ systems.

Mechanisms of Equilibrium

Given that dizziness is a sensation of postural instability, a review of the mechanisms determining balance and equilibrium may help in understanding the pathophysiology of dizziness. Maintenance of balance and equilibrium results from a complex integration of sensory information obtained from the visual, auditory, vestibular, and proprioceptive systems by the cerebral cortex and cerebellum and the use of this information for the appropriate motor response.

The visual system helps in maintaining balance by providing signals from the retina to the occipital cortex, necessary for providing a stable retinal image during head movement. The vestibulo-ocular reflex (VOR) controls the position of the eyes, enabling maintenance of a stable visual image during head movement. The VOR depends on the information relayed by the vestibular nucleus to the sixth (abducens) cranial nerve nucleus in the pons and, via the medial longitudinal fasciculus, to the third (oculomotor) and fourth (trochlear) cranial nerve nuclei in the midbrain. Binocular vision and depth perception also are important visual signals for spatial orientation.

Hearing assists in stability by detecting and interpreting auditory stimuli, which enables one to localize and be oriented in space. Hearing is particularly helpful when other sensory modalities are impaired. Hearing impairment, common in older persons, may be secondary to aging, to disease processes, or to the presence of excess cerumen. Although impaired hearing may be a marker of vestibular dysfunction as both sensory modalities operate through the eighth cranial nerve, studies have reported an independent association between decreased hearing and dizziness.^{4,18}

The vestibular system contributes to spatial orientation at rest, as well as during acceleration, and is responsible for visual fixation during head and body movements. The vestibular system includes the semicircular canals, utricle, saccule, vestibular nerve, and vestibular nucleus in the brainstem. The semicircular canals respond to changes in angular acceleration, and the utricle and saccule respond to linear acceleration. The sensory epithelium of the semicircular canals, utricle, and saccule consists of hair cells. The afferents from these hair cells relay information to the vestibular nuclei in the brainstem. The vestibular nuclei relay this information to the nuclei of the third, fourth, and sixth cranial nerves, spinal cord (vestibulospinal tract), and cerebellum (vestibulocerebellar pathway).

The proprioceptive system provides information about changes in position and movements and helps maintain equilibrium during changes in position. The components of the proprioceptive system are mechanoreceptors in the joints, peripheral nerves, posterior columns in the spinal cord, and multiple central nervous system connections. The afferent impulses relay information to the cerebral cortex via the thalamus and to the cerebellum via the spinocerebellar tract.

The cerebral cortex, cerebellum, and brainstem integrate information received from the visual, auditory, vestibular, and proprioceptive systems and direct the musculoskeletal system via efferent pathways toward the response appropriate for maintaining balance and equilibrium. Lesions in the brain may cause disordered integration of information from these systems, resulting in imbalance/dysequilibrium.

Effects of Aging on Sensory Systems

Evidence suggests that age-related changes occur in each of the vestibular, visual, auditory, and proprioceptive systems. Although these age-related changes do not likely cause clinical disease, they may predispose older persons to the occurrence of dizziness by making them more vulnerable to the effects of superimposed impairments and diseases. Degenerative changes and reductions in the number of sensory cells (hair cells) in the semicircular canals, saccule, and utricle have been reported with aging.^{19,20} Richter noted a significant decrease in the number of cells in Scarpa's ganglion.²¹ Bergstrom found a 37% reduction in the number of nerve fibers in the vestibular nerves of five people over age 75.²² Age-related visual changes include a decrease in visual acuity, dark adaptation, contrast sensitivity, and accommodation.^{23,24} Age-related decline in proprioception has not been extensively studied. Skinner et al. reported a significant deterioration in joint-position sense in older individuals, but Kokemen et al. concluded that there is no major decline in joint-position sensation with aging.^{25,26}

Causes of Chronic Dizziness

Dizziness results from either discrete or combined effects of disorders or impairments in the multiple systems responsible for maintaining equilibrium. Acute and, to a lesser extent, chronic dizziness result when a disorder in one of these systems causes abnormal or decreased sensory input, resulting in a mismatch of information about the movements of the head or body. Discrete causes of chronic dizziness can be divided into central nervous system disorders, vestibular disorders, psychogenic causes, systemic causes, medications, and

miscellaneous. The relative frequency of these causes is unclear, as there has been a wide variability in their reported prevalences.^{9,10,16–18,27–31}

Discrete Diseases Causing Dizziness

Central Nervous System Causes

Cerebrovascular diseases have been identified as a primary or contributing cause of dizziness in 4% to 70% of older patients.^{9,10,16–18,28–32} Vertebrobasilar ischemia results from an obstruction of the blood flow in the vertebrobasilar arteries, most commonly caused by arteriosclerosis leading to either transient ischemic attacks (TIA) or infarction. Because the basilar artery is responsible for the blood supply to the eighth nerve and vestibular nuclei, dizziness is one of the cardinal signs of basilar artery insufficiency. Apart from acute dizziness, which is usually in the form of prodromal symptoms in patients with vertebrobasilar TIA, patients may complain of chronic dizziness following a brainstem infarct. Dizziness may also result from anterior or posterior inferior cerebellar artery ischemia but is uncommon with internal carotid cerebral artery disease.³²

Other central nervous system disorders such as parkinsonism, acoustic neuroma, and basilar artery migraine (rare in older persons) may also cause dizziness.^{33–35}

Vestibular Causes

Vestibular diseases have been identified as a primary or contributing cause in 4% to 71% of cases of dizziness.^{9,16,17,27,28,30,31} Common vestibular diseases causing chronic dizziness in older persons include benign paroxysmal positional vertigo, Meniere's disease, recurrent vestibulopathy, and acoustic neuroma. Ototoxic medications may also lead to complaints of dizziness.

Benign paroxysmal positional vertigo (BPPV), reportedly responsible for between 4% and 34% of cases of recurrent episodes of dizziness,^{9,16,17,27,28,30} is characterized by brief bouts (seconds) vertigo of sudden onset that is provoked by certain changes in the head position (e.g., rolling over in bed into a lateral position, gazing upward, or leaning forward). Another characteristic feature of BPPV is an accompanying rotational nystagmus. The vertigo is often associated with nausea or vomiting. Patients typically experience recurrent bouts of positional vertigo over days to months, with quiescent periods between episodes.

Most BPPV cases have no identifiable cause. The most common known causes are a history of head trauma and viral neurolabyrinthitis.³⁶ The currently accepted pathophysiologic mechanism of BPPV is the presence of free-floating particulate matter, most likely dislodged otoconia (tiny calciferous granules that form part of the

receptor mechanism in the otolith apparatus) in the endolymph of the posterior semicircular canal. The exact mechanism by which free-floating particulate matter causes paroxysmal vertigo and nystagmus is unknown, but presumably it is the result of the movement of the debris causing alterations in endolymphatic pressure.^{37–39} The otoconia have been shown to undergo degenerative changes with aging, which might also be responsible for their dislodgment from the utriculus.⁴⁰ A definitive diagnosis of benign paroxysmal positional vertigo can be made by the Dix–Hallpike test (discussed here).⁴¹

Meniere's disease is an idiopathic inner ear disorder characterized by episodic vertigo, tinnitus, fluctuating hearing loss, and a sensation of fullness in the inner ear. The frequency of this disease has been reported to be 2% to 8% in dizziness cases.^{9,16,17,27,28,30} Males and females are affected equally, with onset usually occurring during the fifth decade of life. The main pathologic finding in patients with Meniere's disease is an excess of endolymph within the cochlea and vestibular labyrinth. The patient develops a varying degree of sensations of fullness or pressure, along with hearing loss, and tinnitus in the affected ear. Vertiginous episodes usually last from 1 to 24 h. The patient may complain of a sense of unsteadiness after the acute episode. In the early stages, the hearing loss is completely reversible, but in later stages, partial or complete hearing loss occurs in about 90% of the patients.⁴² The hearing loss has a sensorineural pattern, with hearing at the lower frequencies tending to be worse.

Recurrent vestibulopathy was first described by LeLiever and Barber in 1981.⁴³ This clinical entity is characterized by recurrent episodes of vertigo, usually lasting from 5 min to 24 h, without auditory or neurologic signs or symptoms. The exact cause is not known.⁴⁴ The absence of auditory symptoms differentiates it from Meniere's disease. Spontaneous recovery has been reported in 62% of patients over an 8.5-year follow-up.⁴⁵

An acoustic neuroma is a benign tumor of the eighth cranial nerve, characterized by tinnitus and progressive unilateral sensorineural hearing loss that is greater for higher frequencies. This tumor has been reported in 2% to 3% of older persons with dizziness.^{17,28} Vertigo is a complaint of 19% of patients, whereas 48% complain of imbalance or disequilibrium.⁴⁶ As the tumor grows, patients may complain of parasthesias or pain in the trigeminal nerve distribution. A large tumor can cause cerebellar ataxia.

Postural Hypotension

In various studies, postural hypotension has been identified as a primary or contributing cause in 2% to 15% of dizziness cases.^{18,27–29} Postural hypotension has commonly been defined as a drop in systolic arterial blood pressure

of at least 20mmHg or a fall in diastolic blood pressure of 10mmHg after standing up from a supine position. However, there are no uniform criteria for postural hypotension in older persons, and at least 15 different definitions exist for postural hypotension.^{47,48} Blood pressure is commonly measured at 1 and 3 min after standing, but in some older persons a significant orthostatic drop occurs only after 10 to 30 min (delayed orthostatic hypotension).⁴⁹ Some older persons complain of dizziness on standing, but their blood pressure changes do not meet the criteria of postural hypotension. In one study of 9672 elderly women, postural hypotension was reported in 14% of the participants, but only 3% of these patients complained of dizziness, whereas 16% of the subjects reported dizziness on standing without any postural blood pressure changes.⁶ In another study, 9% of patients with postural blood pressure changes complained of dizziness, while 31% complained of dizziness on standing with no postural blood pressure changes.²⁹ These results suggest that a postural drop in blood pressure is not always symptomatic and that, conversely, not all dizziness with postural changes is the result of orthostatic blood pressure changes.

Postprandial hypotension, usually defined as a decrease in systolic blood pressure of 20mmHg or more in a sitting or standing posture within 1 to 2 h of eating a meal, may also cause dizziness.^{50,51} A recent study showed that the effects of postprandial hypotension and orthostatic hypotension are additive but not synergistic, suggesting that the two entities have different pathophysiologic mechanisms.⁵² Postprandial reductions in blood pressure may result in falls, syncope, weakness, or dizziness.

Systemic Causes

Systemic disorders may contribute to instability or dizziness by affecting the sensory, central, or effector components. In addition, systemic disorders may result in decreased cerebral perfusion or oxygen delivery, fatigue, or confusion, many of which in turn may result in instability or dizziness. Common examples include anemia, hypothyroidism, congestive heart failure, and diabetes mellitus with anatomic dysfunction. Carotid sinus hypersensitivity or carotid sinus syndrome can also cause dizziness, falls, or syncopal episodes. Wearing tight collars can precipitate dizziness, syncopal episodes, or falls upon sudden head turning or looking up. Carotid sinus syndrome is defined as a sinus pause of more than 3 s or a drop in systolic blood pressure of more than 50 mmHg following carotid sinus massage for 5 s. In one study, carotid sinus syndrome was reported in 45% of patients with dizziness, falls, and syncope.⁵³ However, this high percentage is likely because the study population was a select group referred to a syncope clinic.

The prevalence of dizziness in patients with systemic disorders is not known, but studies have found a significant association between dizziness and a history of angina, myocardial infarction, hypertension, or diabetes mellitus and with the total number of chronic conditions.^{4,17,18,54}

Psychogenic Causes

Psychogenic causes of dizziness have been reported in the range of 0% to 57% in older persons with dizziness.^{9,16-18,29-31,54,55} The most common conditions in older persons are depressive and anxiety disorders, either the primary cause or a contributing factor. Patients usually present with a vague sensation of dizziness, along with other somatic complaints and with symptoms of psychological disorders. Studies have reported an independent association between dizziness and depression or anxiety.^{3,4,17,54}

Cervical Causes

The reported frequency of dizziness caused by cervical spine disorders ranges from 0% to 65%.^{16,27,29,30} Disorders of the cervical spine should be suspected when dizziness worsens with head turning or walking on uneven surfaces. Both proprioceptive and vascular mechanisms have been postulated.^{56,57} *Proprioceptive* deficits in the cervical spine can cause dizziness secondary to the impaired information from proprioceptive receptors present in the facet joints of the cervical spine. In older persons, cervical osteoarthritis most likely causes dizziness via this mechanism. The patient usually complains of pain in the neck on movement, along with a worsening of dizziness. There is often a history of arthritis or whiplash injury. Further examination may reveal a decreased range of motion of the neck or signs of radiculopathy or myelopathy or spastic gait.

A *vascular mechanism* causing cervical dizziness is thought to result from an obstruction to the vertebral arteries. One theory is that when there is an extensive blockage of one vertebral artery, rotation of the head can sufficiently obstruct the other vertebral artery to cause brainstem ischemia.⁵⁶ Another theory is that when a person turns their head or neck, an osteoarthritic spur may press upon the nearby vertebral artery, causing a transient disruption of the blood flow.⁵⁷

Medications

Medications have frequently been reported to cause or contribute to chronic dizziness.^{17,18,28} Several classes of medications, such as anxiolytic drugs, antidepressants, antihypertensive drugs, aminoglycosides, chemotherapeutic agents, and nonsteroidal anti-inflammatory drugs, are known to produce dizziness as a side effect.⁵⁸

Medications may cause dizziness through various mechanisms. Antihistamines and tricyclic antidepressants trigger dizziness through their anticholinergic side effects. Aminoglycosides have direct ototoxic effects when used in high dosages or for longer durations, especially when renal function is impaired. Other ototoxic agents include nonsteroidal anti-inflammatory agents such as aspirin, quinine, loop diuretics, and erythromycin and vancomycin analogues.⁵⁹ Meclizine, often prescribed for dizziness, has anticholinergic properties and may even exacerbate the dizziness caused by nonlabyrinthine disease.⁵⁷ When taking a medication history, one should also inquire about over-the-counter drugs such as cold preparations, which are prone to cause dizziness. In addition to specific medications, an independent association between the use of multiple medications and dizziness has been reported.^{18,54}

Diseases Causing Impairment of Vision

Diseases such as cataracts, glaucoma, and macular degeneration, which are common in older persons, may cause dizziness by impairing the visual functions. Davis, in his study of 117 patients with complaints of dizziness, reported that 26% suffered from disorders of the visual system, but he concluded that it was the major cause of dizziness in only 1% of the cases.²⁸ In this study, 13% of the patients had cataracts. Other studies have also reported an association between poor vision or cataracts and dizziness.^{4,54}

Chronic Dizziness as a Geriatric Syndrome

In the previous section, dizziness in older persons was considered a symptom of one or more discrete diseases. The results of recent studies, however, suggest the possibility of a multifactorial etiology of dizziness.^{3,4,18,30} In these studies, chronic dizziness has been associated with risk factors such as angina, myocardial infarction, stroke, arthritis, diabetes, syncope, anxiety, depressive symptoms, impaired hearing, alcohol consumption, smoking, nervousness, and the use of several classes of medications. In a recent cohort study of a large community sample, the authors found an association between factors in multiple domains and the occurrence of chronic dizziness. The factors that were independently associated with chronic dizziness included anxiety, depressive symptoms, decreased hearing, postural hypotension, impaired balance and gait, the use of five or more medications, and a past history of myocardial infarction. A person with more than five of the risk factors was five times more likely to report chronic dizziness than a person with fewer than two factors.¹⁸ These findings were validated

in a cohort of patients seen in a geriatric assessment center.⁵⁴

An association among the characteristics in multiple domains and dizziness suggests that dizziness may be considered as a geriatric syndrome, similar to delirium and falls.¹⁸ Geriatric syndromes are health conditions experienced more frequently by older than by younger persons and result from the accumulated effect of impairments and diseases involving multiple systems. The importance of considering chronic dizziness a geriatric syndrome is that a multifactorial assessment and intervention strategy, as described in the following section, may be more effective at alleviating the symptom than the standard disease-oriented approach.

The concept of a geriatric syndrome does not preclude the possibility that a single disease may be primarily responsible for impairment in a subset of persons. Rather, it acknowledges that many symptoms such as dizziness in older persons cannot be explained adequately on the basis of a single disease.

Evaluation

Dizziness is a challenging problem for physicians who take care of older persons. The differential diagnosis as presented in the previous section is broad. The potential workup is extensive and expensive. The goal should be to eliminate the cause of the dizziness, if possible. If not, the goal should then be to alleviate the dizziness to the extent possible and to avoid the adverse consequences such as falls, functional disability, and increased depressive symptoms. Based on these goals and on the available evidence, a stepwise approach to the evaluation of chronic dizziness seems warranted. The existence of discrete diseases is usually suggested by the results of the history, physical examination, and routine laboratory evaluation. Only in the subset of patients in whom discrete diagnosis is suggested by their routine evaluation should a targeted battery of expensive tests be pursued, and only if the results of these tests are likely to influence treatment or prognosis. For the majority of older persons in whom a routine evaluation does not suggest a single discrete cause, the clinician should identify the various factors contributing to dizziness, some of which may be amenable to treatment. This approach is based on the fact that identifying and ameliorating one or more of these contributors might help alleviate the dizziness and its adverse consequences. Table 67.1 lists the possible causes of chronic dizziness, the salient history and examination findings, relevant investigations, and treatment.

An evaluation of dizziness begins with the clinical history. The patient should be asked to be as precise as possible about the sensations of dizziness, an often difficult task because patients may experience more than one

TABLE 67.1. Evaluation and treatment of chronic dizziness

Possible causes	History	Examination	Investigations	Treatment
Central nervous system				
Brainstem (vertebrobasilar) and/or cerebellar infarcts/hemorrhages	History of dizziness (e.g., vertigo, near fainting, wooziness) usually associated with slurred speech; visual changes; one-sided weakness and/or gait ataxia; truncal ataxia	Detailed neurologic examination, localizing the lesion	CT or MRI scan; MRI is preferred	Low-dose aspirin or ticlopidine or clopidigrel if infarct; rehabilitation therapy
Cerebellopontine angle tumor: acoustic neuroma, schwannoma, etc.	History of vertigo or dysequilibrium; unilateral hearing loss; tinnitus	Detailed neurologic examination	Audiometry reveals asymmetric hearing loss; which may be further evaluated by MRI	Surgical excision
Parkinson's disease	Dysequilibrium; imbalance; slow motor activities; slow walking, etc.	Increased muscular rigidity; bradykinesia; tremor; orthostatic hypotension	Diagnosis is made by history and examination	Antiparkinson treatment
Vestibulocochlear system				
Benign paroxysmal positional vertigo	Sudden and fleeting episodes of intense vertigo with specific head position (e.g., rolling over in bed into lateral position; looking upward; bending forward); episodes last days to months and are often recurrent	History of episodic vertigo; nystagmus; confirmed by Dix-Hallpike maneuver; along with absence of signs suggesting other pathology, especially central involvement	None	Epley maneuver is helpful in treatment provided the side of the vertigo is known; vestibular rehabilitation and sometimes a short course of vestibular suppressants
Meniere's disease	Episodic vertigo for a few hours; there are no symptoms between episodes; tinnitus; fluctuating hearing loss; sensation of fullness in ears	If unilateral, then bedside vestibulo-ocular reflex test will be abnormal	An audiogram revealing a sensorineural hearing loss (low more than high frequencies) is confirmatory; MRI scan to rule out retrocochlear lesions	Salt restriction and diuretics are the mainstay; during acute attacks vestibular suppressants may be helpful to relieve vertigo; surgical interventions, including endolymphatic decompression, gentamicin perfusion, vestibular nerve section, and labyrinthectomy should be considered only in severe cases
Peripheral nerves				
Diabetes; vitamin B ₁₂ deficiency; hypothyroidism; syphilis; idiopathic	Disequilibrium; worse in dark or on uneven surfaces	Decreased vibration or position sense; steppage gait	Serum glucose; B ₁₂ levels; thyroid function test; VDRL	Treatment of the underlying disease; good lighting; appropriate walking aid and footwear; gait and balance training exercises
Cervical spine				
Degenerative or inflammatory arthritis, spondylosis, whiplash injury	Neck pain, usually episodic dizziness secondary to change in position of the neck, history of trauma or arthritis	Decreased neck range of motion; decreased vibratory or joint position sense; signs of radiculopathy or myelopathy or vertebrobasilar ischemia	Cervical spine series	Treatment of underlying disease; cervical or balance exercises; cervical collar; consider surgery
Vision				
Presbyopia, cataract; glaucoma; macular degeneration	Difficulty in vision; use of bifocals or trifocals	Abnormalities in near/distant acuity	Vision testing; referral to ophthalmologist	Good lighting without glare; appropriate refraction; consider avoiding bifocals or trifocals; drugs for glaucoma; surgery

Hearing Cerumen; presbycusis; otosclerosis	Difficulty in hearing in social situations; unilateral or bilateral deafness	Otoscopy: cerumen; abnormal findings with whisper test, Rinne's test, Weber's test	Audioscopic examination; audiometry	Cerumen removal; ear wax drops; hearing aid; surgery (for otosclerosis); hearing rehabilitation; listening devices
Hypotension Orthostatic volume/salt depletion; drugs; vasovagal attack; autonomic dysfunction; diabetes; parkinsonism; deconditioning	Near fainting; worse when getting up, walking, exercising; may be asymptomatic; complaints consistent with predisposing diseases; medication history	Blood pressure and heart rate; signs of predisposing diseases	Investigations relevant to predisposing diseases	Salt and water repletion; dosage adjustment or removal of the offending drugs; treatment of relevant diseases; ankle pumps; slow rising; elevate head of bed; graduated stockings; reconditioning exercises; drug therapy, fludrocortisone, midodrine, if needed
Postprandial	Same as orthostatic hypotension except the onset is within 1 h of eating	Postprandial blood pressure and heart rate measurement	None	Frequent small meals; avoid exertion after meals; have caffeine with meals; slow rising; avoid antihypertensive drugs with or near meal time
Systemic diseases Cardiac/metabolic/respiratory: e.g., cardiac arrhythmias, valvular lesions, coronary artery disease, cardiomyopathy; heart failure; COPD; diabetes; thyroid disorders; renal disorders; anemia	Symptoms of the underlying diseases	Signs of the underlying diseases	Relevant investigations	Variable, depending on the underlying disease
Psychiatric disorders Anxiety, depression	Usually continuous nonspecific dizziness; fatigue; poor appetite; sleep problems; somatic complaints; poor concentration	Positive results on anxiety or depression screening		Psychotherapy; antidepressant therapy after considering risks and benefits
Medications Ototoxic: aminoglycosides, diuretics, nonsteroidal anti-inflammatory drugs, vestibular suppressants Others: antihypertensives, antianxiety drugs, anticholinergics, antidepressants, anticonvulsants, antipsychotics	Vestibulocochlear symptoms (as discussed above) H/o fatigue; confusion; dizziness often vague, can be continuous, dizziness can be postural	Presence of nystagmus, bedside vestibular function test can be abnormal, abnormal caloric test May have postural hypotension		Eliminate, substitute, or reduce specific offending medication if possible; reduce the drugs to lowest possible dose

manifestation or a vague sensation. The frequency and duration of dizziness, as well as any associated symptoms such as hearing loss, ear fullness, tinnitus, diplopia, dysarthria, and syncopal episodes, are all important. Recurrent episodes of dizziness lasting less than 1 min are seen in BPPV, whereas recurrent episodes of dizziness associated with fluctuating hearing loss or tinnitus and ear fullness are suggestive of Meniere's disease. The clinician should ask the patient whether the dizziness is episodic or continuous. For example, in BPPV, Meniere's disease, or CNS disorders, the dizziness is episodic whereas psychogenic dizziness is usually continuous. The patient should also be asked about any precipitating or provoking factors, such as standing from a supine or sitting position, rolling over in bed, or changing the position of the head or neck (i.e., looking up or from side to side). One should inquire as to whether dizziness occurs after eating meals, which can be caused by postprandial hypotension. The physician should also ask about comorbid conditions, such as cardiac diseases, diabetes, renal disorders, anxiety, or depression, which can predispose or exacerbate dizziness. A careful review of all medications, including over-the-counter drugs, is also important. All patients with complaints of dizziness should be evaluated for depressive symptoms or anxiety disorders.

The physical examination should include measurements of orthostatic changes in blood pressure. Blood pressure and heart rate measurements should be taken after at least 5 min of quiet lying and then at 1 to 2 min after standing. The patient's ears should be examined for excessive wax or structural abnormalities in the external ears. Hearing should be tested by either a whisper test or an audioscope. Near and distant vision should also be tested.

The examiner should look for spontaneous nystagmus. The nystagmus in peripheral vestibular lesions is usually horizontal or rotatory and is suppressed by visual fixation, whereas that in central lesions is vertical and is not suppressed by visual fixation. Frenzel glasses (high-diopter lenses in a frame with a light source) should be used, if available. These lenses eliminate visual fixation and magnify nystagmus. Another possible method of detecting vestibular dysfunction is to do a one-leg or tandem stand on thick foam with the eyes closed, which eliminates visual and proprioceptive input to maintain balance. However, the sensitivity and specificity of this method have not been determined.

In the examination of cranial nerves, diplopia, dysarthria, dysphagia, or facial weakness are suggestive of vertebrobasilar involvement. One should look for cerebellar signs, such as gait ataxia, truncal ataxia, or dysmetria, which suggest etiologies such as a cerebellar stroke or cerebellopontine angle tumors. In the latter,

patients may present with unilateral hearing loss, tinnitus, absence of corneal reflex, and facial parasthesias and ataxia as well as dizziness. Gait and balance examinations should be performed. A poorer performance with eyes closed rather than open suggests a vestibular or proprioceptive etiology. A steppage gait suggests a proprioceptive etiology, as does an improvement in gait when the patient places a fingertip on the examiner's fingertip. Vibration sense testing is a more sensitive test of proprioception than is testing for joint position sense.

Range of neck motion, preferably in a standing position, should be assessed. A decrease in the range of motion, with or without symptoms of dizziness, may be due to a cervical process or, secondarily, to vestibular dysfunction. (The sensation of dizziness on head turning leads to a voluntary restriction in head turning, which, in turn, may lead to a decreased range of neck motion.) Because decreased head turning can interfere with central compensation, recognizing it in patients with vestibular dysfunction is important because vestibular rehabilitation is helpful.

A detailed history and physical examination should help the physician in identifying one or more causes responsible for dizziness. Apart from the history and physical examination, certain provocative tests can be done at bedside to evaluate the vestibular system.

Provocative Tests

1. To see if the vestibulo-ocular reflex (VOR), which helps to maintain visual stability during head movement, is intact, the following three tests can be done. The sensitivities, specificities and predictive values of these tests for vestibular lesions in older persons have not been established.

- a. In the head-thrust test, the patient is asked to fixate on the examiner's nose, and the head is moved rapidly by the examiner about 10° to the left or right. In a normally functioning VOR, the eyes will be fixed on the target. In patients with a vestibular deficit, the eyes are carried away from the target along with the head, followed by a corrective saccade back to the target. For example, in a patient with a right-sided vestibular lesion, head thrusts to the right will produce a slipping away of the pupils from the target, followed by a corrective movement back to the target, whereas head thrusts to the left will produce a normal response of the eyes.^{60,61}

- b. In the postheadshake test, with fixation eliminated by Frenzel lenses, the head is rotated either passively by the examiner or actively by the subject at a frequency of about 2 Hz in the horizontal plane for about 10s, and then the examiner looks for nystagmus when the head is stopped. In unilateral peripheral vestibular lesions, there

is a horizontal nystagmus with the fast phase usually beating toward the stronger ear, whereas in central lesions the nystagmus may be vertical.^{60,62}

2. Dynamic visual acuity testing is done by asking the patient to read a fixed eye chart while the examiner moves the head horizontally at a frequency of 1 to 2 Hz. A drop in acuity of two rows or more from the baseline is suggestive of an abnormal vestibulo-ocular reflex.⁶³ This test is sometimes difficult to perform because patients may be able to read at times when the head is not in motion (i.e., at turnaround points or by resisting movements).⁶⁰

These tests are more helpful in detecting unilateral than bilateral vestibular dysfunction. It is important to remember that compensatory mechanisms may mask a vestibular deficit when these maneuvers are used in patients with long-standing vestibular loss.⁶⁰ If the findings of these tests are abnormal, then the patient can be referred for more sophisticated vestibular testing, such as electronystagmography and rotational testing.

3. The Stepping Test, originally described by Unterberger⁶⁴ and later modified by Fukuda,⁶⁵ is positive when there is a lesion in the vestibulospinal system. The patient is asked to stand at the center of a circle drawn on the floor. The circle is divided into sections by lines passing at 30° angles. The patient is blindfolded and is asked to outstretch both arms at 90° to the body. The patient is then asked to flex and raise high first one knee and then the other and to continue stepping forward at a normal walking speed for a total of 50 or 100 steps. The examiner notes body sway while the patient marches in place with the eyes closed. In a unilateral vestibular lesion or in acoustic neuroma, there will be a gradual rotation of the body (more than 30°) toward the affected side.^{60,65,66}

4. The Dix–Hallpike Maneuver⁴¹ can definitively establish a diagnosis of BPPV.³⁷ The patient is seated on an examination table with the head rotated 30° to 45° to one side. The patient is asked to fix his vision on the examiner's forehead. The examiner holds the patient's head firmly in the same position and moves the patient from a seated to a supine position with the head hanging below the edge of the table and the chin pointing slightly upward. The examiner should note for the direction, latency, and duration of the nystagmus and the latency and duration of vertigo, if present. The diagnostic criteria for BPPV are (1) vertigo associated with a rotatory nystagmus; (2) a latency (typically of 1–2 s) between the completion of the maneuver and the onset of vertigo and nystagmus; (3) a paroxysmal nature of the vertigo and nystagmus (lasting for 10–20 s); and (4) fatigability (decrease in the intensity of the vertigo and nystagmus with repeated testing).³⁷

Routine Laboratory Evaluation

A small battery of laboratory tests should be performed on all patients with chronic dizziness because the prevalence of undetected abnormalities is high and because results often lead to effective treatment. Hematocrit, glucose, blood urea nitrogen, electrolytes, thyroid function tests, and vitamin B₁₂ levels should be ordered in all patients complaining of dizziness. If a cardiovascular etiology is suspected, an ECG to evaluate for the presence of cardiac arrhythmia is indicated. Holter monitoring and tilt table testing are indicated only if there is a strong suspicion of transient/intermittent cardiac arrhythmia or unexplained syncope. Audiometry, which includes pure tone assessment, speech discrimination, impedance measurement, and evoked responses, is recommended for evaluating dizzy patients with hearing loss. Gradual hearing loss is characteristic of acoustic neuroma, while Meniere's disease typically presents with fluctuating hearing loss. Also, in acoustic neuroma an audiogram reveals a sensorineural hearing loss, which is more for higher than for lower frequencies, whereas in Meniere's disease sensorineural hearing loss is more for lower frequencies.

Specialized Testing

Vestibular Function Tests

Several tests for vestibular function that might be considered in patients with a history and physical examination finding suggestive of vestibular disease include electronystagmography, rotational testing, and computerized posturography.

Electronystagmography is the most established and widely used test. Eye movements are recorded with electrodes that record changes in scalp potential produced by the corneal–retinal potential. The procedure consists of a battery of tests designed to record eye movements in response to visual and vestibular stimuli, including oculomotor evaluation, positional testing, and caloric testing.⁶⁷ The oculomotor evaluation involves saccade testing, pursuit testing, optokinetic nystagmus, and spontaneous and gaze-evoked nystagmus. The positional testing is designed to detect nystagmus evoked when the head is held in different positions. The *caloric testing* assesses the symmetry of vestibular functions. This test can indicate the side of involvement in unilateral vestibular lesions. Each ear is stimulated first with warm (44°C) and then cool water (30°C), each instilled over 30 s. The temperature change stimulates or suppresses the respective horizontal semicircular canals, resulting in nystagmus.⁶⁸ A decreased response will occur on the ipsilateral side in peripheral vestibular disorder. Patients

with suspected bilateral vestibular loss should undergo rotational chair testing to confirm the finding.⁶⁷ Aging minimally affects responses to the caloric test.⁶⁹

The *rotational chair test* uses a series of well-controlled rotational stimuli to provoke nystagmus. The patient is seated on a chair in a dark, soundproof room. The patient is asked to fixate on an imaginary visual target while the chair is oscillated at different frequencies and the eye movements are recorded. This test reflects the function of the vestibulo-ocular system. Findings can reveal the degree of peripheral or central vestibular dysfunction; serial measurements can be used to detect improvement or worsening of the dysfunction. The effects of aging on the rotational chair test are not well documented because inconclusive results have been produced by too few studies that lack standardization.⁶⁹

Computerized posturography provides information related to functional ability of the patient to maintain balance. It quantifies the functions of the vestibulospinal system. The patient stands on a platform that is embedded with four sensors to monitor sway. This test has two components, a sensory organization test (SOT) and a motor control test (MCT). The SOT measures the ability of the patient to maintain her balance when visual and somatosensory inputs are systematically disrupted, whereas in the MCT the patient experiences abrupt changes in the center of gravity produced by horizontal movements and rotations of the platform.⁶⁷ Rather than providing localizing information, this test provides information regarding which types of stimuli (visual, vestibular, and proprioceptive) the patient can or cannot use to maintain balance.⁶⁷ This test is useful in providing additional information when peripheral vestibular pathology is suggested by the vestibular function test, but the results are inconclusive.⁷⁰ Effects of aging on posturography have been documented and consist of an inability to perform well with reduced visual or somatosensory information and a general reliance on a hip strategy to maintain balance.⁷¹

Neuroimaging

Not all patients with dizziness need neuroimaging. Magnetic resonance imaging scans should be done if the history or physical examination is suggestive of a stroke or cerebellopontine angle tumor.

Treatment

Treatment is ideally directed toward a specific cause. However, investigators have acknowledged the limitations of a diagnosis-oriented approach for the evaluation and management of chronic dizziness.^{18,72} Also, the presentation sometimes does not permit identification of a

specific cause. Therefore, if the history, examination, and routine laboratory testing do not suggest a discrete cause, therapeutic trials are often the best way to determine significant contributors. Older persons often have multiple comorbid diseases and impairments that contribute to dizziness. The most effective treatment, therefore, may be to ameliorate one or more potential etiologic factors.⁷³

Medical Therapy

Medical therapy for individual diseases is discussed in Table 67.1. Patients should be treated for anxiety or depression. If there is impairment of vision or hearing, it should be corrected. Medication-associated dizziness responds to dosage adjustment or to medication withdrawal. One should try to reduce all drugs to the lowest possible dosages.

Vestibular suppressants, including antihistamines (e.g., meclizine) and anticholinergic agents (scopolamine), are commonly used for symptomatic relief. These agents are effective for acute dizziness but play little role in managing chronic dizziness. Meclizine is a weak antihistaminic agent usually taken orally in doses of 12.5 to 25 mg three times a day, as needed. Vestibular suppressants should not be used long term because of their CNS side effects and because they suppress central and vestibular adaptation and thus may worsen or exacerbate dizziness.⁷⁴ Benzodiazepines (e.g., diazepam) may be beneficial to patients with severe unilateral peripheral vestibular dysfunction. Scopolamine should not be used in older persons due to its anticholinergic side effects such as urinary retention and deficits in cognition.

Rehabilitation

Vestibular rehabilitation therapy is an important and effective management strategy for patients with peripheral and central vestibular causes of dizziness. Studies have shown a reduction in symptoms and disability following rehabilitation therapy.⁷⁵⁻⁷⁸ Vestibular rehabilitation includes combinations of exercises involving head and eye movements (while sitting and standing) designed to provoke vertigo and unsteadiness. It also involves various dynamic balance exercises and exercises to improve gait stability during head movement, visual and vestibular interactions, and vestibular spinal responses. The movements are repeated until they can no longer be tolerated, and the number of repetitions are gradually increased over a period of 6 to 8 weeks.⁷⁹ Initially, the exercises may worsen the dizziness, but over time (weeks to months) movement-related dizziness improves, likely because of central adaptation. Generally, a good functional recovery can be achieved by patients with peripheral vestibular disorders, but rarely does complete recovery occur in patients with central vestibular

dysfunction, although they can experience considerable functional improvement.⁸⁰ Vestibular rehabilitation can be administered in a classroom setting or one-to-one with a physical therapist. Also, patients can perform exercises independently at home after being instructed by a physical therapist. This therapy also has been shown to alleviate dizziness in patients who have anxiety, probably by educating them about their dizziness and by encouraging them to cope actively with their problem.⁸¹

The *canalith repositioning procedure*, introduced by Epley,⁸² is a currently recommended treatment for benign positional vertigo.³⁷ The purpose of this bedside maneuver is to move free-floating debris by the effects of gravity from the posterior semicircular canal into the utricle of the vestibular labyrinth, where it will no longer affect the dynamics of the semicircular canals.⁸² In this procedure, a Dix–Hallpike maneuver is performed with the patient's head rotated 45° toward the affected ear and hanging below the edge of the table, and a vibrator is applied to the ipsilateral mastoid process. After the cessation of the provoked vertigo and nystagmus, the head, which is hanging below the edge of the table, is rotated 45° to the opposite side. This maneuver may induce a brief episode of vertigo. The examiner should hold the head in this position and wait for about 10 to 15 s or until the vertigo ceases. Then the head and body are further rotated until the head is in a facedown position. This maneuver may again induce a brief vertigo. The patient should be kept in the final facedown position for about 10 to 15 s or until the vertigo ceases.

Then, with the head kept in the same position, the patient is brought to a seated position. Once the patient is upright, the head is turned forward with the chin tilted slightly downward. The patient should be instructed not to lie flat and to keep the head relatively upright for the next 24 to 48 h. Another option would be to instruct the patient to wear a cervical collar and neither to lie supine nor to tilt the head upward, downward, or to the right or left more than 30°. ⁸³ These strategies are to prevent the loose debris from gravitating back to the posterior semicircular canal. There are no data available to support these recommendations. Investigators have tried gentle manual vibration of the head instead of using a vibrator during the treatment and have found it effective; 60% of the patients reported improvement with this procedure without using a vibrator and 92% reported improvement with the use of the vibrator.⁸³

In patients who cannot keep their head in a relatively upright position for 1 to 2 days, a different maneuver described by Brandt and Daroff⁸⁴ can be used.⁸⁵ The patient is asked to sit on a table sideways with eyes closed and to rotate the head horizontally about 45°. Then the patient should rapidly lie on their side in the opposite direction and should wait in the same position until the vertigo has resolved or for 30 s. The patient should then

sit up rapidly and wait for another 30 s. The movement is then repeated in the opposite direction.⁸⁵ This maneuver can be repeated every 3 h while awake and can be terminated if the patient is symptom free for 2 consecutive days.⁸⁴ The patient can perform these exercises at home. It usually takes 1 to 2 weeks for the symptoms to be resolved. These exercises likely work either by habituation or by dislodging debris from the posterior semicircular canals.⁸⁵

Physiotherapy in the form of cervical exercises and relaxation techniques has been found to be effective for patients with cervical dizziness.⁸⁶ Progressive, competency-based balance exercises have proved effective in enhancing a sense of stability and may be useful for patients with dizziness related to sensory or motor deficits.

Surgery

Surgical therapy is needed in a small group of dizzy patients. Surgical excision is the treatment of choice for cerebellopontine angle tumors. Surgery is reserved for disabling unilateral peripheral disease unresponsive to medical therapy. Surgical procedures can be ablative or nonablative. Ablative procedures include transmastoid labyrinthectomy and partial vestibular neurectomy. The primary indication for either procedure is uncontrolled Meniere's disease or peripheral vestibulopathy.⁸⁷ Nonablative procedures include endolymphatic sac decompression and posterior canal occlusion. Endolymphatic sac decompression is confined to cases of Meniere's disease but its role is controversial.^{87,88} Surgery is indicated for only those disabled patients of BPPV who are refractory to the canalith repositioning procedure despite multiple attempts. The two procedures used to disable the posterior semicircular canal include singular neurectomy or occlusion of the posterior semicircular canal.^{87,89,90}

Patient Education

Patients should be given basic education concerning the functioning of the balance system and the pathophysiology of dizziness. This knowledge enables patients to understand the body movements responsible for these symptoms and also alleviates their anxiety about this problem.⁸¹ They should be instructed on modifying their activities; for example, if orthostatic hypotension is detected, patients should be instructed to rise slowly from sitting or supine positions. Movements such as looking up, reaching up, or bending down are to be avoided, in part by storing items at home strategically. However, patients should be cautioned not to habitually avoid other movements such as head turning because doing so may compromise central adaptation, thereby exacerbating dizziness. Patients should be instructed to avoid

walking in the dark. They should be reminded to avoid over-the-counter drugs that may exacerbate dizziness.

Nutrition

David A. Lipschitz

Human aging may be defined as a complex interaction between an individual and the environment over time. In relation to external variables that affect aging, perhaps none is more important than nutrition. Evidence obtained from animal studies has shown that life expectancy can be significantly extended by restricting food intake. Nutritional factors have been shown to contribute substantively to many diseases that occur in late life. With advancing age, the risk of developing serious nutritional deficiencies also increases because of age-related reductions in total food intakes combined with the presence of debilitating disease. The presence of malnutrition increases functional dependency, morbidity, mortality, and use of health care resources. This chapter discusses the relevance of these findings and describes rational approaches to the diagnosis and management of nutritional problems in the elderly.

The Role of Caloric Restriction in Aging

Many animal studies have shown that nutritional deprivation delays maturation and significantly prolongs life expectancy.¹ These investigations have shown that caloric restriction causes delays in virtually every biomarker of aging. Classic studies have shown delays in the appearance of the well-described age-related declines in cell-mediated and humoral immunity. This effect has been suggested as the mechanism by which dietary restriction results in the later appearance of neoplasms. Food restriction also leads to a marked reduction in the generation of free radicals postulated to result in many declines in cellular function that occur with age. The mechanism by which food restriction results in prolongation of life span is still not clear. It appears that total calorie intake is a more important variable than are either total protein or fat intakes. Caloric restriction results in the presence of leaner and more active animals who utilize energy very efficiently. Overall meta-

bolic requirements are markedly reduced. This lifelong diminution in metabolic activity has recently been suggested as an important factor in prolonging life.

The importance of these observations in relation to humans remains unclear. Affluent societies who frequently consume high-caloric, high-fat diets usually demonstrate the longest life expectancy. It must be emphasized, however, that the shorter life span noted in the less affluent can be ascribed to pathologic malnutrition, diminished sanitation, and the increased prevalence of communicable diseases. In industrialized societies, high-fat, high-calorie diets are associated with high prevalence rates of age-related diseases, such as atherosclerosis, hypertension, and colon and breast cancer. For these reasons, recent dietary recommendations have focused on the need for a prudent diet that not only restricts total and saturated dietary fats but also avoids excessive calorie intake. These recommendations may be important in the minimization of the role of nutrition in the common cancers that occur in the Western world.

Energy Requirements

Aging results in a significant decrease in energy needs.² The major mechanism is a decrease in resting energy expenditure as a consequence of declines in muscle mass. Reduced thyroid function does not appear to contribute to the reduced energy needs of the elderly. Diminished energy needs also result from age-related declines in physical activity, which has been demonstrated longitudinally in men and confirmed in women. Decreased activity is the result primarily of coexisting diseases, such as bone and joint disorders, loss of postural stability, and chronic diseases that may limit activity, such as angina pectoris and intermittent claudication. However, reduced strength as a consequence of declines in muscle mass does contribute to reductions in mobility.

Total caloric (food) intake is determined primarily by energy needs. Thus, a 30% reduction in energy need will

be accompanied by a 30% reduction of food intake. This reduced caloric intake has been confirmed in both cross-sectional and longitudinal studies. As compared with younger subjects, individuals over the age of 70 consume a third fewer calories. The importance of this effect relates to the fact that the average intake of all nutrients is reduced in parallel. Yet the requirements for virtually every other nutrient, with the exception of carbohydrates, do not decline significantly with age (see following). As a consequence, epidemiologic studies of dietary intakes of healthy elderly individuals reveal deficient intakes. In contrast, biochemical assessments of nutritional status indicate that significant deficiencies of both macro- and micronutrients (vitamins and minerals) are quite rare in ambulatory healthy elderly. This is explained by the fact that inadequate dietary intake of a nutrient is determined by the comparison of the actual intake with the recommended dietary allowance (RDA) for that nutrient. The RDA is generally much higher than an intake that would result in a nutritional deficiency. Nevertheless, decreased intake results in reduced reserve capacity. In the presence of disease with increased nutritional requirements or because of declining intake caused by anorexia, severe nutritional deficiencies are very common in hospitalized or institutionalized elderly individuals with acute or chronic diseases.

Protein Requirements

On first principles it seems likely that, because of declines in muscle mass, aging should result in decreased protein needs. At the current time, the RDA for protein for younger subjects is 0.8 g/kg body weight. Studies in the elderly have shown that, even in healthy elderly subjects, the requirements for protein are modestly increased.³ At the current time a protein intake of 1 g/kg body weight is recommended in healthy elderly. Most importantly, the presence of acute or chronic diseases further increases protein requirements. In this circumstance, protein intake in the older patient is frequently grossly inadequate. This is particularly important in wound healing and in decubitus ulcer, where inadequate protein intake adversely affects outcome.

Although aging results in significant declines in muscle mass, protein synthetic and degradation rates are only minimally compromised. Visceral protein stores and turnover are generally unchanged with aging so that no significant reductions are noted in serum albumin, retinol binding protein, or prealbumin, which reflect visceral protein stores.

Fat Requirements

Aging does not alter any of the specific requirements for any of the essential lipids. Advancing age is generally

associated with an increase in the proportion of body weight as fat, which is the result of decreases in muscle mass accompanied by an increase in fat mass. Body fat stores increase until the seventh decade, after which reductions in total weight and fat stores are frequently noted. Although obesity is not as common a problem in the elderly as it is in younger individuals, approximately 20% of subjects over the age of 65 are significantly overweight. Studies have shown that even in the very old obesity is associated with increased mortality. Furthermore, there is evidence that the risks of atherosclerotic heart disease and stroke in the elderly can be reduced by consuming a diet low in saturated fats and cholesterol. These facts make dietary recommendations in the elderly difficult. For older individuals, a palatable acceptable diet is very important. Recommending drastic changes in dietary intake should therefore be undertaken with caution and with careful clinical judgment. For individuals in their late sixties and early seventies who are very healthy and ambulatory but significantly overweight, hypercholesterolemic, and perhaps hypertensive, an effort to reduce calories, fat, and sodium intake is warranted. In many circumstances, drastic reductions in diet may not be beneficial; this particularly applies to institutionalized elderly where medically prescribed diets are frequently not palatable, are not adequately consumed, and may result in weight loss. It must be noted that the value of serum or high-density lipoprotein (HDL) cholesterol in the prediction of coronary artery disease is less for the elderly than it is for younger subjects.³ For this reason, the efficacy of aggressive dietary or pharmacologic attempts to lower cholesterol in subjects over the age of 70 is far from clear.

Water Requirements

In the elderly, fluid balance is extremely important because of the propensity of the elderly to develop dehydration and the ease at which overhydration can occur in elderly individuals with compromised renal function or other disorders associated with fluid retention. As a general rule, water intake should be 1 mL/kcal or 30 mL/kg body weight. Dehydration is extremely prevalent in hospitalized elderly and is the single most common cause of an acute confusional state in the elderly; this is primarily related to the well-described age-related decline in thirst drive. Studies have demonstrated a decreased ability of the elderly to respond to fluid deprivation, which becomes a particularly serious problem in frail elderly who develop a minor pathologic insult, such as a respiratory or urinary tract infection, resulting in fever, increased metabolism, and fluid loss. If fluid intake does not readily replace fluid lost, dehydration rapidly develops. This leads to confusion, worsening dehydration, and the rapid development of a serious disease that may

be life threatening, warrant hospitalization, and necessitate a prolonged period of recuperation.

For these, aggressive attempts at assuring adequate hydration are essential in the elderly. Furthermore, this must commence soon after the development of a minor or major pathologic stress. Patients and their families must be educated to emphasize the importance of maintaining adequate fluid intake at all times and to carefully monitor intake if a minor illness develops or if fluid requirements are increased, as occurs during heat waves. In the hospitalized older patient, the possibility that confusion or delirium is caused by dehydration should be high on the differential diagnosis list. Physicians must assure that their patients have adequate access to water. Furthermore, total fluid intake should be carefully monitored by frequent weight and intake and output measurements.

Mineral Requirements

Numerous studies indicate that, for a wide variety of minerals and vitamins, intake is significantly lower than the RDA for a large proportion of ambulatory elderly.⁴

Calcium

Of most importance is the evidence that lifelong inadequate intakes of calcium contribute to the high prevalence of osteoporosis in the elderly. It is generally recommended that calcium intake in the elderly be between 1.0 and 1.5 g/day.

Zinc

The prevalence of zinc deficiency is important because of the role that this mineral plays in food intake and in wound healing. In elderly subjects with chronic debilitating diseases, modest zinc deficiency may contribute to anorexia. Although not clinically proven, there is also evidence that zinc supplementation aids in wound healing in general and in the healing of pressure ulcers in particular.⁵ Zinc supplementation has also been shown to improve immune function and impede the rate of development of macular degeneration in the elderly.

Iron

In younger patients, iron deficiency is the most common cause of anemia and the most common global deficiency leading to widespread morbidity and decreased work performance. Aging is associated with a gradual increase in iron stores in both men and women. As a consequence, iron deficiency is rare in the elderly and invariably is caused by pathologic blood loss. It is important to emphasize that the anemia of chronic disease, which is associated with iron-deficient erythropoiesis, including a low serum iron concentration and a reduced transferrin sat-

uration, is frequently misdiagnosed as iron-deficiency anemia in the elderly. This error results in the inappropriate administration of oral iron therapy and unnecessary invasive investigative procedures to identify the source of iron loss. The anemia of chronic disease is associated with an impaired ability of the reticuloendothelial system to recirculate iron obtained from the breakdown of phagocytosed senescent red cells. Thus, in the anemia of chronic disease, iron stores are normal or increased, whereas in iron deficiency iron stores are absent.

Recent studies indicate a correlation between increased iron stores and risks of neoplasia and coronary artery disease. Because aging is associated with increasing iron stores, supplementation with oral iron may not be desirable in older persons. Consuming a multivitamin with minerals containing the RDA for iron, combined with adequate intake from the diet, may result in inappropriately high intakes. If current evidence confirms adverse effects of iron stores, the use of iron-containing supplements in the elderly may well be unwise.

Selenium

There is suggestive evidence that selenium deficiency may contribute to age-related declines in cellular function. The mineral may be involved in minimizing free radical accumulation, as it is essential for the normal function of glutathione peroxidase. Significant selenium deficiency has been reported frequently in the elderly, although syndromes associated with selenium deficiency are very rare (cardiomyopathy, nail abnormalities, and myopathies). There is some evidence that selenium deficiency may contribute to a greater neoplastic risk and declines in immune function.

Copper

Aging generally is associated with increases in serum copper concentrations, although the significance of this increase is unknown. Copper deficiency is very rare and has been reported only in total parenteral nutrition.

Chromium

Recent evidence has suggested an important role for chromium in carbohydrate metabolism. Studies have shown age-related declines in tissue chromium levels. It is possible that chromium deficiency may contribute to glucose intolerance in the elderly, although the therapeutic efficacy of chromium replacement is controversial.

Vitamin Requirements

Studies have shown that dietary intake of many vitamins is inadequate in the elderly, including an intake of 50% or less for folic acid, thiamine, vitamin D, and vitamin E. In other studies intakes were shown to be less than 66%

of the RDA for most vitamins. It must be emphasized again that deficiencies identified on the basis of inadequate intake are invariably significantly higher than the prevalence of biochemical deficiency of most vitamins.

Water-Soluble Vitamins

Vitamin C

Studies have indicated inadequate dietary intake of vitamin C in the elderly. Others have shown a high prevalence of vitamin C supplementation in the elderly. There is no evidence, however, that vitamin C deficiency is of any clinical relevance in healthy elderly or that replacement with megadoses of vitamin C is of any clinical value. In elderly subjects with chronic debilitating diseases, there is some evidence that vitamin C supplementation improves the rate of wound and pressure ulcer healing. There is little evidence that megadoses of vitamin C have any relevant side effects, although falsely negative occult bloods have been reported, as have inaccuracies in serum and urine glucose determinations.

Thiamine

Clinically relevant deficiencies of the B vitamins are very rare in the elderly. Thiamine deficiency, however, is common in elderly alcoholics and can be an important contributing factor in the development of disordered cognition, neuropathies, and perhaps cardiomyopathies. Relevant deficiencies of this vitamin are relatively common in institutionalized elderly.

Folate Acid

Like thiamine, folate deficiency in the elderly is predominantly found in alcoholics. It is also common in elderly subjects who are taking drugs that interfere with folate metabolism (trimethoprim, methotrexate, and Dilantin) or in disorders associated with increased folate needs (hemolytic anemia and ineffective erythropoiesis). Folate deficiency may result in cognitive loss or significant depression and should always be evaluated in the workup of elderly subjects with a memory disorder.

Vitamin B₁₂

Low serum vitamin B₁₂ concentrations have been shown to occur in as many as 10% of otherwise healthy elderly subjects. Many comprehensive workups indicate early pernicious anemia, the commonest cause of vitamin B₁₂ deficiency, whereas in others no obvious cause can be identified. B₁₂ deficiency classically causes a severe megaloblastic anemia. Not uncommonly, the nonhematologic manifestations of B₁₂ deficiency can occur in the absence of anemia; these include gait disorders, sensory and motor neurologic deficits, and highly significant memory loss. This vitamin should be measured routinely in the

workup of any elderly patient with disordered cognition or depression, and replacement therapy should be given to any patients in whom low serum levels are found. The lower limit of normal varies in different laboratories, but a value below 150 pg/mL is highly suspect and should always result in the commencement of replacement therapy.

Fat-Soluble Vitamins

Recent evidence has suggested that vitamin A is one of the only nutrients in which requirements decrease with advancing age. Studies have shown that aging is associated with an increase in absorption of vitamin A from the gastrointestinal tract, accompanied by a reduction of hepatic uptake. These effects make the elderly susceptible to toxicity if excessive amounts of the vitamin are consumed as a supplement. Side effects of daily intakes in excess of 50,000 IU include headaches, lassitude, reduction in white cell counts, impaired hepatic function, and bone pain. The vitamin plays an important role in visual acuity. However, there is no evidence that vitamin A supplements improve age-related declines in eyesight. Vitamin A and its precursor beta-carotene have been suggested as exerting a protective effect against an array of neoplasms. Recent large-scale controlled trials have, however, failed to definitively prove a beneficial effect of beta-carotene in the development of skin cancers.

Vitamin D

Recent studies suggest that vitamin D deficiency may be a serious concern in the elderly. In addition to the vitamin's known role in bone metabolism, it also affects macrophage function in general and pulmonary macrophages in particular. Vitamin D deficiency increases susceptibility to the development of pulmonary tuberculosis by compromising macrophage function. This has been suggested as contributing to the high prevalence of tuberculosis in nursing home patients in whom deficiencies are common and aggravated by diminished exposure to sunlight. In any patient with severe osteoporosis, fracture, or bone pain, vitamin D-induced osteomalacia must be excluded.

Vitamin E

Vitamin E (alpha-tocopherol) is abundant in the diet and deficiencies of the vitamin virtually never occur. It is involved in the function of the enzyme glutathione peroxidase, which is involved in free radical generation. The vitamin also affects the biophysical properties of the cell membrane, reducing the age-related increase in membrane microviscosity. It also influences immune function, and recent evidence indicates that administration of the vitamin enhances immune function in the elderly and may minimize infectious risk. Despite these effects, which

may be of benefit in improving age-related declines in cellular function, no good evidence exists indicating a beneficial effect of vitamin E supplementation in subjects of any age.

Vitamin K

Vitamin K is essential for the production of a number of factors involved in both the intrinsic and extrinsic clotting cascade. There is evidence that vitamin K administration is beneficial in elderly people who have an unexplained prolongation of their prothrombin time. Although dietary intake is adequate, deficiencies can result from the administration of drugs that interfere with the vitamin's absorption or interfere with bacterial flora.

A Practical Approach to Nutritional Assessment

General Considerations on History and Physical Examination

A high index of suspicion of nutritional problems is very important in patients who have a primary diagnosis associated with malnutrition, such as chronic alcoholism, disorders of cognition, chronic myocardial, renal, or pulmonary insufficiency, malabsorption syndromes, and multiple medication use.⁶ In addition, particular attention should focus in the history on evidence of anorexia, early satiety, nausea, change in bowel habits, fatigue, apathy, or memory loss. Physical findings that may also provide clues to the presence of nutritional deficits include poor dentition, cheilosis, angular stomatitis, and glossitis, which is common in a number of vitamin deficiencies. Pressure ulcers or poorly healing wounds, edema, dehydration, and poor dental status are common physical findings in severely malnourished patients.

Clinically, a number of important questions must be addressed in the nutritional assessment. Increased risk of malnutrition can usually be identified from the history and physical examination. Commonly recognized risk factors are listed in Table 68.1. Generally, factors leading to malnutrition can be categorized into disorders resulting in anorexia, inadequate or inappropriate nutrient intake, and social or economic isolation.

Has the Patient Lost Weight?

Weight loss is perhaps the most important finding indicating the presence of malnutrition. Recent studies have clearly indicated that this finding in patients with serious disease is a very poor prognostic sign and is associated with increased morbidity and mortality.⁷ To be significant, weight loss must be involuntary. It has often been said

TABLE 68.1. Causes of weight loss in the elderly.

Anorexia

Inability to purchase or cook food
Decreased activity
No cause identified

that to be significant, weight loss must have exceeded 10% or more of body weight in 6 months, 7.5% or more in 3 months, or 5% or more in 1 month. In older persons, any weight loss that clearly cannot be ascribed to alterations in fluid balance (common in older persons receiving diuretic therapy) should be taken seriously. It must be emphasized that significant malnutrition can be present in individuals who are not underweight. Any significant weight loss that is involuntary indicates that nutritional intake is inadequate and that the patient's needs are not being met.

Is the Patient Underweight?

To determine if the patient is underweight or has lost weight requires an evaluation of body composition.⁸ In

this regard, virtually every anthropometric measure of body composition employs height as the reference point. In both males and females, height decreases by approximately 1 cm per decade after the age of 20. This is caused by vertebral bony loss, increased laxity of vertebral supportive ligaments, reductions in disk spaces, and alterations in posture. Historical estimations of height are also frequently inaccurate in the elderly, and its measurement is difficult in bedridden patients or in those with significant postural abnormalities. For this reason, it has been suggested that alternatives to height should be used in the development of standards for body composition for the elderly. Options suggested include arm length and knee-height measurements.

In general, a gradual increase in weight occurs with advancing age, peaking in the early forties in males and a decade later in females. After age 70, reductions in weight are not uncommon. Lean body mass decreases by approximately 6.0% per decade after the age of 25. By the age of 70, lean body mass has decreased an average of 5 kg for females and 12 kg for males. Thus, in the elderly, fat constitutes a far greater percentage of total weight than it does in subjects of younger ages. Fat distribution also alters with aging. Truncal and intrabdominal fat content increase while limb fat diminishes. Skinfold measurements are often employed to estimate fat and muscle stores. Although the triceps skinfold thickness is the most frequently obtained, multiple skin folds are much more reliable than single measurements. In the elderly, subscapular and suprailiac skinfolds are the best predictors of fat stores in males, while the triceps skinfold and thigh measurements are of greater value in females. Total body water is also decreased in parallel to declines in lean body mass. Evaluating ideal body weight for height can be employed to determine if a patient is underweight. Tables are available for older persons that provide a guide to their ideal body weight. These are based upon an assessment of height, weight, and body frame. On the basis of these tables, being significantly underweight is defined as being 15% below the ideal weight for that individual patient. Unfortunately, current tables are based upon relatively small samples and often are not representative of the individual being evaluated.

A more accurate assessment is the determination of the body mass index (BMI), which is the ratio of weight to height squared. This obviates the need to create gender tables, although the confounding effect of age remains to be determined and the problems with assessing height persist. A standard nomogram is available from which BMI can be calculated from height and weight. It is generally recommended that persons over the age of 65 have a BMI between 24 and 29. As a general rule, a BMI below 22 is a cause for concern and indicates that the patient is significantly underweight, while a value above 29 indicates obesity.

Does the Patient Have Protein-Energy Malnutrition?

This condition is best described as a metabolic response to stress that is associated with increased requirement for energy and protein. The pathophysiologic events leading to this disorder are illustrated in Figure 68.1. The metabolic response to a stress such as injury or infection is characterized by hormonal changes and the release of cytokines that lead to the development of anorexia, despite the presence of increased nutrient needs. In older persons, the negative sequelae of this response can develop quickly. Protein-energy malnutrition (PEM) is associated with marked depletion of visceral protein stores characterized by the presence of hypoalbuminemia. Inadequate supply of protein leads to liver dysfunction, which contributes to the low serum albumin. Decreased clearance of drugs and toxins also occurs, increasing the risk of toxicities and adverse drug reactions. Inadequate supply of protein primarily affects organ systems with the highest turnover of cells, which are the skin, immunohematopoietic system, and gastrointestinal tract. Thus, PEM is characterized by a dry skin and "flaky paint" dermatitis. Impaired immune responses lead to compromised host defenses, increasing the risk of life-threatening infections. Malabsorption also develops as a result of impaired jejunal and ileal mucosal cell proliferation, creating a vicious cycle of malnutrition causing malabsorption and worsening malnutrition. As a result of disease and deficiencies of taste-related nutrients, anorexia is usually present. The disorder is also referred to as hypoalbuminemia malnutrition and is usually diagnosed by the presence of a serum albumin level of less than 3.0 g/dL.

In the elderly, relatively minor stress of short duration can result in PEM. Thus, PEM is common in elderly patients who develop minor pulmonary and urinary infections and is often found soon after an elective surgical procedure. The problem of PEM in the elderly is compounded by the ease at which these patients develop severe dehydration as a consequence of an age-related decline in thirst drive.⁹ This leads to the development of confusion, hypotension, and a vicious cycle in which the patient's overall condition can deteriorate very rapidly. Furthermore, in contrast to younger people, the positive benefits of this disorder in the elderly are limited to a very short period. If nutritional needs are not met within 2 to 3 days of the onset of the acute illness, the declines in immune, hepatic, and gastrointestinal function appear to contribute significantly to increased morbidity, mortality, and prolonged hospital stays.

In the nursing home, PEM should be suspected in any patient who develops an acute medical problem. It is also frequently seen in patients with chronic infections and in those with decubitus ulcers. Any patient presenting with

FIGURE 68.1. Pathophysiology of protein-energy malnutrition. ADH, antidiuretic hormone; ESR, erythrocyte sedimentation rate.

confusion, lassitude, anorexia, decreased activity, or greater functional dependence may have developed an acute medical problem such as an infection, which, if not treated, will result in the development of significant PEM.

Does the Patient Have Isolated Nutrient Deficiencies?

These are quite rare in older persons but should be considered in special circumstances. Zinc deficiency has been reported to be increased in patients with pressure ulcers and may contribute to decreased rates of healing. For this reason, zinc supplementation is frequently prescribed in patients with pressure ulcers. Vitamin D deficiency is relatively common in homebound and institutionalized older persons and may contribute to declines in host defense mechanisms in the elderly. Frank osteomalacia has also been reported. Folate deficiency is limited to patients with malabsorption and to older alcoholics (not uncommon). Vitamin B₁₂ deficiency has been reported to be frequent in older persons. Its level should be measured in any patient being evaluated for memory loss. Low levels warrant replacement. Whether this affects memory is not clear.

Significance of Malnutrition in Older Persons

There is compelling evidence indicating that malnutrition is highly significant in older persons. Being underweight or losing weight is associated with increased morbidity and mortality in older persons. There is even suggestive

evidence that voluntary weight loss may be associated with an increased adverse outcome in older persons. In the acute care hospital setting, the presence of protein-energy malnutrition has been shown to be an independent predictor of increased morbidity and mortality in older persons. This information is important, as studies have shown that the nutritional status of hospitalized patients is often ignored and that nutritional therapy is inadequate with a high complication rate.

Management of Nutritional Problems in Older Persons

Weight Loss and Being Underweight

As indicated, a major predictor of increased morbidity and mortality makes being underweight or losing a significant amount of weight highly relevant clinically. While no study has shown that correcting the decline in weight improves survival in this patient population, it is obvious that every attempt must be made to identify and treat the cause.

The initial approach to management should be a careful attempt to identify the cause of the weight loss and, if found, to aggressively attempt correction. Table 68.1 lists the common causes of weight loss in older persons, highlighting potentially correctable causes. Figure 68.2 lists an approach to treatment of weight loss

FIGURE 68.2. A rational approach to the treatment of weight loss in the elderly.

in the elderly. Identifying a potentially treatable cause such as drug use (digoxin, fluoxetine), thyrotoxicosis, and depression can usually result in weight gain if the underlying condition is corrected with appropriate medical interventions. Other conditions that may well contribute to weight loss that are potentially improvable include social or economic isolation, difficulties with cooking or feeding as a consequence of physical disability, dental or swallowing problems, and not providing palatable or preferred foods. Failure to identify a cause for weight loss is generally accompanied by a poor prognosis despite aggressive medical and nutritional interventions.

Older persons who have experienced weight loss are consuming inadequate calories to meet their needs. Thus nutritionally the aim must be to increase caloric intake. This can be achieved by assuring the use of palatable meals, often recommending diets high in both protein and fats. All too frequently the underweight older person may, for apparent health reasons, be consuming a low-fat, low-protein diet that may well contribute to or minimize the chances of weight gain. In these patients, risks of hypercholesterolemia are small compared with those from losing weight. For this reason, in underweight older persons we often recommend high-fat diets, including red meats, pork, full cream milk, and ice cream, all of which are dense in both calories and proteins. Frequent small meals should be recommended, using nutritional supplements that are calorie dense and high in protein as meal

replacements or late night snacks. Providing supplements with meals is not recommended, as total caloric intake will not be improved. The importance of a comprehensive rehabilitation program cannot be overemphasized. Recent evidence has shown that increased caloric intake can only be achieved when nutritional supplementation is accompanied by an aggressive and proactive program of exercise and physical therapy (Fig. 68.3).¹⁰ Patients who fail to respond to treatment of their underlying medical condition and fail to gain weight despite nutritional and physical rehabilitation carry a very poor prognosis.

Management of Nutritional Problems in the Acute Care Setting

Protein Energy Malnutrition

Figure 68.4 summarizes a rational approach to the management of nutritional problems in the acute care setting. Once a diagnosis of PEM has been made, clinical judgment is extremely important in deciding the appropriate time to commence nutritional support. In the acutely ill patient, attention should first be directed at correcting the major medical abnormalities. Thus, management of infections, control of blood pressure, and the restoration of metabolic, electrolyte, and fluid homeostasis must assume

priority. During this period, fluid and nutrient intake should be recorded so that an assessment of future needs can be made. Once the acute process has stabilized, daily calorie counts should be performed and the patients should be encouraged by the staff to voluntarily consume as much of their food as possible. If fluid overload is not a major concern, the use of polymeric dietary supplements between meals and in the late evening should be considered. The aim is to obtain a caloric intake of approximately 35 kcal/kg, based upon an ideal rather than the actual body weight.

It is our experience that by encouragement alone only 10% of elderly subjects with PEM can consume sufficient food voluntarily to correct their nutritional deficiency. Thus, most subjects require a more aggressive form of nutritional intervention. As a general rule, more aggressive attempts to assure adequate nutrient intake must commence within 48 h of admission. The approach taken depends upon the clinical presentation of the patient and whether or not short-term or more long-term nutritional support is required. For those patients requiring short-term support (fewer than 10 days), peripheral hyperalimentation is the method of choice. Using this approach it is possible, through a peripheral vein, to provide adequate calories and protein to meet the patient's needs using amino acid solutions, 10% dextrose, and intralipid.

Nasogastric feeding should be avoided in any confused older patient because of the risk of aspiration and the need for restraints to prevent the patient from pulling out the uncomfortable and irritating tubes. For those who are

not confused and who have a normal gastrointestinal tract, enteral hyperalimentation through a small-bore nasogastric polyethylene catheter should be considered. These tubes are nonirritating and do not interfere with patient mobility or the ability to swallow food. It is extremely important that after the tube is passed, placement in the stomach be confirmed before commencing nutritional feedings. For patients likely to require nutritional support for periods of 6 weeks or longer, a feeding gastrostomy or jejunostomy is recommended. For both nasogastric feeding gastrostomies, infusions should begin with an undiluted, commercially available polymeric dietary supplement at a continuous rate of 25 mL/h. The supplement should contain no more than 1 kcal/mL, as caloric-dense fluids are too viscous to pass through the tube with ease. The rate can gradually be increased so that after 48 h the total daily protein and calorie requirements of the patient are met by this route.

Enteral hyperalimentation has major side effects of which the attending physician must be aware. One of the most commonly encountered side effects is excessive fluid retention. When nutritional support begins, weight gain is invariably noted within the first 2 to 3 days. This almost certainly reflects fluid retention, as the weight gain is associated with significant reductions in the serum albumin and hemoglobin levels. The average increase in weight during this time in our patients is 1.3 kg, while the level of the serum albumin falls from a mean of 2.8 g/dL in patients before nutritional support to a value of 2.3 g/dL at day 3. Occasionally, and particularly in elderly

FIGURE 68.3. Effect of nutritional supplementation with and without exercise on daily increase in energy (food) intake in underweight older persons. (Adapted from Fiatarone et al., with permission.¹⁰)

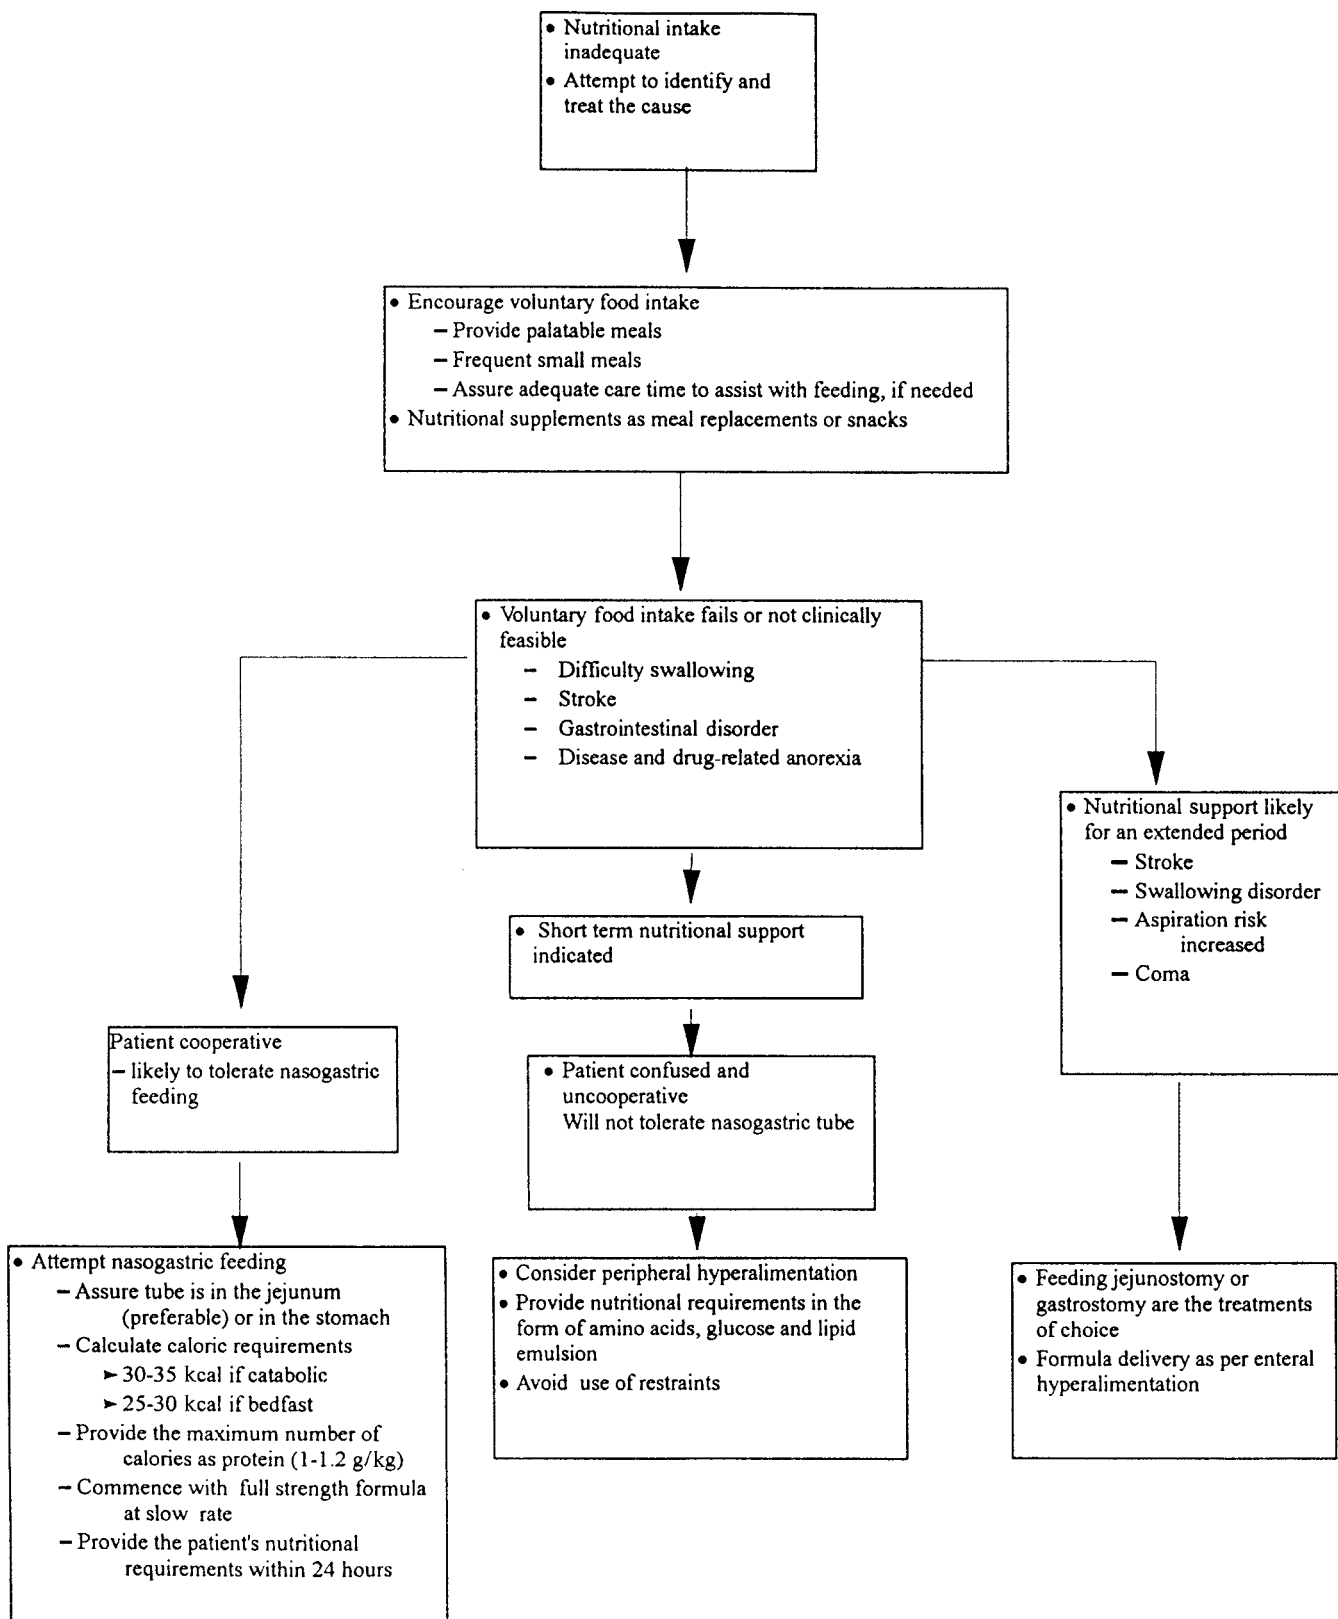

FIGURE 68.4. An approach to the nutritional support of malnourished hospitalized elderly patients.

subjects with inadequate renal function, excessive retention of fluid can result in peripheral edema or even heart failure. When this occurs, diuretic therapy can correct the underlying problem or the use of calorie-dense supplements should be considered. Major alterations in circulating electrolytes have also been described. Hyponatremia and hypocalcemia occur frequently. In addition, hypophosphatemia and decreased magnesium levels can occur, resulting in worsening confusion and delirium. Hyperglycemia and glycosuria are occasionally noted, and frank diabetic coma can develop. An additional problem seen occasionally is severe diarrhea. The risk of diarrhea can be minimized if supplements are given by slow infusion. Bolus administration of dietary supplements through a nasogastric tube increases the risk of diarrhea and, particularly in the elderly, enhances the possibility of vomiting and aspiration pneumonia. Nutritional management requires a great deal of clinical skill, particularly when frail aged subjects are being supported. With suitable training and monitoring, the side effects of enteral hyperalimentation can be minimized and, when they occur, easily corrected.

Although anecdotal evidence has demonstrated that aggressive nutritional intervention can result in weight gain (Fig. 68.5), improved immune and hematologic functions, as well as the return of serum albumin, transferrin, and other parameters of visceral protein stores to the normal range, increases in muscle mass, as measured by anthropometric measurements, usually do not occur.¹¹ Because a major goal of any geriatric rehabilitation is to improve functional independence and improve strength, strategies aimed at improving muscle mass are particularly important. For this reason, the recent observation that administration of recombinant growth hormone can improve muscle mass and performance in frail elderly is particularly significant. It may well be that this will become a useful tool as an adjunct to nutritional support in older patients receiving rehabilitation. A similar beneficial effect of appropriate exercise has also been recently reported. These studies emphasize the need for a comprehensive approach to the management of elderly malnourished patients. Aggressive nutritional intervention is only a part of a complete strategy aimed at restoring, in the appropriate patient, functional independence.

FIGURE 68.5. Response to enteral hyperalimentation in 10 elderly patients with protein-energy malnutrition. Changes in weight and serum albumin are shown.

Nutritional Support of Patients with Pressure Ulcers

Debility, immobility, and prolonged pressure are well-known contributors to the development of pressure ulcers.⁵ There is also good evidence that treatment and prevention of nutritional deficiencies can decrease the risk of developing pressure ulcers and aid in the rate of healing. There is some evidence to suggest that the rate of pressure ulcer healing can be improved by administration of relatively large doses of zinc and vitamin C. In addition, total protein intake has been shown to affect the rate of pressure ulcer healing. In a recent study, we examined the effects of dietary protein intake on pressure ulcer healing in a group of geriatric patients receiving enteral hyperalimentation. A significant increase in pressure ulcer healing rates was found in subjects fed a very high protein formula containing 25% of calories as protein as compared with a group receiving 16% of calories as protein. The percent improvement averaged 76% in the very high protein formula as compared with 36% in the group fed 16% protein diet. This finding was also observed in a recent report that demonstrated a correlation between dietary protein intake and pressure ulcer healing.

Nutritional Support of Long-Term Tube Feeders

Most long-term care facilities have a number of bedbound older patients who are receiving long-term nutritional support either via a nasogastric tube, or more common at the current time, via feeding gastrostomies or jejunostomies. In bedbound patients, energy requirements are determined exclusively via resting metabolic rate and, as such, are generally lower than ambulatory older persons.

In our experience, weight gain can be maintained when as little as 25 kcal/kg body weight is provided on a daily basis.¹² This amount will increase if an active disease process is present, such as an infection or a pressure ulcer. As a general rule, supplements with the highest protein content are favored. This is based on studies in which we have demonstrated that nitrogen balance is only maintained when more than 20% of total calories are provided in the form of protein. It is important to assure that the water needs of patients receiving enteral hyperalimentation are being met. Water needs average 35 mL/kg, even in the bedbound patient. Thus in patients receiving supplements containing 1 or more cal/mL, fluid needs may not be met without the provision of free water, in addition to the dietary supplement.

Paying attention to fluid status is critically important because of the well-known negative sequelae of dehydration in older persons.

Summary

Management of nutritional problems in the elderly constitutes an important challenge. Few health care professionals pay much attention to the nutritional status of their patients, which may have adverse effects on morbidity, mortality, and quality of life. While overnutrition is a common problem in younger persons, aging is associated with increases in the incidence of weight loss, being underweight, and having protein-energy malnutrition. Identifying and appropriately treating the underlying cause is a critical component of nutritional rehabilitation. However, it is important to simultaneously assure that the patient's energy and protein needs are met, which can be done by dietary manipulation and by the use of dietary supplements. In the hospitalized setting, the presence of anorexia and inadequate voluntary food intake may necessitate the need for nutritional hyperalimentation. Peripheral hyperalimentation is recommended for the older confused patient requiring short-term nutritional support and who is unlikely to tolerate nasogastric feeding. For long-term nutritional support, feed via nasogastric tube or percutaneous endoscopic gastrostomy (PEG) placement should be considered. It is important to emphasize that nutritional care is a critical component of comprehensive rehabilitation program that must include physical and occupational therapy if overall improvement of the patient and functional independence are to be achieved.

Exercise

Eric B. Larson and Robert A. Bruce

Introduction

The health benefits of exercise, *particularly for a sedentary society*, have gained an increasingly compelling evidence base in the past decade. For earlier generations of seniors, exercise was a regular feature of everyday life. Beginning sometime after the industrial revolution and culminating in today's most advanced societies, there is a seemingly inevitable tendency leading to everyday lives that require progressively less energy expenditure through exercise.

Exercise in the last half of the twentieth century was viewed primarily as recreation, and especially recreation for younger people. The therapeutic benefits of exercise were initially explored for younger people—in whom the principal benefits are for cardiovascular risk reduction.

We believe that the health benefits of exercise may be even greater in older persons. Younger adults have considerably more physiologic reserve, both muscular strength and cardiovascular capacity. Older individuals, by contrast, experience a progressive decline in many physiologic functions, including muscular strength and cardiovascular capacity.^{1,2} Habitual exercise, by improving strength and maximum aerobic capacity ($\dot{V}O_2$ max) as a result of conditioning effects, can provide added physiologic reserve as well as enhance well-being by reducing effort and fatigue associated with activities of daily living.³ Most importantly, habitual exercise in moderation can slow development of disability and thereby prolong active life expectancy.^{4,5}

In addition to habitual exercise for conditioning, there is increasing evidence that *resistance exercise to improve muscle strength* along with more tailored exercise therapies, including those designed to improve balance, and rehabilitate persons with various chronic disease and acute ailments, may be of particular value for older patients.⁶⁻⁸ Thus, exercise should be considered an important part of general care of so-called healthy agers as well as for persons with age-related illnesses.⁹

Society should focus health promotion on the elderly as well as the young. Life expectancy at age 65 averages at least 15 years for men and 19 years for women,¹⁰ long periods during which risk reduction and health promotion can provide beneficial effects.

Most older people in advanced countries have grown older during an era when advancing technology at home and in the workplace has promoted a lifestyle characterized by progressively less habitual physical activity. A physically active lifestyle (before today's ongoing exercise craze) was usually associated with lower socioeconomic manual labor or the considerable activity provided by raising children. As people aged, they typically became progressively more sedentary. Leisure time was for resting, and heavy physical activity was not viewed as desirable. Thus, it may come as a surprise to many older patients when a physician recommends habitual exercise as a "treatment" or when tailored exercise programs are prescribed as part of a care plan for managing ongoing chronic diseases. There is now a growing evidence base that exercise programs offer measurable health benefits, ranging from increased life expectancy to mitigation of adverse sequelae of aging and of many chronic diseases. Nowadays, the greatest challenge with regard to achieving the health benefits of exercise is caused by limited access to effective programs and poor compliance.¹¹

Exercise and Aging

Dynamic aerobic exercise is commonly defined as the rhythmical alternating flexion and extension of large muscle masses for pleasure or improved fitness and stamina.³ Aerobic metabolism of muscle increases in proportion to the mass of muscles involved and the intensity of exertion. The functional limits are determined by the body's ability to circulate oxygen and substrates and remove CO_2 , metabolites, and heat from the muscles, which is determined by cardiac output and arterial-mixed

venous oxygen (a-v O_2) differences at symptom-limited maximal exercise.¹² Beyond these limits, additional energy for a short interval is achieved by anaerobic metabolism with release of lactate.

A variety of acute changes occur during dynamic aerobic exercise. Knowledge of the physiology of exercise was originally derived from studies of young, typically athletic male volunteers; however, subsequent work has been directed to other adults, including the elderly.¹³ The circulatory response to dynamic exercise is most prominent in the exercising muscle. Blood flow increases from 4 to 7 mL/100 g/min up to 50 to 70 mL/100 g/min due to decreased vascular resistance and opening of capillary beds in working muscles.¹⁴ The muscle itself generates adenosine triphosphate (ATP), increases oxygen consumption, and consumes more substrates, especially free fatty acids. Oxygen extraction at the tissue level increases from 5 to 15 mL/100 mL of nutrient flow.¹⁵ Overall, total oxygen uptake increases 10- to 20-fold in well-trained athletes.

Cardiac output increases linearly with oxygen uptake, and heart rate increases linearly with cardiac output.¹⁵ Stroke volume increases to a lesser extent as a result of enhanced systolic emptying. The increase in cardiac output, however, is not sufficient to account for all the increase in oxygen uptake. Increased extraction of oxygen at the tissue level occurs also.

There is a prominent rise in systolic blood pressure as well as a modest increase in mean arterial pressure. Diastolic blood pressure usually is unchanged or decreases. Arterial vasoconstriction during exercise restricts regional blood flow to the hepatosplanchnic and renal circulations to transfer more blood flow to working skeletal muscle groups and to a lesser extent the coronary circulation.

In the working muscle, heat is generated up to 41°C at maximal effort. A maximum of about 25% of the chemical energy produced is turned into work; 75% is given off as heat and must be dissipated. The most important mechanism for handling excess heat is circulatory; adequate blood flow is required to allow heat to flow from the contracting muscle to the surface for dissipation through the skin. In the lungs, the minute ventilation increases in proportion to the generation of carbon dioxide¹⁴ and aids in heat dissipation.

Most people perform dynamic aerobic exercise repeatedly for a training or conditioning effect. The training effect consists of an increase in the capacity for maximal effort and decrease in circulatory and relative metabolic changes at any given level of submaximal effort. The increase in maximum aerobic capacity ($\dot{V}O_2$ max) that occurs is related to the person's baseline, limitations imposed by the presence of any disease, and the intensity and consistency of duration and frequency of training.¹⁴ Physical training increases $\dot{V}O_2$ max, and because capac-

ity is greater, the effort required for any given level of submaximal exertion as a percent of $\dot{V}O_2$ max, cardiac output, and heart rate is reduced. Approximately half the increase occurs as a result of peripheral changes, that is, an increase in the capacity of aerobic metabolism and extraction of substrate and oxygen at the tissue level. These peripheral changes include an increased density of mitochondria in the muscle, increased amount of mitochondrial enzymes, and therefore an increased capacity to oxidize fat, carbohydrate substrates, and ketones; the amount of myoglobin is increased as is the ability to generate ATP. The net result is an increased capacity for oxygen extraction and a decrease in lactate production during submaximal exercise.¹⁶ The other half of the training effect occurs primarily in the cardiovascular system.^{15,17} Thus, skeletal muscles are more efficient and myocardial oxygen requirements are actually less due to the reduction in afterload.

Dynamic exercise may be sustained for hours without fatigue if activity is below 50% of the individual's maximum oxygen consumption ($\dot{V}O_2$ max).¹⁸ To obtain physiologic adaptation, training should begin at lower levels, gradually increasing to 58% to 78% of $\dot{V}O_2$ max or to 70% to 85% of the individual's maximal heart rate.^{18,19} Exertion at this level, 20 to 40 min three times per week, for several weeks is required for physical conditioning to occur. If not maintained, deconditioning occurs. Thus, *an active life is necessary to maintain the benefits of such training*. Strenuous exertion or training activities sustained above 85% of maximal heart rate can trigger adverse effects such as heart attacks, especially in sedentary persons with coronary heart disease.^{20,21}

Aging alters structures and reduces functions of cells and tissues of all organ systems. $\dot{V}O_2$ max defines the functional limits of aerobic metabolism and the cardiovascular system that occur with aging.^{1,18} In the absence of bronchopulmonary disease or anemia, neither ventilation nor arterial oxygen content limits $\dot{V}O_2$ max before the cardiovascular limits are obtained.

Much research has focused on the relationship of $\dot{V}O_2$ max and age. The general results are that $\dot{V}O_2$ max increases with age during growth and in childhood development, reaches a peak with adolescence, and then declines with advancing age.^{1,22} $\dot{V}O_2$ max is higher in men than women in proportion to differences in amount of skeletal muscle mass. For both men and women, higher values are found in physically active persons compared to those who are sedentary. After adjusting $\dot{V}O_2$ max for weight, the highest value for aerobic capacity is observed during the first decade of life, and a roughly linear decline then follows throughout life. The relationship follows the declining maximal heart rate with age.²³

The rate of decline in $\dot{V}O_2$ max with aging is lower, based on cross-sectional selective sampling of healthy individuals of different ages, compared to the rate of

decline found in longitudinal studies of the same persons over time. In cross-sectional studies, the coefficient for this rate of change averages $-0.4 \text{ ml min}^{-1} \text{ kg}^{-1} \text{ yr}^{-1}$ compared to $-0.9 \text{ ml min}^{-1} \text{ kg}^{-1} \text{ yr}^{-1}$ observed in longitudinal studies.²³ Extrapolations based on cross-sectional data result in implausibly long-lived preservation of aerobic capacity due to selective survival effects whereas, using longitudinal data, the age at which basal or minimal oxygen uptake is intersected (minimal aerobic requirement for survival) corresponds to observed survival of healthy persons.^{18,23} Longitudinal measurements are needed to describe the effects of aging on $\dot{V}O_2 \text{ max}$; such data are difficult to obtain.

The critical observation with regard to exercise and aging is that the rate of decline in weight-adjusted $\dot{V}O_2 \text{ max}$ with aging is not identical in habitually active compared to sedentary men who remain healthy. Regression lines computed for aerobic capacity and age from longitudinal reports of aerobic capacity and aging show separation for active and sedentary men. The slopes were remarkably similar for the same categories of men, even though data²⁴⁻²⁶ were derived from different population samples over different durations between measurements. The slopes of the regression lines calculated were $-0.54 \pm 1.5 \text{ mL min}^{-1} \text{ kg}^{-1} \text{ yr}^{-1}$ for physically active men compared to $-1.32 \pm 0.85 \text{ ml min}^{-1} \text{ kg}^{-1} \text{ yr}^{-1}$ for sedentary men²³; thus, there is a twofold difference in the rate of decline in $\dot{V}O_2 \text{ max}$ based on habitual activity levels. For men in the 50- to 59-year-old range, this is equivalent to a 10-year difference in the intersection of the extrapolated regression lines with the $\dot{V}O_2 \text{ min}$ necessary to maintain life (Figure 69.1).^{3,18}

FIGURE 69.1. Age-related decline in physiologic function, as measured by maximum oxygen consumption ($\dot{V}O_2 \text{ max}$). *Solid lines* represent regression lines based on longitudinal studies of $\dot{V}O_2 \text{ max}$; *dotted segments* are extrapolations based on regression line (decline) observed. Extrapolation of this decline in persons who have been followed longitudinally and classified as habitually active or sedentary suggests that minimum $\dot{V}O_2 \text{ min}$ (3.5 ml/kg/min) occurs at a later age in the habitually active group.

FIGURE 69.2. The relationship between functional aerobic capacity, aging, and functional reserve. Δ functional reserve is the difference between functional reserve for active and sedentary persons at ages 40, 60, and 70, respectively.

olated regression lines with the $\dot{V}O_2 \text{ min}$ necessary to maintain life (Figure 69.1).^{3,18}

The consequences of a difference in the rate of declining aerobic capacity are obviously important for aging persons. One important consequence is expressed by the concept of functional reserve.^{27,28} Functional aerobic reserve can be defined as the amount of reserve between maximum aerobic capacity ($\dot{V}O_2 \text{ max}$) and the weight-adjusted resting oxygen requirement of about 3.5 ml/kg/min , which is the minimal aerobic requirement for survival. Figure 69.2 shows that at age 40 the difference in rates of $\dot{V}O_2 \text{ max}$ and minimal functional capacity associated with survival (or the functional aerobic reserve) is considerable.²⁷ Furthermore, the relative difference between conditioned and unconditioned persons is small. As the two curves diverge and one approaches age 60, there still is considerable functional aerobic reserve but the difference between active and sedentary persons' functional reserve is greater. By the time a person reaches age 70, the functional reserve in the sedentary group becomes much less as aerobic capacity approaches the minimum aerobic requirements for survival, and thus there is more likely to be a clinically significant difference in functional aerobic reserve. The clinical importance of the difference between sedentary and active groups may be manifest as improved ability to withstand the stress of illness, more rapid recovery from illness or injury, and greater likelihood to have the ability to perform activities of daily living during the course of an acute illness or during exacerbations of chronic illnesses.^{3,27} These data form the theoretical basis for postulating that aerobic exercise and conditioning may not only prolong life but, more importantly, prolong *active* life expectancy,^{3,5} the health benefit most desired by patients.

Exercise Programs for Older Persons

It is tempting (and probably justified) to simply prescribe exercise as a general tonic for all older persons. However, there are special benefits for older persons with chronic disease and disabilities for whom more focused prescriptions should be considered. Current evidence supports exercise programs for persons with ischemic heart disease, including those with congestive heart failure, osteoporosis, osteoarthritis, spinal stenosis, degenerative central nervous system diseases such as Parkinson's disease, diabetes, hypertension, peripheral vascular disease, and possibly psychiatric illnesses, such as depression and anxiety disorders.^{8,9,29,30-35} In general, current evidence indicates that older adults with chronic diseases enjoy benefits from exercise. If anything, we believe exercise offers relatively more benefits to older adults in whom the baseline level of risk is higher, and thus the opportunity to reduce risk is greater. We now know that the underlying plasticity of the muscles, autonomic nervous system, bones, and joints exists in both young and old persons and is amenable to the effects of conditioning and therapeutic exercise.^{6,36-39}

Habitual exercise in older adults has been shown to produce as much conditioning effect as in younger persons.^{13,40} The most important concern with regard to the overall health benefits of exercise in older persons is the risk of exercise.⁴¹ Except for the risks, exercise is essentially a "low-cost" intervention and may require relatively little in the way of health care resources. If the individual has time that is not encumbered with other activities (work, raising a family, etc.), the marginal cost to the individual of time spent exercising is low. Thus, the key element to the question of efficacy in older persons is risk and injuries.⁴¹

The hazards of exercise are related to extremes of intensity and duration. When exercise is excessively intense and/or prolonged, extreme fatigue, exhaustion, or delayed recovery is experienced. In addition, more prolonged or intense exercise is associated with increased risk of injury.⁴² Injuries and sudden death are the most important complication for elderly persons.³

The risk of injury has been documented in numerous studies to be directly related to the intensity of training.^{3,41,43} For example, for participants in the Peach Tree Road Race in Atlanta, Georgia, there was a nearly linear relationship between miles run per week and likelihood of suffering an injury in the previous year. At the highest level of training, more than 70% of participants had at least one injury the preceding year.⁴² On the other hand, studies of a "runners' club" from Stanford demonstrate that habitual exercise need not be associated with increased overall utilization of health service.⁴³ In this group of patients with mean age of 58.6 years who ran approximately 27 miles per week, visits to physicians, dis-

ability days, and disability levels were more favorable in the running group compared to a group of community controls. Nonetheless, 35% of the visits to physicians in the runners' club were for running-related injuries.⁴³

The risk of sudden death and nonfatal myocardial infarction is quite small, but detectable, during unsupervised activity.⁴⁴ Risk factors for sudden death among those participating in exercise programs include attaining a heart rate in excess of 85% of that individual's maximum; marked ST depression with exercise despite the absence of chest pain; poor adherence to limiting heart rate; and attainment of above-average $\dot{V}O_2$ max for gender and age due to peripheral mechanisms.²⁰ Overall, however, the risk of primary cardiac arrest in more active individuals is less.⁴⁴ The incidence of primary cardiac arrest attributable to lack of exercise was greatest in older, hypertensive, or obese males.⁴⁵ Bouts of heavy exertion in sedentary people appear to pose a threat.²¹

Thus, any general exercise program should be moderate in intensity and duration and should minimize risk of injury, cardiac arrest, and nonfatal myocardial infarction, as well as excessive fatigue. It may also be important to maintain adequate hydration to counteract fluid losses of sweating.

Four goals should be a part of an exercise program established for older individuals.²⁷ First, the program should increase conditioning, especially endurance. Second, the intervention should improve muscle strength, especially lower extremity strength, given the importance of walking to independent functioning. Both these goals are likely to improve a person's ability to perform activities of daily living, decrease fatigue associated with the day's activity, improve a sense of well-being, and perhaps forestall such adverse events as falls by improving muscle strength. The third goal of an exercise program should be to minimize risk of injury due to the program, and a fourth goal should be to promote enjoyment without causing excessive fatigue.

The components of the exercise program include two essentials: the first is dynamic aerobic exercise^{3,19} in the form of walking, swimming, cycling, jogging, and so forth; the second is a program that promotes lower extremity strengthening. Also desirable are a period to warm up and cool down and muscle and tendon stretching.

The exercise program should be tailored, especially so for older individuals. The program should take account of an individual's physical capacities and coexistent disabilities as well as mitigating social, psychological, and economic factors.¹⁹ Among all forms of exercise available to the elderly, brisk walking is one of the most ideal and has, in fact, been recommended by a number of groups.⁴⁶⁻⁴⁸ Brisk walking does produce a training response in many older individuals. More vigorous exercise may be required for persons to obtain a conditioning effect if they start from higher baseline fitness levels. Physicians

and other health professionals should be prepared to give appropriate guidelines for exercise.¹⁹ In particular, habitually sedentary persons may need to be advised of the normal responses to exercise, which include increased heart rate and breathing; mild perspiration; an increased awareness of one's heartbeat; and, at least initially, mild muscle aches. Such responses are normal and do not indicate that a person should stop exercising.²⁷ The warning signs of *excessive* exercise include severe dyspnea, wheezing, coughing; any form of chest discomfort; excessive perspiration; syncope or near syncope; prolonged fatigue and exhaustion lasting at least half an hour after exercise; and local muscle or joint discomfort. Heart rate guidelines are most appropriate for persons with coexistent cardiac disease. An exercise tolerance test will allow one to calculate the desired heart rate based on the observed or extrapolated maximal heart rate. The typical target heart rate for achieving a conditioning effect is 70% to 80% of maximal heart rate.² There also are tables listing average exercise heart rates for various age groups; however, such tables may be less useful given the wide variation in baseline and maximal aerobic capacity seen in the elderly.

In our own experience, it is perhaps more useful to teach individual guidelines for pacing. One guideline is the so-called talk test in which persons know they are not exercising excessively when they can carry on a normal conversation while exercising. For many elderly persons, a reliable heart rate guide is to aim for an exercise heart rate 15 to 20 beats per minute over their resting heart rate.⁴⁸ Most persons who have not exercised excessively will also find that their pulse returns to resting levels or nearly so within 20 min after stopping exercise. Finally, it is important to emphasize that exercise for conditioning is not "competition." Many people associate exercise with competition and thus need to be counseled to avoid external comparisons. Competitive urges can be focused on the goal of making progress or minimizing decline over time.

Perhaps the most important pacing guide is to emphasize starting a program slowly and increasing activity by small increments. Many older persons abandon exercise programs because they expect too much too fast, become discouraged, and thereby give up their programs before benefits are achieved (Table 69.1).

The duration to be prescribed is driven by the amount of time required to produce the conditioning effect. In general, a minimum of 20 to 30 min of aerobic exercise three times per week at 70% to 80% of maximum heart rate is required to achieve a conditioning effect, which will begin approximately 2 weeks after commencing an exercise program. Moderate exercise (such as brisk walking) is more likely to produce a conditioning effect at levels of 30 to 40 min for 5 days per week, which is the level recommended by the U.S. Prevention Services Task

Force. Deconditioning begins as soon as a program is abandoned. Deconditioning is dramatic and malignant when persons "take to bed."⁴⁹

Table 69.1 demonstrates two programs recommended by advisory groups for elderly individuals.⁴⁸ Both plans begin at extremely modest levels (5 min of walking three times per week or 1/4 mile walking three times per week) and eventually proceed to a brisk walking pace lasting 30 to 60 min.

Compliance, along with low levels of physician counseling, is the major barrier to successful exercise programs in the elderly.^{11,50} This is a common issue for many health promotion activities. More research is required to define strategies for improving compliance with habitual exercise recommendations. A related issue is the relative lack of social and community resources for habitual activity. Much of our advancing technology consists of "labor-saving" devices. In our large northern cities, especially, there may be few opportunities and almost no facilities for older persons to get habitual exercise. During the prolonged cold or wet winters, the opportunity for outside activity is particularly restricted. The social issues involved in creating facilities that provide a range of exercises at reasonable costs have yet to be solved. Walking in shopping malls is a solution that works in some communities. Older adult living communities are beginning to "invest" in exercise facilities containing a treadmill, bicycling, and cross-country skiing and other exercise machines.

Recent work on the feasibility of high-intensity resistance exercise training has demonstrated that rather vigorous, supervised progressive resistance training exercise designed to improve strength is both feasible and effective.^{6,37,38,39,51} Muscle dysfunction is an important factor in the development of falls, fractures, dependence in activities of daily living, and need for institutionalization.^{52,53} The feasibility and effectiveness of strength training represents an important advance, which could lead to effec-

TABLE 69.1. Two examples of brisk walking programs.

Week	Program 1: miles of walking ⁴⁶	Program 2: minutes of walking ⁴⁷

tive programs to reverse frailty. The results also demonstrate that aged, wasted, and unused muscles retain their plasticity at virtually any age.

What emerges as this chapter goes to press is that habitual exercise and tailored exercise programs are important components in the therapeutic armamentarium of geriatric medicine. Habitual moderate intensity exercise is a proven way to reduce risk of death from heart disease⁵³ and will also improve bone density, strength, stamina, and balance, which reduces risk of falling and injury, hypertension, glucose control, sleep, depression, constipation, and other common maladies.^{3,27} Age-related decline in exercise capacity and functional reserve is attenuated by habitual exercise.

The development of specifically tailored programs is likely best accomplished with the assistance of specially trained physical therapists or in group programs often found in senior centers, through voluntary groups such as YMCAs in some residential facilities or in some medical centers. We recently established a program at the University of Washington Medical Center (*Strong and Steady*), whose purpose is to provide seniors with the tools to maintain or increase their level of independent physical function and enhance their health through exercise. The *Strong and Steady Program* uses a combination of exercise and education to accomplish these goals. The services provided through the *Strong and Steady Program* include individual therapy sessions, group classes, and individualized fitness programs. Education focuses on the importance of exercise to health maintenance and measures that can be taken to maintain safe mobility function.

The program includes a comprehensive evaluation and the development of an individualized exercise program. The evaluation performed by a physical therapist focuses on assessment of balance, mobility and fall risk, and components of function such as strength, range of motion, and coordination. The tools of the program include strengthening exercises, balance retraining, aerobic conditioning, flexibility exercises, and gait retraining. More information on the Strong and Steady Program can be found on the University of Washington Medical Center Web site, http://www.washington.edu/medical/uwmc/uwmc_clinicals/bonejo/strong.html.

We believe that programs like Strong and Steady should help address the challenge of providing access to facilities, therapeutic expertise, and programs for older adults—both those with good health and those with chronic disease. The need for such services likely exceeds supply in most communities. Geographic access is often a problem for many patients. Financial viability of the programs themselves is a critical issue. The Strong and Steady Program was started with a small grant from the UWMC Service League to cover modest startup costs. The Program receives most of its revenue from billed charges and is expected to cover operational costs in 2 to

3 years, when it reaches its expected clinical capacity. The services are charged as physical therapy evaluation, therapeutic exercise, balance training, and gait training. Most charges are to Medicare, with supplemental or private pay covering the other 20%. Group classes are all private pay. We believe evidence strongly supports such efforts by clinicians, provider institutions, geriatric self-help activist groups, and older persons in general to promote exercise—both habitual and tailored programs—for long periods of time to maintain strength, fitness, health, and function.

Sleep and Sleep Disorders

Tamar Shochat and Sonia Ancoli-Israel

The prevalence of sleep complaints increases dramatically with age and is estimated to be about 40% in the elderly population.¹ These complaints include difficulty falling asleep, waking up at night, waking up too early in the morning, not feeling well rested, and needing to nap during the day. In an epidemiologic study of more than 9000 participants aged 65 and over, more than half reported at least one sleep complaint occurring most of the time.² Women were more likely to report nighttime complaints but were less likely to nap during the day compared to men. The most common complaint was waking up at night (30%), followed by daytime naps (25%) and difficulty falling asleep (19%). Less than 20% reported rarely or never having any sleep complaint. Sleep complaints were associated with coexisting health disorders, including poor self-perceived health, depressive symptoms, respiratory symptoms, physical disabilities, chronic medical conditions, and medication use. However, of the healthy minority in this study, over one-fourth reported at least one chronic sleep complaint.

Although age-related changes do occur in normal sleep, sleep problems in the elderly are not a consequence of the aging process per se but are strongly related to medical and psychiatric comorbidity as well as psychosocial changes in later life. Furthermore, some specific sleep disorders such as sleep disordered breathing, periodic limb movements in sleep, and REM sleep behavior disorder are more prevalent with age, although not exclusive to this age group.

Physiologic Sleep and Its Measurement

In the 1950s, scientists discovered that sleep is an active process, not, as formerly believed, a passive state not worthy of scientific investigation. By recording brain-wave activity (the electroencephalogram, EEG), eye movements, and muscle tension, it was determined that sleep is broken down into two major states, rapid

eye movement (REM) and nonrapid eye movement (NREM). NREM sleep is further subdivided into sleep stages 1 through 4, which represent a continuum from light sleep (stage 1) to deep sleep (stages 3 and 4). REM sleep is characterized by rapid eye movements similar to those seen in the waking state, as well as muscle atonia.

Healthy human individuals show stable and distinct patterns of sleep architecture, that is, the cyclic alternations of the different sleep stages. Sleep is entered through the transitional stage 1, and followed by stages 2, 3, and 4, respectively. After about 90 min, through stage 2 sleep, REM sleep begins. The first appearance of REM sleep during the night is termed REM latency. This 90- to 100-min cycle repeats itself typically four to five times during the night. However, the internal temporal structure changes, so that at the beginning of the night stages 3 and 4 are long while REM sleep is short, and as the night progresses, the amount of stages 3 and 4 decreases, while the amount of REM sleep increases.

Both REM sleep and non-REM sleep stages 3 and 4 are homeostatically driven; that is, selective deprivation of each of these states subsequently causes a rebound in their appearance once the person is allowed to sleep. This finding leads to the ubiquitous assumption that both are essential in the sleep process and its many functions.³ REM sleep may also be driven by a circadian oscillator, as studies have shown that REM is temporally coupled with the circadian rhythm of temperature.⁴

Specific Clinical Patterns in Aging

Because the prevalence of several medical and psychiatric conditions that affect sleep, as well as the prevalence of specific sleep disorders, is high in the elderly population, it is extremely difficult to portray the picture of the “normal” elderly sleeper. Nevertheless, studies of age-related changes in sleep architecture have found some common characteristics. Sleep efficiency, defined as the

amount of time asleep relative to the amount of time in bed, is decreased to 70% to 80%,⁵ compared to 90% or more in younger adults. Total sleep time is reduced, particularly in the later part of the sleep episode.⁶ The amount of stage 1 sleep, which is the transitional state between wake and sleep, is increased, while the amount of stages 3 and 4 (also termed slow-wave sleep or delta sleep) is much decreased.^{4,7} Specifically, the amplitude of slow-wave activity is significantly reduced.⁸ Therefore, older people spend more of the night in light sleep and are more likely to arouse (awaken) in response to external stimuli during the night.

Changes in the amount of REM sleep and latency of REM (time from sleep onset to the first REM sleep period) in the elderly are controversial.⁵ While some studies report a reduction in the percentage of REM,⁴ others report few or no changes in REM with aging.⁹ Feinberg⁷ reported a shorter REM latency and longer duration of REM sleep in the first sleep cycle. Reynolds et al.¹⁰ reported a "flat" temporal distribution of REM, with no changes in the percentages of REM sleep throughout the night, unlike the increase in REM sleep in the second half of the night typically seen in young adults. Some studies have shown shorter REM latencies in the elderly; however, this may be due to the decrease in the amount of non-REM sleep in stages 3 and 4. Alternatively, as REM sleep is coupled to the circadian rhythm of core body temperature, which has been found to be phase advanced in the elderly population, it is possible that changes in circadian timing account for the reduced REM latency compared to young adults.⁴

Studies looking at gender differences have shown that despite the tendency for women to complain about their sleep more often than men, older women sleep somewhat better than older men.¹¹ This conclusion is consistent with polysomnographic findings showing that slow-wave sleep is more preserved in older women than it is in older men.^{10,12} Sleep maintenance, particularly in the last part of the night, was also reported to be poorer in older men than women.¹⁰ Although sleep disruption in elderly women may be milder compared to elderly men, women tend to report their sleep problems and seek help more often than their male counterparts.

Sleep Disordered Breathing

Definition and Prevalence

Sleep disordered breathing (SDB) or sleep apnea is characterized by complete or partial cessation of breathing, lasting at least 10s, that occurs repeatedly throughout the night. The respiratory disturbance index (RDI) represents the number of complete pauses (apnea) and partial pauses (hypopnea) in respiration per hour of sleep.

There are two types of apnea: obstructive and central. Obstructive apneas are caused by an anatomic obstruction of the airway during sleep. Patients attempt to breathe and may appear to be choking or gasping for breath; however, despite their respiratory effort the airway is shut down. The obstruction may be located in different areas, but most often it is in the lower pharynx, between the base of the tongue and the larynx. Many patients with obstructive sleep apnea are heavy, loud snorers, as snoring in itself is also a result of a partial obstruction of airflow. In mild to moderate cases, obstructive apnea may be related to body position.¹³ Sleeping in a supine position may increase the frequency and severity of the apnea, as the tongue falls back to the anterior neck and oropharynx. Respiratory events may occur in all sleep stages; however, in some patients the length and severity of the events increases during REM sleep.¹⁴

Central apneas are caused by failure of the central nervous system respiratory centers. Respiratory neurons fail to stimulate the motor neurons that activate the respiration process, resulting in an absence of respiratory effort. Central apnea is common in patients with heart failure or stroke. Many patients have mixed apneas, with both central and obstructive components.

Ancoli-Israel et al.¹⁵ have reported the prevalence of SDB with RDI greater than 10 in 70% of elderly men and 56% of elderly women, respectively, compared to only 15% and 5% of younger men and women, respectively.¹⁶

Consequences of the Disorder

Patients with SDB stop breathing in their sleep. To start breathing again, they must awaken. Often these awakenings are so brief that they are not recalled the next morning. However, these short repetitive arousals may cause sleep fragmentation, which in turn may lead to excessive sleepiness during the day. The respiratory events may cause oxyhemoglobin desaturation, which may cause morning headaches and decreased cognitive functioning.

SDB is also an independent risk factor for hypertension¹⁷ and is associated with obesity and cardiac arrhythmias.^{18,19} In severe cases, SDB has been linked to increased mortality.^{20,21} However, in a review of the literature, Wright et al.²² claimed that evidence for an association between SDB and morbidity and mortality was not sound, and other confounding factors such as age, body mass index, smoking, and alcohol use were often not properly considered.

Epidemiologic studies have linked SDB in the elderly with cognitive impairment and dementia.^{23,24} Ancoli-Israel et al. found significant associations between SDB and cognitive functioning in community-dwelling elderly,²⁵ as well as in the nursing home, where

severe apnea was significantly correlated with severe dementia.²⁶

Clinical Presentation

The two chief complaints of the apnea patient are loud snoring (usually the spouse suffers from this and is motivated to seek help) and excessive daytime sleepiness. Patients usually do not complain of sleep disruption, as they do not remember the nighttime arousals. However, the daytime sleepiness may have extreme consequences, as some patients may fall asleep at work or while driving. Morning headaches, confusion, and cognitive impairment are also common, particularly in the elderly. Some studies have linked these disturbances to the hypoxemia or to the excessive sleepiness.^{27,28}

Risk Factors

Patients with SDB are often obese, although this is less true in the elderly. Smoking has been implicated as a risk factor.²⁹

Diagnosis

Sleep disordered breathing (SDB) must be evaluated by an all-night sleep recording. Traditionally, this is done in a sleep laboratory, with a full EEG montage, including a nasal thermistor that records airflow and chest and abdomen movements, and oximetry, to determine oxyhemoglobin level. Portable equipment that can be set up in the patient's home is also available. This alternative is particularly appropriate for elderly individuals who may become confused or disoriented or simply uncomfortable while sleeping away from home. Based on the sleep recording, the RDI is computed and treatment options are evaluated. SDB is diagnosed slightly differently in the various sleep clinics, but generally the cutoff point is an RDI greater than 10 to 15.

Treatment and Management

Weight loss in obese patients with SDB can significantly reduce or eliminate the respiratory events.³⁰ For positional apnea, sewing a pocket to the back of a nightshirt and placing a tennis ball inside the pocket is a simple, noninvasive method to avoid lying in a supine position.³¹ Alcohol and sedating medications should be avoided, as these may exacerbate the severity of the apnea.^{32,33} Smoking cessation may help.²⁹

The treatment of choice for obstructive sleep apnea is continuous positive airway pressure (CPAP).³⁴ This machine is connected by a hose to a face mask worn over

the patient's nose. Positive pressure is administered continuously at an appropriately titrated level, acting as a splint to keep the airway from collapsing during sleep. When used appropriately, CPAP is extremely effective in eliminating the respiratory events, the oxygen desaturations, the snoring, and the excessive daytime sleepiness. CPAP has also been found to improve measures such as mood, general health, fatigue, and functional status even in mild cases of SDB.³⁵ However, CPAP does not cure SDB, and it must be worn every night unless another solution, such as weight loss or surgery (see following), is achieved. Compliance is therefore an important issue, and initial acceptance rate has been found to be 70% to 80%. Long-term compliance has been found to be 80% to 90%.^{36,37}

Surgical procedures for the correction of anatomic abnormalities of the airway have been developed for the treatment of obstructive sleep apnea. Obstructions are most often found in three major regions, including the nose, the soft palate, and the base of the tongue. Usually patients have multiple obstructions. The goal of surgery is to cure the apnea or to obtain results comparable to those observed with CPAP treatment.³⁸

Nasal reconstruction is used for the correction of obstruction in the nasal airway. Pharyngeal reconstruction, or uvulopalatopharyngoplasty (UPPP), is indicated for the correction of excess tissue in the soft palate, a large uvula, and enlarged tonsillar adenoidal tissue. Unfortunately, UPPP is only effective in about 50% of the cases.³⁹ Laser-assisted uvulopalatoplasty (LAUP) is a similar procedure mostly used for the treatment of snoring. Its success rate for obstructive sleep apnea is lower than that of UPPP.^{39,40} Genioglossus advancement is used for obstruction at the base of the tongue, with the tongue being moved forward to enlarge the airway. UPPP combined with genioglossus advancement has a success rate of 61%.⁴¹ Maxillomandibular advancement is indicated for patients who do not respond to other forms of surgery. It is relatively contraindicated in the elderly population as they tend to have more risk factors such as heart disease, for example, atherosclerosis, placing them at risk for complications from this invasive surgical procedure. Tracheostomy was one of the first procedures for obstructive sleep apnea. Today it is used only for severe cases, when all else has failed, or in conjunction with UPPP.

Drug treatments for SDB have generally been only marginally successful. For central sleep apnea, respiratory stimulants such as progesterone and acetazolamide may be appropriate. For SDB associated with REM sleep, tricyclic antidepressants may be indicated, as they reduce the amount of REM, thus indirectly reducing the number of respiratory events.

Oral appliances have been developed for both obstructive sleep apnea and snoring, including the tongue-

retaining device and the mandibular advancement device. Both devices are designed to enlarge the airway at the base of the tongue by advancing the tongue or the mandible forward. Although compliance rates are estimated to range between 50% and 100%, success rates (i.e., achieving a RDI < 10) are only about 50%.⁴² Thus, oral appliances are indicated for patients who do not respond to behavioral treatment such as weight loss or body position, who are intolerant to CPAP, or who are not candidates for surgery.⁴³ Treatment options are based on the severity of the apnea, the patient's medical status, the level of urgency in treating the apnea, and the patient's own preference.

Periodic Limb Movements in Sleep

Definition and Prevalence

Periodic limb movements in sleep (PLMS) is a disorder of unknown etiology, in which patients involuntarily kick their limbs (most often it is their legs) in short, clustered episodes lasting between 0.5 and 5 s and occurring about every 20 to 40 s. The kicks are often accompanied by arousals. These episodes occur repeatedly throughout the night. The myoclonus index (MI) represents the number of kicks with arousals per hour of sleep.

The prevalence of PLMS seems to increase with age. Ancoli-Israel et al.⁴⁴ reported that 45% of randomly selected elderly adults aged 65 years and older had PLMS, compared to 5% to 6% of the younger adult population.⁴⁵

Consequences of the Disorder

As with SDB, the nighttime arousals are often too short to be recalled. However, patients with PLMS may complain of insomnia, as they may have difficulty falling asleep as well as settling back to sleep following these episodes. PLMS occur most often in the first half of the night, during sleep stages 1 and 2. Sleep is fragmented, with reduced amounts of stages 3 and 4 and REM.

Clinical Presentation

In addition to complaining of difficulty falling asleep, patients may also complain of excessive daytime sleepiness, as they suffer from sleep fragmentation throughout the night. They may also note that the bedding is disorganized or jumbled when they wake up in the morning. Bed partners often complain of the leg kicks disturbing their sleep as well, and often it is important to obtain information from the bed partner in diagnosing and assessing the disorder.

Risk Factors

A related disorder that occurs during the relaxed, awake state often just before sleep onset is restless leg syndrome (RLS). Patients report unpleasant sensations in their legs and irresistible movement of the legs. The disagreeable, sometimes painful leg sensations are alleviated by rubbing or squeezing the legs or simply by walking. The prevalence of RLS is not well defined. Most patients with RLS also suffer from PLMS, suggesting that these disorders may be related. Furthermore, many patients with PLMS also suffer from other sleep disorders, including SDB and REM sleep behavior disorder.^{46,47}

Diagnosis and Differential Diagnosis

PLMS is diagnosed in a full night sleep recording in the sleep clinic, which includes the recording of the anterior tibialis muscles to establish the MI. The muscular jerks are often accompanied by EEG signs of arousal, which may appear following the leg jerks. As with SDB, ambulatory equipment is available to record sleep in the comfort of one's own home. PLMS is diagnosed with a MI greater than 5.

PLMS and RLS may be associated with some medical conditions, including uremia, anemia, chronic lung disease, myelopathies, and peripheral neuropathies. Use of medications, such as tricyclic antidepressants and lithium carbonate, and withdrawal from benzodiazepines and anticonvulsants may all induce these disorders. Other movement disorders that should be differentiated from PLMS include the hypnic myoclonus, nocturnal leg cramps, and jerks associated with long-term use of L-dopa.⁴⁸

Treatment and Management

PLMS is treated by medications aimed at reducing or eliminating the leg jerks or the arousals. Dopaminergic agents such as carbidopa/levodopa, pergolide,⁴⁹ and a newer drug, pramipexol, are the treatment of choice for PLMS, as they decrease or eliminate both the leg jerks and the arousals. These medications are also successful for the treatment of RLS.⁴⁹ In one study, carbidopa/levodopa was superior to propoxyphene in decreasing the number of leg kicks and the number of arousals per hour of sleep.⁵⁰ However, carbidopa/levodopa and, to a lesser extent, pergolide may shift the leg movements from the nighttime to the daytime.⁴⁹

Benzodiazepines, such as clonazepam and temazepam, are sometimes used to treat PLMS. These drugs do not eliminate the limb movements but do decrease the arousals, so that the patient sleeps more continuously throughout the night.⁵¹ Triazolam has been shown to be effective in older patients,⁵² although because of age-related changes in pharmacokinetics and the need to

avoid daytime sedation, it is recommended that low doses of triazolam be prescribed in this population.⁵³ Furthermore, caution should be used in prescribing a sedative hypnotic to elderly patients who might have SDB, because sedatives exacerbate the severity of the respiratory events. Some of the longer-acting medications, particularly clonazepam, may not be eliminated by morning, particularly in older adults, causing daytime sedation. Opiates such as propoxyphene or Tylenol with codeine are effective in decreasing the leg kicks; however, the arousals may continue to occur.⁵⁴

REM Sleep Behavior Disorder

Definition and Prevalence

REM sleep behavior disorder (RBD) is a disorder in which the muscle atonia typical of the REM state is absent, causing motor disinhibition presenting as vigorous movements that may be violent or aggressive toward the patient or the bed partner. Vivid dreams are often remembered on awakening and are consistent with the observed behavior. Most often the patients report not being the aggressors in the dream, but being the defenders of themselves or their family members. The harmful behavior is uncharacteristic of the waking individual.

RBD is considered a neuropathologic disorder, although most often it is idiopathic. It has been associated with neurodegenerative impairments such as dementia, parkinsonism, Guillain–Barre syndrome, olivo-pontocerebellar degeneration, and subarachnoid hemorrhage.⁵⁵ Some patients exhibit other sleep disorders, including narcolepsy and PLMS. It is also associated with psychiatric disorders such as depression and drug and alcohol abuse and withdrawal.

The prevalence of REM behavior disorder (RBD) in the population has not been estimated; however, those diagnosed with the disorder are predominantly older men.⁵⁶

Consequences

The majority of the patients report injuries to themselves and to their spouses, including ecchymoses, lacerations, and fractures.⁵⁶

Clinical Presentation

Episodes usually begin during the second half of the night when REM is most abundant, but usually no earlier than 60 to 90 min after sleep onset, which is when the first REM period is expected to occur.

RBD may become more frequent over time. Patients may experience an episode once every 2 to 3 weeks, or as

many as four episodes a night for several nights in a row. Some experience a nightly episode. There have been no reports of spontaneous remission.

One-fourth of the patients report a prodrome in their history, which involved behavioral disinhibition of dreams, or other parasomnias, including sleeptalking, yelling, and limb jerks. Sleep recordings show elevated percentages of REM sleep, as well as a shortened REM latency.

Diagnosis and Differential Diagnosis

A detailed history of the sleep disorder, from both the patient and the bed partner, should include the timing and frequency of the episodes and the type of the behavioral disturbance. Mahowald and Schenck⁵⁷ have suggested minimal criteria for diagnosing RBD, including a history or videotape recording of abnormal sleep behavior, with an EMG recording showing elevated muscle tone and/or phasic limb twitching.

Differential diagnoses include night terrors and sleepwalking, which are also disruptive behavioral enactments during sleep; however, unlike RBD, these are parasomnias that occur during non-REM sleep, often in the early part of the night.

Another differential diagnosis is parkinsonism, as 30% of patients with this disease who are treated with L-dopa may exhibit similar sleep disturbance.⁵⁸ In a longitudinal follow-up study of 29 male patients initially diagnosed with idiopathic RBD, 38% were subsequently diagnosed with a parkinsonian disorder.⁵⁹ Compared with the idiopathic RBD group, those who developed parkinsonism had significantly elevated PLMS in non-REM sleep, as well as elevated REM sleep percentage. The authors implicate the pathology of the pedunculopontine nucleus in these combined disorders.

Treatment and Management

Clonazepam is remarkably efficient in the treatment of both the vivid dreams and the disruptive behaviors in RBD. It can be taken at low doses for extended periods of time with minimal side effects.⁵⁶ Alprazolam may be used when clonazepam is not well tolerated.⁵⁸ However, benzodiazepines may be contraindicated in cases of SDB or excessive daytime sleepiness. Other treatment options include tricyclic antidepressants such as desipramine^{55,60} and carbamazepine.⁶¹

Insomnia

Definition and Prevalence

Unlike SDB, PLMS, or RBD, insomnia is not considered a sleep disorder in itself, but rather a complaint of insuf-

ficient and nonrestorative sleep. There are several possible causes for the insomnia complaint, including medical, psychiatric, drug and medication use, changes in circadian rhythms, and psychophysiological issues.

Insomnia may be short or transient, lasting only a few days to a few weeks. Most often, transient insomnia may be related to a specific event, such as taking an exam, moving to a new house, starting a new job, divorce, or loss of a loved one. The anxiety associated with the stressful event may interfere with sleep and, if not resolved effectively, poor sleep habits may turn into long-term psychophysiological insomnia.

The prevalence of insomnia increases with age.⁶² In a survey of more than 9000 elderly adults 65 years and older, 28% complained of difficulty initiating sleep, and 42% reported difficulty in both initiating and maintaining sleep.² In a study done in the general practice, more than 50% of elderly patients reported insomnia, with 80% of those reporting that the insomnia was a chronic condition.⁶³ Insomnia was associated with poor sleep hygiene and with depression. Women complained of insomnia more than men.^{64,65} The annual incidence rate of insomnia in the elderly was found to be 5% and was associated with depressed mood, respiratory symptoms, poor perceived health, physical disabilities, widowhood, and use of sedatives.⁶⁶ Remission was estimated as 15% annually and was associated with improved self-perceived health, no new medical conditions such as heart disease and stroke, and improved physical functioning.⁶⁶ African-American women were found to have a higher incidence of insomnia than either African-American men or Caucasian men and women.⁶⁷

Clinical Presentation

Insomnia may present as a difficulty in falling asleep, which is referred to as sleep onset insomnia, or as a difficulty in maintaining sleep throughout the night, which is called sleep maintenance insomnia. In sleep onset insomnia, the patient may lie in bed without falling asleep from 30 min to a few hours. With sleep maintenance insomnia, falling asleep is achieved easily, but the patient awakens one to several times during the night and has difficulty falling back to sleep. Some patients have both sleep onset and sleep maintenance insomnia. In the elderly, waking up too early in the morning and having difficulty getting back to sleep is particularly prevalent, often secondary to advanced sleep phase syndrome (ASPS). ASPS is a common circadian rhythm sleep disorder in the elderly, in which the timing of the sleep period is advanced to an earlier hour and wake-up time is correspondingly advanced as well.

Risk Factors

Long-term or chronic insomnia may be caused by chronic medical conditions, such as cerebrovascular disease, arthritis, chronic obstructive pulmonary disease, and neurologic disorders.⁶⁸ The pain and discomfort associated with these disorders may interfere with sleep. Psychiatric disorders are strongly related to the insomnia complaint.⁶⁹ Depression is one of the most common causes of insomnia, and depressive symptoms are very common in the elderly population⁷⁰ (see Chapter 79). Alerting or stimulating medications may cause insomnia, such as CNS stimulants, decongestants, beta-blockers, calcium channel blockers, corticosteroids, bronchodilators, and stimulating antidepressants.³¹ Substances such as alcohol, caffeine, and nicotine can all cause insomnia. Sedating medications may cause daytime drowsiness, which may lead to daytime napping, which subsequently may also lead to insomnia at night. Circadian rhythm changes with age may also present as an insomnia complaint.

Diagnosis and Differential Diagnosis

Unlike the specific sleep disorders already discussed, a sleep recording in the sleep clinic is usually not warranted for complaints of insomnia because insomnia may not occur every night and often patients experience insomnia in their own bed but not in new environments.

As multiple factors may contribute to the insomnia complaint, a comprehensive history should be taken with the patient and, when possible, with the bed partner. This information should include medical and psychiatric history and current medication use, including dosage and time of administration. Possible sleep disorders may present as insomnia, including PLMS and SDB. Identification of the underlying problem causing the insomnia is the key to successful treatment.

A history should also include sleep-related habits such as napping, sleep-wake patterns on weekends versus weekdays, exercise regimens, timing and duration of bright light exposure, and caffeine or alcohol intake. Much of the sleep patterns and habits information can easily be obtained by asking the patient to fill out a sleep log for 1 or 2 weeks. An example of a typical sleep log can be seen in Table 70.1.

Some sleep clinics also use a wrist activity monitor, called an actigraph, which reliably distinguishes sleep from waking based on level of activity,^{71,72} to diagnose insomnia. Patients wear this watchlike device and fill out a sleep log for about a week. Contrasting the objective actigraphic-based information with the subjective reports may reveal some misperceptions of the patient regarding their sleep. For example, insomnia patients may overestimate their sleep latency, that is, the amount of time that

TABLE 70.1. Sleep diary.

Day: ___ Date: ___ Patient ID: _____
 Complete before bedtime:

1. Time actigraph removed for bathing: ___ : ___ am/pm
 Time put back on: ___ : ___ am/pm
2. How many naps did you take today?
 Times: From: ___ : ___ am/pm To: ___ : ___ am/pm
 From: ___ : ___ am/pm To: ___ : ___ am/pm
3. How many cups of coffee or other beverages with caffeine did you drink?
 Times: ___ : ___ am/pm
 ___ : ___ am/pm
4. How many alcoholic beverages did you drink?
 Time: ___ : ___ am/pm
 ___ : ___ am/pm

Complete in the morning:

1. What time did you go to bed? ___ : ___ am/pm
2. What time did you turn out the lights and go to sleep?
 ___ : ___ am/pm
3. How long did it take you to fall asleep? ___ hours and ___ minutes
4. How many awakenings did you have during the night?
5. What time did you wake up in the morning? ___ : ___ am/pm
6. What time did you get out of bed? ___ : ___ am/pm
7. Did you feel refreshed when you got up? yes/no

it takes them to fall asleep^{73,74} and underestimate their sleep efficiency.⁷⁴

Abnormal sleep–wake patterns may indicate a circadian rhythm sleep disorder. These disorders occur when the physiologic propensity for sleep is misaligned with the environmental light–dark cycle. Thus, although sleep may not be disrupted, its timing is inappropriate with respect to the normal environment. Elderly patients often complain of early morning awakenings, which may be caused by advanced sleep phase, that is, they are tired early in the day and they wake up early in the morning, due to an advancement of their sleep–wake cycle. Duffy et al.⁶ have suggested that older individuals have a narrow window of time in which sleep is efficiently maintained, and this window is at an advanced clock time relative to younger adults. It is important to stress that although advanced sleep phase may present as insomnia, there is no sleep disruption associated with it, and only the timing of sleep is inappropriate or inconvenient. The differential diagnosis is important in terms of modes of treatment.

Treatment and Management

As many factors may contribute to the insomnia complaint, identifying and treating the underlying cause is the key for a successful outcome. If insomnia is caused by a painful medical problem, successful treatment of the medical disorder will improve the insomnia as well. If depression is causing the insomnia, treatment of the depression will help resolve the insomnia.

Changing the timing of medication administration may be important for resolving the insomnia. Ideally, stimulating medications should be taken early in the day, while sedating medications should be taken near bedtime.

Some behavioral modification techniques have proven successful for the alleviation of psychophysiologic or primary insomnia. In a recent review by Morin et al.,⁷⁵ 70% to 80% of patients with primary chronic insomnia benefited from nonpharmacologic treatments.

Sleep hygiene⁷⁶ is a set of guidelines aimed at maintaining healthy sleep habits. Commonsense rules include avoiding or limiting naps, particularly late in the day, as daytime napping may interfere with nighttime sleep; avoiding substances that interfere with sleep, such as alcohol, caffeine, and nicotine; maintaining a stable sleep–wake pattern throughout the week; and exercising regularly, but not late in the day (physical or mental stimulation at night may interfere with sleep). For a summary of sleep hygiene rules for the elderly, see Table 70.2.⁷⁷

Stimulus control therapy⁷⁸ is another behavioral technique designed to remove all negative associations from the bedroom environment. The patient is instructed to go to bed only when sleepy. If unable to fall asleep in 15 to 20 min, the patient must leave the bedroom and engage in a relaxing activity, such as reading a magazine or writing a letter. Only when patients feel sleepy again can they return to bed. This procedure should be repeated as needed, until sleep is achieved in less than 15 min. For a summary of stimulus control therapy, see Table 70.3. Stimulus control therapy is appropriate for patients who feel stress, tension, or anxiety that are conditioned to the bedroom or the bed. They are caught in a vicious cycle, in which negative thoughts and feelings disrupt their ability to fall asleep, leading to more intensified adverse thoughts and feelings associated with the bedroom. Learning to associate the bedroom with relaxing feelings of sleepiness breaks the cycle and allows the patient to regain control over their sleep.

Sleep restriction therapy⁷⁹ is based on reducing time in bed to improve sleep efficiency. Many insomniacs try to

TABLE 70.2. Rules of sleep hygiene in the elderly.

-
1. Maintain a regular sleep/wake schedule.
 2. Take no more than one nap per day.
 3. Limit nap time to less than 60 min early in the day.
 4. Exercise regularly.
 5. Spend time in bright outdoor light.
 6. Avoid caffeine, especially after lunch.
 7. Avoid alcohol and nicotine.
 8. Check the effects of medications on sleep.
 9. Limit liquid intake in the evening.

get more sleep by going to bed early and spending more time in bed, when in fact this only worsens the problem. Thus, patients are instructed to stay in bed only for the amount of time that they actually sleep, plus 15 min. Actual sleep time is assessed by a subjective sleep log or an actigraph.^{80,81} When sleep efficiency reaches 85% or above, time in bed may be increased by 15 min. The procedure is repeated until the desired amount of time in bed is reached.

Sleep restriction therapy was found to be superior to relaxation techniques⁸⁰ and comparable to sleep hygiene therapy⁸¹ for the treatment of insomnia in community-residing elderly after a 3-month follow-up.

Bright light therapy is an effective treatment for circadian rhythm sleep disorders. The light–dark cycle is the most important synchronizer of our internal biologic clock, and changes in the timing of bright light exposure effectively shift altered circadian rhythms to a more appropriate phase.

In the elderly, who most commonly have advanced sleep phase syndrome, exposure to bright light in the evening hours on a daily basis delays the sleep episode to a later phase, so that they no longer experience the early morning awakenings that often present as an insomnia complaint. Avoidance of bright light in the early morning hours is also important, as light exposure early in the day causes an advancement of the sleep episode.

There is growing evidence that institutionalized elderly patients receive disturbingly low levels of illumination during the day, and this has been associated with poor sleep at night.^{82–84}

Pharmacologic Treatment

The use of sedative-hypnotics in the elderly population must be approached with caution. Because of changes in metabolic and elimination rates, the lowest effective dose must be used. The specific type of sleep disturbance should

be determined to establish the appropriate type of sedative; that is, a short-acting, fast-absorbing hypnotic would be appropriate for sleep-onset insomnia (e.g., zolpidem or zaleplon), whereas a medium-acting hypnotic should be used for sleep maintenance insomnia (e.g., temazepam). Long-acting hypnotics are usually contraindicated, as they are bound to create excessive daytime sleepiness and diminished performance the following day, and may increase the risk of car accidents.⁸⁵ Ultra-short-acting hypnotics, such as zaleplon, may be used both at the beginning of the night and again, if needed, in the middle of the night, without residual sedation in the morning.^{86,87}

Pharmacologic treatment should be used in combination with behavioral therapy. In a small trial, Morin et al.⁸⁸ compared the effectiveness of behavioral, pharmacologic, and combined behavioral and pharmacologic treatment for insomnia in the elderly. All three modes of treatment were effective compared to placebo in the short term, and the combined approach was slightly better than the behavioral or pharmacologic approaches alone. However, long-term follow-up revealed that those who received pharmacologic treatment alone showed a worsening of their sleep, whereas those who received behavioral treatment alone maintained their gains from posttreatment. For the combined approach group, follow-up results were more variable, that is, some patients maintained their gains in the long run while some did not.

The use of melatonin for the alleviation of insomnia in the elderly has received much attention both in the scientific community and in the general media. Melatonin is a natural hormone that is secreted during the nighttime and is associated with sleep promotion and circadian rhythm regulation. The amount of melatonin secreted at night has been found to drop in the elderly, and this has been associated with the decline in sleep quality in older adults.⁸⁹ Melatonin replacement in elderly insomniacs has been found to improve sleep efficiency.⁹⁰ In a recent study, insomnia patients were able to discontinue benzodiazepine treatment and maintain good sleep quality with melatonin substitution.⁹¹

However, melatonin may be effective only in those insomnia patients whose melatonin levels are particularly low or depleted. Furthermore, caution should be used, as there is still much debate regarding the correct dosage and timing of administration. Finally, melatonin is currently sold as a food supplement and lacks proper quality control.

Sleep Disorders in Dementia

Definition and Prevalence

Dementia is highly associated with sleep disruption. Sleep–wake patterns in dementia are often polyphasic,

with frequent nighttime awakenings and redistribution of sleep episodes throughout the day.⁹² Ancoli-Israel and colleagues have reported that many institutionalized demented patients were neither awake nor asleep for a full hour in the day or night,⁹³ and that while the mildly to moderately demented patients had extremely fragmented sleep at night, the severely demented patients were extremely sleepy during the day and night.⁹⁴

Clinical Presentation

Sleep structure is also altered in demented patients compared to healthy elderly individuals, with significantly lower amounts of stages 3 and 4 and REM sleep and significantly more awakenings, as well as more time spent awake during the night.⁹² Increased stage 1 sleep and decreased sleep efficiency have also been reported.⁹⁵ REM latency has been found to increase in dementia patients, possibly due to the general reduction in the amount of REM found in these patients.⁹⁶

The neuronal degeneration seen in Alzheimer's disease is most likely the cause of these sleep changes. Neuronal structures that are damaged in this population and are implicated in sleep regulation include the basal forebrain and the reticular formation of the brainstem.⁹⁶ As sleep changes are already evident in the early, mild stages of dementia, they may serve as markers of early dementia in clinical assessment.

Nocturnal awakenings, often accompanied by agitation, confusion, and wandering, are typical in demented patients. These events are often referred to as "sundowning" behaviors, and as they typically occur at the same time of day, it has been suggested that they are related to a circadian rhythm disorder.⁹⁷

Support for this hypothesis has come from studies using bright light treatment for circadian rhythm disorders. Satlin et al.⁹⁸ used bright light therapy in the evening to improve sleep and behavioral disturbances in Alzheimer's disease patients. Mishima et al. found similar results using morning bright light therapy.⁹⁹ Lovell et al.¹⁰⁰ reported that bright light therapy in the morning hours decreased agitated behaviors in the late afternoon in a group of institutionalized demented patients.

In a recent study, Martin et al.¹⁰¹ challenged the idea of sundowning by showing that peak levels of agitation occur during various times of the day, but more often in the afternoon, rather than in the evening or night. However, they did find associations between circadian rhythms of activity, agitation, and light exposure, indicating that sleep disruption in demented individuals may be amenable to treatment using bright light exposure.

Risk Factors

Ancoli-Israel et al.²⁶ have reported a strong relationship between demented patients and sleep apnea, with the

most severe apnea in the most severely demented group of patients. This positive association has been confirmed by several research studies, as summarized by Ancoli-Israel and Coy.¹⁰² In a review of the literature, the prevalence of SDB in demented patients ranged between 33% and 70%.¹⁰³ In a recent study of institutionalized Alzheimer's disease patients, the prevalence of SDB was 80% with RDI of 10 or more and 48% with an RDI of 20 or more.¹⁰⁴

Cognitive impairment is a common symptom in both dementia and SDB patients. In SDB, cognitive impairment is associated with the nocturnal hypoxemia, as well as the sleep fragmentation.^{27,28} In an epidemiologic study, Dealberto et al. (24) found a strong relationship between symptoms of SDB and cognitive impairment. Bliwise has suggested that SDB may contribute to cognitive decline in demented elderly, together with cerebrovascular disease and hypertension.^{5,105} Furthermore, he suggests that treatment of SDB may reverse the cognitive decline in demented patients or at least slow the dementia process. In a pilot study, Shochat et al.¹⁰⁶ examined the possibility of treating demented patients with SDB using CPAP. They concluded that CPAP may be tolerated and may partially reverse cognitive decline (e.g., global mental functioning and memory) in some mildly demented patients.

In summary, severe sleep disturbance is commonly found in the demented elderly population, which may be the result of neurodegenerative processes in areas in the brain that regulate sleep/wake and possibly circadian rhythm mechanisms. The high presence of SDB in this population may indicate that neuronal damage is also contributing to the respiratory difficulties during sleep, and these respiratory disturbances may be contributing to the cognitive impairment associated with the dementia.

Herpes Zoster

Kenneth Schmader

Herpes zoster is a neurocutaneous disease caused by the reactivation of varicella-zoster virus (VZV) from a clinically latent state in dorsal sensory or cranial ganglia. VZV reactivation preferentially affects elderly persons and usually results in dermatomal pain and a vesicular skin eruption. Zoster has been recognized since ancient times, but only recently have large numbers of persons experienced the disease, owing to population aging and increasing numbers of immunosuppressed hosts. Although a scourge for the patient, zoster is a remarkable phenomenon for clinical observers. Dr. Hope-Simpson said it best when lecturing the Royal College of Physicians in England: “Herpes zoster is fascinating because it arrives unpredictably, is readily diagnosed—a rare pleasure for most of us—and difficult to explain.”¹

Epidemiology

Risk Factors

Aging

The cardinal epidemiologic feature of herpes zoster is its striking relationship to aging. Primary VZV infection usually occurs during childhood and adolescence in temperate zones (childhood to young adulthood in tropical zones), and VZV establishes a latent infection in more than 95% of the adult population (Fig. 71.1).² However, the likelihood of symptomatic VZV reactivation increases sharply with aging.¹⁻⁵ For example, Hope-Simpson’s study of zoster cases in England showed an incidence of 0.74 per 1000 per year in children under 10 years old, 2.5 per 1000 per year in adults aged 20 to 50 years, and 7.5 per 1000 per year in those older than 60 years old.¹ Ragozzino et al. found a similar dramatic increase with aging in Minnesota, where the incidence of zoster was less than 1 per 1000 per year under 44 years old but peaked at 4 to 4.5 per 1000 per year at ages

greater than 75 years.³ Donahue et al. confirmed this relationship in Boston where they reported an incidence of 1.9, 2.3, 3.1, 5.7, and 11.8 per 1000 person-years for the age groups 25 to 34, 35 to 44, 45 to 54, 55 to 64, and 65 to 75+ years, respectively.⁵

Cellular Immunity

The other strong risk factor for zoster is cellular immune dysfunction. In vitro lymphoproliferative responsiveness to VZV antigens is significantly diminished in immunosuppressed patients and in the elderly. In vivo, zoster is more frequent and severe in patients with hematologic malignancies, organ transplants, HIV infection, immunomediated diseases, and immunosuppressive therapies.⁶⁻¹⁰ Patients with solid tumors are at lesser risk for zoster, but in one large series treated patients of any age with lung, breast, or gynecologic cancers were more likely to have zoster than those with other solid tumors.⁶ Conversely, zoster is not a risk factor for cancer, so the presence of zoster in an elderly patient should not trigger a diagnostic search for a presumed underlying malignancy.¹⁰

Other Factors

Other potentially important but less well-established risk factors include physical trauma, radiation therapy, psychologic stress, and white race. In a case-control study of stressful life events and zoster in the elderly, cases experienced negative life events significantly more often than controls at 2 months before zoster onset [odds ratio (OR) 2.64, 95% confidence interval (CI) 1.13, 6.27] and 3 months before onset (OR 2.64, 95% CI 1.20, 6.04).¹¹ In the Duke Established Populations for the Epidemiological Studies of the Elderly (EPESSE), stressful life events increased the risk of zoster but the result was borderline for statistical significance [adjusted relative risk (RR) = 1.38, 95% CI 0.96–1.97, $p = 0.078$], and methodologic limitations precluded definitive conclusions about these results.¹² Regarding race, in the Duke EPESSE, blacks

FIGURE 71.1. Age-related activity of varicella-zoster virus in a population in a temperate region. (Reprinted by permission of the *New England Journal of Medicine* 1983;309:1366.²)

were four times less likely than whites to develop zoster over their lifetimes, after adjusting for age, cancer, sex, and education (adjusted OR 0.25, 95% CI 0.18–0.35).¹³ In a follow-up prospective study of the incidence of zoster in blacks and whites in the Duke EPESE, blacks were significantly less likely than whites to develop zoster (adjusted risk ratio 0.35, 95% CI 0.24–0.51).¹² Gender, education, residence, season, and exposure to zoster or to chickenpox do not predict zoster.^{1,3,13,14}

Incidence

The incidence of herpes zoster in Western populations of all ages is estimated to be between 1.3 and 3.4 per 1000 person-years.^{1,3,5,15} Estimates of the incidence of zoster in the elderly vary from 3.9 to 11.8 cases per 1000 person-years.^{1,3,5,13,15} The incidence of zoster in populations limited to immunosuppressed patients is substantially higher. For example, the incidence of zoster in HIV-infected individuals ranges from 29 to 51 per 1000 person-years.^{8,16,17} Investigators have used these data to calculate an overall lifetime incidence of zoster of 10% to 20% and to estimate the total number of cases in the United States each year to be at least 600,000.¹⁸ Elderly patients usually experience zoster only once, but second attacks occur in 1% to 5% of zoster victims. With population aging, the total number of zoster cases worldwide will increase significantly in the future.

Transmission

The potential infectivity of the elderly zoster patient is an important component of the disease. Viable, cell-free,

infectious VZV is present in vesicular lesions. Although less infectious than varicella patients, an elderly zoster patient can transmit varicella to an uninfected susceptible host. There is no evidence that the elderly zoster patient transmits varicella or herpes zoster to latently infected individuals.¹⁴ Regarding infection control, susceptible, seronegative persons should avoid contact with the zoster patient until the rash has crusted over. To protect susceptible staff and patients, the Centers for Disease Control recommends a private room and standard precautions for immunocompetent hospital patients with localized zoster. For immunocompromised patients in hospital with localized zoster or any patient with disseminated zoster, the recommendations are a private room with special ventilation and airborne and contact precautions. The risk of VZV transmission is thought to be higher in these patients.¹⁹ Similar measures are advocated for zoster patients in long-term care facilities but modified for the special problems and limited resources of these facilities.²⁰ For example, private rooms may be available only for the patient with disseminated zoster. These precautions no longer apply when the rash has crusted over because VZV is very difficult to recover and the patient is no longer contagious.

Pathogenesis

Varicella-Zoster Virus

The causative agent is a double-stranded DNA virus of the herpesvirus family. The VZV genome contains approximately 125,000 nucleotide base pairs and encodes about 70 gene products.^{21,22} These products include glycoproteins located in the viral envelope that bind to host cell receptors, initiate cellular infection, and stimulate the host immune response. Other protein products include the enzymes thymidine kinase and viral DNA polymerase. Viral thymidine kinase catalyzes the transformation of nucleoside analogues such as acyclovir to the triphosphate form that inhibits VZV DNA polymerase and viral replication.

Primary and Latent Infection

VZV causes primary infection when it invades the respiratory tract of a VZV-naive individual. From the respiratory tract, VZV disseminates in the blood and infects the skin, causing the rash of chickenpox. During this time, VZV also infects dorsal sensory and cranial nerve ganglia where it establishes a latent, lifelong infection. The persistence of VZV in asymptomatic adults has been confirmed by the detection of VZV DNA and RNA in spinal and trigeminal ganglia by in situ hybridization and by amplification of VZV DNA using the polymerase chain

reaction (PCR).^{23,24} The virus is present in both neurons and satellite cells during latency.²² VZV appears to evade the immune system during latency by limiting expression of viral proteins and downregulating the expression of MCH class I antigens.

Reactivation

The molecular mechanisms responsible for VZV reactivation are poorly understood. Available evidence suggests that VZV sporadically replicates throughout life but the host immune response prevents clinical manifestations. As host immunity wanes, the likelihood of reactivated VZV causing zoster increases.²⁵ As with other herpesviruses, cell-mediated immunity is much more important than humoral immunity in defending VZV reactivation. For example, patients with agammaglobulinemia do not have an increased risk for zoster whereas diseases and therapies that affect T cells (hematologic malignancies, AIDS, cancer chemotherapy) markedly increase the incidence and severity of zoster.

Age-related decline in the number and function of T-cell responders to VZV plays a role in the development of zoster in old age. Studying lymphocytes from young ($n = 14$) and old ($n = 15$) subjects, Miller first demonstrated that the proliferative response of these cells to VZV antigen in vitro was significantly less in the elderly.²⁶ Berger et al. confirmed age-related differences in VZV antigen-dependent lymphocyte proliferation by demonstrating a low or absent stimulation index in lymphocytes from 33 of 100 (33%) healthy elderly and 0 of 43 (0%) persons aged 20 to 40 years.²⁷ Burke et al. studied lymphocyte proliferation and skin test reactivity to VZV antigen in 157 healthy, latently infected subjects of all ages.²⁸ Mean stimulation indices declined steadily by decade from a peak mean of 6.28 in 1- to 10-year-olds ($n = 24$) to 2.10 in 60- to 70-year-olds ($n = 12$), 1.56 in 70- to 80-year-olds ($n = 12$), and 1.39 in 90- to 100-year-olds ($n = 13$). In addition, the percent of positive skin test responses to VZV progressively decreased with aging, starting at 89% in 30- to 40-year-olds to 18% in 60- to 70-year-olds, 8% in 70- to 80-year-olds, and 0% in 80- to 100-year-olds. Finally, Hayward et al. used lymphoproliferative responses to VZV antigens to estimate the frequency of VZV-responsive lymphocytes in blood from healthy old ($n = 6$) and young ($n = 6$) subjects.²⁹ Mean responder cell frequency was $1:14,300 \pm 2000$ (one VZV-responsive lymphocyte per 14,300 lymphocytes) in young volunteers and $1:78,000 \pm 6600$ in elderly subjects ($p = 0.002$). Further studies by Hayward et al. have confirmed these findings in larger numbers of subjects.³⁰ Although these studies were limited by cross-sectional design and small sample size, they demonstrated consistent results using similar methodologies. Whether the age-related decline in tests of in vitro VZV cellular

immunity and the age-related increase in herpes zoster are coincidence or cause and effect is unknown.

Clinical Features

Acute Herpes Zoster

Prodrome

As VZV spreads in the dorsal ganglion and afferent nerve, the patient usually experiences a prodrome of pain, discomfort, or paresthesias in the affected dermatome. This distressing prelude bewilders patients, caregivers, and physicians because the cause is not readily apparent and it masquerades as many other conditions in the elderly, such as biliary colic, appendicitis, kidney stones, pleuritis, myocardial infarction, acute musculoskeletal pain, trigeminal neuralgia, and migraine headaches. One potentially useful clue to the diagnosis is tender or hyperesthetic skin in the affected dermatome during this prodrome. The experienced clinician should keep herpes zoster in the differential diagnosis of any acute, unilateral, localized pain syndrome in the elderly, particularly if unexplained after the history and examination.

Rash

After a few days of the prodrome, the rash erupts and the diagnosis of zoster becomes apparent (see Fig. 59.4). The rash begins as an erythematous maculopapular eruption that is unilateral and dermatomal. Within a day or two, vesicles form on this erythematous base. The exanthem may be confluent or scattered about the dermatome and a few satellite lesions may be found in adjoining dermatomes. It appears most frequently on the areas of the trunk innervated by T3 to L3 and on the areas of the face innervated by the ophthalmic division of the trigeminal nerve.^{1,3,31} Typically, the vesicles crust over in 7 to 10 days (2–3 weeks in immunocompromised individuals) and the crusts persist for 2 to 3 weeks. The impact of the rash ranges from an uncomfortable nuisance to serious problem in the elderly, including dissemination to other areas of skin, secondary bacterial infection, scarring, embarrassment and social withdrawal when on the face, and inaccessibility for proper care when on the back.

Pain

The acute neuritis produces significant pain in most elderly patients but the pain experience is remarkably variable, reflecting the variability of many conditions in geriatrics. A small percentage (~10%) of elderly zoster patients undergo little or no pain.³² For those with pain or discomfort, the severity ranges from mild to severe; the

quality includes terms like burning, deep aching, tingling, itching, and stabbing; and the temporal aspects vary from constant to intermittent. The acute zoster pain experience can have a tremendous effect on the patient's quality of life and functional status by interfering with personal care, mobility, sleep, energy, mood, and socialization.

Atypical Presentations

Zoster is no different from other conditions in geriatrics in its ability to present atypically. The rash may be small and inconspicuous or it may be disseminated over several dermatomes. In AIDS patients, chronic, indolent VZV replication can generate a hyperkeratotic, verrucous rash.³³ In other clinical scenarios, the rash may not be present as a diagnostic guide. For example, investigators have described prodromal pain for a month or more before the appearance of the rash, so-called pre-herpetic neuralgia.³⁴ Typical unilateral, dermatomal, neuralgic pain due to zoster can occur without a rash, an event entitled zoster sine herpette.³⁵ Besides dermatomal pain, acute facial palsy, hearing loss, vertigo, and/or dysgeusia (cranial polyneuritis); blurred vision and a painful eye (acute retinal necrosis); fever, delirium, and meningismus (meningoencephalitis); back pain, leg paraparesis and ascending paresthesias (myelitis); and hepatitis may be the first manifestations of zoster without a rash.³⁶⁻³⁹

Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is the most debilitating and feared feature of zoster in the elderly. A common definition of PHN is pain 1 month after the onset of the rash, although alternative definitions include pain after the rash has healed or pain 3 months after rash onset.^{40,41} Like zoster, the overriding epidemiologic feature of PHN is its striking relationship to aging. For example, deMoragas and Kirkland reported pain greater than 1 month in 10% of zoster patients less than 40 years old, 42.3% of those 40- to 59 years old, and 68% of those greater than 60 years old.³² Other risk factors include greater severity of the acute pain, greater rash severity, the degree of sensory impairment in the affected dermatome, and a painful prodrome.⁴²⁻⁴⁴ In the placebo group of a large acyclovir trial in zoster patients over 60 years old, 61% of patients had pain 1 month after rash onset.⁴⁵

PHN victims describe their suffering with words like burning, throbbing, stabbing, shooting, sharp, aching, gnawing, tiring, and tender.⁴⁶ These descriptors and clinical studies have revealed that PHN pain is spontaneous and/or stimulus evoked.⁴⁷ The spontaneous pain usually involves constant pain and/or brief, intermittent shock-like pain. Patients may also note distracting tingling or

itching. Stimulus-evoked pain consists of allodynia or hyperpathia. Allodynia is pain elicited by an innocuous stimulus, but that definition does not convey how terrible this can be for the elderly patient. The touch of bedsheets or clothing may be so unbearable that patients remain partially naked, effectively trapped in their home. Hyperpathia is an exaggerated pain after a mildly painful stimulus. For example, a minor bump of the affected dermatome against an object can send the patient to bed with severe pain that lasts for hours. Cutaneous scarring and disordered sensation is not uncommon in the affected dermatome. Careful sensory testing often reveals a discrete area of tenderness in the affected dermatome but absent or diminished thermal, touch, vibration, or pinprick sensation.⁴⁸ These findings are curious because PHN is a "positive" neurologic phenomenon (pain) but the exam shows "negative" findings (decreased or absent sensation).

PHN profoundly affects the elderly patient's quality of life and functional status. Patients can suffer from a variety of constitutional symptoms including chronic fatigue, anorexia, weight loss, and insomnia. PHN is a well-known cause of depression in the elderly. The social activities of many patients and their spouses are often curtailed by the illness, and the patient's social role may change from a vital member of the community to an inactive individual in a household. Furthermore, PHN can interfere with dressing, bathing, grooming, eating, and mobility. For example, the patient with allodynic skin may be forced to avoid bathing or clothing around the affected area. Instrumental ADLs commonly affected include traveling, shopping, cooking, and housework.

Other Complications

Ocular

VZV reactivates in the ophthalmic division of the trigeminal nerve in 10% to 15% of zoster patients.^{3,40} The appearance and location of the facial rash do not necessarily predict the location and extent of eye involvement. Rash on the tip of the nose, indicating involvement of the nasociliary branch, appears to increase the likelihood of inflammation of the eye. The uvea and the cornea are the most common sites of inflammation, but any part of the eye is vulnerable.^{49,50} VZV-induced damage to these structures can result in glaucoma, optic neuritis, optic atrophy, corneal anesthesia and ulceration, cataract, eyelid scarring and retraction, compromised vision, and blindness.⁵¹ In one study of the natural history of ophthalmic zoster in untreated patients, 50% of patients developed ocular complications and 28% had active ocular disease 6 months or more after rash onset.⁴⁹

VZV can also cause acute retinal necrosis, which is characterized by destructive retinal inflammation and affects adults of any age.^{51–53} Patients do not exhibit facial rash; instead, they present with blurred vision and a painful eye. The fundus shows peripheral yellow-white patches indicative of retinal inflammation. These changes are not specific for VZV but VZV is frequently found in the lesions. The inflammation usually persists for 4 to 5 weeks and is followed by retinal scarring and detachment. Years later, the unaffected eye can develop the same pathology.

Neurologic

Considering the focus and spread of VZV within the peripheral and central nervous system, it is not surprising that zoster is associated with several neurologic complications along with PHN.⁵⁴ Up to 5% of zoster patients develop focal motor pareses involving muscle groups innervated by ventral horn neurons in proximity to dorsal horn neurons of the affected dermatome. The most commonly affected muscles are those of the extremities with zoster of the accompanying dermatome and the face with zoster of the seventh cranial nerve. Oculomotor weakness (cranial neuritis), unilateral diaphragmatic paralysis (cervical zoster), bladder and anorectal dysfunction (sacral zoster), and intercostal muscle weakness (thoracic zoster) have also been reported. These deficits usually occur at the time of or within a few weeks after the onset of the rash. Full or partial recovery of motor function occurs in 65% to 85% of patients within months of the onset of weakness, but VZV-induced facial palsy has a much lower rate of recovery (30%–40%).^{55,56}

Other important neurologic complications include cranial neuropathy, meningoencephalitis, transverse myelitis, and cerebral stroke. Zoster-induced cranial nerve symptoms include facial weakness with involvement of cranial nerve (CN) V or VII; hearing loss, imbalance, hyperacusis, and tinnitus with CN VIII; dysgeusia and mouth lesions with CN V, mandibular branch, and CN IX; and pharyngitis and laryngitis with CN IX, X.^{54,57} The patient may have multiple symptoms because more than one cranial nerve can be involved in an attack. Cephalic herpes zoster (Ramsay Hunt syndrome) refers to VZV-induced facial palsy and otic vesicles, often in association with CN VIII and/or other cranial nerve symptoms.⁵⁴

Clinically overt meningoencephalitis rarely occurs in the elderly. The clinical manifestations of fever, delirium, headache, and meningismus may occur days or weeks before, during, or up to 2 months after the rash.⁵⁸ Most patients survive and regain premorbid cognitive functioning. Cerebral stroke or transient ischemic attacks are a recognized complication of ophthalmic zoster in older patients.^{59,60} VZV appears to infect cerebral arteries adja-

cent to the ophthalmic division of the trigeminal nerve and cause granulomatous angiitis with resultant thrombosis. Weeks to months after zoster, patients present with fixed or transient motor deficits contralateral to the zoster-affected side. The delayed manifestation may preclude the clinician from making the link between the stroke and the prior occurrence of ophthalmic zoster. These patients show segmental narrowing or occlusion of cerebral arteries next to the affected ophthalmic division on a cerebral arteriogram.

Visceral

Under conditions of severe immunosuppression, reactivated VZV can cause pneumonitis, hepatitis, esophagitis, gastritis, cystitis, and arthritis.²⁵ These complications are unusual in the typical elderly zoster patient.

Diagnosis

Clinical

The clinical diagnosis of herpes zoster in the elderly is ordinarily unmistakable and sufficient. Burns and contact dermatitis may infrequently resemble zoster, but the history and clinical course will lead to the diagnosis. The principal condition in the differential diagnosis is zosteriform herpes simplex. The differentiation is most challenging in the elderly when the herpes simplex virus (HSV) reactivates in sacral and trigeminal dermatomes and produces lesions on the buttocks or face that are indistinguishable from zoster. HSV commonly produces a short, mild prodrome; generates smaller, closely grouped vesicles; recurs many times; affects younger adults; and very rarely causes postherpetic neuralgia.²⁵ However, the appearance of the rash and the clinical situation may make it impossible to distinguish the two conditions and lead to misdiagnosis.^{61,62}

Laboratory

Diagnostic testing is useful for differentiating herpes zoster from herpes simplex, for suspected organ involvement, and for atypical presentations. Available tests can provide a definitive diagnosis of herpes zoster by detecting (1) VZV antigens using immunofluorescent antibody (IFA) techniques, (2) VZV replication in culture, (3) VZV antibody by serology, or (4) VZV DNA by the polymerase chain reaction (PCR) in the target specimen (vesicle fluid/scrapings, involved tissue, CSF, or blood) (Table 71.1). Of these options, IFA is the most expedient and useful test because it is rapid, specific, and sensitive.⁶³ A rash specimen is easily prepared by scraping or swabbing the base of an unroofed vesicle, placing the material on a slide, and fixing it by air-drying or acetone. The slide

TABLE 71.1. Laboratory diagnostic tests for herpes zoster.

Test	Sensitivity	Specificity	Turnaround	Comment
IFA	Very high	High	Hours	Preferred test in most patients
Culture	Low	High	Days	Positive test needs confirmatory test
Serology	Moderate	Moderate	Weeks	Retrospective diagnosis
PCR	Very high	High	Hours	Limited availability, expensive

IFA, immunofluorescent antibody (direct or indirect); PCR, polymerase chain reaction.

is stained with an anti-VZV monoclonal antibody that is tagged with an immunofluorescent label. The microscopic detection of fluorescence indicates the presence of VZV antigen and confirms the diagnosis.

Cell culture of infected specimens can isolate VZV. A positive culture shows the typical cytopathic effects (CPE) of in vitro herpes virus infection—distinct foci of enlarged, fused cells that appear multinucleated and contain intranuclear inclusions. However, VZV culture is limited by the slow time for a result (usually several days but as little as 1–2 days with the shell vial technique), the nonspecific nature of CPE (a positive culture requires immunologic confirmation), and significant insensitivity (VZV is very labile).⁶⁴

Serologic tests can provide a retrospective diagnosis if acute and convalescent sera are obtainable and show a fourfold or greater increase in VZV IgG titers. The most sensitive and specific tests are fluorescent antimembrane antibody (FAMA), enzyme-linked immunofluorescent antibody (ELISA), latex agglutination, and radioimmunoassays (RIA).²⁵ Although not useful for acute infection, serologic tests are occasionally helpful for atypical syndromes such as zoster sine herpette. The PCR detects VZV DNA by repeated amplification of target segments of the VZV genome. The PCR is a powerful, extremely sensitive, specific technique that can produce results in a day. Researchers have used the PCR to detect VZV DNA in the rash, conjunctiva, synovial fluid, cerebrospinal fluid, a variety of tissues, and in the air surrounding patients with chickenpox and zoster and in mononuclear cells of asymptomatic elderly persons.^{65–69} The principal disadvantage of the PCR is its extreme sensitivity and potential for false positives.

Prognosis

The prognosis of herpes zoster is related to the duration and severity of pain. The duration and severity of zoster pain is significantly greater in older patients than younger patients. In general, the number of elderly zoster patients with pain declines over weeks to months from rash onset. Specific data on pain duration in elderly zoster patients is limited by the lack of population-based studies of this phenomenon. Nonetheless, data from patient groups and recent clinical trials provide some useful information.

Studies of predominantly older adults in the preantiviral era found that the percentage of patients with any pain 6 months after rash onset was 41% to 46% and one year after rash onset was 28% to 41%.^{1,32} The upper figures in these ranges are partly elevated by referral bias. In a meta-analysis of acyclovir trials, the percent of patients 50 years of age or older with any pain in the placebo group was 54% at 3 months and 35% at 6 months after rash onset (12-month data not available).⁷⁰ These data indicate that a substantial subset of elderly zoster patients have a poor prognosis with respect to pain. Many of these patients are refractory to all treatments, and some may actually get worse over time.⁷¹ Furthermore, some patients have pain-free intervals of weeks or even months only to note the return of their pain. Nonetheless, the geriatrician can offer hope to the acute zoster pain sufferer because the majority of elderly zoster patients note the loss of pain in the weeks or months after rash onset. Furthermore, some patients with long-lasting pain eventually have a good outcome. In a study of 88 patients with PHN of 1 year or more, 31 (35%) had mild pain and no disability after an average of 2 years of follow-up.⁷¹

Treatment

Acute Herpes Zoster

Rash

Recommended treatments for the rash are empirical because there are no clinical trials of topical therapy. The stage of the rash determines the choice of therapy. For an uncomplicated rash, soap and tap water are sufficient to keep the wound clean and provide some comfort. For the patient with multiple, oozing vesicles, wet dressings with aluminum acetate (Burow's solution), acetic acid, or zinc sulfate dry lesions and prevent secondary infection. Calamine lotion, cornstarch, or baking soda are said to be useful by some patients in this phase. The typical rash heals in 3 to 4 weeks. Oral antiviral therapy reduces the time of rash healing by a mean of 1 to 2 days.⁴⁵

Pain

The principal goal of the treatment of herpes zoster in the elderly is the reduction or elimination of pain. Anti-

viral therapy, anti-inflammatory drugs, and analgesics are three strategies to achieve that goal.

Antiviral Therapy (Table 71.2)

Available anti-VZV drugs are nucleoside analogues that are converted first by VZV thymidine kinase and then cellular kinases to the nucleoside triphosphate form. This compound stops VZV from replicating by inhibiting VZV DNA polymerase and by incorporation into the VZV DNA chain. In general, these drugs are safe and well tolerated in the elderly. The most common side effects are nausea and/or vomiting, diarrhea, and headache in about 8% to 17% of patients.^{45,72,73} To be effective, the drugs must be used early during zoster. The beneficial effects occur most when the drugs are begun within 48 to 72 h of rash onset. They are all renally excreted.

Acyclovir

When used early, oral acyclovir can reduce acute zoster pain.⁷⁴ The effect of acyclovir on chronic pain is less apparent because clinical trial data conflict. It is difficult to combine data from available studies because of differences in study methods and definitions of postherpetic neuralgia. Nonetheless, a recent meta-analysis combined the results of five randomized, placebo-controlled trials of oral acyclovir and used any pain at 6 months as the outcome.⁷⁵ None of these studies reported significant differences in the proportion of treated or placebo patients with pain at 6 months, but there was a trend favoring acyclovir in four of the studies. When the data were combined, the summary odds ratio for the incidence of any pain at 6 months for patients treated with acyclovir was 0.54 (95% CI, 0.36–0.81).

Acyclovir is useful for ophthalmic zoster, visceral, and central nervous system infections, and for the immunosuppressed host. Oral acyclovir reduced keratitis, uveitis, and ocular complications significantly in placebo-controlled trials of older patients with ophthalmic zoster.⁷⁶ Depending on the nature of the pathology, some ophthalmologists employ topical corticosteroids to reduce severe inflammation and mydriatics to reduce pupillary sphincter and ciliary body muscle spasm and prevent anterior lens and pupil synechiae.⁷⁷ Intravenous (i.v.) acyclovir, at doses of 10 mg/kg every 8 h for 7 to 10 days, is recommended in severely immunosuppressed patients

with localized zoster and for any patient who develops serious VZV-induced disease such as meningoencephalitis, pneumonitis, acute retinal necrosis, generalized dissemination, or other organ system complications.⁷⁸ Acyclovir i.v. does not appear to affect PHN but it does reduce the likelihood of cutaneous, visceral, or central nervous system complications in the immunosuppressed host.⁷⁹ Oral acyclovir is sufficient for localized zoster in mildly immunosuppressed patients. Acyclovir-resistant VZV, mediated by the lack of thymidine kinase, has been reported only in AIDS and transplant patients on prolonged acyclovir therapy and not in elderly patients.^{80,81}

Famciclovir

Famciclovir is a prodrug that is well absorbed in the gastrointestinal tract and metabolized in the liver to penciclovir. Penciclovir has a chemical structure very similar to that of acyclovir. A placebo-controlled trial of famciclovir in immunocompetent zoster patients more than 18 years old (mean, 51 years old) demonstrated a significantly shorter overall duration of zoster pain in the treated group.⁷³ The proportion of patients with pain at rash healing (the study definition of PHN) was the same in both groups. Of the patients with pain at rash healing (about 54% of the total group), the median duration of PHN was significantly less in the treated group (median time to loss of pain, 60–63 days with famciclovir and 120 days with placebo group, 500-mg dose versus placebo, $p = 0.02$). Similar results were reported in a subgroup analysis of patients over 50 years old. In another trial of immunocompetent zoster patients greater than 18 years old, famciclovir (at doses of 250 mg, 500 mg, or 750 mg three times daily for 7 days) was compared to standard doses of acyclovir.⁸² Famciclovir and acyclovir were equally effective in reducing acute pain and the duration of zoster-associated pain. The efficacy of famciclovir in ophthalmic zoster and the immunosuppressed host is unknown. Famciclovir dosage must be decreased when the creatinine clearance falls below 60 ml/min.

Valacyclovir

Valacyclovir is well absorbed in the gastrointestinal tract and metabolized in the liver to acyclovir, thereby bypassing the poor absorption of acyclovir. Valacyclovir, at 1 g for 7 days ($n = 384$) or 14 days ($n = 381$) was compared to acyclovir in standard doses ($n = 376$) in immuno-

TABLE 71.2. Oral anti-varicella-zoster virus medications.

Name	Active agent	Reduce zoster pain?	Oral dose	Form
Acyclovir	Acyclovir	Yes	800 mg five times daily	Tablet, liquid
Famciclovir	Penciclovir	Yes	500 mg three times daily	Tablet
Valacyclovir	Acyclovir	Yes	1 g three times daily	Tablet

competent zoster patients over 50 years old (mean, 68 years old).⁷² Median days to pain cessation for 7-day valacyclovir was 38 days; for 14-day valacyclovir, 44 days; and for acyclovir, 51 days. The recommended dose is 1 g three times a day, with downward adjustments for renal insufficiency when the creatinine clearance falls below 50 ml/min. A thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome has been reported in severely immunosuppressed patients while taking valacyclovir.⁸³

In summary, antiviral therapy appears to reduce acute pain and the duration of pain in elderly zoster patients who are treated within 72 h of rash onset. The longer the patient presents after 72 h of rash onset, the less sense it makes to prescribe antiviral therapy, unless the patient continues to form new vesicles or has ocular involvement. Acyclovir reduces ocular complications in ophthalmic zoster and organ system complications in the severely immunosuppressed host. The disadvantages of antiviral therapy are marginal or no effect on PHN in some patients, gastrointestinal side effects, and cost. The very early use of antiviral therapy is paramount because days of VZV replication, neuronal destruction, and inflammation have occurred by the time the patient reaches the doctor. Currently available data suggest that acyclovir, famciclovir, or valacyclovir are acceptable agents with factors other than efficacy determining the choice.

Anti-inflammatory Agents

Several well-designed clinical trials of corticosteroids compared to placebo or acyclovir in zoster have shown no significant effect on chronic zoster pain and argue against routine treatment of elderly zoster patients for preventing PHN.^{84,85} The most common adverse effects were gastrointestinal symptoms (dyspepsia, nausea, vomiting), edema, and granulocytosis. Interestingly, corticosteroids reduced acute zoster pain from 2 to 8 weeks after rash onset in most of these trials, although that beneficial effect was not sustained. In the most recent trial, Whitley et al. studied acyclovir plus prednisone ($n = 51$), acyclovir plus prednisone placebo ($n = 48$), prednisone plus acyclovir placebo ($n = 50$), and placebos for acyclovir and prednisone ($n = 52$) in immunocompetent zoster patients of median age 60 to 63 years.⁸⁶ Standard doses of acyclovir were given for 21 days and prednisone was given as 60 mg/day for the first week and tapered over the next 2 weeks. There were no significant differences between the four groups or between prednisone versus no-prednisone groups (hazard ratio, 1.26; 95% confidence interval, 0.91–1.75) in time to cessation of zoster-associated pain. However, time to uninterrupted sleep, return to daily activity, and cessation of analgesic therapy was significantly accelerated in the prednisone versus no-

prednisone groups in this relatively healthy group of 60-year-olds. Therefore, oral corticosteroids may be considered for otherwise healthy older adults with moderate to severe pain and no contraindications to corticosteroids. Some clinicians use corticosteroids for VZV-induced facial paralysis and cranial polyneuritis to improve motor outcomes and pain.

Analgesics

Clinicians should employ analgesics to reduce acute zoster pain regardless of effects on chronic zoster pain. The choice of nonopiate or opiate analgesics depends on the patient's pain severity, underlying conditions, and response to the drug. The principles of excellent pain management, such as scheduled analgesia, use of standardized pain measures, and close follow-up, should be applied to acute zoster pain management as with any other painful condition. If pain control from antiviral agents and analgesics is inadequate, then regional or local anesthetic nerve blocks should be considered. Although there are no randomized controlled trials of this approach for the treatment of acute pain or the prevention of PHN, several published case series have consistently reported acute pain relief from a variety of anesthetic techniques.^{87,88}

The effectiveness of well-managed opiates, regional anesthetic nerve blocks, anticonvulsants, and tricyclic antidepressants in reducing chronic zoster pain is not known but needs to be tested in rigorous clinical trials. In one randomized double-blind study of amitriptyline or placebo during acute zoster in 72 elderly patients, the percentage of patients who were pain-free at 1 and 3 months after rash onset was not significantly different. However, at 6 months after rash onset, 32 (84%) patients in the amitriptyline group were pain-free compared to 22 (65%) patients in the placebo group ($p = 0.05$).⁸⁹ This study was small, the use of acyclovir was unbalanced between the groups, and amitriptyline is a hazardous drug in the elderly. These points argue against using amitriptyline acutely in elderly zoster patients, but the result is interesting and deserves better study with less toxic alternatives.

Nonpharmacologic approaches to zoster pain are also important. Elderly zoster victims need education and reassurance because shingles myths and fears are commonplace. Social support, mental and physical activity, adequate nutrition, and a caring attitude go a long way toward coping with this illness.

Postherpetic Neuralgia

No one treatment is uniformly effective in all elderly PHN patients. Clinicians have employed many treatments for

PHN, but few of these treatments have been evaluated in randomized, double-blind, placebo-controlled trials. However, recent clinical trials indicate that topical lidocaine, gabapentin, opiates, and tricyclic antidepressants can significantly reduce pain in PHN patients.

Topical Therapies

Topical therapies are low-risk interventions that include topical lidocaine, capsaicin, and nonsteroidal anti-inflammatory (NSAID) drugs. The topical lidocaine patch and the topical anesthetic cream EMLA (eutectic mixture of lidocaine and prilocaine) have produced significant pain relief in PHN patients in uncontrolled and controlled clinical trials.⁹⁰⁻⁹³ Galer et al. enrolled PHN patients who were successfully treated with topical lidocaine patches and randomized them to continue the topical patch or receive a vehicle patch for 2 weeks and then cross over to the opposite treatment for 2 weeks.⁹⁴ Patients were allowed to exit either treatment period if their pain relief scores decreased by 2 or more on a 6-item pain relief scale for 2 consecutive days. The lidocaine patch exit time was 14 days and the vehicle patch exit time was 3.8 days ($p < 0.001$), indicating that vehicle-treated patients wanted the active ingredient after a few days. At study completion, 25 of 32 (78.1%) of subjects preferred the lidocaine patch compared to 3 of 32 (9.4%) of vehicle patch recipients. Hence, the topical lidocaine patch provided significantly more pain relief than a placebo patch. The 10 by 14 cm patch contains 5% lidocaine base and other ingredients on a polyester backing. One or more patches are applied over the affected area for 12 h/day. It may take up to 2 weeks to determine whether it is effective. Systemic lidocaine toxicity has not been reported with topical lidocaine preparations. The disadvantages of the patch are application site reactions such as skin redness or rash and substantial cost.

Capsaicin (0.025% or 0.075%), the active principle in hot peppers, has had divergent results in controlled clinical trials and in systematic reviews.⁹⁵⁻⁹⁷ It is difficult to blind patients and investigators because of the burning associated with the treatment. An adequate trial requires 6 weeks of therapy of either the 0.025% or 0.075% concentration applied to the affected area three to four times per day. The utility of the drug is limited by intense burning that becomes tolerable for some patients and unbearable for many others. NSAID creams and aspirin or indomethacin in solution [chloroform, ether, dimethylsulfoxide (DMSO)] are reported to reduce pain in limited studies.⁹⁸⁻¹⁰¹ The extent of clinical benefit from these treatments is uncertain, but these agents deserve further study in large, controlled clinical trials. All topical therapies may be impractical when the involved area of skin is too large or difficult to reach.

Anticonvulsants

Clinicians have used phenytoin and carbamazepine for PHN, but there is little evidence for their effectiveness and they can have significant adverse effects in the elderly. However, there is evidence that gabapentin is effective in reducing the severity of PHN. Rowbotham et al. conducted a randomized, placebo-controlled trial of gabapentin in 229 patients with PHN over an 8-week period.¹⁰² Study participants received an initial dose of 300 mg, and the dose was titrated over a 4-week period to 300 mg tid, 600 mg tid, 900 mg tid, and 1200 mg tid or until intolerable adverse effects. On an 11-point pain scale (0-10), the average daily pain score of treated patients declined from 6.3 to 4.2 compared with a decline from 6.5 to 6.0 in the placebo group ($p < 0.001$). Forty-three percent of the treated group rated their pain as moderately or much improved compared to 12% of the placebo group. On average, treated patients experienced significant improvement in health-related quality of life, sleep, and mood compared to placebo recipients. The adverse effects of gabapentin included somnolence (27%), dizziness (24%), and ataxia (7%). These adverse effects will limit the use of gabapentin in the frail elderly and elderly patients with falls and gait disturbance.

Tricyclic Antidepressants (TCAs)

Five randomized controlled clinical trials of amitriptyline, one trial of desipramine, and one trial of nortriptyline have demonstrated moderate to good pain relief in 44% to 67% of elderly PHN patients.¹⁰³⁻¹⁰⁸ Nortriptyline and desipramine are preferred alternatives to amitriptyline because they cause less sedation, cognitive impairment, orthostatic hypotension and constipation in the elderly. Given the adverse effects of amitriptyline in the elderly and the data supporting its use, Watson et al. compared amitriptyline and nortriptyline in PHN patients using a double-blind crossover design.¹⁰⁸ The two agents reduced pain in roughly 55% of patients but nortriptyline was better tolerated. A conservative dosing regimen of nortriptyline begins with 10 mg at night and increases the dose every 4 to 7 days by the same amount until reduction in pain or intolerable side effects. At least 4 weeks of therapy is required (4-8 weeks recommended) and therapy should be continued for 3 to 6 months if adequate pain reduction.

Opiates

There is increasing evidence that a subset of PHN patients respond to chronic opioid therapy. Small studies of intravenous morphine and oral opioids have reported significant pain relief in PHN.¹⁰⁹⁻¹¹² Watson and Babul conducted a randomized, placebo-controlled, double-

blind, crossover trial of sustained release oxycodone in 38 PHN patients over an 8-week period.¹¹³ The initial dose of controlled-release oxycodone was 10mg every 12h. The dose was increased weekly to 20mg every 12h and to a possible maximum of 30mg every 12h. The results showed significant pain relief in constant, intermittent, and allodynic pain as measured by visual analogue scale and a numerical-verbal 6-point pain scale. Sixty-seven percent of patients expressed marked preference for oxycodone compared to 11% for placebo. The most frequently reported adverse effects were constipation, nausea, and sedation.

Other Modalities

Transcutaneous electrical nerve stimulation (TENS) may be beneficial in some patients and it has little risk.¹¹⁴ The ideal candidate for a TENS trial has truncal or extremity PHN and adequate cognition, vision, and manual dexterity. Some patients derive short-term relief from the application of cold to the affected area. Acupuncture has been used in PHN, but there is little evidence to support its efficacy.^{115,116} Ablative surgical procedures are usually considered for the desperately ill PHN patient who has failed all attempts at medical management. The literature is restricted to case reports or series of limited quality.¹¹⁷ In general, the likelihood of success from surgical procedures appears to be very small whereas the risks are significant. Chronic pain coping strategies, social support, physical activity as tolerated, and a supportive doctor-patient relationship are beneficial for elderly PHN patients.

In summary, available evidence indicates that the lidocaine patch, gabapentin, tricyclic antidepressants (preferably nortriptyline or desipramine), and opiates (e.g., oxycodone) are effective in providing pain relief in a significant number of elderly patients with PHN. The choice for initial treatment depends on patient comorbidity, the drug's adverse event profile, patient preference, and cost. If an adequate trial of the first choice is not effective, then the other agents may be employed. Whether combinations of these agents are superior to single drug therapy is unknown. The chances of pain reduction are likely to be increased if nonpharmacologic principles of chronic pain management are employed. In particular, the value of regular follow-up and a supportive relationship cannot be overstated. If these widely available therapies show no pain reduction after adequate trials, then more specialized treatments are available. Those treatments include regional neural blockade (best if tried <3-6 months of rash onset), spinal cord stimulators, higher-potency opiates (e.g., morphine), and psychologic strategies such as relaxation therapy or cognitive-behavioral therapy. The frontline approaches are in the province of geriatricians but the specialized treatments are probably

best managed in a multidisciplinary pain clinic. These therapies represent a reasonable approach based on available research, clinical experience, and the opinions of PHN experts. This summary does not cover all possible treatments of PHN (there are hundreds), nor will it satisfy every clinician or patient who has their own favorite nostrum.

Prevention

Takahashi et al. developed a live, attenuated varicella vaccine in 1974 by isolating VZV from a child with chickenpox and passing the isolate in human embryonic lung fibroblasts and guinea pig embryo cells.¹¹⁸ The vaccine has been studied carefully for its ability to prevent chickenpox in uninfected children and adults. The vaccine induces protective antibodies and cellular immunity for many years in these individuals. About 85% to 90% of healthy and immunocompromised children and 70% of healthy adults experience long-lasting protection against chickenpox after vaccination.¹¹⁹⁻¹²² In addition, "breakthrough" chickenpox in vaccinees is mild. The vaccine is safe and causes mild, transient side effects of a vaccine-induced rash, sore arm, fever, or fatigue in a minority of vaccinees.

Given that cellular immunity to VZV declines with age, might vaccination of latently infected elderly persons with the varicella-zoster vaccine prevent zoster or postherpetic neuralgia?¹²³ The vaccine induces significant increases in mean anti-VZV antibody levels, interferon-gamma production, T-cell proliferation indices, cytokine secretion, and VZV-specific T-cell responder frequency in the elderly.¹²⁴⁻¹²⁶ Levin et al. reported that, 6 years after vaccination, VZV responder cell frequency was still significantly improved over baseline in 130 individuals aged 55 to 87 years at the time of vaccination.¹²⁷ In this study, 10 herpes zoster-like clinical events were recorded but the patients had little acute pain and no postherpetic neuralgia. Furthermore, the vaccine has been well tolerated, with minor, transient injection site reactions being the most common adverse event. A randomized, double-blind, placebo-controlled Veterans Affairs Cooperative Studies trial is in progress in the United States to evaluate the effects of a more potent formulation of the vaccine on zoster and postherpetic neuralgia in the elderly.

Elder Mistreatment

Terry Fulmer and Maria Hernandez

Elder mistreatment (EM) is a complex syndrome including such actions as abuse, neglect, exploitation, and abandonment of an older person. Such phenomena can be overlooked by clinicians who are not careful to elicit a detailed history and physical to determine the nature of common signs and symptoms, which can be ascribed to aging or disease in old age. In every setting (hospitals, nursing homes, clinics), there is an opportunity to screen, diagnose, and treat cases of elder mistreatment. In this chapter, the authors present an overview of the problem, provide specific screening approaches for different patterns of mistreatment, and discuss intervention protocols for care.

Overview

Elder mistreatment is a form of family violence that takes place in the homes and lives of people every day. Domestic violence is noted to be a major issue in the United States. The goals of Healthy People 2010, the national health promotion and disease prevention initiative, is to increase the quality and years of healthy life and eliminate health disparities.¹ Within that document, domestic violence is addressed within the sections pertaining to age groups (e.g., “infant mortality,” “elder abuse”). There is no overall estimate of prevalence for domestic violence across the lifespan, but instead estimates of different subtypes within age groups.

Family violence encompasses much of what can go wrong among and between individuals in a family or familiar relationship. Physical abuse, financial exploitation, neglect, and abandonment of older adults take place every day.

Elder mistreatment represents an array of interactions between older adults and their caregivers ranging from physical abuse to fatal neglect. It is a part of the constellation of domestic violence that can affect individuals at any point in the lifespan, and it is particularly difficult to

assess in older adults who are likely to have other geriatric syndromes, which may mask or mimic mistreatment. Over the past two decades, mandatory state reporting laws and a heightened sensitivity to the problem have helped clinicians define and channel cases of mistreatment.

Within the broad category of elder mistreatment, four patterns are generally discussed in the literature,² including physical abuse, psychologic abuse, financial abuse, and neglect. Conceptual definitions appear to be consistent but the operational definitions categorize abuse in different ways. For example, Pillemer and Wolf³ note the behavioral category, “withholding of personal care,” is defined in different studies as psychologic neglect, physical abuse, or active neglect. Social scientists have typically used a broader framework than clinicians.

The mistreatment literature is quite compartmentalized. Literature searches on the topic of domestic violence reflect research on mistreatment of women, while child abuse and elder abuse searches come under different terms and, therefore, do not overlap across age groups. Discussion of child abuse and elder abuse take place in specialty journals with little synthesis across the lifespan. This challenge needs to be addressed. Some investigators have begun by looking at widely held beliefs and examining the literature for evidence. In one study, the belief that individuals who are abused as children are more likely to abuse their own children was examined. Studies published between 1965 and 2000 were reviewed. In 10 studies, the relative risk (RR) of maltreatment in children was significantly increased (RR 4.75–37.8), whereas in 3 others the relative risk was less than 2 and not significant. A number of methodologic flaws were discerned across the studies, and none examined mistreatment across the lifespan within families, which needs to be done.⁴ Currently, however, it appears from the evidence that a relationship exists between child abuse and abusing one’s own child. Lifespan studies will help place knowledge of elder mistreatment in a context and frame-

work that can help create more appropriate treatment plans.

Sites of Care

Most older adults live independently or at home with care supports from family or social services. Fewer than 2 million older adults reside in nursing homes, and most do so when they are infirm or at a very advanced age. The discussion of elder mistreatment, therefore, is a discussion, in most cases, of mistreatment in the home setting. Cases come to the attention of authorities and agencies when these older adults come to a point of contact such as the office, the clinic, or the hospital emergency room.

Community Settings

According to Tatara,⁵ abuse in domestic settings is widespread and affects thousands of vulnerable elderly people across the country. Pillemer and Finkelhor⁶ estimated that only 1 of about 14 domestic elder abuse cases comes to the attention of authorities. Data from the National Elder Abuse Incidence Study (NEAIS)⁷ reported approximately 450,000 new cases of abuse and neglect in adults over age 60 in 1996,⁸ all community-dwelling elders. This study used a sentinel approach with a random sample of counties across the nation to detect new cases. Prevalence data for EM came from a random sample survey conducted in the metropolitan Boston area in 1986. In that survey, Pillemer and Finkelhor surveyed more than 2000 older persons and reported 700,000 to 1.2 million annually.⁶

Primary care of the elderly takes place in private offices and clinics. Elder mistreatment screening is thought to take place here, but there are few data-based studies to support this. In health department prenatal clinics, incorporation of an abuse assessment protocol into the routine procedures increased the assessment, identification, and documentation of and referral for abuse among pregnant women. Evaluation was conducted at three matched prenatal clinics; two clinics used the abuse protocol and one did not. An audit was performed at the clinics on a randomly selected sample of 540 maternity patient charts for the 15 months before the protocol was initiated and the 540 records for the 15 months after the protocol was introduced. At the clinics using the protocol, abuse assessment increased from 0% to 88%. Detection of abuse increased from 0.8% to 7%. There were no changes at the comparison clinic. The authors suggested that an abuse protocol should be a routine part of maternity care. The obvious parallels and opportunities for elder abuse screening and detection are apparent.

Emergency departments (EDs) have been noted to be key clinical settings for screening for elder mistreatment.^{4,9-13} Older adults may wait until they are extremely overwhelmed or debilitated before coming forth and seeking the help of EDs at that time. Emergency departments are often the first point of contact for elder neglect victims. The prevalence is not clear; however, in one study,¹⁴ 3153 consecutive visits to the ED over a 6-month period were retrospectively reviewed for abuse and neglect. The records for every person 70 years or older were reviewed daily to detect any suspicion for abuse or neglect as noted by the ED nurses who were specifically trained in elder mistreatment detection. The 3153 visits were made by 2175 people. Of these, there were 127 cases of elder mistreatment (4%). Delirium and dementia were found to be risk factors for EM. In another study, of 182 elder victims of physical abuse who were identified over a 7-year period, 114 (62.6%) were seen in an ED at least once during a 5-year window surrounding the initial identification of abuse. These 114 persons accounted for 628 visits (median, 3; range, 1-46) and 30.6% of the visits resulted in hospital admission. Clearly, EDs are extremely important for the initial screen for EM.

Elder neglect protocols appear to be feasible in busy emergency departments, and neglect can be accurately detected by nurses when screening procedures are in place. In an ED pilot study which focused on neglect, ED nurses received special training and their ability to conduct accurate screening protocols for elder neglect in the context of their busy practice was measured. During a 3-week period, 180 patients older than 70 years of age (90% of all possible elderly patients during the screening hours) were screened to determine if they met the study criteria and could be enrolled into the protocol. Thirty-six patients met the eligibility criteria to enroll in the study, and 7 patients screened positive for neglect by a home caregiver. The nurses were able to screen and detect elder neglect with more than 70% accuracy according to the "gold standard" of the Neglect Assessment Team. Sensitivity was 71%, and specificity was 93%.

Nursing Home Mistreatment

Nursing homes demonstrate different types of mistreatment. There may be abuse or neglect by staff or by other patients. The Omnibus Budget Reconciliation Act (OBRA) of 1987¹⁵ clearly states that abuse in nursing homes will not be tolerated. Since this act, cases on abuse in nursing homes have gone to trial and have been won. National standards for care in nursing homes are based on public policy set forth in the Nursing Home Reform Act of 1987 (Public Law 100-203; Social Security Act, Title C). This law, as part of OBRA, became effective October 1990. The intent of the law and its regulation is

to promote high-quality care and to prevent substandard care, abuse, and neglect. Nurses and other health care providers, including M.D.s, are identified by many states as the professionals who must report suspected abuse and neglect to state officials. Failure to report is usually a misdemeanor and may be punishable by a fine or penalty, although it is clear that punishment alone will not improve reporting. It is when clinicians believe that reports make a difference in care going forward that they readily comply with mandated reporting.¹⁶

Pillemer and Bachman-Prehn,¹⁷ through a literature review of characteristics that predict abuse in nursing homes, found that (1) quality of care increases with the number of beds in a nursing home; (2) nonprofit homes are superior to proprietary homes for medical and personal care; (3) nursing home costs and better service were positively related; (4) nurses and nursing aides with lower levels of education tend to be more abusive than those with higher levels of education; (5) younger staff held more negative attitudes toward older people; (6) nurses were more empathetic toward the residents than nursing aides (or assistants); and (7) staff who work for a long time with older people have fewer negative attitudes toward the elderly. The nursing staff, especially nurses' aides, may have little training in dealing with the problems of institutionalized elderly persons. Sometimes there are ethnic, cultural, or linguistic barriers to good care. The high turnover rate of nurse's aides reflects the high stress of the job, the low pay, and low morale. Prevention of staff burnout lessens the likelihood of institutional elder abuse. Sometimes there is a fine line between protective restraint and abusive or unnecessary restraint. Providing education for employees and a means for ventilating pent-up frustrations reduces elder abuse and minimizes staff turnover in nursing homes.¹⁸

A random sample survey of 577 nurses and nursing aides working in long-term care facilities sought to determine the extent of abuse by nursing home staff. Data suggested that abuse by nursing aides was a prevalent phenomenon within the facilities selected. Of the sample surveyed, at least 23% had observed abuse by a staff member. In addition, 10% of the respondents had self-reported that they committed at least one physically abusive act, and 40% self-reported that they committed at least one psychologically abusive act over the past year.¹⁹ Patient-to-patient abuse can also take place, especially in the context of dementia and mental illness.

Risk Factors

Risk factors can be divided into characteristics of the victim, the abuser, and the situation in which both find themselves.

Victims

Particular groups of elderly people have been identified as having a greater risk for abuse than the general public. Studies have described the demographic, physical, and mental characteristics of older adults who are at risk.^{3,6,20} It appears that those more likely to be EM victims are very old, female, and in poor physical and mental health. Situational factors that increase the risks of victimization include poor social support, low income, and dependency.

Longitudinal risk factors for abuse and neglect in community-dwelling older adults were examined by linking an established cohort of community-dwelling older adults ($n = 2812$) to the elderly protective service database over a 9-year follow-up period.²¹ Protective services saw 184 (6.5%) individuals in the cohort for any indication of mistreatment and 47 for abuse and neglect, for a sampling prevalence of 1.6% (95% CI 1%, 2.1%). In a pooled logistic regression, age, race, poverty, functional disability, and cognitive impairment were identified as risk factors for reported elder mistreatment. However, the authors carefully noted that because of the mechanism for case finding (a social welfare system), the race and poverty risk factors were likely overestimates due to a reporting bias.

Another study examined the characteristics of abused or neglected patients to compare the prevalence of depression and dementia in neglected patients with that of patients referred for other reasons. Using a case-control approach in a large academic hospital-based geriatric clinic, 47 older persons were referred for neglect and 97 were referred for other reasons. Comprehensive geriatric assessment with standard geriatric assessment tools was used in this study. There was a statistically significant higher prevalence of depression (62% versus 12%) and dementia (51% versus 30%) in victims of self-neglect compared to patients referred for other reasons. No overall prevalence of mistreatment was given for the clinic. The authors concluded that geriatric clinicians should consider elder neglect or abuse in their depressed or demented patients.¹¹

Abusers

Abusers are most often care custodians, employees of the facilities, or children of the abused.^{6,19,22-24} These are the individuals with greatest contact with the abused. Theories for why EM might occur have provided some guidance to clinicians in terms of anticipating when these relationships may result in EM. They are briefly reviewed here.

The social learning or transgenerational violence theory contends that violence is learned. Espoused by child abuse experts, this theory contends that abused children grow up to abuse their own children; extended to elder abuse, it further espouses that abused children grow up to abuse their parents as well. As noted earlier, there

are no data to support this theory; only anecdotal case evidence exists. The stressed caregiver theory contends that elder abuse and neglect occur when stresses in the caregiver's life become overwhelming (either from caregiving or external sources) and cause the caregiver to act in abusive or neglectful ways toward the older adult. The isolation theory asserts that a shrinking social network is the major risk factor for elder abuse and neglect, in that no one is able to evaluate the well-being of the older person on a regular basis until it might be too late. The dependency theory holds that functional frailty and medical illness set the stage for EM, because care demands will eventually exceed care resources and set the stage for inadequate care. Finally, the psychopathology of the abuser theory focuses on caregivers who have mental health impairment, such as substance abuse, mental retardation, or some other psychiatric diagnosis. These individuals may not be able to provide appropriate care.²⁵ All these theories are in need of research to determine which aspects, if any, are supported by data.

Situations

According to Fulmer and O'Malley,²⁶ some of the high-risk situations, as experienced from clinical practice, that result in EM are these:

1. Persons with chronic progressive, disabling illnesses that impair function and create care needs that exceed or will exceed their caretaker's ability to meet them, such as dementia, parkinsonism, severe arthritis, severe cardiac disease, severe chronic obstructive pulmonary disease (COPD), severe adult onset diabetes mellitus (AODM) and recurrent strokes.
2. Persons with progressive impairments who are without informal supports from family or neighbors, or whose caretakers manifest signs of "burnout."
3. Persons with a personal history of substance abuse or violent behavior or a family member or caretaker with the same problem.
4. Persons who live with a family in which there is a history of child or spouse abuse.
5. Persons with family members who are financially dependent on them.
6. Persons residing in institutions that have a history of providing substandard care.
7. Persons whose caretakers are under sudden increased stress, caused by, for example, loss of job, health, or spouse.

Diagnosis and Differential

Symptoms of elder mistreatment may result from physical, psychological, financial, or material abuse or neglect, or any combination of these.

The natural history of chronic and acute illness in the elderly may mask the presence of abuse or neglect because it is difficult to determine whether the elderly person's worsening physical condition is due to the natural progression of illness or to omissions or active interventions on the part of a caretaker.²⁶ The interdisciplinary team approach is the most thorough way to avoid overlooking a case of elder mistreatment. One assessment instrument can be found in the appendix, the Fulmer Elder Assessment Instrument.²⁷ This valid and reliable instrument is used to screen individuals who are suspect for EM.^{26,26}

The following observations should raise the index of suspicion that elder abuse has occurred. The caregiver may (1) show a loss of control or fear losing control, (2) present a contradictory history or one that does not or cannot explain the injury, (3) project the cause of injury onto a third party, (4) delay bringing in the elderly person for care, (5) overreact or underreact to the seriousness of the situation, (6) complain continuously about problems that are unrelated to the injury, and (7) refuse consent for further diagnostic studies and remove the patient from the facility. Because some frail elderly persons are prone to underlying conditions (instability of gait, poor vision, and frequent falls) that give rise to trauma, it may be difficult to differentiate accidental from willful injuries. The simultaneous presence of fresh and healing injuries suggests ongoing episodes of trauma, and elder abuse should be considered in the differential diagnosis.

Clinical assessment of EM is made complex by the variations across cultures and groups regarding what constitutes acceptable behavior. Differences in the way people define quality of life, survival needs, and well-being are widespread. Difficult ethical issues are frequently inherent in describing elder neglect and abuse. What if the older person asks the clinician to keep the abusive situation confidential? What if the choice is to return to a dangerous situation? What if there is beginning cognitive impairment, which is not yet impairing function, yet presents issues for decision making? All these complex and disturbing questions are best answered within a team approach where interdisciplinary members can come together with the patient, either in person or telecommunication, to review and evaluate strategies that can improve the situation. Each case is highly individual. Safety and security measures for one person may be perceived as threatening or restrictive to another person. The elderly person's perception of a situation as abuse, abusive, or nonabusive may further influence their perception of whether or where they would seek help in that situation. In one study, Caucasian, African-American, and Korean women were surveyed using case studies as to what they thought constituted abuse. Korean women were least likely to perceive abuse while African-American women were most likely to perceive abuse.²⁸ Given that it is unlikely that there will be

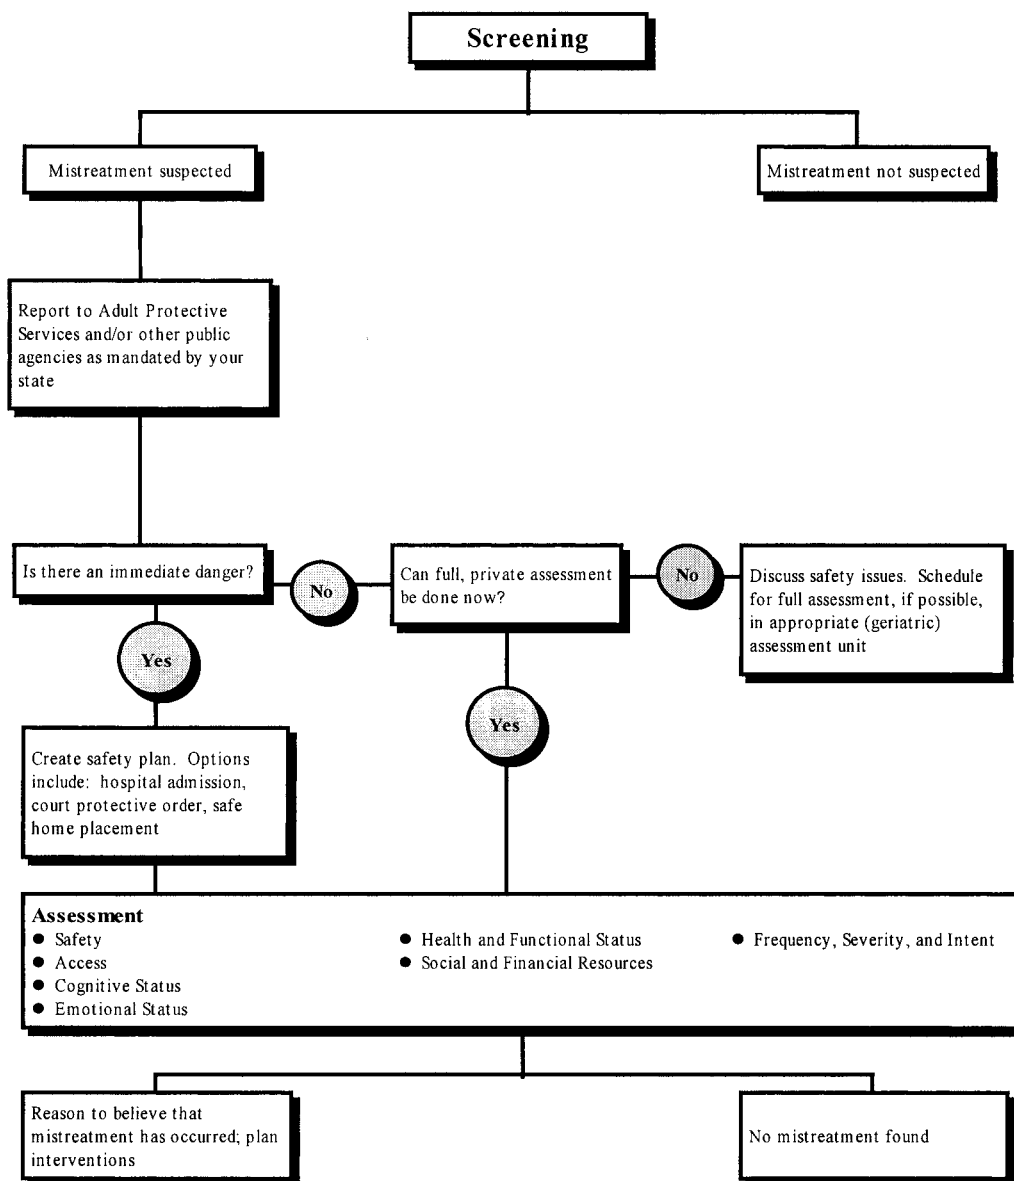

FIGURE 72.1. **Intervention and case management: part 1.** Screening and assessment for elder mistreatment should follow a routine pattern. Assessment of each case should include the

a universal definition that is accepted by all cultures, it is essential that clinicians be aware of the values and cultural beliefs of those for whom they care. Clinicians must also be prepared to use principles of ethical decision making as guidelines for screening and intervention.

Intervention and Treatment

Clinicians have relied on their professional associations to help guide practice protocols. The American Medical Association²⁹ guidelines summarize the clinical approach

to screening and assessment of EM and have developed particularly useful algorithms to help clinicians decide how to develop care plans for those who might be mistreated (Figs. 72.1, 72.2). It is important to note that algorithm 1 indicates screening approaches whereas algorithm 2 indicates intervention approaches.

The focus of intervention and treatment is on maintaining the independence and functional capabilities of both the abused elderly person and their family or support system. Interdisciplinary teams ensure a variety of perspectives from which to consider potential problems and solutions.³⁰ Institutionalization may be the

FIGURE 72.2. **Intervention and case management: part 2.** Case management should be guided by choosing the alternatives that least restrict the patient’s independence and decision-making responsibilities and fulfill state mandated reporting requirements. Intervention will depend on the patient cognitive status

and decision-making capability and on whether the mistreatment is intentional or unintentional. (Reprinted with permission of the American Medical Association. *Diagnostic and Treatment Guidelines on Elder Abuse and Neglect*, 1992:14.)

solution to the problem in cases where abuse is a reflection of a need for care that outstrips the caregiver’s ability to provide it. Great care should be taken before this action, however, as the tensions that potentiate elder abuse may be ameliorated through improved in-home services such as the visiting nurse service, social services agencies, or Meals on Wheels. Sending services into the home also provides trained outsiders who watch and are able to offer informal counseling and support.

Most states have legislation that addresses elder mistreatment; such statutes are usually contained in adult

protective service or domestic violence legislation. Protective services laws with provisions for reporting EM are in place in all 50 states and the District of Columbia.³¹

Summary

Elder mistreatment is a significant clinical problem, and clinicians have an important role in assessing, detecting, referring, and care planning for these victims. The medicalization of the elder mistreatment research portends

very favorably in increasing the number of providers available to intervene in a rapid fashion. Research needs to be conducted in the sensitivity and specificity of EM questions in the clinical setting. In the meantime, clinicians who ask, "Is there any abuse in your home?" will help address this serious issue. Vigilance in assessment and avoidance of labeling signs and symptoms as sequelae of aging are essential.

Frailty

Linda P. Fried, Jonathan Darer, and Jeremy Walston

Clinical Import and Definition of Frailty

Older patients who are frail have been described as the central focus of the practice of geriatric medicine, as they are thought to be the subset at highest risk for adverse outcomes. These outcomes range from falls to dependency, hospitalization, and mortality. Frail patients are the target group for a number of geriatric health care delivery systems, including geriatric assessment. Effective delivery of care to frail older adults has been described as the major challenge to medicine in the twenty-first century.¹

Remarkably, given the centrality of frailty to the practice of geriatric medicine, a standardized definition has been challenging to achieve. Practitioners and researchers have historically assigned a broad range of meanings to “frailty,” from referring to the very old (80 or 85 and older), to those with comorbid diseases, or to the presence of disability and dependency as frailty. Frequently, frailty has been used interchangeably with disability. However, recent work suggests that frailty is likely etiologically related to each of these states but is not identical to them.

The Clinical Syndrome of Frailty

Growing evidence suggests that frailty is a biologic syndrome of decreased reserves in multiple systems that results from dysregulation that can occur with aging and is initiated by physiologic changes of aging, disease, and/or lack of activity or inadequate nutritional intake. It is thought that these changes are manifested in loss of skeletal muscle mass and bone, and in abnormal function in inflammatory, immune, and neuroendocrine systems, as well as in energy regulation; this results in homeostenosis, or a decreased range of physiologic responses available to maintain homeostasis. It is hypothesized that the

underlying system dysregulation might be latent in a non-stressed state, becoming clinically apparent when the system is stressed, for example, by extremes of temperature, infection, or injury. These hypotheses as to the physiology of frailty could explain the clinical picture of frail older adults being vulnerable to stressors, whether endogenous or exogenous, and, through this vulnerability, to the outcomes described above that are clinically associated with frailty.

Although these physiologic alterations may be the underpinnings of frailty (described further below), the clinical presentation, or phenotype, of frailty before the development of adverse outcomes appears centered around weight loss or sarcopenia (loss of muscle mass with aging), resulting weakness, low exercise tolerance or endurance, slowed task performance (such as walking speed), and low activity levels.²⁻⁴ More end-stage frailty is thought to also include biochemical abnormalities consistent with a wasting syndrome, including hypoalbuminemia and hypocholesterolemia.⁵ In a survey of U.S. geriatricians, 97% indicated that clinically apparent frailty involves more than one characteristic being present,⁶ consistent with the definition of a syndrome. The consensus, in this survey and the geriatrics literature, is that this syndrome presents clinically with at least several of the manifestations described here, not including the biochemical abnormalities, in most frail, community-dwelling older adults. There is strong evidence in the literature for pairwise associations between most of these symptoms and signs, suggesting that they may be related in a cycle of frailty (Fig. 73.1).^{4,7} This cycle of physiologic decline is hypothesized to be the basis for the phenotype of frailty in older adults. Clinically, such a cycle appears self-perpetuating once initiated, ultimately leading to a spiral of decline and death.

The components of the cycle of frailty are laid out in Figure 73.1—undernutrition, sarcopenia and weight loss, weakness, lower exercise tolerance, slowed motor performance, and low activity levels. These factors may com-

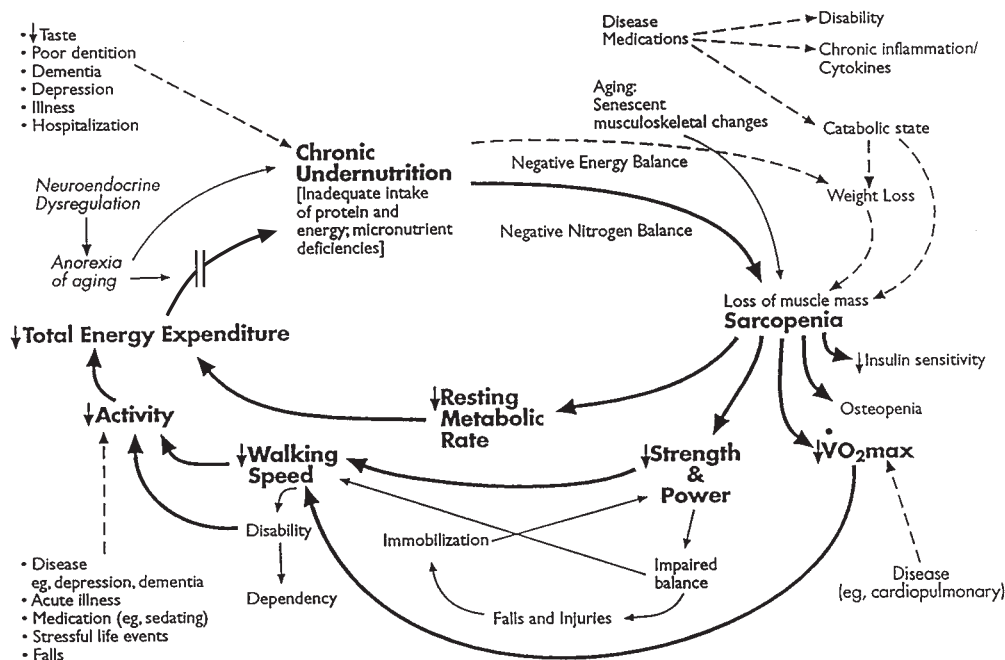

FIGURE 73.1. Cycle of frailty, integrating known pairwise causal relationships between symptoms and signs. Factors central to the cycle are indicated in *bold*. Potential etiologic causes and outcomes are also indicated. (From Ref. 3, with permission)

prise a clinical phenotype of the geriatric syndrome of frailty. A study was conducted to validate whether these components were found in community-dwelling older adults, and whether they, together, predicted a group at high risk of adverse outcomes that geriatricians clinically associate with being frail. To this end, community-dwelling adults 65 years and older in four U.S. communities who were participating in the Cardiovascular Health Study (CHS) were assessed for each of the characteristics described here.⁴ Using the criteria of having three or more of five criteria being present to constitute frailty (Fig. 73.1, Appendix), 6.9% were found to be frail; the 3-year incidence of frailty was 7%. Frailty increased dramatically with age, being present in 3% of those 65 to 70 years of age and increasing to 26% of those 85 to 89. Frailty was more prevalent in women (7%) than men (5%) in the predominantly Caucasian cohort, whereas in a second, smaller group of African-Americans, frailty was twice as frequent as in the first group, found in 14% of the women and 7% of the men. The higher rates of frailty in women are thought to be because women have a lower lean body mass initially, suggesting that loss of muscle mass with aging would lead them to cross a threshold associated with increased vulnerability more rapidly than would men.⁸ Those who were frail in this cohort were at high risk of mortality, falls, hospitalization, and incident or worsening disability, compared to those with none of the frailty manifestations. As seen in Table 73.1, there was a 1.3- to 2.2-fold increased risk of each of these outcomes, after 3 years, for those who were frail at the initial eval-

uation, adjusting for a number of other diseases and health conditions. Thus, this clinical presentation or phenotype of frailty identifies a high risk group of older adults. The screening criteria for frailty based on this phenotype are provided in the Appendix. Future work will offer alternative approaches to identifying those who are frail, with the approach that is ultimately most useful being the one that detects those at highest risk.

Association of Disability and Comorbidity with Frailty

As stated initially, frailty has often been used in the literature as synonymous with disability and comorbidity. Increasing evidence suggests, rather, that these conditions are etiologically related, with frailty being a cause of disability, whereas both comorbidity and disability may exacerbate frailty itself. Support for distinguishing frailty from disability comes, in part, from a survey at six U.S. medical schools which found that 98% of geriatricians thought that frailty was different from disability, with 40% supporting the idea that frailty was usually or always a cause of disability and 13% indicating that they thought disability would also cause frailty.⁶ Additionally, the individual components of the frailty phenotype (see Fig. 73.1) are each, separately, known to predict the development of disability in mobility and activities of daily living (ADLs); this further suggests that the aggregate syndrome of frailty might, itself, be a powerful predictor of

TABLE 73.1. The phenotype of the syndrome of frailty identifies older adults at high risk of adverse geriatric outcomes: Hazard ratios (HR) estimated over 3 years for frail versus nonfrail^a

Outcome	Frail (vs. nonfrail) ^a
Incident fall	Unadjusted HR = 2.06 CI = (1.64–2.59) <i>p</i> < 0.0001
	Covariate adjusted HR = 1.29 CI = (1.00–1.68) <i>p</i> = 0.054
Worsening mobility	Unadjusted HR = 2.68 CI = (2.26–3.28) <i>p</i> < 0.0001
	Covariate adjusted HR = 1.50 CI = (1.23–1.82) <i>p</i> < 0.0001
Worsening ADL (= disability)	Unadjusted HR = 5.61 CI = (4.50–7.00) <i>p</i> < 0.0001
	Covariate adjusted HR = 1.98 CI = (1.54–2.55) <i>p</i> < 0.0001
First hospitalization	Unadjusted HR = 2.25 CI = (1.94–2.62) <i>p</i> < 0.0001
	Covariate adjusted HR = 1.29 CI = (1.09–1.54) <i>p</i> < 0.004
Death	Unadjusted HR = 6.47 CI = (1.09–1.54) <i>p</i> < 0.004
	Covariate adjusted HR = 2.24 CI = (1.51–3.33) <i>p</i> < 0.0001

Note: Covariate adjustment includes age, gender, indicator for minority cohort, income, smoking status, brachial and tibial blood pressure, fasting glucose, albumin, creatinine, carotid stenosis, history of CHF, cognitive function, major ECG abnormality, use of diuretics, problem with IADLs, self-report health measure, CES-D modified depression measure.

^aFrail is defined as three or more of the following factors being present: weight loss, weakness, exhaustion, slow walking speed, and low physical activity (see Appendix for definitions).

developing disability in tasks requiring strength, mobility, or exercise tolerance. This expectation is supported by the findings in Table 73.1, after adjusting for the major diseases present (both clinical and subclinical), age, gender, baseline disability level, health habits, and depressive symptoms. Thus, it appears that disability may result from frailty. These different clinical states are etiologically related, but distinct.

Regarding the role of comorbidity in frailty, it has been hypothesized that frailty is a wasting syndrome that *can*

occur as the end stage of a number of chronic diseases (e.g., congestive heart failure, certain cancers), as well as the consequence of cumulative physiologic changes of aging; this would constitute secondary frailty. This biologic hypothesis differs from other contentions that frailty and comorbidity are the same. As with disability, this was assessed in the CHS study already mentioned, where it was found that those who were older and had more comorbid disease had higher rates of frailty, although 7% of those who were frail had no major diseases and about 25% had only one. The latter group may well represent primary frailty. Additionally, the presence of frailty was associated with higher rates of depressive symptoms and with lower Mini-Mental scores (between 18 and 23), providing some insight into other possible causes.⁴ In a work by Newman et al.⁹ evaluating this same cohort, subclinical and clinical cardiovascular diseases, including infarct-like lesions on brain MRI scan, were associated with the phenotype of frailty. This finding suggests that the extent of atherosclerosis may be a precipitant of frailty, or that the decreased physiologic reserve caused by cardiovascular disease, or other related mechanisms such as inflammation, may be intermediary causes of frailty. Thus, older age and chronic diseases may be etiologic risk factors for frailty, whereas frailty itself may lead to disability in mobility and exercise tolerance-demanding tasks.

The Physiology, Natural History, and Continuum of Frailty

It is likely that frailty includes a range of severity—and reversibility—of physiologic changes. Hypothetically, there is progressive dysregulation of physiologic systems with aging, including sarcopenia or loss of lean body mass, chronic inflammation, immune system compromise, and altered function of the neuroendocrine axis (Table 73.2). These changes may be etiologically interrelated, themselves (Fig. 73.2).⁷ To date, no study has evaluated all these potential etiologies together in a frail population. However, several systems have been individually studied in older, compared to younger, persons, and provide supportive evidence that age-related changes in both the neuroendocrine and the immune systems may influence the development of frailty. For example, there

TABLE 73.2. Age-related alterations in neuroendocrine and immune system markers that may influence the development of frailty.

is a clear, age-related decline in growth hormone, its major messenger molecule IGF-1, and dehydroxyepiandrosterone (DHEA-S),¹⁰ and these declines are related to loss of muscle mass and strength. In addition, the sex steroids estrogen and testosterone clearly affect muscle mass maintenance, and the age-related decline in these hormones correlate with strength loss. Age-related alterations in the hypothalamic–pituitary–adrenal (HPA) axis, along with related increased inflammation, have also been hypothesized to contribute to the development of frailty.¹¹ Cortisol secretion appears to be moderately increased in older, compared to younger, adults, and there is some evidence that HPA reactivity to stress is increased in older adults.¹⁰ Long-term elevations in cortisol levels have been associated with increased insulin resistance, increased rates of osteoporosis and hip fracture, and memory decline. These elevations may contribute to inflammation, which itself may contribute to frailty. High levels of IL-6 downregulate genes important in muscle mass maintenance and act to amplify production of norepinephrine and cortisol via increased HPA axis activity. Based on etiologies of altered body composition in individuals with rheumatoid arthritis, Roubenoff and Rall proposed that age-related losses of lean body mass and strength are influenced by inflammatory cytokines.¹² Frailty appears to present a similar picture. Several recent population studies have also suggested that elevations in the inflammatory cytokine IL-6 predicts functional decline and early morbidity and mortality.^{13,14} These relationships likely contribute to the development of frailty.

More inclusively, Lipsitz et al. posited that there is a decrease with aging, in a number of systems, in the range of responses that are available physiologically to respond to stressors; one example is the decreased complexity of heart rate response with aging.¹⁵ Lipsitz suggests that the aggregate alterations across systems may underlie the clinical vulnerability of frail older adults. Changes at the molecular level may also contribute to the decreased reserve of those who are frail. Even more theoretically, Bortz has proposed a “physics of frailty,” postulating a loss of functional competence at a cellular level, with

thermodynamic decline and a loss of cellular energy stores predisposing to generalized physiologic decline.¹⁶ There is some early evidence that such subclinical changes may not be apparent in the static state, but may be manifested under stress; this has been observed for cortisol responses to a stressor, as already mentioned.¹⁷ However, this has not yet been demonstrated in frail older adults. Buchner and Wagner suggested that a reduced physiologic reserve plus decreased neurologic control and lower energy metabolism, in the presence of a specific physiologic trigger (see following), leads to frailty.¹⁸ Such aggregate declines in reserve across multiple physiologic systems could lead to a subclinical stage of frailty manifesting as decreased ability to maintain homeostasis in the face of stressors such as acute infection. This change would confer greater vulnerability to poor outcomes for patients with such physiologic alterations.

A cycle of frailty, suggested in Figure 73.1, could potentially be initiated at any of multiple points, thus precipitating the transition from a preclinical toward a clinically apparent state. There is evidence from the study performed to validate the frailty phenotype described here⁴ that the presence of only one or two of the major components of the phenotype of frailty does predict development of the full syndrome (with three or more components present) over 3-year follow-up, and also carries an increased risk of the same adverse outcomes listed in Table 73.1, but with weaker associations than the full frailty syndrome. This evidence suggests that there is a prefrail stage that is associated with some risk, even though not yet clinically apparent as frailty. It is possible that this stage is the most remediable.

On the extreme end of the continuum of frailty, an end-stage presentation has been termed “failure to thrive.” This stage has been described as including unexplained weight loss, wasting, dependency, and possibly cognitive impairment.⁵ Signs include hypocholesterolemia and hypoalbuminemia, both known predictors of mortality.^{5,19} Studies of hospitalized patients with these characteristics indicate that this is frequently a nonreversible stage that presages death and identifies patients often not able to

participate in therapy, such as rehabilitation.²⁰ Therapeutic interventions appear unlikely to reverse this presentation or the outcomes, and the goals of treatment are generally stabilization and comfort care.

Acute Precipitants of Frailty

Although the biologic basis of frailty may develop slowly and progressively, Buchner and Wagner¹⁸ suggested that it may develop clinically in a stepwise process, with increments of decline precipitated by acute events, such as an infection or injury. Acute illness is often associated with a period of bed rest and undernutrition, with resulting loss of muscle mass, strength, and conditioning. According to Buchner's proposal, incomplete recovery from an illness, perhaps through inadequate rehabilitation or another acute illness before the period of recovery is complete, puts the individual at risk for still more decline with another insult. This scenario has clinical face validity and is consistent with the evidence for a prefrail stage, as mentioned. If correct, it suggests that it is critical to maximize recovery of strength and function after an acute illness.

Some diseases may contribute to frailty through direct biologic pathways, such as a potential role of atherosclerosis or inflammation. Other diseases could potentially trigger the onset of the cycle of frailty (see Fig. 73.1) by affecting the key components of the phenotype itself: nutritional status, muscle wasting, exercise tolerance, or activity level. For example, depression or congestive heart failure could each lead to both decreased dietary intake and low physical activity. Additionally, it is possible that medications could worsen frailty status, for example, through appetite suppression, increasing inflammation affecting muscle wasting, or lassitude affecting activity levels.

Diagnostic Approaches to Frailty

To decrease the high levels of morbidity and mortality observed in frail older adults, a more consistent diagnostic approach to the identification and management of the frail older adult needs to be developed and put into clinical practice. A diagnostic approach based on signs and symptoms of frailty, rather than either targeting just comorbidity or disability or awaiting the outcomes of frailty, has emerged in the past few years. Chin et al. identified weight loss and inactivity as important criteria in the identification of frail, older adults and provided validation by demonstrating higher levels of mortality and functional decline in that same study.² Fried et al. have validated a more specific phenotype of frailty described previously, which is diagnosed by three or more of five criteria: weight loss, low grip strength, low levels of phys-

ical activity, subjective exhaustion, and slow walking speed⁴ (see Appendix). Whatever approach is used, a screening phenotype will only identify clinically manifest frailty. The subclinical or prefrail stages described here may mark a less-advanced but still vulnerable group, wherein early identification of declines in weight, strength, dietary intake, walking speed, or activity could make a difference in outcomes.

Differential Diagnosis of Frailty

When considering the prevention and treatment plan for clinical care for the frail older adult, it is important to keep in mind the numerous medical illnesses with a cachectic component that may either mimic or trigger frailty.²¹ Frailty is, in part, a wasting syndrome of complex etiology, one that can coexist with acute and chronic disease. It is therefore frequently challenging to differentiate the wasting caused by a specific disease state from the wasting of frailty. Because signs and symptoms of all wasting syndromes often include weight loss, declines in strength and physical activity, and physical exhaustion, it is important that a full differential diagnosis of wasting syndromes that may mimic frailty be considered (Table 73.3). Severe congestive heart failure or cardiac cachexia has a well-described wasting syndrome associated with it. Cachexia related to occult malignancies is also common in older adults. Many connective tissue or collagen vascular diseases can be accompanied by a wasting syndrome, including rheumatoid arthritis and polymyalgia rheumatica. Chronic infections can also lead to wasting. Major depression can also present with several of the classic signs and symptoms of frailty. All these disorders are potentially treatable and must be ruled out in any older adult who presents with wasting symptoms. Because many of these disorders may well trigger the apparently independent and self-perpetuating syndrome of frailty as well as wasting syndromes in their own right, aggressive management of these disorders may slow the corresponding functional and medical declines that lead into the cycle of frailty (see Fig. 73.1).

TABLE 73.3. Differential diagnosis of common chronic diseases of older adults that have wasting features that can mimic or trigger frailty.

Congestive heart failure
Occult malignancy
Chronic infection

Parkinson's disease

Treatment of Frailty

The physiologic and functional vulnerability of frail, older adults should be used to guide their clinical management. Most frail older adults have numerous medical problems, many of which present atypically. The diagnosis and management of these medical problems must be addressed, selecting treatment in context with the overall physiologic and functional tolerance for their treatments, including special attention to altered pharmacokinetics and higher risk for complications in this population. In addition, numerous social, psychologic, and functional issues profoundly affect the health status of frail older adults and need to be included in any comprehensive treatment plan.

Independent of treatment for the numerous medical illnesses that can coexist with frailty, several groups of investigators have evaluated exercise and nutrition as potential treatments for frailty. Most studies have clearly shown a benefit of strength training exercise in improving strength and functionality in frail, older adults.^{22,23} Evans has reported that high-intensity strength training has highly anabolic effects in older adults. He reported a 10% to 15% decrease in nitrogen excretion after initiation of such training, which persisted for the 12-week duration of training.²⁴ In other words, progressive resistance exercise improved nitrogen balance. As a result, older patients performing resistance training had a lower mean protein intake requirement than did sedentary subjects. Tai Chi has also proven beneficial in the prevention of falls and injuries in older adults who practice it on a regular basis, perhaps having similar effects.²⁵ Nutritional interventions are less clearly indicated in frail older adults, at least when they are the only intervention.²⁶ Poehlman et al. have shown that older men and women must increase energy expenditure by 1000 kcal per week to obtain compensatory increases in energy (food) intake and increases in resting metabolic rate.²⁷ Indeed, there appears to be minimal physiologic response to increased protein calorie nutrition in frail persons unless it is done in conjunction with an exercise program.^{23,26,27} A benefit to functional outcomes was suggested in a cohort of very old, frail adults through combining strength training exercises and increased nutrition.²³

The endocrine system has long been proposed to play a role in the development of frailty, and there have been a number of endocrinologic intervention trials seeking to improve muscle mass or strength in older adults. In part, such trials have been based on observations of age-related declines in hormone levels, such as declines in testosterone levels identified in older men. However, no direct relationship of *age-related* decline in testosterone levels to strength has ever been demonstrated. While the replacement of testosterone in *hypogonadal* younger and older men has proven effective in increasing muscle mass and strength, no study has clearly demonstrated a benefit of

testosterone for the treatment of frail, older men with normal, age-related declines in testosterone. Growth hormone and its major messenger molecule IGF-1 have also been extensively studied in older adults, and a number of interventions have been tested to improve muscle mass or strength. Although there is a clear indication for growth hormone (GH) replacement in adults who have pituitary deficiency, no study has yet demonstrated that interventions with growth hormone or GH-releasing factor benefit normal adults or frail older adults.²⁸

Organizational Approaches Effective for Frail Older Adults

Frail older adults, in addition to being clinically vulnerable, have the added difficulty of often being financially and socially vulnerable. They may also have diminished capacity to access appropriate health care services, navigate multiple providers, and obtain supplies and medications. Devising viable and effective systems to coordinate the complexities of frailty care within the increasingly cost-conscious health care environment is a major challenge for providers taking care of frail adults. During the past 30 years, geriatricians have developed and tested numerous models for care of the frail elderly. From this experience a series of best practices is emerging.

To determine the appropriate delivery systems for frail patients, we consider the following questions.

- What are the principles of high-quality care for frail older adults?
- What are the best strategies for delivering care to frail older adults?

Principles of High-Quality Care for Frail Older Adults

Frail older adults are complex, fragile, and often chronically ill patients, and as such require a more intensive approach to the delivery of care than healthy geriatric patients. Traditional medical care, generally designed to treat acute illnesses in patients actively seeking care, tends to employ episodic interactions where physicians perform medical diagnosis and offer treatment options. These traditional models of care often do not provide for the ongoing management of chronic conditions and prevention that frail patients require. They also are not geared to care for patients who require coordination of care or are unable to seek the care they need (Fig. 73.3).

Effective interventions for care of frail older adults incorporate a number of activities that can be distilled into a series of five steps.

Coordinated Care

FIGURE 73.3. Coordination of care.

1. **Targeting:** Successful interventions focus their efforts on high-risk patients with reversible problems or who would benefit from stabilization.

2. **Assessment:** Having the appropriate expertise available to comprehensively identify medical and nonmedical needs is central to implementing effective interventions. Conversely, lack of expertise may lead to missed care needs or failed interventions, Assessing these needs often requires the skills of a multidisciplinary team.

3. **Intervention:** Knowing and using the up-to-date evidence-based interventions that make a difference is vital to improving outcomes.

4. **Implementation:** Patient adherence to treatment regimens is highly variable, requiring time to follow up on patient tolerance of a new treatment plan. There are, however, implementation strategies that physicians and health care teams can perform to improve adherence to treatment plans.

5. **Evaluation:** Assessing the processes and outcomes of care delivery enables providers to modify their approach to be more responsive to the needs of patients or more effective in care. Integrating performance improvement into the design of care facilitates the implementation of real improvements over time.

Successful Care Strategies for Frail Older Adults

Although these five steps are common approaches to management of complex medical issues, with modifications they provide an important framework for the care of frail older adults. Successful care models tend to perform these steps, and many of them have been able to demonstrate improved outcomes such as reduced mortality, reduced hospitalizations, and improved function. Conceptually, the type of care shown to improved outcomes varies by health and severity of frailty status (Fig. 73.4). We briefly describe some of the different care models that have been developed to treat patients across the frailty spectrum, from the prefrail older adult to the acutely ill, hospitalized frail patient, and the frail, dependent individual.

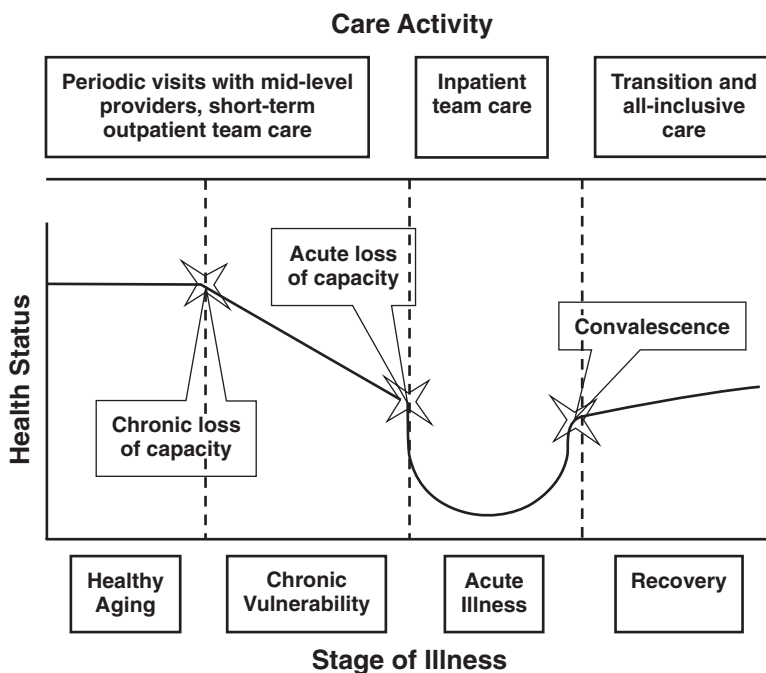

FIGURE 73.4. Geriatric care across settings.

Periodic Visits with Midlevel Providers

Successful models designed to prevent community-dwelling seniors from becoming frail include the use of periodic visits with midlevel providers. Stuck et al. were able to improve function and reduce nursing home days in community-dwelling seniors through a series of home visits by a geriatric nurse practitioner designed to identify unmet needs, facilitate access to appropriate services, and provide limited care recommendations with the support of a geriatrician.²⁹ In an analogous delivery model using geriatric nurse practitioner visits at a local senior center, designed to link seniors to existing community resources, provide chronic disease management and exercise classes, and increase social contact with other elders, Leveille et al. reduced hospital days and improved physical function in community-dwelling chronically ill patients aged 70 and over.³⁰

Short-Term Outpatient Team Care

The use of outpatient multidisciplinary care teams on a short-term basis to perform comprehensive assessments and manage unmet needs can be effective in prefrail and frail patients as well. Hospital days and costs were reduced over a 1-year period through outpatient, multidisciplinary team assessment and short-term intervention in frail older adults with changing medical needs.³¹ Fall prevention in older patients has been achieved using comprehensive assessment by nurse practitioners and physical therapists, coupled with a 3-month intervention in seniors aged 70 and older at risk for falls.³² One-time multidisciplinary geriatric consultation can reduce functional decline in the outpatient setting in elderly patients with urinary incontinence, depression, falls, or functional impairment, when combined with aggressive adherence-improving strategies including phone calls to patients and primary care physicians.³³ Comprehensive assessment followed by interdisciplinary primary care of a population-based sample of community-dwelling Medicare beneficiaries ages 70 and older who were at high risk of hospital admission led to less functional decline and less use of home health care than controls.³⁴ One-time multidisciplinary consultations in isolation appear to be substantially less effective than those utilizing such implementation strategies.³⁵

Inpatient Team Care

Inpatient multidisciplinary teams led by geriatricians can improve clinical and cost outcomes for hospitalized seniors.^{36,37} In addition to geriatrically trained nurses and team care, modifying the hospital environment, for example, through the use of rails and carpets, can help reduce the complications of hospitalization and reduce

length of hospital stay. Multidisciplinary team care can also be effective in an inpatient rehabilitation setting for older patients with reversible functional impairments.³⁸ In contrast, studies evaluating the effectiveness of inpatient geriatric consultation alone have failed to demonstrate an improvement in clinical outcomes for geriatric patients. Further work may need to be performed to clarify the obstacles to finding an effect; in some cases, this may have been due to the methods used for identifying those to receive the care being tested.

Transitional Care

Providing rehabilitation and aggressive clinical follow-up for patients after acute illness can be effective in improving outcomes for elderly patients with acute exacerbations of chronic illnesses or undergoing major surgery and potentially in preventing frailty. Naylor et al. showed that nurses working with specific transitional care protocols, following patients from hospital to home, were able to significantly reduce readmissions and costs.³⁹

All-Inclusive Care

The Program for All-Inclusive Care for the Elderly (PACE), a Health Care Financing Administration (HCFA) demonstration project based upon the On Lok model in San Francisco, has been the most comprehensive care delivery system designed to address the needs of community-dwelling disabled and often frail seniors. In this capitated program, nursing home-eligible patients over the age of 55 are cared for by interdisciplinary teams, primarily in a day hospital setting. Focus is placed upon preventive, rehabilitative, and end-of-life care; short-term hospital and nursing home care are provided as necessary. This all-inclusive model has been successful at reducing hospitalizations by approximately 25%, when compared to the experience of similarly functionally impaired non-PACE seniors.⁴⁰

In summary, a spectrum of geriatric care models can be matched to the stage of frailty in older patients (see Fig. 73.4) and effectively improve outcomes for each stage.

Appendix. Cutoffs Used to Define Frailty

- **Weight loss:** In the past year, have you lost more than 10 lb unintentionally (i.e., not due to dieting or exercise)? If yes, then frail for weight loss criterion. At follow-up, weight loss was calculated as: (weight in previous year – current measured weight)/(weight in previous year) = K. If $K \geq 0.05$ and the subject does not report that he/she was trying to lose weight (i.e., unintentional weight loss of at least 5% of previous year’s body weight), then frail for weight loss = Yes.
- **Exhaustion:** Using the CES-D Depression Scale, the following two statements are read. (a) I felt that everything I did was an effort; (b) I could not get going. The question is asked: How often in the last week did you feel this way? 0 = rarely or none of the time (<1 day), 1 = some or a little of the time (1–2 days), 2 = a moderate amount of time (3–4 days), or 3 = most of the time. Subjects answering “2” or “3” to either of these questions is categorized as frail by the exhaustion criterion.
- **Physical Activity:** Based on the short version of the Minnesota Leisure Time Activity questionnaire, asking about walking, chores (moderately strenuous), mowing the lawn, raking, gardening, hiking, jogging, biking, exercise cycling, dancing, aerobics, bowling, golf, singles tennis, doubles tennis, racquetball, calisthenics, swim-

ming. Kilocalories per week expended are calculated using standardized algorithm. This variable is stratified by gender.

Males: Those with Kcal of physical activity per week <383 are frail.

Females: Those with Kcal per week <270 are frail.

- **Walk time, stratified by gender and height (gender-specific cutoff at median height):**

	<i>Cutoff for time to walk 15 feet criterion for frailty:</i>
<i>Male</i>	
Height ≤173 cm	≥7 s
Height >173 cm	≥6 s
<i>Female</i>	
Height ≤159 cm	≥7 s
Height >159 cm	≥6 s

- **Grip strength, stratified by gender and body mass index (BMI) quartiles:**

	<i>Cutoff for grip strength (kg) criterion for frailty:</i>
<i>Males</i>	
BMI ≤24	≤29
BMI 24.1–26	≤30
BMI 26.1–28	≤30
BMI >28	≤32
<i>Females</i>	
BMI ≤23	≤17
BMI 23.1–26	≤17.3
BMI 26.1–29	≤18
BMI >29	≤21

Summary for frailty: a subject is frail if he/she has 3, 4, or 5 components identified as frail. Intermediate subjects have 1 or 2 components, and subjects with 0 positive frailty factors are considered not frail.

Dementia

Gary J. Kennedy

Dementia is a syndrome of progressive, global decline in cognition that is severe enough to degrade the individual's well-being and social function. Persons with dementia have learning and memory problems, plus at least one of the following: impairments in communication (aphasia), reasoning, and planning (executive function); recognition and manipulation of objects in space (agnosia, apraxia); orientation; and the regulation of emotion and aggression. Dementia is the most common cause of disability among older Americans.¹ With the number of dementia cases projected to double over the next 40 years,² even modestly effective interventions will have substantial benefits if achieved in the population at large. However, rates of underrecognition and undertreatment are considerable.³ A comprehensive approach combining proven interventions can have a major impact on the patient and family's well-being and on the costs of long-term care.

Epidemiology and Costs

There were 360,000 new cases of Alzheimer's dementia diagnosed in 1997, with prevalent cases from all forms of dementia approaching 4 million Americans.⁴ Costs of dementia care provided by professionals, institutions, and agencies total \$100 billion a year. Yet, most persons with dementia are cared for in the community rather than institutions. The expense to the family members providing community-based care is estimated to be an additional \$100 billion. Alzheimer's disease alone affects 8% to 15% of persons 65 and older. The prevalence of dementia increases exponentially, doubling every 5 years at least to age 85, at which point the incidence may decline.⁵ Among individuals 85 and older with a demented first-degree relative, however, the prevalence approaches 50%.⁶ And, despite improved survival rates associated with cardiovascular disease, an increase in vascular dementia may be expected.⁷ Pathogenesis of

primary neuronal degeneration and genetic and other risk factors are discussed in the next chapter. What follows here is a commonsense, evidence-based approach to treatment.

Differential Diagnosis

Table 74.1 characterizes the various cognitive disorders, as well as the specific dementias. The diagnosis is challenging in the early stage because there are no definitive biologic markers, the onset is often insidious, and other reversible causes of cognitive impairment either resemble or accompany dementia. Clinical history from patient and family, physical examination, mental status assessment, and laboratory procedures are carried out to detect reversible or partially reversible disease. Although few dementias are reversible, most have elements that will partially remit.⁸

Delirium (see Chapter 76) is perhaps the most common cognitive disorder and often complicates dementia. The hallmarks are fluctuating level of awareness, impaired attention, disorganized thinking, and demonstrable physiologic disturbance. Symptoms should remit once the disturbance is reversed, but recovery may be delayed in older persons. Delirium can also be chronic and difficult to distinguish from dementia.⁹ Cognitive impairment due to depressive disorders is distinguished by the patient's prominent complaints of difficulty with memory and concentration. Apathy, irritability, and reluctance to complete cognitive testing are apparent. Aphasia is usually absent.¹⁰ However, there is a growing body of evidence that late-life depression accompanied by cognitive impairment often heralds the onset of dementia, even when the initial impairment remits with antidepressant therapy.¹¹

Age-associated memory impairment (AAMI) is characterized by memory complaints in persons age 50 or older whose performance falls 1 SD below the mean on

TABLE 74.1. Differential diagnosis of cognitive impairment in adults.

Condition	Distinguishing features
Dementia	Progressive decline, global cognitive impairment with learning and memory deficits (recent > remote), aphasia, apraxia, agnosia, executive dysfunction; patients tend to minimize deficits
Developmental disorder	Childhood onset without progressive decline; history of diminished educational and work attainment; attention unimpaired
Delirium	Sudden onset and fluctuating course with inattention, disorganized thinking, and altered level of awareness; impairment reversible but recovery may be prolonged by advanced age
Major depressive disorder with cognitive impairment	Memory and concentration complaints prominent; aphasia absent, apathy or irritability present; cooperation with testing difficult, risk of subsequent dementia elevated
Age associated	Age >50, memory complaints prominent; performance below 1 SD from the mean on tests normed with young adults, information retrieval slowed; learning, orientation, communication intact; functional independence preserved
Mild cognitive impairment	Age >50, memory complaints prominent; performance below 1.5 SD from the mean on tests compared to age mates, information retrieval slowed; learning, orientation, communication intact; functional independence preserved
Alzheimer's disease	Insidious onset with smooth, inexorable decline, cortical atrophy; apolipoprotein E ₄ allele, and cardiovascular disease elevate risk; more rapid decline in middle-stage onset; mood disturbance early, psychosis and behavioral disturbance later in the course
Vascular dementia	Sudden onset, fluctuating course with temporary improvements or prolonged plateau; multiple infarcts, diffuse white matter lesions, diabetes, cardiovascular disease present; focal neurologic exam
Huntington's disease	Autosomal dominant but incomplete penetrance inheritance pattern; atrophic caudate nuclei; premorbid DNA testing quantifies risk, age of onset, severity
Parkinson's disease	Characteristic tremor with unilateral onset, bradykinesia, bradyphrenia, cognition may be spared
Acute cognitive impairment due to stroke, traumatic brain injury	Focal neurologic exam; circumscribed rather than global cognitive deficits may improve significantly over 6 months
Frontal lobe degeneration, Pick's disease	Personality, sociability, executive function prominently impaired; disinhibition, impaired judgment, and social indifference significant; aphasia, apraxia, amnesia, loss of calculation less notable
Lewy body dementia	Sudden onset, fluctuating level of awareness, psychosis (visual and auditory hallucinations more often than delusions) prominent, parkinsonian signs and falls; adverse response to typical antipsychotic
Corticoclear degeneration	Marked visuospatial impairment, substantial apraxia, memory behavior disturbance less prominent
Creutzfeldt–Jakob disease	Rapid progression, death in 6–12 months, characteristic EEG, myoclonic jerks
Alcohol-related dementia	Massive, prolonged abuse; may remit with abstinence
Normal pressure hydrocephalus	Gait disturbance (“magnetic gait”), incontinence, ventricular enlargement disproportionate to cortical atrophy
AIDS dementia	HIV positive, may present with behavioral disturbance, parkinsonian features

tests normed for younger adults. Although lower memory scores are predictive of dementia, only 1% to 3% of these individuals will experience global cognitive decline in the ensuing 12 to 24 months.¹² In contrast, 5% to 15% of persons with mild cognitive impairment (MCI) will develop dementia within the year. MCI is characterized by performance between 1 and 1.5 SD below the mean on tests of memory. As with AAMI, persons with MCI have memory complaints but do not meet diagnostic criteria for dementia; they exhibit slowed information retrieval, but orientation and communication are usually intact.¹³

Although a histologic examination of brain tissues sets the criteria for “definite” Alzheimer’s disease, the diagnosis of “probable” Alzheimer’s dementia can be accurately made in 90% of cases by history from the patient and family and clinical examination.¹ “Possible” cases may have atypical features but no identifiable alternative

diagnosis. Alzheimer’s disease is the most frequent dementia. The onset is insidious; the decline is smooth, but more rapid in the middle stage in which behavioral disturbances emerge. Individuals with Alzheimer’s disease often minimize their deficits, unlike persons with MCI or depression. Alzheimer’s and Pick’s disease represent cortical dementias in which there is primary neuronal degeneration.¹⁴ Huntington’s and Parkinson’s disease represent the subcortical dementias. Dementia associated with Lewy bodies overlaps with both Parkinson’s and Alzheimer’s disease in presentation and distribution of pathology.

The secondary neuronal degeneration of the vascular dementias is caused by angiopathic disorders, most commonly ischemic heart disease and arrhythmias, hypertension, and diabetes. Hemiparesis, gait disorder, and other signs of past stroke also suggest vascular dementia. However, the pathology of vascular dementia is fre-

quently of a mixed type (cortical and subcortical) with diverse presentations in which the loss of brain volume, ventricular dilatation, bradykinesia, and the cognitive deficits are difficult to distinguish from Alzheimer’s disease.

Although perceptual distortions are common in dementia, when visual or auditory hallucinations are prominent, signs of Parkinson’s disease are evident, the onset was abrupt, and the course characterized by lucid moments alternating with confusion, Lewy body disease may be diagnosed.¹⁵ Paranoid delusions, falls, and depression are also characteristic of diffuse Lewy body dementia. More importantly, patients with diffuse Lewy body disease experience marked disruptions in dopaminergic systems, accounting for their exquisite sensitivity to antipsychotic medications.¹⁶

Alzheimer’s, vascular, and Lewy body disease make up the majority of dementia diagnoses. Table 74.2 offers a simplified algorithm that will capture 95% of the dementias encountered by the average practitioner. The rare dementias would be easy to overlook were it not for their distinctive features. Marked deficits in visual perception and praxis out of proportion to memory impairment suggest corticonuclear degeneration. Changes in affect, typically depression but also hypomania and irritability preceding signs of dementia, suggest a non-Alzheimer’s diagnosis.¹⁷ Early deterioration in personality, loss of social inhibitions, and frontal lobe atrophy indicate Pick’s dementia.¹⁸ Physical signs such as the tremor and bradykinesia of Parkinson’s disease, the choreoathetoid movements of Huntington’s disease, the myoclonic twitching of Creutzfeldt–Jakob disease, or the pseudo-bulbar palsy of vascular dementia may not present before intellectual deterioration is observed. Huntington’s disease is typical of the subcortical dementias in that various cortical functions, including communication,

praxis, and visual perception, are generally spared. Emotional disturbances and personality change are regular features of Huntington’s disease and are frequently the first signs of the illness.¹⁹ Normal pressure hydrocephalus is characterized by incontinence, abnormal (“magnetic”) gait, and ventricular atrophy out of proportion to cortical loss.

Dementia may also be secondary to infectious systemic disease such as syphilis or acquired immunodeficiency syndrome.²⁰ Transmissible disorders of the prion type (Creutzfeldt–Jakob disease) may also cause dementia through exposure to infected foodstuffs or transplanted tissues or extracts.²¹

Diagnostic Procedures

Routine diagnostic laboratory procedures include complete blood count, blood chemistries, liver function studies, serologic test for syphilis, thyroid-stimulating hormone and vitamin B₁₂ and folate levels, and cardiogram. In less than 1% of patients will these procedures detect a reversible cause of dementia. However, the identification of comorbid conditions whose less than optimal treatment compounds the disability or worsens the prognosis of the dementia will be more substantial. Chest x-ray, human immunodeficiency virus (HIV) test, and test of Lyme disease may also be included, based on physical examination and history. For patients with syncope or suspected seizures, an electroencephalogram may be ordered. A review of prescribed and over-the-counter medications and intake of alcohol and tobacco products is mandatory. Medications may be the most common cause of reversible dementia.

Imaging studies are used to confirm the diagnosis when clinical findings are equivocal, to distinguish one demen-

TABLE 74.2. Simplified algorithm for the differential diagnosis of dementia.

Insidious onset with smooth decline and motor function minimally impaired? YES NO → ↓ Alzheimer’s dementia	Abrupt onset or fluctuating course, little if any psychosis? History of stroke or significant ischemic brain injury on CAT scan or MRI YES NO → ↓ vascular dementia	Marked fluctuation in cognitive impairment, hallucinations prominent, signs of Parkinson’s syndrome evident, falls YES ↓ Lewy body disease

tia from another, and to detect reversible causes. Because the incidence of irreversible dementia is age related, the detection rate for reversible causes with imaging declines with advancing age. Computerized tomography of the brain, without contrast, should be performed when focal neurologic signs are present, when change in mental status is sudden, or when trauma or mass effects are suspected. Magnetic resonance imaging may be indicated when vascular dementia is suspected. However, the white matter changes seen on T₂-weighted images are not necessarily indicative of dementia.¹ Functional imaging studies with positron emission tomography or single photon emission computerized tomography may detect the temporoparietal metabolic deficits of Alzheimer's disease or the diffuse irregular deficits of vascular dementia when objective signs of memory impairment are equivocal.²² Functional imaging is far from being a routine clinical procedure. As treatments become available for early intervention, however, the desire for early detection may yet bring functional imaging into everyday practice.

Cognitive Assessment

Cognitive assessment should be conducted without family present to avoid distractions and any potential embarrassment over failed items. Because the patient is asked to actively demonstrate errors, considerable care is required to place the person at ease and accurately administer the exam. It is useful to discuss findings and recommendations in the individual interview and then gain the patient's permission to share the information with family. A premium is placed on openness and disclosure. However, certain individuals will be too anxious or suspicious to be examined alone or to accept a discussion of findings and recommendations in their presence. In such cases, tact and ingenuity are required to obtain consent for disclosure to the family. The use of a cognitive screening instrument allows the clinician to demonstrate the presence and, with longitudinal administrations, the course of deficits objectively.

A number of factors may influence cognitive performance yet not be indicative of dementia. These aspects include inefficient learning strategies, slowed processing capacity, reduced attention, sensory deficits, and age-associated memory impairment.²³ Age, education, and other demographic factors also alter performance.²⁴ Language, visuospatial ability, and abstract reasoning are less affected by age than memory and learning. Long-term and procedural memories are relatively preserved, whereas recent and episodic recall decline.²⁵ For example, the older musician may perform pieces from early life with both facility and feeling but not recall what was played the next day. New music will be impossible to master, despite good command of the instrument.

The Mini-Mental State Examination (MMSE) is the most widely used screening exam for impaired cognition in the United States and has been translated to a number of languages and normed for age and education. Molloy and Standish²⁶ have standardized the administration procedures for the MMSE to reduce test time and uncertainty about scoring (Table 74.3). Their techniques also reduce test anxiety. A perfect score is 30, with mild to moderate impairment falling between 18 and 24. For persons with fewer than 9 grades of education, a score of 17 or less is evidence of at least mild impairment. The average decline in MMSE scores among Alzheimer's patients is 2 to 4 points per year. In the study by Kelman et al. of 1855 older community residents, an impaired MMSE score whether mild, moderate, or severe was a stronger predictor of mortality than physical disability, number of conditions, or age.²⁷

MMSE scores of 19 and above, memory loss and disorientation, repetitiousness, loss of interests, and change in personality characterize mild Alzheimer's dementia.²⁸ Although depression may appear early, delusions, agitation, sleep disturbance, and wandering are more characteristic of moderate dementia. Persons with moderately advanced dementia have MMSE scores ranging between 10 and 19. They require supervision to complete tasks of daily living, such as dressing, and to be safe from dangerous wandering. Severe dementia is evidenced by marked aphasia, loss of capacity to recognize family, incontinence, and dependency in all aspects of daily living.

Of the widely used screens for cognitive impairment, the Clock Drawing Test is the briefest, requiring less than 5 min to complete. The patient is asked to draw a clock face with all the numbers and hands and then to state the time as drawn. The number 12 must appear on top (3 points), there must be 12 numbers present (1 point), there must be two distinguishable hands (1 point), and the time must be identified correctly (1 point) for full credit. A score less than 4 is considered impaired.²⁹ The Free and Cued Selective Reminding may be useful to distinguish age-associated memory impairment from dementia. The Free and Cued Selective Reminding test reduces the age-related decrements in learning and processing to elicit genuine deficits in recall, which are characteristic of dementia. The measures may also be less sensitive to educational attainment.²³ For intellectually gifted persons, those with higher educational attainment, and when decline is subtle, referral to a neuropsychologist is warranted. For annual screening of seniors in primary care without signs or symptoms of dementia, the MMSE combined with the Clock Drawing Test provides adequate sensitivity and specificity.²⁹ Serial assessments at 6-month intervals are helpful when the diagnosis remains suspect. However, like imaging studies, none of the cognitive screening or neuropsychologic batteries can be considered diagnostic.

TABLE 74.3. Standardized Mini-Mental State Examination.

Preparations

Ensure that the patient is willing and that vision and hearing aids if needed are in place. Ask “*Would it be all right to ask you some questions about your memory?*”? Ask each question a maximum of 3 times. If the patient does not respond score the item as 0. If the answer is incorrect, score 0. Do not hint, prompt, or ask the question again once an answer has been given. If the patient answers, “*What did you say?*” do not explain or engage in conversation—merely repeat the same directions up to a maximum of 3 times. If the patient interrupts or wanders from the task, redirect the person by saying “*I will explain in a few minutes when we are finished. Now if we could just proceed please . . . we are almost finished.*”

Begin by saying I am going to ask you some questions and give you some problems to solve.

	<u>Max Score</u>
1. (Allow no more than 10 seconds for each reply)	
a) “ <i>What year is this?</i> ” (Accept exact answer only)	1
b) “ <i>What season is this?</i> ” (In the last week of the old season or first of the new, accept either)	1
c) “ <i>What month of the year is this?</i> ” (On the first day of the new month or last day of the previous, accept either month)	1
d) “ <i>What is today’s date?</i> ” (The day before or after is acceptable, e.g., on the 7th accept the 6th or 8th)	1
e) “ <i>What day of the week is this?</i> ” (Exact day only)	1
2. (Allow no more than 10 seconds for each reply)	
a) “ <i>What county/borough are we in?</i> ”	1
b) “ <i>What province/state/country are we in?</i> ”	1
c) “ <i>What city/town are we in?</i> ”	1
d) If in the clinic, “ <i>What is the name of this hospital/building?</i> ” (Exact name of hospital/institution/building only)	1
If in the patient’s home “ <i>What is the street address of this house?</i> ” (Street name and house number or equivalent in rural areas)	
e) If in the clinic “ <i>What floor of the building are we on?</i> ” (Exact answer only)	1
If in the home “ <i>What room are we in?</i> ” (Exact only)	
3. “ <i>I am going to name 3 objects. After I have said all 3, I want you to repeat them. Remember what they are because I am going to ask you to name them again in a few minutes.</i> ” (Say the objects slowly at 1-second intervals)	3
“ <i>BALL (1 second) CAR (1 second) MAN. Please repeat the 3 items for me.</i> ”	
(Score 1 point for each reply on the first attempt. Allow 20 seconds for the reply, if the patient cannot repeat all 3 on the first attempt, repeat until they are learned but no more than 5 times)	
4. “ <i>Now please subtract 7 from 100 and keep subtracting 7 from what’s left until I tell you to stop.</i> ” (May repeat 3 times if the patient pauses—allow 1 minute for answer. Once the patient starts do not interrupt until 5 subtractions have been completed. If the patient stops, repeat “keep subtracting 7 from what’s left” for a maximum of 3 times. See scoring examples below)	5
5. “ <i>Now what were the 3 objects that I asked you to remember?</i> ” (Score 1 point each regardless of the order; allow 10 seconds)	3
BALL CAR MAN	
6. Show the patient a wristwatch and ask; “ <i>What is this called?</i> ” (Accept “wristwatch or “watch” but not “clock” or “time”)	1
7. Show a pencil and ask; “ <i>What is this called?</i> ” (Do not accept “pen”)	1
8. <i>I’d like you to repeat a phrase for me: say “no if’s, and’s, or but’s.”</i> (Exact reply only)	1
9. “ <i>Read the words on the page and then do what it says.</i> ” (Hand the patient the sheet with CLOSE YOUR EYES on it. Instructions may be repeated 3 times but patient must close eyes for correct score)	1
10. Ask if the patient is right or left handed. The paper is held in front of the patient and should be taken with the nondominant hand.	3
“ <i>Take this paper in your right/left hand, fold it in half, and place it on the floor.</i> ”	
Takes paper with nondominant hand = 1	
Folds it in half = 1	
Places it on the floor = 1	
11. Give the patient a pencil and paper and say “ <i>Write any complete sentence on this piece of paper.</i> ” (Allow no more than 30 seconds. Sentence should make sense. Ignore spelling.)	1
12. Place intersecting pentagons design, pencil, and paper in front of the patient. Say: “ <i>Please copy this design.</i> ” Allow multiple attempts up to 1 minute. To be correct the patient’s copy must show a 4-sided drawing within two 5-sided figures. Ignore rotation and distortions.)	1

Scoring serial sevens:

93, 86, 79, 72, 65	5 points
93, 88, 81, 74, 67	4 points
92, 85, 78, 71, 64	4 points
93, 87, 80, 73, 64	3 points

Assessment of Functional Impairment

Although the examination of cognition occurs between patient and practitioner, functional impairment is more reliably assessed with collateral informants, most often family.³⁰ An assessment of activities of daily living not only covers the maintenance of physical hygiene and grooming, but also the more instrumental tasks such as management of finances, property, and household chores. Patients may appear in immaculate condition as a result of attentive caregivers, yet not be able to shop, cook, bathe, dress, or pay the bills without total assistance. The Global Deterioration Scale and Functional Assessment Staging (Table 74.4) is a widely used measure of dementia-related dependency.³¹

Treatment

The comprehensive approach to dementia care seeks to preserve the patient's independence by delaying disability to the end of the natural life span. There are five elements to the comprehensive approach. First is accurate diagnosis of the specific dementia and recognition of other conditions that contribute excess disability. Second is caregiver education, counseling, and support. The third element is the pharmacologic palliation of cognitive impairment. Fourth are interventions, both pharmacologic and environmental, to lessen behavioral and psychological disturbances. Fifth is early advance care planning in anticipation of late-stage and end-of-life care issues.

Reduction of Excess Disability

Beyond recognition of the specific dementia, the optimal treatment of associated conditions is critical. One-half of persons with dementia have a concurrent physical or mental illness that contributes to their functional impairments. Half that number will experience at least temporary benefits from treatment of the comorbid condition. And, in half that group, the benefits will last a year or more.³² Weight control, exercise, elimination of tobacco use, and minimizing alcohol intake represent good preventive health at any age, perhaps more so for individuals with dementia. However, some persons would rather not forgo real pleasures in the present for the promise of potential benefits in the uncertain future. For patients with suspected vascular dementia, the use of 325 mg aspirin daily should be recommended.³³

Counseling and Coaching the Caregiver

The cornerstones of caregiver counseling are education, emotional support, and telephone availability. When combined with support groups, these techniques delayed nursing home admission an average of 9 months without increasing the caregiver's burden.³⁴ The majority of dementia care is provided by female family members who vary widely in their capacity to adapt to the burdens of the illness.³⁵ Rehabilitation of the patient should always include consultation with the family, and failure of the family to appear should alert the clinician to future problems. Most families are remarkably creative in providing care. Others seem enmeshed, trapped in maintaining

conflict rather than resolving it.³⁶ Clinical depression is a problem for 20% to 60% of the primary family caregivers.^{37,38} The focus of care in these instances shifts to the family member and includes supportive psychotherapy or antidepressant medication. In rare instances, elder abuse, most often in the form of neglect, will require involvement of community agencies.

Caregivers should be instructed to modify the physical environment to be safe and predictable. A regular schedule of activities including rising, meals, medications, and exercise lessens the burden on memory. Unfamiliar people, places, and events require accommodation for which the patient is poorly equipped. Travel that disrupts the person's routine will be disorienting. Cherished holidays are better celebrated in the patient's home. The withdrawal of firearms, opportunities to cook or smoke unsupervised, and automobile driving requires compassion and at times imagination.

Psychotic and affective disturbances occur in as many as 80% of patients and account for much of the needed caregiver counseling. Behavioral disturbances are more distressing than forgetfulness or incontinence. Aggression, assault, accusations, nighttime wandering, and loss of capacity to recognize the caregiver predict nursing home admission.^{39,40} Pharmacologic improvement of cognition will help, but behavioral and other measures often need to be instituted, as discussed in subsequent sections.

Pharmacologic Palliation of Impaired Cognition

Brietner predicts that medications emerging in the next two decades will significantly reduce the morbidity of Alzheimer's disease.⁴¹ Simply delaying the onset of dementia by 5 years would reduce the prevalence by one-third.⁴² Until those agents have been administered to a generation at risk, however, the pharmacologic alternative will continue to be drugs that may palliate but cannot prevent the disability of dementia (Table 74.5). Because the common dementias overlap diagnostically, every patient with the diagnosis of dementia should be offered a trial of a cholinesterase inhibitor.⁴³ In mild to moderately impaired persons, cholinesterase inhibitors may improve cognition, delay decline, lessen the disability in activities of daily living,⁴⁴ improve psychologic and behavioral disturbances including psychosis,^{45,46} and forestall nursing home admission.⁴⁷

Using randomized controlled trials of cholinesterase inhibitors, Livingston and Katona⁴⁸ performed a number needed to treat analysis to calculate the number of patients receiving active treatment needed to demonstrate a beneficial effect compared to placebo. For example, 29 patients with atrial fibrillation would need to be treated with coumadin to prevent stroke in 1. In contrast, with 10mg donepezil, 6 (95% confidence interval, 4–12) Alzheimer's patients need to be treated to stabilize

TABLE 74.5. Agents used to palliate the cognitive impairment of dementia.

Generic name	Trade name	Initial dose	Final dose	Arrhythmia potential	Hypotensive potential	Sedative potential	Precautions	Advantages
Anticholinesterases								
Donepezil	Aricept	5 mg qd	10 mg qd	Bradycardia	Low	Low	Transient, initial GI upset, abrupt withdrawal leads to abrupt decline, may interact with paroxetine	Once a day dosing, safety
Rivastigmine	Exelon	1.5 mg bid	6 mg bid	Low	Low	Low	Transient, initial GI upset, titrated up at 2-week intervals, abrupt withdrawal leads to abrupt decline, bid dosing	Wider dose range, no drug interactions
Galantamine	Reminyl	4 mg bid	16 mg bid	Bradycardia	Low	Low	Transient, initial GI upset, titrated up at 4-week intervals, abrupt withdrawal leads to abrupt decline, bid dosing	Wider dose range, nicotinic receptor modulation
Antioxidants								
Selegiline	Eldepryl	5 mg qd	5 mg bid	Low	Moderate	Low	Potentially life-threatening diet and drug interactions are rare at recommended doses	Available as a transdermal patch
Alpha-tocopherol	Vitamin E	30 IU qd	1000 IU bid	NA	NA	NA	Liver toxicity, coagulopathy	Low toxicity, OTC
Others								
Extract of <i>Ginkgo biloba</i>	Ginkgold Tebonin forte	60 qd	60 qid	Low	Low	Low	qid dosing, an "herbal" not subject to FDA quality controls, few data available at max dose	Low toxicity, OTC

T_{1/2}, half life; OTC, over the counter; FDA, U.S. Food and Drug Administration; NA, not applicable; AD, Alzheimer's disease; VaD, vascular dementia.

or reverse cognitive decline by 1 year in 1 person; with 12 mg rivastigmine, 5 (95% confidence interval, 4–7) patients need to be treated.

On average, cholinesterase inhibitors restore the person to a level of impairment seen 6 months previously. Although the effect is palliative, the less impaired time and delay in nursing home admission may be precious, particularly for patients whose improvement is marked. The side effects of cholinergic enhancement are nausea, diarrhea, sweating, bradycardia, and insomnia; these are most often are transient, occurring in 10% to one-third of patients at the initiation of treatment depending on the agent. To lessen adverse reactions, the cholinesterase inhibitors should be taken with meals and not at bedtime. Promethazine may be administered to counter nausea and vomiting but should not be required beyond the initial phase. The medication should be titrated up at 2- to 4-week intervals to the maximum recommended or tolerated dose. Phasing in the increase on an every other day schedule may enhance tolerability. Roughly one patient in four will experience improvement readily noticeable to family and practitioner within weeks of beginning the drug. That number increases to one in three by the third month of treatment.⁴⁹

However, the majority of those who are not obviously better will experience less decline in the coming months with medication than without. As a result, the identification of genuine nonresponders who might be offered an alternative cholinesterase inhibitor is a real dilemma. Also, there is as yet no evidence for or against switching from one cholinesterase inhibitor to another. In theory, use of serial MMSE assessments might demonstrate a stabilizing effect of the medication. In practice, patients and families who find the benefits trivial compared to the burden of side effects, cost, and pill taking will opt to withdraw from treatment. However, cholinesterase inhibitors should not be withdrawn simply because the patient has been admitted to a nursing home. When withdrawn, the cognitive impairment of genuine responders will fall to that of patients treated with placebo. However, once the patient is bedbound, free of behavioral disturbances, and no longer recognizes family or caregivers, the benefits of the drug are questionable.

Two cholinesterase inhibitors are approved and a third is under consideration (galantamine) by the FDA for mild to moderate Alzheimer's disease. Donepezil possesses a prolonged action and specificity for brain tissue. The starting dose is 5 mg once daily and should be increased to 10 mg. Although it is metabolized by the cytochrome P-450 system, drug interactions are rare. Many practitioners find it has an alerting effect in late-stage patients.⁴³ Rivastigmine (Exelon) is a brain-specific cholinesterase inhibitor administered twice daily. The dose ranges from 1.5 to 6 mg bid.⁵⁰ Patients able to tolerate the gastrointestinal difficulties of higher doses may

benefit more. It is not metabolized by the cytochrome P-450 system, and drug interactions are thought to be rare.

Rivastigmine also inhibits butylcholinesterase, which may be more active in the latter stages of dementia, but the clinical significance of this property is uncertain.⁵¹ The acetylcholinesterase inhibitor galantamine (Reminyl) is a plant-derived alkaloid with nicotinic receptor-modulating activities. Its capacity to allosterically modulate nicotinic receptors avoids the undesirable cardiovascular effects of direct nicotinic stimulation.⁵² However, the clinical significance of this property is uncertain. Galantamine is taken twice daily at doses ranging from 4 to 16 mg. Because multiple enzymes of the cytochrome P-450 system metabolize galantamine, drug interactions should be rare.⁵³

Although the cholinesterase inhibitors should not be prescribed together, many practitioners combine them with vitamins C (500 mg) and E (400–1000 IU bid). Both are antioxidants and appealing in theory, but evidence of benefit in dementia exists only for vitamin E. The author generally discourages patients from adding extract of *Ginkgo biloba* to the foregoing regimen for reasons of minimal benefit, cost, and possible coagulopathy, particularly in the presence of high-dose vitamin E. Selegiline, a selective monoamine oxidase-B inhibitor, and vitamin E (α -tocopherol) reduce the rate of functional decline and delay nursing home placement in moderately impaired persons with dementia. However, cognitive performance is not enhanced, and the combination of the two agents is no more beneficial than vitamin E alone.⁵⁴ Estrogen is associated with lesser prevalence of dementia among more highly educated women in epidemiologic studies. It also has a trophic effect on cultured neurons. However, the use of estrogen to treat established cases of or prevent Alzheimer's disease has not yet been convincingly demonstrated.⁵⁵

Management of Behavioral and Psychologic Symptoms

Mental and behavioral disturbances are prevalent, occurring in more than half of community-residing elders who meet diagnostic criteria for dementia.⁵⁶ Their relative prevalence is displayed in Table 74.6 with significant differences between vascular dementia and Alzheimer's disease noted. The causes of behavioral symptoms are usually multiple, including the caregiving context, the caregiver's capacities and tolerance, as well as the patient's disease. Intervention to make the disturbed behavior less disruptive is a more realistic goal than outright elimination. A wait-and-see attitude may be reasonable when transient depression occurs, but agitation and psychosis are more likely to be persistent and disruptive.²⁸ The key to behavioral intervention is improved communication and patient perception. Adequate time

TABLE 74.6. Prevalence of specific^a behavioral or psychological symptoms among community-residing persons with dementia.

Apathy	25%
Depression (Vascular > Alzheimer's)	24%
Agitation/Aggression	24%
Irritability	20%
Delusions (Alzheimer's > vascular)	18%
Anxiety	17%
Hallucinations	14%
Pacing, wandering	14%

^aMore than half of diagnosed persons exhibited one or more symptoms. Source: Data from Lyketsos et al. *Am J Psychiatry*. 2000;157:708–714, with permission.

must be allowed to communicate. Visual cues and verbal suggestions should be coupled. Caregivers should stay at eye level with the patient, avoid provocative stances or gestures, speak softly and slowly, use “sound bite”-size statements or instructions, check that the patient understands and is ready, eliminate visual distractions, reduce ambient noise, and attend to one thing at a time. Glasses and hearing aids should be available, and they will need to be replaced when lost.

Characterization of the three-point sequence or ABC's of problematic behavior is central to the task of management.⁵⁷ First, the caregiver is asked (A) to identify the “Antecedents” or triggering events such as changes in daily routine, interpersonal conflict, emotional or physical stressors. The antecedents can then be removed or minimized as a preventive measure. (B) The caregiver should describe the “Behavior” in detail, how often it occurs, when and where it is most likely to happen, and how long it lasts. Caregivers may need to step back and observe or take note to provide sufficient detail and to set the baseline for objective measurement of improvement. This observation period also refines recognition of antecedents and how the problem behavior fits into other aspects of the patient's life. (C) The caregiver identifies the “Consequences” of the behavior, how the caregiver or others react to reinforce or deter the activity, and what happens when the activity ceases.

Roca⁵⁸ advocates a different three-part approach to behavioral disturbances of encompassing empathic, behavioral, and medical perspectives. The patient's point of view, the environmental precipitants, and the extent to which unrecognized or undertreated diagnoses contribute to the disturbances are each assessed to arrive at effective interventions. The male resident of the facility who is occasionally combative and wanders out of the home provides an example of each perspective. The man may have been a boxer early in life who is now protecting himself from the intrusion of unfamiliar nursing staff. Staff should be alerted to his characteristic defense. He may have a bed near the entrance to the facility and simply be following others out as a result of echopraxia. Or, he may have a past history of bipolar illness with

untreated mania as the explanation for his behavior. The intervention should be tailored to the individual characteristics of each patient.

Agitation

Behavioral disturbances naturally cluster into predominantly psychotic or affective groups, with agitation occurring in both.⁵⁹ Agitation is a common, persistent problem, and the etiology varies. Delirium may be the most frequent acute cause. However, environmental stressors such as sleep deprivation and unfamiliar or chaotic surroundings can induce confusion indistinguishable from toxic delirium. Patients may be “talked down” and reoriented, but attempts to flee or remove intravenous lines or life supports as a result of delirium require medication, most often an antipsychotic agent such as haloperidol. Depression, psychosis, anxiety, boredom, and pain also contribute to agitation.⁶⁰ Mania in dementia may also cause agitation, particularly when elevated mood, irritability, and hyperactivity appear. Frontal lobe degeneration impairs the person's judgment and capacity to sequence steps to gain attention or comfort. Patients whose needs cannot be accurately expressed because of aphasia may also become agitated. Their inability to comprehend spoken cues may compromise staff efforts to reassure them. Recognizing the impediments to communication will lessen the caregiver's frustration and justify the time and patience required to reduce, if not prevent, agitation. Impairments in hearing and vision add to the problem.

Psychotic Symptoms: Delusions, Hallucinations, Paranoia, Suspicions

It is important to distinguish persistent false beliefs or perceptions from transitory illusions that result from impairments in vision, hearing, and cortical deficits.⁶¹ Similarly, if antecedents can be identified, they may be manipulated to reduce the problem to manageable proportions. Change in routine and caregiving personnel should be minimized. Better lighting to reduce shadows, correct sensory deficits, a modulated level of activity, and attention may also be effective. The suspicious person may be set at ease by reassurance or redirection to a less threatening theme or activity. Distraction, physical activity, or gentle touch (the elbow is neutral territory) may also restore trust. Attention provided when suspicions are silenced will lay a foundation for trust and reassurance at more problematic times.

However, when patients act on their delusions through reclusiveness, threats, accusations, or assault, antipsychotic medication is necessary. Suspicious patients may retain enough regard for an empathic physician that they will consent to medication to restore sleep, alleviate

stress, or help control their temper. Patients can be informed that family or nursing staff will place liquid medication in their juice or cereal each morning if they agree. Consent need not be renewed with each dose.

Affective Symptoms: Apathy, Depression, Anxiety, Sleep Disturbance

Loss of interest, initiative, and responsiveness are seen in at least one-quarter of persons with dementia.⁵⁶ For patients who sleep too much, exercise, coffee, or tea may be useful. Other patients who are apathetic or nap too frequently may benefit from low-dose methylphenidate (5–15 mg after breakfast and lunch). Transient depressive symptoms are not uncommon in dementia, but persistent depressed mood and suicidal behaviors are less frequent. Depressed expressions may be evoked when the patient is reminded of sad events, when frustration overwhelms, or when the person feels neglected or alone. To lessen depressive expressions as well as apathy, caregivers should focus on pleasant memories, avoid or minimize frustrating, unpleasant circumstances, and increase pleasurable activities and social interaction. Teri et al.⁶² found that combined behavioral and psychoeducational approaches significantly improved depressive symptoms in the majority of dementia patients and their caregivers. However, when there is a prior history of major depressive episodes, an antidepressant may be indicated.

Sleep disturbance is common in dementia and disrupts both the patient's and the caregiver's rest. A brief assessment of the sleep pattern, time spent in bed, and daytime activities can identify the need for changing the sleep schedule, adding exercise, or prescribing medication. If physical discomfort awakens the patient, an analgesic at bedtime may help. Holding fluids after 6:00 P.M. may reduce the frequency of nighttime urination. Sedation will solve the problem, but predisposes the patient to falling and increased daytime confusion.

Verbally Disruptive Behaviors

Verbally disruptive behaviors include screaming, abusive language, and repetitive verbalizations. These behaviors disturb others and may signal the person's unmet needs. In theory, screaming may result from cortical disinhibition or be reinforced by attention. However, it more often results from undiagnosed and untreated pain, physical discomfort, sensory deprivation, or social isolation. Often the behavior can be reduced in frequency and volume without resorting to sedation. Individual social interaction is most effective. Examples include simple conversation, range of motion exercises, and sensory stimulation with photos, fabrics, fragrances, and occupational therapy games.⁶³

Family and staff generally prefer a little unpleasant vocalization to a patient made inaccessible with psychotropics. However, risk to the patient and risk to others must be parceled out. The concept of negotiated autonomy helps to avoid futile power struggles over patient rights. Negotiated autonomy means that once the patient is dependent on others, the autonomy of those others becomes a shared concern. Behavior that is disagreeable to others with whom the patient resides or on whom the patient depends is a justified focus of intervention. Thus, accommodation rather than autonomy is the issue.

Sundowning

Increased confusion at evening time can usually be managed by recognizing that change in the environmental routine triggers the problem. Patients who become troubled at change of shift in the nursing home or hospital may be responding to the increase in stimulation. Others may be bothered by the reduction in stimulation as daylight fades. In either situation, providing the optimum of stimulation is preferable to medication. Food, brief personal contact, music, or improved hearing or vision are only some of the alterations in the care routine that reduce sundowning.⁶³

Indiscreet or Unwelcome Sexual Behavior

Demented persons seeking sexual gratification should not be labeled pathologic even though they may disturb caregivers and facility staff. However, when sexual advances are unwelcome or when self-stimulation is not managed discreetly, more may be required than directing the patient to a private area. The problem should be discussed directly with the patient at the time of the behavior and disapproval indicated for the circumstances surrounding the act, not the impulse. A matter-of-fact approach with family and staff also helps alleviate their reluctance to discuss the issue. Pathologic sexuality in dementia is more often seen with frontal lobe disease and represents disinhibition rather than willfulness. Staff and family will be less morally outraged once the neurologic basis of the behavior is explained.

Difficulties Accepting Personal Care

Efforts to assist with feeding, bathing, or transfer from bed to chair or toilet are sometimes met with assaultive behavior, particularly when the caregiver is not familiar with the patient. Assaultiveness results from protective reflexes and disinhibition directly related to the dementia. Apraxia, aphasia, and agnosia, made worse by impairment in vision and hearing, reduce the patient's ability to complete or comprehend simple tasks or to recognize the caregiver. It is helpful to educate staff that the

objectionable behavior is the result of neurologic deficits and protective responses rather than malice. With time, staff become accustomed to the patient's needs and, through perseverance and intuition, develop an effective routine of care. Two persons may be required for bathing to prevent assault. The time saved by team approach to "problem bathers" more than compensates for the added personnel. Nonetheless, for some patients, a low dose of risperidone, olanzapine, or the short-lived benzodiazepine lorazepam is necessary to counter combativeness.

Willful Behavior and Personality Disorders

Despite accusations that objectionable behavior is "done on purpose," most often staff and family are mistaken in attributing willfulness to the demented person's behavior. However, individuals with personality disorders may also become demented. Problematic interpersonal relations across adult life are the key indicator that psychotropic medications may not be beneficial. Limit setting and confrontation are more effective. Because the behavior is part of an established pattern, staff should adjust their expectations accordingly.

Falls, Wandering, Pacing

Gait disturbance due to apraxia, quadriceps weakness, rigidity, sedatives, and poor vision predispose the patient to falls, soft tissue injury, and fractures. Physical therapy, if the patient will actively engage and sustain the benefits, may reduce the risk but not eliminate it. A change in medications may help, but environmental modifications are more likely needed. Restraints are usually employed to reduce the risk of falls. However, they degrade the patient's quality of life, cause soft tissue injury, and have led to documented cases of strangulation. As a result, there has been a national effort to reduce if not eliminate restraints in long-term care.⁶⁴ The dilemma of balancing safety and freedom should be shared with staff and family to reach a consensus. The substituted judgment of family in an informed or negotiated model of consent is most helpful.⁶⁵ Faced with the progressive decline in a loved relative, the family may choose near-term freedom from restraints and sedation rather than long-term freedom from injury.

The patient who walks about the backyard or enclosed garden of a nursing home presents no problem. However, when someone with dementia becomes lost in the neighborhood or wanders into traffic, safety becomes the issue. In the acute care setting, where wandering poses a more imminent risk, placing the patient under close observation may be necessary. In nursing facilities, an ankle bracelet set to electronically trip an exit alarm can help staff to redirect the patient to a safe destination. A family

member may volunteer to provide supervised walking. Alternatively, physical therapy or other forms of low-risk exercise may be substituted. Exercise for the demented person is an underutilized modality to remedy behavioral disturbance. Caregivers should seek to determine whether there is a temporal or event-related pattern to the wandering. Do reminders of leaving (hat, coat) need to be removed? Pictures of family prominently displayed in the patient's room may assist when helping the patient to "go home." Pacing or wandering may also signal unmet needs or discomfort. Staff may need to experiment with toileting, snacks, or analgesics to find the right solution.

Catastrophic Reactions

Persons with dementia can be transiently overwhelmed, displaying anxious confusion, unwarranted suspicions, or tearful self-reproach. This catastrophic response follows overstimulation and a sense of failure or threat. An overbearing attitude, rapid questions, excessive commands, or too much noise or activity can provoke the response. Criticism, whether real or implied, such as intrusive efforts to correct or reorient the person, may also contribute. Patient fatigue or conflict with certain individuals may also be to blame. To counter a catastrophic reaction, it is helpful to change the subject or defer the task to a less distressing time. A soothing tone, with empathic comments spoken slowly with eye contact, may abort the response. At times it will be necessary to create a distraction or to remove the patient from the source of conflict or supply a pleasurable alternative.

Medications for Behavioral and Psychologic Disturbances

"Start low, go slow" is the catchphrase of prescribing for older adults. However, the most common error when using medication to control behavioral disturbance is failure to follow through, to monitor the effects, and to adjust doses accordingly. A short-acting benzodiazepine (lorazepam 0.5 mg oral or intramuscular) can help the patient through procedures such as a CAT scan or MRI. For sleep disturbance, however, low doses of the sedating antidepressant trazodone (25–50 mg) may be effective. Hypotension may ensue as the dose is increased.⁶⁶

Antipsychotics

Haloperidol (0.5 mg), and risperidone (0.5 mg) are available in liquid form, which allows the dose to be given in food or a beverage for patients who have difficulty swallowing or accepting pills. Haloperidol, because of its lengthy track record, lack of cardiovascular effects, and availability of an intramuscular injection, may be pre-

ferable for short-term use in acute care settings. Although more expensive, the atypical antipsychotics are preferable for longer-term treatment. Risperidone, a mildly sedative atypical antipsychotic, does not induce movement disorders or hypotension at low doses (1–2 mg daily). Katz et al.⁶⁷ found it superior to placebo for the treatment of suspiciousness and aggressive behavior in dementia; however, at 2 mg, extrapyramidal signs began to appear. Olanzapine (2.5–10 mg) is less likely to induce extrapyramidal effects than risperidone but may cause somnolence, gait disorder, and elevated fasting blood glucose. It rarely lowers blood pressure, and the weight gain associated with its use may be desirable for some individuals. It also reduces agitation, aggression, and other manifestations of psychosis, as well as reducing their impact on caregivers.⁶⁸ Quetiapine (Seroquel) is more sedative than olanzapine but less likely to cause extrapyramidal effects. It is also relatively free of interactions with other drugs. At a mean dose of 100 mg (25 mg initially then up to 50 mg bid), it reduces behavioral disturbances, most notably hostility.⁶⁹

In summary, both the typical and atypical antipsychotic medications are modestly effective for psychosis in dementia. They exhibit a therapeutic window in which low doses are ineffective and high doses are either ineffective or induce intolerable side effects. Based on the controlled trials, ease of administration, and duration in clinical practice, risperidone is the initial choice, followed by olanzapine then quetiapine. If these agents fail, either a typical antipsychotic or clozapine would be next in line. If extrapyramidal side effects appear with risperidone, another atypical antipsychotic should be substituted. Although antipsychotics have been the main treatment of aggression, valproate (125 mg twice daily to start) has gained increasing recognition as an antiaggression agent, as well as a mood stabilizer. It is relatively safe, and not amnestic, arrhythmogenic, or hypotensive, but should be monitored with the same therapeutic levels used for anti-convulsant therapy.⁷⁰

Antidepressants

For the agitated or sleep-deprived depressed patient, trazodone is an effective antidepressant but is hypotensive and very sedative (25 mg initial dose). Nefazadone (50 mg twice daily to begin) is virtually free of amnestic and arrhythmic effects and is less sedative than trazodone. Sertraline (25 mg to begin) is not sedative and improves the signs of depression among nursing home residents in the late stages of dementia.⁷¹ Citalopram (20–40 mg), which is FDA approved for recurrent depression, is somewhat longer acting than sertraline. Paroxetine (10–20 mg daily) is a more calming selective serotonergic reuptake inhibitor. Like sertraline and citalopram, it is free of cardiovascular and amnestic risk but may cause

nausea and jitteriness in a minority of persons. For the frail patient in whom no risk of side effects can be tolerated, bupropion (75–150 mg twice daily), which is selectively noradrenergic, is reasonable.

In similar instances, methylphenidate (5–15 mg after breakfast and lunch) may be prescribed and has the advantage of rapid onset of therapeutic response for the apathetic or somnolent patient.⁷² Venlafaxine (25–100 mg twice daily) has the advantage of lacking sedative and hypotensive properties but may impair appetite.⁷³ In contrast, mirtazapine (7.5–30 mg) will improve sleep and appetite.⁷⁴ Antidepressants are frequently effective in combating anxiety. Sertraline, venlafaxine, and paroxetine are each FDA approved for one or more of the anxiety disorders and are less sedating than the benzodiazepines. Some practitioners also use nefazadone for this purpose.

Preparations for Late-Stage and End-of-Life Care

In the early stage of the disease, when incapacity is minimal, the practitioner should anticipate the need for supportive services and urge referral before the need becomes acute. Arrangements for home health aides, day treatment, respite care, and residence in nursing facilities can be patched together with a good deal of continuity. However, providing these arrangements exceeds the capacity of any one individual and is best coordinated by a social worker or other professional functioning as a case manager. Legal advice for the management of financial assets is another important area of consideration for the family. Nursing home placement will devastate even substantial estates, and prolonged care at home is also expensive.⁷⁵ Durable power of attorney assigned to a family member while the patient is still capable of exercising the necessary judgment will ensure adequate access to resources once the person is no longer able to manage financial decisions.

Cost considerations aside, patients and families need assistance throughout the treatment process to confront end-of-life care issues early, while the patient can still participate in appointing a surrogate decision maker and expressing preferences about future care. The appointment of a durable power of attorney for health care decisions (health care proxy) is the first step. A backup proxy may also be appointed. Some ethicists prefer the appointment of a health care proxy over the designation of advance directives. The proxy is empowered to act across an array of contingencies, which may be difficult to anticipate. However, the use of “feeding tubes” (gastrostomy or nasogastric tube), “breathing machines” (respirators), and “artificial kidney” (hemodialysis) for reasons beyond treatment of acute illness will be rejected by most older patients under circumstances of irreversible loss of mental ability. Late-stage dementia patients become so

impaired that they are unable to allow others to feed them or to swallow without aspiration. Difficulty with feeding may signal terminal decline. Artificial nutrition and hydration through a gastrostomy tube has not been demonstrated to reduce suffering or prolong life in advanced dementia.⁷⁶ Further, feeding tubes are associated with aspiration pneumonia, fecal and urinary incontinence, cellulitis at the tube site, and other morbidities. Placement of a feeding tube also signals loss of the human contact gained through spoon-feeding.

Given the real risks and scant benefits of feeding tubes, their use is considered an option rather than an imperative. When those who care for the person are at odds about placing a feeding tube it is helpful to determine by consensus the specific goal to be achieved by the treatment. Typical examples include decubitus healing or a return to oral feeding. The involved parties can then agree to a time limited trial of tube feeding and, if the desired goal is not met the tube can be removed once proven to be ineffective.⁷⁷ (Also see Chapter 29.)

Cardiac resuscitation should also be carefully discussed before the indication arises. Late in the stage of dementia, when the patient has lost awareness of caregivers and surroundings, the use of antibiotics or hospitalization for acute illness has not been shown to prolong life and is associated with significant distress and agitation. These are difficult decisions, but they are more easily approached when the practitioner anticipates the need and is experienced in the discussion.⁷⁷

Medical Legal Issues

Physicians are increasingly being called upon to provide affidavits and expert testimony regarding the capacity of an older individuals to manage assets and property and to make essential life decisions. A credible evaluation should include a diagnostic assessment that emphasizes the evaluation of functional capacity and is substantiated by validated measures of cognitive impairment and functional deterioration. Ideally, the evaluation should include a visit to the allegedly incapacitated person's home where the ability to manage personal documents, mail, medications, financial transactions, and telephone can be directly observed. A history of functional decline from collateral informants and a review of medical assessments to ensure that reversible causes of mental impairment have not been neglected are mandatory. The report should delineate life skills that are preserved, as well as those that are deficient. For example, an individual may take pride in keeping house and preparing meals but not be able to balance the checkbook or make change in the market. A court-ordered financial guardian and assistance with shopping are required, but a housekeeper is not. (See also Chapter 84.)

Summary

A comprehensive approach based on evidence from the scientific literature promises to reduce the disability of dementia substantially in the near future. However, the use of medications and modifications in staff or family's approach to the patient still requires ingenuity and perseverance. Even modest individual benefits, when spread over the large numbers of older Americans who will become demented, means sizable reductions in projected costs of care.

Neurobiologic Basis of Age-Related Dementing Disorders

Patrick R. Hof, Thierry Bussière, Joseph D. Buxbaum, and John H. Morrison

Over the past decade, we have witnessed a remarkable increase in our knowledge of the structural, molecular, and biochemical determinants of Alzheimer's disease (AD). Alzheimer's disease is the most common form of dementia, as it affects approximately 11% of the population over age 65, and up to 50% of individuals over 85 can be diagnosed as having "probable AD."¹ The exact pathogenic events that lead to dementia are not yet known, although numerous hypotheses regarding the formation of the typical lesions of AD have been proposed and many risk factors have been identified. The current knowledge of the pathologic changes that occur in AD suggests that structurally and functionally AD is predominantly a disease of the cerebral cortex. However, it is not a generalized loss of cortical function: it involves only certain populations of neurons that share specific regional and laminar distribution and connectivity patterns, whereas other neuron types are spared.² Thus, different degrees of neuronal vulnerability exist in AD that can be related to the morphologic and biochemical characteristics of select neuronal populations and connections.

In this context, neuroanatomic analyses of nonhuman primate brain have considerably expanded our knowledge of the organization of the major afferent and efferent systems of the cerebral cortex, as well as its intrinsic organization. These analyses have fostered the development of an organizational scheme for the cerebral cortex that relates various molecules of interest to specific groups of neurons or circuits and have been particularly illuminating in regard to the organization of neocortical connectivity and interactions between the neocortex and the hippocampus. Furthermore, specific histochemical techniques have made it possible to investigate issues such as neuronal typology, connectivity, and localization within the context of their neurochemical identity. Certain neuron types within the cerebral cortex and some of the major cortical afferent systems have now been characterized as to the presence of structural proteins and neurotransmitters, and the extension of these studies

to the human cerebral cortex is currently on its way. There are obvious limitations as to the application of such experimental paradigms to the study of the human brain, and it should be kept in mind that the human brain has become the object of intensive analyses with chemically specific techniques only relatively recently. However, many of the histochemical procedures work very reliably in the postmortem human brain, and to some extent it is possible to draw certain correlations across species that have allowed for the application to the human brain of organization principles described in several species of nonhuman primates. Such correlations have been particularly useful in regard to issues pertaining to the neuropathology of AD, as well as to the normal functional anatomy of the human cerebral cortex, although caution must be used when transposing information extracted from analyses of the monkey to the human brain.

Overview of Neuronal Vulnerability in Dementia

It is instructive to consider briefly the links between the distribution of pathologic changes in AD and related dementing conditions and the localization of specific elements of the cortical circuitry that are affected by these alterations. The current state of knowledge on the molecular components of the principal neuropathologic lesions observed in AD can be considered in the context of observations that relate the neurochemical phenotype of a given neuron to its relative vulnerability or resistance to the degenerative process. Selective neuronal vulnerability has been particularly well studied in AD but is a cardinal feature of all the major age-related neurodegenerative disorders.² The notion of differential vulnerability can be best understood in the context of an inclusive and integrative definition of neuronal typology that includes single cell morphology, regional and laminar location, connectivity, and neurochemical phenotype. This approach is useful

FIGURE 75.1. Examples of neurofibrillary tangles (NFT) (A) and senile plaques (SP) (B) from the hippocampus of a severe Alzheimer's disease (AD) case. Note the flameshape morphol-

ogy of NFT and the more variable features of SP. In (B), several SP stained with an anti-amyloid protein antibody are visible. *Bar* (on B) 100 μ m (A); 200 μ m (B).

to explore the cellular organization of the neocortex, as well as the cellular pathologic changes in diseases such as AD, as it considers the complex relationships among these morphologic and functional parameters.

In a very general sense, the most vulnerable group of cortical neurons includes large pyramidal cells, and more specifically those providing long corticocortical projections between association neocortical areas and hippocampal projections. These systems utilize the excitatory amino acid neurotransmitter glutamate and are driven by glutamatergic input. The occurrence of modifications in the expression during aging or dementia of some of the various subunit proteins that constitute the glutamate receptors, in particular those subunits regulating calcium permeability through the receptor channels, may determine susceptibility to calcium-mediated toxicity, which may play an important role in the degenerative processes leading to neuronal death in dementing illnesses. For example, neurons that express high cytoplasmic levels of certain calcium-binding proteins may have an increased calcium-buffering capacity and are likely to resist the toxic effects of abnormal intracellular calcium concentrations. Other neurons, in particular, pyramidal cells, are not equipped with such molecular mechanisms and demonstrate enhanced vulnerability to a variety of noxious stimuli that may lead to the formation of the neurofibrillary tangles (NFT), one of the cardinal pathologic changes of AD. It appears, therefore, that specific neurochemical and morphologic characteristics of certain pyramidal neurons may predispose them to degeneration, as well as NFT formation. Because only certain neuronal circuits are affected in AD, the relevance and impact of pathologic alterations in AD are best understood within the context of the organized systems that underlie neocortical function. For example, integrated processing in a given sensory modality such as vision involves the simultaneous activity of numerous distinct

cortical domains that have extensive, ordered interconnections establishing a distributed, hierarchical system and subserving the proper integration of the visual information. Similarly, cognition and language, not modality-specific functions, presumably rely on more complex networks. Such corticocortical circuits are provided by the particular neurons that degenerate in AD, leading in turn to a global neocortical disconnection syndrome that presents clinically as dementia.^{2,3}

Lesion Types and Distribution in Alzheimer's Disease

Alzheimer's disease is a neurodegenerative disorder classically characterized by the presence of two major types of histopathologic lesions, neurofibrillary tangles (NFT) and senile plaques (SP), in the cerebral cortex (Fig. 75.1). The distribution and density of NFT and SP have been analyzed in great detail and constitute the basis of the neuropathologic diagnosis of AD.⁴ NFT are characterized by the accumulation of abnormal components of the neuronal cytoskeleton that form paired helical filaments, whereas SP are composed of dystrophic neurites and glial elements with or without a central amyloid core.^{3,5,6} These lesions are consistently observed throughout the brain but predominate in the cerebral cortex, where NFT are located in the soma of large pyramidal neurons, and SP are distributed throughout the cortical regions but are particularly numerous in association areas.⁷ Tangles are also found in a number of subcortical structures connected with the cerebral cortex, such as the amygdala and the thalamus, as well as cholinergic and aminergic nuclei in the basal forebrain and brainstem. Variable densities of SP are also observed in other subcortical structures, such as the cerebellum and basal ganglia. Other pathologic alterations commonly seen in the brain of AD

patients include neurophil threads, which also contain paired helical filaments and appear early in the course of the disease, granulovacuolar degenerations, diffuse amyloid deposits, and amyloid angiopathy.

Severe neuronal loss in the hippocampal formation and association regions of the neocortex, leaving primary sensory and motor areas relatively spared, is commonly observed in the brain of AD patients, involving the large cortical neurons, and correlated with the presence of NFT in neocortical association areas.² Also, synapse loss, together with increased synaptic size, is an early marker of the dementing process because a strong association

between loss of neocortical synapses estimated by immunolabeling for the synaptic protein synaptophysin and cognitive impairment has been reported, which appears to be a better correlate of cognitive deficit than NFT densities.⁸ Synaptic damage and synapse loss have also been reported in the neocortex of elderly nondemented individuals, suggesting an age-dependent mechanism for the loss or remodeling of synapses in the neocortex.⁹

At the regional level, NFT are more numerous in the temporal cortex, followed in descending order by the frontal cortex, the parietal cortex, and the occipital cortex (Fig. 75.2).^{3,4,7} NFT are observed primarily within layers

FIGURE 75.2. Regional distribution of NFT and amyloid deposition in the cerebral cortex in normal aging compared to very mild AD and severe AD.^{2,4,7,10-12}

NFT appear first in the hippocampal formation and entorhinal cortex. Cases with incipient dementia show low numbers of NFT in the inferior temporal cortex and prefrontal cortex. During subsequent stages in the progression of AD, NFT are found throughout the cerebral cortex, although generally lower densities are present in primary sensory and motor cortices compared with association regions. Senile plaques are present principally in the hippocampal formation and temporal neocortex in normal aging, but it should be noted that the primary visual cortex may contain relatively high levels of amyloid deposition as well. In AD cases, amyloid is present throughout the neocortex. In terms of regional densities it is interesting to note that the hippocampal formation shows somewhat less amyloid deposition than the association neocortex. It should be kept in mind that these patterns are inferred from typical cases and provide a generic overview of the distribution of these lesions from a neuropathologic standpoint, but do not serve as a quantitative measure that can be used as a correlate of the severity of the dementing process, and do reflect the considerable case-to-case variability in numbers of lesions.

NORMAL AGING

VERY MILD AD

SEVERE AD

Neurofibrillary tangles

III and V in the neocortex, although their density varies considerably among cortical regions, primary sensory and motor regions having many fewer NFT than association areas.^{7,10,11} Similar differences are found in other sensory systems. In addition, considerable differences in laminar NFT distribution exist among neocortical regions. With a few exceptions, SP show a generally comparable distribution among neocortical areas.^{11,12} In the medial temporal lobe, layer II of the entorhinal cortex, the subiculum, and the CA1 field of the hippocampus represent particularly vulnerable cortical domains that consistently display very high NFT densities in AD (Fig. 75.2, 75.3).^{2,7,13} The distribution of SP in the hippocampal formation is variable, with certain zones displaying high SP densities and amyloid deposition, such as layer III of the entorhinal cortex, the molecular layer of the dentate gyrus, and the superficial layer of the subiculum.¹⁴

There are strong correlations between the distribution of SP, NFT, and neuron loss among regions and layers of the cerebral cortex and the neurons of origin of certain long corticocortical and hippocampal projections.^{10-13,15-17} The neurons of origin of corticocortical projections can be ascribed to three categories, feedforward, feedback, and lateral connections, based on their localization in the cortical layers and the distribution of their axonal terminals in the regions where they project (Fig. 75.4).^{18,19} In this scheme, feedforward connections ascend within the hierarchy of a given modality (i.e., from a primary sensory area to an association area), feedback projections descend the same hierarchy, and lateral connections link cortical regions at the same hierarchical level. Feedforward connections originate mostly from neurons located in the superficial layers of the cortex and terminate in the deep portion of layer III and in layer IV of the target cortical region, feedback projection neurons are located principally in layers V and VI and project to layers I and VI, and lateral connections originate from layers V and VI and project to layers III to VI (Fig. 75.4). The distribution of NFT indicates that elements of feedforward, lateral, and feedback projections can all be affected by the degenerating process of AD. Considering that layer V contains generally higher NFT densities than layer III in association areas suggests that feedback as well as lateral projections may be at higher risk in AD than feedforward systems.

Interestingly, most of the projection neurons from the occipital and temporal association cortex to the frontal and from the occipital cortex to the temporal cortex are located in layer III. The regional and laminar distribution of SP suggests that they may be related to NFT formation (see Figs. 75.2, 75.4), in that their distribution appears to reflect the degeneration of the terminations of projections from neurons affected by NFT formation,¹⁰ although multiple neuronal systems are involved in SP formation.²⁰ The distribution of NFT and SP in the hip-

FIGURE 75.3. Regional and laminar NFT formation and neuronal loss in normal aging and AD. The flameshaped structures represent a semiquantitative assessment of NFT densities. An estimate of the percent of neuronal loss is shown by the gray scale (see % equivalent at *bottom*). In normal aging (CDR 0), a few NFT are consistently observed in layer II of the entorhinal cortex (EC) and the superior frontal cortex (SFC) remains devoid of NFT. There is no neuronal loss in normal aging. In contrast, very early AD (CDR 0.5) is characterized by higher NFT densities in the EC. Very rare NFT are observed in SFC. The neocortical areas show no neuronal loss, but a significant degree of neuronal loss is present in layer II of the EC. In definite AD (CDR 2), NFT are found in very high densities in layer II of the EC, but in moderately high densities in SFC. The degree of neuronal loss parallels NFT densities in these regions. The size of boxes reflects tissue shrinkage, due to neuronal loss, in AD.

pocampal formation also outlines specific projections. The perforant pathway that projects from layers II and III of the entorhinal cortex is affected severely and early during AD, and the presence of NFT in the neurons of origin of this pathway and its termination in the dentate

gyrus are correlated with high densities of SP in the molecular layer of the dentate gyrus.²¹ High densities of NFT in layer V of the entorhinal cortex are correlated with the degeneration of connections to the amygdala and association cortical areas part of the limbic lobe, and the projections from the hippocampus to the entorhinal cortex, amygdala, and neocortical areas, originating from the CA1 field and the subiculum, are consistently affected, as are amygdala nuclei projecting to the entorhinal cortex and hippocampus.²¹

Molecular Constituents of Neurofibrillary Tangles

The presence of intracellular fibrillar aggregates in certain cerebral regions is a common feature of several neurodegenerative disorders, as well as of aging. Neurofibrillary tangles have been extensively studied as a neuropathologic signature for AD. The molecular dissection has shown that the microtubule-associated proteins (MAP) tau are the main components of these aggregated structures in AD. Tau proteins are derived from a unique human tau gene located on chromosome 17q21–22 (see details in Fig. 75.5). Importantly, exons 2, 3, and 10 are

alternatively spliced, giving rise to six different isoforms in the adult human brain.²² The expression of these isoforms is developmentally regulated, as only the shortest isoform is present in the fetal brain (called fetal isoform) and all the six tau variants are present in the adult brain. Moreover, the isoforms are differentially distributed among neuronal populations. Also, tau proteins undergo some posttranslational modifications, which is important in the context of pathologic conditions.²²

Tau proteins belong to the family of the microtubule-associated proteins (MAP), together with MAP1, MAP2, MAP3, and MAP4 in the nervous system. These microtubule-associated proteins are involved in the formation of the cytoskeleton by enhancing the polymerization of tubulin monomers and stabilizing microtubule bundles (Fig. 75.6).²³ The amino-terminal part of tau proteins is referred to as the projection domain, as it forms extensions from the microtubule core. These extensions are able to make connections with cytoskeletal components, such as neurofilaments, and with cytoplasmic elements or the neural plasma membrane. The projection domain is also involved in signal transduction pathways. The carboxy-terminal part of the molecule binds to microtubules through a flexible array of distributed weak sites and is referred to as the microtubule-binding

FIGURE 75.4. The laminar distribution of NFT and SP (*black triangles* and *black disks*, respectively, in the *center panels*) matches the distribution of corticocortically projecting neurons along neocortical hierarchies. Feedforward projection ascend the hierarchy, originating from a region involved in primary processing (such as the primary visual cortex), and terminating in an association cortex dealing with more complex types of information (such as a visual region located in the parietal lobe and integrating visual motion). The feedback projections are reciprocal to the feedforward projection and descend the same

hierarchy.^{18,19,40} Not shown on this diagram are lateral connections that interconnect cortical regions located at the same functional level in the hierarchy. The NFT are found in the same cortical layers in which the neurons providing feedforward and feedback corticocortical projections are located, and they are slightly more numerous in the deep layers, suggesting a stronger correlation with feedback projections. Senile plaques are observed in higher densities in layer IV and the lower portion of layer III, which corresponds to the zone of termination of feedforward projection.

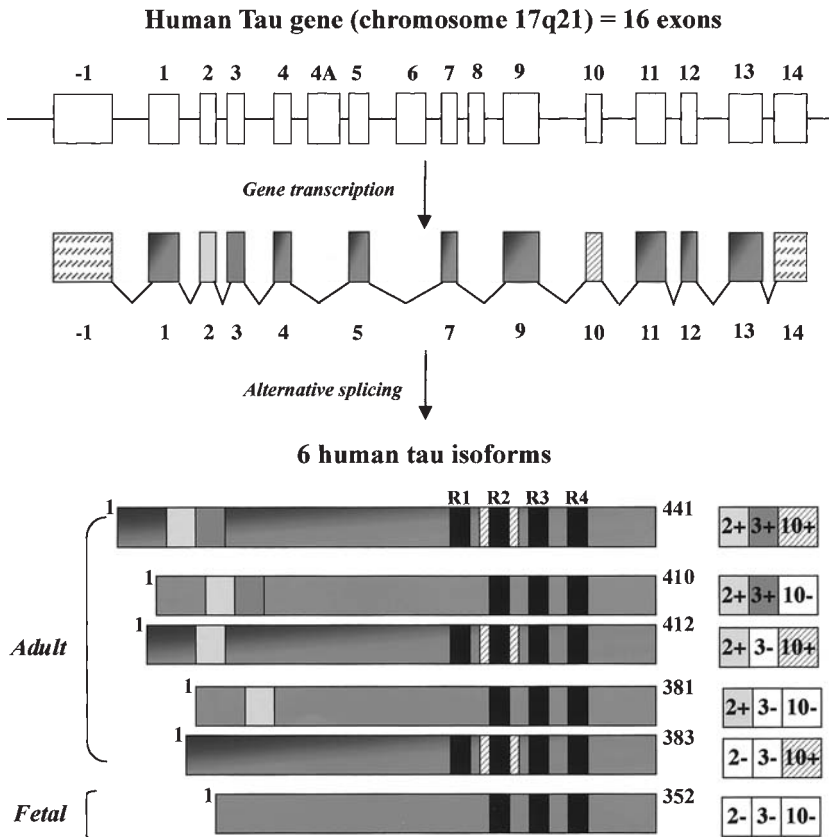

FIGURE 75.5. Schematic representation of the human Tau gene and the six tau isoforms present in the human brain. The human tau gene is located on the long arm of chromosome 17 at position 17q21. It contains 16 exons, with exon 1 a part of the promoter (*upper panel*). Exons 4A, 6, and 8 are not transcribed in humans (*middle panel*). Exons 1 and 14 are transcribed but not translated. Exons 1, 4, 5, 7, 9, 11, 12, and 13 are essential constitutive elements of the gene, and exons 2, 3, and 10 undergo alternative splicing, giving rise to 6 different mRNAs, translated in 6 different tau isoforms (*lower panel*). These isoforms differ by the absence or presence of one or two 29-amino-acid inserts encoded by exon 2 (*light box*) and 3 (*dotted box*) in the amino-terminal part, in combination with either three (R1, R3, and R4) or four (R1–R4) repeat regions (*black boxes*) in the carboxy-terminal part. The fourth microtubule-binding domain is encoded by exon 10 (*hatched box; lower panel*). The number of amino acid varies between 441 (longest tau isoform) and 352 residues (fetal tau isoform).

FIGURE 75.6. Neurofilaments and microtubules are the major components of the neuronal cytoskeleton. Microtubules constitute the network responsible for the axonal transport of soluble proteins and vesicles between the neuronal cell body and the synapses (anterograde transport), or between the synapses and the cell body (retrograde transport). In physiologic conditions, a dynamic equilibrium exists such that polymerization of tubulin monomers occurs at one end of the microtubules and

depolymerization occurs at the opposite end. Finally, polymers of tubulin are stabilized by specific proteins called microtubule-associated proteins (MAPs). Tau proteins belong to this class. Nonphosphorylated tau proteins promote the polymerization of tubulin monomers into microtubules and also stabilize the bundles of newly formed microtubules. Conversely, phosphorylation of tau proteins abolishes their binding to microtubules and results in depolymerization and eventually NFT formation.

domain. It regulates the rate of microtubule polymerization, stabilizes the forming microtubules, and is also involved in interaction with functional proteins such as protein phosphatase 2A or presenilin 1.²²

Tau proteins exhibit about 70 potential phosphorylation sites, and at least 30 of them have been described by using different biochemical or immunohistochemical techniques. At any given time, the phosphorylation state of the sites results from the regulated activity of kinases and phosphatases. The binding between tau proteins and microtubules and the subsequent microtubule stabilization depends partially on the phosphorylation state. Hyperphosphorylated tau proteins aggregates have been described in AD, as well as in several other neurodegenerative diseases, the so-called “tauopathies.”²² Extensive studies have shown that a specific distribution of the tau lesions, as well as different electrophoretic patterns of tau proteins, could discriminate among these disorders (Fig. 75.7). In AD, the filamentous tau inclusions are known as paired helical filaments (PHF), based on their ultrastructural appearance. These PHF exhibit specific biochemical properties that distinguish them from the normal tau proteins. PHF form insoluble polymers that are not found in normal samples obtained from biopsy materials. The electrophoretic profile of abnormally phosphorylated tau proteins shows a triplet of bands at 55, 64, and 69 kDa, and a minor band at 72 to 74 kDa. Dephosphorylation of PHF tau proteins before their electrophoretic migration

shows that this triplet results from the aggregation of the six tau isoforms.²²

In addition to AD, NFT are observed in a variety of neurodegenerative disorders. Remarkably, these disorders can be identified on the basis of their biochemical profile of tau isoforms. Figure 75.7 summarizes the typical tau profiles in postencephalitic parkinsonism (PEP), Guamanian amyotrophic lateral sclerosis/parkinsonism-dementia complex (ALS/PDC), corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), Pick's disease, and frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17). Neurofibrillary tangles are found in variable densities in the brain of patients who survived the influenza pandemic in the years 1916 to 1926 and who later developed PEP. The biochemical analyses have shown that the six isoforms of tau proteins are hyperphosphorylated, aggregate into NFT, and display an AD-like electrophoretic pattern (triplet tau55, tau64, and tau64).²⁴ Nevertheless, the distribution of these proteins, predominantly in association cortices and subcortical brain regions but also in primary motor cortex and basal ganglia, differs from that in AD, where the triplet of tau proteins is mostly restricted to the hippocampal formation and association neocortex. It should be mentioned that heterogeneity exists among cases. A similar electrophoretic profile of tau proteins has been described in cases with Guamanian ALS/PDC. The regional and laminar distribution of the tau triplet differs

FIGURE 75.7. Schematic representation of the different electrophoretic profiles of pathological tau proteins using a phosphorylation-dependent monoclonal antibody (in frames), with their isoforms composition (right of each frame). The six tau isoforms are involved in the formation of the tau55, tau64, tau69 AD triplet with the minor tau74 variant. This pattern is also described in postencephalitic parkinsonism (PEP), Guamanian amyotrophic lateral sclerosis/parkinsonism-dementia

complex (ALS/PDC), and some families with FTDP-17 (left panel). The typical progressive supranuclear palsy/corticobasal degeneration (PSP/CBD) doublet tau64, 69 is related to the aggregation of hyperphosphorylated tau isoforms with exon 10. The FTDP-17 families with mutations in exon 10 or intron 10 exhibit the same profile (middle panel). Hyperphosphorylated tau proteins without exon 10 that aggregate in Pick's disease are detected as a tau55, 64 doublet (right panel).

from that in AD cases, as both cortical and subcortical areas are affected, and cortical layers II and III are preferentially involved.²⁵ In contrast to these two conditions, the electrophoretic pattern of tau proteins in CBD and PSP has been described as two major bands with an apparent molecular weight of 64 and 69 kDa (PSP/CBD tau doublet), although a minor 74-kDa band is also detected.^{26–29}

The characteristic lesions described in the brains of patients affected by Pick's disease, the so-called Pick bodies, are also detected with antibodies against phosphorylated sites present within tau proteins. By Western blotting, these antibodies reveal two bands with an apparent molecular weight of 55 and 64 kDa (Pick tau doublet) and a minor band at 69 kDa.^{30–32} The importance of tau proteins as the major component of fibrillar lesions has been emphasized by the emergence of a new class of neurologic syndromes called frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17).^{33–35} This designation includes different disorders sharing some clinical and pathologic features and for which a genetic linkage with chromosome 17q21–22 has been demonstrated.³⁶ The neuropathologic features are frontal and temporal atrophy, severe neuronal loss, gliosis affecting both the gray and white matter, and superficial spongiosis. The presence of filamentous inclusions in neuronal cells, or in both neuronal and glial cells, has been described. The presence of these lesions is caused by mutations on the Tau gene that always segregate with the pathology, underlining the direct role of tau proteins in the pathogenic mechanism. At least 17 mutations on the Tau gene have been described in different families. Some mutations result in a tau profile similar to that observed in PSP and CBD (tau64, tau69), whereas others are resolved as a typical AD tau triplet. These disease-specific tau profiles highlight well the fact that various etiopathogenic mechanisms can lead to a comparable neurodegenerative process resulting in the formation of NFT, which can be understood as a general response to neuronal injury.

Neuronal Types Prone to Neurofibrillary Tangle Formation

The number of NFT does not account for the total population of pyramidal neurons, indicating that only certain subpopulations of pyramidal neurons are selectively susceptible to paired helical filament aggregation. The large neocortical pyramidal cells in layers III and V represent the most affected cell class, whereas smaller pyramidal neurons in layers II, VI, and the upper part of layer III are more resistant to NFT formation. Also, the spiny stellate cells and small pyramidal cells in layer IV are not

affected by this process as are the many morphologic types of inhibitory interneurons. The large pyramidal neurons in layers II, III, and V of the entorhinal cortex and those in CA1 field and subiculum are all severely affected. Considering the morphology and connectivity of the vulnerable neurons, it is interesting to note that all are efferent cells that send long projections to other cortical regions or to subcortical structures, and all are large pyramidal neurons.^{16,17} However, other cellular characteristics are also linked to vulnerability to the degenerative process because certain large efferent neurons, such as the principal cells in the CA3 field and the large neurons of the dentate hilus, are generally relatively resistant to degeneration in AD, and in subcortical structures, NFT appear in several nuclei that project to the cerebral cortex, such as catecholaminergic cell groups in the brainstem and cholinergic neurons in the nucleus basalis of Meynert.

Certain pyramidal neurons in the human and monkey neocortex have been shown to be enriched in neurofilament protein.^{16,17,37} Neurofilament protein immunoreactivity in the primate neocortex is restricted to the perikaryon and dendrites of a subpopulation of large pyramidal neurons. Interestingly, neurofilament proteins, as well as other cytoskeletal proteins, have been implicated in NFT formation,^{2,38} and pyramidal cells expressing high levels of nonphosphorylated neurofilament protein appear to be highly susceptible to NFT formation. The distribution of neurofilament protein-containing neurons corresponds to the distribution of corticocortically projecting cells, as demonstrated by studies in the macaque monkey.³⁹ The correlation between origins of long corticocortical projections and neurofilament protein-containing neurons is particularly visible in the primary visual cortex of monkeys and humans, where layer IVB cells and the Meynert cells are the only large, strongly immunoreactive neurons. These neurons form well-established connections to the parietal lobe and subserve visuomotor functions known to be affected during aging and AD.⁴⁰ These observations on visual projections therefore demonstrate the existence of a neurochemically defined neuronal subpopulation that is vulnerable in AD and can be correlated with a functionally characterized projection system.

We have also reported in the macaque monkey that many long association corticocortical projections originate from neurofilament protein-containing neurons, and, in some of them, 90% to 100% of the neurons of origin of the projection contain neurofilament protein,³⁹ which is particularly the case of projections from the temporal to the prefrontal and parietal neocortex that are known to be involved in networks subserving many aspects of the cognitive functions.⁴¹ In fact, the laminar distribution of neurofilament protein-containing neurons in visual association, prefrontal, and anterior cingulate in

FIGURE 75.8. Involvement of neurofilament protein-immunoreactive pyramidal neurons in layer III of the area 9 in an AD case. In this sample labeled for neurofilament protein and tau protein, a few normal neurons are labeled (*arrows*) and an intracellular NFT is seen developing within a neurofilament protein-immunoreactive neuron (*arrowhead*). Bar 30 μm .

human cerebral cortex is very similar to the distribution of NFT in that the layers that have high NFT density in an AD brain no longer contain a high density of neurofilament protein-immunoreactive neurons.^{16,17} A comparable situation exists in the hippocampal formation where layers II, III, and V of entorhinal cortex and the pyramidal neurons of the subiculum have a very high density of neurofilament protein-immunoreactive neurons in the normally aging human brain and present with a dramatic loss of these neurons in AD.²

These observations demonstrate that neurofilament protein-containing neurons are highly vulnerable in AD, and quantitative analyses have demonstrated a severe loss of neurofilament protein-containing neurons in layers III and V in the inferior temporal and superior frontal cortex (Fig. 75.8). The severity of the loss correlates with the size of these neurons in that the neurofilament protein-containing neurons larger than $6000\mu\text{m}^3$ of perikaryal volume are the most affected, with up to 60% cell loss, whereas the smaller-size neurons ($2000\text{--}6000\mu\text{m}^3$ of perikaryal volume) are not affected.¹⁶ In addition to regional distribution and relationship to connectivity, NFT identified by antibodies to neurofilament and tau proteins have revealed dynamic cellular alterations in vulnerable neuronal populations during normal aging. Layer II of the entorhinal cortex contains neurofilament protein-immunoreactive neurons and also displays

immunoreactivity to tau protein, suggesting the existence of transitional forms of NFT during aging.² In AD cases, most NFT in the entorhinal cortex progress to an end stage and are no longer immunoreactive to neurofilament protein, and transitional forms of NFT are observed in the frontal cortex, indicating that a time-dependent process takes place in the formation of NFT in certain neurofilament protein-containing neurons (Fig. 75.9).^{2,6,20}

Interestingly, certain neurons, such as the pyramidal neurons of the CA1 field, do not normally express detectable levels of neurofilament protein in young adults but do form NFT in AD. Such neurons show increasing levels of neurofilament protein immunoreactivity during aging before accumulation of tau protein, suggesting that high levels of neurofilament protein are a necessary substrate for the formation of NFT.⁴² Thus, one of the neurochemical characteristics of the vulnerable neurons in AD is the presence of high somatic and dendritic concentrations of nonphosphorylated neurofilament proteins, even though this may be only one aspect of the phenotype associated with selective neuronal vulnerability. In addition, when the monkey data are considered together with the distribution of neurofilament protein-containing neurons and NFT in humans, it is likely that the human homologues of the neurofilament protein-containing, corticocortically projecting neurons of the macaque monkey are those that are highly vulnerable in AD.

These neuronal networks use glutamate as their neurotransmitter. Disruption of glutamate metabolism and glutamate receptor-mediated excitotoxicity represents one of the major mechanisms of neuron death in many neurodegenerative disorders. Glutamate receptor-mediated excitotoxicity presumably results from increased calcium flux leading to toxic intracellular concentrations of this ion, and this mechanism is likely associated with all types of ionotropic glutamate receptors that are involved in facilitating or regulating calcium fluxes. Although the *N*-methyl-D-aspartate (NMDA) receptor has been the receptor subtype primarily associated with calcium flux into the neuron, it is now clear that both kainate and α -amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors also modulate calcium influx.⁴³ Thus, the glutamate receptor profile of cortical neurons and related circuits has emerged as an important parameter when correlating identified neurons and circuits with susceptibility for vulnerability to degeneration through excitotoxicity, because the defining characteristics of a given glutamatergic projection with respect to ion fluxes depends on the subunit composition of the receptors that dominate that system.

Abnormal functioning of glutamatergic receptors and resulting increases in intracellular calcium concentration are also linked to a variety of pathologic molecular events, such as production of free radicals, increased

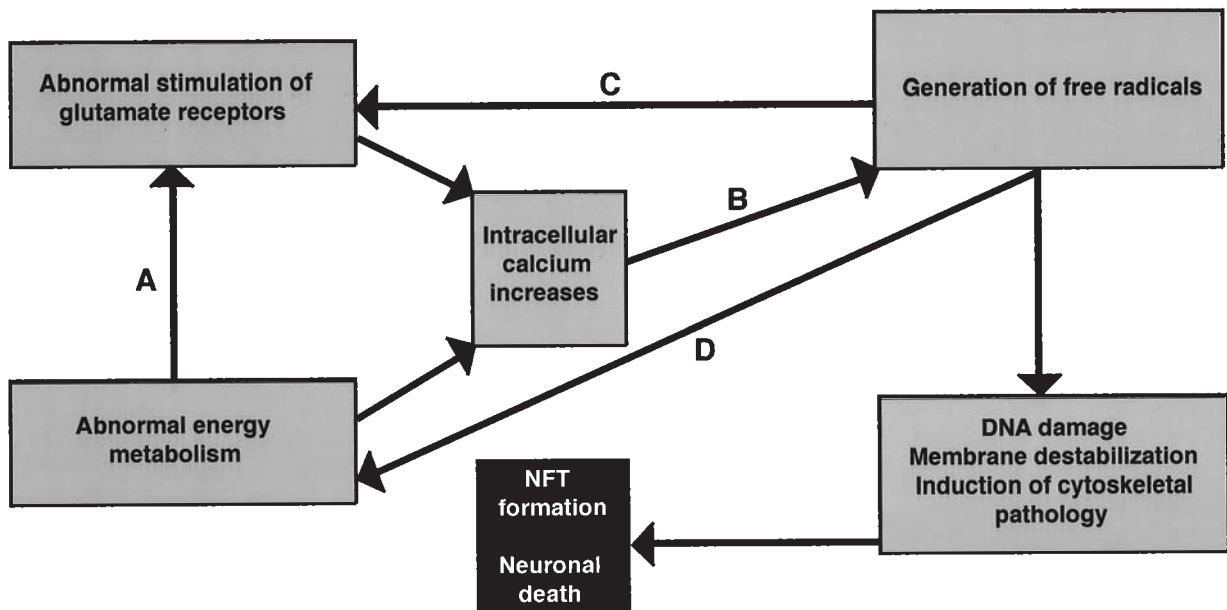

FIGURE 75.9. Mechanisms through which an imbalance in excitatory neurotransmission can induce a molecular cascade resulting in neuronal damage and death. Impaired energy metabolism can result in abnormally elevated stimulation of ionotropic glutamate receptors through depolarization of membranes (A) as well as increasing intracellular calcium. Elevated calcium can trigger the generation of free radicals by activating a number of calcium-dependent enzymatic reactions (B). Free

radicals are extremely reactive products that will induce direct damage to cellular structure and result in neuronal death. Free radicals also affect glutamate receptors by further increasing the release of excitatory amino acids (C) as well as energy metabolism by inducing mitochondrial dysfunction (D). It is likely that all these pathways participate in the formation of NFT in the AD brain.

release of excitatory amino acids, destabilization of lipid membranes, and damage to the cytoskeleton, that are all involved in the final processes leading to NFT formation and cell death (see Fig. 75.9). Autoradiographic, immunocytochemical, or in situ hybridization studies have demonstrated severe alterations in the distribution and density of several glutamate receptor subunits in the cerebral cortex in normal aging and AD.⁴⁴ In addition, changes in the expression of specific glutamate receptor subunits leading to functional decline without neuronal degeneration are known to occur during normal aging.^{45,46} For instance, in aged monkeys, compared to juvenile and young adult monkeys, the NMDA receptor levels decrease specifically and consistently in the outer molecular layer of the dentate gyrus in the hippocampal formation, where the perforant path terminates, but there are no significant differences in expression of AMPA or kainate glutamate receptor subunits and no morphologic reflection of degeneration of the perforant path.^{45,46} These data also suggest that the intradendritic parcellation of a particular neurotransmitter receptor is modifiable in an age-related and circuit-specific manner and that such changes may be an underlying condition for age-related memory impairment.^{2,45}

It should be noted that several classes of GABAergic

interneurons containing the calcium-binding proteins parvalbumin, calbindin, and calretinin, as well as a variety of neuropeptides, are largely resistant to the degenerative process, even in severe cases displaying very high densities of NFT and SP.³ The cellular distribution of calcium-binding proteins is largely coextensive with that of GABA in cortical interneurons, and these proteins subdivide the GABAergic neurons into nonoverlapping morphologic subtypes that together account for the vast majority of the GABAergic cells.⁴⁷ Moreover, parvalbumin-immunoreactive neurons have been shown to be resistant to degeneration in the cerebral cortex of Huntington's disease, Pick's disease, Guamanian ALS/PDC, PEP, PSP, CBD, and frontal lobe dementia, but not in Down syndrome and Creutzfeldt-Jakob disease. Calbindin- and calretinin-containing cells are also resistant in most of these disorders, except in frontal lobe dementia, where calbindin-immunoreactive neurons are vulnerable.³ The combination of factors such as high cytoplasmic levels of calcium-binding proteins, certain neuropeptides, and GABA with the morphologic features of locally projecting interneurons may confer some resistance to these neurons in many neurodegenerative illnesses and contrasts sharply with the morphologic phenotype of the vulnerable cells.

Molecular Biology of Amyloid and Its Role in Alzheimer's Disease

In addition to the intraneuronal accumulation of PHF, AD is characterized histopathologically by the presence of extracellular deposits of an amyloid peptide ($A\beta$) in plaques.⁴⁸ Plaques are spherical structures 15 to 20 μm in diameter, consisting of a peripheral rim of abnormal neuronal processes and glial cells surrounding a core of deposited materials. Brain $A\beta$ has both soluble and insoluble species, with aggregation states from monomer to higher molecular weight oligomers. Soluble brain $A\beta$ is predominantly a random coil and α -helical folded peptide. Insoluble $A\beta$ is β -sheeted and forms either fibrillar or amorphous deposits. These $A\beta$ fibrillar aggregates are thought to act as a nidus for subsequent deposits of other proteins, including α -antichymotrypsin, components of the complement cascade, and apolipoproteins E and J (apoE, apoJ).⁴⁹ $A\beta$ production and release are normal physiologic events. $A\beta$ peptides are normally present in the media of amyloid protein precursor-(APP-) expressing cultured cells and in human and rodent cerebrospinal fluid.⁵⁰⁻⁵³ Recently, there have been reports showing evidence there could be two distinct

pools of intracellularly generated $A\beta$: a pool that is eventually secreted and a pool that is destined to remain within the cell.^{54,55} The relative importance of intracellular versus extracellular $A\beta$ has not been determined at this point. Level of $A\beta$, as determined by ELISA, correlates exceptionally well with AD progression.⁵⁶

$A\beta$ is proteolytically derived from a larger integral membrane protein, the amyloid precursor protein (APP). APP is an integral membrane glycoprotein containing the $A\beta$ region, which includes 28 amino acids of the ectodomain and 11 to 14 amino acids of the adjacent transmembrane domain.^{48,57} The APP gene is localized on chromosome 21 at 21q21.2.^{58,59} APP can be processed by at least three secretases, namely α -, β -, and γ -secretase (Fig. 75.10). In the nonamyloidogenic pathway, α -secretase cleaves the amyloid precursor protein within the $A\beta$ domain, releasing an extracellular portion. The cleavage within the $A\beta$ domain prevents deposition of the intact amyloidogenic peptide. α -Secretase generates a soluble N-terminal fragment of APP known as $sAPP\alpha$, and its C-terminal counterpart of about 10 to 11 kDa remains embedded in the membrane. The 10- to 11-kDa C-terminal product may undergo an additional cleavage by a protease γ -secretase activity. The protease termed " β -secretase" initiates $A\beta$ generation by creating an

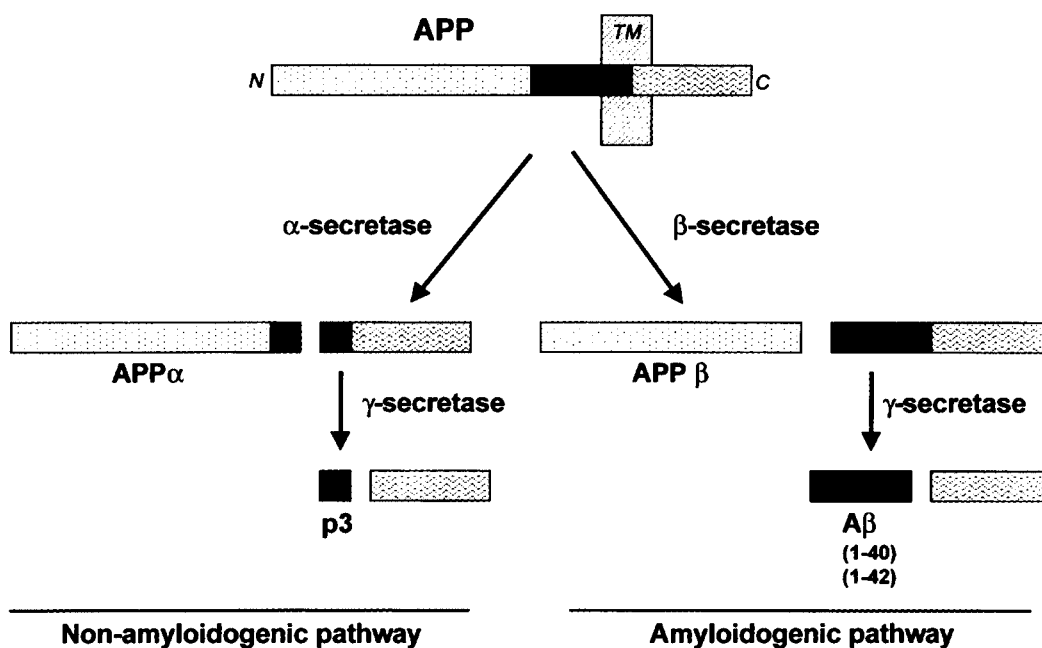

FIGURE 75.10. The amyloid protein precursor (APP) is a single transmembrane domain protein that exists as eight different isoforms transcribed by an alternative splicing mechanisms from a single gene located on chromosome 21. The normal function of APP is still unknown. The differential proteolytic cleavage of APP by α -, β -, or γ -secretase leads to the formation of different proteolytic products, which are involved in two differ-

ent pathways called the nonamyloidogenic and the amyloidogenic pathway. α -Secretase cleaves APP within the $A\beta$ domain (black box), and the consecutive cleavage by γ -secretase gives rise to the nonamyloidogenic p3 fragment. Conversely, β -secretase cleaves APP before the $A\beta$ domain, and the consecutive cleavage by γ -secretase generates the amyloidogenic $A\beta$ peptides that will aggregate into senile plaques.

approximately 12-kDa C-terminal fragment.⁶⁰ This 12-kDa fragment may then undergo “ γ -secretase” cleavage within the hydrophobic transmembrane domain to release the 40-, 42-, or 43-residue A β peptides.⁵² The varying C-terminal of A β may be a feature of crucial importance because A β peptides display distinct physical properties and, in particular, exhibit aggregation behavior that can vary according to their length.⁶¹ It has been shown recently in fibroblasts with a disrupted TACE (tumor necrosis factor α -converting enzyme) gene that two classes of α -secretase exist, one involved in the basal secretion and the other involved in regulated secretion.^{62–64} TACE, a member of the ADAM family (a disintegrin and metalloprotease family) of proteases, has been demonstrated to play a central role in regulated α -secretase cleavage of APP. Four groups have now identified a candidate for β -secretase (BACE), also known as Asp-2.^{65–68} Interestingly, presenilin 1 (PS1) appears to facilitate a proteolytic activity that cleaves the integral membrane domain of APP by γ -secretase.⁶⁹ It is possible that presenilins are γ -secretase or that they facilitate γ -secretase activity through some other mechanism.

Genes may be related to disease in two ways: through autosomal dominant mutations, by themselves sufficient to cause the disease (i.e., deterministic mutations), or, alternatively, through gene variations (polymorphisms) that may increase disease risk without being sufficient by themselves to cause the disorder. This latter group is referred to as susceptibility genes. Although it is currently thought that most cases of AD occur sporadically, autosomal dominant transmission has been identified in families with early-onset AD, defined as beginning before the age of 65 years. These cases are relatively rare; worldwide, only several hundred families are currently known that carry deterministic mutations.⁷⁰ Extensive research carried out during the past two decades has isolated a number of genes that when mutated cause AD, that is, APP on chromosome 21,^{71,72} the presenilin 1 (PS1) gene on chromosome 14, and the presenilin 2 (PS2) gene on chromosome 1.⁷³ Mutations in these genes lead to early-onset AD and only explain a small proportion (5%–10%) of total AD cases. Furthermore, trisomy 21 (Down syndrome) increases the risk of AD, perhaps due to the tripled genetic dosage of APP. In addition, a number of susceptibility genes are also currently being studied, with polymorphisms of the apolipoprotein E gene receiving the most attention. The presence of the apolipoprotein E4 (apoE4-) allele has been identified as a genetic risk factor for sporadic and familial AD with late onset.

Several different pathogenic mutations have been found in exons 16 and 17 of the APP gene to date. These mutations are missense mutations. The early-onset AD mutations are located outside the A β amyloid sequence, close to the C-terminal γ -secretase cleavage site,⁷¹ within the transmembrane domain, or at the N-terminal β -

secretase cleavage site within the extracellular part of APP.⁷⁴ One mutation is located inside the A β amyloid sequence next to the α -secretase cleavage site.^{75,76} The localization of mutations led to the hypothesis that they might influence the activity of the respective secretases, resulting in the aberrant processing of APP.⁷⁷ Indeed, mutations at codons 716 and 717 lead to a selective increase in the production of A β peptides ending at residue 42/43.^{78–82} The mutations at codons 670 to 671, on the other hand, appear to augment the production of both A β 40 and A β 42(43),⁸³ whereas the mutation at codon 692 has a more complicated effect on APP processing, causing impaired α -secretase cleavage, increased heterogeneity of secreted A β species, and increased hydrophobicity of the A β .⁸⁰ This mutation also has clinical features in some cases similar to those of cerebral hemorrhage with amyloidosis of the Dutch type and in other cases more similar to AD.

The homologous membrane proteins presenilin 1 (PS1) and presenilin 2 (PS2) were identified in 1995 as the genes responsible for a substantial fraction of early-onset, autosomal dominant AD.^{73,84} Mutations in the PS1 gene on chromosome 14 are the most common cause for autosomal dominant familial AD (FAD)⁷³; these account for 30% to 50% of all early-onset cases⁸⁵ and are the primary cause of AD with onset before the age of 55 years. To date, more than 50 PS1 mutations and 2 PS2 mutations have been reported in FAD. All mutations in the PS are missense mutations, except for the mutation of a splice acceptor site resulting in the deletion of exon 9. Pathogenic mutations in PS modify APP processing, thereby leading to an augmentation of A β 42(43) secretion. AD patients carrying PS1 or PS2 mutations have significant increase of plasma A β 42(43) level together with deposition of A β 42 in the brain.^{86–88} In fibroblasts from such patients, the APP metabolism is shifted toward an increase of A β 42(43) production. Similarly, the presence of mutated PS1 increases A β 42(43) in transfected cells and in transgenic mice.^{89–92} How the mutant PS influences the production of A β 42(43) peptides remains uncertain. In neurons of PS1-knockout mice, secretion of A β is drastically reduced, leading to the accumulation of α - and β -cleaved C-terminus stubs of APP.^{69,93} This finding gives evidence that PS1 is obligatory for proteolysis of APP at the γ -secretase cleavage site.

In addition to the deterministic genetic mutations found in APP are the presenilins, genetic factors that modify the risk of getting AD. ApoE alleles on chromosome 19 are considered important risk factors for the development of late-onset AD. ApoE is a 34-kDa component of various lipoproteins, including chylomicrons, very low density lipoproteins (VLDL), and a subset of high-density lipoproteins (HDL).⁹⁴ These lipoproteins regulate plasma-lipid transport and clearance by acting as ligand for lipoprotein receptors such as LDLR and low density

receptor-related protein (LRP).^{95,96} ApoE is polymorphic and is encoded by three alleles (ApoE2, -3, and -4) that differ in two amino acid positions. In general, it seems that E4 allele increases the risk for developing AD by about threefold, and that the E2 allele decreases the risk.⁹⁷ The presence of one or two E4 alleles is associated with earlier onset of disease and an enhanced amyloid burden in brain but has little effect on the rate of progression of dementia.⁹⁸ Thus, the homozygous E4/E4 subjects have an earlier onset (mean age, >70 years) than heterozygous E4 subjects (mean age of onset for E2/E3, over 90 years).⁹⁹

The most obvious hypothesis is that ApoE E4/E2 polymorphisms might influence the production, distribution, or clearance of A β . This hypothesis is supported by observations that first, the subjects with one or more ApoE4 alleles have a higher burden than do subjects with no E4 alleles.¹⁰⁰ Second, there is evidence that both ApoE and A β may be cleared through the lipoprotein-related (LRP) receptor and that ApoE4 and A β peptide may compete for clearance through the LRP receptor.⁹⁵ Third, transgenic mice that overexpress APP develop a significantly lower number of A β deposits when bred to an ApoE knockout background.¹⁰¹ These findings strongly support a role of ApoE in the aggregation or clearance of A β in the brain. It should be noted that the ApoE genotype influences the onset of AD in patients with Down syndrome and in those with APP mutations but not in families with presenilin mutations.¹⁰¹

In summary, biochemical studies in postmortem tissue support a role for A β in AD. In addition, all available genetic evidence support a role for this peptide in AD. For these reasons, therapies targeting A β represent important therapeutic avenues for AD.

Conclusions

Clearly, other degenerative processes play an important role in AD, and they may also contribute to the clinical characteristics of the disease. Some cortical networks may be more sensitive to the effects of additional deleterious factors known to be involved in AD, such as inflammation free radicals, and potential amyloid toxicity, which may act in a synergistic manner with their morphologic and molecular phenotype to render them particularly vulnerable.¹⁰² However, the generalized loss of long corticocortical projections emerges functionally as the most devastating component of AD and that most directly related to dementia. Thus, the degeneration of presumed corticocortical circuits within the neocortex appears therefore to be the necessary factor for the clinical expression of the dementia in AD.^{2,3}

It should be kept in mind, however, that in sharp contrast to AD patients, many elderly individuals maintain near-normal levels of cognitive performance while sus-

taining significant compromise of hippocampal circuits and may rely more on neocortical than on hippocampal circuits for memories essential for daily activities.¹⁰³ Healthy elders may present with difficulties in learning and retrieving new information, and their major limitation may be the amount of new information they can learn within a given period of time in comparison to younger individuals. Unlike patients with early AD, healthy elders are able to retain the new information after some delay, whereas patients with mild cognitive impairment retain little of it.¹⁰³ This impairment in information retention that characterizes the very early stages of AD is correlated to neuronal loss in the entorhinal cortex and to volumetric changes in the temporal lobe. Similarly, the volume of the temporal horn of the lateral ventricle increases in these patients, which may correlate with the selective loss of projections from the entorhinal cortex.^{2,3,103-105} In fact, normal brain aging may be defined as intact cognitive abilities in the presence of scarce neurofibrillary pathology in the entorhinal cortex, which may represent a stable age-related asymptomatic AD-like neurofibrillary pathology. This idea points to the differential involvement of hippocampal and neocortical circuits between aging and dementia and indicates that whereas normal brain aging presents as a minimal pathology of discrete medial temporal regions, AD is a disease of the neocortical circuits (see Figs. 75.2, 75.3, 75.4).

This interpretation of the pathologic features of AD suggests that the debilitating effects of dementia result from changes restricted to the association neocortex. Considerable hippocampal alterations may occur in absence of neocortical involvement and with only minor disruptions in activities of daily living of the individual that are not sufficient for a diagnosis of dementia. The cells that provide the most vulnerable projections appear to be highly specialized neurons that share identifiable morphologic and neurochemical features. As the elements of the biochemical and anatomic phenotype that are linked to differential cellular vulnerability in AD are increasingly recognized, functional correlations are likely to emerge between cellular changes, neurochemical characteristics of vulnerability, and affected cortical pathways. It is hoped that this understanding will make it possible to design therapeutic strategies to protect or rescue the neurons at risk in AD. The protection of these neurons appears to be an attractive avenue for intervention in the management of AD and may be more practical than the development of a cure.

Delirium

Sharon K. Inouye

Delirium, defined as an acute alteration in attention and cognition, is a common, serious, and potentially preventable source of morbidity and mortality for older persons. Delirium is a clinical diagnosis, based on observation of the patient at the bedside. Although the exact diagnostic criteria continue to evolve, the criteria for delirium appearing in the Diagnostic and Statistical Manual Version IV (DSM-IV) of the American Psychiatric Association are widely used as the current diagnostic standard¹ (Table 76.1). However, these criteria were based on expert opinion, and their diagnostic performance has not been tested. The Confusion Assessment Method (CAM)² provides a validated tool, which is currently in widespread use for rapid identification of delirium (see Table 76.1). The CAM algorithm, which is based on the presence of the features of acute onset and fluctuating course, inattention, and either disorganized speech or altered level of consciousness, has a sensitivity of 94% to 100%, specificity of 90% to 95%, positive predictive accuracy of 91% to 94%, and negative predictive accuracy of 90% to 100% for delirium.²

Although it can occur in any setting, delirium is most common in settings where the frailty and illness acuity of patients are most severe. The incidence of delirium increases with age, cognitive impairment, frailty, illness severity, comorbidity, and other risk factors for delirium (see following). The emergency room and acute hospital have the highest overall rates of delirium. Acute alteration in mental status represents a leading presenting symptom for acutely ill older persons, accounting for at least 30% of emergency evaluations of older persons. In the hospital setting, the intensive care and postoperative settings have the highest rates of delirium.³ Although not well studied, delirium occurs with some frequency in nursing home and rehabilitation settings. Although less frequent in the community setting, delirium is an important presenting symptom to community physicians, and can serve as a barometer for underlying health status of elderly persons, often heralding serious underlying disease.

Epidemiology and Risk Factors

Because of its frequency in this setting, most of the epidemiologic studies of delirium have involved hospitalized older patients. Previous studies have measured the prevalence of delirium, that is, cases present at the time of hospital admission, as 14% to 24%, and the incidence of delirium, that is, new cases arising during hospitalization, as 6% to 56%.⁴⁻¹⁶ The rates of postoperative delirium range from 10% to 52%.⁴⁻¹⁶ Hospital mortality rates in patients with delirium range from 25% to 33%, as high as mortality rates associated with acute myocardial infarction or sepsis.^{4,5,10,11,17-24} Delirium has not been well examined in nursing home or community settings. In terms of the costs of delirium, it has been estimated that each year delirium complicates hospital stays for more than 2.3 million older persons, involving more than 17.5 million inpatient days and accounting for more than \$4 billion (1994 dollars) of Medicare expenditures related to hospitalization.²⁵ Moreover, delirium is associated with substantial additional costs after hospital discharge because of the increased need for institutionalization, rehabilitation services, home health care, rehospitalization, and other health care services.

Delirium is usually a multifactorial syndrome,¹⁴ as are many other common geriatric syndromes, such as falls, incontinence, and pressure sores. In some cases, delirium may be caused by a single factor, but more often delirium is the result of the interrelationship between patient vulnerability at the time of admission (i.e., predisposing factors) and the occurrence of noxious insults during hospitalization (i.e., precipitating factors). For example, patients who are highly vulnerable to delirium at baseline (e.g., such as cognitively impaired or severely ill patients), can be pushed into delirium by the presence of only a mild insult, such as a single dose of a sedative medication for sleep. By contrast, patients who are not vulnerable would be relatively resistant, with delirium resulting only after repeated exposure to multiple

TABLE 76.1. Diagnostic criteria for delirium.

Diagnostic and Statistical Manual Version IV (DSM-IV) diagnostic criteria

- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of a general medical condition.

The Confusion Assessment Method (CAM) Diagnostic Algorithm^a

Feature 1. Acute onset and fluctuating course
 This feature is usually obtained from a family member or nurse and is shown by positive responses to the following questions: Is there evidence of an acute change in mental status from the patient’s baseline? Did the (abnormal) behavior fluctuate during the day, that is, tend to come and go, or increase and decrease in severity?

Feature 2. Inattention
 This feature is shown by a positive response to the following question: Did the patient have difficulty focusing attention, for example, being easily distractible, or having difficulty keeping track of what was being said?

Feature 3. Disorganized thinking
 This feature is shown by a positive response to the following question: Was the patient’s thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Feature 4. Altered level of consciousness
 This feature is shown by any answer other than “alert” to the following question: Overall, how would you rate this patient’s level of consciousness? (alert [normal], vigilant [hyperalert], lethargic [drowsy, easily aroused], stupor [difficult to arouse], or coma [unarousable]).

^aThe diagnosis of delirium by CAM requires the presence of features 1 and 2 and either 3 or 4.

noxious insults, such as general anesthesia, major surgery, multiple psychoactive medications, immobilization, and infection. Moreover, the effects of multiple risk factors appear to be cumulative. Clinically, the importance of this multifactorial etiology is that removing or treating one factor alone often is insufficient to resolve the delirium. Attention should be paid to the multifactorial predisposing and precipitating factors that may be contributing to the delirium.

Predisposing or vulnerability factors for delirium include preexisting cognitive impairment or dementia, severe illness, high number of comorbid diseases, functional impairment, advanced age, chronic renal insufficiency, dehydration, malnutrition, depression, and vision or hearing impairment.^{8,13,24,26–30} Dementia is a leading risk factor for delirium, consistently identified across studies. Patients with dementia have a two- to five-fold increased risk for delirium. Moreover, one-third to one-half of delirious patients have an underlying dementia. Nearly any chronic medical illness can predispose to delirium, including diseases involving the central nervous system (e.g., Parkinson’s disease, cerebrovascular disease, mass lesions, trauma, infection), as well as diseases outside the central nervous system, such as infectious, metabolic, cardiac, pulmonary, endocrine, and neoplastic conditions. The occult presentation of systemic disease—sometimes presenting only with delirium—is an important tenet of geriatric medicine. One validated predictive model,¹⁵ developed to determine delirium risk at the time

of hospital admission, identified the following independent predisposing factors: severe underlying illness, vision impairment, baseline cognitive impairment, and high BUN/creatinine ratio (used as an index of dehydration).

Medications, the most common precipitating factors for delirium, contribute to at least 40% of delirium cases.^{14,31,32} Many medications can lead to delirium; the most common are those with recognized psychoactive effects, such as sedative-hypnotics, narcotics, H₂-blockers, and medications with anticholinergic effects. In previous studies, use of any psychoactive medication was associated with a 4-fold increased risk of delirium.^{8,14} Sedative-hypnotic drugs have been associated with a 3- to 12-fold increased risk of delirium; narcotics with a 3-fold risk; and anticholinergic drugs with a 5- to 12-fold risk.^{24,28–30,33,34} Delirium increases in direct proportion to the number of medications prescribed, an effect that is likely caused by adverse effects of the medications themselves, as well as the increased risk of drug–drug and drug–disease interactions. Recent studies provide strong evidence that inappropriate use and overuse of psychoactive medications are common in older patients, and that many cases of delirium and other related adverse drug events may be preventable.^{35–38}

Other precipitating factors for delirium include medical procedures or surgery, intercurrent medical illnesses, infections, immobilization, use of indwelling bladder catheters, use of physical restraints, dehydration, malnutrition, iatrogenic events, electrolyte or metabolic

derangement, alcohol or drug intoxication or withdrawal, environmental influences, and psychosocial stress.^{10,19,22,26,39–44} Immobilization can lead to delirium and functional decline within just a few days, yet physicians routinely order bedrest or no activity in 57% of patient-days of hospitalization, often without medical justification.^{45,46} Moreover, medical devices (e.g., indwelling bladder catheters and physical restraints) can contribute to immobilization, as well as other adverse effects. Iatrogenic events, occurring in 29% to 38%^{47–49} of older patients, include complications of diagnostic or therapeutic procedures, transfusion reactions, bleeding due to overanticoagulation, and the like. Insufficiency of any major organ system can precipitate delirium, particularly renal, hepatic, or respiratory failure. Occult respiratory failure is an increasing problem in older patients, who often lack the typical signs and symptoms of dyspnea and tachypnea, and who are easily overlooked by measuring oxygen saturation alone. Acute myocardial infarction or congestive heart failure commonly present as delirium in an elderly patient, without the expected symptoms of chest pain or dyspnea. Occult infection represents another noteworthy cause of delirium, because older patients frequently fail to mount the expected febrile or leukocyte response to severe systemic infections, including pneumonia, urinary tract infection, endocarditis, abdominal abscess, or septic arthritis. Metabolic disorders are important contributors to delirium: these include hyper- or hyponatremia, hypercalcemia, acid–base disorder, hypo- and hyperglycemia, and thyroid or adrenal disorders. A validated predictive model¹⁴ for delirium risk based on exposure to precipitating factors during the course of hospitalization identified the following five independent precipitating factors: physical restraint use, malnutrition, more than three medications added during the previous day (70% of these were psychoactive medications), indwelling bladder catheter, and any iatrogenic event.

Pathogenesis

To date, the fundamental pathophysiologic mechanisms of delirium remain unclear. Delirium has been thought to represent a functional rather than structural lesion, with characteristic electroencephalographic findings demonstrating global functional derangements and generalized slowing of cortical background (alpha) activity.^{50,51} Delirium is considered to be the final common pathway of many different pathogenic mechanisms, culminating in the widespread reduction of cerebral oxidative metabolism with failure of cholinergic transmission. Proposed mediators have included adenosine, beta-endorphin, histamine, somatostatin, lymphokines, tryptophan, phenylalanine metabolites, various neuropeptides,

and cortisol.^{52–55} A recent study⁵⁶ has found that changes in large neutral amino acids, which are precursors of several neurotransmitters, may play a role in delirium. Although delirium has been considered a transient syndrome, several of these basic mechanisms may not be completely reversible, particularly those resulting in hypoxic brain injury. In addition, the dose and duration of the insult, as well as the presence of preexisting cognitive impairment, may greatly influence the reversibility of the delirium.

Clinical Presentation

The key features of delirium are acute onset and inattentiveness. Determining the acuity of onset requires accurate knowledge of the patient's previous level of cognitive functioning. With delirium, the mental status typically changes over hours to days, as distinguished from dementia in which the changes occur more insidiously over weeks to months. Extra effort may be required to ascertain baseline information from a reliable source, such as a family member, caregiver, or nurse. Another key feature is the fluctuating course of delirium, with symptoms tending to come and go or increasing and decreasing in severity over a 24-h period. Lucid intervals are characteristic, and can be misleading even to experienced clinicians. Inattention is recognized as difficulty focusing, maintaining, and shifting attention. Delirious patients appear easily distracted, have difficulty following commands or maintaining a conversation, and often perseverate with an answer to a previous question. On cognitive testing, patients may manifest difficulty with simple repetition tasks, digit spans, or reciting months backward. Other key features include a disorganization of thought and altered level of consciousness. Disorganization of thought is a manifestation of underlying cognitive or perceptual disturbances, and is recognized by disorganized or incoherent speech, rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject. Altered level of consciousness is typically manifested by lethargy, with reduced awareness of the environment. Although not cardinal elements, features frequently associated with delirium include disorientation, cognitive deficits (e.g., memory impairment, dysnomia), psychomotor agitation or retardation, perceptual disturbances (e.g., hallucinations, misperceptions, illusions), paranoid delusions, emotional lability, and sleep–wake cycle disruption.

Clinically, delirium can present in either hypoactive or hyperactive forms. The hypoactive form of delirium, which is characterized by lethargy and reduced psychomotor activity, is the most common form in older patients. This form of delirium is often unrecognized and is associated with a poorer overall prognosis.^{57–59} The

hyperactive form of delirium, in which the patient is agitated, vigilant, and often hallucinating, is rarely missed. Importantly, patients can fluctuate between the hypoactive and hyperactive forms—the mixed type of delirium. Moreover, partial or incomplete forms of delirium have been recognized to be common,^{60,61} particularly during the resolution stages of delirium, and have been shown to adversely influence long-term prognosis.

Diagnosis and Differential Diagnosis

Delirium is a clinical diagnosis, relying on astute observation at the bedside, careful cognitive assessment, and history taking from a reliable informant to establish the patient's baseline functioning. Previous studies have documented that clinicians may fail to detect delirium in up to 70% of affected patients.^{62–64} Identifying the potentially multifactorial contributors to the delirium is of critical importance, because many of these factors are treatable and, if left unaddressed, may result in substantial morbidity and mortality. Because the potential contributors are innumerable, the search requires keen clinical judgment combined with a thorough medical evaluation. The challenge is enhanced by the frequently nonspecific or atypical presentation of the underlying illness in older persons. In fact, in the elderly population, delirium may be the *only* sign of life-threatening illness such as sepsis, pneumonia, or myocardial infarction.

The first step in evaluation should include formal cognitive assessment and determination of any acute change from the patient's baseline level of cognition. Because cognitive impairment is readily missed during regular conversation, a brief cognitive screening test, such as the Mini-Mental Status Examination,⁶⁵ is recommended. Attention should be assessed with simple tests, such as a forward digit span (inattention indicated by inability to repeat five digits forward) or reciting the days of the week or the months backward. A comprehensive history and physical examination remain the cornerstones of the evaluation of delirium. The history should be directed toward establishing the patient's baseline level of cognitive functioning and the course of any mental status changes, as well as obtaining clues about potential precipitating factors or insults, such as recent medication changes, new infections, or medical illnesses. The physical examination should include a detailed neurologic examination for focal deficits and a careful search for signs of falls or head trauma, infection, or other acute medical processes.

Because of the frequent contribution of medications to delirium, review of the medication list, including over-the-counter medications, should be carried out in every patient. The majority of older patients will be on at least several medications during hospitalization, heightening

the potential for adverse events as well as drug–drug or drug–disease interactions. In older patients, medications may cause adverse effects even at recommended dosages and at measured serum levels that are within the “therapeutic range.” Thus, medications with psychoactive effects should be removed or minimized whenever possible. When these medications cannot be removed, dosage reductions or substitution of less toxic alternatives should be considered. The side effects and interaction profiles of all current drugs should be reviewed. Finally, chronic medication and alcohol use should be assessed specifically to evaluate for any potential withdrawal risk. In older patients, substance use is commonly unrecognized or overlooked, particularly during the early phase of hospitalization.

Evidence-based strategies estimating the predictive value of laboratory tests in delirium assessment are lacking. Thus, the laboratory evaluation must be based on clinical judgment, and should be tailored to the individual situation. An astute history and physical examination, review of medications, targeted laboratory testing (e.g., complete blood count, chemistries, glucose, renal/liver function tests, urinalysis, oxygen saturation), and search for occult infection should assist with identification of the majority of potential contributors to the delirium. The need for further laboratory testing (such as thyroid function tests, B₁₂ level, cortisol level, drug levels or toxicology screen, ammonia level) will be determined according to the individual patient's clinical picture. In patients with cardiac or respiratory diseases, or with related symptoms, an electrocardiogram, chest radiograph, and/or arterial blood gas determination may be warranted. The indications for cerebrospinal fluid examination, brain imaging, or electroencephalography remain controversial. Overall, the diagnostic yield for these procedures are low, and they are probably indicated in less than 10% of delirium cases. Cerebrospinal fluid examination is indicated for the febrile delirious patient where meningitis or encephalitis must be excluded. Brain imaging (such as computed tomography or magnetic resonance imaging) should be reserved for cases with new focal neurologic signs, with history or signs of head trauma, or without another identifiable cause of the delirium. Electroencephalography, which has a false-negative rate of 17% and false-positive rate of 22% for distinguishing delirious and nondelirious patients,^{51,66} plays a limited role and is most useful to detect occult seizure disorders and to differentiate delirium from nonorganic psychiatric conditions.

The differential diagnoses for delirium include a variety of conditions associated with confusion and altered mental status, most commonly dementia, depression, and nonorganic psychotic disorders. The paramount challenge in differential diagnosis is distinguishing dementia, a chronic confusional state, from delirium

alone or delirium superimposed on dementia. The differential diagnosis is crucial, however, because of the prognostic significance of delirium, which often represents a medical emergency. Obtaining the clinical history is critical to making the distinction between delirium and dementia. These two conditions are distinguished by the acuity of symptom onset in delirium (dementia is much more insidious), and the impaired attention and altered level of consciousness associated with delirium. Disorientation and memory impairment, while commonly recognized features, are not useful in differential diagnosis because they may be present with both conditions and may be absent in delirium. Differentiating depression and nonorganic psychotic disorders from delirium can pose other challenges for the clinician. Although paranoia, hallucinations, and affective changes can occur with delirium, the presence of key delirium features of acute onset, inattention, altered level of consciousness, and global cognitive impairment will assist with the diagnosis of delirium. In cases involving an uncooperative patient or where an accurate history is unavailable, establishing the diagnosis with certainty may not be possible. In these cases, because of the potentially life-threatening nature of delirium and its high occurrence rate in the older hospitalized population, the recommendation is to manage the case as a presumptive delirium and search for reversible causes (e.g., intercurrent illness, metabolic derangements, drug toxicity), until further information can be obtained.

Figure 76.1 presents an algorithm for the evaluation of altered mental status in the older patient. The first step in the evaluation is to establish the patient's baseline cognitive functioning and the time-course of any cognitive changes. Chronic impairments, developing or progressing over months to years, are most likely attributable to a dementia, which should be evaluated accordingly (see Chapter 74). Acute alterations occurring over hours to weeks, which may be superimposed on an underlying dementia, should be further evaluated with cognitive assessment to determine whether delirium is present. If delirium features are not present (see Clinical Presentation section above), then further evaluation for major depression, acute psychotic disorder, or other psychiatric disorders (see Chapters 78 and 79) is indicated.

Clinical Course and Prognosis

Delirium has been previously considered to be a transient, reversible condition; however, recent studies^{60,61} have documented that delirium may be more persistent than previously believed. A delirium duration of 30 days or more is typical in older patients, and a prolonged transitional phase characterized by cognitive, affective, or behavioral abnormalities is quite common. In fact, as few

as 20% of patients had complete resolution of all delirium symptoms at 6-month follow-up in one study.⁶⁰ Delirium appears to have greater deleterious effects on long-term cognitive functioning in patients with underlying cognitive impairment or dementia. Long-term detrimental effects are likely related to the duration, severity, and underlying cause(s) of the delirium. Whether delirium itself leads to permanent cognitive impairment or dementia remains controversial; however, previous studies document that at least some patients never recover their baseline level of cognitive functioning.

Delirium had been documented to be an important prognostic determinant.⁶⁷ Previous studies^{8,10,18,21,28,29,34,60,68-79} have shown that delirium is an independent predictor of prolonged length of hospital stay, increased morbidity and mortality, and higher rates of institutionalization and functional and cognitive decline, even after controlling for age, gender, dementia, illness severity, and baseline functional status.

Prevention and Management

Prevention of Delirium

Primary prevention of delirium, that is, preventing delirium before it occurs, is the most effective strategy to reduce delirium and its attendant complications. Table 76.2 indicates well-documented delirium risk factors and tested preventive interventions for each risk factor. These risk factors were selected because current evidence supports both the clinical relevance and the remediable nature of each risk factor with practical interventions. A controlled clinical trial⁸⁰ demonstrated the effectiveness of a delirium prevention strategy targeted toward these risk factors. Implementation of these preventive interventions resulted in a 40% risk reduction for delirium in hospitalized older patients.

Nonpharmacologic Management

Nonpharmacologic approaches should be used for management of every delirious patient. These approaches include strategies for reorientation and behavioral intervention, such as ensuring the presence of family members, orienting influences, use of sitters, and transferring a disruptive patient to a private room or closer to the nurse's station for increased supervision. Personal contact and communication are critical, incorporating reorientation strategies, simple instructions, and frequent eye contact. Patients should be encouraged to participate in decision making about their care as much as possible. Eyeglasses and hearing aids (if needed) should be worn as much as possible to reduce sensory deficits. Mobility, self-care, and independence should be enhanced;

TABLE 76.2. Delirium risk factors and potential interventions.

Risk factor	Interventions
Cognitive impairment	Therapeutic activities program Reality orientation program (reorienting techniques, communication)
Sleep deprivation	Noise reduction strategies Scheduling of nighttime medications, procedures, and nursing activities to allow uninterrupted period of sleep
Immobilization	Early mobilization (e.g., ambulation or bedside exercises) Minimizing immobilizing equipment (e.g., bladder catheters)
Psychoactive medications	Restricted use of prn sleep and psychoactive medications (e.g., sedative-hypnotics, narcotics, anticholinergic medications) Nonpharmacologic protocols for management of sleep and anxiety
Vision impairment	Provision of vision aids (e.g., magnifiers, special lighting) Provision of adaptive equipment (e.g., illuminated phone dials, large-print books)
Hearing impairment	Provision of amplifying devices Repair of hearing aids
Dehydration	Early recognition and volume repletion

physical restraints should be avoided because of their adverse effects of immobility and increased agitation and their potential to cause injury. Clocks, calendars, and the day's schedule should be provided to assist with orientation. Room and staff changes should be kept to a minimum. A quiet environment with low-level lighting is optimal for the delirious patient. Allowing an uninterrupted period for sleep at night is of key importance in the management of the delirious patient; this requires coordination and scheduling of nursing and medical procedures, such as medications, vital signs, intravenous fluids, and treatments. Hospital-wide changes may be needed to ensure a low level of noise at night, including hallway noise and conversations. Nonpharmacologic approaches for relaxation, including music, relaxation tapes, and massage, can be effective for management of agitation in delirious patients.

Pharmacologic Management

Pharmacologic approaches should be reserved for patients with severe agitation, which may result in the interruption of essential medical therapies (e.g., intubation, intraaortic balloon pumps, dialysis catheters) or which may endanger the safety of the patient, other patients, or staff. However, clinicians must be aware that any drug used for the treatment of delirium will have psychoactive effects and may further cloud mental status and obscure efforts to follow the patient's mental status. Thus, the drug should be given in the lowest possible dose for the shortest duration. Neuroleptics are the preferred agents of treatment, with haloperidol representing the most widely used and tested treatment for delirium.⁸¹ Although newer neuroleptics are available, fewer data are available to support their use. If parenteral adminis-

tration is required, intravenous haloperidol results in rapid onset of action with short duration of effect, whereas intramuscular use will have a more optimal duration of action. The recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, repeating the dose every 20 to 30 min after vital signs have been checked, until sedation has been achieved. The endpoint should be an awake but manageable patient, not a sedated patient. The average elderly patient who has not previously been treated with neuroleptics should require a total loading dose not exceeding 3 to 5 mg haloperidol. Subsequently, a maintenance dose of one-half the loading dose should be administered in divided doses over the next 24 h, with tapering doses over the next few days. The leading side effects of haloperidol include sedation, hypotension, acute dystonias, extrapyramidal side effects, and anticholinergic effects (e.g., anticholinergic delirium, dry mouth, constipation, urinary retention).

Benzodiazepines are not recommended for treatment of delirium because of their tendency to cause oversedation, respiratory depression, and exacerbation of the confusional state. However, they remain the drugs of choice for treatment of withdrawal syndromes from alcohol and sedative-hypnotic drugs. For geriatric patients, lorazepam (starting dose, 0.5–1.0 mg) is the recommended agent of this class, because of its favorable half-life (10–15 h), lack of active metabolites, and availability of a parenteral form.

Terminal Phase

Management of delirium at the end of life poses particular challenges for the clinician. Because delirium occurs in more than 80% of patients at the end of life, establishing the goals of care with the patient and family is

a crucial step, including discussions about the potential causes of the delirium, intensity of medical evaluations considered appropriate, and—in some cases—the need for titration between alertness and adequate control of pain and agitation. Even in the terminal phase, many causes of delirium are potentially reversible; however, the burdens of evaluation (e.g., invasive testing) or definitive treatment (e.g., surgery for brain metastasis or reduction in narcotic dose) may not be consistent with the goals for care. In all cases, symptom management should begin immediately, while evaluation is under way. Nonpharmacologic approaches should be instituted in all patients, with pharmacologic approaches for selected cases. Haloperidol remains the first-line therapy for delirium in terminally ill patients. In end-of-life care, there is a lower threshold for the use of sedative agents. Sedation may be indicated as an additional therapy for management of severe agitated delirium in the terminally ill patient, which can cause considerable distress for the patient and family. Because sedation poses the risks of decreased meaningful interaction with family, increased confusion, and respiratory depression, this choice should be made in conjunction with the family according to the goals for care. If sedation is indicated, an agent that is short acting and easily titrated to effect is recommended. Lorazepam (starting dose, 0.5–1.0 mg p.o., i.v., s.q.) is the recommended agent of choice; however, midazolam (starting dose, 0.5–1.0 mg i.v. or s.q.) may be useful for short-term sedation where rapid onset and titration are required. Because the risks of respiratory suppression and hypotension with midazolam are great, the patient must be closely monitored.

System-Wide Changes

The optimal management of delirium requires system-wide changes to improve the quality of hospital care for older patients.⁸² Interventions needed to reduce delirium rates include education of physicians and nurses to improve recognition and heighten awareness of the clinical implications; encouragement of cognitive assessment of all elderly hospitalized patients; provision of incentives to change practice patterns that lead to delirium (e.g., immobilization, overuse of psychoactive medications, bladder catheters, and physical restraints); and creation of systems that enhance high-quality geriatric care (e.g., geriatric expertise, case management, clinical pathways, and quality monitoring for delirium). With its common occurrence, its frequently iatrogenic nature, and its close linkage to the processes of care, incident delirium serves as a valuable marker for the quality of hospital care and provides an opportunity for overall improvement in care for the older population.

Cerebrovascular Disease and Stroke

Stanley Tuhim

Stroke is a major public health problem afflicting primarily older adults. It is the third leading cause of death in the United States and is surpassed only by heart disease worldwide.^{1,2} In the United States, more than 700,000 new strokes occur annually.³ Stroke is also the leading cause of disability in the United States, with an estimated 4 million stroke survivors in this country living with stroke-related deficits.¹ Over 70% of stroke survivors remain vocationally impaired, over 30% require help with activities of daily living, and 20% walk only with assistance.⁴ Approximately half of stroke survivors return to some form of employment, but this figure declines with age.⁵

The incidence of stroke doubles in each successive decade after age 55 and occurs approximately twice as often in African-Americans as in whites at all ages. It is more common in men under age 75 but is equally common among older men and women.^{3,6,7}

Stroke is actually a heterogeneous group of diseases. There are two main categories, hemorrhage and infarction, which result from different pathophysiologic mechanisms: extravasation of blood from a damaged vessel in hemorrhage and ischemia or insufficient blood perfusing brain tissue in infarction. These categories can be further subdivided pathophysiologically. Subarachnoid hemorrhage is leakage of blood at the brain surface into the cerebrospinal fluid, usually the result of rupture of an aneurysm in an artery at the base of the brain (circle of Willis). Less often, the bleeding may be caused by rupture of a vascular malformation or trauma to a surface vessel. Intracerebral hemorrhage (ICH) usually is caused by rupture of a small artery or arteriole with leakage of blood into the brain parenchyma.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) accounts for 5% to 10% of all strokes. Incidence rates vary from 6 to 16 per 100,000, with the highest rates reported from Japan and

Finland.⁸⁻¹⁰ Women are affected more often than men by a ratio of 3:2, and incidence increases with advancing age.^{8,11} SAH patients in the Framingham Study averaged 63 years of age.¹² Tobacco use and heavy alcohol consumption have been identified as risk factors for SAH.^{13,14} Hypertension does not play as important a role in SAH risk as in other forms of stroke, although use of cocaine and other noradrenergic stimulants has been associated with SAH, possibly by precipitating rupture of an aneurysm during an acute hypertensive episode.¹⁵

Arteriovenous malformations (AVMs) can also cause SAH, but frequently produce intraparenchymal hemorrhage as well. They are rarely the cause of SAH in the elderly. Bleeding is less brisk than with ruptured saccular aneurysms, and symptoms may develop more slowly. AVMs usually present in adolescence or early adulthood, causing headache, seizures, or hemorrhage. In the elderly, the cause of SAH is more often undetermined than in younger patients. Amyloid angiopathy or unrecognized head trauma is often thought to be responsible.

Morbidity and mortality are high in SAH. About 12% of SAH patients die before receiving medical attention.^{16,17} The 90-day mortality rate among those who do reach medical attention is about 25%, and 40% of survivors suffer residual cognitive, motor, and sensory deficits.¹⁷ Early mortality results from the direct effects of the initial or recurrent bleeding, whereas medical complications or ischemia, secondary to vasospasm induced by subarachnoid blood, are responsible for most deaths beyond the first week.

The Hunt and Hess Scale is widely used to grade the severity of SAH (Table 77.1).¹⁸ Grade 1 and 2 patients have a good prognosis, while grade 4 and 5 patients usually do poorly and are usually not considered candidates for surgical intervention. Grade 3 patients have the most variable outcomes. The Glasgow Outcome Scale (see Table 77.1), originally developed for head trauma, is frequently used to grade outcomes in SAH.¹⁹ The majority of patients with SAH harbor saccular aneurysms as

TABLE 77.1. Global measures in subarachnoid hemorrhage (SAH).

Hunt and Hess Scale	
Grade	Neurologic status
1	Asymptomatic
2	Severe headache, stiff neck, no neurologic deficit except cranial nerve palsy
3	Drowsy, minimal neurologic deficit
4	Stuporous, moderate or severe hemiparesis
5	Deep coma, decerebrate

Glasgow Outcome Scale	
Category	Outcome
1	Good recovery, independent lifestyle
2	Moderate disability, independent lifestyle
3	Severe disability, conscious but not independent
4	Vegetative
5	Dead

the cause of bleeding. Saccular aneurysms form at the bifurcation of large arteries and are probably caused by a combination of congenital and degenerative changes in arteries. Hemodynamic stresses at arterial bifurcations lead to degenerative changes in the internal elastic lamina, weakening of the arterial wall, and aneurysmal outpouching. The most common sites for aneurysm formation are within the anterior circulation, at the junction or bifurcation of the major cerebral arteries. Posterior circulation aneurysms are less common, the most common sites being the bifurcation of the basilar artery and the vertebral artery–posterior inferior cerebellar artery junction.

Diagnosis of SAH

Most aneurysms remain asymptomatic until they bleed, but some larger aneurysms compress adjacent nerves, brain tissue, or meningeal structures, causing headache and neurologic dysfunction. When aneurysms rupture, they leak blood into the cerebrospinal fluid (CSF) under arterial pressure. Patients usually describe a sudden onset of severe headache, often “the worst headache of my life.” There is usually some alteration in consciousness, ranging from deep coma with massive bleeding to sleepiness or agitation with lesser amounts of bleeding. Unless bleeding also occurs directly into brain, patients do not have major focal neurologic signs.

When a patient presents with the abrupt onset of severe headache, with or without meningismus or subtle neurologic signs, SAH must be considered. The differential diagnosis may include other causes of headache, such as migraine or infectious meningitis, but if SAH is considered, a computerized tomographic (CT) scan should be obtained; this can show the presence of blood in the subarachnoid space, confirming the diagnosis. The

location of blood may indicate the likely location of the aneurysm and the amount, and the thickness of blood indicates the likelihood of subsequent vasospasm.²⁰ Because of variability in magnetic resonance scanning techniques and interpretation skills, for the present, CT scan remains more accurate than MR imaging in most centers, with a yield approaching 95% if done within 24 h of stroke onset.²¹ If a CT scan cannot be performed or fails to confirm the diagnosis of SAH, a lumbar puncture should be performed to allow examination of the CSF.²² All patients with SAH have blood in the CSF when tapped within 48 h. Some patients have a small “warning leak” before massive aneurysmal rupture. These small hemorrhages are often missed by CT and will be detected only by lumbar puncture. No patient in whom SAH is suspected should leave the hospital without a lumbar puncture. Findings diagnostic of SAH include the constant red or pink appearance of the CSF on collection. In this instance, the presence of xanthochromia in the supernatant after prompt centrifugation distinguishes pathologic SAH from leakage induced by trauma during the spinal tap. Centrifugation should be performed immediately after collection to avoid hemolysis of red blood cells *ex vivo*. Red blood cells in the fluid with a cell count that remains constant from the first tube collected to the last, and the presence of white blood cells in greater proportion than that found in the periphery, are also indicative of true SAH. Xanthochromia may not be present if the CSF is collected within 6 h of ictus and may be the only abnormality remaining if lumbar puncture is delayed several days.

Unless the patient's condition precludes treatment, angiography should be performed to determine the cause of bleeding. Conventional (catheter) angiography will detect approximately 95% of aneurysms and all AVMs. If an initial angiogram is negative, a repeat study, usually performed 1 to 2 weeks later, will detect an aneurysm in about 2% of cases.²³ Magnetic resonance angiography (MRA) and CT angiography are useful as complements to conventional angiography and as screening tests in high-risk, asymptomatic individuals, but are not as sensitive in imaging small (<5 mm) aneurysms. Sequential transcranial Doppler (TCD) examinations are useful for detecting vasospasm. It is helpful to obtain a TCD before surgery and as close to the ictus as possible to serve as a basis of comparison for determining if flow velocities begin to rise (preceding the onset of clinical symptoms of ischemia secondary to vasospasm).

Treatment

Obliteration of the aneurysm is the key treatment for aneurysmal SAH. This intervention removes the possibility of recurrent bleeding and allows treatment of vasospasm with hypervolemic, hypertensive therapy. A

large international study demonstrated that early operation prevents rebleeding, but overall outcome was no different between those operated within 3 days of initial SAH and those operated from 15 to 32 days afterward. Mortality was higher in patients operated between 4 and 14 days.¹⁷ Recently, endovascular techniques have been developed that allow obliteration of aneurysms via intraluminal embolization with detachable coils, which can usually be accomplished with minimal additional morbidity to the patient. Selection of aneurysms with suitable configurations is crucial. The durability of the procedure requires further evaluation, however.

Delayed cerebral ischemia can develop because of constriction of the major arteries arising at the base of the brain during the first week after SAH. Preventative treatment with nimodipine, a dihydropyridine calcium channel blocker, is begun as soon as ischemic aneurysmal SAH is recognized and continued for 21 to 28 days. In the event that focal or global neurologic deficits develop due to vasospasm, elevation of blood pressure and increasing intravascular volume can be effective therapy.

Intracerebral Hemorrhage

Nontraumatic intracerebral hemorrhage (ICH) is localized bleeding in the brain parenchyma. Approximately 50,000 new cases occur in the United States every year, with a twofold increase expected in coming years due to increasing age and changes in racial composition of the population.^{24,25} ICH accounts for 10% to 15% of all strokes and is associated with the highest mortality.²⁶ ICH can be classified into primary and secondary, depending upon the underlying etiology of bleeding. Primary ICH originates from spontaneous rupture of small vessels pathologically affected by chronic hypertension and accounts for 78% to 88% of all ICH.²⁷ Secondary ICH occurs in a minority of patients in association with amyloid angiopathy, structural vascular abnormalities, tumors, or impaired blood coagulation.

Epidemiology

The incidence of ICH ranges from 10 to 20 persons per 100,000 overall but increases with age to approximately 100 per 100,000 persons aged greater than 75.^{28–30} ICH is more frequent in men, particularly after the age of 55 years,^{30,31} and occurs more frequently in African-Americans²⁸ and Japanese.³² For example, the incidence of ICH in the African-American cohort was 50 per 100,000, twice that of whites, in the National Health and Nutrition Examination Survey Epidemiologic Follow-up Study.³³

Hypertension is the most important risk factor for spontaneous ICH.^{34,35} Hypertension increases ICH risk most dramatically in persons who are not compliant

with antihypertensive medication,^{36,37} whereas improved control of hypertension reduces the incidence of ICH.²⁹ Excessive use of alcohol also increases the risk for ICH, probably by impairing blood coagulation and directly affecting cerebral vessel integrity.^{38,39}

Pathophysiology

Intracerebral hemorrhages occur most commonly in the basal ganglia, thalamus, cerebral lobes, and brainstem (predominantly pons).²⁷ Ventricular extension occurs in 40% of cases, especially in association with deep, large hematomas. Intraparenchymal bleeding usually results from rupture of one of the small penetrating arteries originating from the large superficial arteries. This bleeding was considered a monophasic event that stopped quickly as a result of clotting and tamponade by increased parenchymal pressure in the surrounding regions. As patients have obtained more rapid access to medical care and CT scans have been obtained nearer the time of initial ictus, it has become apparent that hematomas continue to expand over time. For example, Brott et al.⁴⁰ observed hematoma expansion in 26% of patients within 1 h and in another 12% by 20 h of initial CT scan. The factors that predispose to hematoma expansion are poorly understood, but it has been attributed to continued bleeding from the primary source and mechanical disruption of surrounding vessels and may be associated with acute hypertension.^{41,42} Compression of surrounding structures by the hematoma causes dysfunction and ultimately cell death. This physical damage is compounded by biochemical effects of blood products from the hematoma that initiate pathophysiologic processes in the surrounding parenchyma, producing edema and neuronal damage. Edema formation starts immediately in the perihematoma region and usually persists for up to 5 days. Both vasogenic and cytotoxic edema follow due to disruption of the blood–brain barrier and failure of the Na-K pump with swelling of neuronal and glial cells, causing further damage.⁴³

Clinical Features

Decreased level of consciousness is almost always seen with large hematomas,⁴⁴ presumably because of raised intracranial pressure and direct compression or distortion of the thalamic and brainstem reticular activating system mediating arousal and attention.⁴⁵ In ICH originating in putamen, caudate, and thalamus, contralateral sensorimotor deficits of varying severity usually occur due to involvement of the internal capsule. Higher cortical dysfunction, including aphasia, neglect, gaze deviation, and hemianopia, may occur because of disruption of connection fibers in the subcortical white matter. In infratentorial ICH, signs of brainstem dysfunction include gaze

abnormalities, cranial nerve abnormalities, and contralateral motor deficits. Ataxia, nystagmus, and dysmetria are prominent when the ICH involves the cerebellum.⁴⁶ Common nonspecific symptoms include headache and vomiting due to raised intracranial pressure and meningismus resulting from intraventricular extension of blood.^{44,47,48}

Approximately 25% patients who are alert when they reach the hospital deteriorate within the first 24 h after onset. Presence of large hematomas and ventricular blood increases the risk for subsequent deterioration. Hematoma expansion is the most common cause underlying neurologic deterioration within the first 3 h. Worsening cerebral edema is also an important contributor in patients who deteriorate 24 to 48 h after onset.^{49,50}

Mortality following spontaneous ICH ranges from 23% to 58%. Clinical severity as measured by the initial Glasgow Coma Scale Score (GCS), hematoma volume, and presence of ventricular blood on initial CT scan have been consistently identified as predictive of high mortality.^{51,52} Broderick et al. found that 1-month mortality was best predicted by a combination of initial GCS score and hematoma volume. In this study, patients with GCS less than 9 and hematoma volume greater than 60 mL had a mortality of 90%. Patients with GCS of 9 or greater and hematoma volume less than 30 mL had a mortality of 17%.⁵¹

The long-term functional outcome in ICH survivors is similar to that observed with cerebral infarction. Approximately 40% of the patients are functionally independent after 1 year.⁵³ Age, initial GCS, presence of ventricular blood, hematoma volume, and initial disability predict long-term outcome.^{53,54} The likelihood of a second ICH is low. Hill et al. reported an annual incidence of 2.4% for recurrent ICH (fourfold higher among lobar hemorrhages) and 3% for ischemic stroke among 307 survivors of primary ICH.⁵⁵ The site of ICH is usually different from the first ICH, and the likelihood of recurrence is much greater in those with persistently uncontrolled hypertension.⁵⁶

Diagnostic Investigations

Although clinical features such as headache, smooth rapid onset of focal deficits, and decreased alertness suggest the diagnosis of ICH, distinguishing definitively between cerebral infarction and ICH requires brain imaging.⁵⁷ On the initial CT scan, the location and size of the hematoma, presence of ventricular blood, and hydrocephalus should be noted. Selected patients should undergo conventional angiography to look for secondary causes of ICH, such as aneurysms, arteriovenous malformations, and vasculitis. Magnetic resonance imaging with gadolinium and magnetic resonance angiography can also be used for screening secondary causes of ICH,

although their sensitivity is not well established,⁵⁸ and may be particularly useful in identifying underlying tumors. American Heart Association (AHA) guidelines recommend angiography for all patients without a clear cause of hemorrhage who are surgical candidates, particularly young, nonhypertensive patients who are clinically stable. Conventional angiography should be considered in patients who have subarachnoid blood associated with parenchymal clot or have recurrent hemorrhages because of the high likelihood of an underlying vascular anomaly.²⁵

Management

In the era of thrombolytic treatment, early differentiation between infarction and ICH using CT scan is crucial, so that thrombolysis can be considered for infarct patients. In patients with ICH, emergent neurosurgical consultation should be obtained when there is rapid deterioration, clinical evidence of transtentorial herniation, or hydrocephalus on CT scan. Hyperventilation, intravenous mannitol, and intraventricular catheter placement for cerebrospinal fluid drainage in such circumstances can preserve brain tissue until surgical decompression can be performed, although its benefit has not been proven except in cerebellar hemorrhage (see following).

The risk of neurologic deterioration and cardiovascular instability is highest in the first 24 h after onset. Patients may require intubation for deteriorating level of consciousness. Approximately 30% of patients with supratentorial ICH and almost all patients with brainstem or cerebellar hemorrhage demonstrate decreased consciousness and require intubation.⁵⁹ Cardiovascular instability can also occur with increased intracranial pressure and must be treated promptly to avoid the deleterious effects of hypertension or hypotension in the presence of limited autoregulatory capacity.

Mass effect as a result of the volume of clot, perihematoma edema, and obstructive hydrocephalus remain the major secondary causes of mortality in the initial days after ICH. Treatment with osmotic agents and hyperventilation are only transiently effective and should be used only in the presence of impending cerebral herniation. Randomized trials of steroids have failed to demonstrate efficacy in ICH.^{60,61}

Management of Blood Pressure

Elevated blood pressure, seen commonly after ICH, is associated with hematoma expansion and poor outcome.⁶² Elevated blood pressure may be secondary to uncontrolled chronic hypertension or occurs as a protective response to preserve cerebral perfusion. There is considerable controversy regarding treatment of blood pressure in the acute period after ICH. Most patients

with ICH have chronic hypertension with cerebral autoregulation adapted for higher than normal blood pressures.⁶³ Furthermore, cerebral perfusion pressure and autoregulatory capacity may be compromised due to elevated ICP.⁶⁴ AHA guidelines recommend antihypertensive treatment only when mean arterial pressure is 130 mmHg or greater. Intravenous beta-blockers and vasodilators such as hydralazine or angiotensin-converting enzyme (ACE) inhibitors should be used because they have limited effect on cerebral circulation.^{25,65}

Ventricular Blood and Hydrocephalus

Presence of ventricular blood is associated with high mortality in patients with ICH.^{66,67} This association may be related to the development of obstructive hydrocephalus or direct mass effect of the ventricular blood clot on periventricular structures that is associated with global hypoperfusion of overlying cortex. Ventricular blood also interferes with the normal CSF functions by inducing local lactic acidosis.^{67,68} External CSF drainage using ventricular catheters may improve control of ICP, although the beneficial effect on hydrocephalus and neurologic status appears to be marginal. The risk of infection and clotting within the catheter limit prolonged use of external CSF drainage.⁶⁹ Pang et al. demonstrated that lysis of ventricular blood using thrombolytic agents administered via intraventricular catheter can rapidly clear blood from the CSF and improve outcome in dogs.⁷⁰ The use of intraventricular thrombolysis has been reported in small series of patients with intraventricular extension of ICH. Either tissue plasminogen activator or urokinase has been used. Administration until ventricular blood resolved resulted in improvement in ventricular dilatation and neurologic status in almost all patients.⁷¹⁻⁷⁴ A randomized trial testing the safety and efficacy of this procedure is under way.⁷⁵

Surgical Evacuation

The goals of surgical evacuation of hematoma are to reduce mass effect and minimize release of neurotoxic products from the clot; however, with the exception of cerebellar hematomas, the benefit of surgical decompression is unclear. Cerebellar hematomas are unique from a surgical perspective because they can be approached without significant damage to higher cortical and primary motor pathways. Morbidity and mortality is related to compression of the brainstem.⁴⁶ Patients with large (>3 × 3 cm) hematomas and those with a decreased level of consciousness or clinical evidence of brainstem compression require early craniectomy because greater benefit is observed in patients who undergo surgery before deterioration of consciousness. Studies of surgical evacuation of unselected supratentorial ICH have not

demonstrated significant efficacy, although selected patients with large superficial hematomas may be candidates for evacuation.

Recent studies have focused on developing surgical approaches allowing evacuation of clot with minimal damage to overlying normal tissue including stereotactic and endoscopic approaches. Techniques to liquefy the clot by irrigation with fluid at a high pressure or thrombolytics are under investigation. Repeated injection of fibrinolytic agents, usually at 6- or 12-h intervals using a stereotactically placed catheter can result in complete removal of hematoma.^{76,77} The observed risk of inducing rebleeding is less than 5%. These efforts have been supplemented by high-pressure ultrasound irrigation systems and special drills to break the clot into easily removable fragments.⁷⁸ A recent pilot study of 12 patients whose mean age was 69 years (range, 55–82) demonstrated this approach leads to a 50% clot volume reduction in 3 days with a low rate of additional bleeding or death. This approach may produce successful clot reduction with less morbidity, especially in the elderly or unstable patient, than open craniotomy, but has yet to undergo full evaluation.⁷⁹

Seizures and Epilepsy

Most seizures associated with ICH occur at the onset of intracerebral hemorrhage or within the first 24 h.^{80,81} Seizures are most frequently associated with lobar hematomas, with an incidence ranging from 24% to 54%. Recurrent seizures (epilepsy) develop in 13% to 15% of ICH patients. Because there is no clear association between the use of prophylactic anticonvulsants and the subsequent development of epilepsy in these patients, prophylactic anticonvulsants for all patients are not advisable. Anticonvulsants should generally only be administered to patients who have already suffered a seizure or undergo a neurosurgical procedure.^{80,81} Anticonvulsants can usually be discontinued after the first month in patients who have had no further seizures, although patients who have a seizure after 2 weeks of onset of ICH are at higher risk for recurrence.⁸²

Cerebral Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) occurs exclusively in older adults (age >60 years), affecting the cerebral vasculature selectively, favoring the superficial lobar regions, and generally sparing deeper structures typically affected in hypertensive ICH. Amyloid deposition can be demonstrated by Congo red or other stains in the small and medium-sized cortical and leptomeningeal vessels. The incidence of CAA rises dramatically with age; in an autopsy series, CAA was present in 5% of those 60 to 69

years of age but rose to 50% in those over age 80.⁸³ In addition to the lobar location, the other distinctive feature of CAA is the tendency for recurrence, uncommon in hypertensive ICH. As many as eight distinct hemorrhages have been reported in a single individual.⁸⁴ CAA occurs with increased frequency in patients with Alzheimer's disease, and at least 40% of patients with CAA-related ICH have histologic changes of Alzheimer's disease at autopsy.⁸⁵

Ischemic Stroke

Infarction accounts for about 80% of strokes. There are three main subcategories of infarction: (1) cardioembolic, (2) large vessel atherothrombotic, and (3) small vessel or lacunar stroke.

Cardioembolic Infarction

Embolism from thrombi that form in the heart or that occur in large veins and pass through the heart via a right-to-left shunt account for approximately 30% of ischemic strokes. A variety of cardiac sources of embolism have been identified including valvular lesions, hemostasis secondary to rhythm disturbances, hypokinesis of the left ventricle, either globally as in a cardiomyopathy or focally secondary to infarction, or rarely tumors. Atrial fibrillation is the most widely recognized cardiac abnormality associated with ischemic stroke. It is a condition of the elderly, occurring in 0.1% of those 50 to 59 years of age and increasing gradually to 4% of those over age 80. The proportion of strokes attributed to atrial fibrillation also increases with age, rising from 7% of strokes in the sixth decade to 36% for those in the ninth decade.⁸⁶ The development of transesophageal echocardiography has provided additional insight into the source of cerebral emboli. With this technique it is possible to detect thrombus in the left atrial appendage, which is generally the site that harbors clot in a fibrillating atrium but is not visible on transthoracic echocardiogram. Spontaneous echo contrast ("smoke") is often seen in a fibrillating atrium (and sometimes in other situations) and is thought to represent platelet-fibrin aggregates that are a precursor to thrombus formation. A patent foramen ovale (PFO), the most common conduit for paradoxical emboli, is also readily diagnosed by this procedure.

Transesophageal echocardiography has also led to appreciation of atherosclerotic plaque in the ascending aorta and aortic arch, especially in elderly patients. These plaques can be ulcerated and serve as a nidus for clot formation or protrude into the lumen as a highly mobile peduncle, likely to embolize to more distal arteries. The thickness of this plaque has been correlated with the risk

of stroke.⁸⁶⁻⁸⁸ Because it is a somewhat invasive procedure, transesophageal echo is not done routinely in most centers, but patients who have no obvious source of stroke should undergo transesophageal echocardiography to determine if one of these embolic sources is present.

Lacunar Infarction

Lacunae are small, deep infarcts caused by degenerative changes within small penetrating arteries that bring blood to the internal capsule, basal ganglia, cerebral white matter, thalamus, and pons. Hypertension is the most important cause of lipohyalinosis, the most common mechanism of disease within the media of these microscopic arteries. Sometimes microatheroma originating at the orifice of these penetrating arteries leads to occlusion. Lacunar infarcts are the most common vascular lesions found within the brain at necropsy. In various series and registries, they account for at least 25% of ischemic strokes. The neurologic symptoms depend on the region of ischemia. The most common clinical presentations are (1) pure motor stroke, due to infarction in the pons or internal capsule, characterized by weakness of the face, arm, and leg on one side of the body; (2) pure sensory stroke, due to infarction in the lateral part of the thalamus and/or posterior limb of the internal capsule, characterized by numbness or paresthesia of the face, arm, leg, and trunk on one side of the body without weakness; (3) ataxic hemiparesis, due to infarction in the subcortical white matter or pons, characterized by a combination of incoordination and weakness on one side of the body without other major findings; and (4) clumsy hand-dysarthria due to pontine infarction, characterized by markedly slurred speech and difficulty with fine motor control of one hand.⁸⁹

Patients suffering from these syndromes do not demonstrate prominent visual, cognitive, or behavioral abnormalities. The diagnosis of lacunar infarction is based on the presence of risk factors, the nature of the clinical signs and symptoms, and the results of neuroimaging tests. Most often, patients with lacunar infarction have a history of hypertension or diabetes. The presence of prominent headache, vomiting, or a decreased level of alertness makes lacunar infarction unlikely. The clinical symptoms and signs should be compatible with a small, deep lesion. Aphasia, hemianopia, and signs of anosognosia or inattention are strong evidence against lacunar disease. CT or MRI should show a small, deep infarct or be normal. In some cases, the clinical and neuroimaging tests are equivocal and do not establish a lacunar cause. In these patients, a search for other ischemic causes, such as coagulopathy, an embolism of cardiac origin, and large artery ischemic disease, is warranted.

Large Artery Occlusive Disease

The large vessels that bring blood into the brain are prone to atherosclerotic narrowing most commonly at sites of origin or bifurcation, especially the bifurcation of the common carotid into the internal and external carotid arteries in the neck. Atherosclerotic stenosis leads to infarction by reducing blood flow distal to the point of stenosis and by acting as a nidus for adhesion and aggregation of platelets producing either thrombosis at that location or embolization to and occlusion of more distal, narrower arteries. The neurologic symptoms will depend on the artery affected.

In general terms, symptoms of cerebral ischemia can be divided into those that arise from the anterior circulation, supplying the anterior three-fourths of each hemisphere, and the posterior circulation, supplying the occipital lobes, posterior thalamus, cerebellum, and brainstem.

The anterior circulation consists of the paired internal carotid arteries that give off the ophthalmic arteries and then branch into anterior and middle cerebral arteries. Atherosclerotic lesions are most common at the origin of the internal carotid arteries in the neck and the middle cerebral stem. The posterior circulation consists of the paired vertebral arteries, which give rise to the posterior inferior cerebellar arteries before joining to form the basilar artery that gives off the paired anterior inferior and superior cerebellar arteries and penetrating branches supplying the brainstem before bifurcating into paired posterior cerebral arteries. Symptoms and signs of posterior circulation ischemia are highly variable and overlap with those of the anterior circulation, but vertigo, diplopia, nausea, and vomiting are common complaints heard in brainstem or cerebellar disease; nystagmus, disconjugate eye movement abnormalities, gait or limb ataxia, crossed (i.e., ipsilateral face and contralateral limb or body) sensory or motor deficits, and hemianopic visual field loss are indicative of posterior circulation ischemia. Confusion and memory loss can be seen, especially in embolic occlusion of the basilar artery, blocking penetrating branches that supply the thalamus.⁹⁰

Diagnosis and Treatment

In June 1996, the FDA approved the use of tissue plasminogen activator (t-PA) in acute ischemic stroke, if given within 3 h of symptom onset. This decision signaled a virtual revolution in the diagnosis and management of acute stroke. For the first time, a proven safe and effective treatment was available, but the time frame for its use required a much more expeditious response than was customary for patients, emergency medical services, doctors, and hospitals. The public needed to be educated to recognize a stroke and react appropriately (only one-third of patients experiencing a stroke recognize it as

such), and care providers needed to be educated to respond to stroke as an emergency. When signs or symptoms are recognized, emergency medical services should be contacted and the patient brought to the nearest hospital capable of caring for stroke as an emergency.

Once at the hospital, prompt triage is necessary because of the possibility of life-threatening cardiorespiratory effects. Assessment should begin with evaluation of the patient's airway, breathing, and circulation, followed by a general medical and neurologic history and physical assessment. Determining the time of symptom onset and presence of signs of trauma or medical conditions that would predispose to a particular stroke type or preclude the use of t-PA are crucial. Ancillary tests should include a complete blood count, prothrombin and activated partial thromboplastin times, serum glucose and electrolytes, electrocardiogram, and chest x-ray. A CT scan should be performed as quickly as possible to exclude intracranial hemorrhage or a nonischemic cause of the patient's symptoms. Conditions that may mimic a stroke include encephalitis, hypoglycemia, seizure, brain tumor, subdural hematoma, and migraine. If these conditions are excluded by history, physical, and imaging findings, most patients who arrive within 3 h will be candidates for intravenous thrombolysis. Exclusion criteria are listed in Table 77.2.

The only exclusion criterion that may be altered by treatment is the patient's blood pressure. Consideration for thrombolysis is one of the very few clinical circumstances in which elevated blood pressure should be treated in the setting of acute ischemic stroke. Before

TABLE 77.2. Characteristics of patients with stroke who may be eligible for intravenous tissue plasminogen activator therapy.

Age >18 years
Diagnosis of ischemic stroke causing clinically apparent neurologic deficit
Onset of symptoms <3 h before possible beginning of treatment
No stroke or head trauma during the preceding 3 months
No major surgery during the preceding 144 days
No history of intracranial hemorrhage
Systolic blood pressure <185 mmHg
Diastolic blood pressure <110 mmHg
No rapidly resolving symptoms or only minor symptoms of stroke
No symptoms suggestive of subarachnoid hemorrhage
No gastrointestinal or urinary tract hemorrhage within the preceding 21 days
No arterial puncture at a noncompressible site within the preceding 7 days
No seizure at the onset of stroke
Prothrombin time <15 s or international normalized ratio <1.7, without the use of an anticoagulant drug
Partial thromboplastin time within the normal range, if heparin was given during the preceding 48 h
Platelet count >100,000/mm ³
Blood glucose concentration >50 mg/dL (2.7 mmol/L)

Source: Adapted from TPA Stroke Study Group Protocol Guidelines.

initiation of thrombolysis, the patient's blood pressure should be less than 185/110, which may be accomplished with the intravenous administration of labetalol 10 mg. This dose may be repeated or doubled every 20 to 30 min until the desired blood pressure is attained. Other agents such as enalapril or nitroprusside may also be used.

Intravenous Thrombolytic Therapy

The results of three phase III trials of thrombolysis with intravenous t-PA have been reported. The only one with clear-cut positive results was the NINDS t-PA Stroke Study in which 624 patients were treated with 0.9 mg per kilogram t-PA administered within 3 h of onset; half were treated within 90 min. Patients treated with t-PA were 30% more likely to have minimal or no disability 3 months later. The major risk of treatment was intracerebral hemorrhage, which occurred in 6.4% of patients treated with t-PA but in only 0.6% of those who received placebo. Mortality was similar in both groups (17% t-PA, 20% placebo). Patients with the three major stroke subtypes (lacunar, cardioembolic, large-vessel occlusive) benefited similarly.⁹¹

In two other large, randomized trials with longer treatment windows, t-PA was not more effective than placebo, although post hoc analyses suggest there may be a benefit beyond three hours if patients are appropriately selected. Subsequent studies have demonstrated that local hospitals can perform thrombolysis with intravenous t-PA given within 3 h with results similar to those in the NINDS trial.⁹²

Intra-arterial Thrombolysis

Intra-arterial thrombolysis, in which a microcatheter is advanced to and sometimes through the obstructing clot, is only available at selected centers but has gained increased acceptance because of a recent randomized trial and multiple positive reports of case series. PROACT II demonstrated that patients with arteriographically confirmed occlusion of the middle cerebral artery (MCA) or its two main branches who received intraarterial thrombolysis with prourokinase within 6 h of onset had better outcomes at 3 months poststroke than those who received only low-dose intravenous heparin. No randomized trials of intra-arterial thrombolytic therapy for vertebrobasilar disease have been completed, but several reports of improved outcome relative to the usual poor prognosis in this condition has led many authorities to recommend its use, particularly in patients who cannot be treated with intravenous t-PA within 3 h of onset.⁹³

Antithrombotic Therapy

During the past 30 years, anticoagulation with continu-

ous infusion of intravenous unfractionated heparin has probably been the most widely used acute stroke treatment, yet no clinical trial to date has adequately tested its efficacy. Recently, several trials of anticoagulation by different methods have reported conflicting results. The International Stroke Trial enrolled nearly 20,000 patients within 48 h of symptom onset in a 3 × 2 factorial design in which patients received subcutaneous heparin at a dose of 5,000 or 12,500 IU twice daily, or no heparin with or without 300 mg aspirin daily. There were no differences in the primary outcome measures (death at 14 days; death or dependency at 6 months) among any of the treatment groups.⁹⁴ There was an increased risk of hemorrhage in the high-dose heparin group. This study has been criticized because of the unconventional (by American standards) method of heparin administration, lack of monitoring of anticoagulant effect, lack of blinding, and failure to obtain neuroimaging before randomization and initiation of treatment.

The Trial of ORG 10172 in Acute Stroke Treatment evaluated the low molecular weight heparinoid (LMWH) danaproid versus placebo in 1281 acute ischemic stroke patients. Patients were treated with continuous intravenous infusion for 7 days beginning within 24 h of symptom onset. There was no significant reduction in stroke progression, 7-day mortality, or risk of stroke recurrence. There was a trend toward a better 3-month outcome in the large-vessel atherosclerotic subgroup (68% versus 55% favorable outcome). Another double-blind placebo-controlled trial randomized 2750 patients to a high or low dose of a different LMWH, nadroparin, or placebo subcutaneously, begun within 48 h of symptom onset. There was a significant dose-dependent effect among the three study groups in favor of the LMWH in the main outcome measure, that is, death or dependency after 6 months.⁹⁵

The Heparin in Acute Embolic Stroke Trial (HAEST) compared the LMWH dalteparin 100 IU/kg twice daily to aspirin 160 mg daily, begun within 30 h of symptom onset in treatment of 449 patients with acute ischemic stroke and atrial fibrillation. There was no difference in the frequency of stroke recurrence in the first 2 weeks following stroke and no difference in functional outcome at 2 weeks or 3 months.⁹⁶

Despite the lack of evidence supporting its use, intravenous unfractionated heparin remains in widespread use in patients not eligible for thrombolysis, especially those with presumed cardioembolic infarction, antiphospholipid-antibody syndrome, extracranial carotid or vertebral artery dissection, cerebral vein thrombosis, and impending large-vessel thrombosis. It is usually given as a continuous intravenous infusion with a goal of maintaining the partial thromboplastin time at 1.5 to 2.0 times normal.

Antiplatelet Therapy

Early treatment with aspirin is commonplace for patients not treated with thrombolysis or anticoagulation. This practice arose because aspirin was of proven benefit in secondary stroke prevention and in the acute management of myocardial ischemia, but recently two trials evaluated its benefit in more than 40,000 patients treated within 48h of stroke onset. In the International Stroke Trial, although there was no difference in the primary outcome measures among treatment groups, secondary analyses demonstrated a small (2.8% versus 3.9%) decrease in the rate of recurrent ischemic stroke in patients treated with aspirin. The Chinese Acute Stroke trial randomized 21,106 patients to aspirin 160mg or placebo for 4 weeks and demonstrated a slightly lower mortality rate (3.3% versus 3.9%) and recurrent stroke rate (1.6% versus 2.1%) in the aspirin group.⁹⁷

Other oral antiplatelet drugs (e.g., clopidogrel, dipyridamole, ticlopidine) effective in secondary prevention have not been studied in acute stroke. A phase II study of abciximab, a GPIIb, IIIa receptor antagonist effective in acute myocardial infarction (MI) and in coronary artery stenting procedures, demonstrated safety and showed a trend toward better outcomes in the treated group. A phase III study is underway.⁹⁸

Neuroprotection

Ischemic neuronal death results from a cascade of events set in motion by insufficient supply of oxygen and nutrients. As the understanding of the process grows, so does interest in drugs that may interfere with one or more steps in the process. However, several approaches that showed promise in laboratory models have foundered in clinical trials. Potentially, neuroprotective agents, such as dihydropyridine calcium channel blockers (nimodipine), *N*-methyl-D-aspartate-receptor antagonists (aptiganel), antibodies to intercellular adhesion molecules (elinomab), free radical scavengers (lubeluzole), and other agents with multiple putative mechanisms of action (citicoline, clomethiazole) have failed to show efficacy in phase III trials. Various explanations, including adverse effects limiting tolerable doses, inadequate delivery of drug to ischemic tissue, and delay in administration, have been given for the failure to replicate in clinical stroke positive responses shown in laboratory models. Although research continues and enthusiasm is high for the discovery of a potentially effective agent or combination of agents, no effective neuroprotective agent has yet been demonstrated.⁹⁹

Acute Stroke Units

Thrombolysis is currently the most dramatic and effective form of acute stroke therapy, but is applied to only

TABLE 77.3. Effectiveness of different acute stroke interventions.

Intervention	Percent stroke population treatable	Percent absolute risk reduction	NNT
Stroke unit	80	6.6	15
Aspirin	80	1.2	83
Thrombolysis	5	6.5	15

about 2% of all strokes in the United States. Aspirin is more widely applicable, and, while statistically significantly better than placebo in two large trials, its use results in an absolute risk reduction of about 1% in the outcome events measured; this translates into treating 100 patients to prevent one poor outcome. Anticoagulation is still widely used but is of no proven benefit. By far the most widely applicable, effective acute stroke intervention is the use of dedicated acute stroke units. In randomized trials, this approach reduces death or dependency from stroke by as much as thrombolysis but is applicable to all stroke patients.¹⁰⁰ The form that dedicated acute stroke units take varies from site to site and from country to country. Some focus on the initial 48h, whereas others include rehabilitation programs, but numerous studies have demonstrated their effectiveness relative to general medical or neurologic services. Although the characteristics of these units may vary, they share an integrated approach to patient care in which an interdisciplinary team including physician, nurse, and therapist are involved primarily in the care of stroke patients, work together as a team, and provide closer monitoring and more rapid assessment and treatment of the patient. As a result, short-term and long-term mortality rates are lower, hospitalizations are shorter, and patients are more likely to be discharged to home. The overall cost of the illness is also reduced¹⁰¹ (Table 77.3).

Stroke Prevention

Although effective treatment of acute stroke exists, it is far preferable to prevent its occurrence. Effective prevention encompasses addressing stroke risk factors and treating specific etiopathologic mechanisms identified in a given individual.

Stroke Risk Factors

Hypertension is the most important modifiable stroke risk factor, as was first demonstrated by investigators in the Framingham Heart Study, who found that stroke risk increased proportional to both systolic and diastolic blood pressure throughout the measured range.¹⁰² This effect has been found to be consistent across many

TABLE 77.4. Effectiveness of different secondary stroke prevention strategies.

Intervention	Percent of TIA/ischemic stroke eligible	Absolute risk reduction	Relative risk reduction	NNT

populations.¹⁰³ Subsequent studies have demonstrated that reduction of blood pressure lowers stroke risk.¹⁰⁴ Treatment of isolated systolic hypertension is also clearly beneficial, especially in the elderly.^{105,106} The choice of specific antihypertensive agent is less important than obtaining satisfactory control and should be determined by individual patient characteristics, although a recent study suggested that an ACE inhibitor may provide stroke protection beyond its antihypertensive effect.¹⁰⁷ Because ACE inhibitors are generally well tolerated in the elderly, this class of agents should be considered as initial antihypertensive treatment in a stroke-prone individual. Recent national guidelines suggest blood pressure of less than 140/85 (135/80 in diabetics) as the appropriate treatment goal.¹⁰⁸

Hyperlipidemia

Elevated serum cholesterol is an important risk factor for coronary artery disease but its role in stroke is unclear. The Multiple Risk Factor Intervention Trial (MRFIT) screened 351,000 men and demonstrated a curvilinear relationship in which serum cholesterol greater than approximately 240 mg/dL was associated with an increased risk of ischemic stroke mortality, whereas a level less than 140 mg/dL was associated with an increased rate of intracerebral hemorrhage.¹⁰⁹ However, in a meta-analysis of 45 studies, the Prospective Studies Collaboration failed to find a relationship between total cholesterol and stroke among 450,000 individuals.¹¹⁰ Similarly, neither the Framingham Study¹¹¹ nor the Cardiovascular Health Study¹¹² demonstrated a relationship between cholesterol and stroke. Consistent with these primarily negative findings, early cholesterol reduction studies showed a beneficial effect on heart disease but not stroke.

Surprisingly, the more recent results in trials using hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors consistently demonstrated a relative risk reduction of 20% to 30% for stroke, similar to the risk reduction demonstrated for the various cardiovascular

events studied,^{113,114} This seemingly paradoxical finding may be explained by the putative beneficial effects of statins on platelets, plaque stabilization, smooth muscle cells, endothelial cell function, or inflammation, in addition to lowering LDL cholesterol.¹¹⁵ The effect of triglycerides on stroke risk is also unclear, but a recent study of gemfibrozil demonstrated a similar degree of stroke risk reduction with minimal effect on high-density or low-density lipoproteins but significant lowering of triglycerides, suggesting triglycerides may also play a more significant role in stroke than previously recognized.¹¹⁶ Current guidelines suggest treating individuals with coronary artery disease whose LDL cholesterol is greater than 130 mg/dL with a target less than 100 mg/dL. In view of the results of recent trials, extending these recommendation to patients with cerebrovascular disease seems prudent.

Other Factors

The Framingham Study was also among the first prospective cohort studies to demonstrate an increased stroke risk in cigarette smokers. Smokers had twice the risk of stroke as nonsmokers, but that risk was eliminated within about 2 years of cessation.¹¹⁷

Most studies have shown an increased risk of stroke with heavy alcohol consumption, but recently moderate consumption (<2 drinks/day) has been shown to be protective against stroke.¹¹⁸ While urging heavy drinkers to decrease or eliminate their alcohol consumption is advisable for many reasons, the idea of encouraging nondrinkers to begin is controversial.

Elevated levels of homocysteine in the blood, termed hyperhomocysteinemia, has recently been associated with increased risk of stroke and myocardial infarction.¹¹⁹ Individuals with levels above 15 μmol/L appear to have five times the risk of stroke of those with levels below 10 μmol/L. The efficacy of reducing stroke risk by lowering blood homocysteine levels with a combination of vitamins B₆, B₁₂, and folic acid is currently being assessed, but recommending the use of a multivitamin containing these elements, especially in the elderly, appears prudent.

Conditions Requiring Treatment

Atrial Fibrillation

As mentioned, atrial fibrillation (AF) is a particularly important risk factor in the elderly. Chronic AF in association with valvular heart disease increases stroke risk 17-fold, while in the absence of valvular disease stroke risk is still increased 5-fold.¹²⁰ Recent studies have identified factors that increase stroke risk in nonvalvular AF including older age, hypertension, recent onset of

congestive heart failure, diabetes mellitus, a history of systemic embolism, or cerebral ischemia. Poor left ventricular function and increased left atrial size on echocardiogram also increase risk.¹²¹

Chronic anticoagulation with warfarin has been shown to be very effective in reducing stroke risk in patients in AF with and without a history of stroke. Anticoagulation should be prescribed for all patients who have had cerebral ischemic symptoms in the setting of AF unless there is a specific contraindication, and prophylactically in most patients who have been asymptomatic but have the additional risk factors mentioned, especially those over age 60.¹²²

Carotid Stenosis

Narrowing of the lumen of the internal carotid artery is associated with an increased risk of stroke. A residual lumen of less than 20% of normal is highly correlated with the development of total occlusion of the internal artery or the development of symptoms related to that artery.¹²³ Endarterectomy is the most widely used specific treatment for this condition. In the past decade, several large-scale randomized trials involving symptomatic and asymptomatic individuals have provided data that allow a rational selection of appropriate patients for this procedure. In both the European Carotid Stenosis Trial (ECST)¹²⁴ and the North American Symptomatic Carotid Endarterectomy Trial (NASCET),¹²⁵ individuals with symptoms referable to a highly stenotic (70%–90%) carotid artery randomized to the nonsurgical arms had an estimated 28% 2-year stroke rate. The ipsilateral stroke rate was 22% in ECST and 26% in NASCET in these patients. Individuals with moderate symptomatic stenosis had stroke rates approximately one-half those of the highly stenotic groups. The benefit of surgery in reducing subsequent stroke risk in the symptomatic highly stenotic groups was clear-cut. This benefit disappeared once the degree of stenosis was less than 50% by NASCET criteria (comparable to approximately 75% by ECST criteria).¹²⁶ In the Asymptomatic Carotid Atherosclerosis Study, the benefit of carotid endarterectomy to asymptomatic individuals with at least 60% stenosis was less dramatic, and women with asymptomatic carotid stenosis may not benefit from endarterectomy at all.¹²⁷

The benefit of surgery must be balanced against the risk for each individual. Life expectancy also plays a role in the decision-making process, because early morbidity including stroke and death is associated with the procedure; this should be less than 3% in experienced hands. Given these caveats, endarterectomy can be performed safely even in the very elderly and should be recommended for appropriate individuals of any age whose life expectancy is great enough to anticipate benefit despite the risk of early perioperative morbidity.

Antiplatelet Therapy

Antiplatelet therapy is the most commonly prescribed stroke prevention remedy and is usually appropriate for any symptomatic individual who does not require anticoagulation. Most patients are maintained on enteric-coated aspirin, with 325 mg daily the most commonly prescribed dose in the United States. However, much controversy exists. There is no consensus regarding the optimal dose, with recent recommendations suggesting a range of 50 to 325 mg,¹²⁸ although other authorities suggest higher doses are more effective if tolerated.¹²⁹ Newer medications such as Aggrenox (a combination of 25 mg aspirin and 200 mg dipyridamole in a sustained-release formulation), ticlopidine, and clopidogrel have been shown to have somewhat greater efficacy than aspirin in randomized trials, but maintenance on these medications currently costs in excess of \$1000/year in the United States for an individual purchasing their drugs at a retail pharmacy. Because the differences among various agents are small when compared with the effect of taking no antiplatelet agent and compliance has been shown to be a major problem, attention should be directed at ensuring patients are compliant with whatever regimen is prescribed.

Conclusion

Despite recent advances in stroke treatment, prevention remains the most effective means of reducing the overall burden of stroke. Secondary prevention in patients who have experienced a transient ischemic attack (TIA) or stroke targets those at highest risk, but primary prevention in individuals at high risk because of the presence of the factors discussed here is also of great importance. Even among those with no identified stroke risk factors, on a population basis lower salt intake (accompanied by increased dietary potassium and calcium),¹³⁰ a diet high in folic acid and low in saturated fats, and no more than moderate alcohol consumption can forestall the development of vascular disease risk factors and reduce stroke incidence.

Abnormalities of Posture and Movement

José C. Masdeu and María Cruz Rodríguez-Oroz

There exists a large group of cases where the gait in old people becomes considerably disordered, although the motor power of the legs is comparatively well preserved. A paradoxical state of affairs is the result: testing of the individual movements of the legs while the patient reclines upon the couch shows little, if any, reduction in the strength . . . But when the patient is instructed to get out of bed and to walk, remarkable defects may be witnessed. The patient, first of all, appears most reluctant to make the attempt. His stance is bowed and uncertain. He props himself against the end of the bed and seeks the aid of the bystanders. Encouraged to take a few steps, he advances warily and hesitatingly. Clutching the arms of two supporters, he takes short, shuffling steps. The legs tend to crumple by giving way suddenly at the knee joints. Progression, as far as it is possible, is slow and tottery.

McDonald Critchley, 1948¹

Postural abnormalities in older persons lead to falls, which are discussed in Chapter 66. This chapter first reviews the neurologic basis of postural impairment, and its etiology and treatment; it concludes with a review of other movement disorders. Of the topics discussed here, postural impairment has the greatest impact on disability and is by far the most prevalent. Although most older people have preserved distal function of the extremities, so that they can write and brush their teeth, many have poor postural reflexes, a cautious gait, and risk falling. Despite its prevalence, for many physicians, the condition is still as mysterious as it was for Dr. Critchley, whose masterful quote introduces this chapter. For this reason, it is discussed here in some detail.

Postural reflexes become most evident and are most critical when the person stands and walks, but they are also involved in a number of other motor activities. Dr. Critchley noted that his patients fared well while in bed, but had he asked them to move up in bed, he would have witnessed a marked impairment in the ability to perform this simple maneuver. Caregivers to the elderly are instinctively so aware of this fact that they make sure to place the patient in an adequate position in bed. Other-

wise, the patient may remain in an awkward or uncomfortable position, unable to shift in bed as required to correct it. The postural system runs in the background, controlling those movements we do not attend to. This “automatic pilot” of the motor system has its own neural pathways and is affected by specific diseases, the object of this chapter. *Stance, equilibrium, and balance* are terms that refer to the ability or act of maintaining the erect posture. Gait or ambulation presupposes the ability to stand, although the neural mechanisms underlying these two motor functions are far from identical. Surprisingly, some patients experience more difficulty standing than walking, for instance, those with orthostatic tremor.² The emphasis of this chapter is not so much on the diagnosis of neurologic disorders that secondarily result in ambulation difficulties, such as stroke causing hemiplegia, but on disorders that primarily affect the ability to stand or walk, often without overt weakness, as described in Critchley’s quote.¹ Disorders of stance and gait can be the presenting syndrome of many different pathologies along the neuraxis. Clinical localization before the use of ancillary diagnostic testing is essential if ancillary procedures are to be applied in a focused and economical manner that will minimize the likelihood of false-positive findings.³

When diagnosing postural disorders, it is useful to think about the neurologic systems underlying the control of gait and balance.^{4,5} At the simplest level, gait requires sensory information and a motor output. Sensory information includes proprioception, vision, and vestibular input. On the motor side, the corticospinal, vestibulospinal, and reticulospinal tracts convey to the cord output from higher centers. In their turn, the anterior horn cells through their axons stimulate muscles that turn that output into specific movements.

Sensory systems can be tested by exploring the performance of the patient while one or two varieties of sensory input are removed and the postural reflexes depend on the remaining sensory information. For

instance, the Romberg test explores the patient's ability to maintain a steady upright posture with vision removed and the base of support reduced by keeping the feet together. Proprioceptive or vestibular loss will result in difficulty maintaining balance. To test the intactness of the corticospinal tract, spinal cord, peripheral nerves, and muscles, the examiner asks the patient to wiggle her toes, to draw a circle on the floor with each foot, and to extend the big toe against resistance. Proximal muscle strength in the legs can be tested by asking the patient to rise from a low chair without using her arms to prop herself up. Despite the patient's ability to complete quite well all these tasks, they may still have difficulty walking and a propensity to falling. This apparent discrepancy highlights the importance of neural systems critical for posture, which are distinct from the system mediating volitional leg and foot movements.⁴ In addition to the vestibular and cerebellar input, the function of the basal ganglia and of several brainstem nuclei, including the pedunculopontine nucleus, plays an important role in the control of postural and locomotor activity. Normally, this activity is unconscious, carried on in the background, for instance, while the person concentrates their attention on fetching something from the refrigerator, rather than on the activity of walking.

Epidemiology

Postural disorders are particularly frequent in the elderly population. The Duke study of normal aging estimated that gait disturbances affect 15% of the elderly, being the most frequent neurologic impairment in this age group.⁶ Among the elderly, falls are the leading source of injury-related deaths.⁷ In the United States, about 9500 deaths among people age 65 years or older are attributed each year to a falling episode. Falling is also a major cause of morbidity among older people. Eighty-four percent of the approximately 200,000 hip fractures occurring yearly affect people older than 65. Most of these cases are related to a fall. Hip fracture is the most common injury leading to hospitalization in this age group.⁸

Etiology of Postural Disorders in Older Adults

Unlike that in younger adults, postural impairment in older people seldom results from a single etiology. Most often, partial impairment of multiple systems is responsible for the impaired balance and gait witnessed by the clinician. In about one-fourth of the cases, however, one of the factors contributing to postural impairment can be corrected enough to reverse the disability. The task of the clinician is to identify the causes contributing to postural

impairment and to sort out the correctable ones. Still, a large number of elderly patients have idiopathic postural impairment: the identifiable causes do not explain satisfactorily why an individual patient has a tendency to fall.

The multifactorial genesis of postural impairment in the older adult cannot be overemphasized. Studies of falls have illustrated that individuals who fall typically have more than one risk factor for falling.⁹ Robbins and coworkers found that the predicted 1-year risk of falling ranged from 12% for persons with none of three risk factors (i.e., hip weakness assessed manually, unstable balance, and taking four or more prescribed medications) to 100% for persons with all three risk factors.¹⁰ It is also likely that older persons with vestibular dysfunction alone will not experience gait difficulties, but the rule is that proprioception and vision are also impaired to some extent. As a result, the vestibular dysfunction becomes symptomatic. To sensory deficits, impairment of central processing is added in many older adults. Corticobasal-ganglionic-thalamocortical mechanisms can be affected by a drop of dopaminergic neurons or neurons belonging to other systems, as in many of the disorders considered later in this chapter, fiber damage by chronic ischemia in the white matter watershed, lateral to the ventricular angles, or other mechanisms still poorly understood.

In some published series, the majority of patients were assigned a primary cause for their gait or postural disorder.^{11,12} Other authors failed to find a cause in the majority of patients.¹³ This discrepancy may reflect (1) different patient populations; a single diagnosis may be more readily identifiable in a general medical or neurologic practice, whereas in gait disorders clinics the proportion of idiopathic gait disorders is larger, possibly because patients with Parkinson's disease and other readily identifiable disorders are not referred to specialized centers for evaluation; or (2) a different diagnostic approach; sensory deficits, for instance, are very prevalent in the elderly with or without gait disorders; finding a sensory deficit, some clinicians may consider it responsible for the gait disorder, whereas others may think that a different etiology must be at work to explain the clinical picture. Whether a given etiology is the main culprit for the patient's gait difficulties is often not the key question, but rather whether a correctable cause can be found and addressed. Even a modest functional improvement may forestall the dismal consequences of repeated falls.

In a series of 120 older adults referred to a neurologist for an undiagnosed gait disorder, Sudarsky reported the frequency of each etiology.¹² Sensory deficits represented the largest single neurologic cause of postural instability. This etiology, myelopathy, and multiple infarcts accounted for half the cases. In 14% of the cases, the etiology remained undetermined. The rest fell under the categories of parkinsonism, cerebellar degeneration, hydrocephalus, an assortment of other causes (including

neoplasms and subdural hematoma), psychogenic gait disorders, and toxic or metabolic causes. In 50 consecutive patients older than 50 years of age admitted to a neurologic service because of walking difficulty, Fuh and coworkers identified the following causes: multiple cerebral infarcts, 24%; myelopathy, 22%; parkinsonism, 12%; cerebellar degeneration, 8%; brain tumor, 6%; Binswanger's, 4%; Alzheimer's, 4%; other diseases, 10%; and unknown etiology, 10%.¹⁴ The miscellaneous category included a patient with chronic inflammatory demyelinating polyneuropathy. Patients with undetermined gait disorder were older than 60 and had "senile gait." Potentially treatable causes of gait impairment were found in nearly one-third of patients.

Following is an anatomic list of the major etiologic categories responsible for postural impairment. They are listed from the more peripheral causes, including muscle weakness, to the etiologies affecting primarily the control centers of the brain.

Muscle Weakness

Many older adults with gait difficulties blame their problem on muscle weakness. With age, muscle mass and strength decrease, even in normal people. Muscle mass is lost at a rate of 0.5% to 1.0% annually in women and men over 60 years, and muscle strength loss ranges from 20% to 40% from the third to the eighth decades and may be even greater in the eighth decade.¹⁵ Weakness is due to loss of muscle mass and contractility (force/cm² of muscle cross section). The good news is that vigorous physical activity is associated with maintaining muscle strength, mass, and contractility.¹⁵ Diseases of muscle or the neuromuscular junction are rarely responsible for gait impairment in the older adult. Polymyositis and myasthenia gravis can give rise to limb weakness. In this case, isometric weakness is more pronounced than the gait impairment, alerting the clinician to the possibility of muscle disease. Disorders of muscles and joints are discussed in Chapters 42 through 46.

Sensory Deficits

Sensory deficits ranked first as the responsible etiology in some series of unselected patients referred for postural impairment.¹² While often proprioception, vestibular function, and vision are all affected, there are specific disorders that involve one modality more than the other two.

To clarify testing for sensory function crucial for gait, it is important to review briefly the physiology of sensory postural control. Proprioception, vestibular function, and vision are all required because no single sense can measure directly the position of the center of gravity of the body to place it within the base of support, a

condition of stability in bipedal stance and gait.⁵ The somatosensory input provides information on the orientation of body parts relative to one another and to the support surface. Vision measures the orientation of the eyes and head in relation to surrounding objects. The vestibular system measures gravitational, linear, and angular accelerations of the head in relation to inertial space. As the person stands or walks, the brain must quickly select the sensory inputs providing accurate information, because often one or more of the three sensory systems may provide information that is misleading for the purposes of balance control. For instance, when a person stands beside a large bus that begins to move slowly, the visual system conveys the false impression that the person is moving in the opposite direction. Nashner has called *sensory organization* the process of selecting and combining sensory information appropriate for balance control.⁵ Faulty sensory organization, or one that relies primarily on an impaired sensory system, may lead to unsteadiness when walking. Some simple clinical maneuvers, such as Romberg's, can help sort out gross deficiencies in one sensory modality, and specialized testing with posturography is seldom needed to evidence subtler changes.

Proprioception

Somatosensory input dominates the control of balance when the support surface is steady. Even with vision removed, a patient with bilateral vestibular loss but good proprioception can stand normally.⁵ Several disorders that can affect primarily proprioception are reviewed in turn. Many other disorders can affect proprioception in the older adult, including toxic neuropathies induced by cisplatin or nitrous oxide.

Vitamin-Induced Neuropathies

B₁₂ Deficiency

Pernicious anemia with deficient production of intrinsic factor is the most common cause of B₁₂ deficiency, many cases occurring in older people.¹⁶ B₁₂ deficiency is also observed due to chronic intestinal malabsorption and rarely to dietary deficiency. The daily requirement for B₁₂ is only 5 µg/day. Neuropathy and myelopathy (subacute combined systems degeneration) can occur without hematologic manifestations.

The onset is insidious, beginning with distal paresthesias, weakness, and unsteadiness of gait, particularly difficulty walking in the dark. Proprioceptive loss in the legs and sensory ataxia can grow quite severe. Lhermitte's sign is often present, reflecting damage of the dorsal columns. Tendon reflexes are typically depressed to absent. An extensor plantar response is characteristically observed, and, with time, a spastic-ataxic gait as well.

B₁₂ assay is used for screening, and Schilling test for confirmation of true pernicious anemia. The disorder is important to recognize as it is occasionally encountered in the elderly and is a treatable cause of imbalance and gait disorder. With B₁₂ therapy, gait improves fully in a majority of patients with duration of neurologic signs under 3 months.¹⁶

Megadose Pyridoxine Neuropathy

Chronic ingestion of megadoses (2–6 g/day) of *pyridoxine* (vitamin B₆) has also been associated with an ataxic peripheral neuropathy.¹⁶ Both proximal and distal parts of the body are simultaneously affected by sensory loss of the large fiber modalities. The other major clinical features are ataxia and pseudoathetosis without severe weakness. Sensory loss may be heralded by Lhermitte's sign, severe paresthesias, or dysesthesias.¹⁷ Pyridoxine intoxication kills dorsal root ganglia cells at high doses and impairs their metabolism at lower toxic doses, so that both their peripherally and centrally directed axons degenerate. Axonal regeneration can occur when excessive pyridoxine is eliminated.¹⁶ Diagnostic testing for this disorder relies on the history and on the improvement subsequent to elimination of excessive pyridoxine intake.

Chronic Immunomediated Disorders

Paraneoplastic Sensory Neuropathy (Anti-Hu)

This disorder affects primarily the dorsal root ganglia cells. Paresthesias or dysesthesias generally move from a distal to proximal direction, but some cases have shown early sensory changes in proximal areas, including the face.¹⁶ Position and vibration sense are most severely affected, with consequent severe sensory ataxia as well as pseudoathetosis in the outstretched limbs.¹⁸ There is early, widespread absence of reflexes. The associated neoplasm is most often a small cell cancer of the lung. The neuropathy may precede the clinical appearance of the carcinoma for longer than 3 years but more often by only a few months. The neuropathy often progresses in a subacute fashion but may then level off. Although treatment of the underlying neoplasm usually has no effect on the neuropathy, there are some rather dramatic single cases associated with reversal after effective treatment of the primary neoplasm. Pathologic observations show a lymphocytic infiltration of dorsal root ganglia with a marked depopulation of dorsal root ganglion cells and Nageotte nodules. The peripheral sensory axons degenerate, but there is also degeneration in the centrally directed axon because the dorsal columns, particularly the gracile sectors, are severely affected.

This type of carcinomatous neuropathy is often associated with cerebrospinal fluid and serum antibodies that react with dorsal root ganglia (IgG anti-Hu antibodies).

These antibodies also react with a brain nuclear protein and an identical antigen that is highly specific for small cell lung cancer.¹⁸ The spinal fluid of these patients often contains a few mononuclear cells (5–50/mm³) with elevations of protein as high as several grams. Unfortunately, the response to immunosuppression is usually poor.¹⁹

Sensory Neuropathy of Sjögren's Syndrome

Sjögren's syndrome, characterized by keratoconjunctivitis sicca, xerostomia sicca, and a rheumatoid-like arthritis, is often accompanied by a sensory polyneuropathy or polyganglionopathy.^{20,21} More frequent in women, this disorder can present with gait disorder due to deafferentation.^{21,22} Minor salivary gland biopsy is frequently positive.²⁰ Vasculitic neuropathy or nonspecific epineurial inflammation may be found on nerve biopsy. Antibodies to extractable nuclear antigens are the most specific serologic marker of Sjögren's syndrome, but this was present in only 10% of patients with the sicca complex and neuropathy but no arthritis.²⁰ Treatment with immunosuppression is not satisfactory. There are preliminary data suggesting a better response to low-dose oral alpha-interferon or zidovudine.^{23,24}

Chronic Idiopathic Ataxic Neuropathy

Chronic ataxic sensory neuropathy is a slowly progressive illness with distal paresthesias and sensory ataxia, areflexia, normal strength, and a profound loss of proprioceptive and kinesthetic sensation extending up to the most proximal joints.²⁵ Many of these patients have uncomfortable paresthesias with a severe loss of balance in the dark. The ataxia may be accompanied by pseudoathetosis. Sabin has studied several patients with sensory ganglionopathies who complained bitterly of very uncomfortable "pulling" and "stretching" sensations when they tried to move about and as a result confined themselves to bed and chair existence.¹⁶ Many patients have a serum monoclonal, mostly IgM, or polyclonal gammopathy; and some have elevated cerebrospinal fluid gamma globulin levels in spite of low normal total cerebrospinal fluid protein levels.²⁵ Response to immunosuppressant strategies has been poor.²⁵

GALOP Syndrome

Some of the milder cases of chronic ataxic neuropathy may actually have GALOP (gait disorder; autoantibody; late-age onset; polyneuropathy), a milder syndrome, often responsive to treatment.^{26,27} GALOP is characterized by the presence of IgM antibodies reactive with central myelin antigen (CMA). Pestronk and coworkers described nine patients, of an average age of 70 years, with anti-CMA antibodies, eight of whom had disabling difficulty with ambulation, "out of proportion to that

expected for age.²⁷ The gait disorder developed over a period of 2 to 15 years and presented as slow ambulation and frequent falling, particularly backward. Patients walked with small steps and had difficulty turning. Some of them had moderate distal weakness in the legs, but a sensory loss in a stocking distribution was common, although not as pronounced as that seen in ataxic sensory neuropathies. Romberg sign was strikingly positive. Most helpful for diagnostic testing is an ELISA assay detecting very high titers (>1:10,000) of serum IgM binding to a central nervous system myelin antigen (CMA) preparation that copurifies with myelin-associated glycoprotein (MAG).²⁶ Some patients who were treated with intravenous immunoglobulin or cyclophosphamide experienced improvement.²⁷

Chronic Inflammatory Demyelinating Polyneuropathy

Although not typically the main presentation, gait impairment can occur in the demyelinating polyneuropathies.¹⁶ Hyperacute Guillain-Barré syndrome (GBS) is misdiagnosed in the emergency room when a healthy-appearing patient is observed to stagger about with a bizarre ataxia and complain of only tingling paresthesias. Examination reveals good strength, which may be sustained only in irregular bursts, damped reflexes, and normal sensation as tested in the usual way. The patient is often released from the emergency room with a diagnosis of hysteria, but hours later may require emergency care for evolving widespread flaccid paralysis. This early ataxic phase of GBS might also be caused by a physiologic effect of large fiber demyelination that is concentrated in the posterior roots. Some patients recovering from GBS go through a phase of ataxia that is out of proportion to loss of strength or position sense. Likewise, chronic inflammatory demyelinating polyneuropathy (CIDP) may present as an ataxic syndrome. The degree of gait impairment corresponds to the degree of motor-sensory loss.²⁸ Occasionally, CIDP may induce ataxia by causing a vestibular syndrome.²⁹ CIDP relapses are treated with corticosteroids or intravenous immunoglobulin.³⁰

Vestibular Disorders

Older people who complain of unsteadiness when walking often have a normal standard neurologic examination. Fife and Baloh used rotational vestibular testing and quantitative posturography to study 26 such individuals older than 75 years of age and found vestibular impairment in all of them, as compared to age-matched controls.³¹ Lesions of the vestibular region may present with unilateral or bilateral findings. Unilateral findings are not uncommon in vascular disorders, such as the

Wallenberg syndrome, which is not rare in older patients. With infarction, patients tend to fall to the side of the infarct. Their gait is broad based and lurching. Removal of vision by environmental darkness or impaired eyesight affects negatively their ability to ambulate and predisposes them to falls. Initially, most of these patients have a prominent headache and are nauseated. In addition to the impairment of balance and ataxia ipsilateral to the lesion, they have a crossed sensory loss (on the ipsilateral face and contralateral body), an ipsilateral Horner's syndrome, and ipsilateral palatal weakness, with hoarseness and dysphagia. Atherosclerotic vascular disease of the vertebral or posteroinferior cerebellar arteries may occlude these vessels and is responsible for this syndrome in about half of the cases.³² Most the rest are caused by cardiogenic emboli. Spontaneous dissection of the arterial wall is a frequent cause in younger,³³ but not in older, patients, where temporal arteritis should be suspected, particularly in the very old with a high sedimentation rate.³⁴ In a small autopsy series of patients with temporal or giant cell arteritis, the vertebral arteries were found to be affected in all cases.³⁵ Polymyalgia rheumatica may be present but is not a universal finding. The superficial temporal arteries are often tender and swollen, with a faint pulse. Temporal arteritis responds well to prednisone therapy.

Bilateral findings are present in Wernicke's encephalopathy of vitamin B₁ deficiency, occasionally seen in elderly with a poor nutritional status.

Vision

Visual loss and, particularly, distorted visual input can have a major effect in the gait of an older person who already has some sensory loss in the other two modalities essential for maintaining balance, namely, proprioception and vestibular function. Before lens implants became commonplace, older adults having cataract surgery often went through a period of time when they found it difficult to walk normally and were afraid of falling. Eventually their brain learned to integrate the new visual information for the purpose of maintaining balance. To a lesser degree, some of the same difficulty can result from a change in prescription glasses in persons who have proprioceptive or vestibular impairment. On the other hand, these patients find it helpful to walk in areas that are well lighted, optimizing the use of visual clues and thus facilitating steadiness. The diagnosis and treatment of visual disorders is discussed in Chapter 60.

Spinal Claudication

The term *spinal claudication* comprises several disorders that cause the patient to experience radicular pain or leg weakness after having walked or stood still for a while. It

differs from vascular claudication in the localization and nature of the pain, but more so in that peripheral pulses are not markedly depressed. Spinal claudication generally results from compression of the cauda equina and the lumbosacral roots by a narrow spinal canal, with tight lateral recesses leaving little room for the exiting roots. In some patients, compression of the radicular arteries, and particularly the artery of Adamkiewicz, feeding the conus and epiconus, may cause cord ischemia and leg weakness. Three factors play in this anatomic situation: (1) the patient was born with a narrow canal; (2) degenerative disease of the spine with facet joint and ligament hypertrophy contributes to crowding even further the space available to the cauda equina, roots, and radicular vessels; and (3) exaggeration of the lumbar lordosis in the upright position worsens the compression of these structures.

Although this syndrome is real, it is rare. Unfortunately, some older adults who complain of gait difficulties have a lumbosacral MRI performed "just in case." When this test shows marked degenerative changes in their spine, with a narrow canal, the tendency is to diagnose the disease based on the imaging findings. Particularly in this case, it is extremely important to correlate carefully the imaging findings with the clinical presentation. Severe degenerative changes are the rule in MRI of the lumbosacral spine in persons older than 70 years and may be found in asymptomatic subjects of all ages.³⁶⁻³⁸ The clinical history is more important than the imaging findings to make the diagnosis. The history must be scrutinized. Other causes of gait impairment cause "gait claudication" because patients tire from having to attend to their gait and being fearful of a fall. For instance, many patients with parkinsonism have to sit after having stood for a short while because their "legs get heavy." Anxiety over a fall can cause "weak legs." Onset or worsening of characteristic radicular pain, on the other hand, favors spinal claudication. MRI findings are helpful to plan the surgery, but some surgeons prefer to rely on CT, which shows bone changes better than MRI. EMG may show denervation changes in a radicular distribution or, rarely, may be normal in the resting state. By themselves, EMG changes are not diagnostic. The treatment of true spinal claudication is surgical decompression.

Cervical Myelopathy

Although lumbosacral stenosis is seldom the cause of gait difficulties in the older adult, cervical myelopathy from cervical spondylosis was the second most common cause in both Sudarsky's and Fuh's series.^{12,14} Because it is potentially treatable, cervical myelopathy should be considered in any older adult presenting with postural impairment in the upright position. Some patients

present with the characteristic clinical picture of cervical radicular pain and spastic paraparesis, but most do not have radicular pain. Initially, at the time when surgery is most likely to be successful and prevent further deterioration, the gait impairment may be very subtle, noticeable to the patient but yielding minimal findings on neurologic examination.³⁹ The paucity of findings may delay the diagnosis. In the Yale series, the investigators believed that the diagnosis had been delayed on average by 6.3 years.³⁹ The earliest consistent symptom in all their 22 patients was a gait abnormality. These patients may become unsteady when closing their eyes and standing with feet together. They are unable to walk in tandem. The brachioradialis reflex may be depressed and, instead, a brisk finger flexor response is elicited when percussing the brachioradialis tendon (inverted radial reflex). Careful testing of vibratory sense may reveal a sensory level in the cervical region. Sometimes the patient perceives the stimulus better in the thumb than in the small finger. Early diagnosis is important, because the myelopathy of cervical spondylosis is often progressive if untreated.³⁹

In terms of diagnostic testing, all the precautions discussed in the previous section on spinal stenosis apply here as well. MRI of the cervical spine is helpful, but, in the absence of the clinical findings, the presence of spondylitic changes by themselves does not make the diagnosis. Rather severe changes can be seen in asymptomatic older adults.⁴⁰⁻⁴³ Plain x-rays are helpful in determining the shape of the cervical spine, the alignment of the vertebrae, the status of the bone, the vertical extent of the disease process, the degree of anterior and posterior osteophytes, and the nature of the disk spaces. Baseline plain x-rays are also quite useful when surgery is being considered for comparison with postoperative x-rays or when the patient cannot undergo MRI, for instance, in the case of someone bearing a pacemaker. Several recent studies agree that MRI is the screening test of choice in most instances.^{39,44} Bony osteophytes can be seen as black ridges compressing the canal and, if the compression is severe, causing high-intensity changes in the spinal cord on T₂-weighted images.

In addition to the narrowing of the spinal canal by spondylitic hypertrophy of bones and ligaments, two changes are frequently observed in the cord itself: decreased diameter and a hyperintense signal on T₂-weighted images. How often a hyperintense area is observed depends on the stage of progression, with gliosis and microcavitation of the gray matter, and other poorly understood factors. In some series, as many as 40% of the patients have this finding.⁴⁵ Although some have found the presence of this finding and its irreversibility after surgery to predict a poor outcome, others have not.^{45,46} MRI may show other changes within the spinal cord itself due to chronic compression such as syrinx formation.

MRI is also of great value in the differential diagnosis of myelopathy, as conditions such as tumor and infection can be easily ruled out. In multiple sclerosis, an abnormal signal may be found in the spinal cord and elsewhere in the brain due to the presence of plaques. MRI is a satisfactory alternative to myelography for most patients with suspected cervical spondylotic myelopathy.⁴⁴

However, MRI scan is not so good as CT in showing osteophytes or ossification of the posterior longitudinal ligament. If surgical treatment is contemplated, thin-slice CT of the cervical spine after intrathecal introduction of a nonionic water-soluble contrast material is of great help. MRI scan, CT scan, and CT myelography are all complementary tests and not mutually exclusive. CT myelography is most valuable when deciding on the surgical approach, either anterior or posterior. CT myelography also allows for accurate measurement of the spinal canal in the axial, sagittal, and coronal planes. A canal diameter less than 12 mm in the anteroposterior plane is considered stenotic. Ossification of the posterior longitudinal ligament (OPLL) is sometimes found in patients with cervical spondylotic myelopathy. OPLL may be segmental or continuous in the cervical spine. CT myelography is particularly useful for diagnosing this entity, which has significant bearing on the type of surgical procedure to be performed.

Somatosensory evoked responses can be normal in half of patients with symptomatic cervical myelopathy.⁴⁷ Motor responses from magnetic stimulation and spinal cord evoked potentials are more sensitive.⁴⁸⁻⁵⁰ Occasionally, these electrophysiologic tests can be useful when the clinical picture is less than conclusive.⁵¹ More often, in mild cases they are inconclusive as well. Postdecompression improvement of somatosensory evoked responses has predicted faster recovery but not the 1-year outcome of surgical patients.⁵² Most neurosurgeons do not require these data as part of the presurgical battery.

Cerebellar Disorders

Cerebellar lesions may affect posture by causing disequilibrium and by altering limb and trunk kinematics and interlimb coordination.⁵³ The cerebellum does not appear to actually generate postural and gait synergies because these automatic responses, albeit very dysmetric, are present in dogs with total cerebellectomies.⁵⁴

Disturbances of gait and balance are primarily caused by lesions of the vestibulocerebellum and spinocerebellum or their connections. Lesions of the cerebellar hemispheres cause irregular timing, force, and cadence of leg movements, leading to inaccurate and variable stepping.⁵⁵ Lesions of the *vestibulocerebellum*, or floccular-nodular lobe, can produce balance, and gait disturbances that resemble those caused by vestibular lesions.⁵³ Tremor of

the head and trunk, truncal imbalance, and swaying and falling in all directions are characteristic of vestibulocerebellar lesions. Vestibular nystagmus may be present. The clinical syndrome caused by lesions of the *spinocerebellum* is best characterized by alcoholic cerebellar degeneration, which primarily affects the anterior lobe of the cerebellum but also involves the olivary complex and the vestibular nuclei.⁵⁶ Patients with alcoholic cerebellar degeneration have a widened base, instability of the trunk, and a slow and halting gait with irregular steps and superimposed lurching. The gait abnormalities are accentuated at the initiation of gait, on turning, and with changes in gait speed. These patients may have severe gait ataxia without nystagmus, dysarthria, or arm dysmetria. Even the heel-to-shin test may give little inkling of the severity of the gait disturbance. Interestingly, if patients stop drinking and have adequate nutrition, the gait improves such that the steps are no longer irregular and tandem walking or sudden movements are necessary to demonstrate the gait ataxia.⁵⁶ Although most often patients with cerebellar lesions tend to fall to the side of the lesion, some patients with lesions in the tonsillar area develop increased tone (and increased reflexes) in the ipsilateral side and fall to the contralateral side.

Ischemic and hemorrhagic strokes are the most frequent causes of cerebellar dysfunction in the older adult.⁵³ Gait impairment is the most frequent presentation of infarcts in the territory of the superior cerebellar artery.³² In the older age group, infarction in the territory of the posterior inferior cerebellar artery is caused by atheromatous vascular disease as often as by embolic disease. Presumed cerebral embolism was the predominant stroke mechanism in patients with superior cerebellar artery distribution infarcts.³²

The clinical presentation of cerebellar hemorrhage may be acute, subacute, or chronic.^{57,58} Variations in location, size, and development of the hematoma; brainstem compression; fourth ventricular penetration; and development of hydrocephalus result in variations in the mode of presentation of cerebellar hemorrhage. These hemorrhages most frequently occur in the region of the dentate nucleus. Patients present with occipital or frontal headache, dizziness, vertigo, nausea, repeated vomiting, and inability to stand or walk. They often have truncal or limb ataxia, ipsilateral gaze palsy, and small reactive pupils. Horizontal gaze paresis, parietic nystagmus, and facial weakness are also frequent. Frank hemiparesis is absent. Ocular bobbing and skew deviation may be present. Not all patients present such a dramatic picture; those with small (usually less than 3 cm in diameter) cerebellar hematomas may present only with vomiting and with no headaches, gait instability, or limb ataxia. Anatomic findings that predict deterioration with cerebellar hemorrhage include displacement of the fourth ventricle, brainstem deformity, hydrocephalus, and

compression of the basal cisterns.^{59,60} In some series, a hematoma larger than 3 cm also worsens prognosis.⁶⁰ Clinically, patients fare poorly who have abnormal corneal and oculocephalic responses, a Glasgow coma score less than 8, and motor response less than localization to pain.⁶⁰

Degenerative diseases of the cerebellum include disease restricted to the cerebellum and diseases with extracerebellar involvement, such as olivopontocerebellar ataxia (OPCA) or multisystem atrophies, discussed in greater detail later.⁵³ Spinocerebellar degenerations typically begin at a younger age.

Paraneoplastic cerebellar syndromes can be seen in bronchial, breast, and ovarian cancer.⁵³ The symptoms include ataxia of gait and stance, limb ataxia, terminal tremor, gaze-evoked nystagmus, and disturbed smooth pursuit eye movements.

Toxic cerebellar syndromes in older people are frequently caused by slower drug metabolism and reduced tolerance.⁵³ All centrally acting drugs may lead to cerebellar disturbances of stance and gait. The drugs most frequently responsible for toxic disturbances include alcohol, antiepileptic drugs, lithium, and tranquilizers.

Vascular Disease

Vascular disease of the brain ranks among the top three causes of gait impairment in the older adult.^{12,14} Those affected are patients referred for progressive gait impairment, not stroke patients with secondary hemiparesis and gait difficulty. Vascular disease causing this syndrome most often affects the supratentorial compartment in the form of lacunar disease or ischemic disease of the white matter. Less often, it involves the posterior circulation, involving vestibular or cerebellar structures, as already described, and very rarely other brainstem structures important for gait, such as the mesencephalic locomotor center. Lacunar disease is discussed first, followed by white matter disease and finally the syndrome of the mesencephalic locomotor center. CT and MRI are the diagnostic tests most useful for the study of these syndromes.

Lacunar Disease of Gait: Critical Structures

Ischemic brain disease tends to follow one of three patterns, discernible by clinical evaluation and with the help of neuroimaging procedures: (1) cortical infarcts, most often related to embolic disease; (2) subcortical disease, often in the form of widespread lacunes and white matter changes, most often related to arteriolar disease; and (3) a mixture of the two patterns, often related to atherosclerotic disease of the major vessels.³ The second and third types of cerebrovascular disease tend to cause gait and

balance impairment early in the course of the disease. Subcortical infarcts strategically located may impair equilibrium and gait with little or no limb weakness on isometric testing. These lesions tend to affect structures with a critical role in gait and balance mechanisms, including the corticobasal-ganglionic-thalamocortical loop. Although acute stroke tends to be associated with overt neurologic findings, gait impairment may be neglected as a neurologic finding and yet be the result of small, "silent" lacunar strokes.⁶¹ In a cohort of clinically asymptomatic patients studied during the Asymptomatic Carotid Artery Stenosis trial, Brott and coworkers documented lacunar strokes with CT in 11% of the patients.⁶² These patients were more likely to have gait impairment.

Thalamic Ataxia or Disequilibrium

Inability to stand or walk despite minimal weakness has been recorded with thalamic infarction or hemorrhage, particularly when the superior portion of the ventrolateral nucleus or supratthalamic white matter was involved.^{63,64} It has also been reported in patients with lesions in the internal capsule or corona radiata who had the syndrome of unilateral ataxia and crural paresis (ataxic hemiparesis).⁶⁵ Alert, with normal or near-normal strength on isometric muscle testing and a variable degree of sensory loss, these patients could not stand and some with acute lesions could not sit up unassisted; they fell backward or toward the side contralateral to the lesion. These patients appeared to have a deficit of over-learned motor activity of an axial and postural nature. In the vascular cases, the deficit improved in a few days or weeks. However, these patients had a tendency to sustain falls during the rehabilitation period.

Capsular and Basal Ganglia Lesions

A tendency to fall despite good strength was recorded by Groothuis et al.⁶⁶ in a patient with a small medial capsular hemorrhage involving the most lateral portion of the ventrolateral nucleus of the thalamus and by Labadie and coworkers in patients with acute lesions in the basal ganglia.⁶⁷ Multiple bilateral lacunae involving the basal ganglia can be attended by gait impairment.

White Matter Disease

In controlled studies of elderly prone to falling, impaired gait and balance correlated with the presence of white matter disease on CT or MRI.⁶⁸⁻⁷² Periventricular white matter changes were present in cases of "lower body parkinsonism."^{73,74}

Because the histology underlying these changes remains elusive in some cases, Hachinski et al. coined the descriptive term leuko-araiosis for the CT findings.⁷⁵ Several authors have reported normal histology, but

ischemic changes similar to the findings in subcortical arteriosclerotic encephalopathy (SAE) have been present in cases with pronounced changes on T₁-weighted MM or CT.⁷⁶ Amyloid angiopathy has been incriminated in the genesis of white matter disease in some elderly individuals.^{77,78} In addition to white matter changes, amyloid angiopathy results in subcortical hemorrhages. Some ischemic leukoencephalopathies of middle-aged and older people, such as CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), are familial.⁷⁹

Pontomesencephalic Gait Failure

The laterodorsal region of the midbrain contains the mesencephalic locomotor region, which plays an important role in locomotion in animals.⁸⁰ In humans, loss of neurons in the pedunculopontine nucleus has been found in progressive supranuclear palsy and victims of Parkinson's disease, but not in patients with Alzheimer's disease, implying perhaps a role of this nucleus in ambulatory mechanisms. Discrete vascular damage in this region can give rise to a disorder bearing striking resemblance to the idiopathic gait failure experienced by many elderly individuals, which in most cases does not have a clear anatomic correlate.^{81,82}

Toxic or Metabolic Encephalopathies

Because these encephalopathic disorders are often treatable causes of gait impairment, it is important to recognize metabolic or toxic agents, most often in the form of medications. Psychotropic, diuretic, antihypertensive, and antiparkinsonian medications, especially if used in improper doses, may contribute to falls in the elderly by decreasing alertness, depressing psychomotor function, or causing weakness, fatigue, dizziness, or postural hypotension.⁸³⁻⁸⁵ These adverse physiologic effects may be exacerbated by altered drug metabolism in elderly individuals. Although not confirmed by all studies, there is good evidence that hypnotic-anxiolytic drugs, particularly benzodiazepines, increase the risk of falls.^{10,86-88} The role of diuretic, antihypertensive, and other medications linked to orthostatic hypotension in increasing the risk of falls is uncertain and needs further investigation.⁸⁴ Several studies have found an association of falls with the number of medications being taken; this could reflect synergistic effects among drugs, but could also be related to the poorer health of individuals taking multiple medications.

Patients with metabolic encephalopathy often display an insecure gait and may fall over backward if displaced. This phenomenon is particularly dramatic with uremia and hepatic failure, in which asterixis may impair stance.¹²

Parkinsonian Syndromes

The parkinsonian syndromes share an impairment in posture and gait. Spontaneous movements on the part of the patient are diminished. There is increased resistance to passive range of motion. The concatenation of these clinical findings is known as *parkinsonism*. However, although the most frequent entity responsible for parkinsonism is idiopathic Parkinson's disease, some other disorders can induce a similar disturbance, and a careful differential diagnosis must be considered, as is discussed next.

Parkinson's Disease

Parkinson's disease (PD) is a common disorder among the elderly population. Thus, its incidence increases with age from less than 10 per 100,000 at age 50 to more than 200 per 100,000 at age 80.⁸⁹ After the ninth decade, its incidence appears to decline, but these data are likely to be an artifact derived from poor ascertainment and the smaller size of the population of this age. The gender distribution shows a slightly greater incidence in males, and there is no conclusive evidence for race differences. Epidemiologic studies have been conducted trying to identify risk factors for PD. Apart from increasing age, the strongest risk factor associated with PD is the presence of disease in a family member.

Clinical manifestations in PD are caused by the loss of dopaminergic cells in the pars compacta of the substantia nigra (SNpc), and the subsequent loss of nigrostriatal dopaminergic modulation of the neural mechanism for movement control.⁹⁰

Clinical Features

The cardinal manifestations of Parkinson's disease are tremor, rigidity, akinesia, and postural instability with associated gait disorder. Postural and gait disturbances usually appear later in the course of typical Parkinson's disease, whereas they are an early manifestation of the "Parkinson plus" disorders, such as progressive supranuclear palsy, striatonigral degeneration, multisystem atrophy, and corticobasal ganglionic degeneration.⁹⁰

Tremor

The parkinsonian tremor is typically a resting tremor that disappears when a voluntary movement is performed. Electromyographic recording of the muscles involved shows a rhythmic alternating activity at 4 to 6 Hz between agonist and antagonist muscles. Distal joints are preferentially affected (i.e., metacarpophalangeal), and some distracting maneuvers, such as counting, induce an increment in its magnitude. In some patients there is also

a postural tremor of higher frequency (7–12 Hz), with additional involvement of more proximal joints.

Rigidity

Parkinsonian rigidity consists of an involuntary increment in muscle tone in flexor and extensor muscle groups. This sign is clinically expressed by stiffness of the muscles at palpation and on passive range of motion, and by the spontaneous flexion of the joints in all extremities. It is caused by a continuous muscle activity that makes relaxation impossible. The most typical feature of rigidity is an augmented resistance to passive joint displacement on examination that can be smooth (lead pipe-like) or ratchet (cogwheel-like). Simultaneous movements in other body segments provoke an increment in rigidity (Froment's rigidity sign). It is more evident when the passive movement is slowly executed, a feature that separates it from spasticity, in which the tone increases with a higher velocity of motion. When rigidity is severe, it may even restrict the range of passive displacement of a joint.

Akinesia

Although, strictly speaking, *akinesia* means absence of movements, this term includes both the slowness and clumsiness in the execution of movements and the reduction of spontaneous and induced movements. More specifically, *bradykinesia* refers to the slowness of the movement, which is more evident during complex tasks when several muscle groups are working on a sequence of movements. *Hypokinesia* refers to the poverty of spontaneous movements, a reduction in their amplitude, and their occasional freezing. It is easily recognized in the reduction of the frequency and amplitude of automatic movements such as blinking, arm swing while walking, step length, reaching movements, and writing (micrographia).

The three cardinal features of Parkinson's disease usually appear asymmetrically, affecting first one half of the body and spreading to the contralateral limbs and to the axial muscle in further stages. This pattern is of diagnostic importance, because other parkinsonian syndromes tend to cause rigidity and akinesia of both sides of the body from the inception of the disease.

Postural Instability and Gait Disturbance

These abnormalities begin at a later stage of the disease, usually after other signs have already appeared, and they are responsible to a great extent for the deterioration in the motor condition and quality of life of parkinsonian patients.⁹¹ If posture and gait disturbances start when the cardinal features of Parkinson's disease are already

present, the diagnosis is not difficult. Even when gait is affected early, however, it has characteristics that can help the diagnosis, especially in the early stages.⁹² Initially, patients have a mildly flexed posture that slowly worsens, evolving to flexion of the knees, trunk, elbows, wrists, and metacarpophalangeal joints, with the arms adducted to the trunk. Loss of postural reflexes may occur soon after the diagnosis, but it is not disabling until intermediate or advanced stages, when the patient loses the capacity to make rapid postural adjustments and becomes prone to falling forward or backward. On clinical examination, postural reflexes can be tested by standing behind the patient and pulling them backward on the shoulders ("pull test"). Normally, this maneuver only elicits a contraction of the tibialis anterior muscle that will correct the backward tilt. With milder disease, patients may take one or two steps backward until catching themselves, but in more advanced stages they will be unable to maintain their equilibrium, and the examiner must keep them from falling.

As the disease progresses, stride length becomes progressively shortened. At this point shuffling is a common finding, and turning is typically made up of several small steps. In a more advanced stage gait freezing appears. Initially it occurs when starting to walk (start hesitation), turning (turn hesitation), or passing through narrow spaces and in stressful situations. Eventually, this phenomenon may occur at any time, especially with environmental stimuli such as sounds or visual stimuli that attract the patient's attention, causing them to stop.⁹³ With gait freezing, the patient's feet seem to be stuck to the floor and they become unable to raise their legs. Freezing is caused by the simultaneous contraction of agonist and antagonist muscles in the leg, instead of the alternating sequence necessary for a plantar flexion followed by a dorsal flexion of the foot. The base of support is narrow, and the patient does not accompany the attempt to move the feet with truncal or swing movement. Freezing can be overcome using sensory tricks, mainly visual, for instance, by stepping on a piece of paper on the floor, or with a different motor strategy such as a military march.⁹⁴ Once gait has been initiated, the first two or three steps are even shorter than usual. Sometimes the patient may raise her feet a few millimeters, but instead of taking a normal step, she drags her foot forward a few centimeters, developing a shuffling gait. Once gait has been initiated, it is not infrequent that the forward flexor posture, shifting the center of gravity forward, and the failure of postural reflexes make the patient walk faster in a shuffling way trying to restore her center of gravity (festinating gait) and finally falling forward. Forward falls are more frequent than backward falls in Parkinson's disease, whereas in parkinsonian disorders other than idiopathic Parkinson's disease the patient tends to fall backward.

Differential Diagnosis

A parkinsonian gait can be observed in conditions other than idiopathic Parkinson's disease. However, some subtle differences in posture and gait, and the presence of signs not usually present in Parkinson's disease, may help in the diagnosis. Because the disorder of gait and posture in Parkinson's disease is basically induced by a deficit in striatal dopaminergic modulation, any other process disrupting the same mechanism can cause a similar disorder. There are several illnesses in which the degenerative process involves not only the substantia nigra, as in Parkinson's disease, but other structures as well. These entities include multisystem atrophies (i.e., striatonigral degeneration, pontocerebellar atrophy, Shy-Drager), corticobasal ganglionic degeneration, progressive supranuclear palsy (PSP), Alzheimer's disease, diffuse Lewy body disease, Creutzfeldt-Jakob disease, the rigid variant of Huntington's disease, and some even less common disorders. The differential diagnosis is based on the presence of clinical findings that are atypical for Parkinson's disease, such as cerebellar disturbances, severe autonomic failure, limb apraxia, supranuclear ophthalmoplegia, early cognitive impairment, marked postural instability, or absence of response to levodopa treatment. Beside these atypical findings, the characteristics of the parkinsonian syndrome itself often differ from typical Parkinson's disease. For instance, resting tremor is usually absent, and the syndrome conforms to the more rigid akinetic forms of parkinsonism. Some of these disorders affect at onset both halves of the body, including the axial muscles. The facial expression has been compared to a "perplexed face," with a widened palpebral opening and a wrinkled forehead. Postural and gait disturbances occur earlier in the course than in Parkinson's disease, and consist mainly of a marked postural instability, with frequent falls forward and backward, and a shuffling or freezing gait. The base of support is generally wider than in Parkinson's disease. Other differential diagnostic considerations include subcortical vascular disease and normal pressure hydrocephalus.

Beside these primarily neurologic diseases, there are some systemic disorders than can induce a clinical picture similar to that of Parkinson's disease, including gait abnormalities; this is the case with hypothyroidism, hypoparathyroidism, and other endocrine disorders and depression. Drugs easily induce parkinsonism among the geriatric population, so this possibility should be taken into consideration during the differential diagnosis. The most important medications are neuroleptics, antihypertensives (reserpine, alpha-methyl dopa, some calcium channel blockers), and other antidopaminergic drugs such as metoclopramide used as antiemetics. Parkinsonism may be also secondary to encephalitis and to toxins such as carbon monoxide, manganese, mercury,

methane, cyanide, and MPTP, but these are rarely seen in daily practice.

Treatment

Pharmacologic Therapy

Levodopa, which is transformed into dopamine by the remaining nigral neurons, continues to be the "gold standard" in the treatment of Parkinson's disease. It is administered with a peripheral dopa-decarboxylase inhibitor (benserazide or carbidopa) to prevent its peripheral conversion to dopamine and increase its cerebral bioavailability. Dopamine in the systemic circulation causes a number of side effects, including nausea, vomiting, hypotension, and cardiac arrhythmias. Levodopa treatment, however, is not a panacea. After several years of levodopa treatment, and perhaps due to the natural evolution of the disease, the originally smooth response becomes less than satisfactory. Mobility begins to fluctuate depending on levodopa intake first ("wearing off") and in a random way later ("on-off"), and the patient may experience dyskinesias or involuntary movements during the phase of motor benefit, as well as psychiatric symptoms. The origin of these complications is not completely understood, but the pulsatile administration of levodopa is known to be a risk factor.⁹⁵ Recently, therapeutic strategies have been developed to provide a more steady dopaminergic stimulation. Slow-release levodopa formulations and direct dopamine agonists, including bromocriptine, pergolide, lisuride, ropinirole, and pramipexole, maintain more stable striatal dopaminergic stimulation. Direct agonists are being used in the initial stages of the disease, alone or in association with low doses of levodopa, to prevent or delay the development of these complication.⁹⁶ The most common side effects of these drugs are nausea, orthostatic hypotension, and psychiatric complications.

Early in the disease, levodopa is generally more effective than direct agonists and, with selegiline (see following), tends to be preferred as the first-line drug. However, a clinical trial using a dopamine agonist as monotherapy in the early stages of the disease has shown a lesser incidence of motor complications than with the use of levodopa alone after 5 years of treatment.⁹⁷ Another strategy to maintain steady dopaminergic stimulation involves the use of entacapone, a peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme that accelerates the catabolism of levodopa.⁹⁸ Its use in association with levodopa prolongs the elimination half-life of levodopa, increasing the time of pharmacologic benefit and providing a more physiologic dopaminergic stimulation. At present, it is used mainly in patients with motor complications.

Gait freezing usually responds to levodopa therapy and dopamine agonists. However, sometimes the benefit

is of less magnitude than for the rest of the parkinsonian features. In our experience, the use of amantadine as coadjuvant therapy is useful in these cases. Its mechanism of action is not clear, but it has anticholinergic and antiglutamatergic activity. The main side effects are livedo reticularis and ankle edema, plus the usual anticholinergic side effects. In a few cases freezing can be aggravated by levodopa therapy, and it is then extremely difficult to treat.

Anticholinergic therapy has no clear benefit for parkinsonian gait. These drugs were used mainly to treat sialorrhea and tremor; tremor responds just as well to levodopa therapy. Their adverse effects, more pronounced in an older population (urinary retention, angle-closure glaucoma, constipation, and cognitive and psychiatric deficits), have contributed to making them obsolete.

So far we have considered symptomatic treatments that simply alleviate the motor deficits in Parkinson's disease. However, after the diagnosis of Parkinson's disease is made, the degenerative process of the dopaminergic neurons of the substantia nigra continues and contributes decisively to the patient's worsening. Neuroprotective therapies are being developed, directed at preventing neuronal death and rescuing those neurons in the process of degeneration.⁹⁹ No drug has proved its efficacy in clinical trials, but there are several experimental studies showing the neuroprotective activity of selegiline.¹⁰⁰ Because this drug inhibits monoamine oxidase B (MAO B), an enzyme that favors the catabolism of dopamine, it increases the bioavailability of dopamine in the synaptic cleft and symptomatically improves the parkinsonian syndrome. For this potential neuroprotective activity and its demonstrated symptomatic effect, it is generally used as monotherapy in early stages and in later stages as coadjuvant therapy.

Surgical Therapy

Until recently the only surgical indication in Parkinson's disease was disabling drug-resistant tremor, treated with thalamotomy or thalamic stimulation. Other surgical techniques used in the 1950s had been abandoned after dopamine became available because they caused unacceptable side effects, partly because discrete target localization was difficult with the techniques then available. Stereotactic surgery, supported by sophisticated neuroimaging and electrophysiologic techniques, is now used for the treatment of the disease itself. It is known that, in Parkinson's disease, as a consequence of the dopaminergic deficit some structures of the basal ganglia, mainly the subthalamic nucleus and the pars interna of the globus pallidus (GPi), are hyperactive.¹⁰¹ This hyperactivity induces a decrease of motor cortex activation and explains the typical akinesia of Parkinson's disease. Thus, lesioning or inhibiting the activity of these nuclei affords

a great improvement of many parkinsonian features, including gait and freezing. The first surgical approach of this new era was to lesion the GPi. This procedure, termed pallidotomy, improved the tremor, rigidity, and akinesia in the contralateral limbs and abolished drug-induced dyskinesias, but gait, and particularly freezing, were not uniformly improved.¹⁰² As lesions are not generally undertaken bilaterally, because of the risk of causing cognitive deficits, the therapeutic profile of this technique is limited. Bilateral stimulation of the GPi or subthalamic nucleus is the other neurosurgical approach. This technique allows a bilateral therapy while minimizing the risk of cognitive impairment. When applied to the subthalamic nucleus or GPi, all cardinal features of Parkinson's disease, including slow gait and freezing, are significantly reduced, by 51% for subthalamic nucleus and by 33% for GPi.¹⁰³⁻¹⁰⁵ Specifically, the benefit induced in gait and axial symptoms was 50%. Other surgical strategies, such as the grafting of fetal mesencephalic neurons, have shown little usefulness in controlled trials and can cause untoward side effects, such as marked spontaneous dyskinesias.

Physical Therapy

Treatment of the parkinsonian gait at any stage of the disease should not be exclusively pharmacologic or surgical.^{92,106} There are specific rehabilitation programs with exercises directed to reduce rigidity and to increase the range of joint motion.¹⁰⁷ More importantly, patients are trained to improve posture and minimize the forward displacement of the center of gravity. Tricks to overcome gait freezing and to lengthen step stride can be very helpful in these patients.

Other Parkinsonian Syndromes

Progressive Supranuclear Palsy

Progressive supranuclear palsy (PSP) is a neurodegenerative illness that involves (1) the nigrostriatopallidal system producing rigidity, bradykinesia, and postural instability; (2) the cerebral cortex, mainly the frontal lobes, inducing cognitive and behavioral changes; and (3) the cholinergic nuclei of the pons and mesencephalon, as well as other areas of the brainstem, inducing supranuclear gaze palsies, axial motor abnormalities, sleep disturbances, dysarthria, and dysphagia.^{108,109} Neuropathologically it is characterized by neuronal loss and gliosis of the affected areas. Neurofibrillary tangles, of a type different from the ones found in Alzheimer's disease, appear in some neurons of the affected areas.

The average annual incidence rate (new cases per 100,000 person-years) for ages 50 to 99 years is about 5.3.¹¹⁰ The age of onset (at the end of the sixth and the beginning of the seventh decades of life) and the initial

symptoms are quite similar to those of Parkinson's disease. However, the course is quicker, with survival of around 6 to 9 years. Although this entity shares a number of clinical signs with Parkinson's disease (bradykinesia, rigidity), there are some features that help in the differential diagnosis. Thus, in PSP the most frequent presenting sign (60%) is gait disturbance with instability and frequent falls, in contrast to Parkinson's disease in which this abnormality is prominent only after several years of evolution. Usually the patient does not have the flexed posture of Parkinson's disease and, on the contrary, there is often a dystonic hyperextension of the neck. Although the typical parkinsonian signs may be present to some extent from the beginning, the bilateral presentation with a more prominent involvement of axial musculature is a distinctive feature. Resting tremor is not a common finding, although it may be present in 5% to 10% of cases. Another differential feature is that medication with L-dopa has little effect on the parkinsonian signs of PSP.

Later in the evolution, the diagnosis becomes easier. PSP patients usually have a contracted rather than flaccid face, dysphagia, spastic dysarthria rather than the hypophonia of Parkinson's disease, emotional incontinence, and cognitive decline in frontal and executive functions. Patients with atypical presentation may have a dementia suggestive of Alzheimer's disease. The eye findings are most characteristic. There is a supranuclear paresis of eye movements, with eyelid retraction. Saccades are slow and hypometric, with range limitation in both upward and downward directions. Limitation of upgaze is not uncommon in Parkinson's disease, but in PSP downgaze is often affected earlier and more prominently than upgaze. The restriction of eye movements can be easily overcome by the doll's eye maneuver, indicating damage of the supranuclear mechanisms of eye movement control.

Beside the parkinsonian syndrome, nonspecific changes in personality with irritability, social withdrawal, and emotional lability are frequent in early PSP, and very often they are the presenting features. Thus, an erroneous diagnosis of depression is frequent at this point of evolution and, for the geriatric specialist, it is important to bear this in mind.

The diagnosis is based on the clinical features. There are no specific biologic markers of PSP. In advanced stages, there may be bilateral frontal and midbrain atrophy on MRI. Positron emission tomography (PET) studies demonstrate global cerebral hypometabolism, with more profound involvement of the frontal cortex, and a reduction in the dopaminergic input to the caudate and putamen. The differential diagnosis, beside Parkinson's disease, should include corticobasal ganglionic degeneration (CBGD), multisystem atrophies (MSA), mainly striatonigral degeneration, progressive subcortical gliosis, diffuse Lewy body disease, Creutzfeldt-Jakob disease, Alzheimer's disease, Pick's disease, the rigid

form of Huntington's disease, and primary pallidal atrophies. Patients suffering from multiple small-vessel lesions in the brain may also resemble patients with PSP.

Treatments based in the replacement of neurotransmitters or receptor stimulation have been of little benefit. Dopaminergic stimulation with levodopa or, more reliably, with dopaminergic agonists at high doses, such as bromocriptine at more than 10 mg in three or four divided doses, often improves slightly the parkinsonian signs, often at the price of inducing complications such as agitation, confusion, or hallucinations. Anticholinergic, cholinergic, and noradrenergic drugs and antidepressants have been tested with even less benefit. Among them, amantadine seems to be the second most efficient drug following dopaminergic medication. In some trials, it has been reported that gait improves with amitriptyline (100 mg/day in two doses), considered the third choice of drug. Fluoxetine and other blockers of serotonin reuptake have not proved beneficial. In two individual cases, apraxia of eyelid opening improved slightly with desipramine, but the ratio of benefit to adverse events is poor with this drug. Idazoxan, a presynaptic alpha-2-receptor blocker, was given to improve gait, but the side effects make it impractical. Recently, a trial with a better tolerated analogue, efaroxan, has not shown efficacy in motor signs of PSP patients (Rascol). Local infiltration with botulinum toxin is useful in the treatment of dystonic features (retrocollis and blepharospasm).

Physical therapy seems to be of little benefit against instability. It is important, however, to instruct relatives in the physical care these patients require. Surgical treatment is not currently an option for PSP.

Corticobasal Ganglionic Degeneration

Corticobasal ganglionic degeneration (CBD) is a rare neurodegenerative disease affecting, often asymmetrically, the frontoparietal cortex, predominantly involving the perirolandic area where atrophy is maximal.^{111,112} The temporal cortex is usually preserved. Other affected regions include the substantia nigra, basal ganglia, thalamus, periaqueductal gray matter, colliculi, oculomotor complex, red nucleus, and dentate nucleus. Neuronal loss and gliosis are prominent in these areas, but the typical neuropathologic feature of CBD is the presence of ballooned or achromatic neurons. Neurofibrillary tangles are also frequently identified.

The incidence of CBD is unknown. It begins after the fifth decade of life, without gender differences. Mean survival is 5 to 10 years, although immobility often occurs 3 to 5 years into the illness. The cause of CBD is unknown. Clinically, it debuts with an asymmetric akinetic rigid syndrome without tremor or with a tremor that is more rapid (6–8 Hz) and jerky than in Parkinson's disease (PD). Rather than resting, it tends to be a pos-

tural and action-type tremor. The upper limb is involved first, spreading to the ipsilateral leg in later stages, but it is not rare to begin with gait difficulties because of leg clumsiness, jerking, or stiffness. Less often, the leg and arm are affected simultaneously, or the disease starts with dysarthria or aphasia. Along its course, the contralateral limbs are also affected and the patient develops postural instability, hypomimia, dysarthria, and dysphagia. As with the rest of atypical parkinsonisms, the response to levodopa or dopaminergic agonists is very poor.

Cortical dysfunction gradually emerges between the first and third year of evolution. Apraxia and cortical sensory loss (agraphesthesia, astereognosia, impaired two-point discrimination) are the most typical findings, which sometimes may be recognized in the affected limb (usually the hand) from the beginning. Memory loss, personality and behavioral changes, and mild aphasia are less frequent. A purposeless, maintained elevation of the akinetic hand or arm that has been termed "alien hand/limb" is typically, although not exclusively, observed in patients with CBD; it may also be seen in other diseases, such as PSP and AD. As the disease progresses, the arm goes into a dystonic posture, typically with adduction and flexion of the elbow and wrist. Action and reflex myoclonus in the more affected limb develop in later stages in 50% of cases. Eye movement abnormalities are frequent, predominantly in horizontal saccades, but, in contrast to PSP, without limitation of range.

Initially, diagnosis is based on clinical findings. In more advanced stages, PET depicts decreased metabolism and SPECT may show decreased cerebral perfusion in the affected areas, including cortex, basal ganglia, and thalamus of the hemisphere contralateral to the most affected hemibody. As the disease progresses, atrophy in the same areas may become evident on MRI. Electrophysiologic studies may help in elucidating the characteristics of tremor and the presence of myoclonus. When the disease is fully established, it is not difficult to recognize. However, initially it may be misdiagnosed as Parkinson's disease. The presence of signs of cortical dysfunction (apraxia and sensory impairment in the affected limb), and the absence of benefit with levodopa treatment, are suggestive of CBD. The differential diagnosis must be made with progressive supranuclear palsy, Pick's disease, multisystem atrophy, diffuse Lewy body disease, Parkinson's disease with dementia, and the different forms of asymmetric cortical degeneration syndromes (ACDS).

Pharmacologic treatment is not successful. The rigid akinetic symptoms improve little with dopaminergic medication. Baclofen can be tried to help rigidity and tremor. Action tremor may respond in some degree to propranolol in the early stages of the disease, but the benefit vanishes as the disease progresses. The elective drug in the treatment of myoclonus and tremor is clonazepam (0.15 mg/day). Physiotherapy is useful to avoid

dystonic painful contractures and to preserve maximum functionality throughout the course of the disease.

Multiple System Atrophy

The term *multiple system atrophy* (MSA) refers to a group of progressive neurodegenerative disorders, clinically characterized by the presence of a rigid akinetic syndrome, poorly responsive to levodopa, and cerebellar and autonomic disturbances combined in different proportions.¹¹³⁻¹¹⁵ As parkinsonian features are accompanied by these atypical signs, "atypical parkinsonism" or "parkinson-plus" are terms also commonly used for this group of disorders. From a neuropathologic point of view, neuronal loss and gliosis are observed mainly in the substantia nigra, striatum, locus ceruleus, pontine nuclei, cerebellar Purkinje cells, inferior olives, and intermediolateral cell columns of the spinal cord. Glial cytoplasmic inclusions in both astrocytes and oligodendrocytes are always present in MSA, mainly in several areas of the motor cortex, the supraspinal autonomic system, and their areas of projection. These inclusions are not specific for MSA; they can also be seen in other neurodegenerative diseases, including progressive supranuclear palsy and corticobasal ganglionic degeneration.

The average annual incidence rate of MSA for ages 50 to 99 years is about 3.0.¹⁰ The age of onset is usually the end of the fourth and the beginning of the fifth decades of life, with a mean survival of 5 to 6 years. A slight male predominance (1.3:1) has been reported in some series. Depending on the relative predominance of the symptoms, three different entities are distinguished in MSA: (1) when the clinical picture is one of levodopa-resistant Parkinson's disease, but without relevant autonomic or cerebellar deficits, the disorder is termed *nigrostriatal degeneration (SND)*; (2) prominent cerebellar dysfunction defines the entity as *olivopontocerebellar atrophy (OPCA)*; and (3) when the autonomic system is preferentially affected, it is called the *Shy-Drager syndrome (SDS)*. Some authors have eliminated the SDS from this classification, grouping all cases with autonomic dysfunction in the other two groups, based on the predominant feature. However, there is a relatively high proportion of patients with an overlapping picture in whom there is no clear preponderance of basal ganglionic, cerebellar, or autonomic findings. Pyramidal signs are also found frequently in the clinical examination of these patients. Depression, personality changes, and an attentional or executive deficit are not rare, but a more pervasive cognitive decline is not a typical finding. A peripheral neuropathy has been documented in about 18% of cases.

The rigid akinetic syndrome is the most common disturbance and the presenting form in the majority of cases. Although the age of presentation is younger than the typical age of onset of Parkinson's disease, it may initially

resemble Parkinson's disease. The differential diagnosis is based mainly in the poor response to levodopa therapy, early postural instability, and rapid progression. Besides, and in contrast to Parkinson's disease, the beginning is symmetric (both hemibodies affected), and resting tremor is not a common finding, although it may be present. However, it is important to realize that about one-third of patients suffering from MSA have a moderate improvement in response to levodopa that may be maintained along the course of the disease or may vanish in the following years of progression. Another typical feature of patients with MSA is the early development of levodopa-induced dyskinesias, preferentially in facial and neck musculature, and frequently without relief of the parkinsonian dysfunction.

Early in the disease, the most frequent autonomic disturbances are orthostatic hypotension (defined as a minimum fall of 20 mmHg in the systolic or 10 mmHg in the diastolic blood pressure when the patient stands up from being seated), urinary disorders that simulate outflow obstruction or incontinence in men and incontinence in women, and impotence in men. These symptoms may be the initial complaints in almost 50% of cases. A high proportion of patients (95%) have abnormal electromyography (EMG) of anal and urethral sphincters. During the evolution, 80% to 90% of patients suffer severe autonomic failure. Patients with Parkinson's disease may also have postural hypotension, especially induced by dopaminergic drugs, and urogenital disorders, but usually of a milder intensity. Constipation and decreased sweating are also frequent. The presence of inspiratory stridor, although not as prevalent, is very indicative of MSA.

Ataxia, dysarthria, and kinetic tremor with dysmetria are frequently seen as the expression of the cerebellar involvement. Myoclonus is also a common sign. Abnormalities in ocular movements are typical. Nystagmus, ocular dysmetria, fixation instability, and jerky pursuit are frequently observed, in contrast to the supranuclear ophthalmoplegia that characterizes progressive supranuclear palsy.

The diagnosis is mainly based on the clinical findings and their progression pattern. In SND, T₂-weighted MRI shows hypointense signal in the putamen. Atrophy of the posterior fossa (cerebellum and brainstem) is characteristic of olivopontocerebellar atrophy. Even before structural changes can be seen on MRI, a metabolic reduction in these structures can be detected with PET. This technique, and the less expensive SPECT, can show early in the disease a reduction in putaminal dopaminergic receptors, whereas in Parkinson's disease dopaminergic receptors are upregulated. EMGs are useful to demonstrate a denervation of the anal and urethral sphincters, and the tilt table test may help in the diagnosis of orthostatic hypotension. The differential diagnosis with Parkinson's

disease may pose a problem mainly in the initial stages. The most important differences have been described in the previous paragraphs. Progressive supranuclear palsy, corticobasal ganglionic degeneration, and vascular parkinsonism are the other entities to bear in mind whose distinctive features have already been mentioned.

Although the response is not excellent, levodopa and dopamine agonists are the most useful drugs. Parkinsonian features may respond mildly or more strongly in about one-third of patients. To assess the efficacy of these drugs, a dose of 1500 mg/day should be tried, because more than the usual dose for Parkinson's disease patients is sometimes needed to obtain a benefit. When levodopa is not useful, no response is obtained with dopaminergic agonists either. Amantadine, 100 mg twice daily, and anticholinergic drugs also may be tried. It is important to realize that surgery is not indicated in these patients. Orthostatic hypotension may improve with simple measures, such as avoiding large meals or extreme heat, standing up slowly from a seated or recumbent position, increasing salt intake, or wearing pressure stockings. When these preventive strategies are not enough, treatment with fludrocortisone (0.4 mg/day in two doses) or indomethacin (25 mg three times/day) should be tried. Other drugs that may help are ephedrine, midodrine, phenylpropanolamine, caffeine, and ergots. Anticholinergic drugs such as oxybutynin (5–10 mg/day) and more recently tolterodine (2 mg twice a day) may improve urinary incontinence. Desmopressin nasal spray at night may also be helpful. When tremor and myoclonus are prominent, clonazepam or valproate are used, but with scarce benefit.

Late-Life Hydrocephalus

Although not a frequent cause of gait disorders in older people, symptomatic hydrocephalus presents initially with a gait disorder and it should be recognized because it is potentially treatable.¹¹⁶ Particularly after CT became available, several authors found enlarged ventricles to be frequently present in patients with gait disorders.¹¹⁷ From this finding they concluded that symptomatic hydrocephalus was common and shunting procedures multiplied. However, even in series with carefully selected patients, some failed to improve after shunting, suggesting that hydrocephalus was not the cause of their gait disorder.¹¹⁸ For this reason, it is important to apply more sensitive diagnostic criteria in the workup of these patients.¹¹⁹ The classical syndrome consists of slowly progressive gait impairment, with instability. Urinary incontinence may be present, but is not necessary for the diagnosis. Only very late in the course of the disorder may the patient have cognitive slowness or impaired attention. Onset of cognitive impairment before gait dis-

turbance suggests a different process. The diagnosis is made with CT or MRI, which show enlarged ventricles. The cortical sulci may be compressed or enlarged outside the high parietal convexity.^{120,121} In dubious cases, a pattern of decreased perfusion or metabolism in the association cortex of the parietal lobes on SPECT or PET predicts a poor outcome.¹¹⁹ This pattern is usually seen in Alzheimer's disease and Parkinson's with dementia. CSF manometrics are not predictive of which patients will improve after shunting.¹²²

Rare Etiologies: Neoplasms, Subdural Hematoma

Seldom, an older person with a worsening gait disorder may harbor a frontal tumor or a subdural hematoma. Meningiomas carry a better prognosis but are not as common as glioblastomas or metastases in the older age group. By the time the patient becomes symptomatic, these lesions can be easily identified by MRI scanning. CT is less sensitive than MRI, particularly for glioblastoma. Also, poor definition of cortical boundaries may make it difficult to differentiate a glioma from a meningioma on CT on a noncontrast study. On a contrast study, the more homogeneous pattern of a meningioma and the presence of a dural tail help differentiate this lesion from glioblastomas. However, some meningiomas may have cystic areas that enhance poorly. Calcification in a meningioma and changes in the cortical bone are better appreciated on CT, but these characteristics are seldom critical for the diagnosis. Also, in the case of glioblastomas, the extent of the tumor is better visualized by MRI than by CT. Neither technique, however shows accurately the extent of brain infiltrated by malignant glial cells. MRI is also more sensitive than CT for the detection of metastatic brain disease. In patients prone to falls, a subacute deterioration should raise the suspicion of a subdural hematoma, particularly when a worsening in gait is accompanied by changes in mental status. Although MRI depicts these lesions with more accuracy than CT, symptomatic subdural hematomas are well seen with CT and can be adequately managed neurosurgically without the need of MRI.

Psychogenic Postural and Gait Disorders

Psychogenic gait disorders caused are rare and generally do not present a diagnostic dilemma. It is important, however, not to mislabel an organic gait disorder as a psychogenic one, and therefore some of the characteristics of these disorders are reviewed briefly here. On the other

hand, psychogenic factors often play a role in aggravating the functional consequences of an organic gait disorder, and sometimes they are amenable to specific treatment.¹²³

During panic attacks, patients may feel that their legs are weak and they become unsteady. To protect themselves from a perceived risk of falling, they may adopt a gait pattern described as "walking on ice."¹²⁴ They crouch forward, abduct their arms, and shorten their stride. Sometimes these patients cling to walls or furniture and may not venture away from the house.¹²³ A similar gait pattern, described as cautious gait, is very common in patients with organic gait disorders. A major difference is that the cautious gait in patients with anxiety tends to occur episodically, in the context of a panic attack, whereas organic gait disorders are generally more persistent. Other features that differentiate psychogenic from organic gait disorder include dramatic moment-to-moment fluctuations in performance, excessive hesitation, resembling slow motion or walking through a viscous fluid, and buckling of the knees without falling.¹²⁴ A psychogenic Romberg test is characterized by buildup of sway, with a consistent tendency to fall toward the observer. It can often be overcome by distraction, for instance, by examining the pupils while the patient quietly stands.¹²³

Of the 60 patients with "hysterical gait disorders" described by Keane,¹²⁵ some manifested a hemiparesis or paraparesis, but the largest group had an assortment of ataxic gaits, characterized by dramatically exaggerated sway but avoiding falls. Some patients exhibited "tightrope balancing," walking on a narrow base while keeping their arms abducted. Others were described as "tremblers," not to be confused with patients with orthostatic tremor, an organic disorder.² Overall, a neurologic examination can easily pinpoint the nature of the problem in about three-quarters of patients with psychogenic gait disorders.¹²⁴

Excessive Movement Disorders in the Elderly

Excessive movements in the elderly may be rhythmic, in which case they are called *tremor*, or not, in which case they are called *myoclonus* if they are very fast (lightning-like) or hyperkinesias in all other cases. Hyperkinetic movements may have the speed of normal volitional, reaching movements, and then they are called *chorea*, if they are predominantly distal, and ballismus, or *hemiballismus* (it is usually unilateral), when they are predominantly proximal. When the hyperkinesias are very slow and tend to present mainly as abnormal postures, they are called *dystonia* when predominantly proximal and *athetosis* when they involve the hand. However, par-

ticularly in adults, the term dystonia is often used to encompass both true dystonia as well as athetosis.

Tremor

Tremor is an involuntary oscillation of a body part produced by alternating or synchronous contractions of reciprocally innervated antagonistic muscles.¹²⁶ The clinical presentation of this abnormal movement serves as the basis for its classification and reflects the underlying pathology. *Resting tremor* occurs when the affected body part is resting, inactive, and fully supported against gravity. *Postural tremor* is seen with maintenance of a fixed antigravity posture (i.e., the hand holding a teacup). *Action or kinetic tremor* is a rhythmic discontinuity of a movement present in a limb during goal-directed movements.

Tremor in the elderly is mainly associated with three entities: Parkinson's disease, essential tremor, and metabolic or toxic disorders. From a pathologic point of view, resting tremor is the consequence of damage in the substantia nigra pars compacta (SNpc). Thus, it is typically observed in Parkinson's disease, discussed already. Other neurodegenerative disorders resembling Parkinson's disease (parkinsonism plus) and included in its differential diagnosis may, rarely, present as resting tremor, described earlier. Although vascular lesions, tumors, or infections may involve SNpc and induce resting tremor, they are very uncommon in clinical practice.

Postural tremor in the elderly is a very prevalent disorder with many possible etiologies. It may be associated to metabolic or toxic disorders or may appear without concomitant illness or focal neurologic lesion. In this case, it is termed essential tremor (ET). In *essential tremor*, the most common finding is postural tremor of a limb, usually absent at rest and less evident during movement. Sometimes, it may be accentuated when a goal-directed action is performed provoking an action tremor. It may occur in a wide range of frequencies (4–12 Hz). The hands are the body part most frequently involved, with rhythmic movements consisting of flexion-extension of the wrist and adduction-abduction of the fingers.¹²⁷ Frequently, tremor is unilateral at the beginning, spreading later to the contralateral side. Handwriting is tremulous and letters become sharp and angulated, being very different from the typical micrographic letter of Parkinson's disease. The second body segment most frequently involved is the cranial musculature (head, tongue, voice). Although it may appear in isolation, it is more common for tremor in this location to begin in later stages and to be associated with hand tremor.¹²⁷

Involvement of the legs and trunk are rare and late occurrences. During the evolution of the disease, the tremor increases in amplitude and decreases in fre-

quency. The increment in amplitude interferes with the execution of fine movements, inducing more incapacity.¹²⁸ Essential tremor may be a familial illness with a younger age of presentation or may occur sporadically, in which case the peak age of onset is later. In both instances it is more frequent with advancing age. Prevalence figures for individuals older than 40 years of age range between 0.4% and 5.6%, affecting at least 5% of people age 65 and older, without gender differences. The etiology of the sporadic cases is unknown. Familiar cases are dominantly inherited, and markers for two genes have been recently identified.¹²⁹ One important clinical characteristic is that this type of tremor is ameliorated by alcohol consumption.

Drug treatment of essential tremor may be very effective but not necessarily simple. At present there is no agreement about the drug of choice.¹²⁸ Propranolol has been classically considered the first-line drug at daily doses between 80 and 200 mg. It decreases tremor amplitude, but the response is often incomplete. Other β -blockers (metoprolol, nadolol, atenolol, timolol, pindolol) are less effective than propranolol. In elderly people, frequently one can observe concomitant disorders such as atrioventricular block, asthma, or diabetes that are relative contraindications for the use of β -blockers, especially those blocking the β_2 -subtype. Patients with bronchospasm may benefit from metoprolol (100–200 mg/day), a selective β_1 -antagonist. Primidone (50–250 mg/day in a single dose at bedtime) has been demonstrated to be as effective as propranolol and can be used as the drug of choice, particularly in the case of patients suffering from the aforementioned disorders. However, the sedative effect sometimes constitutes a limiting factor that prevents the achievement of the dose needed for tremor control. Other useful drugs in some cases are phenobarbital (120 mg/day) and the benzodiazepines, such as diazepam or clonazepam (1–3 mg/day).

Recently, it has been suggested that when propranolol and primidone are not efficient, alprazolam could be tried.¹²⁸ If treatment with monotherapy does not control tremor, combinations of more than one drug may be considered. Other drugs, such as gabapentin, carbonic anhydrase inhibitors (methazolamide), amantadine, clonidine, clozapine, flunarizine, and nimodipine, have not been proven effective in controlling essential tremor, although they have been reported to be helpful in isolated cases. Patients unsuccessfully controlled with pharmacologic treatments may improve with surgery. Surgery is aimed at blocking the activity of the ventralis intermedium nucleus (Vim) of the thalamus, either by performing a lesion (thalamotomy) or by placing an electrode for high-frequency stimulation that resembles the effect of thalamic ablative surgery. Long-term follow-up studies show that this treatment remains effective for years.¹³⁰ However, surgery in elderly patients is not

without limitations. The benefit to risk ratio must be weighed carefully, in consultation with centers that specialize in this procedure.

Metabolic or toxic disorders that may be associated with postural tremor must always be taken into consideration.¹³¹ The most frequent are hyperthyroidism, pheochromocytoma, hypoglycemia, uremia, liver failure, alcohol withdrawal, hypothermia, toxicity due to lithium, and tricyclic antidepressants, valproic acid, neuroleptics, steroids, amiodarone, isoproterenol, theophylline, or cyclosporine A.

Postural tremor also may occur in the context of familial and acquired peripheral neuropathies. It has been suggested that tremor in these circumstances represents enhanced physiologic tremor.

From a mechanistic point of view, action tremor originates as the consequence of pathology in the dentatorubrothalamic projection. Vascular lesions or degenerative disease involving the cerebellum are the most frequent causes of action tremor, which is less frequent than resting or postural tremor in the elderly. Available drugs do not ameliorate this type of tremor, and the only effective treatment is the surgical treatment as described for postural tremor.

Chorea

This movement disorder consists of arrhythmic, rapid, often jerky, purposeless movements that may be simple or complex but rarely interfere with voluntary motion. They may affect axial musculature (orofacial, neck, truncal) and the limbs. When the involuntary movement of a limb is proximal, of wider amplitude, and brisker it is termed ballismus. Chorea may be the clinical expression of a degenerative neurologic disease, may appear in the context of a systemic or metabolic illness, be secondary to drugs, or may be induced by a vascular lesion.

Primary Neurologic Diseases

Senile chorea is the most frequent cause of choreic movements in the elderly. Contrary to Huntington's disease, it is an insidiously developing and generalized chorea, primarily involving the limbs, with mental preservation and without a family history. It usually affects people older than 60 years of age. Neuropathology shows caudate and putamen atrophy to a lesser degree than in Huntington's disease, but the genetic study is normal in these individuals.¹³²

Huntington's disease is an autosomal dominant inherited disease that tends to become clinically obvious at an earlier age. Only 50% of cases of Huntington's disease develop after age 65 years. In these cases, a milder progression of the disease may be expected. The clinical

picture is characterized by the presence of chorea, behavioral and mental decline, and a positive family history.

Among metabolic and systemic illnesses, it is important to note that a number of metabolic disorders may provoke choreic movements.¹³³ Among them the most relevant are hypocalcemia, hypoglycemia, hyperglycemia, hyponatremia, hypernatremia, hypomagnesemia, hyperthyroidism, hyperparathyroidism, hypoparathyroidism, hepatic encephalopathy, polycythemia vera, and neoplastic metabolic and autoimmune disorders. These entities are relatively frequent in older people and should be recognized and treated. Thus, blood tests carried out to exclude these abnormalities are mandatory when facing chorea in the elderly. Other systemic illnesses such as systemic lupus erythematosus or primary antiphospholipid antibody syndrome may be on occasion associated with chorea, but they are very rare in older people. Chorea may be induced by the chronic consumption of drugs such as neuroleptics (haloperidol, chlorpromazine, thioridazine, etc.), antiparkinsonian drugs, anticonvulsants (phenytoin, carbamazepine), stimulants, steroids, opiates, calcium channel blockers, digoxin, or lithium, to name the most frequent.¹³³ Although any body segment may be affected, tardive dyskinesias due to chronic treatment with neuroleptics affect mainly the mouth, producing lip-smacking, tongue protrusion, or grimacing.

Cerebrovascular disease (infarction or hemorrhage) involving different parts of the basal ganglia may induce chorea or ballismus, usually affecting the contralateral hemibody (hemiballismus). It has classically been thought that hemiballismus or hemichorea was the consequence of a lesion in the subthalamic nucleus. Nowadays it is known that lesions located in other structures of the basal ganglia (i.e., caudate, putamen, globus pallidum) or in the thalamus may result in hemichorea and that a lesion in the subthalamic nucleus sometimes is not associated with chorea or ballismus.

Mild chorea should not be treated, as the consequences of therapy may be worse than the problem. When necessary, chorea in the older person is treated with very small amounts of antidopaminergic drugs, mainly D₂ antagonists. Haloperidol at 0.5 to 20 mg/day and pimozide at 1 to 10 mg/day at bedtime are the most specific. Keep in mind the risk of inducing parkinsonism and depression.

Dystonia

Dystonia is characterized by involuntary sustained muscle contraction that produces twisting movements and abnormal postures in axial muscles and limbs. Sometimes jerky movements resembling tremor in the affected body segment may be superimposed. Dystonia is classified according to the distribution of body regions affected as *focal*, *segmental*, *multifocal*, and *generalized*.

When a hemibody is affected, it is termed *hemidystonia*. If the cause of the dystonia is known, it is classified as *secondary* or symptomatic. If it is not known, the dystonia is *primary* or idiopathic. Generalized dystonia is rare among the geriatric population. In this age group, most frequent are focal and idiopathic forms.¹³⁴ At the beginning, they appear frequently during movement (action dystonia) and disappear at rest. As the process evolves, dystonic contractions may affect muscles not normally activated in a task, causing what is called the “overflow” phenomenon and inducing the patient to adopt bizarre postures. Their onset is usually in the fourth or fifth decades and affect women more often than men. Generally, the initial symptoms are insidious and intermittent, extending in 20% to 30% of cases to neighboring areas. Cranial and cervical structures are most frequently affected (78% of patients with dystonia).

Cranial Dystonia

Blepharospasm is an involuntary, intermittent, or sustained bilateral eye closure produced by spasmodic contractions of the orbicularis oculi muscles, often exacerbated by bright light.¹³⁵ A mild contraction of the frontalis is frequently seen when the patients try to open their eyes. Milder forms have only a cosmetic consequence, but in more severe cases blepharospasm interferes with vision and the patients become unable to drive, to read, and, in summary, to lead a normal life. It affects women more often than men, and onset peaks around the sixth decade of life. In *oromandibular dystonia*, spasms occur in the region of the jaw, lower face, and mouth. Typically the dystonia takes the form of jaw closure, opening, protrusion or lateral deviation, lip tightening or pursing, or lingual dystonia. It is frequently triggered by actions that involve the muscles affected, such as biting, chewing, or speaking. Frequently seen in edentulous people with poorly fitting dentures, it may improve when the dentures are fixed.

Craniocervical Dystonia or Meige’s Syndrome

This syndrome is the association of blepharospasm and oromandibular dystonia. The most typical, complete clinical picture consists of involuntary eye closure, forced opening of the jaw, and tongue protrusion.¹³⁶ However, any sort of oromandibular dystonia as described in the previous paragraph may be observed accompanying blepharospasm. Sometimes cervical dystonia (torticollis, anterocollis, etc.) and even pharyngeal dystonia may be associated. Trunk and limbs are usually preserved. It is almost exclusively an illness of elderly people, with a higher incidence in the sixth and seventh decade, and is more frequent in women. The differential diagnosis is with tardive dyskinesia and the spontaneous buccolingual

dyskinesias of the elderly, more frequent in edentulous people. A previous history of neuroleptic consumption and a different phenomenology helps to separate these entities.

Other Focal Dystonias

Cervical dystonia (torticollis, anterocollis, or retrocollis) and limb dystonia (mostly task specific such as writer’s cramp) have their onset at younger ages. Leg dystonia is frequently the first sign in children displaying primary dystonia, but is rarely seen in adult patients. When it occurs as an isolated sign in the elderly, a diagnosis of Parkinson’s disease must be considered.

Treatment of focal dystonia has shifted in the past few years from the pharmacologic field toward the use of the botulinum toxin, and training guidelines for its use have been established.¹³⁷ Botulinum toxin injection in muscles that are tonically contracted induce partial weakness and therefore avoid the sustained abnormal posture that characterizes dystonia. It is especially effective in the treatment of blepharospasm and laterocollis. Oromandibular dystonia is among the most challenging forms of focal dystonia to treat with botulinum toxin. However, in this type of dystonia the pharmacologic treatment is also ineffective.

Pharmacologic therapy includes a number of drugs with variable efficacy.¹³⁸ In younger patients, anticholinergic therapy at high doses may be helpful. Although not demonstrably superior, trihexyphenidyl (up to 12 mg/day) is most broadly employed. In older people, the central adverse events associated with this drug, including confusion, hallucinations, drowsiness, and memory loss, are a limiting factor. Benzodiazepines (diazepam, lorazepam, clonazepam) are used as a second-option treatment. Clonazepam is more active in blepharospasm than in other types of dystonia. GABA agonists such as baclofen may be helpful for oromandibular dystonia. Monoamine depleters (tetrabenazine in Europe), lithium, anticonvulsants (carbamazepine, primidone), and a number of other drugs have been used in different combinations with irregular benefit. Dopaminergic antagonists, extensively used in the past, help little in the long run and have a higher risk of inducing parkinsonism, sedation, and tardive dyskinesias in the geriatric population. Surgical treatment has been revitalized in the past few years for the treatment of dystonia. Thalamotomy, pallidotomy, and deep brain stimulation of the thalamus or globus pallidus have been reported to be effective in the treatment of generalized dystonia.¹³⁹ However, results are better in cases of hemidystonia or in generalized dystonia. Peripheral denervation surgery was used in the past to treat cervical dystonia. This technique has been essentially abandoned because of the superiority of botulinum toxin in controlling the involuntary muscle contraction.

Myoclonus

Myoclonus is a shocklike involuntary muscle contraction originating in the central nervous system by abnormal neuronal discharges.¹⁴⁰ A physiologic classification of myoclonus can be made by taking into account the location in the neuroaxis of the neurons discharging abnormally and causing the muscle contraction. Thus, myoclonus can be *cortical, reticular, spinal, or proprio-spinal* in origin. From a practical point of view, this movement disorder may be classified on the basis of its clinical presentation as *spontaneous, reflex* when it occurs in response to auditory, visual, or somatosensory stimuli, and *action* when it is driven by a voluntary movement. Depending on the body segment affected by the myoclonic jerks, they may be *focal, segmental, multifocal, or generalized*. They may be *physiologic*, such as the typical nocturnal myoclonus; *essential*, usually familial and associated with dystonia; and *secondary* to a high number of metabolic disorders, toxic substances, anoxia, or in the context of a more diffuse neurologic or neurodegenerative disease, in which case they are typically associated with other neurologic abnormalities such as epilepsy, ataxia, or dementia.¹⁴¹

In the elderly, the most common form of presentation is spontaneous multifocal or generalized myoclonus, aggravated by action and sometimes aggravated also by sensory stimuli. Severe action myoclonus is very incapacitating. Frequently, the origin is cortical and is secondary to metabolic or toxic encephalopathies, and is a minor proportion to neurodegenerative diseases. Any metabolic abnormality may induce myoclonus, but the most frequent causes are renal failure, hyponatremia, hypokalemia, and liver failure, which may show myoclonus as an initial sign. Vitamin E deficiency secondary to malabsorption may course with action myoclonus and ataxia as prominent signs. In addition to bismuth intoxication, the list of drugs causing myoclonus is long, and in the geriatric population the possibility of drug abuse or an overdose should always be considered. Beside multifocal or generalized myoclonus, reticular reflex myoclonus may be also observed in metabolic and toxic disorders. Treatment always consists of the correction of the metabolic defect or suppression of the toxic agent.

The association of myoclonus and dementia in elderly patients deserves special attention. It is observed in Alzheimer's disease¹⁴² and also in other neurodegenerative diseases such as corticobasal ganglionic degeneration, typically associated to limb apraxia and a parkinsonian syndrome. Huntington's disease, prion-related encephalopathies such as Creutzfeldt-Jakob disease, herpes simplex infections, and subacute sclerosing panencephalitis are less prevalent but may cause myoclonus. Other neurodegenerative diseases (different

variants of spinocerebellar degeneration, and olivopontocerebellar atrophy) may feature myoclonus and ataxia, particularly among the geriatric population.

To treat myoclonus, first consider the correction of a metabolic disorder, or the suppression of an offending drug. When that is not an option, a number of medications may help. Clonazepam (2–15 mg/day), piracetam (8–20 mg/day; not available in the United States), sodium valproate (1200–3000 mg/day), and primidone (500–1000 mg/day) are the most useful drugs, particularly in cortical myoclonus.¹⁴³ Clonazepam is the most effective, but piracetam is better tolerated. Different combinations of these drugs are frequently needed to control severe myoclonus. Fluoxetine (10–20 mg/day) may be used in combination, especially to treat reticular reflex myoclonus.

Depression, Anxiety, and Other Mood Disorders

Harold G. Koenig and Dan G. Blazer, II

Depression

Mood disorders are the most common reversible psychiatric conditions in later life, and the vast majority are usually treated by primary care physicians and geriatricians. Depression, the prototype mood disorder, is a painful emotional experience that involves intense suffering which can drain life of meaning, excitement, and pleasure. Early epidemiologic research appeared to show that depression was unusually common among older persons.^{1,2} In his description of the psychosocial stages of human development, Erik Erikson identified the struggle between integrity and despair as the primary developmental task in late life.

Although aging is often accompanied by loss and unwanted change, most elders do not suffer from depression. In fact, recent studies indicate that serious depressive disorders are actually less common among older than among younger persons in American society.³⁻⁵ This is surprising, given the many reasons why the elderly should be depressed, such as declining health, loss of function, death of family and loved ones, shrinking financial resources, and biologic changes in the brain that predispose them to emotional disorder. Despite this, however, the current cohort of persons over age 65 experience only about one-quarter the rate of major depression and one-sixteenth the rate of bipolar disorder as do persons under age 45.⁶

Epidemiology of Depression

Major depressive disorder, a clinically significant and persistent depression associated with other symptoms, such as weight loss and insomnia, is less frequently diagnosed in old age than at other stages of the life cycle. The NIMH Epidemiologic Catchment Area (ECA) study surveyed more than 5700 elderly persons at five sites across the United States; major depression was diagnosed in less than 1% (0.4% in men, 1.4% in women).⁶ A number of epidemiologic studies among community-dwelling and

institutionalized adults have confirmed these findings.⁷⁻¹² On the other hand, when depressive *symptoms* are examined (dysphoric feelings that fluctuate from day to day and may or may not interfere with functioning), their prevalence in older adults is relatively high. The proportion of elders scoring above symptom scale cutoffs in studies conducted between 1980 and 1990 has been consistently between 10% and 15%.⁴ Persons over 80 years of age have higher rates of depressive symptoms than other age groups, although this is almost completely accounted for by the increased number of chronic illnesses and functional disability.¹³ Aging per se, then, does not appear to be associated with depression.

There has been some controversy over the low rates of major depressive disorder diagnosed in older adults by the ECA surveys. These rates have either been rejected and attributed to methodologic problems, or accepted and ascribed to cohort or period effects. Those who argue that rates are falsely low claim that depression is just as common in older as younger persons, but that elders are (1) less likely to report depressive symptoms (because of the stigma of psychiatric illness), (2) less likely to recall symptoms (due to cognitive impairment), (3) less likely to have symptoms that fit nicely into diagnostic categories, and (4) more likely to express emotional symptoms as somatic complaints. In a study of more than 1300 community-dwelling adults age 60 or over, Blazer et al. reported that 27% of participants experienced significant depressive symptomatology, whereas less than 1% fulfilled criteria for a major depression.⁵ Blazer concluded that current diagnostic methods for depression are not well suited for assessing older adults.

Even if the foregoing arguments are true, however, they do not fully account for the low rates observed.¹⁴ More likely, age differences in rates are real and can be explained by cohort or period effects. The cohort effect maintains that persons age 65 or over born before 1920 are simply more psychologically healthy (for whatever reason) than either later or earlier cohorts; their low rate

of major depression in later life, then, may simply reflect the fact that this cohort never experienced much depression.¹⁵ Alternatively, a period effect argues that most persons now age 65 or older endured hard times during the Great Depression and Second World War; since the war, however, these Americans have experienced a higher quality of life and greater well-being (especially in economic terms) than ever before. On the other hand, the 76 million members of the baby boom generation (born between 1946 and 1968) have been accustomed to high standards of living; as that cohort ages, increased competition over resources, declining economic prosperity, and lower standards of living may have led to increasing rates of depression, alcohol, and drug abuse (as now observed).¹⁶ Finally, lower rates of depression among the elderly may represent an age effect; in other words, older persons may possess a greater capacity to adapt to social stressors as a result of cumulative life experiences.

Although rates of depression among community-dwelling older adults are low, this is not true for those hospitalized with medical illness or living in nursing homes. The rate of major depression in acutely hospitalized elders is about 13% to 20%; moreover, an additional 30% of these patients experience minor depressive disorders.^{10,17} Likewise, rates of depression and other mood disorders are high among patients in nursing homes, where rates of major depression commonly exceed 15% and minor depression

ranges from 30% to 35%.¹⁸⁻²¹ The prevalence of bipolar disorder, while only about 0.1% in the community, may be as high as 10% in nursing homes.²⁰ Unfortunately, between 80% and 90% of depressed elders in acute medical settings go undiagnosed, despite the fact that brief self-rated scales exist that readily detect depression within less than 2 min. For example, the Koenig depression scale consists of 11 yes-no items that cover most of the major symptoms of depression and has been validated against depression diagnoses in medical patients (see Appendix).²² The decision on whether to screen, however, is a complex one that involves many considerations.²³

Depressive illness complicates the medical management of older patients. An increase in all-cause mortality has been reported in community-dwelling, acutely hospitalized, and chronically institutionalized older adults with depression.^{21,24} Mortality has been attributed to decreased social support, poor nutrition from loss of appetite, possible adverse effects of depression on the immune system, increased carelessness, and loss of motivation for self-care. Increased cardiovascular mortality, in particular, has been associated with depression.^{25,26}

Etiology

As already indicated, the causes for depression in later life are multiple. Figure 79.1 displays the genetic, biologic,

FIGURE 79.1. Etiologic model of depression in later life.

and psychosocial factors that play a role. Genetic factors and brain changes resulting from aging and disease predispose the older adult to depression; stressful life events and health problems can then precipitate a mood disorder if the elder's cognitive appraisal of events is negative and their coping resources inadequate.

Genetic and Biologic Factors

Family studies and molecular genetics suggest that both major depression and bipolar disorders are at least partly inheritable, although the contribution by genetic factors in late-life depression is less than for the early-onset variety. The risk of depression for immediate relatives of index cases with onset after the age of 50 years is only one-half to one-third that of relatives of patients with early-onset disorder (age, <50).²⁷ The activity and metabolism of neurotransmitters with aging may also affect late-life depression.²⁸

Recent interest among clinical investigators has been directed to depression in older adults that is associated with subcortical hyperintensities on magnetic resonance imaging, a syndrome referred to as vascular depression. This depressive syndrome is more common in men, is associated with hypertension, and may have phenomenologic characteristics different from late-life depression not associated with vascular changes.²⁹ Vascular depression may not be as responsive to long-term intervention as nonvascular depression.

Demographic and Psychosocial Factors

Mood disorders are nearly twice as common among women than men,⁶ although this pattern may reverse in later life.³⁰ Depression is more common in elders with lower incomes and less education,^{5,31,32} those who live in rural settings,³² and those who are divorced or separated.^{5,31} Persons with a prior history of psychiatric illness are especially vulnerable when facing the major adjustments required in later life, particularly with health problems.¹⁰ Although many depressions in the elderly are "late onset" (first episode after age 60), a significant minority represent recurrences of mood disorder first diagnosed in young adulthood or middle age.³³

High social support has been reported to buffer against depression in later life;^{5,30} only certain types of support, however, afford such protection. Goldberg and colleagues found that size of the support network was of less importance than its homogeneity (similar age, similar interests), number of confidants, having a husband as a confidant, and level of intimacy.³¹ Such support, particularly if perceived by the elder as helpful (high subjective support), may both prevent and facilitate recovery from depression; on the other hand, being married or having a large social network may prolong depression if they exert

a "smothering" effect.³⁴ A brief social support scale designed specifically for use in chronically ill older adults has now been developed.³⁵ This scale is included in the Appendix.

Negative life events also commonly precipitate depression in later life.⁵ Loss of a spouse is especially difficult for the older person whose marriage has been lifelong and satisfying. Approximately 15% of bereaved adults develop a depressive disorder that requires some form of outside intervention.³⁶

Religion, particularly when used regularly to cope with stressful life events, has been associated with greater well-being,³⁷ lower rates of depression,³⁸ and faster recovery from depression.^{39,40} Many older persons attend church, pray, and read the Bible or other religious scriptures; these behaviors and cognitions are frequently used to cope with the losses associated with aging.^{41,42} Studies in both community-dwelling and hospitalized elders have now demonstrated an inverse relationship between religiosity and depressive symptoms.^{37,42-46} Active involvement in the religious community and strong religious beliefs appear to reinforce each other and together enhance well-being.⁴⁷

Physical Illness

Physical health has a major impact on the emotional states of older adults. Medical illness often leads to disability, chronic pain, and changes in the brain that both cause distress and limit cognitive flexibility and coping options. Most epidemiologic studies find physical health to be the strongest predictor of well-being and emotional health, regardless of age, sex, or race.^{10,31,32} Depressive disorders in physically ill older adults are usually psychologic reactions to progressive disability, chronic pain, side effects from drugs, financial insecurity, or feelings of guilt over being a burden. Less often, depressive disorder results from vascular changes in the brain (vascular depression).⁴⁸

Cognitive Appraisal and Coping

Lazarus⁴⁹ emphasized that it is not the particular stress itself (e.g., physical illness, loss of a spouse) that is important in determining the impact of the stressor. Rather, it is the individual's *cognitive appraisal* of the meaning of the event or situation. What is stressful for one older person may not be stressful for another. The cognitive appraisal of the stressor, as well as the perception of adaptive tasks and the selection of coping behaviors, depend heavily on the person's background, health factors, other concurrent stressors, and underlying attitudes toward self, others, current circumstances, and future.

If one feels that one must always be productive to have self-worth, and if illness impairs ability to function and

forces dependency, then illness will impose much greater stress than if the person placed less value on productivity and independence. Studies have shown that medical illness can interact with dysfunctional attitudes to precipitate and maintain depression.⁵⁰⁻⁵² For example, cognitive distortions have been associated with several aspects of disability in patients with chronic low back pain or headache; cognitive variables (in particular, unjustified generalization based on a single incident) account for more disability than would be predicted by severity of pain or number of pain treatments.^{53,54} Dysfunctional attitudes, then, may underlie depression in older adults who employ maladaptive rules for interpreting the personal significance of illness-related events.

Clinical and Diagnostic Considerations

The type, number, severity, time course, and combination of symptoms determines whether a depressive disorder is present. Most older persons experience episodes of depressed mood, loss of interest, fatigue, or discouragement that last from hours to days or weeks; yet, these episodes are not severe enough to warrant a diagnosis of major depression or even one of the other affective disorders. These episodes require no more treatment than an encouraging and supportive word from a friend or a good night's rest. Other persons, however, may find themselves locked into a depressive syndrome that will require outside intervention. In a longitudinal study of normal aging, Gianturco and Busse⁵⁵ found that 70% of community-dwelling older men experienced some degree of depression at some time during their 17-year study. Differentiating clinically significant depressive disorders from minor mood fluctuations, or from other psychiatric or medical conditions that mimic depression, is not easy.

Major Depressive Disorder

Major depression is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) as a depressed mood or a marked loss of interest that is experienced most of the day nearly every day during a 2-week period or longer. In addition, at least four of the following eight symptoms must be present: (1) weight loss (>5% of body weight in a month) or loss of appetite, (2) insomnia or hypersomnia, (3) psychomotor agitation or retardation, (4) fatigue or loss of energy, (5) feelings of worthlessness or guilt, (6) diminished concentration, (7) thoughts of suicide, or (8) loss of interest (including decreased sexual interest). According to DSM-IV, these symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

The symptoms of major depression can be divided into two groups: vegetative (or somatic) and cognitive

(or psychologic). Vegetative symptoms include insomnia, anorexia or weight loss, fatigue, concentration difficulties, and psychomotor agitation or retardation. Cognitive symptoms include depressed mood, irritability, hopelessness, guilt, feeling worthless or as a burden, loss of interest, social withdrawal, and suicidal thoughts. Cognitive symptoms can help identify depression in medically ill older patients whose somatic symptoms confuse the diagnostic picture. Somatic symptoms, however, cannot be ignored and may be important for recognizing severe forms of depression. One study found that loss of interest, insomnia, suicidal thoughts, and hypochondriasis best differentiated depressed from nondepressed medically ill older patients; fatigue, weight loss, genital symptoms, and somatic anxiety, on the other hand, were only weakly or not related to depression.⁵⁶

Melancholic and Psychotic Depressions

Melancholic depression is a form of major depression that is associated with weight loss, insomnia, psychomotor retardation, profound loss of interest or pleasure (anhedonia), and a mood that does not fluctuate with external circumstances. Psychotic depression is a major depression that is associated with delusional thinking (bizarre ideas that the person cannot be talked out of), marked paranoia or suspiciousness, and, more rarely, auditory hallucinations. Older persons with depression are more likely to experience delusions than younger persons with depression.³³ Delusions often involve persecution, having an incurable illness, or focus on somatic complaints involving the abdomen. These individuals respond particularly well to electroconvulsive therapy (ECT) as opposed to antidepressants.

Dysthymia

A dysthymia is a chronic depression lasting 2 years or longer that does not fulfill the criteria for major depression. A "double depression" occurs when major depression is superimposed upon chronic dysthymia. Verwoerdt suggested that dysthymic disorder (depressive neurosis) is less frequent in the later part of the life cycle.⁵⁷ Community data, however, indicate that dysthymic disorder in the elderly is less frequent, but that the difference in rates between younger and older persons is not so great as for major depression.⁶ Although chronic depressions are difficult to treat when they are related to character pathology, studies have shown a good response to adequate doses of tricyclics; psychotherapy may be very helpful to these individuals who may have difficulty relating to others.

Minor Depression

Minor (or subthreshold) depression has received much attention in the literature in recent years. The diagnosis is often one of exclusion, but the condition is defined as

a less severe depressive episode than major depression and not as chronic as dysthymia. Criteria for the diagnosis appear in the Appendix (of DSM-IV). The diagnosis involves 2 weeks or more of depressed mood or loss of interest, together with between one and four of the traditional eight symptoms of depression (sleep disturbance, loss of sexual interest, guilt, loss of energy, difficulty concentrating, appetite disturbance, psychomotor agitation or retardation, suicidal thoughts). Beekman and colleagues⁵⁸ have estimated the frequency of minor depression in the elderly to be between 8% and 13% in community samples. The clinical significance of minor depression has not been established, nor has the effectiveness of treatment. The syndrome may actually, in most cases, be a prodrome or a residual of major depression (or a less severe manifestation of the same basic psychopathology as major depression). Treatment studies are difficult to perform because the “distance to recovery” in terms of symptom reduction is lower than for major depression. Nevertheless, some large clinical trials have suggested that antidepressant medications may be effective when compared to placebo.

Depression Not Otherwise Specified (NOS)

This depression subtype is often intermittent and unexplained by psychosocial or biologic factors; it is a milder form of mood disorder that does not fulfill either the severity or length criteria for major depression. Two subcategories for depression NOS may be seen by clinicians working with depressed elders. First, the syndrome may fulfill the criteria for dysthymic disorder; however, there are intermittent periods of normal mood lasting more than a few months. Second, some elders may experience a brief episode of depression that does not meet the criteria for major affective disorder and is apparently not reactive to psychosocial stress (so that it cannot be classified as an adjustment disorder). Although not an official diagnostic category, the term “minor depression” is included in the Appendix to DSM-IV. Patients with depression NOS may or may not fulfill DSM-IV criteria for minor depression.

Bereavement

Bereavement, a universal human experience, cannot be classified as a psychiatric disorder. Normal symptoms of grief include sensations of somatic distress such as tightness in the throat, shortness of breath, sighing respirations, lassitude, and loss of appetite. The bereaved may be preoccupied with the image of the deceased. Pathologic grief may occur if the usual symptoms are either delayed, persist beyond the expected period of time, or become unusually severe. Delayed grief can be distinguished from normal grieving by symptoms of overactivity without a sense of loss, frequently accompanied by psy-

chomatic complaints. When grief is unusually severe it may be associated with marked feelings of worthlessness, hopelessness, or suicidal ideation. Patients who fulfill the symptom criteria for major depression 2 months after bereavement, however, should be treated just like any other patient with major depression.

Adjustment Disorder with Depressed Mood

The DSM-IV category of adjustment disorder with depressed mood is reserved for those individuals who exhibit a maladaptive reaction to an identifiable stressor; here, the relationship of the syndrome to the stressful event is clear. Stressors for older adults may include life events such as retirement, marital problems, difficulty with children, loss of a social role, and an ill-advised change of residence. Depressive symptomatology often develops secondary to physical illness. When an episode of depression accompanies a physical illness and exceeds the level of symptoms expected, then the diagnosis of adjustment disorder is indicated.

Mood Disorder Caused by a General Medical Condition

The essential feature of mood disorder due to a general medical condition (formerly known as organic mood syndrome) is a disturbance in mood that results from direct physiologic effects of a general medical condition. General medical conditions likely to have such physiologic effects include hypothyroidism, hypercalcemia, B₁₂ deficiency, and illnesses that directly affect the brain (tumor, some kinds of stroke) (Table 79.1).

Substance-Induced Mood Disorder

Prescription medications such as antihypertensives, antianxiety (benzodiazepines) drugs, chemotherapeutic agents, and other drugs with CNS effects may precipitate a mood disorder (see Table 79.1). Chronic alcohol, cocaine, or other illicit drug use, or withdrawal from these substances, often evoke a depressive-like syndrome and such use must be part of screening.

Differential Diagnosis

Psychiatric conditions with depressive symptoms may be confused with depression; these include hypochondriasis, alcoholism, the organic mental disorders, delusional disorders, and schizophrenia. Hypochondriasis is both a symptom of depression and a separate disorder itself. The essential features are an unrealistic interpretation of physical sensations as abnormal and a preoccupation with the imagined physical illness underlying these sensations. Between 60% and 70% of depressed persons in one study were found to have hypochondriacal symp-

TABLE 79.1. Physical illnesses and medications associated with depression.

Physical illnesses	Medications
End-stage renal disease (especially with uremia)	CNS drugs Benzodiazepines
Cardiovascular disease	
Postmyocardial infarction	Alcohol
Postcoronary artery bypass surgery	Levodopa
Cardiomyopathy (congestive or other)	Amantadine
Endocrine disorders	Major tranquilizers
Thyroid (hyper- and hypothyroidism, thyroiditis)	Stimulants (rebound)
Parathyroid (hyper- and hypoparathyroidism)	Antihypertensives
Adrenal (Cushing's and Addison's diseases)	Beta-blockers
Disorders of insulin secretion	Clonidine
Hypopituitarism	Reserpine
Metabolic or nutritional disorders	Methyl dopa
Hypokalemia or hyperkalemia	Prazosin
Hyponatremia or hypernatremia	Guanethidine
Hypocalcemia or hypercalcemia	Chemotherapeutic drugs
Hypomagnesemia	Vincristine
Metabolic acidosis or alkalosis	L-asparaginase
Hypoxemia	Interferon
Vitamin deficiencies (B vitamins, folate)	Tamoxifen
Neurologic diseases	Steroids
Parkinson's disease	Prednisone
Stroke	Estrogen preparations
Alzheimer's disease	
Subdural hematoma	Anticonvulsants
Amyotrophic lateral sclerosis	Procarbazine
Temporal lobe epilepsy	Diphenylhydantoin
Multiple sclerosis	
Normal-pressure hydrocephalus	Others
Cancer	Cimetidine
Brain tumors (primary or secondary)	Digitalis
Pancreatic cancer	Nonsteroidal anti-inflammatory drugs
Lung cancer (oat cell)	
Bone metastases with hypercalcemia	
Miscellaneous	
Hepatic failure with encephalopathy	
Anemia	
Infections (particularly viral)	
Chronic pain	

toms.⁵⁹ When hypochondriacal complaints appear in later life for the first time, there is a high likelihood that either depression or an undetected physical illness is present.

Hypochondriasis as a disorder is usually distinguishable from depression by (1) the length of the episode (hypochondriasis persisting for years), (2) the degree of suffering by the patient (more among depressed patients), (3) and the waxing and waning course of symptoms in depression, which by nature is cyclic. Differentiating the older adult with hypochondriasis or generalized anxiety disorder from the one who is depressed has therapeutic implications; hypochondriacs often do not tolerate antidepressants because of real or imagined side effects.

Alcoholism, although less frequent in older than in younger persons, still occurs in about 5% to 8% of persons over age 60. A heavy alcohol intake may cause

both physical and psychologic symptoms that mimic depression. Conversely, many alcoholics drink to relieve the pain of depression that recurs when they become sober; in this case, depressive disorder has been "masked" by the alcohol problem. The same principles apply to elders who abuse prescription drugs.

The sudden appearance of a psychosis in later life, with paranoid or delusional thinking, may herald the onset of a major depression. Differentiating depression from late-life schizophrenia or delusional disorder may be difficult, but the latter are not usually associated with profound depression. Late-life schizophrenia seldom begins suddenly; instead, it is characterized by gradual withdrawal, bizarre complaints, and paranoia.

Finally, it may be difficult to distinguish an agitated depression from panic disorder with secondary depres-

sion. These conditions can often be differentiated by determining which symptoms arose first; patients with a primary panic disorder will report a history of anxiety symptoms that precede the onset of depression, whereas those with primary depression report that their depression came before the onset of panic. The comorbidity between depression and anxiety disorders is discussed further next.

Manic Episodes and Bipolar Disorder

A manic episode is defined as a distinct period of abnormally elevated or expansive mood associated with at least three of the following symptoms: grandiosity, decreased sleep, pressured speech, flight of ideas, distractibility, increased activity, and excessive involvement in pleasurable activities (DSM-IV). A single episode of mania, either by itself or associated with prior episodes of depression, allows for the diagnosis of bipolar disorder (bipolar, type I). Less severe mood swings that have lasted for 2 years or more are termed *cyclothymia*, and other states not meeting any of the criteria for a specific bipolar disorder are labeled *bipolar disorder not otherwise specified*. Bipolar type II is a patient with a history of one or more major depressive episodes and periods of hypomania (but not full-blown mania).

Bipolar disorder is not as common in persons over age 65 as it is in younger persons. The presentation of bipolar disorder in later life may be atypical with a mixture of manic and dysphoric symptoms.⁶⁰ Euphoria may be less common and is replaced by irritability or cognitive impairment. The term manic delirium has been used to describe a state of altered consciousness that may be difficult to distinguish from organic brain syndrome, dementia, and even schizophrenia.⁶¹ Older manics may have different symptomatology from younger patients, including less intense levels of overactivity, less intense sexual drive, and less disturbed thought processes.⁶² Longer hospitalization, greater residual psychopathology, and a diminished response to pharmacotherapy have also been associated with older age. Increased cerebral vulnerability from stroke, head trauma, or other neurologic disorders is an important etiologic factor in late-onset mania.⁶³⁻⁶⁵

Diagnostic Evaluation

There is a greater likelihood that mood disorders in later life will be accompanied by physical illness.⁶⁶ Diagnostic evaluation, then, should be thorough and comprehensive. A patient's history should focus on the length of the current episode, any history of previous episodes, a history of drug or alcohol abuse, therapies tried in the past, and an assessment of the patient's suffering, particularly with respect to suicidal thoughts. If possible, con-

firmation of the patient's responses should be obtained from a relative or caretaker. In the physical examination, attention should be directed toward such neurologic findings as lateralization, tremor, muscle tone, and slowed reflexes.

Laboratory Workup

Thyroid function studies (T_4 , TSH), complete blood cell count, serum electrolytes, vitamin B_{12} level, and drug levels are often helpful in identifying reversible organic causes of depression. Vitamin B_{12} deficiency may present with depressive symptoms, as well as dementia, in the face of a normal serum B_{12} level or hemogram; methylmalonic acid and homocystine levels should be checked in depressed patients with low normal serum B_{12} levels. A head CT scan or MRI scan can rule out brain tumors, although when the history is not suggestive and the neurologic exam is normal, the yield from these tests is very low. Imaging may also identify a vascular depression. Nevertheless, a routine CT or MRI is not indicated in the laboratory workup of late-life depression. An electrocardiogram, as well as renal and liver function tests, can be helpful if psychopharmacologic treatment is contemplated.

Management of Depression

Once a diagnosis has been made and the patient's safety ensured, management includes one or more of the following specific treatments: psychotherapy, pharmacotherapy, or electroconvulsive therapy (ECT). Regardless of which modality is chosen, all depressed elders require psychologic support, which involves listening, empathy, and demonstration of concern, in other words, good clinical care. Many patients with minor depressions or adjustment disorders may improve with this intervention alone. Primary care physicians, nurses, or social workers may provide such support. The clergy may also be a helpful resource, given the important role that religion plays in the lives of many older adults.⁶⁷

Psychotherapy

Psychotherapy avoids the side effects associated with psychoactive drugs.⁶⁸ A wide variety of psychotherapies are available to the clinician for use in elderly depressed patients; only a few, however, have proven efficacy in late-life depression. Insight-oriented and psychoanalytic psychotherapy has not been studied systematically with depressed elders. Thus, we focus primarily on cognitive-behavioral and time-limited therapies.

Cognitive therapy (CT) is designed to train patients to identify and correct the negative thinking in depression that contributes to its maintenance.⁶⁹ Depressed patients

overgeneralize, catastrophize, and think in terms of extremes. It is easy for this negative thinking to convince the patient that he or she is inadequate and ineffective, dissipating hope. Cognitive restructuring helps to break the vicious cycle of depressive thinking. Recall from Figure 79.1 the central role that cognitive appraisal plays in the causal path that leads to depression. Cognitive interventions may enable the older person to view their disabilities and other life stressors in a more positive light, as well as disrupt negative ruminations.

Behavioral therapy (BT), on the other hand, involves positive reinforcement of behaviors that alleviate depression (pleasurable activities) and the negative reinforcement of behaviors that lead to depression (withdrawal, etc.).⁷⁰ In BT, the patient is encouraged to keep weekly activity schedules, and mastery and pleasure logs, and to complete other homework assignments. A variant of cognitive-behavioral therapy is interpersonal therapy (IPT).⁷¹ IPT is similar in approach to CT, but the focus of therapy is on the interpersonal interactions of the patient. IPT has been employed in many clinical trials among younger and older subjects, usually in conjunction with medication. Brief dynamic therapy (BDT) stresses the importance of the patient–therapist relationship, emphasizing the realistic collaborative aspects of the therapeutic alliance rather than focusing on the transference as in classical dynamic therapy.⁷²

Thompson and colleagues compared the efficacy of CT, BT, and BDT in a study of 91 elders with major depression.⁷³ After 6 weeks of treatment, 52% of patients were in full remission and 18% showed significant improvement. CT, BT, and BDT were equally effective and significantly superior to the control group. Group psychotherapy, using an educational problem-solving approach, may be a particularly effective, inexpensive, and acceptable form of treatment for older adults, especially those who are socially isolated.^{74,75} For elders suffering from unresolved grief reactions following bereavement, mutual self-help groups led by nonclinicians have been shown to be equally effective as participation in formal psychotherapy groups.⁷⁶

Pharmacotherapy

Because of the excellent response of many depressed older adults to drug therapy, antidepressants should always be considered when depressive symptoms threaten the elder's ability to function. The five major classes of medications used to treat mood disorders are (1) selective serotonin reuptake inhibitors (SSRI), (2) other novel antidepressants (venlafaxine, mirtazapine, bupropion, nefazodone), (3) tricyclic antidepressants, (4) monoamine oxidase (MAO) inhibitors, and (5) mood stabilizers (lithium carbonate, carbamazepine, valproic acid). SSRIs and newer non-SSRI antidepressants have

taken over as the drugs of choice for depression in late life. These have largely displaced the second-generation tricyclic antidepressants (nortriptyline or desipramine), although the latter continue to have a place in the treatment of late-life depression, particularly severe depression with melancholic symptoms (Table 79.2).

SSRIs such as fluoxetine, sertraline, paroxetine, or citalopram are now the drugs of first choice for geriatric depression. Initial doses must be small (10mg/day or 10mg every other day for fluoxetine; 12.5 or 25mg/day for sertraline; 5–10mg/day for paroxetine) to reduce the likelihood of unpleasant side effects. The newer antidepressants, although generally devoid of the orthostasis, anticholinergic, and cardiac side effects of tricyclic antidepressants, have their own unpleasant effects that affect their use in older patients; these include weight loss, excessive stimulation and agitation, insomnia, gastrointestinal side effects, tremor, and disequilibrium. Because of its long half-life (10–14 days in frail elders), fluoxetine should be used cautiously in older patients, although it may also enable patients to take the drug only three or four times per week, thereby reducing cost. Sertraline, paroxetine, and citalopram with shorter half-lives are more quickly cleared from the body but can create problems when the medication is abruptly discontinued (due to a withdrawal syndrome). Among the oldest-old, inappropriate secretion of antidiuretic hormone (ADH) may occur with the use of these drugs. SSRIs can interfere with the P-450 enzyme system in the liver, and therefore decrease the metabolism of certain drugs such as warfarin. Such potential interactions are present with every SSRI, even the newer ones, although they are purported to be less of a problem with sertraline and citalopram.

Patients who do not respond to traditional SSRIs, or who after being on these drugs for some time lose their responsiveness, may be tried on venlafaxine, which inhibits the reuptake of both serotonin and norepinephrine. Patients may be started on doses of 25mg twice daily, and increased gradually up to 150mg twice daily if necessary. Blood pressure should be monitored because this drug has been associated with worsening of hypertension. Mirtazapine is another novel antidepressant with relatively few side effects that may be tried either initially or after the patient has failed a trial with SSRIs. Mirtazapine has the benefit of being sedating, particularly at low doses. Patients should be started on 15mg at bedtime, and then after a week or two increased to 30mg, the dose at which most older adults respond. A few patients, however, may require as much as 45mg/day given at bedtime. As with venlafaxine, blood pressure should be monitored; also, be aware that agranulocytosis occurs in about 0.1% of patients of all ages.

Until recently, nortriptyline, desipramine, and doxepin were popular drugs for treating older adults with

TABLE 79.2. Recommended doses, reported side effects, and therapeutic blood levels of antidepressants in older persons.

Drug	Dose/day (initial maintenance), mg	Therapeutic serum level, ng/dL	Relative sedation	Relative anticholinergic	Postural hypotension
Heterocyclics					
Doxepin	25–100	>100	++++	++++	++++
Nortriptyline	10–75	50–150	+++	+++	+++
Desipramine	25–125	>125	++	++	+++
Trazodone	50–300	NA	++++	+	+++
Nefazodone	100–600	NA	+++	+	+
SSRIs					
Fluoxetine	5–20	NA	+	+	+
Sertraline	25–100	NA	+	+	+
Paroxetine	10–20	NA	+	++	+
Citalopram	20–40	NA	+	+	+
Others					
Venlafaxine (S/NRI)	25–75	NA	+	+	+
Mirtazapine	15–45	NA	+++	+	+
Bupropion	75–300	NA	+	+	+
MAO inhibitors					
Phenelzine	15–45	>80% inhibition of MAO	+	++	+++
Mood stabilizers					
Lithium carbonate	150–600	0.4–0.7 mmol/L	++	0	0
Valproic acid	250–1250	50–100 ng/mL	++	0	0
Stimulants					
Methylphenidate	5–30	NA	0	0	?

NA, not applicable; four plus signs, strong; three plus signs, moderate; two plus signs, weak; one plus sign, negligible; zero, none; MAO, monoamine oxidase; SSRI, selective serotonin reuptake inhibitor; S/NRI, serotonin/norepinephrine reuptake inhibitor.

endogenous depressions. If used today, lower doses than those for younger adults are preferred, because high blood levels may occur even at reduced dosages.⁷⁷ Doses of 10 to 50 mg of nortriptyline or 25 to 75 mg of desipramine at bedtime are often adequate to relieve symptoms, although blood levels should be followed to ensure a therapeutic dose.

For patients with an agitated depression who need sedation, trazodone at doses from 50 to 300 mg/day or nefazodone at doses of 100 to 300 mg/day may be tried. Because they are virtually devoid of anticholinergic side effects, trazodone and nefazodone are attractive drugs for use in elderly patients. Nevertheless, their antidepressant potency is questionable at doses that elders can usually tolerate, and side effects such as excessive drowsiness, orthostasis, and priapism are reasons for caution (although less so for nefazodone than for trazodone).

Bupropion is another antidepressant that may have special advantages in certain patients. Elders who have psychomotor retarding (slowed down in physical movements and mental activity), or are unmotivated, fatigued, frail, and at high risk for falling, may find bupropion helpful. Doses beginning at 75 mg/day and increasing to 225 or 300 mg/day are recommended; any single dose should not exceed 150 mg, usually requiring bid (twice a day) or tid (three times a day) dosing. Toxicity at the higher doses may be manifested by tremor, unpleasant

gastrointestinal side effects, or visual hallucinations. Stopping or reducing the dose readily reverses these symptoms. Bupropion has also been associated with an increased risk of seizures, especially in patients with anorexia nervosa or bulimia; thus, a history of seizures should be ruled out before starting this drug.

Combinations of an SSRI and a tricyclic antidepressant, bupropion, or trazodone may help in resistant depressions. For instance, 10 to 20 mg of fluoxetine, 25 to 50 mg of sertraline, or 10 to 20 mg of paroxetine may be used with 10 to 50 mg of nortriptyline or 25 to 50 mg of trazodone at night to achieve the desired antidepressant effect and minimize side effects such as insomnia. Note that all SSRIs interfere with the hepatic metabolism of tricyclics and will increase their blood levels; thus, if an SSRI is added to a regimen that includes a tricyclic antidepressant, the dose of the latter should be reduced by one-half or greater and blood levels carefully monitored. Much attention has been directed toward the cytochrome P-450 group of enzymes and the potential for toxic drug–drug interactions secondary to the effects of the SSRIs upon these enzymes. In general, commonly used medications when used in moderation do not result in side effects. Nevertheless, the clinician should review the specific medications prescribed to the patient, perhaps with a computer-assisted program, to avoid these drug–drug interactions.

St. John's wort is a natural herb that has been used for the treatment of depression, particularly in Europe. The preparations that can be bought over the counter in health food stores in the United States are of uncertain composition and purity. These preparations should not be used for a patient with a clinical diagnosis of depression, because there are known effective treatments that have been tested (antidepressants already described), approved by the FDA, and have careful guidelines and requirements for their preparation. St. John's wort is currently being evaluated in a multisite study funded by the NIH's Office of Alternative Medicine.

Before starting therapy with an antidepressant, the older patient should undergo a thorough history and physical examination to identify contraindications. When using tricyclics, special effort should be employed to elicit a history of closed-angle glaucoma, difficulty with urination, severe dizziness with standing, seizure disorder, severe hypertension, recent myocardial infarction, or unstable angina. The physical examination should include measurement of orthostatic blood pressure changes, as well as examination of the liver and prostate for enlargement. Baseline liver and kidney function test results should also be obtained because most antidepressants are metabolized in the liver and excreted in the urine.

An electrocardiogram should be obtained before starting therapy with antidepressants, especially tricyclics or tetracyclics; even patients on SSRIs may be at increased risk for developing cardiac complications, particularly in the presence of atrial arrhythmias. If a left bundle branch block, bifascicular block, second-degree heart block, or prolongation of the QT interval (>480 ms) are present, antidepressants should not be started until a cardiac consultation has been obtained or the patient is under careful observation in the hospital. Patients with atrial fibrillation may experience an acceleration in heart rate due to anticholinergic side effects that enhance conduction through the atrioventricular (AV) node. Simple first-degree AV block or bundle branch block does not increase the risk of cardiac complications. A follow-up electrocardiogram, after the start of treatment, is essential in all patients with heart disease. The dose should be decreased or the drug should be stopped if there is a marked prolongation of the PR, QT, or QRS durations or if AV block worsens or ventricular arrhythmias increase. Use of tricyclic antidepressants concurrently with quinidine, procainamide hydrochloride (Pronestyl), or other type I antiarrhythmics may produce additive cardiac effects.

To ensure compliance, patients should be informed of possible side effects, such as dizziness with sudden standing, difficulty with urination, dry mouth, and constipation for tricyclic antidepressants, and side effects such as nausea, headache, weight loss, agitation, insomnia, and loss of sexual interest for SSRIs. These effects are often

experienced soon after starting the drug therapy, but often gradually improve after a couple weeks of therapy. patients should also be warned that antidepressant effects may not occur before 6 to 8 weeks of treatment. When there is concern over the patient's suicidal potential, no more than 1 g of a tricyclic antidepressant should be dispensed at any one time; fatal overdose with the SSRIs, bupropion, velafaxine, mirtazapine, and nefazodone is much more difficult. Once a response is achieved, antidepressants should be continued for 6 to 9 months and then gradually tapered. Given the high rate of relapse in older adults, some experts are now recommending long-term maintenance therapy at the same dose that achieved a therapeutic response, especially if the elder has experienced a recurrence of a successfully treated episode. Lifelong treatment may be indicated for those with a history of one or more relapses.⁷⁸ Monoamine oxidase inhibitors are an alternative to the heterocyclic antidepressants and SSRIs, although they are not easy to use in the treatment of depression in older patients.

Lithium carbonate may be useful in preventing the recurrence of unipolar depression, although its efficacy in this regard is not as established as for bipolar disorder. Although lithium alone is a poor antidepressant, it may be used to augment the antidepressant effects of tricyclics. Lithium may sensitize postsynaptic adrenergic receptors, thereby enhancing the effects of tricyclic antidepressants. Anticonvulsants such as carbamazepine or valproic acid are especially useful in treating older patients who rapidly cycle between depressed and manic or agitated moods. In general, the use of lithium or anticonvulsants by nonpsychiatric physicians in the treatment of depression or management of bipolar disorder in older patients is not recommended.

In general, benzodiazepines should not be used to treat geriatric depression as these can induce excessive sedation and may even worsen the depressive state.^{79,80} The possible exception is alprazolam, which has been reported to have antidepressant, as well as antianxiety, effects. At doses of 2 to 4 mg/day, the antidepressant effects of this drug have been reported to equal those of imipramine. Nevertheless, elders may easily become dependent on alprazolam, and it is difficult to get them off the drug once started.

Low doses of stimulants such as methylphenidate (5–15 mg two or three times/day) may enhance the appetite and mood of an apathetic older adult. At such doses, side effects are rare (especially if the last dose is given before 2 P.M.), and abuse or addiction is seldom encountered; nevertheless, blood pressure should be monitored and these drugs avoided in patients with unstable angina. Furthermore, tolerance may occur, requiring an escalation of dose to achieve the desired effect. Stimulants have been used to treat depression in medically ill older patients,¹⁰ although it remains unclear

whether they actually treat the mood disorder or simply activate retarded patients.

Major depression in patients with dementia should be treated with antidepressant medication. Start with an SSRI, bupropion, or mirtazapine (if sleep is a problem). Avoid tricyclics if possible. The starting dose of tricyclics, if used, should be low (e.g., 10 mg nortriptyline, increasing slowly to a maximum of 50 mg/day). Anticholinergic effects can worsen dementia and may precipitate an acute delirium.

The treatment of acute mania is best accomplished with lithium carbonate; supplementation with benzodiazepines or phenothiazines may be necessary. The anti-convulsant valproic acid is increasingly being utilized as a first-line agent to control both manic episodes and agitation/aggression in elderly patients. In rare circumstances, a manic episode will respond only to ECT.

Recent studies have demonstrated the effectiveness of combined use of tricyclic antidepressants (specifically nortriptyline) and IPT in both the treatment of a depressive episode and the prevention of relapse once the episode remits.⁸¹ The combination of medications and psychotherapy was especially beneficial in decreasing the likelihood of recurrence once an episode responded to therapy, even in the most severely depressed sample members.

Electroconvulsive Therapy

For severe depressions that are persistent and refractory to psychotherapy and pharmacotherapy, ECT is the most effective treatment.⁸² It is particularly effective in major depression with either melancholic or psychotic features. Of the 1400 ECT treatments per year given to psychiatric inpatients at Duke Hospital, 70% are for patients age 60 or over. Despite its remarkable effectiveness and general safety, ECT is still usually performed only after other methods of treatment have failed. In cases where the patient becomes suicidal or attempts to starve to death, ECT is the treatment of choice because of its rapid effect.

For an adequate therapeutic response, treatments are usually given three times per week for a total of 8 to 12 times; this can be done as an inpatient or outpatient. A marked improvement usually is noted after one of the treatments. Following this improvement, two or three further treatments are usually given. The overall success rate for ECT in drug nonresponders is about 80%, a rate similar in both younger and older patients. In the absence of prophylactic drug therapy, the relapse rate 1 year following ECT exceeds 50%. Maintenance ECT (weekly or monthly) or concurrent use of antidepressants decreases the relapse rate to around 20% in the year following ECT.

Confusion following ECT varies from patient to patient, depending on underlying level of cognitive

impairment. There is less confusion after unilateral than bilateral electrode placement during ECT and also less confusion after brief pulse stimulation than after sine wave stimulation. It is difficult to evaluate the effects of ECT on memory, because depression itself affects memory. Significant cognitive impairment is not a contraindication to ECT, because if this impairment is caused by depression, it may improve as the depression improves.⁸³ Most memory impairment induced by ECT disappears by 6 months after treatment.⁸⁴

Prognosis

The natural history of major depression follows a pattern of remission and relapse. Until recently, most follow-up studies indicated that one-third of depressed elders recovered completely from an index episode, one-third experienced a partial recovery or relapsed soon after recovery, and one-third remained continuously ill.¹¹ The results from follow-up studies, however, depend largely on the sample. British investigators Baldwin and Jolley,⁸⁵ however, reported that 60% of depressed elders remained continuously well or had further episodes with complete recovery during a 3- to 8-year follow-up period. Factors associated with better outcome are female sex, current employment, and high level of subjective social support.^{3,86} Other positive prognostic factors include an extraverted personality style, absence of severe symptomatology, a family history of depression, a history of recovery from previous episodes, no substance or alcohol abuse, no other comorbid major psychiatric illness, minimal intercurrent life changes, and religious coping style.^{38,85,86} On the other hand, poor outcomes have been associated with delusions, significant cognitive impairment, and physical illness.^{85,87,88} More recent studies indicate that when antidepressant therapy is combined with psychotherapy or ECT, a remission can be achieved in about 80% of cases (similar to the response rate in younger depressed patients).⁸⁹⁻⁹²

Little is known concerning the outcome of bipolar disorders in older persons. There is some information to suggest that early-onset bipolar disorder may "burn out" with time. Shulman and Post⁹³ found that few of their sample of elderly persons with bipolar disorder had the early-onset variety. When mania occurs for the first time in an elder who previously had unipolar depression, the illness may have a poorer prognosis than unipolar depression; the strong association between late-onset mania and progressive neurologic disorders (such as Alzheimer's disease and other dementias) accounts for this.⁹⁴

Suicide and Its Prevention

Cross-sectional epidemiologic studies have shown that suicide rates in later life are higher than at younger ages,

and suicide ranks among the top 10 causes of death in persons over age 65.⁹⁵ After nearly 40 years of declining suicide rates in the elderly, since 1980 these rates have begun to increase. Risk factors for suicide include sex (male), race (white), marital status (divorced or separated), economic status (low), mental illness, previous suicide attempts, and health. Although men of all ages have a higher suicide rate than women, older men have a higher rate than any other age by sex group;¹⁵ in fact, the higher rate of suicide in the elderly results largely from the higher risk in older white males. Elderly patients with mental illness, particularly depression and schizophrenia, are at high risk for suicide. When depression coexists with other mental disorders, the risk increases further.

The presence of alcohol abuse or dependence is a major risk factor for suicide, especially among elderly white males; this is particularly true for late-onset alcoholics, who often drink in response to psychosocial stressors. Thus, an inquiry about alcohol use is essential when evaluating safety risk in older patients with depression.

Poor health status is another major risk factor for suicide in later life. In 1928, Cavan noted that physical illness led to suicide when a person's capacity to endure severe pain was exceeded.⁹⁶ In a review of 391 cases of suicide, she found that 23% had physical illness; in two-thirds of this group, the suicide was directly related to the illness. The close relationship between physical illness and suicide has been repeatedly demonstrated by other investigators, particularly in men and in patients with coexisting depression or organic brain syndrome. MacKenzie and Popkin provide an excellent review of the association between medical illness and suicide.⁹⁷

Involvement of family in helping to monitor an elderly suicidal patient at home is vital in preventing suicide. Inquiry about a "plan" often reveals the means by which the act might be attempted; the family should be instructed to remove from the house weapons such as guns, large knives, and all but necessary medications. If the family cannot assure the physician that at least one family member can be with the patient at all times until the risk of suicide has passed, then hospitalization is the safest course. If hospitalized, the patient should be placed in an environment with windows of shatter-proof glass or safety screens and should not have access to open stairwells or laundry chutes. Potentially harmful devices, such as razors, scissors, knives, forks, ropes, and breakable glass bottles or glasses, should also be removed from the patient's environment. Adequate doses of psychotropic medication should be utilized for the confused or psychotic patient. The quickest and safest form of treatment in the severely depressed and suicidal elder is ECT.

Anxiety Disorders

Anxiety is a common symptom experienced by elderly persons, particularly those with physical health problems.⁹⁸ Clinicians evaluating an elderly person with a complaint of anxiety must first decide if the symptom is due to some underlying medical illness. If not, then the clinician must determine whether the anxiety is a result of psychiatric illness or represents a normal response to life events. The signs and symptoms of anxiety are both cognitive and physical, and include difficulty with concentration, dizziness or faintness, tremulousness, insomnia, fears of "going crazy" or dying, tachycardia, diaphoresis, and shortness of breath. Many of these signs and symptoms are also seen in a wide range of medical and other psychiatric disorders from which they must be distinguished.

Epidemiology

Anxiety syndromes typically begin in early life and decrease in frequency after the age of 65. The ECA surveys found that 6% of persons over age 65 fulfilled criteria for an anxiety disorder *within the past month*.⁹⁹ Other studies have reported rates of clinically significant anxiety as high as 20% in some elderly populations.¹⁰⁰ Phobia is the most common psychiatric disorder in elderly women, who are also more likely than men to be diagnosed with any of the anxiety disorders.⁹⁹ Medical illnesses that increase the vulnerability of older persons to anxiety include Parkinson's disease, chronic obstructive pulmonary disease, and early dementia, where rates of anxiety disorder range from 8% to 38%.¹⁰¹⁻¹⁰³ Elderly persons with anxiety disorder tend to be high utilizers of health services, and therefore commonly come into contact with medical personnel.

Diagnostic Evaluation

Anxiety disorders seldom present for the first time in later life, although generalized anxiety disorder or panic disorder are known to do so.¹⁰⁴ The general rule is that late-onset anxiety is presumed to have a medical cause until proven otherwise. Table 79.3 presents psychiatric and medical causes for anxiety in older patients. Evaluation consists of a comprehensive history, physical examination, and battery of laboratory tests, including electrolytes, thyroid studies, and an electrocardiogram. A history of caffeine intake—tea, colas, or coffee—should be elicited, as well as over-the-counter drug use. Prescription medications that cause anxiety include sympathomimetics, corticosteroids, theophylline, calcium channel blockers, opiates, and amphetamines. Withdrawal from chronic benzodiazepine use may cause a prolonged withdrawal

TABLE 79.3. Medical and psychiatric causes of anxiety in the elderly.

Medical disorders	Psychiatric disorders
Cardiovascular	Anxiety disorders
Myocardial infarction	Panic disorder
Paroxysmal atrial tachycardia	Agoraphobia
Hypothermia	Social phobia
Mitral valve prolapse	Simple phobia
Hyperkalemia	Obsessive-compulsive disorder
Dietary	Posttraumatic stress disorder
Caffeine	Generalized anxiety disorder
Vitamin deficiencies	Other psychiatric disorders
Drug-related	Major depression
Anticholinergic toxicity	Dementia
Akathisia (antipsychotics)	Psychosis
Antihypertensive side effects	Adjustment disorder to negative life events
Digitalis toxicity	Sleep disorder
Theophylline	Somatoform pain disorder
Thyroid replacement therapies	Somatization disorder
Antidepressants (SSRIs, bupropion)	Personality disorders
Neurologic	Substance abuse, dependence, withdrawal
Central nervous system infections	Alcohol
Central nervous system masses	Sedative/hypnotics
Postconcussion syndrome	Prescription drugs
Temporal lobe epilepsy	Over-the-counter drugs (decongestants, diet aids)
Parkinson's disease	
Endocrinologic	
Insulinoma	
Hypoglycemia	
Hypo- or hyperthyroidism	
Hypo- or hypercalcemia	
Pheochromocytoma

syndrome in the elderly associated with anxiety. All patients should be asked about alcohol use and when the last drink was taken. When physical and psychiatric symptoms of anxiety overlap in patients with medical problems, a diagnosis of anxiety disorder should be reserved for those who either had anxiety symptoms before the onset of the medical illness or continue to have symptoms after the physical condition has been treated.

Diagnostic assessment is often complicated by a heavy overlap between anxiety disorders and depressive disorders. Although only 2% of older psychiatric inpatients have an isolated anxiety disorder, nearly 40% with major depression fulfill criteria for anxiety disorder.¹⁰⁵

Clinical Features

The major anxiety disorders noted in DSM-IV include generalized anxiety disorder, panic disorder with and without agoraphobia, posttraumatic stress disorder, obsessive-compulsive disorder, and phobia (social or simple). Because of their prevalence in later life and impact on functioning, we focus here on generalized anxiety disorder (GAD), panic disorder, and obsessive-compulsive disorder (OCD). To meet the DSM-IV criterion for GAD, the person must have experienced excessive or unrealistic anxiety nearly every day for 6 months or longer and have had at least 6 of 18 possible symptoms during that period of time. The 18 symptoms

are grouped into symptoms of muscle tension, autonomic hyperactivity, and vigilance or scanning. The 1980–1981 ECA surveys found that the 1-year prevalence of GAD among 5700 persons aged 65 or over was 2.2%, the highest of any anxiety disorder except phobias.¹⁰⁶

To meet DSM-IV criteria for panic disorder, a person must experience recurrent episodes of severe anxiety or fear, accompanied by at least four of the following symptoms: shortness of breath, palpitations, sweating, dizziness, nausea, choking, depersonalization, numbness or tingling, hot flashes, and chest pain, all usually accompanied by a fear of dying or going crazy; at least four such episodes must have occurred within a 4-week period. These intense periods of anxiety usually occur spontaneously, without warning, and typically last only about 5 to 10 min. Panic disorder may or may not be associated with agoraphobia (the fear of being in public places or situations from which escape may be difficult). The 1-year prevalence of panic disorder in persons over age 65 in the ECA studies was 0.04% in men and 0.41% in women.¹⁰⁷ Although usually a chronic illness that develops in early adulthood, late-onset panic disorder can occur and is characterized by fewer symptoms and less avoidance.¹⁰⁸ Panic disorder in older adults with heart disease is both prevalent and underdiagnosed.¹⁰⁹ Almost one-third of older persons with chest pain and no evidence of coronary artery disease are reported to have late-onset panic disorder.¹¹⁰

OCD is characterized by recurrent obsessive thoughts or compulsive behaviors that cause a significant disruption in social or occupational functioning. The person has little control over the obsessive thoughts, which are recurrent and persistent; he or she is often compelled to perform repetitive behaviors or rituals (washing hands, counting, checking locks, etc.) to avoid feeling overwhelmingly anxious. Epidemiologic studies report a 1-year prevalence between 0.9% and 1.5% in the geriatric populations.^{111,112} Many older persons with this disorder resist hospitalization for medical problems because it may disrupt their compulsive activities.

Other psychiatric diagnoses, particularly alcoholism, can lead to complaints of anxiety in older patients. Anxiety can be part of an alcohol withdrawal syndrome that occurs when alcohol use is temporarily halted; alternatively, alcohol may be used to self-medicate an underlying anxiety disorder. There is also considerable overlap between the anxiety disorders and dementia, where it may be difficult to distinguish anxiety from agitation.¹¹³

Management

After treating reversible medical problems and arriving at a specific psychiatric diagnosis, the clinician must choose from a wide range of psychotherapeutic and drug treatment options. If the anxiety symptoms are minor and associated primarily with stressful life circumstances,

treatment largely involves supportive, problem-focused counseling to help the patient choose a healthy coping strategy. If an anxiety disorder is diagnosed, then more specific therapies are indicated.

Behavioral Therapies

Behavioral therapies are commonly used to treat anxiety disorders in both younger and older adults (Table 79.4). Progressive muscle relaxation is commonly used for patients with GAD, panic disorder, or social phobia.¹¹⁴ This therapy involves the systematic tensing and relaxing of muscle groups, beginning first with the facial muscles and gradually moving down to the neck, upper arms, abdomen, legs, and feet. This technique is often combined with rhythmic breathing and visualization. Studies have shown that progressive muscle relaxation is effective in relieving the anxiety of patients with chronic pulmonary diseases and with cancer.^{115,116}

Another behavior technique is called graded exposure; it is used to treat phobias and compulsive behaviors. The person is repeatedly exposed to the feared stimulus until the fear of that stimulus is gradually lost. Systematic desensitization combines progressive muscle relaxation with breathing and visualization; it prevents the stimulus from arousing anxiety by associating it with a deeply relaxed state.¹¹⁷ Other behavioral techniques include biofeedback, meditation, social skills training, assertiveness training, and participant modeling. Studies have now demonstrated the effectiveness of behavioral therapies for treating anxiety disorders in older adults.¹¹⁸ Cognitive therapy is commonly used with behavioral techniques to achieve better outcomes.

TABLE 79.4. Management of anxiety disorders in the elderly.

Condition	Treatment
Panic disorder (with or without agoraphobia)	Desipramine, clonazepam, alprazolam, phenelzine, exposure therapy, cognitive-behavioral therapy
Agoraphobia without panic disorder	Cognitive-behavioral therapy, exposure therapy
Social phobia	Cognitive-behavioral therapy, exposure therapy, beta-blockers, phenelzine, serotonin-reuptake inhibitors
Simple phobia	Graded exposure and systematic desensitization
Generalized anxiety disorder	Buspirone, clonazepam, β -blockers, behavioral therapy, psychotherapy
Obsessive-compulsive disorder	Serotonin-reuptake inhibitors, behavioral therapy, psychodynamic therapy
Posttraumatic stress disorder	Psychotherapy, behavior therapy, nortriptyline, clonazepam, phenelzine

Benzodiazepines

The pharmacologic management of anxiety disorders is most successful when used in combination with cognitive and behavioral therapies. Antidepressants and benzodiazepines are the mainstay of pharmacologic treatment for anxiety disorders. Between 17% and 50% of all older adults use benzodiazepines for problems with anxiety or medical problems.¹¹⁹

All benzodiazepines work equally well in relieving anxiety; only the side effect profiles of these drugs differ. Elderly persons often respond to low doses of medication. Furthermore, elders are at greater risk for the development of toxicity because of pharmacokinetic changes with aging, such as slowed hepatic metabolism and reduced glomerular filtration rate. Because they bind tightly with plasma albumin (reduced in some elders) and distribute preferentially to fatty tissue (increased in elders), benzodiazepines with a long half-life tend to accumulate and have toxic side effects. The half-lives of diazepam and chlordiazepoxide in older adults is nearly three times that in younger persons.¹¹⁴ For this reason, short-acting benzodiazepines such as lorazepam and oxazepam are the drugs of choice. These drugs are conjugated in the liver, eliminated in the urine, and have no active metabolites (as do alprazolam and diazepam). Oxazepam is typically started at a dose of 7.5 mg (1/2 a 15-mg tablet) given three times per day, which can then be gradually increased up to a maximum of 45 mg/day. Lorazepam is usually initiated at a dose of 0.25 mg (1/2 a 0.5-mg tablet) three times per day and tapered upward to a maximum of 3 mg/day.

Alprazolam is a benzodiazepine with an intermediate half-life of 12 to 15 h in the elderly. At a single dose of 0.5 to 2.0 mg, alprazolam is effective for the immediate relief of severe anxiety, particularly during a panic attack. However, it has an active metabolite that can build up in the elderly and cause toxic reactions.¹²⁰ As noted earlier, alprazolam can induce dependence, particularly in those with a history of alcohol or benzodiazepine abuse, and is difficult for some elders to discontinue (see following).

It is generally best to use short-acting benzodiazepines in elderly patients; however, there are some indications for using longer-acting agents such as diazepam, chlordiazepoxide, or clonazepam. One indication is where anxiety is constant throughout the day and night and is clearly interfering with ability to function. Many elderly persons have taken these drugs for years and do not abuse them.¹²¹ Of the longer-acting agents, clonazepam is the safest; doses of 0.25 to 1.0 mg twice a day is usually effective, although some patients will do well on a once a day or even once every other day regimen. Clonazepam, however, has been reported to be depressogenic, so it must be used with caution in mixed anxiety-depression states.

When discontinuing benzodiazepines that have been taken regularly for several months or more, the clinician must gradually taper these compounds to avoid inducing seizures or delirium. Alprazolam, in particular, can produce severe dysphoria and psychotic-like symptoms if the drug is tapered too rapidly. The discontinuation of this medication should be accomplished over several months. Alternatively, one might switch to clonazepam (on a mg/mg basis), and then gradually discontinue the clonazepam.

Benzodiazepines can induce a number of side effects about which clinicians must educate their patients. Side effects include oversedation, confusion, memory loss, and disorientation, particularly when used with other CNS suppressants. Benzodiazepines have been shown to cause disequilibrium in older adults and increase the risk of falling and hip fractures; antidepressants and neuroleptics, however, are equally as dangerous in this regard.¹²² Benzodiazepines can also impair ventilation during sleep, which may worsen sleep-related breathing disorders such as chronic obstructive pulmonary disease, congestive heart failure, and sleep apnea.¹²³ Cognitive impairment may also be induced or exacerbated by these drugs.¹²⁴ Other problems include disinhibition (particularly in demented elders), impaired driving, and paradoxical agitation.

Antidepressants

Antidepressants are effective and safe treatments for anxiety disorders in older adults. When initiating therapy, we start patients on both antidepressants and benzodiazepines, gradually tapering off the benzodiazepine once the antidepressant has had a chance to take effect. This approach is particularly effective because of the heavy overlap between depressive and anxiety syndromes in later life.¹⁰⁵ We start patients on a low dose of an SSRI and gradually increase the dosage to adults over a period of weeks. All the new SSRIs are effective antianxiety agents if taken at an adequate dose for a sufficient period of time (6–8 weeks). Initially, however, these drugs may exacerbate the patient's symptoms, and therefore should be used concurrently with a benzodiazepine. We typically begin patients on clonazepam at a dose of 0.25 to 1.0 mg twice per day. An alternative to beginning an SSRI is to start 25 mg desipramine per day and increase by 25 mg every 4 days until a therapeutic serum level is achieved (>125 ng/ml). Regardless of antidepressant used, after 6 to 8 weeks, the clonazepam is gradually tapered off over a 4-week period.

Clomipramine, fluoxetine, and fluvoxamine are specifically indicated for obsessive-compulsive disorder. The side effects associated with clomipramine (orthostatic and anticholinergic effects), however, limit its use in the elderly. Fluoxetine, on the other hand, may be associated

with gastrointestinal symptoms that make it intolerable unless initiated at a very low dose (10 mg every other day) and gradually increased to 20 or 40 mg per day (if tolerated). Fluvoxamine may be the drug of first choice for older adults with symptoms of OCD. It is typically begun at 25 mg twice daily and increased up to a maximum of 100 mg three times per day as tolerated. Headache can be a problem if the dose is not gradually increased. Unfortunately, fluvoxamine is quite expensive at the doses needed to treat OCD.

Other Drugs

Other treatments for anxiety disorders include buspirone, beta-blockers, and sedating antihistamines. Buspirone is a serotonin agonist that has no cross-tolerance with the benzodiazepines. It has a slow onset of action, and initially may even exacerbate anxiety because of its activating effects. Buspirone is a safe drug to use over the long term given its lack of addictive potential and lack of psychomotor impairment, and it interacts with virtually no other medications. It is specifically indicated for generalized anxiety disorder. At least one study in elderly patients with chronic health problems has demonstrated a significant improvement of anxiety with this drug.¹²⁵ A major drawback is cost; the usual dosage of 10 mg three times per day costs about \$90 to \$180 per month, which may be prohibitive for some elders. Also, buspirone is rarely effective in patients who have taken benzodiazepines previously or have a history of substance abuse.

Beta-blockers are effective in blocking the autonomic symptoms that accompany anxiety (palpitations, sweating, trembling); they do not, however, affect the cognitive aspects of anxiety. Because of this, beta-blockers are not effective in panic disorder, because they do not diminish the psychologic anxiety associated with panic. Propranolol can be very helpful at doses from 10 mg twice a day to 40 mg three times per day in patients with social phobia, performance anxiety, or generalized anxiety disorder. Note, however, that beta-blockers have been associated with depression, and may exacerbate depression if present concurrently with anxiety; furthermore, there are a number of medical contraindications that limit its use in elderly patients.

Antihistamines are frequently used both over-the-counter and by prescription to reduce anxiety. In general, these drugs should not be used to treat anxiety disorders in older adults because of their anticholinergic, drying, and nonspecific sedative effects. Neuroleptics should only be used if anxiety is associated with psychotic symptoms.

Appendix

11-Item Abbreviated Duke Social Support Index (Self-Administered)

1. Other than members of your family, how many persons in this area within one hour's travel (of your home/from here) do you feel you can depend on or feel very close to?	<i>Number</i>

	None 00
[scoring 0 = 1, 1-2 = 2, >2 = 3]	
2. (Other than at work) How many times during the past week did you spend some time with someone who does not live with you, that is, you went to see them or they came to visit you, or you went out together?	
	None 00
	Once 01
	Twice 02
	Three times 03
	Four 04
	Five 05
	Six 06
	Seven or more 07

[scoring 0 = 1, 1-2 = 2, >2 = 3]

3. (Other than at work) How many times did you talk to someone—friends, relatives or others—on the telephone in the past week (either they called you, or you called them)?	None	00
	Once	01
	Twice	02
	Three times	03
	Four	04
	Five	05
	Six	06
	Seven or more	07

[scoring 0 or 1 = 1, 2-5 = 2, >5 = 3]

4. (Other than at work) About how often did you go to meetings of clubs, religious meetings, or other groups that you belong to in the past week?	None	00
	Once	01
	Twice	02
	Three times	03
	Four	04
	Five	05
	Six	06
	Seven or more	07

[scoring 0 or 1 = 1, 2-5 = 2, >5 = 3]

5. Does it seem that your family and friends (i.e., people who are important to you) understand you most of the time, some of the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3
6. Do you feel useful to your family and friends (i.e., people important to you) most of the time, some of the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3
7. Do you know what is going on with your family and friends most of the time, some of the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3
8. When you are talking with your family and friends, do you feel you are being listened to most of the time, some of the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3
9. Do you feel you have a definite role (place) in your family and among your friends most of the time, some of the the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3
10. Can you talk about your deepest problems with at least some of your family and friends most of the time, some of the the time, or hardly ever?	Hardly ever	1
	Some	2
	Most	3

11. How satisfied are you with the kinds of relationships you have with your family and friends—very dissatisfied, somewhat dissatisfied, or satisfied?

Very dissatisfied	1
Somewhat dissatisfied	2
Satisfied	3

If NO FAMILY OR FRIENDS: Would you say that you are very dissatisfied, somewhat dissatisfied, or satisfied with *not having* any of these relationships?

Brief Koenig Depression Scale

Please answer yes or no to the following statements/questions about how you have been feeling in the past week.

	<u>1</u>	<u>0</u>
1. I often became bored.	Yes	No
2. I often became restless and fidgety.	Yes	No
3. I felt in good spirits.	No	Yes
4. I felt I had more problems with memory than most.	Yes	No
5. I could concentrate easily when reading the papers.	No	Yes
6. I preferred to avoid social gatherings.	Yes	No
7. I felt downhearted and blue.	Yes	No
8. I felt happy most of the time.	No	Yes
9. I often felt helpless.	Yes	No
10. I felt worthless and ashamed about myself.	Yes	No
11. I often wish I were dead.	Yes	No

Scoring: Scores of 3 or higher suggest that further evaluation is necessary for the diagnosis of possible clinical depression. (*Source:* Koenig HG, Blumenthal J, Moore K. New version of brief depression scale. *J Am Geriatr Soc.* 1995;43:1447, with permission.)

Late-Life Psychosis

Steven C. Samuels and Deborah B. Marin

Five percent of community elders have paranoid delusions at any given time,¹ and 20% will develop a psychotic episode at some point in their lifetime.² Epidemiologic data are limited for late-life psychosis because aged subjects were not included or diagnostic criteria excluded late-onset cases. Females tend to develop psychosis at a later age of onset than males.³ Psychosis, defined as a delusion or a hallucination, is a symptom rather than a specific disease. A delusion is a fixed false belief, and a hallucination is a sensory perception devoid of any actual stimulus. In the elderly, psychosis is associated with significant morbidity and mortality and negatively affects the quality of life for the patient and caregiver. Patients with psychosis routinely present to health care providers at more advanced stages of disease. The presence of psychosis is associated with increased behavioral disturbance, risk of institutionalization, and health care costs.

The elderly patient with psychosis may have a broad range of diagnoses including delirium, dementia, affective disorders, schizophrenia, delusional disorder, general medical conditions, or substance use. Less common causes of psychosis in the elderly include posttraumatic stress disorder and brief reactive psychosis. Parkinson's disease, chronic obstructive pulmonary disease (COPD), and severe pain are examples of medical conditions that may be complicated by psychosis. Dopaminergic agents, anticholinergic drugs, opiates, and steroids are some of the medications that may cause these symptoms. Psychosis may be related to intoxication or withdrawal from prescription or over-the-counter drugs, herbal preparations, street drugs, and alcohol. Misuse of prescription and over-the-counter drugs is more common in the elderly than illicit drug abuse. Moreover, psychosis attributed to medical conditions or medication is more common in the aged than primary psychiatric causes of psychosis. The astute geriatrician is able to recognize psychosis, determine potential etiologies, initiate a diagnostic workup, and begin treatment. Consultation with a

geriatric psychiatrist may be helpful as the interaction between medical illness, brain disease and psychopathology is often complex in the patient with late-life psychosis. Table 80.1 lists the differential diagnosis of psychosis in late life. Common examples of medical conditions that have been associated with psychosis are listed in Table 80.2. Medications and substances associated with psychosis are listed in Table 80.3.

Sites of Care

The patient's treatment setting (inpatient, outpatient, home care, long-term care) may assist the clinician in determining the diagnosis and allocating the available resources when establishing a care plan. For example, in the acute medical, surgical, and intensive care units, psychosis is frequently seen in the context of a delirium. In any setting, a newly diagnosed psychosis should be viewed as a delirium until proven otherwise. The basic principles of delirium management are to determine and treat the underlying cause of the acute confusional state and maintain patient safety. This approach may require symptomatic management with judicious use of antipsychotic agents in combination with environmental modification and reorientation⁴ (also see Chapter 77). The reason for an acute admission may give significant clues as to the etiology of the psychosis. For example, a temporal relationship between the onset of the psychosis and initiation or change in a medical condition suggests that the medical condition may be aggravating or causing the psychosis.

The presentation of psychosis in the outpatient setting may falsely lead the clinician to view the psychosis as less serious than in the acute care setting. However, the acute presentation of psychosis in the ambulatory setting still obligates the clinician to consider a general medical condition or substance as potential contributors. The patient's psychoses may fluctuate in relationship to the

TABLE 80.2. Examples of medical conditions that are associated with psychosis.

Infections (e.g., urinary tract, meningitis, abscess)
Neoplasms (e.g., primary and metastatic, also paraneoplastic syndromes)
Endocrinopathies (e.g., diabetes, thyroid disease)
Traumatic injury (e.g., subdural; ophthalmologic injury)
Vasculopathies (e.g., CVA, vasculitis)
Degenerative diseases (e.g., Alzheimer’s disease, Parkinson’s disease)
Nutritional (e.g., vitamin deficiencies, malnutrition)
Severe pain
Special sense impairment (e.g., decreased acuity, prolonged isolation)
Cardiac disease (e.g., hypoperfusion, postcardiac surgery)
Pulmonary pathology (hypoxia, COPD)
Hepatic failure
Renal disease (e.g., uremia)
Hematologic (e.g., anemia, DIC)
Gastrointestinal (e.g., impaction, obstruction)
Autoimmune diseases

status of the primary psychiatric disorder, medical comorbidity, or medication change. In addition, environmental change, illness, or hospitalization of the caregiver, or non-adherence to medication are psychosocial factors that may contribute to psychosis. Another common scenario in the outpatient setting is the misuse of over-the-counter preparations including herbal remedies. These compounds may have problems with quality control and have significant potential for neuropsychiatric side effects such as psychosis.⁵

The home setting may be the primary site to find psychotic patients, yet it is often difficult for the clinician to make entry into the home. Often, the more severely psychotic patients will not voluntarily visit primary care physicians unless they have somatic delusions. Severely paranoid patients may refuse entry to any “strangers,” including home care workers. In the home care setting, psychosis is common and a significant predictor of disability.⁶⁻⁸ The reported rates of psychosis in the home setting may be artificially low, however, because the more severely psychotic patients may refuse to participate in the surveys that generate these data.

The physical state of a patient’s residence provides an exceptional opportunity to infer psychosis in patients who may otherwise go undiagnosed. For example, a severely paranoid patient may have “extra locks” on the door or may have altered the environment in such a way as to imply psychosis. Shades may be drawn, the phone disconnected, or the number changed. The patient who believes “my house is not my home” or “that man is not really my husband” or “someone stole my money” (when it was actually misplaced) are some common scenarios of demented patients with psychosis. In the context of a psychotic patient refusing evaluation, emergency psychiatric evaluation by a mobile crisis team or emergency room team may be necessary. The logistics of getting the patient evaluated are dependent on local ordinances. Most localities allow the patient’s individual liberty to be usurped by societal protection with the caveat that the judicial system must review the case. Psychotic patients who remain in the community may benefit from aggressive use of antipsychotic agents, as the presence of psychosis is a consistent predictor of institutionalization in elderly patients with dementia and psychosis.⁹

Long-term care facilities include nursing homes, assisted living facilities, adult homes, and state psychiatric hospitals. The prevalence of psychosis in the nursing home is approximately 10%,¹⁰ including patients with delirium, dementia with psychosis, or affective disorders with psychosis. The relatively high rate of psychopathology in the nursing home aged may result from the transfer of patients from the state psychiatric hospitals to nursing homes and the high percentage of dementia patients who reside in these settings.

Nursing homes are mandated by regulation to follow specific guidelines for assessment and documentation regarding antipsychotic medication use. Proper assessment requires quantifying and objectively identifying the symptoms that are being targeted with the antipsychotic agent. Center for Medicare & Medicaid Services (formerly Health Care Finance Administration) guidelines have been established to defined disruptive behaviors that will justify the use of antipsychotics in the nursing

home.^{11,12} The guidelines suggest objective documentation of symptoms, quantification of symptoms, persistence of symptoms, a search for a preventable cause, and that symptoms cause a danger to self or others. Other acceptable justifications for antipsychotic use per HCFA guidelines include psychosis that impairs function or causes distress, as continuous yelling, screaming, or pacing that result in functional impairment. Behavioral disturbance and psychosis in nursing home patients is episodic, tend to be mild, and do not worsen over time,¹³ suggesting that an empiric attempt at trials of or reduced doses of antipsychotics in these patients makes clinical sense. The HCFA guidelines have resulted in reduction of antipsychotic use in the nursing home.¹⁴

Adult homes and assisted living facilities are other long-term care facilities that provide less intensive nursing care than nursing homes. Private payment is the most common payment structure for assisted living, whereas nursing or adult homes are increasingly dependent on state-funded entitlements. Prevalence data for psychosis in assisted living facilities and adult homes are sparse, but the prevalence rates of psychosis in the adult home would be expected to be higher than the assisted living facility on the basis of patient mix. Psychosis associated with dementia or depression is expected to be the more common diagnosis in assisted living facilities, whereas severe and persistent mental illness (schizophrenia, schizoaffective disorder) is expected to be the more common diagnosis in the adult homes. One may hypothesize that residents of assisted living facilities have a relatively high functional level before admission compared with the adult home patient, who often has a diagnosis of schizophrenia or schizoaffective disorder. If the patient requires skilled nursing, they may receive care either in the nursing home or in a residence with constant nursing care.

State psychiatric hospital patients have severe functional impairment secondary to psychiatric illness and are unable to survive safely in the community. The "state hospitals" have dramatically decreased in size from a peak in the 1950s due to deinstitutionalization initiatives. The patients who remain are the "sickest of the sick," with prevalence rates of psychosis approaching 75%. Patients in these facilities often receive multiple antipsychotic agents and have relatively high rates of tardive dyskinesia and moderate to severe functional impairment.^{15,16} The poor prognosis for schizophrenic and schizoaffective patients who reside in the state hospitals is that they are at advanced risk of developing a progressive dementia after age 65. Risk factors for development of this dementia are low education and high rates of positive (psychosis) and negative symptoms (apathy, amotivation, withdrawal). The cognitive loss correlates with functional impairment and loss of ability to attend to activities of daily living.¹⁷⁻²¹

The following sections review psychosis associated with schizophrenia, dementia, and affective disorders in later life.

Schizophrenia

The community prevalence rates of schizophrenia in individuals over age 65 ranges from 0.1% to 0.5%,²² and incidence rates in those patients over age 60 years suggest an increase of 11% for each 5-year incremental age increase.²³ One model of differentiating elderly schizophrenic patients is based upon age at disease onset.²⁴ Late-onset schizophrenia is defined as onset over age 40 and very late onset schizophrenia is defined as onset over age 60. Late-onset schizophrenia is more likely than earlier age onset schizophrenia to present with visual or olfactory hallucinations, persecutory delusions, partition delusions (beliefs that others in a neighboring space are controlling the patient), third-person running commentary, and derogatory auditory hallucinations.^{25,26} Compared with earlier-onset schizophrenia, late-onset forms of schizophrenia are less likely to have formal thought disorder, negative symptoms, or soft neurologic signs.²⁵⁻²⁸ In contrast, late-onset disease is associated with a higher likelihood of organic causes and sensory impairment.²⁴ When the geriatrician is considering a diagnosis of schizophrenia in a patient, careful evaluation of cognition and neurologic status including the special senses is warranted.

The practicing geriatrician is likely to treat patients with schizophrenia. The notion that most elderly schizophrenic patients are institutionalized is a myth that probably results from the term dementia praecox used by Kraepelin. This term implied deterioration in cognition for the patients described, and later studies did not confirm this belief.²⁹ In fact, although most elderly schizophrenic patients have significant symptoms and functional disability, they do not demonstrate significant cognitive impairment or live in an institution.

Dementia

Psychosis may co-occur with several forms of dementia. Psychosis occurs in up to one-third of Alzheimer's disease (AD) patients at any given time^{30,31} and has also been associated with vascular dementia, Parkinson's disease, dementia with Lewy bodies, Pick's disease, prion-related dementia, substance-induced persisting dementia, and dementia secondary to medical conditions such as anoxia or head trauma.³²⁻³⁴

Psychosis in dementia needs to be differentiated from misidentification or confabulation. An example of misidentification is when a patient with dementia

believes that her reflection in the mirror is another person or that individuals in a picture hanging on a wall or on the television are “real.” In the first example, the patient may refuse to enter a room with these objects for fear of experiencing these events. Misidentification is best treated with nonpharmacologic interventions rather than antipsychotic medications. Removing the offending structure (mirror, wall hanging, or television) may be effective.

Confabulation is defined as making up an answer or explanation to compensate for deficits in cognition. Distinct from psychosis, confabulation is exemplified by the man who has misplaced his keys and now states “my wife stole them.” Misidentification and confabulation may be found in many of the dementia subtypes and appears to be most common in the early to middle stages of AD.

Similar to confabulation, psychosis is more common in the early to middle stages of AD. Although psychosis is a predictor of institutionalization, the intensity of an individual’s psychosis may vary. A patient who is neither a danger to themselves or others, nor significantly functionally impaired, may not require the more restrictive setting of an institution.

Psychosis and Alzheimer’s Disease

Patients with psychosis and Alzheimer’s disease (AD) have a more rapid rate of decline than those AD patients without psychosis.³⁵ The incidence of psychosis in AD ranges from 5% to 50%, depending on age and the population studied. Although the range of hallucinations and delusions overlaps, the mean rate of hallucinations appears to be less common than delusions.³⁶ In one large community sample of patients with probable AD, 22% had delusions, 3% had hallucinations, and 9% had both.³⁷ The patients with hallucinations had less education, increased stage and duration of dementia, and were more likely to be African-American. Hallucinations were associated with falls and anxiolytic use. Delusions were associated with increased age, antihypertensive use, depression, a more impaired health status, and aggression.

Compared to early- or middle-stage patients, the advanced-stage AD patients may be unable to report their psychosis. Behavioral disturbances in the advanced-stage patient may be related to psychosis, although instrumentation to measure psychosis in the advanced-stage AD patient is lacking. Agitation in advanced-stage patients may reflect pain, bladder outlet obstruction, fecal impaction, incontinence, hunger, feeling cold, or overstimulation. Identification of these unmet needs can help delineate the optimal pharmacologic and nonpharmacologic treatment approaches. For example, the advanced-stage AD patient who is in pain may benefit from an

empiric trial of analgesic, or the poorly nourished patient who may be hungry should be fed more frequently.

Psychosis in Parkinson’s Disease

Psychosis in the context of Parkinson’s disease (PD) poses special challenges. Although psychoses occur in 10% to 15% of PD patients, proper attribution of the psychosis to the PD or its treatment may be difficult. The subcortical circuitry that is dysfunctional in PD may also be responsible for the generation of psychotic symptoms in the disease.³⁸ Anticholinergic and dopaminergic agents, both utilized to treat PD, are notorious for causing psychosis.³⁹ Because conventional antipsychotic agents may worsen the motor symptoms of PD, atypical antipsychotics have become the choice for treating psychosis associated with PD. Clozaril is the best studied with a clinical trial supporting its use.^{40,41} A mean dosage of 25 mg clozaril was significantly better than placebo for drug-induced psychosis in PD. Parkinsonism was not worsened by the medication; in fact, tremor improved in the clozaril-treated group. Clozaril did not significantly change cognitive status during the 4 weeks of the study. Limitations of clozaril include the potential for agranulocytosis and the requirement for blood monitoring. Case reports have described the benefit of risperdal, olanzapine, and quetiapine for psychosis associated with PD, although the motor effects of these medications has not been predictable.^{42,43}

Psychosis and Dementia with Lewy Bodies

Much recent press has focused on dementia with Lewy bodies (DLB), with some suggesting that it is the second most common progressive degenerative dementia.⁴⁴ Psychosis has been associated with DLB and is one of the proposed core clinical features. Consensus groups have proposed clinical criteria that include parkinsonism, dementia, cognitive fluctuation, and visual hallucinations.^{44,45} We recently challenged the validity of these criteria.⁴⁶ Visual hallucinations may not be useful in differentiating DLB from other dementia subtypes.⁴⁷ In the DLB sample, as in PD, visual hallucinations may be related to medication use. For example, in our review of the DLB literature, 85% of those patients with visual hallucinations were receiving either dopaminergic or anticholinergic medication and 29% of those without visual hallucinations were receiving these medications.⁴⁶ Medications and over-the-counter preparations may be related to the psychosis in any elderly patient. The medication list should be carefully reviewed so nonessential medications may be decreased or eliminated.

Psychosis Associated with Vascular Dementia

Hallucinations occur in 1% to 10% of stroke patients and are most commonly associated with right-sided temporoparietal lesions, cerebral atrophy, seizures.⁴⁸⁻⁵⁰ Other neuroimaging studies suggest that vascular lesions may be important in the pathogenesis of late-life paranoid psychosis.⁵¹ Patients with vascular dementia may be more susceptible to adverse effects (including psychosis) from medications and to subtle changes in chronic medical conditions. Empirical evidence to support one pharmacologic agent over another is lacking for vascular dementia with psychosis. Our practice is the empiric use of atypical antipsychotics such as risperdal, olanzapine, and quetiapine.

Comparison of AD with Psychosis and Late-Life Schizophrenia

Jeste and Finkel recently compared AD with psychosis to late-life schizophrenia.⁵² Highlights of the comparison between these conditions revealed that the incidence of AD with psychosis (30%–50%) is much more frequent than the incidence of elderly schizophrenia (less than 1%). Bizarre and well-systematized delusions are rare in psychosis associated with AD whereas they occur frequently in late-life schizophrenia. Hallucinations are more commonly visual in AD and auditory in schizophrenia. Schneiderian first-rank symptoms such as thought insertion, thought broadcasting, or thought withdrawal are more common in schizophrenia than in AD. The misidentification of caregivers is frequent in AD but rare in schizophrenia. A past history of psychosis is very common in schizophrenia, yet rare in AD with psychosis. Psychosis usually remits as AD advances, compared with schizophrenia, where it usually persists. Therefore, the need for years of maintenance antipsychotic use is uncommon in AD with psychosis but common in schizophrenia. Active suicidal ideation is rare in AD with psychosis but present in up to half of schizophrenia patients. Approximately 10% of elderly schizophrenics complete suicide.⁵³

Delusional Disorder

Delusional disorder appears to be a distinct diagnostic entity from schizophrenia, schizoaffective disorder, bipolar disease, and dementia with psychosis. This disorder is characterized by nonbizarre delusions of at least 1-month duration. A nonbizarre delusion is a delusion that could happen in real life, such as being followed or loved from a distance. There are no controlled trials of

elderly patients with delusional disorder to aid in the management principles for these patients. If delusions are interfering with the patient's social, occupational, or other areas of functioning, we offer a trial of an atypical antipsychotic agent while attempting to build a therapeutic alliance.

Affective Disorders with Psychosis

Affective disorders with psychosis include major depression, bipolar disease, and schizoaffective disorder. Severely depressed patients with psychosis commonly have delusional themes about excessive guilt, being punished, or somatic problems. Manic patients often have grandiose delusions. Elderly patients are at increased risk for completing suicide compared with younger patients,⁵⁴ and psychosis is a risk factor for suicide completion.⁵³ Therefore, psychotic patients should be carefully assessed for suicidal intent and plan.

Patients with major depression and psychosis should be treated with antidepressants and antipsychotics. The specific antidepressant choice is beyond the scope of this chapter. Antidepressants with anticholinergic load or cardiotoxicity should be avoided in elderly patients. After the resolution of psychotic symptoms, the patient may be tapered off the antipsychotic, but should remain on the antidepressant for continuation and maintenance treatment. If the patient's psychosis reappears on removal of the antipsychotic, it may be necessary to continue the patient on an antipsychotic and attempt to reduce or remove this at a later date.

The atypical antipsychotic, olanzapine, has been approved as a stand-alone agent for acute mania but has not been studied in bipolar patients over age 65 for this indication.⁵⁵ Electroconvulsive therapy (ECT) is a very effective treatment alternative in elderly patients with affective disorders and psychosis. Although ECT suffers from stigma in the medical and lay communities, it is a safe alternative treatment for affective disorder with psychosis that offers the advantage of a more rapid rate of response than pharmacotherapy. Psychiatric evaluation will assist the patient and the clinician in determining the feasibility of ECT for a particular patient.⁵⁶

Specific Clinical Patterns with Aging

As patients age, the quantity and severity of medical comorbidities and medication use increase and adherence to treatment regimens may decrease. These complexities are compounded by the pharmacokinetic and pharmacodynamic changes that occur with age and the potential for drug–drug interactions.^{57,58} Brain changes that occur with aging may contribute to the development

or course of the disease associated with psychosis. Additionally, the aging brain may be more susceptible to additional environmental or biologic stressors. The combination of one or several of these factors may contribute to specific clinical patterns of psychosis seen with aging.

Pathogenesis

The pathogenesis of psychosis remains unclear. Theories abound, and there may be several final common pathways leading to psychosis. For example, neurochemical, *in vivo* imaging, and neuropathologic studies support the relationship between basal ganglia abnormalities and psychosis. Studies attempting to explain the pathophysiology of psychosis are limited by lack of uniformity in patient selection, clinical and neuropathologic diagnoses, psychotic rating methodology, medication and substance use, and medical comorbidity.

Approach to Differential Diagnosis

After the history and examination reveal the presence of hallucinations or delusions, the evaluation should focus on whether medical conditions, their treatments, or other substances (e.g., medications, toxins, over-the-counter preparations, herbal compounds) are contributing factors. The psychosis may also result from substance intoxication or withdrawal. The next step is to determine whether the active phase symptoms of schizophrenia are present, the duration of symptoms, and their relationship to mood symptoms. Figure 80.1 is a decision tree for the differential diagnosis of psychotic disorders based on the DSM-IV.⁵⁹

Treatment Approaches

Treatment for psychosis in late life involves some core principles. The newly diagnosed psychosis in a patient should be viewed as a potential delirium until proven otherwise. General medical conditions and offending substances should be sought as probable contributors. Management should focus on problem behaviors and functional status rather than on the severity or duration of the psychotic symptom *per se*. Goals of treatment should be realistically defined and reviewed with the patient and caregivers. Adequate time should be given to test whether an intervention is realizing the therapeutic goals set.

In general, the older patient with psychosis requires lower doses of antipsychotic medication compared with the younger patient, with some authors recommending a dosage 15% to 25% of that of a young schizophrenic

patient.⁵² Atypical antipsychotics appear to be preferential to conventional antipsychotic agents but are not free from potential adverse effects. Medication treatment in combination with psychological education, environmental manipulation, and behavioral modification appear to be the standard of care in treating elderly patients with psychosis.

Pharmacologic Agents

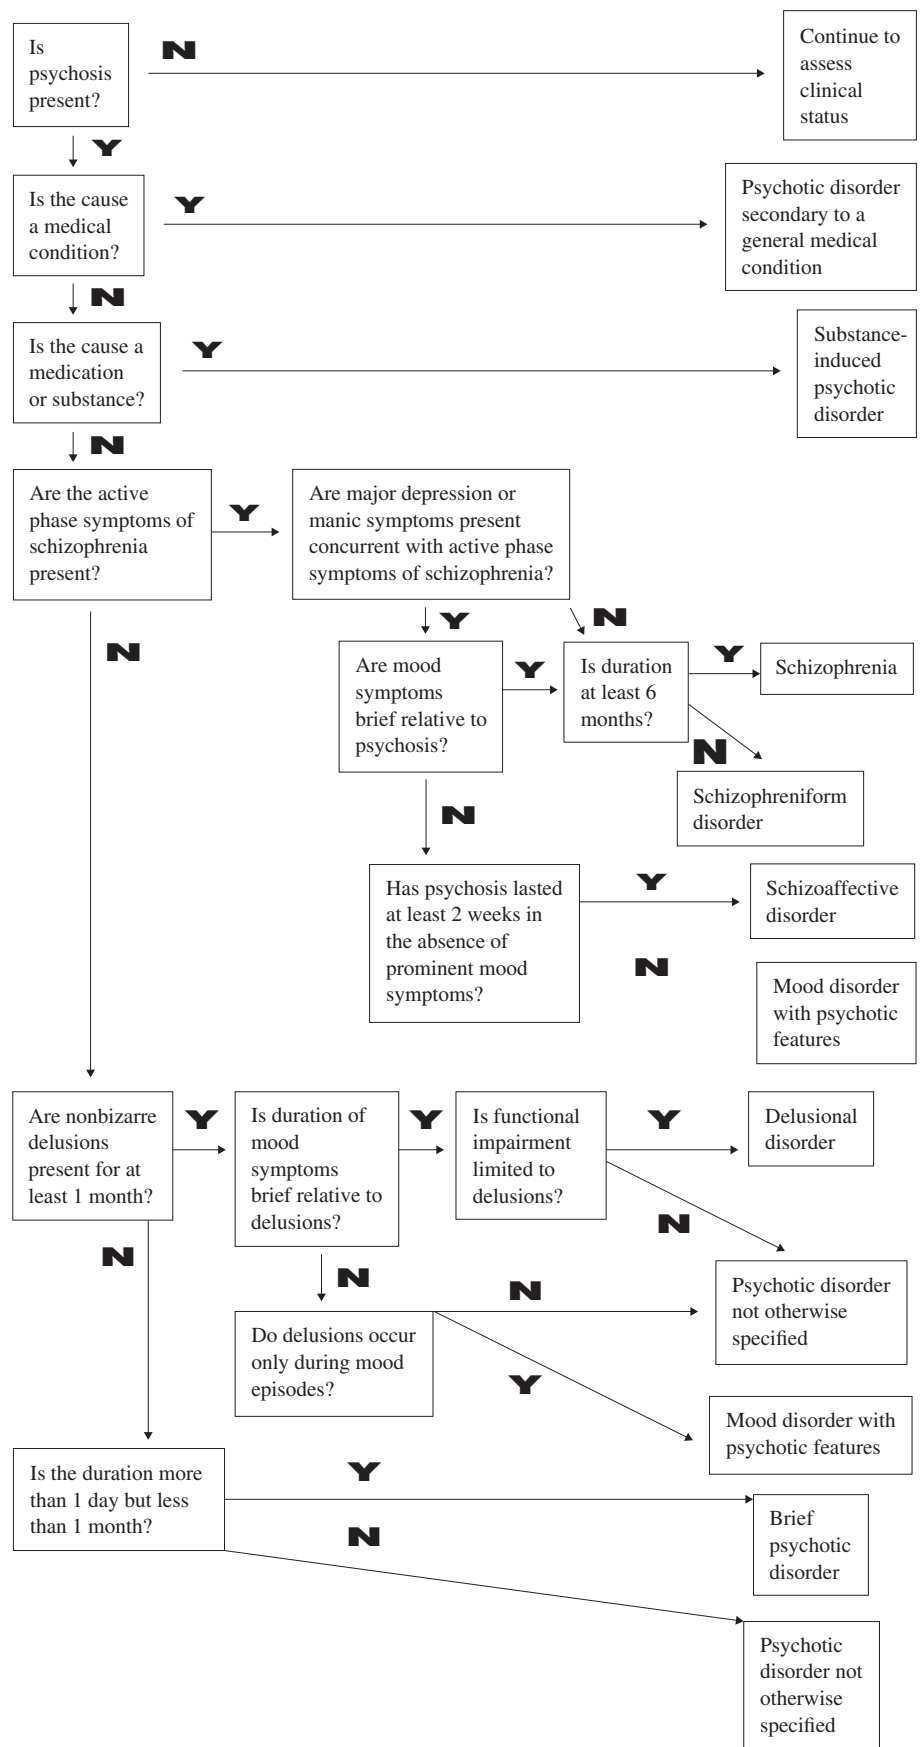

Traditional Antipsychotics: Do They Still Have a Role?

Haloperidol is the most commonly prescribed antipsychotic agent, and thioridazine is commonly prescribed for agitation because of its sedating effects. These “traditional” agents may no longer be the ideal choices for the management of psychosis in later life.

Cardiac conduction irregularities such as prolongation of QTC and polymorphic ventricular tachycardia (torsades de pointes) have been associated with intravenous haloperidol⁶⁰ and oral thioridazine.^{61,62} A recent “Dear Doctor” letter issued by the FDA and labeling changes in the product information warn of thioridazine’s adverse cardiac conduction profile. These is a black box warning label about the thioridazine’s dose-dependent risk of QTC prolongation and the recommendation that EKGs and serum potassium levels be obtained at baseline and periodically monitored.⁶³

The traditional antipsychotic agents have variable degrees of dopaminergic, alpha-adrenergic, anticholinergic, and histamine effects. The dopaminergic effects (primarily D₂ blockade) are presumed to result in the therapeutic effects and the extrapyramidal side effects such as tremor, bradykinesia, akathisia, rigidity, and dystonic reactions. The higher potency agents (e.g., haloperidol, fluphenazine) have relatively higher ratios of dopaminergic blockade to adrenergic, anticholinergic, and histaminic effects. The lower-potency agents have higher ratios of anticholinergic, histaminic, and adrenergic effects relative to dopaminergic effects. Adrenergic blockade increases the risk of orthostatic hypotension. The histaminic blockade results in sedation and weight gain. The peripheral and central anticholinergic effects may lead to dry mouth, blurry vision, urinary retention, constipation, and confusion. Aging-related brain changes and disease-related brain changes (e.g., from AD, PD, stroke) place elderly patients at increased risk of side effects from the traditional antipsychotic agents. In one metaanalysis of 16 double-blind controlled studies using conventional antipsychotics for dementia, 20% of patients had a significant side effect (i.e., sedation, orthostatic hypotension, or extrapyramidal effects).⁶⁴ The lower-potency agents should be avoided in elderly

FIGURE 80.1. Differential diagnosis of psychotic disorders. (Adapted from DSM IV.)

patients who are at increased risk of side effects from these agents.

A meta-analysis of antipsychotic agents used for inpatients with behavioral disturbance associated with dementia or other neurologic conditions demonstrated an effect size of 18%.⁶⁵ The placebo group had a 41% response rate and the treatment group had a response rate of 59%. The relatively high placebo response rate may have under-represented the true differences between groups. Other limitations of the study include heterogeneous groups, generalizability only to inpatients, and dated nature of the study as conventional agents were the only antipsychotics available. Despite their widespread use, there is not a substantial evidence base from which to recommend conventional antipsychotics for behavioral disturbance associated with dementia. One placebo-controlled cross-over study compared fixed low-dose haloperidol (0.5–0.75 mg/day) to standard dose haloperidol (2–3 mg/day) for 6 weeks in AD patients with psychosis.⁶⁶ Patients receiving standard doses of haloperidol performed superior to low-dose haloperidol or placebo, although there was increased extrapyramidal risk in the standard-dose haloperidol group.

Tardive Dyskinesia

Tardive dyskinesia (TD) is a significant problem in the elderly, leading to functional disability and social stigma. All antipsychotic agents, regardless of potency, carry the risk of tardive dyskinesia. Jeste et al. estimated the 12-month incidence of TD in patients over age 55 years to be 25%, the 2-year incidence to be 34%, and the 3-year cumulative incidence to be 53%.⁶⁷ Age, female gender, length of exposure to neuroleptic medication, and the presence of extrapyramidal signs appear to be significant risk factors for TD.^{66,68,69}

There was great hope that the introduction of atypical agents would reduce or eliminate the risk of TD from antipsychotic agents. Few studies have compared typical to atypical agents in the risk of TD. Jeste et al. compared haloperidol to risperidone in schizophrenic patients (mean dose, 1 mg/day for both agents) and found that TD was significantly more likely to occur with haloperidol than risperidone.⁶⁹ Case reports of TD associated with atypicals are in the literature.⁷⁰ Comparing long-term effects of atypical agents to typical ones is not practical because the atypicals have not been available to patients as long. Short-term incidence studies of TD reveal only part of the story. The short-term studies may reveal the development of mild to moderate TD, but moderate to severe TD may develop over the longer term, and the atypical agents have not yet been used long enough. Hence, longer-term studies of the atypical agents are required to determine the rates of side effect development for the atypical agents in the elderly.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a rare but life-threatening event that has been associated with both typical and atypical antipsychotic agents.⁷¹ Clinical evidence suggestive of the syndrome includes fever, rigidity, mental state changes, autonomic instability, elevated CPK, and previous administration of an antipsychotic agent. The prognosis from NMS is good, with most patients recovering within 2 weeks.⁷² Complications arise from prolonged fevers, electrolyte abnormalities, and hypoxia. Treatment for NMS is primarily supportive with conflicting evidence regarding the utility of dopaminergic agonists such as dantroline. The pathophysiology of NMS remains elusive.

Clozapine

Clozapine is primarily indicated for patients with schizophrenia who have not responded to two previous antipsychotic trials. The agent has increased D₂-receptor affinity and specificity for mesolimbic and mesocortical circuits. Agranulocytosis, a rare but fatal side effect from clozapine, is found more commonly in the older than younger patients.⁷³ The risk of agranulocytosis requires a weekly evaluation of white blood cell and neutrophil counts. The more common side effects from clozapine include sedation, hypersalivation, hypotension, constipation, sweating, nausea/vomiting, urinary incontinence, fever, tachycardia, and weight gain.⁷⁴ Discontinuation rate from side effects in elderly patients has approached 25% in some series.^{74,75} The emergence of side effects and discontinuation rate from the medication appear related to the rate of dose titration. Starting doses of 6.25 mg clozapine are recommended for elderly patients with slow titration rates (e.g., increase by 6.25 mg q 3–7 days). The doses needed for psychosis associated with dementia appear to be lower than that required for psychotic mood disorders, which are lower than the doses required for primary psychotic disorders.⁷⁶ The monitoring requirements for clozapine prevent its use as a first-line agent.

Risperidone

Risperidone is a 5-HTA receptor antagonist in addition to D₂ blocker. It has low histaminic, alpha-1-, and alpha-2-adrenergic effects. This altered mechanism of action may explain its wider therapeutic index compared with conventional antipsychotic agents. Although there are many case reports, open trials, and chart reviews on the effects of risperidone in the elderly,⁷⁷ there are only a few controlled double-blind studies with risperidone for agitation and psychosis in the elderly persons with dementia. In one 12-week study of 625 patients with dementia (73% Alzheimer, 15% vascular, and 12% mixed), risperidone

at 0.5, 1.0, and 2 mg each day was compared with placebo.⁷⁸ The dose of 1 mg per day was optimal for the treatment of psychosis and aggression in patients with dementia and behavioral disturbance. The most common side effects from risperidone included extrapyramidal side effects (EPS), peripheral edema, and somnolence. Hypotension has also been observed in the elderly. Although there was a dose response for therapeutic efficacy with risperidone (2 mg/day > 1 mg/day > 0.5 mg/day), the higher dose (2 mg/day) was associated with elevated dropout rates (42% versus 27% for placebo) from side effects such as EPS and falls.

In a pooled analysis of phase 3 data using risperidone in approximately 1000 demented elderly patients, EPS occurred in 9% of placebo-treated patients, 14% of risperidone-treated patients, and 24% of haloperidol-treated patients.⁷⁹ The same group found risperidone to be effective (and superior to haloperidol) in a 13-week trial of 344 patients with behavioral disturbance associated with dementia. The dosage of 1 mg/day was optimal in reducing the severity and frequency of aggression.⁸⁰ Taken together, the evidence for using risperidone for behavioral changes associated with dementia suggests an initial dosage of 0.25 to 0.5 mg per day titrated to 1 mg per day. The half-life of 20 h allows for once daily dosing. Risperidone is available in tablets, oral solution, and orally disintegrating tablets, which may facilitate administration to select elderly persons with dementia.

Olanzapine

Olanzapine is an antagonist of dopamine and serotonin and has affinity for histaminic, alpha-1-adrenergic, and M-1 muscarinic receptors.⁸¹ The incidence of parkinsonian side effects is less than 10%. Olanzapine is efficacious in treating both positive symptoms (hallucinations and delusions) and negative symptoms (amotivation, withdrawal, apathy) of schizophrenia. There are limited controlled data in elderly patients with delirium, affective disorder with psychosis, or psychosis associated with Parkinson's disease. The most common side effects associated with olanzapine are somnolence, dizziness, weight gain, and agitation. Other common side effects are constipation, rhinitis, dry mouth, and dyspepsia.

Approximately 10% of patients treated with olanzapine have increases in their ALT and GGT that are dose related and reverse after drug discontinuation. Dysarthria and decreased ADLs have been reported in a case series of four elderly patients who received 5 to 10 mg olanzapine. Their conditions improved after olanzapine was stopped.⁸² Dosing adjustments are not required for renal impairment or based solely on age. It appears that the combination of factors that decrease clearance of the drug, such as age, cigarette smoking, and gender, are necessary before a dosing reduction. Weight gain is a

significant problem associated with the use of olanzapine. Patients with a low body mass index are more likely to gain weight than those with high pretreatment body mass index.⁸³ One case series reported a mean gain of 10 kg in 7 months.⁸⁴ Increased blood sugar levels and triglyceride levels have also been associated with olanzapine. Olanzapine is 93% protein bound, primarily to alpha-1-glycoprotein and albumin. Time to peak concentration is 6 hours and the elimination half-life is 52 h in those over age 65 years. Careful monitoring is recommended in conjunction with drugs that prolong the QT interval. There have been no cases of agranulocytosis with olanzapine, although long-term use of this agent is limited.

Olanzapine has the potential to interact with other medications. For example, carbamazepine, rifampin, and omeprazole increase the clearance of olanzapine, necessitating dosage adjustments. Ciprofloxacin inhibits the metabolism of olanzapine, increasing the risk of toxicity when the two drugs are coadministered. When olanzapine is added to haloperidol (perhaps in the context of a planned substitution of agents), there appears to be an increased risk of parkinsonism,⁸⁵ possibly due to inhibition of cytochrome P-450-2D6 or increased D₂ blockade. Clozapine and olanzapine have not been directly compared in controlled clinical trials in the elderly. One recent study compared olanzapine (5, 10 or 15 mg) to placebo for agitation in AD.⁸⁶ Olanzapine was superior in measures of delusions, hallucinations and agitation as measured by the neuropsychiatric inventory (NPI). There was no significant difference in vital signs between the groups.

Quetiapine

Quetiapine, an atypical antipsychotic that is structurally similar to clozapine and olanzapine, has demonstrated efficacy for the positive and negative symptoms of schizophrenia. The agent has high affinity for serotonergic (5HT-2) and moderate affinity for dopaminergic (D₂) receptors, purportedly related to its relatively low potential for parkinsonism. Clinical trials have reported no difference in EPS severity between patients treated with quetiapine or placebo. The agent also has affinity for alpha-1-adrenergic and alpha-2-adrenergic and H₁ histaminic receptors but not muscarinic receptors. The most common side effects observed with quetiapine are dizziness, somnolence, constipation, postural hypotension, dry mouth, dyspepsia, and headache. Additional side effects include agitation, insomnia, tachycardia, and peripheral edema. The elimination half-life of quetiapine is 6 h, necessitating dosing two to three times per day. The peak concentration occurs 1.5 h after administration, and food increases absorption. The drug is 83% protein bound and hepatically metabolized with several active metabolites. Antipsychotic efficacy has been demonstrated in a dose

TABLE 80.4. Comparison of antipsychotic agents used in the elderly.

Drug name (chemical class)	D ₂ receptor antagonism	5HT _{2a} receptor antagonism	Anticholinergic effects	Orthostasis	Sedation	Parkinsonism	Effect of food on absorption
Clozapine (dibenzodiazepine)	Low	High	Very high	High	Very high	Rare	None
Risperidone (benzisoxazole)	High	High	Low	Moderate	Low	Low	None
Olanzapine (thienbenzodiazepine)	High	High	Low	Moderate	Moderate	Very low	None
Quetiapine dibenzothiazepine	Moderate rate	High	Very low	Moderate	Moderate	Rare	Increases
Haloperidol	High	None	Low	Low	Moderate	High	Decreases

range of 150 to 750 mg per day, and clinical trials for schizophrenia have shown effectiveness in dosages of 300 to 400 mg with a maximum dosage of 750 mg per day. Renal impairment does not necessitate dosage adjustment. In contrast, patients with hepatic impairment require a decrease in dosage.

Transient serum transaminasemia may require discontinuation of the agent. The levels normalize after medication discontinuation, and there are no reports of irreversible hepatic damage associated with quetiapine. Patients over age 65 have diminished clearance of quetiapine, and a reduction in dosage may be necessary. Patients who have predisposition to hypotension should have a slower titration schedule to a lower target dose. Leukopenia but not agranulocytosis has been reported with quetiapine. Weight gain of greater than 7% above baseline has occurred in one-quarter of patients.⁸⁷ A possible association between quetiapine and cataract formation necessitates ophthalmologic examination at initiation of therapy, shortly thereafter, and at 6 months.

Potential drug–drug interactions with erythromycin, fluconazole, phenytoin, and ketoconazole (increased quetiapine levels by P-450 3A4 inhibition) justify a reduction in quetiapine dosing. Close monitoring of international normalized ratio (INR) is required in patients taking warfarin with quetiapine. There are no published clinical trials specific to elderly patients comparing quetiapine to placebo. The response to quetiapine in published clinical trials has been variable; up to one-third of patients have dropped out from studies because of lack of efficacy, and sustained efficacy has been called into question.^{88–90} Case reports support the use of quetiapine for psychosis associated with Parkinson's disease

without worsening motor symptoms,⁴³ perhaps suggesting a therapeutic niche.

For agent comparisons, see Table 80.4.

Symptom Treatment in Addition to the Usual Management

Several additional approaches complement pharmacotherapy in the treatment of psychosis in later life. All medical conditions have the potential to aggravate psychosis in a direct or indirect manner. Focus on stabilizing and maintaining patient overall health with preventive screenings, thorough histories, and examinations should have a positive effect on reducing the severity and duration of psychosis in late life.

Treatments for medical problems pose another possible contributing factor. For example, a flare-up of a chronic condition or a new acute medical condition may lead to changes in the medication profile of a patient. The medications list should be frequently reviewed and the clinician should ask, “Are any of these medications nonessential?” An affirmation will lead to a medication adjustment that may substantially reduce the psychosis or even prevent its initiation.

Pragmatic nonpharmacologic approaches for psychosis may include cognitive behavioral approaches to minimize the effect of the psychosis on the patient's interpersonal relationships. For example, a patient may be “coached” to not spontaneously offer the content of a delusional system to others or use the technique of “thought stopping” to temporarily eliminate an internal psychotic

Hepatic metabolism	Protein binding	T _{1/2} (h)	Dosing	Dose/day (mg)	Weight gain	Cost/day	Other
Extensive	97%	8–12	Twice daily	50–900	High	500 mg \$22 brand \$14 generic	Agranulocytosis; decreased dose in elderly
Extensive P-450	88%	20–30	Once or twice daily	0.25–6	Low	2 mg \$3 brand	Decreased dose in elderly; prolactin increase
Weak P-450	93%	31	Once daily	5–20	Significant	10 mg \$8.50 brand	Decreased dose in elderly
Extensive P-450	83%	7	Twice daily	100–800	Moderate	600 mg \$13 brand	Decreased dose in elderly
Extensive P-450	90%	21	Once or twice daily	0.5–8	Low	3 mg 18 cents (generic)	Decreased dose in elderly; prolactin increase

stimuli. Other general health maintenance measures such as optimal nutrition and exercise regimens may also have benefit, although the evidence base is very limited. Education about late-life psychosis may improve patient adherence to prescribed treatment regimens and offer needed support to overwhelmed caregivers who are at increased risk of excess morbidity and mortality.

Mechanisms of Paying for Health Care*

Bruce C. Vladeck

Although they account for less than 13% of the population of the United States, persons 65 and older incur almost 40% of this nation's total health expenditures, because the burden of illness increases as people age and, on average, older Americans have better access to needed health services than any other age group. The overall levels of health care spending in the United States are so high, and the U.S. population so large, that this also means more money is spent on health care of older people in the United States than is spent on the health care of the entire population of any other nation in the world.¹ Yet the \$400 billion we are now spending annually on health services for older Americans still falls far short of providing older people with all the services they need and has clearly not produced a system of care that is entirely satisfactory either to patients or to physicians.

Older Americans are the only class of citizens of this country with an entitlement to universal health insurance, through Medicare. For all its virtues and undeniable successes, however, Medicare has some significant shortcomings, both as a health insurance mechanism and as a major source of financing for the health care delivery system. Thus, any examination of payment for health services for the elderly in America must address what Medicare does and how it does it, what it has accomplished, what it does not do, and the mechanisms that fill in some, but certainly not all, of the gaps. This chapter follows that sequence.

Medicare: Background Considerations

A logical place to begin a discussion of Medicare in a textbook on geriatrics is to acknowledge that an individual's 65th birthday generally tends to be without any particular clinical significance, although it has major

implications for health insurance coverage and often for health service arrangements. The significance of age 65 arises, in turn, from Medicare's roots in the Social Security system, from which it arose and to which it remains organically connected. The identification of 65 as "normal" retirement age arose, in turn, from the historical accident of its use in Germany's social insurance scheme implemented in the late nineteenth century, the progenitor of other national social insurance programs. Medicare Hospital Insurance, generally known as Part A, parallels Old Age and Survivors Insurance (what is generally called Social Security) in that it is a compulsory, universal social insurance program, financed by payroll taxes on all wage and salary earners (and a parallel tax on the self-employed), and paying benefits to anyone with a work history or, under differing circumstances depending on the particular program, their dependents or survivors (in the case of Medicare, that includes spouses or widows over age 65 and disabled minor children). Medicare also contains Part B, or Supplemental Medical Insurance, which legally is a purely voluntary insurance program, one-quarter of which is financed by monthly premiums paid by beneficiaries, the balance by general federal revenues. Medicare's connection to Social Security is also reflected in its coverage of roughly 5 million nonelderly disabled persons, who qualify because they receive Social Security Disability Income (SSDI) benefits and have passed the 2-year waiting period between SSDI eligibility and Medicare coverage.

What Medicare Covers—and Does Not Cover

As is widely recognized, Medicare provides health insurance for those services covered in a typical private health insurance package at the time Medicare was enacted in 1965. Due to fiscal constraint, those benefits have not

*Prepared with the assistance of Maureen Furletti, MHS

MEDICARE PART A (HOSPITAL INSURANCE) COVERED SERVICES	
COVERED SERVICES...	IN 2000, THE BENEFICIARY PAYS...
HOSPITAL STAYS: Semiprivate room, meals, general nursing and other hospital services and supplies.	For each benefit period, the beneficiary pays: <ul style="list-style-type: none"> • A total of \$776 for a hospital stay of 1-60 days. • \$194 per day for days 61-90 of a hospital stay. • \$388 per day for days 91-150. • All costs each day beyond 150 days.
SKILLED NURSING FACILITY (SNF) CARE: Semiprivate room, meals, skilled nursing and rehabilitative services, and other services and supplies.	For each benefit period, the beneficiary pays: <ul style="list-style-type: none"> • Nothing for the first 20 days. • Up to \$97 per day for days 21-100. • All costs beyond the 100th day in the benefit period.
HOME HEALTH CARE: Intermittent skilled nursing care, physical therapy, speech language pathology services, home health aide services, durable medical equipment and supplies, and other services.	<ul style="list-style-type: none"> • Nothing for home health care services. • 20% of approved amount for durable medical equipment.
HOSPICE CARE: Pain and management relief, and supportive services for the management of a terminal illness. Home care is provided. Also covers necessary inpatient care and a variety of services otherwise not covered by Medicare.	<ul style="list-style-type: none"> • Limited costs for outpatient drugs and inpatient respite care.
BLOOD: From a hospital or skilled nursing facility during a covered stay.	<ul style="list-style-type: none"> • For the first 3 pints.

MEDICARE PART B (MEDICAL INSURANCE) COVERED SERVICES	
COVERED SERVICES...	IN 2000, THE BENEFICIARY PAYS...
MEDICAL EXPENSES: Doctors' services, inpatient and outpatient medical and surgical services and supplies, physical, occupational and speech therapy, diagnostic tests, and durable medical equipment (DME).	<ul style="list-style-type: none"> • \$100 deductible (pay once per year). • 20% of approved amount after the deductible, except in the outpatient setting. • 50% for most outpatient mental health. • 20% of first \$1,500 for all physical therapy services and 20% of first \$1,500 for all occupational therapy services, and all charges thereafter. (Hospital outpatient therapy services do not count towards limit.)
CLINICAL LABORATORY SERVICE: Blood tests, urinalysis, and more.	<ul style="list-style-type: none"> • Nothing for services.
HOME HEALTH CARE: (for those beneficiaries who do not have Part A) Intermittent skilled care, home health aide services, DME and supplies, and other services.	<ul style="list-style-type: none"> • No less than 20% of the Medicare payment amount (after the deductible).
BLOOD: As an outpatient, or as part of a Part B covered service.	<ul style="list-style-type: none"> • For the first 3 pints plus 20% of approved amount for additional pints (after the deductible).
Part B also helps pay for: x-rays, speech language pathology services, artificial limbs, kidney dialysis and kidney transplants, some preventive services, some outpatient drugs, emergency care, limited chiropractic services, breast prostheses following a mastectomy, limited ambulance services, the services of practitioners	

been significantly improved since, although understanding of the medical needs of the elderly, patterns of medical care, the organization of the health system, and private insurance have all changed dramatically in that same period. Thus, although Medicare provides reasonably extensive coverage of acute inpatient hospitalization, for example, it provides essentially no coverage at all for most dental services, correction of refractive error, or hearing aids (Fig. 81.1). The fact that Medicare does not, with a few exceptions, cover outpatient prescription drugs is a problem of such magnitude in itself that it is discussed separately.

Because of these and other limitations on Medicare coverage, because there are such substantial deductibles and copayments, and because—like most private health insurance policies of the 1960s but hardly any today—there is no cap or limit on the total out-of-pocket expenses of beneficiaries, Medicare currently covers, on average, barely half the total medical care costs of its beneficiaries. Thus, essentially every Medicare beneficiary who can seeks some additional or supplemental form of insurance (Fig. 81.2).

Medicare beneficiaries can obtain supplemental coverage in one of four ways. The most fortunate have sup-

FIGURE 81.2. Type of supplemental health insurance held by Medicare beneficiaries, 1998. (Source: HCFA. Medicare 2000: 35 Years of Improving Americans' Health and Security, July 2000.)

plemental insurance provided as a retirement benefit by a former employer; in 1997, about a third of beneficiaries had such coverage, but that proportion is dwindling rapidly, as employers seek to cut back on retiree health benefits. Another 27% purchases individual supplemental or "Medigap" policies, the provisions of which are summarized in Figure 81.3. Although the characteristics of the Medigap market differ dramatically from one state to another, premiums for Medigap plans have been rising sharply in most of the nation in the past decade.

About 15% of Medicare beneficiaries have sufficiently low incomes to qualify for either full or partial coverage under Medicaid, the state-administered, federal-state health insurance program for the poor. About the same proportion of beneficiaries is enrolled in Medicare managed care plans, which are permitted considerable freedom in establishing their own premiums, copayments, and deductibles, but which universally have lower out-of-pocket expenses than "traditional" fee-for-service Medicare. Approximately 12% of beneficiaries, or some 4.5 million individuals, are left with Medicare coverage only. Those "Medicare-only" beneficiaries are highly concentrated in the income range just above Medicaid eligibility and tend to have the highest out-of-pocket costs even though their incomes are relatively limited.

In general, the costs of supplemental insurance, in addition to the costs of all those services that are covered neither by Medicare nor by supplemental policies, leaves a significant burden of out-of-pocket expense. The median elderly household spends slightly more than 20% of its income on out-of-pocket health expenses, and even

the most affluent beneficiaries, those in the upper 4% of the income distribution, spend roughly the same proportion of their income on out-of-pocket health costs as the median nonelderly family (Fig. 81.4).

Effects of Medicare

The dramatic improvements in life expectancy, health status, and quality of life among elderly Americans in the past three decades are the result of multiple, interactive factors. Improvements in medical knowledge and technology, in the training and expertise of physicians and other health professionals, and in incomes, education, and nutrition among both the elderly and nonelderly have all played a part. But Medicare has played an independent role as well. Before the enactment of Medicare, persons over the age of 65 actually used fewer hospital and physician services than younger people, despite their greater burden of illness; now, of course, they use substantially more. People 65 and over are now much more likely to have a usual source of medical care—and much less likely to have to rely on clinics or emergency rooms—than other age groups in the population.² Also, many medical advances that have helped transform the practice of medical care for the elderly, such as joint replacement, angioplasty, and the use of lasers in ophthalmic surgery, required significant financial investments by hospitals and physicians that were in turn financed, at least in part, by the availability of Medicare reimbursements for the services.

A coinsurance, coverage for 365 additional days during lifetime after Medicare benefits end, payment of Part B coinsurance (generally 20% of Medicare-approved expenses), and coverage of the first three pints of blood.

One of the more interesting attempts to identify the causes of improved health among America's elderly was that of Manton and Vaupel, who noted that the United States had historically done quite poorly on international comparisons of life expectancy, determined from birth or early adulthood, but seemed to catch up as people aged. Using data from five countries with excellent longevity

statistics, they then found that, measured from age 80, the United States had the longest life expectancy. They attributed this finding to greater relative and absolute access to medical care for older Americans than their counterparts in other countries, a phenomenon they attributed in part to Medicare policies.³

FIGURE 81.4. Elderly health spending as a percentage of income, 1998. (Source: HCFA. Medicare 2000: 35 Years of Improving Americans' Health and Security, July 2000.)

Medicare and Providers

Medicare is not only a critical force in the life of its beneficiaries, providing them with their major vehicle of access to medical care, it is also a critical force in the professional life of most providers of medical care in the United States. It is the single largest source of revenue for most American hospitals, home care agencies, clinical laboratories, durable medical equipment suppliers, and practitioners in many medical specialties, including of course, internal medicine and geriatrics, and a significant source of revenue for other physicians, many nursing homes, and other health care organizations as well. Medicare's facility and operational standards, data and reporting requirements, and quality-of-care measures are pervasive not only because of Medicare's importance in itself but because other insurers and public agencies often rely on or defer to them.

Because so much money is involved, and because it is believed that provider behavior and beneficiary access to care are affected not only by the absolute level of payment but also by what is paid for and how it is paid, the mechanisms of Medicare payment receive considerable attention from providers themselves, policy makers, academics, and policy analysts. Medicare's principal payment systems are summarized in Figure 81.5.

The mores of politics essentially require every provider group to insist that its level of payment is woefully inadequate. There is probably no platonically correct level in any event, but where data are available, they permit drawing the following conclusions. Since the Prospective Payment System was adopted in 1993, on average general hospitals have been paid more than their costs for treating Medicare patients, although private insurers frequently paid an even larger premium over costs;⁴ before the Balanced Budget Act of 1997, most skilled nursing facilities and home care agencies prospered under Medicare payment arrangements; many have lost money since, although their finances appeared to have stabilized by calendar year 2000;⁵ specialty psychiatric and rehabilitation facilities have also done reasonably well; and the provision of clinical laboratory and durable medical equipment services to Medicare has been an extremely profitable business. As for physicians, Medicare has traditionally paid less than private insurers, but the ratio of Medicare payments to average private payments rose rather dramatically during the latter half of the 1990s, more because private payers squeezed their payments than because of Medicare increases. The Physician Fee Schedule was implemented for Medicare in 1992, with the principal objective of shifting a substantial share of Medicare physician payments away from surgery and procedure-intensive specialty care toward more generalist, "cognitive" services. There has been some reallocation of physician spending as a result, but perhaps less than

family practitioners, general internists, and geriatricians might have hoped, at least in part because of the inadequacies of the coding/categorization system for Medicare evaluation and management services and the political skills of procedure-oriented specialists.⁶ Roughly half of all the physician services for which Medicare pays fall into the fivefold classification of "Evaluation and Management," yet that system fails to adequately capture or describe the full range of noninterventional physician services.⁷

Medicare Managed Care

In the 1990s, when the growth of managed care arrangements dominated the private health insurance sector in the United States, much attention was paid to the relatively smaller role managed care plans continued to occupy in the Medicare program. In fact, health maintenance organizations (HMOs) had been included in Medicare since the program's inception, as traditional prepaid group practices (the term HMO was not even invented until the early 1970s) such as Kaiser-Permanente and Group Health of Puget Sound. These programs were permitted to retain enrollees who had been members before retirement and were paid on a cost-reimbursement method, at a time when cost reimbursement was the dominant mode of payment for all Medicare providers. Beginning in 1985, Medicare began to pay HMOs on a full-risk basis; that is, a flat capitated monthly rate was established by formula for every county in the United States by a formula that, in principle, established the equivalent of 95% of per beneficiary costs in the conventional fee-for-service program. HMOs that were able to provide the basic Medicare benefit package at lower cost were given the option of returning the excess to the government (an option that was never exercised), establishing a stabilization fund, or providing additional benefits—the option that was most widely chosen. Beneficiaries retained the option of enrolling or disenrolling from HMOs at will, thus making it necessary for the plans to offer significant additional benefits to get beneficiaries to forsake free choice of providers and agree to having their access to care "managed."

Medicare enrollments in HMOs grew from roughly 1 million, at the time risk contracting was introduced, to more than 6 million by 1997, although that growth was characterized by peaks and valleys rather than a steady increment. Medicare managed care was highly concentrated in a few areas of the country, notably the West Coast, which has always had higher levels of managed care enrollments since the creation of Kaiser-Permanente during World War II, and south Florida, which has long been characterized by extremely high fee-for-service

FIGURE 81.5. Medicare payment systems. (Sources: Medpac June 2000 Report to Congress; Ways and Means 1998; Green Book; Medicare Explained 1999; and conversations with HCFA staff.) ¹In 1998, Medicare payment to cost ratios for inpatient and outpatient hospital services was 102.6%. Private payers payment to cost ratio was 113.6% for hospital services in 1998.

(Source: Medpac Report to Congress, June 2000.) ²Until their PPS implementation dates, rehabilitation and psychiatric hospitals are paid on a reasonable cost basis within TEFRA limits. ³Until implementation of PPS in October 2000, home health agencies receive payment under a cost-based reimbursement system, referred to as the interim payment system.

costs. Extensive study of Medicare managed care plans during this period revealed that they did indeed use fewer days of inpatient hospitalization and more office visits than were typical in fee-for-service arrangements, and that they provided an overall quality of care comparable or in some cases superior to that prevailing in the fee-for-service community in the same areas, but that they probably undersupplied services to the sickest and most chronically ill enrollees.⁸ Surveys of beneficiaries showed that the overwhelming proportion of Medicare managed care beneficiaries were highly satisfied with their plans—not a surprising finding when one remembers that dissatisfied beneficiaries were always free to disenroll at will—but the great majority of those not enrolled in HMOs did not want to be—hardly a surprising finding either.⁹

For a growing share of for-profit HMOs, Medicare managed care proved a profitable venture because, although payment was set at 95% of the average costs for fee-for-service enrollees, the HMOs almost invariably enrolled relatively healthier beneficiaries. Some of this risk selection resulted from carefully designed marketing strategies of the HMOs (so-called “cherry-picking”), but most of the phenomenon was attributable to the fact that beneficiaries with the greatest burden of chronic illness were more likely to have established relationships with particular physicians or hospitals who may not have participated in particular HMOs, while restrictions of freedom of provider choice were most acceptable to beneficiaries without established physician relationships, especially those who had recently relocated to retirement areas in Florida, Arizona, or California.¹⁰

The Balanced Budget Act of 1997 sought to achieve a substantial expansion of Medicare managed care enrollment by creating a new Medicare Part C for capitated plans (renamed “Medicare + Choice”), expanding the types of managed care plans that would be eligible to enroll beneficiaries and receive capitated payments, and establishing an annual open enrollment period with extensive concomitant beneficiary education. At the same time, however, the U.S. Congress fiddled with the payment formula for Medicare + Choice plans to eliminate some of the windfalls from risk selection, to reduce some of the geographic inequities that arose from discrepancies in fee-for-service costs across communities, and to provide incentives for plans to enter more rural communities. The net result was a significant constraint on increases in payment rates in most metropolitan areas that already had considerable Medicare managed care enrollment. Combined with difficult times for the HMO industry in its private business, rapidly rising pharmaceutical costs, and a continuing inability among the plans to effectively manage utilization, this led to a substantial contraction, rather than expansion, of Medicare managed care (Fig. 81.6).

Medicare: Long-Term Financing Issues

During the 1990s, the long-term financing of Medicare became a major political issue. There were several reasons: preoccupation of political leadership with federal budget deficits at a time when Medicare accounted for roughly 10% of the total budget and was the most rapidly growing component; growing recognition of the longer-term implications for Medicare and Social Security financing of the aging of the “baby boom” generation, reinforced by a well-organized and well-financed campaign to convince policy elites and the general public of the existence of a serious impending “entitlements crisis” that required an immediate scaling-back of the national commitment to income support and health insurance programs; and the very rapid rate of increase in Medicare costs in the first 6 years of the 1990s. Most concretely, and most immediately, the Hospital Insurance Trust Fund appeared to be about to run out of money. In the spring of 1997, it was projected that the Fund would be insolvent by 2001 unless major policy changes were undertaken.¹¹

The Balanced Budget Act of 1997 reduced future Medicare expenditures by more than \$200 billion (although at the time it was enacted it was projected to save only half that much) and created a National Bipartisan Commission on the Future of Medicare to address the long-term financing problems and report back to the Congress. In the period immediately following enactment of the Balanced Budget Act, Medicare expenditures actually fell for the first prolonged period in the program’s history. These reductions caused considerable turmoil and financial stress for many nursing homes, teaching hospitals, and especially home health agencies.¹² However, the savings achieved by the Balanced Budget Act and other administrative initiatives, and, more importantly, the enormous economic boom of the late 1990s to which the Balanced Budget Act is believed to have contributed, have combined to dramatically improve the long-term financial prospects of Medicare. By the spring of 2000, the Hospital Insurance Trust Fund was projected to remain solvent for another 25 years, and the financial well-being of the program continued to improve throughout the year.¹³

Thanks in small part to the very rapidity with which Medicare’s financial circumstances changed after the Balanced Budget Act was enacted, and in much larger part to serious ideological and philosophical divisions among its members, the National Bipartisan Commission was unable to reach any agreement and issued no report. The recommendations of its cochairmen, however, have subsequently become the basis for further discussions of Medicare “reform” in the early years of the twenty-first century. That “reform,” supported by many conservatives who favor a smaller role for government progress, would

transform Medicare from a defined-benefit, government-operated insurance program to one in which the government annually made a defined contribution toward purchase of a private health plan, with the size of that contribution determined by a bidding process. If private plans offered prices lower than Medicare’s current costs, premiums for “traditional” Medicare would increase. Under such a system, the government’s contribution to Medicare coverage for any given beneficiary would be determined not by the costs of the services that beneficiary actually consumed, but by some fraction of the average price bid by private insurance plans. Beneficiaries would either have to opt to enroll in low-cost plans, which would likely have very restrictive provider networks or utilization limitations, or pay higher out-of-pocket premiums to maintain their current coverage. There are many practical and conceptual, as well as philosophical, objections to such a scheme, but in the current political environment its adoption remains a possibility.¹⁴

What Medicare Does Not Cover: Prescription Drugs

When Medicare was enacted in 1965, outpatient prescription drugs played a much smaller role in medical therapeutics than they do today, and they were much less expensive. As a result, most private insurance plans offered limited, if any, coverage for pharmacy, and the failure to include a pharmacy benefit in Medicare was hardly noted. By now, however, the absence of prescription drug coverage in Medicare has become a real crisis. Total spending on prescription drugs for Medicare beneficiaries now averages roughly \$1000 per year.¹⁵ Two-thirds of beneficiaries have at least some insurance coverage for prescription drugs through employer-sponsored or individual Medicare supplemental policies, through Medicaid, or through HMO enrollment, but few of those policies cover the full cost of pharmaceuticals,

FIGURE 81.7. Distribution of Medicare beneficiaries by drug coverage status and source of coverage, 1996. (Source: Davis M, Poisal J, Chulis G, Zarabozo C, Cooper B. Prescription drug coverage, utilization, and spending among Medicare beneficiaries. *Health Affairs*. 1999;18(1)231-243, with permission.)

and thus more than 40% of those expenditures come directly out of pocket. Perhaps more importantly, there is very strong evidence that, although beneficiaries who lack insurance coverage for prescription drugs have poorer health status than those with coverage, they obtain significantly fewer prescriptions—almost 25% fewer. Absence of coverage is thus a significant barrier to access to needed pharmaceuticals, especially among low- and moderate-income beneficiaries (Fig. 81.7).

As of this writing, proposals to provide prescription drug coverage to Medicare beneficiaries are the subject of heated political discussion, but it is not clear what policies will emerge from that process.

What Medicare Does Not Cover: Long-Term Care

As significant as the problem of prescription drug coverage is for many Medicare beneficiaries, the single largest share of out-of-pocket expenditures is attributable not to drugs but to long-term care. Medicare does provide some coverage for skilled nursing facility services, and rather more expansive coverage for home health care, but both were clearly intended to apply only to limited, short-term, postacute episodes, and although a considerable loosening in the definitions of the home health benefit in the 1990s permitted its application to a growing share of real long-term cases, that loosening was largely ended by the Balanced Budget Act (Fig. 81.8).

At any given time, about 4% of all Americans 65 and older reside in nursing homes, but Medicare pays less than 10% of the total costs of nursing home care. Some relatively affluent patients, or those with affluent families, pay for nursing home services entirely from private resources, but for the great majority of nursing home patients, Medicaid is the primary source of financing. Medicaid currently pays for just under half of all national nursing home expenses, but that figure is misleading, for two reasons. First, Medicaid, which by law is always a payor of last resort, pays nursing homes only the *difference* between the approved Medicaid rate for nursing home care and the beneficiary’s contribution, generally defined as the person’s entire income less \$32.50 per month for a “personal needs” allowance. The beneficiary contribution, which generally consists of a monthly Social Security check, is considered “private” expenditure in the National Health Accounts. Second, many long-stay nursing home residents attain Medicaid eligibility only after having exhausted their private resources in the first part of their nursing home stay; nursing homes are thus free to charge particularly high prices to “private” patients, with the perverse effect that that accelerates their spending down to Medicaid eligibility.

Since policy analysts first recognized, some 20 years ago, that Medicaid, which was originally thought of primarily as health insurance for low-income children and their mothers, was spending the lion’s share of its money on nursing home care for frail seniors, many of whom had become poor only as a result of their need for long-term care, there has been widespread recognition that *something* should be done to rationalize the financing of long-term care services, especially as the population continues to age and the number of people in their late seventies and

FIGURE 81.8. Long-Term Care Financing, 1998. (Source: Graves TN, Kassner E, Mullen F, Coleman B. Long term care fact sheet. Washington, DC: AARP Public Policy Institute; 2000.)

eighties living alone—the population most at risk for needing long-term care services—continued inexorably to increase. But, although there has been a considerable shift in patterns of formal long-term care services away from institutions and toward community-based care, neither the division of responsibility for financing those services nor the intellectual framework within which one could fully reconstitute those financing patterns has changed very much. Solving the problem of financing long-term care thus remains very much a long-term problem.

Medicare's Safety Net

Although Medicaid pays for the greatest share of nursing home costs for the elderly, its role in assisting other Medicare beneficiaries should not be overlooked. Of the 6 million people who are dually eligible for Medicare and Medicaid, perhaps a quarter are receiving formal long-term care services. For the rest, Medicaid is an essential supplemental insurer, covering not only the copayments and deductibles for Medicare, but also those services for which Medicare does not pay at all, including outpatient prescription drugs, dental, vision, and hearing services and medically necessary transportation. Because of the way most states maintain their Medicaid data, it is almost impossible to tell how spending on behalf of dually eligible beneficiaries is allocated between long-term care and acute services, but given the interrelationships among age, poverty, and ill health, it is reasonable to assume that the community-dwelling dual eligibles are relatively high users of acute care services—as are individuals in the long-term care system.

The rules for achieving Medicaid eligibility are bewilderingly complex and vary considerably from one state to another. The relevant point is that, although almost all individuals legally entitled to Medicare have either enrolled or consciously chosen not to, many individuals, including many Medicare beneficiaries, who are legally entitled to Medicaid benefits are not enrolled. Reasons for failure to utilize Medicaid benefits include lack of awareness, the rigors of the enrollment process, and difficulties meeting documentation and other requirements associated with enrollment or because state eligibility officials, themselves confused, fail to enroll individuals who in fact are eligible. Medicaid is thus a very effective safety net for those it catches, but many still fall through the holes.

Conclusions

America's elderly are the beneficiaries of enormous public expenditures for their health care, which has produced, on average, a level of access to modern, high-

technology care unparalleled in the world. At the same time, elderly persons in the United States remain more at risk for crippling out-of-pocket medical expenses or the inability to obtain access to needed care for financial reasons than their counterparts in other industrial nations. The United States spends so much on health care for its elderly because its services are so expensive, not because its public programs are especially generous in design or philosophy.

Within the next 30 years, the number of persons 65 and older in the United States, who are thereby eligible for Medicare, will double. Assuming that health care costs continue to grow more rapidly than general inflation, that means that the real costs of supporting the Medicare program, even as currently defined, may triple. During the same time, the costs of health services that Medicare does not cover, such as outpatient prescription drugs, can be expected to increase even more rapidly than other health care costs. One is reminded of the old joke concerning the review of a bad restaurant: there are only two problems—the food is lousy and the portions are too small. For Medicare, the benefit package is woefully inadequate, but maintaining only those benefits will be increasingly expensive in the years to come.

On the other hand, all those people 65 and over are going to be here 30 years from now, regardless of how Medicare is constituted or whether it exists at all. One can assume, at least for purposes of discussion, that ours will continue to be a society that is generous and socially concerned enough to be unwilling to deny needed health services to elderly people who could benefit from them. Someone, in other words, is going to have to pay. The only real question is who.

Policy debates about the long-term direction and configuration of Medicare touch on many putative subjects, and take many different forms, but the central underlying question is how responsibility for the costs of medical care for the elderly are to be shared. If one believes that the elderly are already bearing an excessive share of their medical costs (especially when compared to younger, more affluent groups in society), then one set of future directions for Medicare is implied. However, that does not appear to be a view that currently controls the commanding heights of the American political debate. Whatever the outcome, the future of Medicare is ultimately and essentially a political question, and the outcome will be politically determined.

Justice and the Allocation of Health Care Resources

Nancy S. Jecker

There is growing concern in the United States, and in many other developed nations, that health care expenditures are too high and are growing too rapidly. Between 1950 and 1990, U.S. health expenditures grew 3% per annum, faster than expenditures for other goods and services. Economists forecast that if health spending in the United States continues to outpace other areas of the economy at this rate, by 2030 health care will consume almost one-third of the gross national product.¹

One of several factors responsible for increasing health care costs is the changing demographics of populations in most developed countries. Since 1900, the proportion of older people relative to younger people has increased, and demographers predict that this trend will continue well into the twenty-first century. An aging population significantly affects health care costs because elderly individuals, as a group, consume health care at higher levels than other age groups. In the United States, persons 65 and over account for approximately 12% of the population, but they use one-third of the nation's total personal health care expenditures (exclusive of research costs).² If present levels of disability remain stable, future spending increases will occur primarily in the areas of chronic, supportive care needed by frail and disabled elderly persons.³ Although it is sometimes assumed that the high cost of caring for the elderly is due to an "excessive" use of high-technology services at the end of life, recent studies cast doubt on this assumption.⁴

As efforts to reduce health care expenditures are implemented, the impact on patients and physicians is becoming more apparent. Increasingly, physicians must attempt to balance the twin goals of providing the best possible care for patients while simultaneously limiting the use of costly tests and procedures.^{5,6} Rationing, often thought to be an inevitable feature of future reforms, is being discussed with growing frequency.

This chapter addresses the general problem of justice in the allocation of scarce health care resources. It looks first at the question of current health care allocation and

asks, "According to what criteria are scarce health care resources currently distributed?" Next, it explores proposals for more justly distributing health care resources. The chapter closes by relating decisions about allocating health care to the more general goal of establishing a just society.

De Facto Rationing

Health care rationing refers to the denial of beneficial health care under conditions of fiscal or resource scarcity. Although it is often assumed that rationing is a problem looming in the future, in fact, in the United States, health care is already rationed in many unplanned and informal ways.

Poor and Uninsured Populations

First and foremost, rationing of care occurs for patients who are poor or uninsured. Thus, patients who lack access to mainstream providers often receive health care through an emergency department.⁷ There, physicians may be encouraged, for purely economic reasons, either to treat those who have an undesirable reimbursement status as outpatients or to transfer such patients to public hospitals. These policies and other factors place patients without health insurance at greater risk for suffering medical injury due to delayed diagnosis or treatment or otherwise substandard medical care.⁸ Such factors may also help to explain why the poor and poorly educated die at higher rates than those with higher incomes or better education.^{9,10} Unplanned rationing also takes place when long waits at emergency departments cause persons in need of urgent care to leave without receiving care.¹¹⁻¹⁴ In a recent survey of 277 public and private hospitals, 38% reported that overcrowding sometimes required holding admitted patients in the emergency department for 24 h or longer until beds in appropriate care units

became available. Among responding hospitals, 40% acknowledge diverting ambulances to other hospitals for reasons of overcrowding.¹⁵

Geographic Variations in Utilization of Health Care Resources

In addition to de facto rationing based on ability to pay for care, unplanned rationing also may occur on the basis of geographic location. Wennberg demonstrates substantial geographic variations in utilization of health care resources, primarily related to differences in the capacity of the local health care system and the practice style of local physicians.¹⁶ For example, capacity influences the intensity of terminal care for Medicare enrollees, with residents of areas with high per capita supplies of acute care beds more likely to die as inpatients in hospitals and more likely to be admitted to intensive care units during their last 6 months of life.¹⁷ Although it is commonly assumed that geographic variations occur as a result of physicians failing to conform their practice to standards of scientific medicine, this assumption is not borne out. Geographic variations are equally present in communities served primarily by academic medical centers. For example, populations living in Boston and New Haven, served by some of the nation's most distinguished teaching hospitals, utilize strikingly different per capita amounts of hospital care, despite remarkable similarities in demographic features and other factors that predict the need for care.¹⁸ For several decades, the per capita amount of care provided to residents of Boston has been about 60% higher than the per capita amount provided to residents of New Haven. These differences are driven by Boston's relatively greater per capita supplies of hospital beds. These findings reinforce the notion that capacity, not medical science, drives the rate of hospitalization.

The phenomenon of geographical variation does not necessarily demonstrate that health care is rationed to patients who reside in geographic areas where medical resources and personnel are less abundant. This disparity occurs because "rationing" does not simply mean reduced access; instead, it implies reduced access to *beneficial* treatments. There is no evidence to suggest, however, that more intensive medical treatments always yield benefits for patients. As Wennberg noted, "There is no scientific evidence that more is always better. There are few studies of the outcomes of hospitalization versus less intensive ways of treating patients with the same disease profiles; and those that have been done show no advantage from more intensive care."¹⁹ For example, outcomes in terms of life expectancy are no different for populations living in Boston and New Haven, despite Boston's greater hospital capacity and despite the fact that Bostonians are more likely to die in the hospital.

What can we conclude about the ethical implications of geographic variability? Certainly, geographic variation makes evident that the distribution of health care occurs in a morally arbitrary and unplanned fashion. The flow of resources often takes place in an unconscious rather than a deliberate and thoughtful manner. Not only do individual patients tend to be unaware of the influence of geographic location, but the influence of supply on utilization occurs without clinicians' explicit knowledge of the relative level of available resources. For example, clinicians serving populations in hospital referral regions where the supply of acute care hospital resources is relatively low do not appear to be aware of constraints on their practice of medicine.²⁰

In addition, geographic variation highlights the importance of creating a more explicit, publicly accountable approach to health care allocation because, to the extent that health care allocation occurs in an unplanned fashion, whatever rationing this entails will not be applied consistently. De facto rationing raises serious questions of fairness because it fails to treat patients who are similarly situated in a similar fashion. Therefore, whatever benefits and burdens medical services confer are distributed on the basis of a morally arbitrary fact—where persons happen to live. A more deliberate system can better approximate the ideal of fairness by attempting to specify morally relevant differences between persons and make these the basis for rationing. For example, the quality, length, or likelihood of medical benefit a patient is expected to receive represents more sound criteria for rationing than do morally arbitrary factors, such as whether a patient happens to live in Boston or New Haven. No one would suggest that Bostonians are morally more deserving of medical services by virtue of living in Boston.

Other Examples

Other examples of unplanned rationing include slowing reimbursement and use of health care resources by means of bureaucracies that impede, inconvenience, and confuse providers and patients. The impact of bureaucracy is evident, for example, in statistics revealing that 59.7% of Medicaid or welfare denials result from problems with paperwork or documentation.²¹

Rationing also may be an unplanned outcome of the culture of modern medicine, which trains physicians to cure disease and prolong life while downplaying the significance of care-oriented, low-technology therapies aimed at providing comfort and improving the quality of patients' lives.²² For example, evidence suggests that adequate palliative care is frequently unavailable for dying patients,²³ infants²⁴ and children,^{25,26} burn patients,²⁷ cancer patients,²⁸ postoperative patients, and elderly patients.²⁹ To the extent that physicians lack the knowl-

edge or skill to offer palliative care services, rationing occurs by default rather than by a deliberate decision for which any individuals are held accountable.^{30,31} Within palliative care, more costly, high-technology modalities of pain management are sometimes favored over low-technology modalities, such as oral medication, without differences in patient outcomes.^{32,33} Access to palliative care is also restricted for patients who are not terminally ill because needed services have traditionally been reserved for end-of-life care rather than made available to patients and families throughout the illness trajectory.³⁴

To the extent that society at large devalues the lives of ethnic minorities, women, the elderly, or other groups, there is every reason to think that this will be reflected, perhaps unconsciously, in health care decisions. Thus, age-based rationing of health care may occur when patient age is discretely factored into decisions to admit patients to the hospital, provide intensive care, terminate therapy, or initiate vigorous treatment.³⁵

Discrimination based on group membership can also occur as the result of inattention to the differential effects that policies have for different segments of society. For example, although age-based rationing appears gender neutral, it would, in fact, have a disproportionate effect on women because more women than men fill the ranks of older age groups.³⁶ Likewise, although the job-based insurance system is not explicitly gender based, it more negatively affects women as a group because women are more likely than men to work on a part-time, part-year, or temporary basis, or in nonunion or low-wage jobs—job categories that offer health care benefits less frequently.³⁷ Women who work outside the paid labor force, whether caring for children or tending to disabled elderly relatives, are also disadvantaged under a workplace insurance system. Although many women receive workplace health insurance through spouses, this factor can lead to economic dependence and places women at risk of losing coverage through divorce or widowhood.

Likewise, limited awareness of the effects of policies on racial groups may contribute to racial differences in health insurance coverage,³⁸ infant mortality,^{39,40} life expectancy,⁴¹ access and outcome in organ transplantation,⁴²⁻⁴⁴ use of revascularization procedures after coronary angiography,⁴⁵ survival following cardiac arrest,⁴⁶⁻⁴⁸ inadequate emergency department analgesia,⁴⁹ and drug therapy for human immunodeficiency virus (HIV) disease.⁵⁰

In summary, although rationing of health care is rarely put forward and defended in a public manner, rationing of health services nonetheless occurs. Unplanned and informal rationing often reflects morally arbitrary criteria, such as geographic location, or medically irrelevant factors, such as the ability to pay.

Proposals for Explicit Health Care Rationing

The problem with the de facto rationing described here is that it does not even aspire to meet ethical standards. Thus, implicit rationing is typically not thought through, not applied consistently, not accountable to the public, not decided democratically, and not insulated from arbitrary and unfair manipulation. In light of these concerns, most would prefer a planned and public system of allocating health care over the present approach. While critics cast doubt on the idea that explicit rationing constitutes proper public policy,⁵¹ most agree about the value of openly debating health care policies and reaching agreement about fundamental principles of justice in health care. In North America, Europe, and other developed countries, public opinion has been solicited regarding rationing of health care and the need to set limits in health coverage. These efforts enable public opinion to become visible and play a role in health policy deliberations.^{52,53}

The Oregon Proposal

Various proposals for explicit rationing of health care have been defended as ethically sound. Perhaps the most well known is Oregon's plan to deny Medicaid reimbursement for certain categories of medical services.⁵⁴ Oregon's plan was the outgrowth of the 1989 Oregon Basic Health Services Act, a central goal of which was to extend Medicaid to all Oregonians falling below the federal poverty level. The means proposed to pay for this included restricting medical services to current Medicaid eligibles. The Oregon Health Services Commission was responsible for determining the relative priority of medical services. In the Commission's initial plan, a computer generated a list of diseases rated by a formula taking into account the cost of treatment, length of benefit, and quality of well-being after treatment. How far down the list treatments were covered would depend on the availability of funds in each biennium. At some point along the list, a line would be drawn and diseases and injuries that fell below it would not be covered.

After coming under intense criticism, the Commission formed an Alternative Methodology Subcommittee to develop an alternative approach to prioritizing services.⁵⁵ The revised approach excluded cost as a significant factor in prioritizing services; instead, it considered the perceived benefit of various treatment categories to individuals and society, as well as their perceived necessity. The revised plan emphasized preventive care and treatable, life-threatening conditions that affect many, rather than conditions that are minor or are fatal and incurable. For example, organ transplants were moved from the bottom

to near the middle of the priority list, and familiar ailments, such as pneumonia, were placed near the top.⁵⁶

Oregon's proposal explicitly incorporates rationing, most notably rationing based on the likelihood, quality, or length of medical benefit that a patient will receive from treatment, and rationing based on the imminence of a patient's death. A number of ethical arguments have been adduced in support of each proposal. Rationing based on medical benefit is defended on utilitarian grounds, by arguing that services that generate the greatest amount of benefit merit the highest priority. According to this approach, payoff to patients, and to people generally, is the measure of justice in health care allocation. Medical benefit is also defended on nonutilitarian grounds. For example, it is argued that if people were to devise a just distribution scheme without knowing how such a scheme would affect them, or what their health care needs would be, they would prefer a distribution that assigned people the greatest entitlement to resources when they would have the greatest chance of actually benefiting.⁵⁷

Various ethical reasons can also be advanced in support of rationing based on the imminence of a patient's death. Such an approach arguably has the advantage of saving the greatest number of lives. Alternatively, the justification for applying this criterion may rest on the belief that a patient whose death is imminent is in greater need of health care and that health care should be given first to those with the greatest need.⁵⁸

Critics of both a medical benefit and an imminent death criterion express the concern that these approaches may have adverse effects on elderly persons.⁵⁹ As older persons, on average, have a lower life expectancy than younger persons, rationing that takes into account the duration of medical benefit will disproportionately affect older persons. Likewise, to the extent that advanced age correlates with poorer outcomes for medical procedures, rationing based on medical benefit will adversely affect the elderly as a group. Regarding the criterion of imminent death, the elderly are at greater risk of being denied treatment if, as a group, they are found to be at increased risk of mortality for various medical interventions. Thus, although medical benefit and imminent death are age blind, they may be found to have adverse effects on the geriatric population.

Age-Based Rationing

Age is also put forward as an explicit basis for allocating limited health care resources. Perhaps the most prominent proponent of age-based rationing is Daniel Callahan, who argues that "government has a duty, based on our collective social obligation, to help people live out a natural life span, but not actively to help extend life beyond that point."⁶⁰ According to this approach, public-

funded life-extending care should not be available to older persons. Instead, government should pay only for medical services intended to improve the quality of life of elderly persons.

Ethical arguments favoring age-based rationing often appeal to society's duty to younger age groups. For example, it is argued that unless age-based limits to health care are set, we will cheat our children and future generations out of adequate health care or other essential goods, such as education.^{61,62}

Alternatively, age-based rationing is defended by arguing that although it initially appears to favor one group of people over another, in fact it affects all persons equally over time.⁶³ This reasoning applies because, over time, each person ages. Therefore, over time, all persons experience both the advantage of greater access when they are young and the disadvantages of reduced access during old age.

Age-based rationing is also justified on utilitarian grounds, by arguing that investing health care dollars in younger persons represents, on average, a better return on investment because the young generally have a greater number of years ahead to live. Another utilitarian defense of age-based rationing points out that a great financial gain could be obtained by limiting health care to the elderly because the elderly use a disproportionate share of health care dollars. According to one estimate, more than 50% of patients hospitalized for myocardial infarction are over age 65.⁶⁵ If treatment for this condition were rationed on the basis of age, a major reduction in health care expenditures would be achieved.

Opponents of age-based rationing hold that a just distribution of health care requires meeting the essential needs of all persons, irrespective of age.⁶⁵ Thus, if older persons have, on average, a greater need for health care resources, then they are entitled to receive a greater share of such resources. Alternatively, opponents claim that the allocation of health care should depend more on the quality of benefit that medical interventions can produce than on the number of years a patient lives.⁶⁶

In addition, critics of age-based limits maintain that society has special duties to older persons that forbid placing age-based limits on medical care. Such duties may stem from the belief that older persons are more deeply embedded within the fabric of social life. According to this position, "The more personally interwoven a person becomes with others through time, the greater the damage done to the social fabric when that person is torn away by death."⁶⁷ Alternatively, special duties may spring from the contributions that older persons as a group have made to the creation of social goods, such as science, technology, medicine, and culture.⁶⁸ Proper recognition of these contributions requires ensuring that the elderly themselves reap the benefit that these social goods offer.

Finally, as already noted, age limits on health care adversely affect women because the population of older adults includes more women than men.⁶⁹ Among the population aged 65 and over, there are only 68 men per 100 women. The disparity in the numbers of men and women is greatest within the oldest age groups. Thus, for the group aged 85 and over, there are a mere 45 men per 100 women.⁷⁰ Denying lifesaving medical care to older women also harms women disproportionately, as women have more future years to live. At age 65, a woman can anticipate living about 18 more years, whereas a man at this age can expect only 14 more years. Women who reach age 75 can look forward to 12 more years of life; by contrast, men at this age will live an average of 9 more years.⁷¹

National Health Insurance

Age-based rationing focuses on a personal quality of individuals and uses this as a basis for distinguishing between persons, whereas other approaches emphasize similarities rather than differences between persons. For example, those who advocate applying a principle of equality to the distribution of health care insist that, morally speaking, it is not possible to discriminate between individuals and assign people different rights to health care. Instead, whenever anyone enjoys access to a health care service, justice requires making that service equally available to everyone with similar health care needs.⁷²

The more precise interpretation of an egalitarian principle depends upon how the concept of “need” is elaborated.⁷³ Thus, to say that resources must be equally available to everyone who needs them may mean that people should have equal access to every service from which they stand to benefit. Understood in this sense, a principle of equality applies to all areas of health care. Alternatively, if “need” refers only to services that provide especially important benefits, then the principle of equality applies only to “basic” or “essential” services. On the latter interpretation, although nonessential services may be unequally distributed, services that provide very important benefits to people must be equally accessible.

The goal of making basic health care equally available to everyone, irrespective of factors such as a person’s income or geographic location, was one of the central aims of the Canadian health care system. The Canadian health care system is a publicly funded system based on the philosophy that health is a right, not a commodity.⁷⁴ Thus, in Canada, universal access to provincial health insurance solves the problem of the uninsured by preventing it from occurring. The 1984 Canada Health Act was the first to explicitly state the principles that have become the cornerstone of the Canadian health care

system: accessibility, portability, comprehensiveness, universality, and public administration. Because the Canadian Constitution specifies that health care coverage will be a matter of provincial jurisdiction, to be implemented by individual provinces, these five principles have served as the federal government’s criteria for judging the eligibility of provincial health plans to receive federal funding. In Ontario, for example, the criterion of universality is met by provincial regulation establishing that all who “make their home and are ordinarily present in Ontario are eligible for coverage,” so long as they reside in the province for 3 months.⁷⁵

Like the United States, Canada’s health care system is facing increasing demands that stretch the limits of the public sector. The federal government has reduced its financial contribution, leaving the Canadian provinces that administer health insurance plans in financial crises. These economic limits will challenge the principles of universality and comprehensiveness that form the cornerstone of the Canadian approach to justice in health care. Whether Canada’s system of universal coverage can withstand future challenges will depend, in large part, on the strength of its ethical and social foundations. Specifically, the ability to meet future challenges will require restating and reaffirming the reasons for commitment to a principle of equality in health care. It will also call upon Canadians to prioritize competing values, such as universality and comprehensiveness. For example, if limiting benefits and rationing health services is necessary to place the goal of universality on surer footing, are such limits ethically and socially acceptable?

In Canada, support for a principle of equality in health care is generally articulated by emphasizing altruistic and humanitarian concern for others.⁷⁶ First, government shoulders the social and ethical responsibility to secure the general social welfare. Thus, Canadian policymakers tend to take for granted that government is responsible to protect the most vulnerable members of the society, even when doing so imposes a cost on other citizens. As expressed by the federal Advisory Committee on Health Insurance, universal access recognizes “the need for the mutual insurance of all members against the more serious dangers, a compulsory insurance so that the more secure cannot stand aside and leave the risks to be loaded on the shoulders of the less secure.”⁷⁷

Second, the ethical principle of humanitarianism, or care and concern for fellow citizens, is evident in the historical development of Canada’s system of universal health insurance. Reflecting this ethical premise, the Royal Commission on Health Service identifies the factors that support public, as opposed to purely private, interest in health care as including, “A deepening of our humanitarian concern for our fellows,” together with, “A recognition of the well-being of members of the population and that the well-being of a proportion of the

population at any given time is seriously curtailed because of mental or physical disease.⁷⁸

Generally speaking, support for applying a principle of equality to the distribution of basic health care comes from a variety of sources. First, it can be said that basic health care services provide a very special and important kind of benefit.⁷⁹ Unlike other benefits, the preservation of life and health (and the resources necessary to achieve this) is a prerequisite for whatever else a person wants to do in life. Therefore, even if inequalities are ethically tolerable in other areas, they should not be within health care.

Furthermore, although we may consider ourselves as exerting control over many important aspects of our lives, we often lack control over our health and need for health services.⁸⁰ For instance, whether one inherits a gene predisposing the person to breast or ovarian cancer, or a gene for Huntington's disease, is the result of the "natural lottery" rather than the result of individual decisions. Likewise, the fact that an individual is born with fetal alcohol syndrome, is injured in a flood, or experiences kidney failure from contaminated meat is not the result of that individual's conscious choices. To the extent that disease is genetically based, or is influenced by choices others make, or occurs as the result of natural disaster, there is no basis for holding people "accountable" for having diseases. In these kinds of cases, allocating health care on the basis of merit lacks ethical underpinning, and a system of treating people equally gains ethical support. Even if merit-based allocation is suitable in other spheres, such as distributing the benefits and burdens associated with offices and positions in a society, it often does not fit the circumstances leading to ill health and the need for health care services.

It is also argued that the value of equal respect requires applying a principle of equality to basic services. Gutmann, for example, maintains that inequality of access to basic health care conveys to people that they are not equally worthy human beings.⁸¹ It is analogous, she argues, to tolerating inequalities in other fundamental areas, such as the right to vote or access to police protection, which are essential to liberty and security. One reason that showing equal respect for persons is important is that it has a profound effect on people's capacity to develop and maintain self-respect. Self-respect, in turn, determines an individual's sense of their own worth; it affects their self-confidence and ability to carry out the important goals they set for themselves.

Summary and Conclusions

In summary, this chapter addressed the problem of how to allocate scarce health care resources between different individuals and groups in society. It demonstrated

that competing conceptions of justice lead to very different distributive approaches. Moreover, the problem of health care rationing is hardly a problem that looms in the future. Instead, rationing occurs as a pervasive feature of present health care systems.

Creating a more just health care system will require societies to engage in open debates about the rationing of health care services. At a deeper level, the choice societies face must be founded on a more fundamental vision of a just society.⁸² To what extent does a just society emphasize equality between persons? To what extent must it stress the value of individual freedom? How does a just society balance the value of health with other values, such as the environment or education? These questions lie at the very heart of contemporary health care debates.

Medical Treatment and the Physician's Legal Duties

Marshall B. Kapp

Older patients enter into relationships with physicians and other members of the health care team to obtain medical care. These relationships can be characterized as both contractual (i.e., based on a mutual exchange of explicit or implicit promises) and fiduciary (i.e., based on the trust the dependent patient must invest in relying on the more knowledgeable and powerful health care provider). Within either of these frameworks, the resulting relationships implicate a variety of legally enforceable obligations on the part of the physician.

Thus, some familiarity with treatment-related legal requirements and associated potential liabilities is essential to the practicing geriatrician. Additionally, geriatricians often have the opportunity, and sometimes may be required, to contribute medical expertise to the resolution of legal issues, as in cases where a physician's affidavit or testimony is the central piece of evidence regarding mental competence in a contested guardianship or will probate proceeding.

Many legal issues affecting geriatric practice are basically generic. For instance, physicians must be aware of the legal doctrines of informed consent and confidentiality regardless of their patients' age.¹ There is nothing inherently distinctive about older patients from a legal perspective. Many generic legal issues, however, take on unique twists or special urgency when applied to older patients. This difference may be related to a particular older person's physical or mental decline, impaired sensory perception, well-developed life history and set of values, outliving of concerned family members or presence of intermeddling family members, and increased risk of institutionalization. Further, there exists a subset of medically related issues that pertain exclusively to elderly patients, because in some situations legislators have consciously made chronologic age by itself a relevant criterion for some specific purpose. For example, achieving age 65 by itself qualifies one for Social Security retirement benefits,² and a person gains protection under the Age Discrimination in Employment Act (ADEA) auto-

matically at age 40.³ This chapter outlines a few of the most salient legal issues arising within the physician-older patient relationship.

Medical Malpractice

The quality of medical practice is regulated through several means. Important forms of regulation include professional licensure and disciplinary requirements, oversight by Peer Review Organizations (PROs)⁴ and other public and private (e.g., Joint Commission on Accreditation of Healthcare Organizations) agencies that audit the quality of care provided to Medicare beneficiaries and others, mandatory reporting of certain adverse actions against physicians to the National Practitioner Data Bank (NPDB),⁵ extensive federal and state statutes and regulations governing nursing facilities and home health agencies, and in extreme cases (e.g., when gross neglect is charged), criminal prosecution. Physicians ordinarily are particularly apprehensive about civil medical malpractice tort lawsuits brought by individual patients seeking monetary damages for allegedly negligent care, even though older patients tend to sue their physicians less often than their younger counterparts and with less success.

Much attention has been paid recently to the prevalent phenomenon of medical errors.⁶ There have been calls for mandatory reporting of serious errors to a government agency, but fears have been expressed by physicians about the potential ramifications of such reporting in terms of generating an increased rate of malpractice lawsuits.⁷

Another relatively recent development with possible litigation-related implications is the expanding enrollment of Medicare beneficiaries in various forms of managed care organizations (MCOs). This enrollment has been encouraged by the Medicare + Choice (Medicare Part C) program created by the Balanced

Budget Act (BBA) of 1997.⁸ Much political discussion has taken place regarding the right of individuals who obtain medical coverage as a fringe benefit of present or prior employment to personally sue their MCO as well as, or instead of, their own physician for alleged negligence;⁹ the future of lawsuits brought by Medicare beneficiaries against MCOs for negligence in denying payment for services is, at present, uncertain but bears close watching.

Informed Consent

The fundamental ethical principle of autonomy or self-determination is embodied in the legal doctrine of informed consent. There are three essential elements that must be present for a patient's choices about treatment to be considered legally valid.

First, the patient's participation in the decision-making process and the ultimate decision must be voluntary. The usual definition of voluntariness in the context of consent is that the person giving or withholding consent must be so situated as to be able to exercise free power of choice without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion. It means simply that the person must be free to reject participation in the proposed intervention. The physician must do all possible to minimize any intimidation that might unfavorably affect the quality of the patient-physician relationship, and the patient-institution or patient-agency relationship when applicable, and to make sure that advice and recommendations are conveyed in as nonpressured and empathetic a manner as possible.

The second bedrock requirement for valid consent is that the patient's agreement be sufficiently informed. The informed consent doctrine commands that the health care provider, before undertaking an intervention, must disclose certain information to the person who is the subject of the proposed intervention (or that person's authorized surrogate; see following).

The disclosure standard enforced in a slight majority of American jurisdictions is referred to as the "professional," "reasonable physician," or "community" standard. Under this test, the adequacy of disclosure is judged against the amount and type of information that a reasonable, prudent physician would have disclosed under similar circumstances.

A substantial minority of states have adopted a more expansive standard of information disclosure: the "reasonable patient" or "material risk" standard. This standard dictates that the physician communicate the information that a "reasonable patient" in the same situation would need and want to make a voluntary and knowledgeable decision. Under this approach, the

patient must be told about all material risks, that is, those factors that might make a difference to a reasonable, average patient under comparable circumstances.

The patient's age may affect what information is material to that person's decision-making calculations. For instance, a likely side effect that will not manifest itself for another 20 years may not be very important to an older person. However, the probability that a particular intervention will be accompanied by a great amount of physical pain or discomfort may make quite a difference to an old, frail individual. Physicians always should take into account the physical and mental effects of aging, among numerous other factors, when deciding what information regarding an intervention might be material to the specific person and how to communicate that information most usefully.

Within these standards of disclosure, the following informational items have usually been enumerated as essential components of the ideal informed consent process: (1) diagnosis; (2) the general nature and purpose of the proposed intervention; (3) the reasonably foreseeable risks, consequences, and perils of the intervention; (4) the probability of success; (5) reasonable alternatives; (6) the result anticipated if nothing is done; (7) limitations on the professional or health care facility; and (8) advice (i.e., the physician's recommendation).

The third essential element of legally effective consent is that the patient must be mentally able to engage in a rational decision-making process. The topic of evaluating a patient's decisional capacity is discussed in Chapter 84. When the patient lacks sufficient present cognitive and emotional capacity to make medical choices, a proxy or surrogate decision maker must be involved (see following).

The Research Context

The issue of participation by older persons, particularly those residing long term within nursing facilities, in biomedical and behavioral research protocols is a growing ethical (see Chapter 86) and legal concern. Legal questions are especially vexing when the problem being clinically investigated is mental impairment and the proposed human subjects are institutionalized as well as cognitively and emotionally compromised. The policy and practice challenge is to protect impaired elderly persons from exploitation and avoidable harm, while facilitating the conduct of important, high-quality research on problems (such as dementia) that affect older persons disproportionately.

Most biomedical and behavioral research conducted in the United States is regulated under federal law that seeks to protect the rights and well-being of potential human subjects.¹⁰ The Office of Protection from Research

Risks (OPRR) within the Department of Health and Human Services (DHHS) has—and has exercised—the authority to suspend an institution's human subjects research activities for noncompliance with applicable regulations.

At present, there are no particular legal restrictions unique to older research subjects; thus, participation by the elderly in research protocols is governed by the same law that applies to subjects of all ages. For incapacitated persons, consent for research participation may be obtained legally from those individuals who are empowered to make other decisions on the older person's behalf; federal regulations refer to the use of a “legally authorized representative” for consent to research activities.¹¹

However, a 1998 report by the National Bioethics Advisory Commission (NBAC) contained a number of recommendations for specially protecting potential human research subjects (of all ages) who have impaired capacity to personally consent to their own research participation.^{12,13} Among other items, NBAC recommended:

- Institutional Review Board (IRB) membership should include at least two persons familiar with mental disorders
- A special standing panel of DHHS should be created to handle especially troubling research protocols
- Research using mentally impaired subjects should be disapproved if people without such impairments could be used
- For protocols involving greater than minimal risk, there should be an independent assessment of a potential subject's capacity, and the protocol must detail the assessment process

These recommendations will likely set the agenda for policy discussion in this arena for the foreseeable future.

The endeavor of conducting legally defensible geriatric research, particularly with demented, institutionalized subjects, presents a variety of challenges concerning site and subject selection, capacity evaluations, comprehension and retention of relevant information, choice and authority of proxy decision makers, and minimization of coercive influences. Nonetheless, the geriatric research enterprise is an essential one, and the legal challenges must be met appropriately.

Surrogate Decision Making

As noted, proxy decision making concerning an older person's participation in a research protocol sometimes is necessary when the person lacks sufficient capacity to make their own decisions rationally. Similarly, physicians involved in the diagnosis and treatment of older patients frequently must confront substitute decision makers responsible for intervening on behalf of patients whose

cognitive or emotional deficits are so severe that they prevent the patient from personally making and communicating autonomous choices.¹⁴ The topic of surrogate decision making by third parties acting for the incapacitated patient is a complex and legally inexact one.

There are several alternative ways to delegate legally what would ordinarily be the patient's authority to make decisions for the proxy or surrogate to exercise that power on behalf of the incapacitated patient. These delegation mechanisms may be characterized as follows: (1) delegation of authority beforehand by the patient, through methods of advance planning; (2) delegation of authority by operation of statute, regulation, or broad judicial precedent; (3) informal delegation of authority by custom; and (4) delegation of authority by a court order in the specific case.

The two most important current devices for advance health care planning are the living will (in some jurisdictions called a “declaration”) and the durable power of attorney for health care.¹⁵ The Patient Self-Determination Act (PSDA) passed by Congress as part of the Omnibus Budget Reconciliation Act (OBRA) of 1990,¹⁶ in the aftermath of the United States Supreme Court's decision in *Cruzan v. Director, Missouri Department of Health*,¹⁷ imposes a number of requirements on hospitals, nursing homes, health maintenance organizations, preferred provider organizations, hospices, and home health agencies that participate in the Medicare and Medicaid programs. Among these are mandates that the provider create and distribute to new patients or their surrogates a written policy on advance directives, consistent with applicable state law; the provider inquire at the time of admission or enrollment whether the patient has previously executed an advance directive; and, if no advance directive has been executed previously and the patient currently retains sufficient decisional capacity, the provider inquire whether the patient wishes to execute such a directive now.^{18,19}

In some circumstances, particular facets of decision-making authority may devolve or pass from the patient to someone else by operation of a statute, regulation, or judicial precedent. One well-known example of this form of substitute decision making is the representative payee concept that is utilized to manage regular government benefit payments, including pension and disability checks from the Departments of Veterans Affairs and Defense, Railroad Retirement Board, and Civil Service; Old Age, Survivors, and Disability Insurance benefit payments under Title 2 of the Social Security Act; and Supplemental Security Income benefit payments to the aged, blind, or disabled under Title 16 of the Social Security Act.

As another example of this type of power delegation is found in the federal Medicare-Medicaid requirements for nursing facilities. These regulations provide that, for a facility resident who is (1) adjudicated incompetent in

accordance with state law or (2) found by the physician to be medically incapable of understanding his or her rights, the right to make decisions devolves to the resident's guardian, next of kin, sponsoring agencies, or representative payee.

It is in the area of decision making about care of the critically ill patient that statutory, regulatory, and judicial guidance about substitute decision making is clearest. Twenty-seven states and the District of Columbia had enacted legislation generally lumped under the rubric "family consent" or "default" statutes.²⁰ These statutes set forth legal authority empowering designated relatives, and sometimes others, to make particular kinds of medical decisions on behalf of incapacitated persons who have not executed a living will or durable power of attorney. In addition, courts in many jurisdictions have formally recognized the family's authority to exercise an incapacitated person's rights on his or her behalf and, just as importantly, most of these judicial decisions explicitly establish legal precedent for families to act in future cases without the need for prior court authorization in individual cases.

As a general matter, in the absence of a specific statute, regulation, or court order delegating authority to a substitute decision maker, or a court order finding an individual mentally incompetent and appointing another named person to act as guardian or conservator, neither the family as a whole nor any of its individual members (nor nonrelatives, for that matter) has any automatic legal authority to make decisions on behalf of patients who cannot speak for themselves. Nevertheless, it has long been a widely known and implicitly accepted medical custom or convention to rely on families as decision makers for incompetent persons, even in the absence of express legal power. Even when there is no explicit judicial or legislative authorization in one's own state, the legal risk for a physician or health care institution for a good faith treatment decision made in conjunction with an incompetent patient's family is very slight. In fact, the few courts that have been presented with the question in the context of litigation have virtually unanimously ratified the family's authority.

In some cases, however, informal substitute decision making—that is, the extralegal "muddling through" process that governs a great deal of medical, and especially geriatric, practice—by the physician and family members may not work satisfactorily. The family members may disagree among themselves. They may make decisions that seem to be at odds with the earlier expressed or implied preferences of the patient or that clearly appear not to be in the patient's best interests (e.g., a family's financially or psychologically driven selfish choices). The family may request a course of conduct that seriously contradicts the physician's or facility's own sense of ethical integrity.

When such situations occur, judicial appointment of a guardian or conservator empowered to make decisions on behalf of an incompetent ward may be practically and legally advisable.²¹ However, because guardianship usually entails an extensive deprivation of the individual's basic rights, may be imposed in the absence of meaningful procedural safeguards, and involves substantial financial, time, and emotional costs, the "least restrictive alternative" doctrine dictates that it be pursued only as a last resort when less formal mechanisms of substitute decision making have failed or are unavailable.

Additionally, when guardianship is sought, consideration should be paid to the possibility of strictly limiting such guardianship in terms of both duration and extent of transferred powers. Because courts possess the authority to impose such limitations, under either specific state "partial or limited guardianship" statutes or the courts' inherent equity powers, physicians who deal with substitute decision makers who purport to be the patient's legal guardian should request to see a copy of the official court order creating the guardianship, to verify the existence and extent of the guardian's authority.

Institutional Ethics Committees

Standards of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) require that hospitals have "a mechanism" in place for resolving ethical disputes. One such mechanism is the institutional ethics committee (IEC), variants of which have now been established in many hospitals, as well as nursing homes,²² hospices, and home health agencies. The IEC is an internal interdisciplinary body that helps an institution or agency and its professional staff to make difficult treatment decisions in an ethically acceptable manner.

Institutional ethics committees differ among institutions and agencies in terms of precise size, composition, structure, procedures, and organizational placement. IEC functions may include policy drafting, staff and public education, and/or case consultation on a concurrent or retrospective basis. Consultation with an IEC probably exerts a legal prophylactic effect, in terms of reducing unnecessary guardianship petitions, deterring possible lawsuits against the institution or agency and its staff, and making it easier to defend against the very rare malpractice cases that might be filed in this context.

"Do Not" Orders

"Do Not" orders from the attending physician to other members of the health care team are predicated on prospectively made decisions to withdraw or withhold certain types of medical interventions from specified

patients. Most attention has been devoted, especially in the acute hospital environment, to “do not resuscitate” (DNR) orders (also called “No Codes”), or instructions by the physician to refrain from attempts at cardiopulmonary resuscitation (CPR) in the event of a cardiac arrest. However, other kinds of “do not” orders also are important, particularly in the long-term care environment. Among these are “do not hospitalize” and “do not intubate” orders.

Legally, deciding about implementing “do not” orders should be handled according to the same substantive principles and procedural guidelines that apply to other treatment decisions. In fact, by allowing and encouraging certain decisions to be made prospectively, before a crisis develops, “do not” orders probably reduce any potential legal risk and certainly should curtail legal anxiety.

The legal status of “do not” orders when the patient is mentally competent is unambiguous. It parallels the situation of medical intervention generally, including intervention that would be life prolonging or even lifesaving. In other words, a competent adult patient has the constitutional, common law, and (in many states) statutory right to voluntarily and knowingly refuse basic (e.g., CPR) or advanced cardiac life support or any of its specific components, hospitalization, or any other form of medical intervention and to demand a precisely written “do not” order. Courts have not ordered competent elderly patients to endure medical interventions over their stated objections. The wishes of close family members should be considered by the physician (assuming the competent patient has expressly or by implication authorized family participation in their medical care), but should never be permitted to override the decision of a competent patient.

Under the PSDA, acute and long-term settings should have a written policy statement regarding the institutional or agency philosophy and any relevant technologic and staffing limitations concerning various “do not” situations. A copy of this statement should be presented to every decisionally capable patient or an incapacitated patient's most likely substitute decision maker at or before the time of admission. Extensive, regular staff education should be carried out concerning the provider's policies. Physicians customarily should discuss treatment preferences and objectives openly and honestly with patients who are capable of participating in such decisions. As a matter of course, physicians should document the results of these discussions; such documentation might provide useful evidence later on of the patient's wishes and the good faith quality of the decision-making process.

When a capable patient has made a “do not” decision, he or she must be able to reevaluate and reconsider that decision continually in light of any change in physical or mental condition that materially affects (i.e., that might

really make a difference in) the possible benefits and burdens of different treatment alternatives. A “do not” decision can be revoked or modified at any time. It is part of the physician's duty to continually update the patient with new information pertinent to “do not” decisions.

For the mentally incapacitated patient, clarification of respective rights and responsibilities may be available from the patient's previously executed advance directive or from the expressions of a legislatively or judicially designated proxy. Even in the absence of a valid advance directive or explicitly legally authorized proxy, “do not” orders are still permissible for incapacitated patients according to the same general legal principles governing other kinds of decisions about life-sustaining medical treatment, that is, balancing—from the perspective of the patient—the likely benefits and burdens of the particular intervention. The only pertinent distinction between “do not” orders and other decisions to limit the use of life-prolonging medical interventions lies in the prospective nature of the former.

In an effort to clarify this area further, a number of state legislatures have passed specific legislation on this subject. JCAHO standards also address “do not” orders explicitly. Moreover, at least 42 states have in place protocols for writing and implementing Do Not Resuscitate orders pertaining to out-of-hospital situations.^{23,24}

The physician's and health care institution's responsibility to adopt, educate about, and communicate concerning a clear policy on “do not” orders applies with full force when presently incapacitated patients are involved. When a patient is not presently capable of participating fully in decision making, the communication and negotiation about potential “do not” management strategies must encompass available, interested family members. The family has the same legal authority to make “do not” decisions for an incapacitated relative as to make other types of medical decisions. Even in the absence of specific legal authorization, in this sphere as elsewhere it is the medical custom or convention to involve families in “do not” decisions. From a practical risk management perspective, extensive interaction with family members concerning such decisions is a prudent, protective practice.

Conversely, whether or not the family possesses the legal authority to veto a physician's proposed “do not” decision has emerged as a controversial issue, as part of the larger “futile treatment” debate.^{25,26} Proceeding with entry and implementation of a “do not” order in the face of family opposition entails, from a practical standpoint, a certain risk of legal challenge after the fact. However, the realistic risk of being held liable for this conduct is small when the “do not” order was appropriate in terms of expressed patient wishes, the clinical prognosis, and the imbalance between the likely benefits and burdens of the intervention for the patient.

A communication and negotiation process that is marked by compassion, clarity, and patience should resolve family–physician disagreement peacefully in most situations. When serious disagreement between physician and family or among family members themselves does surface and persist, consultation with an IEC may be advisable; a judicial declaratory judgment and injunction may be sought, but should be considered only as a last resort.²⁷

During the communications process, the family should be informed that the continuing propriety of a “do not” order will be reevaluated regularly and that it can be rescinded or modified if prognosis or other factors materially change. As would be true for any clinical action predicated on an inaccurate factual basis, a physician or health care institution might be found legally liable for basing a “do not” order on an incorrect evaluation of the patient’s condition and prognosis.

The attending physician should make appropriate use of available professional consultations with relevant clinical specialists, while retaining ultimate medical control and responsibility for the patient. The insight of nurses and other team members who are familiar with the patient also should be sought out and considered.

The wishes of the patient (if ascertainable), the family, and significant others should all be recorded. The judgments of involved health care professionals, as well as the reasoning underlying those judgments, should be documented completely and candidly, as well as any attempts to change the mind of the patient or family. Honesty and accuracy in record keeping is the best defense for the physician and health care facility against any subsequent allegations of negligence or malevolent intent. Failure to put decisions and orders in writing not only exposes the physician to greater legal risk but also engenders possible inappropriate responses by other team members based on the mixed and confused signals that they are given.

Once a “do not” order has been entered into a medical record, it should remain a permanent part of that document. If it is later modified or rescinded, the modification or rescission also should be noted in the record.

Along with documentation, there is the need for communication among appropriate health care team members and institutions once a “do not” order has been written. A decision to refrain from certain interventions needs to be made known to those responsible for carrying out the order because, in the absence of such an order, the health care team normally is obligated to treat the patient with the full medical arsenal available. Communication is chiefly an organizational responsibility, and each hospital, nursing home, and home health agency should have a provision in its written policies detailing its procedures for assuring that all pertinent members of the health care team are informed accurately and promptly

of “do not” orders or other treatment limitations concerning particular patients. Regular interdisciplinary case reviews on various institutional units are one means of communication that should be considered. Special markings on the outside of the medical chart, discreetly but clearly signifying particular treatment restrictions, are also a valuable communicative tool.

Even when a long-term care facility resident needs to be, and with the resident’s or surrogate’s permission is, transferred to an acute care hospital for treatment of a specific remediable problem (such as acute infection), other treatment limitations may remain appropriate because of the person’s other, underlying, nonremediable deficits. In those circumstances, the transferring facility should have a clear, effective, ongoing mechanism in place for communicating “do not” orders directly to hospital personnel. Especially because hospital medical staff (and even more particularly house staff) may have strong preconceptions about resuscitation and other aggressive therapy for older persons who reside in long-term care facilities, it is the facility’s duty to transmit to the receiving hospital, at or before the time of the transfer, as much background as feasible concerning preferences, values, and instructions that should guide treatment for that person. The transfer agreement between the long-term care facility and any other health care facility should contain a written provision addressing the communication of this sort of information.

Finally, decisions to limit specific elements of treatment should not signify total disregard or the “writing off” of an older person. Physicians in the past often have been intimidated from providing sufficient pain relief to critically ill patients because they feared criminal prosecution or professional disciplinary action for the overprescription of controlled substances. In the past decade, a number of legal initiatives have been aimed at changing this climate of apprehension to encourage the more appropriate prescribing of pain medications,²⁸ including the enactment in many states of “Intractable Pain Statutes.” Indeed, it is widely recognized today that neglect of continuing palliative care, including effective pain management, could alienate patient and family and expose the physician and health care facility to lawsuits charging abandonment, neglect, or even abuse. Alleviating suffering is a basic goal of medical care and a part of the standard of care legally and ethically owed by health care professionals, even when “cure” of underlying disease is no longer possible. Management goals should consist of the following: remaining in physical and emotional contact with the dying person; relieving terminal symptoms (such as pain, confusion, anxiety, or restlessness); providing nourishment and hydration so long as they are palliative; skin care, bowel and bladder care, and personal grooming; and supporting the family through the period of dying, death, and bereavement. High-dose

narcotic agents and sedatives can be used despite the possible risk of suppressed cerebral function and respiratory depression (there is controversy about how real this risk actually is), because the therapeutic intention is to control the symptoms of human suffering, not to precipitate an earlier death.

One disturbing development in 1999 was the introduction in Congress of the Pain Relief Promotion Act (PRPA) (the Hyde–Nickels bill). The bill was designed to override Oregon's physician-assisted suicide law (discussed next), by making it a violation of the federal Controlled Substances Act to administer opioids or other drugs to hasten a patient's death. However, the most likely effect—unintended but foreseeable—of this bill if it were passed and signed into law would be to “chill” responsible pain management by discouraging, for reasons of apprehension about criminal prosecution, all physicians from adequately treating the suffering of their dying patients.^{29,30}

Physician-Assisted Suicide

Current U.S. law is unambiguous in its condemnation, particularly through state homicide statutes, of health care providers engaging in active (voluntary, positive) euthanasia (i.e., actively and intentionally doing something such as administering a lethal injection to hasten the death of a patient). In addition, almost all states explicitly legislatively condemn physician-assisted suicide (i.e., actively helping a patient to purposely take his or her own life), through either a specific statute on the subject or judicial interpretations of their general homicide statutes.

In 1997, the U.S. Supreme Court unanimously upheld the validity of state laws making it criminal for physicians or other health care professionals to assist a patient to commit suicide. In these decisions, the Court rejected the notion of any federal constitutional right to physician-assisted suicide.^{31,32}

Although the federal Constitution does not require it, the door is open legally for particular states to choose, as a matter of their own respective public policies and politics, to decriminalize physician-assisted suicide or even active euthanasia. Thus far, Oregon is the only state that has accepted this invitation.^{33–35}

Adult Protective Services

Every state has assembled an array of programs under the general rubric of adult protective services (APS). The traditional definition of this concept is a system of preventive, supportive, and surrogate services provided to adults living in the community, enabling them to maxi-

mize independence and to avoid abuse and exploitation. APS are characterized by two elements that can be mixed in several different ways: the coordinated delivery of services to adults at risk and the actual or potential authority to provide substitute decision making concerning these services.

The services feature consists of an assortment of health, housing, and social services, such as homemaker, house repair, friendly visits, and meals. Ideally, these services are coordinated by a caseworker who is responsible for assessing an older individual's needs and bringing together the available responses. Many state APS statutes mandate that social service agencies undertake both casework coordination and delivery of services.

The second component of an APS system is authority to intervene on behalf of the client. Ordinarily, the client (if capable of making autonomous decisions), with the encouragement of the physician will consent to a proposed service plan. Alternatively, the decisionally capable client may delegate decision-making authority to someone else through a durable power of attorney instrument. However, if the client refuses offered assistance but some form(s) of intervention appears necessary, the legal system may be invoked to authorize appointment of a surrogate decision maker over the person's objections.

In some states, APS offices rely, in the case of recalcitrant individuals, on the traditional methods of legal intervention in the lives of elderly persons, namely, involuntary commitment and guardianship. Legislation has been enacted in several jurisdictions, however, that creates special procedures to obtain court orders for protective services, for placing the client in an institution, for emergency orders when there is imminent danger to the client's health or safety, or for orders authorizing entry into an uncooperative client's home. These special procedures may be in addition to, or in place of, the existing guardianship apparatus and usually bypass the procedural protections that have been gradually built into extant guardianship laws.

Court orders obtained under an APS statute often are time limited; upon expiration, the APS agency must pursue standard guardianship to continue imposing services over the client's objection. However, during its duration, a court order authorizing APS intervention may be very broad. If the court does not limit it, for example, a protective services order may result in the placement of a person in a hospital, nursing home,³⁶ assisted living complex, boarding home, hospice, or mental institution. As a matter of standard practice, physicians should ascertain carefully the exact nature and scope of a protective services order before accepting as legally effective the purported informed consent of a public or private social service agency offered on behalf of a patient-client.

Those states that have created new court processes to authorize unconsented-to intervention, on either an

emergency or a longer-term basis, also have established standards for identifying candidates for protective services or protective placement. Most of these states follow the same general statutory pattern. First, certain behavioral disabilities are enumerated, such as the inability to care for oneself adequately or to protect oneself from abuse and exploitation by others. Next, a number of causes for this incapacity are listed, most of which involve impairment of mental functioning. "Infirmities of aging," "senility," and "advanced age" were terms often used in earlier statutes to denote impairment in older persons, but such statutory language is rare today. In a very few states, physical impairment alone is considered a sufficient basis for intervention when the condition is likely to lead to self-neglect or victimization by others, even when there is no evidence of mental incompetence; most of these provisions have been invalidated by the courts on constitutional grounds or amended by state legislatures.

In the context of APS, physicians frequently are called on to contribute their expertise and skills in (1) identifying candidates for services; (2) providing evidence if guardianship or commitment litigation takes place; (3) exploring voluntary alternatives; and (4) planning and placement. Physicians often are in a unique, central position to identify initially those individuals who meet the eligibility criteria for, and could significantly benefit from, the intervention of an APS program. Notifying a designated APS agency of the existence and identity of such patients is incumbent on the physician in the more than 40 states with mandatory reporting statutes for suspected adult abuse and neglect (including self-neglect). In states without mandatory reporting laws, physicians making good faith voluntary reports to APS are immune from any liability connected with that reporting.³⁷

Just as written reports and live courtroom testimony are sought from physicians in routine guardianship cases, so too is this form of evidence highly valued in special protective services proceedings. The deference paid to physician opinion may be even greater in the latter situation, where less stringent eligibility criteria and procedural formalities often empower the presiding judge with even broader discretion in making findings and fashioning remedies.

As noted, it frequently is best for APS interventions to be accepted voluntarily by older persons who need help to maximize self-control over their lives. The physician has a duty to counsel decisionally capable patients about available long-term care alternatives—both institutional and home- and community based—and their relative advantages and disadvantages, or at least to direct patients to appropriate information sources.

Finally, the physician's potential contribution to service planning and placement activities for the nonindependent elderly patient should not be forgotten. The ultimate

goal is not simply to obtain protective services, whether on a voluntary or involuntary basis. Rather, the key is to assure the quality and appropriateness of the services actually provided for the older individual involved. Identification, referral, and evidence presentation should not be the end of physician involvement. Social service agencies are not merely a convenient place to deposit unwanted elders, and it is just as possible for an older person with limited personal resources to be "dumped" harmfully into the community as into a nursing home or public mental institution.

Older individuals are entitled to receive reasonable continuity of care from their physicians. If an older person changes placement (e.g., moves from a private home to an assisted living complex or a nursing facility), the principle of nonabandonment legally obligates the physician to facilitate continuity of medical care either by continuing to treat the patient personally or by making a referral to another competent, willing physician whose services are acceptable to the older person.

Confidentiality

In the course of performing their professional activities, physicians every day learn very personal, intimate information about their older patients. This knowledge of personal patient information imposes certain duties of confidentiality on the physician. Fulfilling these duties can, in specific factual situations, raise substantial legal questions.

As a general legal precept, physicians have the duty to hold in confidence all personal patient information entrusted to them. This obligation has been enforced through civil damage suits based on both statutory (legislative) and common (judge-made) law and embodied in virtually all state professional practice acts and implementing regulations. Some states have enacted statutes that provide monetary damages for physician breach of confidentiality even if the patient is unable to prove any tangible injury. State medical practice acts provide that violation of the duty of confidentiality is a potential ground for revoking, denying, or suspending a physician's license to practice medicine. Detailed federal regulations³⁸ are being developed to safeguard the privacy of medical records, based on a mandate in the Health Insurance Portability and Accountability Act of 1996.³⁹ The patient's reasonable expectation of privacy extends to all members of the health care team.

The difficulty in applying this general legal principle to concrete situations involving older patients is that the physician's duty to maintain as confidential the disclosures and medical records of the patient is not an absolute, inflexible obligation. The fact that a duty is not absolute does not mean it is not important. However,

when a duty is only *prima facie*, or presumptively applicable, one must consider whether there are relevant factors present that justify or even compel overriding that *prima facie* obligation in a particular case.

The first exception to the usual rule of confidentiality is that a patient may waive, or give up, the right to confidentiality if this is done in a voluntary, competent, and informed manner. This is accomplished daily in the health care area to make information available to third-party payers such as the Health Care Financing Administration that operates Medicare⁴⁰ and Medicaid, quality-of-care evaluators and auditors such as JCAHO inspectors or reviewers from the state's Peer Review Organization (PRO), and other public and private entities including long-term care ombudsmen and the patient's legal representatives. The physician has an obligation to cooperate fully in the patient-requested release and transfer of medical information. The patient's waiver of confidentiality and request for release of information should be honored only if it has been documented thoroughly in writing. Further, the identity and legitimate authority of the record seeker should be verified satisfactorily.

Second, when the rights of innocent third parties are jeopardized, the general requirement of confidentiality may yield. For instance, the expressed threat of a dangerous psychiatric patient to kill a specific victim, coupled with the patient's apparent present ability (not hard to imagine even for an elderly person in today's climate of easy handgun availability) and intent to make good on the threat, arguably should be reported to the intended victim and to law enforcement officials.⁴¹

Questions about confidentiality versus disclosure will arise increasingly in the context of automobile driving by older persons.⁴² Once the patient has developed age-related neurodegenerative illness and sensory impairments, the decision to stop driving may develop into an area of tension between patient and physician if informal and noncoercive attempts at persuasion fail to bring about voluntary abstinence from the roads.⁴³ Physicians must be knowledgeable about relevant mandatory reporting requirements regarding unfitness for driving; the law on this point varies among the states.⁴⁴ Only a few jurisdictions presently have statutes that expressly mandate physicians to report impaired drivers to public authorities.⁴⁵ Even in the absence of a mandatory reporting statute, some physicians have been held civilly liable when they should have foreseen a patient's dangerous driving but did nothing to prevent it and the patient then harmed an innocent third party in a motor vehicle accident.⁴⁶ Further, physicians should inform driving-impaired patients of the patients' own legal responsibility to notify the state concerning their impairment.

Third, the patient's expectation of confidentiality must yield when the physician is mandated by state law to report to specified public health authorities the existence

of certain enumerated conditions reasonably suspected in a patient. The physician should be familiar with the content of mandatory reporting statutes and regulations in force in their own jurisdiction. Such requirements may be based on the state's inherent police power to protect the health, safety, and welfare of society as a whole. This rationale would support, for example, reporting requirements concerning infectious diseases or vital statistics (e.g., birth and death). Alternatively, reporting of certain conditions may be obligatory under the state's *parens patriae* ("father of the country") power to protect those individuals who are unable to care for their own needs. Mandatory reporting of elder abuse or neglect would be justified on this ground (see Chapter 73).

Finally, the physician may be compelled to reveal otherwise confidential patient information by the force of legal process, that is, by a judge's issuance of a court order requiring such release. This order is a possibility in any type of lawsuit in which the patient's physical or mental condition is in dispute.

The Health Insurance Portability and Accountability Act (HIPAA) of 1996⁴⁷ stipulated that if Congress did not enact comprehensive requirements regarding standards with respect to privacy of individually identifiable health information by August 1999, DHHS should issue regulations on this subject. On November 3, 1999, DHHS published proposed comprehensive rules setting federal standards in this sphere⁴⁸ after the close of the public comment period on February 17, 2000, DHHS had an opportunity to modify the regulations before they would be issued in final, binding form. Once adopted, the federal rules will supersede state medical records confidentiality laws, unless a state law is more stringent in its protections of patient privacy than the federal requirements.

The right of privacy may be particularly important to today's older individuals who, as part of a cohort predating computers and modern mass communication technologies, often assign an even higher value to personal privacy than do members of subsequent generations. The right of privacy too often is compromised in treating older patients, particularly those with cognitive or emotional deficits.

An older person who has significant mental capacity may, nonetheless, through appearance or demeanor leave the impression that it is appropriate to discuss his or her clinical problems and management with relatives or friends. Every safeguard should be employed to adhere to the ordinary standards of confidentiality unless there is express, or at least unambiguously implied, permission from the patient to do otherwise or the mental condition of the patient is so disabling as to dictate involving relatives or friends within the decision-making circle. Particularly in situations of marginal or questionable patient capacity, the physician should be scrupulous in making sure that the patient has no objection to family or friend

involvement. When the family or others with appropriate authority are involved, confidential communications about the patient should be carefully handled to avoid unauthorized disclosure beyond those with a right and a need to have access to the information.

Conclusion

In some respects, as older patients as a group tend to bring disproportionately few malpractice claims against their physicians, legal liability concerns are less of a factor in geriatrics than in many other branches of medicine. In many ways, however, the elderly offer physicians a set of complex and unique legal challenges. This chapter has outlined some of the more salient legal considerations confronting and guiding physicians who care for older patients, in the hope of raising awareness of these issues in a way that will be beneficial both to physicians and to the older individuals who depend on them.

Determination of Decision-Making Capacity

Jason H.T. Karlawish and Robert A. Pearlman

An older person's decision-making capacity determines their ability to direct his or her care. They can choose whether to receive a test or a treatment, and even direct others to make choices for them. If the patient lacks decision-making capacity, however, they may not be able to exercise their autonomous choices. Other people may need to decide for them.

Decision-making capacity and the related concept of competency have received extensive conceptual development in bioethics and the law.^{1,2} This development has occurred largely because decision-making capacity is one of the essential components of the theory of informed consent. This theory is a robust guide for difficult decisions such as determining whether a person should be hospitalized against their will, have a surrogate assume authority over their own care, or even be enrolled in potentially risky research. Unfortunately, clinical medicine has been slow to adopt this theory into the day-to-day practice of medical decision making.³

Two clinical conditions emphasize the need for geriatricians to understand these concepts and to know how to apply them in clinical practice. First, elderly people are more likely than younger adults to experience illnesses that impair their ability to make decisions.^{4,6} These illnesses include neurodegenerative dementias, psychiatric illnesses, delirium, and impairments in hearing and vision. In fact, the initial diagnostic clue that a patient has one of these potentially treatable *medical* problems may be the discovery of the *ethically challenging* problem that a patient has difficulty making a decision. Second, an appreciable number of elderly people refuse life-sustaining treatment that their health care providers recommend. Although refusing treatment may be a reasonable clue that a patient has impaired decision-making capacity, disagreement with a physician's recommendation is not the sole grounds for finding a patient incompetent.⁷ A physician who is skilled at assessing decision-making capacity will find this clinical circumstance an ideal opportunity to assess the patient's

decision-making capacity and to discuss options of care, including palliative care.

Collectively, these points illustrate that the ability to assess decision-making capacity is not simply a matter of reluctantly accommodating the dictates of law into the practice of medicine. It is actually part of the competent and ethical practice of geriatric medicine. A physician who can efficiently practice the skills of assessing how a patient makes a decision has effective skills to foster communication with a patient and to identify clinically significant impairments in a patient's cognition and emotion. In this way, the physician fulfills the roles of the "doctor" as teacher and healer. The purpose of this chapter is to summarize the importance of determining decision-making capacity and to explain the standards for assessing it and judging competency. Following this introductory material, the chapter discusses particularly challenging situations and proposes mechanisms for physicians to improve the quality of their skills.

The Concepts of Competency and Decision-Making Capacity

The terms competency and decision-making capacity are often used interchangeably, or they are distinguished on the basis of the person's profession. A common and technically correct distinction is that a judge determines whether a person is competent while a physician determines whether the person has decision-making capacity. Clinical practice, however, illustrates that this distinction collapses. The consequences of a physician's judgment that a patient lacks decision-making capacity are that the patient is not competent to make the decision.⁸ Regardless of who is assessing a person's ability to make a choice, however, the terms competency and decision-making capacity do have meaningful differences.

The difference between "decision-making capacity" and "competence" is that the former describes a person's

abilities to make a decision. It is assessed according to a number of standards, described next. In contrast, competency describes the judgment that a person's decision-making capacity is adequate to make a particular decision. The former is a condition of a person, whereas the latter is a judgment that integrates information which describes a person's capacities and the context and consequences of the decision.⁹

Competency and decision-making capacity are distinct concepts. It is entirely possible that a physician could determine that a person lacks decision-making capacity but is competent to make a decision, as might happen frequently if physicians took the time to examine, in detail, their patients' choices. For example, a patient who agrees to take hypertension treatment may fail to understand certain facts about that treatment. ("The pills work because they reduce stress.") But, although this misunderstanding represents impaired decision-making capacity, it has harms that are essentially nil. Hence, given the context and consequences, any reasonable practitioner (or judge) would conclude that the person is competent to take the medication. A less common scenario is the patient who has decision-making capacity but is not competent, as would occur in the case of a legal criterion that establishes who is competent. For example, a very bright 12-year-old may fulfill the standards of decision-making capacity but, as a child, as a matter of law, is not competent.

The Importance of Assessing Decision-Making Capacity

The essential attributes that a person needs to make a decision are cognitive skills and a set of values that allow the person to categorize and weigh the importance of information. A number of medical diseases and geriatric syndromes can impair these attributes. These diseases include neurodegenerative dementias such as Alzheimer's disease and frontotemporal dementia, psychiatric diseases such as major depression and anxiety, and medical illnesses that precipitate the common clinical syndrome of delirium.

Data document notable prevalence of incompetency and impairments in decision-making capacity among patients with some of these disorders. Among patients with Alzheimer's disease who have a Mini-Mental Status Examination score between 12 and 30, the inability to understand information needed to make a decision about medical care is extremely common (nearly 90%). Nearly half these patients may retain the ability to appreciate information, however.¹⁰ Moreover, a patient's competency will vary depending upon the decision at hand. In one study, 20% of Alzheimer's disease patients were competent to complete an advance directive.¹¹ Psychiatric illnesses can also affect decision-making capacity and lead

to incompetency. A study that compared the competency of hospitalized patients with depression and schizophrenia found that the prevalence of incompetency varied from 52% of the patients with schizophrenia to 24% of the patients with depression.¹² Finally, patients without clinically significant impairments in cognition or affect can be incompetent. For example, 12% of hospitalized patients with angina were not competent to make a treatment choice,¹² and among studies of cognitively normal, community-dwelling elderly, 22% were not competent to complete an advance directive¹¹ and 7% to consent to treatment of a hip fracture.¹³

Three key conclusions can be drawn from these data. First, not all patients with diagnoses that classically affect cognition have impaired decision-making capacity. Second, an affective disorder such as depression can affect decision-making capacity. Finally, some patients with a diagnosis that typically affects cognition may have impaired decision-making capacity. For the clinician, this means that the model of using risk factors to generate pretest probabilities of a diagnosis can be adapted into the practice of assessing decision-making capacity. A patient with an illness such as major depression or mild dementia is more likely to have impaired decision-making capacity than one who does not.

The importance of assessing a patient's decision-making capacity rests in the need to balance two simultaneous ethical commitments to adult patients—to respect an adult person's autonomy and to promote that person's health and well-being. When a person has decision-making capacity, their autonomy is generally honored and decision making occurs in light of medical recommendations and patient values and preferences. In short, a patient gives an informed consent. Patient well-being is assured because a patient who understands a clinical situation and participates in decision making is more likely than the physician to know what is best for their well-being. For example, when a patient refuses a life-sustaining treatment because they give greater weight to quality of life than to the potential quantity of life, this personal choice reflects their assessment of the trade-offs between quality and quantity of life. However, a patient who cannot think through such trade-offs lacks decision-making capacity and may not be competent. If the patient is not competent, respecting that patient's choice as autonomous is both an ethical and medical error. In this situation, the physician's duty is to seek the decision of others, in particular, family or a surrogate, to make the decision.

In summary, it is important to assess decision-making capacity because it serves as a means to balance a physician's simultaneous commitments to respecting a patient's autonomy and promoting their well-being.¹⁴ Having assessed a patient's decision-making capacity, a physician then judges whether the patient is competent to make the decision.

The Standards for Assessing Decision-Making Capacity

At least one of five standards constitutes decision-making capacity.¹⁵ These standards were developed in law and bioethics, and they are intuitively sensible elements of how a rational person ought to make a decision. They provide the foundation for the judgment of a patient's competence. The physician assesses the patient's performance on each standard and then uses the results of these assessments to decide whether a patient's decision-making capacity is inadequate to make the decision.

The five standards of decision-making capacity are listed in Table 84.1. The first is the ability to communicate a choice, which describes a patient's ability to consistently state a choice ("I do not want the surgery."). Unlike the other standards, this standard makes no claim upon the patient's reasons. In a sense, it is the simplest standard. A physician assesses this by asking the patient "What would you like to do?" Much of the day-to-day practice of clinical medicine relies upon this standard or even a weaker version of it, namely, a patient's nonverbal acquiescence to an intervention such as checking their blood pressure. Diseases that can impair a patient's ability to fulfill this standard include communication disorders and extreme states of anxiety that cause a patient to rapidly change choices.

The second standard is the ability to make a reasonable choice. Like the first, this standard is quite simple but unlike the first it introduces content to the choice. The content is the "reasonableness" of the choice in which reasonableness is not necessarily defined by the patient's values but the values a "reasonable person" has; this is obviously a blunt standard to apply. For example, a physician who relies solely upon this standard would likely find that an otherwise healthy patient who refuses a low-risk and likely beneficial intervention such as surgery for a noninvasive breast cancer would have impaired decision-making capacity. Hence, adherence to this standard alone risks a paternalistic practice of medical decision making. Diseases that can impair a patient's ability to fulfill this standard include those that cause delusions and marked deficits in judgment such as dementia and schizophrenia.

Standards three through five are more substantive than the first two because they require the physician to assess

the patient's functional cognition. The third standard, appreciation, describes a patient's ability to recognize that, regardless of her choice, the facts of the decision apply to her. These facts include the diagnosis ("I know you said I have cancer and that's what this is.") and the options for treatment ("I can leave it alone or have the surgery."). This standard requires that the patient recognize the relevance of the facts regardless of how the patient values those facts. Diseases that cause delusions or disassociation are likely to impair a patient's ability to fulfill this standard.

The fourth standard of decision-making capacity is reasoning. The ability to reason describes a patient's ability to generate consequences and compare them. ("If I have the surgery, I will have given up on my faith in my ability to heal myself. If I do not have the surgery, I'll take a chance the cancer could spread.") To fulfill this standard a patient has to recognize the different options, generate the consequences of each, and compare them. The ability to achieve this standard is impaired by conditions that reduce executive function, which means the ability to attend to and compare more than one concept. Diseases that impair attention such as delirium and frontal dementia can impair a patient's ability to fulfill this standard.

The fifth standard of decision-making capacity is understanding, the patient's ability to paraphrase back the meaning of the information that the physician disclosed to her. ("A surgery will involve cutting into my skin, removal of my gallbladder, and a 3-week period of recovery.") To fulfill this standard a patient has to "say back" or paraphrase the information the physician disclosed. In doing this, the patient demonstrates that they grasp the meaning of the information. Obviously, the more facts the physician discloses, the more difficult it becomes for the patient to achieve understanding. Indeed, a physician could set the fact content so complex that even a colleague would "fail." Clearly, a judgment is required as to what facts are essential for making the decision. Understanding is most dependent on a patient's memory and language. Hence, diseases that impair memory and language such as Alzheimer's disease and aphasia can significantly impair a patient's ability to fulfill this standard.

In theory, the five standards exist along a continuum from the simplest (communicating a choice) to the hardest (understanding). One study of patients with Alzheimer's disease suggests that this is in fact true.¹⁰ However, patients with depression and schizophrenia have a different pattern of complexity.¹² The significance of this is that the physician cannot simply rely upon the "hardest standard" as a screen for decision-making capacity. Instead, a physician can consider these standards as generally falling into two categories: the first two standards are simpler and the last three are more stringent.

TABLE 84.1. The standards for assessing decision-making capacity.

The ability to make a choice
The ability to make a reasonable choice
The ability to appreciate
The ability to reason
The ability to understand

How to Assess Decision-Making Capacity

The standards of decision-making capacity provide structure to the physician's assessment. The physician uses the results of the assessment to decide what degree of performance on which of the standards is adequate to decide that a patient has decision-making capacity. A physician needs to have set routines to assess the standards and to use the results of the assessment. General rules to assess decision-making capacity are to use open-ended questions that allow the patient to think aloud, to use silent pauses rather than a battery of questions, and to sit face-to-face with a patient rather than at an unequal posture such as standing at the foot of the patient's bed.

To begin an assessment it is sensible to inform the patient of the purpose of the questions that will follow. A useful opening script might be as follows. "I'd like to take some time to go over the options of treating your breast cancer. One of my roles as doctor is as teacher. I'm a doctor of medicine, so my responsibility is to teach you about your health and options for taking care of it." To then focus on the issue of assessing decision-making capacity a physician might say, "I'd like to go over the decision you face. Can we talk about what you see as your medical problems and the options for taking care of them?"

Table 84.2 describes scripted lines to demonstrate how to assess each of the standards. Assessing the abilities to make a choice and a reasonable choice are relatively straightforward. Little skill is needed to assess these standards beyond giving the patient the opportunity to actually make a choice. As simple as this is, in the conduct of a busy office practice, a physician can forget to ask the patient the simple questions listed in Table 84.2.

TABLE 84.2. How to assess decision-making capacity.

The ability to make a choice:
“So those are the options. What would you like to do?”
The ability to make a reasonable choice:
Same as ability to make a choice. Physician judges whether the decision is “reasonable.”
The ability to appreciate:
Appreciate illness: “Can you tell me in your own words what you see as your problem?”
Appreciate treatments: “Can you tell me in your own words what you see as your options for your problem?”
The ability to reason:
Comparative reasoning: “Regardless of whether you want to try surgery or medicine, how would taking the medicine be different from having the surgery?”
Consequential reasoning: “Regardless of whether you want to try surgery or medicine, how would having the surgery affect your daily life? What about the medicine?”
The ability to understand:
“Can you tell me in your own words what I told you about the reasons for and against having the stress test?”

A key point in the assessment of appreciation is to have the patient separate their choice from their appreciation of its direct relevance to their situation, which is not an immediately obvious task to most patients. Hence (see Table 84.2), a physician asks the patient to separate the choice from appreciation of the options. Open-ended probes can be useful to allow a patient to clarify an answer. A physician assesses reasoning by asking the patient to compare options and generate consequences of options. To assess the ability to understand, the physician should ask the patient to say in their own words the information the physician has disclosed. In the case of complex information, it is sensible to disclose just parts of the information at a time. It is generally not useful to disclose information and then ask a person “Do you understand?” Most people avoid admitting their misunderstanding.

The assessment of decision-making capacity occurs throughout the daily practice of medicine. When a patient participates in the decision, does not evince any cognitive impairment or affective disorders, and agrees to a recommended treatment that has benefits and minimal risk compared with alternative treatments, it is reasonable for the physician to presume that the patient has decision-making capacity. This scenario describes much of outpatient practice. Conversely, when a patient is comatose, delirious, severely demented, or severely psychotic, it is reasonable for the physician to either observe that the patient does not have the capacity to make decisions or decide that further simple questions are needed to assess decision-making capacity.

However, between these two points there is an enormous middle ground. The principal question for a physician is what circumstances or clinical data should suggest an evaluation of a patient's decision-making capacity. Physicians should question a patient's decision-making capacity when the patient's cognition or affect appears out of the ordinary,¹⁶ such as described in Table 84.3.

These conditions fall into several categories: cognitive impairment, behavioral abnormalities, affective disorders, “unreasonable” or unusual choices, and a choice that is antithetical to previously held values and preferences.^{2,17,18} These conditions do not signify the lack of decision-making capacity or incompetency, but they do signify clues that there may be impairments in decision-making capacity and even incompetence. For example, a Mini-Mental State score that suggests cognitive impairment does not of itself describe impaired decision-making capacity, and a physician who uses it to do so would produce both false-positive and false-negative assessments of decisional capacity.^{7,19} Similarly, problems with behavioral functions may indicate problems that interfere with decisional capacity, yet the link between these two constructs has not been validated.²⁰ After one of these triggering cues, the physician needs to consider whether to assess the patient's decision-making capacity.

TABLE 84.3. Clues that may warrant an evaluation of decision-making capacity.

Cognition and neurobehavioral functions
Mini-Mental State examination score suggesting marked cognitive impairment
Disorientation
Change in preferences each time patient is approached
Attention deficits (e.g., somnolence)
Disability with language
Impaired short-term memory
Impaired reasoning
Impaired recognition
Acute change in functional status
Diminished independence in activities of daily living
Functional decline in social activities
Acute change in behavior
Psychologic modifiers of cognition and reasoning
Untreated depression
Distorted patient assessment of self, world, and future
Anxiety
Delusions
Paranoia
False beliefs
Unreasonable or unusual choices
Wanting high-burden (e.g., side effects, risks)/low-benefit treatment when available, alternative treatments seem to have better profiles
Refusing high-benefit/low-burden treatment when available, alternative treatments seem to have worse profiles
Inability to express a reason for such a choice
Shift in values or preferences
Expressing a preference for or against treatment that conflicts with long-standing values or previously expressed preferences
Family members communicate that the patient is not evincing a choice that makes sense according to the patient's history

How to Make the Judgment of Incompetence

All adult patients are competent until proven otherwise. The burden of proof that the patient is not competent rests upon the physician. The general approach to assessing whether a patient lacks decision-making capacity and is not competent is to use a sliding scale concept of competency assessment.²¹ The concept describes the physician's judgment about the adequacy of a patient's decision-making capacity in the context of the consequences of the various alternatives. The physician must categorize the consequences of the various alternatives. Then, given these potential consequences, the physician judges whether the patient has adequate decision-making capacity to make the decision.

With treatments that are relatively safe and likely to provide large benefits, it is reasonable to set a simple standard for assessing the decision-making capacity of a patient who agrees with this treatment. For example, agreement to receive antibiotics for an acute and reversible bacterial infection may be sufficient evidence of capacity to make a competent choice. However, the

refusal of this treatment would warrant a close assessment of the patient's appreciation, reasoning, and understanding. Assessing these higher standards is not meant to challenge the patient's decision, but to assure the patient and the physician that the patient's choice respects their values. In general, a high standard should be applied when a patient refuses a high-benefit and low-risk intervention or needs to make a decision about an intervention with high risks.

As in all medical judgments, physicians can make false-positive or false-negative errors. A false-positive error describes judging that a patient is incompetent when, in fact, they are competent. In contrast, a false-negative error describes judging that a patient is competent when, in fact, the person is incompetent. These errors have unique consequences. A false-positive error causes the patient to experience a loss of autonomy, respect, and dignity that can lead to feelings of frustration and loss of control to the degree that a patient feels imprisoned. Second, this type of error threatens trust in the doctor. Third, family members and physicians who are making the decisions for the patient are often inclined to "overtreat" when compared to the preferences of patients.^{22,23} This tendency increases the likelihood of iatrogenic complications and unnecessary health care costs. Fourth, it is possible that surrogate decision makers may choose to undertreat the patient. This attitude also may augment the patient's feelings of loss of respect and may result in significant harm, especially if the treatment under consideration is life sustaining and the patient dies as a result. Fifth, this error may result in unnecessary court proceedings and costly delays in treatment.

In contrast, a false-negative error undermines the principle of beneficence. This type of error increases the risk of an incoherent treatment policy. For example, patients with decisional capacity usually make medical choices that conform with personal values about the goals of their health care. When patients who have lost decisional capacity are still making decisions, this coherence is seriously threatened. Finally, false-negative errors undermine the desired societal protections afforded by surrogate decision makers.

To minimize these kinds of errors, physicians should appreciate the value of instruments that measure the patient's ability to perform each of the standards. These instruments can aid the assessment of decision-making capacity and the judgment of competency. In general, these instruments rely upon scoring a patient's answers to questions. There are two possible standards to describe what is a normal score: matching scores to the independent judgment of a clinician who is expert in assessing competency²⁴⁻²⁷ or setting a cutoff score based on some degree of deviation from the scores of cognitively normal persons^{10,12} or the scores of the subject population.²⁸ Instruments exist to assist in assessing a patient's ability

to execute an advance directive,^{11,24,28} enroll in research,²⁹ refuse emergent medical care,²⁵ and consent to hospitalization³⁰ or to treatment of a medical illness.^{10,27} Although the value of these instruments has not been demonstrated in day-to-day clinical practice, research suggests that an instrument as simple as operationalized definitions of the standards for assessing decision-making capacity can produce moderate interrater agreement.³¹ Clinicians will find these instruments particularly useful in the care of patients who face a common decision such as a geriatrician who cares for nursing home patients who need to execute an advance directive.

The value of instruments is that they can structure an assessment and limit the variability between physicians. In this way, patients are assured a fair assessment, which is particularly important because physicians have poor interrater reliability when they assess a patient's competency.³² Another potential advantage of instruments is that the range of scores on the instrument can be correlated with scores on a brief and standardized measure of cognition. Knowing this relationship, a patient's score on a measure of cognition allows the physician to estimate the likelihood that the patient is competent. A score that falls below a cutoff signals the need to scrutinize the patient's decision-making capacity.

A final advantage of scales is that they formalize the concept of "marginal competence." The term describes the patient whose performance is impaired but not so much as to be obviously incompetent. In psychometric terms, this is the patient who lies just a few points above the cutoff of incompetence. The clinical significance of this concept is that it identifies a patient who may have limited capacity to make some decisions or who needs particular attention during follow-up care. It also identifies a patient who needs alternative or additional approaches to imparting information and trying to ensure comprehension.

What About When . . . ?

Case 1: Fluctuating Mental Status

History

A physician enters a 76-year-old female patient's room before morning rounds to obtain informed consent for a diagnostic procedure. The physician finds the patient to be somewhat confused. Her Mini-Mental State examination score is 24.

Considerations

The patient's subtle confusion is both a clinical and ethical clue of a potential problem. The patient may have a delirium and may lack decision-making capacity. The

Mini-Mental State score suggests cognitive impairment, but it is an insensitive measure of decisional capacity. An interview is required to assess both the patient's decision-making capacity and the cause of the confusion. If the physician judges that the patient lacks decision-making capacity and is not competent at this time, the non-emergency procedure should be deferred. It would be premature to proceed by obtaining proxy consent.

Case 2: Decisional Capacity for Executing an Advance Directive

History

An older person desires an advance directive. Another physician has communicated that the purpose of a directive is to avoid overtreatment and abuses by the health care "system" near the end of life. The patient states that she wants a directive to avoid any unnecessary treatment.

Considerations

Decisional capacity to choose a treatment is not the same as capacity to complete an advance directive.³³ Choosing a treatment involves a real and immediate decision in the present time. Choosing treatment in a directive is more complicated. Patients need to understand and appreciate that the choices articulated in a directive will be used in the future when they are no longer capable of participating in decision making, that some choices involve medical treatments and designating a proxy, and that their choices may change over time, and if they do, the patient should change their directive. The patient should also be able to reason through the consequences of different treatments and health states.

Case 3: Patient Refusal of Psychiatric Consultation for Evaluation of Competency

History

An older man who resides in a nursing home is refusing oral antibiotics for a lower extremity cellulitis. In preliminary discussions with the physician, he refuses to discuss his problem or the reasons for the treatment. The patient refuses to see a psychiatrist for an evaluation of his competency.

Considerations

Refusal of a minimal risk and beneficial treatment signals a need to examine decision-making capacity. The reasons for the refusal should be explored. The patient may express legitimate concerns that have nothing to do

with decision-making capacity. The reasons may extend beyond the nature of the specific decision and pertain to mistrust or loss of autonomy and control in the nursing home. The patient should be informed that the use of a second opinion minimizes the risk of errors in judgment. This communication should not convey a threat; instead, it is information about options. If the patient continues to refuse the assessment, the physician should recalibrate the usual balance between competency and incompetency. Instead of the default case of favoring competency, the physician should set them in equilibrium and seek substantial evidence of decision-making capacity from sources such as caregivers.

Case 4: Depression and Treatment Refusal

History

An 88-year-old female patient involved in a home care program has long-standing depression. Multiple treatment trials have not provided appreciable benefit. She is refusing admission to the hospital for intravenous antibiotics for cellulitis of her lower extremity.

Considerations

The blanket use of a psychiatric diagnosis to determine impaired decision-making capacity is not appropriate. The physician must determine whether the diagnosis is directly affecting the patient's decision making. For example, if the patient does not have any hope, feels worthless, or cannot envision a better future, then this likely would modify their ability to rationally weigh the benefits and burdens of a recommended treatment. It would further suggest that the depression is affecting the patient's decision making and be grounds for the determination of incompetency. On the other hand, if the depression is not severe or due to its chronicity has become an authentic part of the patient's personality, then decision-making capacity might not be compromised.^{34,35}

Case 5: Requesting Cardiopulmonary Resuscitation Despite Terminal Illness

History

An older patient with disseminated breast cancer has failed the previous course of chemotherapy. Her physician decides that it would be sensible for the patient to have a "Do Not Resuscitate Order" on the chart. The physician asks the patient whether she would want them to try to restart her heart after it stops. Much to the physician's surprise, the patient states that she wants cardiopulmonary resuscitation (CPR). The physician wonders whether the patient is competent.

Considerations

Many patients consider CPR to be more effective than it is. In the physician-patient interview to assess decision-making capacity, the physician should review the patient's understanding of the likelihood of successful cardiopulmonary resuscitation in their circumstances. If the patient continues to desire CPR despite the likelihood of its failure, the basis for their preference should be explored. Reliance upon hope is not evidence of impaired decision-making capacity.

How Should Physicians Assure Quality Improvement?

The determination of a patient's decision-making capacity is a linchpin to the practice of quality medicine because it promotes patient self-determination and attempts to ensure beneficent outcomes. In general, physician skills and responsibilities have not been subjected to formal quality assurance. However, studies suggest that physicians' knowledge and skills in assessing decision-making capacity and competency may be highly subjective and arbitrary.³⁶ Thus, physicians need mechanisms to develop their knowledge and skills to determine decision-making capacity and competency.³⁷

Physicians and physicians in training have several mechanisms to ensure the quality of their skills to assess decision-making capacity. Education should focus on knowledge of the standards for assessing decision-making capacity and the skills to assess the standards and the patient's cognitive abilities and affect. Physician training of these skills should involve faculty mentoring and role modeling and expert critique from physicians such as psychiatrists. Routine clinical encounters with patients can serve as an opportunity to refresh skills in assessing decision-making capacity. Periodically, a physician should take the time to assess an evidently competent patient's decision using the methods outlined in Table 84.2.

After a physician determines that a patient has impaired decision-making capacity, if the clinical circumstances are nonemergent and the decision can be deferred, opportunities exist to improve a patient's decision-making capacity. Stopping or changing medications, repeating the assessment, or providing decision aids may improve the patient's decision-making capacity.³⁸ This process of managing decisional incapacity offers opportunities for quality assurance monitoring.

At the level of the hospital or nursing home, quality determinations of decision-making capacity can be ensured by clear policies that define who is responsible for these determinations, how it should be done, where the data should be documented, who should be involved if the determination is ambiguous, and how to resolve conflicting impressions by any of the stakeholders

(patient, family, surrogate, physician). Policies should stress the attending physician's responsibility and participation because the determination is grounded, in part, on understanding the patient's situation, prognosis, and psychologic issues. Policies also can support witnessing the information provided in the process of informed consent.

The mistaken judgment that a patient is competent may occur when a physician discloses limited information. Audits can promote quality assurance by reviewing similar cases and situations and identifying and evaluating lack of consistency. Random audits also can ask patients about their understanding of a current or recent treatment. Little attention is given to assessing decisional capacity when a patient or family is not objecting to a recommendation. In other words, there may be unrecognized problems with determination of decisional incapacity in circumstances when all stakeholders in the decision are in agreement.³⁹ When this type of audit was used in a psychiatric hospital, half the respondents who assented to treatment appeared to have impaired decision-making capacity.⁴⁰ Audits that characterize problems determining decision-making capacity can serve as catalysts for educational activities.

Summary

Decision-making capacity is a central determinant of an older person's ability to direct their own care. When a patient has decision-making capacity, patient autonomy and self-determination are generally honored. Decision making occurs in light of medical recommendations, patient preferences, and professional standards. When a patient lacks decision-making capacity, however, the substituted judgment and best interests of the patient are brought to bear.⁴¹ The risks of physical and ethical harms to the patient are substantial if a patient receives treatment without competent consent. In between these situations are patients who have difficulties making a decision but are likely competent. For these patients, assessing decision-making capacity structures the practice of effective communication and will likely reduce encounters with "difficult" or "demanding" patients.

All physicians in clinical practice should be comfortable with assessing decision-making capacity. The physician needs to remember three important considerations: (1) the purpose of assessing decision-making capacity and competency is to resolve the tension between respect for the patient's self-determination and the promotion and protection of their well-being; (2) decision-making capacity and competency both refer to a patient's ability to make a specific decision; and (3) the patient is presumed to be competent unless something triggers a question of impaired decision-making capacity.

When a decision involves choices between interventions that are relatively safe and likely provide large benefits, it is reasonable to accept a low standard of decisional capacity, such as the mere evidence of a choice. However, refusal of these interventions or a decision that involves greater than minimal risks or only marginal benefits should require a higher standard, such as requiring the patient to demonstrate understanding, appreciation, and reasoning. In general, this process will serve the interests of both the patient and physician because it fosters effective communication.

The need for a combination of clinical judgment and common sense in the determination of decision-making capacity raises the possibility of wide variations in clinical practice. Educational programs, role modeling, use of second opinions, provision of advisory feedback from ethics committees, and other quality assurance mechanisms should be implemented to minimize this occurrence.

Ethical and Policy Issues in End-of-Life Care

Melissa M. Bottrell, Christine K. Cassel, and Emily R. Felzenberg

Clinical medical ethics combines the disciplines of philosophy, behavioral science, law, and medicine to resolve moral issues and value conflicts in medicine. All physicians face ethical dilemmas, but the practice of geriatric medicine is particularly rich and ethically complex with respect to end-of-life care. Elders often face chronic illnesses for which treatments are costly or risky, have uncertain outcomes, or are unable to offer meaningful disease modification or prolongation of life.¹ The ambiguity regarding beneficial outcomes colors decisions about often difficult trade-offs between treatments that may offer potentially significant reductions in quality of life versus treatments that may not extend life but may increase comfort and thus quality of life. Decisions to change the focus of care from curative interventions to more palliative care can produce anxiety for patients and family members. Additionally, many elders may have conditions that profoundly impair communication and cognition. The result is often uncertainty about who should make health care decisions, what constitutes informed consent, and how to ascertain what decision should be made. Finally, in the broadest sense, care for elders accounts for the largest segment of health care spending, half of which comes from public programs, leading to questions about the relative value of health care compared with other goods available in the market and the value of marginally effective or futile treatments when survival is not likely to be long. Such issues pose ethical questions about intergenerational resource transfers and ultimately moral issues related to rationing of medical resources.

Approaching these difficult ethical issues requires both an awareness of how these concerns intersect the practice of geriatric medicine and a systematic approach to examine the issues. Bioethics offers numerous systematic approaches to ethical analysis of moral dilemmas, for which examples and training can be found in numerous texts.¹⁻³ Many of these approaches use a set of basic principles that undergird both attitudes of the public as well

as personal values of physicians.⁴ These principles commonly include beneficence, respect for persons, fidelity, and justice. For purposes of this chapter, discussion of issues in geriatric medicine and end-of-life care is focused through the lenses provided by these principles.

Discussion and implementation of decisions surrounding end-of-life care are critical. Attempts to improve end-of-life care often focus on enhancing the role of patients (and when appropriate, family members) as partners in the decision-making process and resolving conflicts that interfere and may even prevent health care providers from creating a good dying experience for patients and their families.⁵ Using the principles of respect for persons, beneficence, fidelity, and justice together with the systematic approach offered by clinical medical ethics, the clinician can better address and resolve issues of ethical importance in end-of-life care, including understanding and appropriately managing ethical conundrums brought forth by issues of patient autonomy, withholding and withdrawing life-sustaining treatment, futility, do not resuscitate (DNR) orders, and physician-assisted suicide.

Transition Decisions: From Life-Sustaining Treatment to Palliative Management

Decisions to forgo life-sustaining treatment occur under a multitude of conditions. They can be provoked when it is decided not to resuscitate a patient with advanced dementia, to maintain a resident in a nursing home rather than transfer them to the hospital for diagnostic or treatment interventions, to replace chemotherapeutic treatments focused on curing cancer with palliative radiation, or not to administer antibiotics to a bedbound elder with severe chronic obstructive pulmonary disorder (COPD). In each case, the decision-making process must use a benefit/burden analysis comparing the benefits of

treatment options against potential burdens of the treatment and potential side effects. Such decisions also take place within a larger social context such that benefit/burden analyses may differ for an older patient compared with a younger patient because of personal fears about aging and disability or stereotypes of aging.⁶ Some authors claim that advanced age may give persons a different perspective on what remains of life and the so-called closing biography—suggesting greater acceptance of mortality. Yet, providers cannot assume this stance simply because of patient age and must approach each patient individually. Within that analysis, the decision-making team of patient, family, and clinical professionals must consider how to respect the patient's autonomy within their cultural context, support the family, and, to the extent possible, relieve the burden while also recognizing that some treatment courses may be futile.

Respecting Patient Autonomy

Because freedom is so central to our philosophy as a nation, it follows that autonomy is an integral part of medicine in the United States. Mechanisms to respect patient autonomy run throughout the health care endeavor, from patient education materials regarding particular treatments or diseases, to physician training in how to communicate with patients, to forms for informed consent and advance directives. These tools aim to create an environment in which it is possible for the clinician to ascertain the beliefs, perspectives, and concerns of the patient so as to focus health care decisions in a manner that enhances patient autonomy. Autonomy may also conflict with beneficence, as for example, when a patient refuses a proposed treatment despite the physician's best recommendation. Further, in this multicultural nation, not all individuals or families expect to express their autonomy in medical decisions in the manner most typically expected in legal contexts, especially when making the emotionally and technically fraught decisions at the end of life.

Advance Directives

The practical difficulties and ethical dilemmas surrounding patient autonomy can be most obviously seen through examination of advance directives. In the United States, estimates of the percentage of persons who have executed advance directives range from 4% to 20%. Highly educated Caucasians are generally more receptive than other groups to advance directives and tend to forgo life-sustaining treatment at a higher greater rate. Those who are poor and nonwhite, particularly Hispanics and

blacks, may feel apprehensive about treatment limitation because they already feel that they have restricted access to care, and thus are hesitant to give the health care system an additional reason to withhold care.⁷ Further, elders commonly do not complete an advance directive because they feel they can rely on others, in particular, their families, to make decisions for them, and, in fact, expect family members to help make complex health care decisions. Thus, for many elders, the particularly Western view of autonomy that stems from the individual and is expressed through a legal document does not apply to their expression of autonomy.

For these elders, respect for persons may flow from a broader family perspective that includes considerations of family burdens of care or expectations that a particular family member (i.e., a son or daughter) is the appropriate decision maker.⁸ When an elder is cared for by family at home or is a longtime nursing home resident, specialized knowledge of the patient that comes from being surrounded by family members and clinicians who know the patient further helps to ensure that the patient's vision of autonomy is supported. In practice, however, modern medical practice often involves myriad transitions between settings, through which neither the knowledge of the patient nor explicit directives about the patient's end-of-life care preferences through advance directives are transferred.

Inconsistencies in care between settings often result from the patient's inability to communicate, lack of uniformity in advance directives or advance directive policies, fear of liability on the part of the institution, physician, and other health care providers, and absence of an advance directive. Even when advance directives exist and are accessible, they have limitations because the language is often ambiguous or lacks specific directions for the situation at hand. In unclear situations of patient preferences, nursing home staff may transfer residents to hospitals, and emergency medical technicians (EMTs) may administer cardiopulmonary resuscitation (CPR), although this may be contrary to patient wishes. A number of strategies are available to combat the lack of continuity of care and breaches of support for patient autonomy. Physicians should encourage patients to designate a specific health care proxy or surrogate who, depending on state law, can be empowered to speak for the patient when the patient is unable to do so. Further, improved communication between health care professionals and institutions is necessary. For example, hospital physicians and other clinicians should meet staff in nursing homes that regularly admit patients to their service. Doing so could provide contacts to which the clinician could turn when context is missing regarding the preferences or concerns of a particular patient or family and thus provide alternatives means by which to clarify patient's wishes.

As another approach, Oregon developed the Physician Orders for Life-Sustaining Treatment (POLST), a comprehensive, one-page order form to convey preferences for life-sustaining treatments during patient transfer from one care setting to another. The form specifies four categories of care, including (1) do not resuscitate (DNR) orders, (2) comfort care, (3) antibiotic use, and (4) tube feeding.⁹ Studies show use of the POLST leads to consistent respect for patient preferences to limit life-sustaining interventions.^{9,10} The POLST attempts to overcome problems regarding lack of availability of advance directives, failure to comply with the patient's DNR order because the patient's wishes are not known, and physician fear in signing DNR orders because care may be compromised or cannot be implemented without translation into a physician's order.

A high degree of respect for patient wishes is implied in the POLST. Several features contribute to the form's effectiveness and consistency, including its statewide standardization, the pink color that makes it hard to ignore, easily locatable and clearly stated orders, acceptable and understandable language about the orders, and language specific to comfort care for pain and suffering. Specifically, the POLST, unlike an advance directive, limits specific treatments according to patient wishes and concurrently implements the preferences by putting them into the form of physician orders. The POLST offers a promising way to ensure patient end-of-life treatment preferences are respected.

In addition to the POLST, several state legislatures are considering policies allowing EMTs to accept DNR (do not resuscitate) orders of patients being transferred to hospitals, hospitals are honoring advance registration of DNR orders to ensure compliance of out-of-hospital DNR orders (i.e., those written in nursing homes), and advocates are supporting wallet cards, bracelets, or other forms of DNR order identification to increase compliance with patient wishes.

Withholding or Withdrawing Life-Sustaining Treatment

Although patient preferences as expressed in advance directives may provide an outline of how to approach a patient's care, at some point, decisions about treatment plans include hard choices of more than simply adding comfort care but also whether to withhold or withdraw life-sustaining interventions. Patients have a right to refuse treatment even if it is life sustaining.⁴ Withholding life support is defined as not providing a patient with medical interventions, such as CPR—the procedure most frequently withheld. Withdrawing life support is defined as removing previously initiated medical interventions, such as mechanical ventilation—the procedure most fre-

quently withdrawn.¹¹ In the clinical setting, definitional distinctions between withholding and withdrawing are often made. In some cases, it may seem morally and conceptually easier to withhold a particular procedure, such as mechanical ventilation when the outcome of beginning the procedure is less certain, than to withdraw treatment, because although a treatment may not provide meaningful outcomes, treatment withdrawal would result in death. Moreover, the timing of decisions often makes the distinctions between withdrawal and withholding seem relevant. Withholding can occur relatively suddenly if the patient goes into cardiac arrest. Withdrawing is often a gradual process and may involve administering analgesics and sedatives to the patient while removing a treatment. In practice, withdrawing is documented more frequently than withholding.^{11,12}

Physicians often become morally, legally, and even psychologically committed to a treatment's completion, once started,¹² especially when the patient has been receiving the intervention for a long time. Thus, intervention withdrawal tends to occur more commonly for treatments that are invasive, expensive, scarce, or lead to a quick death once withdrawn, and tends to occur less often when treatments have been in place for a period of time or for the management of iatrogenic complications.¹³ Physicians may be "committed" to the ventilation or dialysis support that they initiated, even though the treatment fails to clearly benefit the patient. Treatment continuation may even cause patients to receive unwanted treatments despite their ethical and legal rights or that of their surrogates to refuse life-prolonging interventions. Health care professionals, including physicians and nurses, often lack training with regard to the clinical aspects of withdrawing intensive life-sustaining treatment, such as palliation of dyspnea. Such skills are necessary to provide effective end-of-life care.

Despite the common use of the terms in practice, the definitional distinction between withholding and withdrawing lacks logical validity and moral relevance. All treatment decisions contain some of the elements of a withhold or withdrawal decision—the morally and legally relevant distinction between treatment decisions is that, irrespective of whether a life-sustaining treatment was withheld or withdrawn, the outcome is the patient's death. The patient's right to remove or not initiate life-sustaining treatments has both a moral and a legal grounding.

Legal Protections for Patient Autonomy

The legal basis for respecting patient decisions at the end of life stems from a variety of sources—most famously from two cases that involved the withdrawal of life

support. Karen Ann Quinlan and Nancy Cruzan were young women in persistent vegetative states whose families wished to have their life support removed. In *Quinlan*, the New Jersey Supreme Court recognized the right to withdraw medical interventions from an incompetent patient in accordance with the family's belief that the patient would have wanted treatment withdrawn.^{12,14} In *Cruzan*, the U.S. Supreme Court affirmed the right to withdraw artificial life-sustaining treatments once the incompetent patient's wishes are known with relative confidence.^{12,14} Many similar cases involve elderly people who lacked capacity because of dementia and in which the family sought to limit life-sustaining interventions. With very few exceptions, the cases all were upheld so long as the decision to limit treatment was consistent with the patient's values. Philosophically, because the state has an interest in protecting and ensuring the continued life of its citizens, these cases validate the state's legal interest and right in interpreting an individual's preference, including those who are incompetent, to forgo life-sustaining treatment.¹²

Artificial Nutrition and Hydration

Within the context of decisions to withdraw or withhold care, decisions regarding forgoing artificial nutrition and hydration often raise special concerns. Legally, intravenous lines or tubes are considered medical procedures and thus are subject to the same benefit to burden analysis as any other technical intervention, such as dialysis or mechanical ventilation; surrogates and patients have the right to refuse them as with any medical treatments.¹⁵ At the same time, providing food and water is felt by some to be a moral duty and an essential form of supportive care.¹⁶ The idea of food and water is also emotionally comforting to a family in their caring for a dying patient.⁴ Decisions to forgo nutrition and hydration typically commonly concern patients with moderate to severe loss of cognitive function due to Alzheimer's disease or dementia, strokes resulting in loss of ability to swallow, end-stage diseases (e.g., metastatic cancer), end-stage organ failure, and treatment complications (e.g., infection, aspiration pneumonia).⁴ Such situations, in which a family already carries a heavy emotional burden, are only made worse by the emotional feelings often connected to food and water.

However, the eating process is a human contact quite different from intravenous, gastrostomy, or jejunostomy feedings. Continued intervention may result in fluid overload and significant discomfort whereas death after withdrawal may be more comfortable. Therefore, understanding and evaluating the reasons offered to forgo artificial hydration and nutrition and thus withhold or withdraw life-sustaining treatment are essential to pro-

viding effective end-of-life care. Clinicians, patients and family members must consider when artificial nutrition and hydration may prolong dying and patient suffering, acknowledge that these treatments may lead to poor quality of life, and thus make the more humane choice to allow the patient to die.

Do Not Resuscitate Orders

DNR (do not resuscitate) orders are recommended for most terminally ill patients¹⁷ and so require consideration in end-of-life care. People of very advanced age or with multiple advanced chronic illnesses who suffer an unwitnessed, out-of-hospital, cardiac arrest have restorative success approaching zero. Even for witnessed arrests, a return to earlier functioning is unlikely, making the success rate of CPR administered in nursing homes 0% to 5%.⁹ A DNR orders clinicians to not pursue efforts to restore cardiac function if the heart stops beating or lungs stop functioning.¹⁷ For patients with primary lung disease, patients may also elect to forgo intubation and mechanical ventilation because it is painful and unlikely to lead to a return to an acceptable quality of life. For these patients, cardiac arrest may be reversed with a quick attempt at resuscitation, such as defibrillation, but the patient may want a DNI (do not intubate) order. For patients with very end stage disease, a DNR/DNI order covers both.

The DNR order does not exclude or prohibit use of other medically suitable interventions. As with other medical decisions to forgo life-sustaining treatment, deciding whether to administer CPR requires evaluation of the ethical considerations such as the potential likelihood of clinical benefit and the patient's preferences. Unlike most medical treatments, however, a presumption in favor of sustaining life exists legally, ethically, and medically, making CPR the correct course of treatment unless a DNR order is in place, or unless the treatment is refused or deemed medically futile. Unlike many treatments, CPR does not require a physician's order but does require a contrary order in the form of a DNR order to withhold it. It is the only medical treatment of this sort, because success depends on immediate response.¹

Because current policy dictates CPR be attempted for every patient in cardiac arrest who does not have a DNR order, CPR raises unique challenges with regard to decisions to forgo life-sustaining treatments. First, a CPR decision is conditional, depending on whether cardiac arrest actually occurs within a health care setting. Further, the success of CPR depends on factors such as how quickly it is administered after cardiac arrest, the skill of the resuscitation providers, access to a cardiac monitor, the patient's general health and well-being, and the underlying medical conditions. Although CPR may

restore life with effective circulation after a cardiac arrest in some patients, CPR is often unsuccessful in patients with advanced disease and contravenes the concept of a gentle or dignified death.

With DNR orders, as for other medical interventions, informed choices are required and must be based on clear information about the benefits, risks, and alternatives available to the patient. In practice, many elders have mistaken perceptions of the effectiveness of CPR as well as mistaken understandings of the procedure based on television or popular media. Some studies have shown that when elders are fully informed about the low probability of restorative success and the actual steps that occur in CPR, such as chest compression and the potential for cracked ribs in frail elders, they opt for DNR status over CPR.¹⁸ Yet, clinicians often fail to comprehensively discuss CPR.¹⁸ Fully informed communication about end-of-life care options must include comprehensive discussion of CPR, other medical interventions, and palliative care options. Recommendations about CPR should be clear and definitive so the patient or surrogate, their families, and other health care providers (such as nursing home nurse aides) understand the decision and have the opportunity to ask questions. To the extent possible, a DNR decision should be made with the support and assistance of the geriatric care team as well as family members to stave off potential conflicts at the last moment. The DNR order must reflect the patient's preferences, values, and beliefs and be careful not to impose the physician's value judgments or the surrogate's wishes. Finally, consulting with social workers, spiritual guidance counselors, or ethics committees can support sound and just decisions and ensures that the patient's wishes are respected.¹⁹

Futility

Decisions to withhold or withdraw care may be prompted not only by desires to focus on quality of life but also by recognition that some treatments may be futile. Considerations of treatment futility may be more common in geriatrics because older people have limited life expectancies.²⁰ In terms of justice, ethicists argue that physicians have a responsibility to avoid harm to patients that may result from providing futile treatment, as well as larger social concerns that providing futile treatments limits the availability of scarce resources for use by others for whom treatments would be effective. If futility were a straightforward empirical assessment, many end-of-life decisions could be easier. Many authors have thus examined the concept and proposed decision criteria. Unfortunately, although some futility judgments are justified, applying the concept in practice may not be an appropriate tactic because futility judgments are often fraught

with "confusion, inconsistency and controversy."¹ Nevertheless, the concept is worthy of discussion because the term and the concerns about futile treatments often inform considerations about end-of-life care in the elderly.

Strict and Loose Definitions of Futility

Strict definitions of futility, which could be applied to fairly and uniformly guide decisions to withhold or withdraw life-sustaining treatments, are based on objective criteria and the medical expertise of physicians.¹ Lo proposed three strict criteria, which include the following. (1) *The treatment lacks a pathophysiologic basis*—no ethical or legal justifications can be offered to continue treatment when there is no physiologic benefit for the patient. (2) *Despite maximal treatment, cardiac arrest occurs*—when optimal therapy fails, treatment is medically futile to continue. For example, CPR is ineffective when it would fail to effectively restore circulation to a patient in cardiopulmonary arrest. (3) *When the treatment has already failed for the patient, it is deemed futile and lacks a medical, ethical, or legal reason to continue repeating failed interventions.* For example, the patient does not respond to CPR and remains asystolic even 30 min after CPR was initiated.

Lo also offered four looser definitions for futility that could be applied to end-of-life care for elders. (1) *A small probability of success exists with the treatment.*¹ The difficulty is determining an appropriate cutoff point (i.e., 1% versus 5%) for futility in this probabilistic approach. Even if a quantitative threshold is stated, disagreement between patients and their surrogates may result because no single probability can be applied to define an unacceptable risk in every potential set of circumstances. In addition, although a probability may be small, it still may be considered worthwhile. The concern then becomes how to measure a small probability of survival, especially as data regarding effectiveness of clinical interventions in elders and especially the oldest-old are often unavailable.

(2) *Physicians do not believe the treatment will succeed in achieving any desired goals.*¹ This determination raises controversial value judgments. Patients or family members may desire treatment to achieve nonmedical, short-term goals, such as allowing family from far distances to see the patient before death. In such circumstances, physicians may have a moral duty to act with compassion and sustain life despite the lack of a legal duty to do so. Experts generally agree that patients should be informed in a comforting matter if even a small chance of success exists because of the need to support fully autonomous decision making on the part of patients or health care proxies. This definition of futility, however, can be used to guide treatment choices for patients when

palliative care becomes the most humane treatment approach.⁶

(3) *The patient's quality of life is not acceptable.*¹ Treatments may be termed futile when patients, family members, or clinicians judge the patient's quality of life unacceptable, such as when the patient is permanently unconscious and will never regain cognitive functioning. However, use of this definition by physicians exclusively to guide end-of-life decision making runs the risk of paternalistically imposing the physician's values upon patients. Advocates for the disabled and other vulnerable populations, such as the elderly, oppose the quality of life criterion suggestions as being discriminatory and disguised value judgments about the value of the lives of those less able bodied. Moreover, competent elderly patients, having learned to cope with chronic illness and find ways to enjoy life, tend to more highly regard their own quality of life than their family does. Patients with Alzheimer's disease who are incompetent and cannot communicate, but who do not appear to be suffering, create complex quality of life judgments for their family and physician.¹

(4) *The expected efforts and resources required outweigh prospective benefits.*¹ The issue is whether the benefits to the patient are worth the costs to society as a whole. This consideration recognizes arguments about rationing in which cost rather than benefit becomes the deciding factor and in which treating patients with poor prognoses of survival may deny treatment to other patients with better prognoses.²¹ Use of this criterion may appear to have an objective basis, but moral implications implicit in the definition make it a poor definition to use for final determination of when treatments should or should not be applied for particular patients.

The difficulties inherent in each and every one of the strict and loose definitions and the disagreement among physicians that persist in its application to patient care means that futility, at this time, is only one of many points to consider in making decisions for patients at the end of life. The principle of beneficence speaks to the physician's obligation to do what is best for the patient. Beneficent care requires attention to technical expertise as well as compassionate care, and allows for greater leniency in the physician's response to patient or surrogate requests for interventions decided to be futile, especially when death is imminent. In geriatrics, adequate knowledge of clinical medicine and biomedical science is as important as a caring approach to the patient.

In practice, physicians who are concerned that they are being asked to support futile treatment should focus on ongoing communication, consultation with ethics committees, and second opinions from colleagues to help minimize potential mistakes in futility judgments, keep value judgments in check, and simultaneously protect the professional and moral integrity of physicians and patient

autonomy. Keeping the patient informed and discussing the intervention's futility with the patient or surrogate is an important ethical and legal obligation and the best approach. Such discussions are usually beneficial to patients or surrogates and reinforce the principles of care, including respect for patients. Most patients or surrogates will eventually support the physician's judgment¹ and appreciate unambiguous and compassionate communications and recommendations.

Euthanasia and Physician-Assisted Suicide

In the broadest sense, euthanasia, physician-assisted suicide (PAS) and decisions to withhold or withdraw life-sustaining treatment share common objectives such as relief of pain and suffering and respect for patient autonomy. The importance of these issues in end-of-life care for elders is highlighted by ethical, legal, political, and societal trends that frame the debate, along with religious and philosophical beliefs.^{22,23}

Active euthanasia, also called mercy killing, causes death and ends suffering by intentionally administering medication directly to end the patient's life.¹⁷ Euthanasia is generally categorized in three ways: that is, voluntary when a patient requests it, involuntary when a patient expresses opposition, and nonvoluntary when a patient has lost capacity and cannot make decisions or express his or her wishes.^{1,23} Involuntary euthanasia, although practiced in the form of lethal injections for death row inmates, is always immoral if considered as part of a health care plan. As respect for patient autonomy is potentially the only acceptable justification for active assistance in dying, nonvoluntary euthanasia is not an acceptable practice.¹

The fine distinction between euthanasia and physician-assisted suicide involves the physician providing to the patient a lethal dose of medication, on the patient's request, with the intent to allow the patient to end his or her own life.¹⁷ The patient independently must perform the final act. Physician assistance in dying may range from providing the patient with information about committing suicide to prescribing medication. Because the patient must carry out the deed, concerns about compelling a patient against his or her wishes and abusing the powers associated with being a physician and the physician's role are lessened, although still a potential consideration. Still, being relieved of the moral responsibility for the suicidal act does not relieve the physician of further moral responsibility in physician-assisted suicide. Each situation necessitates careful consideration of the intent, motivation, justification, and results of the decision. Again, as with most end-of-life decisions, discussion with the patient and his or her family is critical and

allows for more effective and meaningful palliative care practices.¹

In practice, a physician is not, however, assisting with suicide if the physician is providing treatments to relieve pain and suffering even if the patient's death might be hastened.¹⁷ In such circumstances, the underlying illness, not the treatment provided or withheld, is the cause of the patient's death. The distinction between "killing" in the sense of euthanasia or PAS versus "allowing to die" in the sense of withholding or withdrawing care, or providing high doses of narcotics or sedatives to relieve pain but that also may result in patient death, is useful in practice. However, many philosophers consider the distinction problematic. These authors find the distinction between "killing" and "letting die" to not be a sound basis for moral judgment. Second, the idea that the disease causes the patient's death rather than the withholding/withdrawing of treatment may not be tenable because death may not have occurred in the absence of this factor. Third, assisted suicide and letting die cannot be distinguished by the intent of the patient. A patient who is refusing treatments and who has had adequate informed consent also recognizes death as an outcome and thus the distinction lacks moral weight. Conversely, the U.S. Supreme Court has held that there is a rational distinction between killing and letting die,^{24,25} and that those who ask their doctors to commit assisted suicide and those who forgo treatment are not similarly situated.²⁶

Concerns about active euthanasia and assisted suicide should not make physicians reluctant to relieve distressful symptoms in terminally ill patients. Indeed, fears that terminal distress will not be adequately relieved impel some people to seek active euthanasia and assisted suicide. Physicians should continue to partner with patients and families to ensure that patients are fully informed of consequences and feel more assured that they will not be abandoned when the plan of care moves from curative to palliative.

Physician-Assisted Suicide and Conflict with the Physician's Role

Physician-assisted suicide and euthanasia cause conflicts for the physician's healing role, because, traditionally, a physician has a duty to preserve life.¹ Arguments against physician-assisted suicide emphasize the sanctity of life,¹ debate the passive (e.g., withholding treatment) versus active (e.g., physician-assisted suicide) killing distinction, discussed earlier, and examine the potentials for abuse, especially with vulnerable populations.^{1,25,27} Other authors argue that the physician's professional ethics and integrity may be jeopardized by performing PAS.^{25,27} The trust in the physician-patient relationship

could be breached, and patients may forgo seeking a physician's care. Lack of diligence in ensuring that the patient's requests are voluntary and that the appropriate patient receives physician-assisted suicide,¹ as well as inevitable mistakes,²⁵ are additional concerns. Important, but often inarticulated, are the religious beliefs of ethicists and policymakers on this issue. Respect for religious freedom requires allowing individual choice even if it conflicts with one's own values.

Justifying Physician-Assisted Suicide

Arguments in favor of physician-assisted suicide focus on showing respect for individual autonomy,¹ recognizing the right of competent people to choose the course of their life and death, the importance of comfort and relief of suffering, and a justice argument for treating "like cases alike." If competent, terminally ill patients can refuse treatment and thus hasten death, suicide becomes the only option for patients when treatment refusal will not suffice to hasten death. Physician-assisted suicide then serves as a compassionate alternative to unbearable suffering, because physical and emotional suffering cannot always be relieved.¹ Although society has a strong interest in preserving life, that interest may diminish when a person is terminally ill and has reached his or her "closing biography," has said good-bye to family, and wishes to exit "on his or her own terms," usually described as death with dignity. Personal liberty is limited when there is a complete prohibition on assisted death, warranting the allowance of physician-assisted suicide in certain cases. In circumstances where suicide would happen with or without assistance, PAS allows a more humane and controlled method of end-of-life decision making.¹ Religious tolerance requires respect for personal objections to all killing, but religious tolerance also requires us to respect those whose beliefs support a right to end their own lives, especially in the context of intractable suffering and ultimately terminal illness. The political debates in numerous states and in the U.S. Congress demonstrate the depth of feeling on both sides.

Legal Issues and Physician-Assisted Suicide

Voluntary euthanasia and physician-assisted suicide have been openly condoned in the Netherlands for more than 10 years. Although critics argue that abuses occur, such as euthanasia of disabled infants and elderly persons with dementia, popular support in the Netherlands remains high. In the United States, Oregon has legalized a very limited form of PAS. The U.S. Supreme Court has unanimously ruled that no constitutional right to physician-

assisted suicide exists. Statutes prohibiting physicians from providing lethal medication for use by competent, terminally ill patients do not violate the Due Process or Equal Protection Clauses of the Constitution. The Court found no fundamental liberty interest in committing physician-assisted suicide, protected by the Due Process Clause of the 14th Amendment.^{24,25,27} The Court also implied a right to adequate palliative care and held state laws constitutionally valid in distinguishing between prohibiting intentional acts to hasten death and permitting acts to relieve pain while unintentionally hastening death. States considering legalization of PAS are required to ensure palliative care is adequate and effectively implemented.²⁴

Safeguards and Guidelines for Performance of PAS

Consideration of legalized PAS must include guidelines to balance a humane response to a patient's individual values with providing adequate protection to vulnerable populations. Such guidelines must clarify that a tolerable death and well-controlled pain and suffering should result from comfort care.²⁸ Thus, physician-assisted suicide is only acceptable for terminally ill patients with incurable conditions whose illnesses are accompanied by severe pain and unrelenting suffering. Adequate palliative care must be provided. The patient's decision must be voluntary and informed, and asking for assistance in dying must be a continuous, clear, and convincing request to end suffering. The patient's ability to make sound decisions must be demonstrated, including identification and treatment of depression. The doctor-patient relationship should have been maintained over a period of time and be meaningful to best understand the patient's desire for physician-assisted suicide. More than one physician should evaluate the patient to confirm that the choice is voluntary, informed, and rationally reached. The concept of such careful guidelines lies behind Oregon's legalizing a narrowly defined form of the practice.²⁸

Physician-Assisted Suicide in Oregon

Physician-assisted suicide became an option for terminally ill patients in Oregon with the passage of Oregon's Death with Dignity Act. A terminally ill person can request a prescription to end his or her life if he or she qualifies under the law's requirements.²⁹ Because care for terminally ill patients is also considered the purview of hospice care, however, conflicts between hospice care philosophy and physician-assisted suicide continue to be the subject of debate.³⁰ In the first 2 years after the Supreme Court upheld the law, 56 persons received pre-

scriptions for a lethal dose. Of those 56, 43 died of the lethal dose, 11 died of the underlying disease, and 2 remained alive as of January 2000.³¹ Requesters were, on average, in their early seventies, and cancer was the most common illness. Patients expressed concern over inadequate pain control, losing autonomy due to illness, and losing control over bodily functions. The number of requesters remains small and has not resulted in an overwhelming rise in physician-assisted suicide, as initially anticipated and feared. Moreover, in some local communities, fears that clinicians would be faced with requests for PAS have prompted regional improvements in pain management and other end-of-life care services.³²

Physician-Assisted Suicide and the Elderly

As life expectancy grows, many older people face years of isolation and decline. Some may want to assert a right to a dignified death on their own terms, making PAS an option. This phenomenon may be responsible for the increase in suicide rates among elderly men in the United States. On the other hand, abuses could occur in this vulnerable population. Pressure could result, including influencing elderly people to choose physician-assisted suicide rather than more expensive palliative care options. Families may choose physician-assisted suicide to relieve caregiving burdens and even encourage physicians to impose value judgments in quality of life on the patient or surrogate.

In one study comparing attitudes of elderly outpatients and their families toward PAS, family members held more favorable attitudes toward PAS than patients in cases of terminal illness (59.3% versus 39.9%), in cases of chronic illness (25.3% versus 18.2%), and in cases of mental incompetence (55.6% versus 34.0%).³³ Moreover, family members poorly predicted patient attitudes toward PAS. Thus, focusing on the patient's interests rather than family preferences or a physician's moral judgments becomes an important direction and goal for end-of-life care decisions.

Conclusion

The particular ethical quandaries posed by geriatric care at the end of life require that physicians, patients, and families candidly discuss and consider end-of-life care. Decisions to withhold and or withdraw life-sustaining treatment are grounded in respect for patient autonomy, beneficence, and considerations of medical futility. Artificial nutrition and hydration and DNR orders pose particular concerns but can be managed by partnering with patients in their care. Physician-assisted suicide may be a

final option for some patients in some states but should be approached with awareness of important guidelines for protecting patients against potential abuses. Even without formal ethics training, the practitioner who cares for elders daily manages personal dilemmas brought about by the sensitive issues inherent in end-of-life care. By applying the principles of medical ethics to the thoughtful care of older adults, geriatricians can set an example in the care of patients with difficult ethical problems generally and in end-of-life care specifically.

Ethical Challenges to Research in Geriatric Medicine

Greg A. Sachs and Harvey Jay Cohen

For many years, one of the main items on the agenda of advocates for improved health care for older people has been the promotion of research on the medical problems that affect the elderly. Until the 1980s, it was quite common for people over age 65 to be excluded from clinical trials, even from studies of disease that disproportionately affect the elderly, such as heart disease and cancer. Many clinical problems of older people received little or no research funding. Clearly, great strides have been made in the past two decades. There is a National Institute of Aging at the National Institutes of Health, geriatric medicine fellowships train investigators in research around the country, journals specializing in geriatric medicine and gerontology are flourishing, general medical journals abound with articles related to the care of the elderly, and clinical trials include older subjects, many even focusing specifically on older adults. Yet, as research involving older human subjects has gone forward, many important ethical challenges to the conduct of this research have either emerged or resurfaced.

In this chapter, we discuss three main aspects of the ethical challenges to research in geriatrics. First, we briefly review the principles of research ethics of the past 50 years as applied to human subjects of all ages. Second, we highlight the ways in which geriatric research presents special challenges. Third, we discuss the most recent developments and controversies in research ethics, many of which challenge the traditional model of research ethics.

Historical Overview

Discussions of the ethics of research involving human subjects for at least the first 40 years following World War II were dominated by concerns about informed consent. This attitude is not surprising, given that, starting with the Nazi experiments on concentration camp prisoners, many

of the most egregious abuses of research subjects and most ethically suspect research involved either non-consenting or uninformed subjects. Table 86.1 lists some of the most important of these troubling cases, as well as many of the international and U.S. responses in terms of guidelines and regulations for the ethical conduct of research involving human subjects. It is worth noting that the amount of activity in the last few years, especially with respect to federal oversight and both proposed and actual regulatory action, is greater than at any time since the development of the U.S. research oversight structures in the 1970s. We address many of these regulatory developments in the final sections of this chapter.

In the United States, much of the current institutional review board (IRB) apparatus and attention to informed consent and consent forms flows from federal regulations that were adopted following the reports of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (the National Commission).¹ Although formulating standards relating to informed consent was an important part of the work of the National Commission, it is important to recognize (as the National Commission did) that many other ethical principles need to be addressed when evaluating research.² First, informed consent is not a primary level ethics principle, *per se*. The fundamental principle that gives rise to the attention on informed consent is the principle of respect for persons. This principle, as stated by the philosopher Immanuel Kant, requires treating people as ends rather than as means to an end. To some extent, researchers use their subjects as a means rather than an end, as a means to obtain an answer to their research question. Using people in this fashion becomes ethically permissible only when the individuals are autonomous (“capable of deliberation about personal goals and of acting under the direction of such deliberation”) and they give their competent, voluntary, informed, and comprehending consent or permission to be used in this fashion. Another equally important ethical conviction found by

TABLE 86.1. Important events in ethics and regulation of research: 1945–2000.

1945: Uncovering of details of Nazi war crimes, including experimentation on prisoners
1949: Nuremberg Code on medical experimentation

1966: Henry Beecher <i>New England Journal of Medicine</i> paper on “unethical or questionably ethical procedures” in the research literature
1972: Story of the Tuskegee Syphilis Study breaks
1974: Federal regulations on research published (45 CFR 46); National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research established
1978: Belmont Report (and other U.S. guidelines and regulations emanating from the work of the National Commission)
1980: President’s Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research formed; worked through 1983
1995: Advisory Committee on Human Radiation Experiments Final Report; National Bioethics Advisory Commission (NBAC) created; Presidential Tuskegee apology
1999: Research suspended at several institutions by FDA or Office of Protection for Research Risks (OPRR); gene therapy trial death; calls for new research ethics regulation, training and certification

the National Commission that flows from the principle of respect for persons is that individuals who have diminished autonomy, whether their capacity for self-determination is diminished by mental illness or by incarceration in a prison, are in need of and should receive special protection. Several of the National Commission’s reports specifically address the needs of various vulnerable populations, such as children and prisoners. Importantly, the National Commission and subsequent federal regulations did not specifically address the needs of the two vulnerable populations of most concern in geriatrics research: subjects with dementia and subjects who reside in long-term care facilities.

Two other fundamental ethical principles were identified by the National Commission as central to research: beneficence and justice. Sometimes beneficence is divided into two principles, nonmaleficence and beneficence, the former meaning not inflicting harm on others and the latter referring to the obligation to promote good. Clearly, although investigators do not set out to intentionally harm their subjects, some clinical trials involve invasive testing, drugs, or new surgical procedures that do carry the risk of harm to subjects. Thus, consideration of whether a trial should be done (or for an individual, whether or not they choose to consent to participate), often involves a complex consideration of potential benefits to participants, to others with the condition under study, or to the state of scientific knowledge, weighed against the trial’s risks or burdens. Clinicians, of course, are familiar with these concepts in terms of both

the Hippocratic dictum “do no harm” and the general orientation toward doing what will help one’s patients. The National Commission discussed an additional obligation for researchers to promote the public good when they accept public support for their research endeavors.

Justice has to do with treating people fairly, giving each individual what is due or owed to him or her. In the research arena, as discussed by the National Commission and others since, the primary concern has been the fair or equitable distribution of both the burdens and benefits of research. There is a general concern about disadvantaged or vulnerable populations being used as research subjects because of convenience or ease of recruitment, resulting in these populations being subjected to a disproportionate amount of the risks of research. Many disadvantaged populations, particularly those without regular access to health care, are simultaneously at risk of not gaining access to the fruits of the research endeavor, such as new and expensive medications or the latest diagnostic testing and surgical procedures. Justice calls for the equitable distribution of research burdens and benefits within the society. An interesting development in this area in the 1990s that was discussed in the third edition of this text was new federal regulations mandating the inclusion of minorities and women in clinical studies to overcome what has been deemed inadequate representation in trials conducted over the past few decades—quite different from the approach that views these groups as vulnerable populations needing special protection from research risks or from exploitation and overuse as subjects.

What Is Different About Research on Older People?

This question is not a trivial one. If one believes that older people are not inherently very different from younger people, why should there be any special concerns, recourse to different ethical principles, or need for special regulations in considering the conduct of research involving older people? In fact, as part of an effort to overcome ageist stereotypes, much has been written about successful aging and the ways in which the vast majority of older people are cognitively intact, functionally independent, and active. Focusing for a moment on this view of aging and older people, one would have to say that there really should be no difference between research on younger subjects and research on older subjects. For research on older subjects, one still needs competent, voluntary, informed, and comprehending consent for a subject to participate. One would still expect investigators to minimize the risk to older subjects and maximize the potential benefits. One would still look for an equitable

distribution of the benefits and burdens of the research involving older subjects. Although some potential older subjects may be vulnerable and in need of special protection, most are not. Indeed, one would hope that IRB consideration of studies involving older subjects would focus on expectations of possible harm to subjects based on knowledge of their circumstances and clinical or physiologic condition, not age per se.

Lack of Research on Older People

On the other hand, there are matters relating to the history of clinical investigation, the clinical realities of geriatric medicine and research, and the presence of special populations within the general older population that we argue merit special attention and consideration. The first of these, the history of clinical investigation involving older people, is probably one of the most obvious to clinicians eager to practice what has been called evidence-based medicine, focusing on what the research literature can tell us about the diagnosis, evaluation, and treatment of diseases and clinical syndromes. Quite simply put, there has been little information from clinical trials on older people, especially the oldest-old (those over age 85). It was quite common even in the 1960s and 1970s for large clinical trials on diseases common in older people, such as diabetes mellitus or hypertension, to exclude subjects over the age of 65.³ It is only in the last several years that many larger clinical trials have enrolled sufficient numbers of older subjects, or, alternatively, that separate trials focusing specifically on older people have been conducted, to be able to answer whether results found in younger populations generalize to older people.

Some of the more gratifying outcomes of many of these trials are findings, as in the Systolic Hypertension in Elderly Program (SHEP) study, demonstrating that older subjects not only often benefit from the same interventions tried in younger patients but that sometimes the marginal benefit is greatest in the oldest.⁴ Another recent example is the North American Symptomatic Carotid Endarterectomy Trial (NASCET), a study of carotid endarterectomy that demonstrated the greatest benefits for many severities of carotid stenosis accrued to the oldest subjects, including those over age 85.⁵ The relative lack of research information is even more apparent when one considers some conditions that affect predominantly older people or those who reside in nursing homes. It is not clear whether the lack of attention to research on older people was due to practical difficulties in conducting geriatric research (discussed in more detail following), a lack of interest in older people and their problems per se, or other causes. Regardless of the cause, from the perspective of the ethical principle of justice discussed

earlier, older people were not receiving their fair share of either the burdens or the benefits of clinical research. Although this has been changing for the better in recent years, considerable room for improvement remains. A review of the recent experience of the Southwestern Oncology Group, one of the major cancer cooperative study groups in the United States still found the typical cancer protocol subject to be much younger than the typical patient with cancer.⁶

Clinical Realities Making Geriatric Research More Difficult

A priori, there may not be major differences in the ethical principles guiding research on older and younger subjects, but it is clear that the clinical realities of geriatric medicine and the older population have a major impact on the actual conduct of research.^{7,8} First, because older people are more likely to have comorbid conditions and to be on multiple medications, there is increased tension between selecting subjects who have only the condition of interest (yielding fewer confounding factors) and selecting subjects who will be more representative of typical older adults who have other health problems in addition to the condition under study (yielding results that are more generalizable to the broader population of the elderly). Second, trying to screen, recruit, and formally enroll older subjects may be more complicated because of communication and cognitive problems, such as hearing deficits, strokes, and dementia. Third, several studies, especially population-based studies involving subjects of all ages, suggest that older people have lower participation rates than do younger people. That is, even when eligible and approached for recruitment into a research study, older people may be more likely to refuse. Last, once people are enrolled in a study, there is a greater risk of attrition due to illness or death. Taken together, these clinical realities suggest that conducting research using older human subjects is indeed likely to be more time consuming, more expensive, and more difficult.^{7,8}

There is an important caveat to the foregoing formulation. One should not assume that older patients are less willing to participate in research. A recent study of older and younger breast cancer patients found that older women were less likely to be offered the option of participating in clinical trials than younger women. For those who were offered enrollment, however, the older and younger women participated in similar proportions.⁹ We must be careful not to let the biases of physicians or researchers drive research participation. The cohort of aging Baby Boomers may have different attitudes toward research from preceding cohorts of older potential subjects.

Special Population No. 1: People with Cognitive Impairment

As discussed earlier, the competent, voluntary, informed, and comprehending consent of an individual is crucial to making that person a research subject. Unfortunately, older people are at considerable risk for conditions in which an altered mental status calls into question the ability to give informed consent. Impaired decision-making capacity and an inability to give informed consent may be a temporary condition, as with a postoperative delirium, or it may be permanent, as with severe Alzheimer's disease. Geriatric medical research is not unique in its need to confront this consent dilemma; researchers in neurosurgery,¹⁰ intensive care medicine,¹¹ and emergency medicine¹² often want to study potential subjects who are not capable of giving informed consent at the time the study is to be conducted. Researchers in these other fields, however, often do not encounter their potential subjects until they have already lost decision-making capacity. Providers in geriatric medicine and some geriatric researchers, on the other hand, often know patients or potential subjects before the loss of decision-making capacity, raising additional interesting questions about the assessment of decision-making capacity, advance consent for research, and proxy consent. The greatest ethical dilemma arises from cases in which the ultimate choice is between forgoing promising research because informed consent cannot be obtained or making do without the ideal informed consent, perhaps accepting some creative alternatives.

In looking at research on people with cognitive impairment, we restrict our discussion to the consideration of the paradigm presented by research on Alzheimer's disease or other progressive dementias. We choose to limit our discussion to this area because the ethical dilemma is starkest when the condition to be studied is the same as the condition causing the loss of decision-making capacity. While it is true that individual investigators, patients, and families may face challenging decisions, for example, regarding proposed use of an investigational chemotherapy for a cancer that has occurred in a patient with dementia, it is clear that research on cancer could proceed even if it were to be limited to patients who can give informed consent for themselves. Research on Alzheimer's disease, at least studying subjects beyond the earliest stages of the illness, requires using people who cannot give informed consent.

The assessment of individuals' capacity to give informed consent for themselves is an important first step in deciding whether or how to enroll potential subjects in research protocols. It is important to emphasize that declaring someone unable to make decisions or to give consent should not be based on diagnostic labels or categories. That is, giving someone the diagnosis of

Alzheimer's disease does not automatically confer the status of incompetence upon that individual. Rather, one should take the approach that the ability to give informed consent for research, like clinical decision-making capacity, is task specific.¹³ More complex information and more complicated decisions require greater degrees of cognitive function. For example, a patient with moderate Alzheimer's disease still might be able to give consent for a study involving an interview on symptoms of depression, but it is likely that this patient would not be capable of understanding and giving consent for a protocol involving a reservoir for the intraventricular infusion of a nerve growth factor into the cerebrospinal fluid. Unfortunately, although it is easy to describe the task-specific or "sliding scale" concept of decision-making capacity assessment, at this time there are no standard or widely accepted scales for operationalizing this concept in the conduct of research. The assessment simply must be carried out on a case-by-case basis with each research protocol and each potential subject. Importantly, standard measures of cognition and severity of dementia should not be taken as direct measures of the ability to give consent. Even people with Mini-Mental State Exam scores as low as the 10 to 20 range may be able to give valid consent for some projects.

In clinical practice, providers are becoming more familiar with advance directives and the concept of advance care planning for clinical decision making in the event of patient incapacity. Formal advance directives are legal documents that allow patients to indicate specific treatment preferences (living wills, medical directives) or to appoint a proxy to make decisions (durable powers of attorney for health care, health care proxies). It has been suggested that a similar approach be taken with consent for research on dementia.¹⁴⁻¹⁶ Cognitively intact older people or patients with the very earliest stages of Alzheimer's disease, for example, could be encouraged to execute advance directives for research purposes. Similar to clinical advance directives, a research advance directive could indicate the kinds of research projects in which someone would or would not want to participate in the future or could designate a proxy to make research enrollment decisions.

Such an approach appears logical and consistent with clinical decision-making practices, but there are at least three important concerns about research advance directives.¹⁶ First, because it is not clear how helpful clinical advance directives are proving to be and because there has been even less experience with research advance directives, one hesitates to recommend wide adoption of such an unproven policy. Second, the legal status of research advance directives is not clear because most state laws creating advance directives focus on clinical decisions, especially those pertaining to the use of life-sustaining treatments.¹⁵ Third, although information

contained in a research advance directive might be useful, there is the concern that promoting their use might create the impression (or even lead to regulations or laws) that they are required to do research on dementia. Because a minority of adults execute clinical advance directives, and one can assume that even fewer would execute research advance directives, one can envision a scenario in which research advance directives actually end up inhibiting rather than promoting dementia research.¹⁶

What then should be done for cases in which the potential subject is impaired so that informed consent cannot be obtained and research advance directives are either not an option or not present? The current model for obtaining permission to do research on cognitively impaired subjects involves what sometimes is called proxy consent plus subject assent.^{17,18} Informed consent is sought from a proxy, usually a close relative, who speaks on behalf of the impaired individual. Ethical support for this part of the process is based on the belief that a family member or other proxy is best suited for giving consent because (1) he or she knows the potential subject best and is most likely to make a decision that would be in keeping with the subject's values and what that subject might have decided for him or herself (making a substituted judgment); (2) the proxy has the best interests of the subject at heart and will make the "best decision"; or (3) as a closely involved family member, the proxy is the person most likely to be affected by the decision, other than the subject, and thus has a stake in making the decision.^{19,20} Clearly, in clinical practice, there is a long-established tradition of turning to family members when a patient cannot make decisions.

Concerns about proxy consent center on potential conflicts of interest (proxies volunteering subjects because the proxy hopes to benefit in the future from the research) or data from clinical decision-making studies that demonstrate significant discord between what patients say they would decide for life-sustaining treatment vignettes and what their proxies predict the patients would want.^{21,22} In general, it is probably safe to presume that the number of cases in which families will knowingly act contrary to the wishes or interests of a subject are very few in number and one can trust proxy decision making. In addition, because there are other reasons to support proxy decision making besides the ability to construct a substituted judgment, the data on patient-proxy discord need not eliminate proxy consent as a viable option.²⁰

The assent of the subject is the other half of the model that is coupled with proxy consent. Assent refers to the willingness of a subject to agree to go along with a research protocol even if the subject cannot provide informed consent. This concept also has been applied to consent for research involving children.²³ This is a

particularly useful construct for approaching dementia research if one thinks of it as an opportunity to try and obtain useful information from a potential subject about their values and preferences that can help guide research participation decisions, rather than just thinking of assent as the lack of objection to research procedures. One empirical study on research decision making for dementia supports the ability of even very impaired subjects with dementia to give strikingly revealing and informative reports on their values and preferences when given information about specific dementia research protocols.²⁴

Ethical issues in research on subjects with cognitive impairment received a great deal of attention in the latter part of the 1990s, including position statements by the American Geriatrics Society and the Alzheimer's Association and a report and proposed regulations from the National Bioethics Advisory Commission (NBAC).²⁵⁻²⁷ The NBAC report and proposed regulations generated a great deal of controversy. NBAC called for such matters as assessment of potential subjects' decision-making capacity by independent assessors; continued use of a two-tiered approach to risk assessment (minimal risk and greater than minimal risk); significant restrictions on research that does not hold out the potential of direct benefit to subjects; and limited use of advance consent for research.²⁷ The NBAC proposals were criticized by some as not going far enough in protecting a vulnerable population and by others for potentially inhibiting or prohibiting important research.^{28,29} Being assailed from both sides of the debate has contributed to NBAC's proposals not being implemented to date.

Special Population No. 2: Residents of Long-Term Care

The second population that sharply focuses some of the ethical concerns specific to research in geriatric medicine and gerontology is the long-term care population, especially people residing in nursing homes. Because of the high prevalence of dementia in nursing homes, some of the concerns about research in these facilities are identical to the concerns about research on dementia already discussed. There are distinct concerns about research in nursing homes, however, that relate to the nature of life within these institutions.³⁰

First, although nursing homes are increasingly used as sites for research, unlike academic hospitals they are not research institutions, nor are they solely medical care delivery sites. Indeed, efforts are made in many nursing homes to emphasize the social nature of the institution, the "nursing home as home," rather than seeing them as stepdown units from hospitals. The bulk of care in nursing homes is provided by nurses' aides and the role of physicians is somewhat limited with respect to day-to-day life. Most of the staff is unlikely to be familiar with stan-

standard research procedures and may be uncomfortable with research. Considerable education and encouragement may be needed to gain the trust and cooperation of a nursing home's staff for a research project.

Second, much has been written about the issue of nursing homes as environments in which individual autonomy may be limited.^{31,32} Even seemingly simple things such as choosing a roommate or deciding when to get out of bed in the morning or what to eat often are out of the control of a nursing home resident.³³ Life within any "total institution" certainly challenges the ability of even cognitively intact and healthy people to make decisions freely, let alone people who are ill or frail. Thus, it is easy to see why there would be concerns about the ability to obtain voluntary and uncoerced consent in a nursing home, even if it is informed and comprehending consent. Specifically, one wonders if nursing home residents, who are dependent on staff for so much, feel truly free to refuse to participate in research conducted on site. Obviously, these concerns are heightened when nursing home staff or physicians are themselves participating in a research project, especially if they are helping to recruit and enroll subjects. In addition, even if the consent process can be made voluntary and uncoerced, concerns remain about privacy and confidentiality in the research process because nursing homes are places where these two commodities often are in short supply.

A third area of ethical concern in nursing home research relates more to the principles of beneficence and justice than to autonomy and informed consent. Although great progress has been made in the past several years in improving conditions in nursing homes, much remains to be accomplished, and a large gulf exists between the best and worst facilities. An interesting ethical question arises in deciding where to do nursing home research. Should research be limited to only the best facilities, where the residents' needs all are being met, thus avoiding the possibility of exploiting the most vulnerable and needy residents who receive inferior daily care? From the research standpoint, a superb facility probably facilitates efficient conduct of a study, but it may limit the generalizability of one's results to similar top-notch nursing homes. From an ethics standpoint, restricting research to the best facilities may avoid exploiting the most vulnerable, but it also prevents residents in other nursing homes from sharing in the benefits of research participation as well as its burdens. By this we mean not only the benefits derived from the knowledge generated by research studies, but also the benefits provided by research participation that include increased social interaction, increased attention, and the feeling of contributing to something important. Clearly, a balance must be struck between these competing concerns in deciding which nursing facilities to select for research projects.³⁰

Evolving Ethical Controversies Within the Research Community

Much of what has been discussed to this point fits within a model of research ethics that was quite stable through most of the 1980s and 1990s: trustworthy researchers interacting with individual subjects, guided by the principles of respect for persons (with a heavy emphasis on autonomy and informed consent), beneficence, and justice. More recently, several problems or concerns have arisen, some of which represent challenges within the foregoing framework and others that challenge the framework itself. We discuss four of these evolving ethical challenges in research at large: (1) trust and the research community; (2) confidentiality in research; (3) research and the private sector; and (4) likely future research ethics challenges. These developments are not unique to research in geriatric medicine, but we believe that they are of such importance that they warrant discussion here.

Trust and the Research Community

In the late 1990s, the Office of Protection for Research Risks (OPRR; subsequently replaced by OHRP, the Office for Human Research Protection) and the Food and Drug Administration (FDA) temporarily suspended the clinical research operations at several universities and medical centers.³⁴⁻³⁶ While several of these research suspensions were thought by some in the research community to have been due to technical noncompliance with institutional review board (IRB) and other regulations, and that no research subjects were placed at risk of harm, some cases clearly were more serious. IRB members from one institution, for example, complained of a lack of support and resources for their work, and an audit provided examples of research being conducted without IRB review and of protocols being reviewed by panels that included the researcher.

Following shortly on the heels of several of these research suspensions, a research subject participating in a gene therapy study at the University of Pennsylvania died.³⁷ This case received significant attention initially because of the death being the first one associated with a gene therapy trial. Subsequent investigations uncovered a host of research protocol irregularities at the University of Pennsylvania and other universities conducting gene therapy trials. These irregularities included deviations from protocols, changes being made in protocols without approval by IRBs or other supervising bodies, and adverse events not being reported to appropriate authorities.

Coupled with the Office of the Inspector General's (OIG) report citing deficiencies in the existing research

oversight structure and process,³⁸ many additional actions and proposals for strengthening research regulation have come from the federal government. These measures have included new requirements for education and certification in research ethics for investigators, research staff, and IRB members; directives to IRBs to take a more active role in monitoring of ongoing research; and NBAC's most recent report proposing a complete overhaul of the federal structure supervising the nation's IRBs.³⁹

In response to these developments, many research and professional organizations have made public statements reaffirming their commitment to the ethical conduct of research involving human subjects. Although geriatrics researchers have not played a prominent role in the cases just mentioned, the American Geriatrics Society is one of the organizations that promulgated a position statement on the ethical conduct of research.⁴⁰ At the heart of these efforts is the desire to reassure the public that the research community still deserves the trust that it has enjoyed in the past several decades. Some investigators believe that if that basic trust is lost, no amount of regulation or oversight will make up for the harm that will come to the research enterprise.

Confidentiality in Research

Privacy and confidentiality are two things that researchers have always been required to respect in their dealings with their subjects. In the past, this did not place too many demands on most researchers. Most research was conducted at a single institution; investigators controlled the (mostly hard copy) data relating to their own subjects; subjects were promised that their identity would be kept confidential; and separate sheets with subject code numbers and names and locked file cabinets often sufficed. Today, most clinical trials are multicenter studies, sponsored by pharmaceutical or biotechnology firms, with data transmitted to coordinating centers to be reviewed by other investigators and statisticians, a data monitoring and safety board, and eventually the FDA or other regulators. Electronic transmission of research data is becoming commonplace. In addition, medical records in clinical practice are more routinely being kept in electronic formats. The electronic medical record is not only allowing clinicians to more readily communicate important clinical information to all involved in a patient's care, but it is also allowing health services researchers and other clinical investigators to assemble data sets and identify potential subjects in a fraction of the time required previously. By linking data from existing clinical records, research data sets, and administrative data sources such as Medicare claims, researchers are able to ask and answer questions using information on thousands or even hundreds of thousands of subjects.

Clearly, multicenter studies, electronic data transmission, and electronic records all hold great promise for research. Simultaneously, however, they greatly increase the potential for violations of confidentiality for subjects. As of this writing, new federal regulations governing medical records, including stronger requirements for written consent before allowing access to any records, have just been implemented. These controversial regulations, like many other efforts to regulate research, attempt to balance access to the potential benefits of research against the potential harms that might ensue. It remains to be seen if these new restrictions on the flow of medical data result in the proper balance or if research is inhibited excessively.

Research and the Private Sector

One trend in research mentioned in the section immediately above has been the increasing role of for-profit pharmaceutical firms, equipment manufacturers, and biotechnology companies. Not only are these entities financing more of the nation's research than in the past, more research is being conducted, directed, and supervised by commercial research organizations (CROs) outside academic centers. The combination of commercial interests driving research, private control and oversight of research, and increasingly complex relationships between researchers and commercial entities has raised a number of ethical concerns. First, there is concern that the desire of commercial firms to keep information from competitors may inhibit the free exchange of information that is an integral part of how research usually proceeds. Second, there is the concern that commercial firms profit motives will unduly influence the research process. For example, will they be less willing to publish negative studies, an already important challenge in the existing clinical trials literature? Will CROs and private IRBs be less thorough in their scrutiny of protocols because of a conflict of interest? Will this perceived conflict of interest further challenge the public's trust of the research enterprise? Third, many concerns have been raised about the impact of relationships with industry and the potential conflicts of interest created for researchers, clinicians, and academic centers.^{41,42} Some concerns exist that greater commercial ties lead to potentially biased presentations of research, such as in review articles or journal supplements. Surveys suggest that most academic centers have not yet formulated adequate policies for dealing with these potential conflicts of interest.^{43,44}

Another way in which ethical concerns have been raised by the commercialization of research relates to how many academic researchers and centers have learned to follow many of the practices formerly reserved to the for-profit sector. Researchers have created for-

profit biotechnology firms to try and reap the financial gains from results of their work that might lead to successes in the marketplace. Most academic centers have offices or departments devoted to similar ventures and more aggressive patenting practices. International controversy exists around the patenting of genes and gene products. Lawsuits have been filed seeking access to financial gains that may have resulted from research findings. Marcia Angell has argued that these ethical issues surrounding academic centers and the for-profit sector are one of the greatest challenges to the very soul of academic medicine.^{41,42}

Likely Future Challenges

Many of the coming ethical dilemmas for research in geriatric medicine are identifiable today. Some of these will certainly be continuations of the issues already discussed, including debates over tighter regulation of human subject research and the evolving relationship between industry and academia. Others may be existing controversies that will take center stage in the public debate. Controversies that we would place in this category would include the use of stem cells in clinical trials (especially relevant for geriatrics as many of the diseases targeted for this kind of work are age-associated diseases such as Alzheimer's disease, Parkinson's disease, and stroke), and debates over both who will pay for research and who will have access to expensive technologies and drugs that result from research successes. Finally, other ethical dilemmas will arise because of advances in technology and the debate over whether we ought to do the things that become possible because of science. Similar to the debate over human cloning, it is likely that the field of aging will face concerns over whether we should pursue research that may extend the life span. We may very well find ourselves in debates over whether it is "right" to pursue antiaging interventions, arguments over the impact on society if such interventions work, and competing claims for access to these therapies versus efforts to protect individuals and society from potential harms.

Conclusion

Research in geriatric medicine is growing in important ways at this time in history. Ethical issues particular to geriatrics research, as well as those challenges facing the broader research community, also loom large at this time. For research on geriatric medicine to continue to make inroads on the health problems of older adults, it is essential that these ethical issues continue to be addressed in a thoughtful and effective manner.

- Paclitaxel
for advanced ovarian cancer, 474
for androgen-independent prostate cancer, 462
for non-small cell lung cancer, 451
risk of neuropathy in treating breast cancer with, 404
- Paget's disease
of bone, 642–644
effect of calcitonin on bone resorption in, 637
mammary and extra-mammary, 878
- Pain
acute and chronic, 323–342
due to bone metastases, in prostate cancer, 463
in degenerative arthritis of the spine, 656–658
in herpes zoster, 1045–1046
obsession with, 355
in osteoarthritis, treatment of, 586–588
perception of
age-related changes in, 324–325
by the patient, 253
postoperative
control of, 863
management of, 253–254
in pressure ulcer care, management of, 969
and quality of life, 303–304
reduction of tissue perfusion in response to, 247–248
residual, after amputation, 273
shoulder, 661–664
as a symptom of osteoarthritis, 574–575
treatment of, in herpes zoster, 1048–1049
undertreated postoperative, as a risk factor in delirium, 674
untreated or undertreated, in the elderly, 282
in vertebral compression fractures, 659–660
- Pain Relief Promotion Act (PRPA), 1227
- Paired helical filaments (PHF), properties of, 1101
- Palliation
in advanced pancreatic cancer, for jaundice and pain, 426
in benign prostatic hyperplasia, 760–761
in cervical cancer, with radiotherapy, 478
of impaired cognition, pharmacologic, 1085–1086
of joint pain with corticosteroid injections, 588
in metastatic breast cancer, 405–406
in metastatic pancreatic cancer, 426
in metastatic prostate cancer, 460–462
in non-Hodgkin's lymphoma, 501–502
in respiratory insufficiency, 864–865
in soft tissue injuries, 661
transition to, from life-sustaining treatment, 1243–1244
of xerostomia, with salivary substitutes, 907
- Palliative care, 138
avoiding a sense of abandonment connected with, 295
changing legal status of, 1226–1227
in dementia, 343–350
in hospital or intensive care, 299
in moderate dementia, 345–346
rationing of, 1214–1215
research on, 312
- Pallidotomy, in Parkinson's disease, 1150
- Pamidronate, bisphosphonate drug, for osteoporosis, 633–634
- Pancreatic cancer, 424–426
advanced, 426
- Pancreatic disorders, 845
- Pancreaticoduodenectomy (Whipple procedure), 425
- Pancreatitis, acute, mortality from, 845
- Pancuronium, association with high relative risk of postoperative pulmonary complications, 863
- Panic disorder, 1176
differentiating from depression, 1168–1169
gait disorders accompanying attacks, 1154
management of, in terminal care, 864
- Papain, for wound debridement, 972
- Papanicolaou test
in physical examination of the older woman, 741–742
for screening for cervical cancer, 379–381, 481
- Papaverine, for penile injection, 724–725
- Papillary carcinoma, thyroid, 712
- Papillary hyperplasia, from ill-fitting dentures, 912
- Papillomavirus, effect of
in cervical cancer, 475–476
in vulvar cancer, 479
- Parainfluenza virus type 1, reinfection with, association with giant cell arteritis, 596
- Paraneoplastic sensory neuronopathy, 1142
- Paraneoplastic syndromes, 613
cerebellar, gait disturbances in, 1146
- Paranoid delusions, in community elders, prevalence of, 1185
- Parathyroidectomy, minimally invasive, 641
- Parathyroid hormone (PTH)
effect on bone loss, 631
effects of, on bone, 638–639
- Parkin* gene, mutation in, and peak incidence rate of Parkinson's disease, 20
- Parkinsonian syndromes, 1147–1153
and REM sleep behavior disorder, 1035
- Parkinson's disease (PD), 1147–1150
age-specific incidence of, 20
psychosis in, 1188
rehabilitation in, 273–274
symptoms of, 1081
- Paroxetine, for treating agitated or sleep-deprived patients with dementia, 1090
- Partial foot amputation, 271–273
- Parvalbumin-immunoreactive neurons, associated with Down syndrome and Creutzfeldt-Jakob disease, 1104
- Parvovirus B19, association with giant cell arteritis, 596
- Pathogenesis
of age-associated diabetes mellitus, 683–684
of age-associated glucose intolerance, 682–683
of benign prostatic hyperplasia, 756–757
of cervical cancer, 475–476
of delirium, 1115
of falling, in the elderly, 980–981
of herpes zoster, 1044–1045
of infectious diseases, 802–803
of lung cancer, 443–444
of myelodysplastic syndromes, 490
of peripheral arterial disease, 562
of polymyalgia rheumatica and giant cell arteritis, 595–596
of presbycusis, 894
