Preface

Since the publication of the third edition of *Geriatric Medicine*, extraordinary advances have occurred in the science of aging and the potential for biomedical research to give us answers to many, if not most, of the age-related disorders that threaten the quality of life in older years. At the most basic level, the successful mapping of the human genome was declared complete in the fall of 2000. Understanding the map of the human genome is as important as understanding the map of genomes of important laboratory species, ranging from the microscopic worms and fruitflies used in most classic genetic studies to rodents such as laboratory mice, and eventually to primates, on which much of the research on the aging human brain is done. The genetic maps of all of these species, including our own, does not answer clinical questions, but it does open the door to dramatic, rapid, and efficient answers to questions about the genetic polymorphisms related to diseases in humans.

The telomerase story also unfolded since the third edition. Telomerase is an enzyme responsible for maintaining the telomeres—the redundant DNA portions at the end of chromosomes—whose shortening seems to be linked directly to cell senescence, apoptosis, and the control over cell death, which, at the level of the individual cell, seems to be linked to the decline of organ function and eventually aging and death within the organism. The potential for genetic manipulations by which telomerase maintains and restores telomere length within individual tissue cultures gives great promise for potential approaches to restoring function lost through degenerative diseases, such as macular degeneration and other disorders related to epithelial aging. In addition, the maintenance of telomeres has been intriguingly associated with the malignant immortality of cancer cells, and yet it appears possible to prevent degeneration without creating uncontrolled growth or malignancy. Understanding this single genetic mechanism may give us clues not only to degenerative neurological and epithelial disease, but also perhaps to cancer, another age-related human disease. Scientists have also discovered that stem cells from embryonic and adult tissues can potentially create new tissues and new organs. Perhaps most excitingly, it appears that brain cells themselves can be replaced through this mechanism. Thus, stem cell research holds promise for treatment of Alzheimer's and Parkinson's disease, as well as for potentially growing new functioning organs that could be used for transplantation with much reduced risk of rejection because they are genetically fashioned to match the recipient's immune status.

Because of these and many more similar advances, it is more and more important for the practicing clinician to be conversant with the literature of basic science and to stay abreast of such developments. Our patients come to us having read about these developments or having seen television reports, and we should be able to answer their questions and share the excitement. We should also be educating them about the realistic limits, understanding that many of these developments will not provide immediate cures but are promising future developments.

Secondly, we owe it to ourselves to share the excitement of our colleagues in basic science, as well as the general public, in recognizing that aging research has come into real prominence in the last decade. We also need to be well informed about the rampant marketing of bogus dreams of anti-aging potions that the marketplace is all too ready to foist onto our patients. The aging of the baby boomers has created a huge and growing market for anti-aging therapies. Many are safe, effective, and worthwhile. However, in some instances, such as vitamin supplementation or hormone replacement, controversies exist and individual patient decision should be informed by knowledgeable and free discussions based on real science. This information can come from you, the clinician. It can also come from internet sources, but internet sources increasingly are also full of inadequate and misleading information and, thus, it becomes even more important for us to be able to relay to our patients legitimate sources of information. Some of the most useful include the following:

- On terra firma, the *National Institutes of Health* is a complicated maze of 75 buildings. But on the Web (<http://www.nih.gov>), it is a snap to move from the National Cancer Institute to Mental Health to Alternative Medicine. Log on to www.clinicaltrials.gov to search for clinical trials by disease.
- The *National Institute on Aging*, one of 25 institutes and centers of the National Institutes of Health, leads a broad scientific effort to understand the nature of aging and to extend the healthy, active years of life. Visit <http://www.nia.nih.gov/> for a description of its mission, sponsored research programs, news and calendar of events, and health information, including NIA publications and videos, a resource directory for older adults, and various internet links of Federal websites of interest to the aging community.
- At their website, the *Centers for Disease Control and Prevention* (www.cdc.gov) provides a calendar of events, current topics, and recent reports and publications. Click on their “Data and Statistics” for CDC health data standards, scientific data, surveillance, health statistics reports, and laboratory information. The website also includes information about grant and cooperative agreement funding opportunities, as well as press releases and current health news. On their “Publications, Software, Products” link, one can order and download brochures, catalogs, publications, software, slides, and videos. Consumers can browse their “Health Topics” from A (Acanthamoeba infection) to Z (Zoster), get the latest on health “Hoaxes and Rumors” (i.e., deodorants cause breast cancer), or check out the travel section to find out if they will need vaccines for a trip abroad. Or stay close to home and find a link to your local state health department.
- The *Food and Drug Administration* is the primary resource for information about safety alerts/recalls and product approvals of drugs, cosmetics, foods, medical devices, biologics, animal feed and drugs, and radiation-emitting products. Ongoing clinical trials are also profiled. Go to <http://www.fda.gov>.
- *HealthWeb* (<http://www.healthweb.org/>) is a collaborative project of the health sciences libraries of the Greater Midwest Region of the National Network of Libraries of Medicine and those of the Committee for Institutional Cooperation. Currently, there are over 20 actively participating member libraries. The goals of the HealthWeb project include the development of an interface that provides organized access to evaluated noncommercial, health-related, internet-accessible resources, including those currently available, as well as new resources developed in collaboration with other organizations. The interface integrates educational information so the users has a one-stop entry point to learn skills and use material relevant to their discipline, including geriatrics and gerontology.
- The *National Aging Information Center* (<http://www.aoa.gov/NAIC/>) serves as a central source for a wide variety of information on aging for older people, their families, and those who work for or on behalf of older persons. NAIC resources include program and policy-related materials for consumers and practitioners and

demographic and other statistical data on the health, economic, and social conditions of older Americans. The NAIC bibliographic database contains references to program- and policy-related materials on aging not referenced in any other computer system or print resource.

- The *GeroWeb*, sponsored by the Geroinformatics Workgroup at the Wayne State University Institute of Gerontology, is designed as an online resource for researchers, educators, practitioners, and others interested in aging and older individuals. (<http://geroserver.iog.wayne.edu/GeroWebd/GeroWeb.html>)
- The *Alzheimer Research Forum's* intended audience is Alzheimer researchers and other researchers whose work may bring understanding to Alzheimer's. The site has news, holds online forums, conducts online polls ("What are your 10 most wanted research tools?"), provides information on conferences, research funding, and includes a reagent company directory. Visit them at <http://www.alzforum.org/home.asp>.
- The Federal Interagency Forum on Aging-Related Statistics was initially established in 1986, with the goal of bringing together Federal agencies that share a common interest in improving aging-related data. The Forum has played a key role by critically evaluating existing data resources and limitations, stimulating new database development, encouraging cooperation and data sharing among Federal agencies, and preparing collaborative statistical reports. Their website (<http://www.agingstats.gov/>) provides information from their latest report. *Older Americans 2000: Key Indicators of Well-Being*, as well as links to aging-related statistical information on Forum Member websites, ongoing Federal data resources relevant to the study of aging, past products of forum activities, and agency contacts.
- *AgeLine* is a free searchable electronic database of 60,000 summaries of publications about older adults and aging, including books, journal and magazine articles, and research reports. Coverage is sporadic between 1966–1977, but more comprehensive coverage exists from 1978–present. <http://research.aarp.org/ageline/home.html>
- The Centers for Medicare and Medicaid (CMS), formerly the Health Care Financing Administration (HCFA), is a federal agency within the U.S. Department of Health and Human Services. CMS runs the Medicare and Medicaid programs and the State Children's Health Insurance Program (SCHIP), and also regulates all laboratory testing (except research) performed on humans in the U.S. By visiting the CMS website at <http://cms.hhs.gov> physicians and other health care professionals can gain quick access to professional publications and program forms and learn about the Medicare program and CMS contracts with Medicare health plans, as well as statistics, data, and the latest CMS research and program analysis. Consumers can find information on what Medicare covers, who is eligible, and how to enroll. They can also get a personalized report on Medicare health plans, nursing homes, dialysis facilities, participating physicians, and prescription drug programs in their area.

While we have a glut of information, we also have real ethical challenges facing us. The advances in genetic knowledge and potential alterations of genes through gene therapy have led to real caution because of highly visible adverse consequences to subjects of human studies. People are very concerned about the degree to which genetic information can be kept private and justifiably concerned that such information not fall into the hands of employers or insurers. The country will continue to be embroiled in deep disagreements about the use of human stem cells for research. The dramatic promise that they hold has come up against deep-seated religious beliefs of those who feel that embryos that are surplus and intended for discarding are indeed human life and ought not to be used for experimentation. These and other ethical issues will continue to be important as science progresses.

In their chapter, Greg Sachs and Harvey Cohen discuss the ethical issues in clinical research, including the ethics of research with Alzheimer's disease, a paradigmatic disorder where patients cannot fully make their own decisions and yet where research

is very high stakes and needs to be offered to those suffering from the ravages of this disease. Ethical issues also continue to surround treatment decisions and, in particular, those around expensive potential life-prolonging and intrusive measures for older individuals. The challenge—especially in the United States—is how to balance the promise of these disorders with the increasing inequities in our health care system, in particular in a situation where more and more people under the age of 65 have no health insurance at all.

All of these issues will continue to intensely involve the public, and thus clinicians will need every possible resource to stay informed as citizens and to provide important answers for their communities and their patients. Along these lines, we have expanded this edition by 18 chapters, devoting an entire section to the emerging field of palliative medicine and increasing our coverage on surgical issues, care management, and pharmacology.

Health care providers will increasingly be called upon to practice what has come to be known as “evidence-based medicine.” So much of health care—particularly the prescribing of medications—is extremely costly and, as we know well in geriatrics, carries risks of its own. For this reason, it is more and more important that clinicians understand the evidence behind the use of any interventions, both diagnostic and therapeutic. The science of evaluating evidence is a statistical one, and the standards for doing so have been articulated by leaders in the field. One of those leaders, Rosanne Leipzig, is deputy editor of this edition of *Geriatric Medicine*. She has looked at every single chapter through an evidence-based lens and, whenever possible, provided up-to-date information about the quality and strength of the evidence for the diagnostic and treatment recommendations included in each chapter. We are very fortunate that Dr. Leipzig has joined the *Geriatric Medicine*, 4/e, team and can give us this added dimension of balance and rigor to the expertise of our world-class roster of authors.

I also want to thank Harvey Cohen, Eric Larsen, and Diane Meier, Associate Editors, who have contributed enormously to the production of this book. We have worked hard together and learned a great deal from each other. Thanks also to Carol Capello in her role as Managing Editor. Carol has now taken us through two editions of *Geriatric Medicine*, and we hope we can persuade her to work with us on the fifth edition of *Geriatric Medicine*.

Christine K. Cassel

Contents

Preface	vii

Part I Basics of Gerontology

1 Evidence-Based Medicine and Geriatrics	3
<i>Rosanne M. Leipzig</i>	
2 Molecular and Biologic Factors in Aging	15
<i>Charles Mobbs</i>	
3 Physiology of Aging	27
<i>George E. Taffet</i>	
4 The Demography of Aging	37
<i>S. Jay Olshansky</i>	
5 Epidemiology and Aging	45
<i>Tamara B. Harris</i>	
6 Psychosocial Influences on Health in Later Life	53
<i>Elizabeth C. Clipp and Karen E. Steinhauser</i>	
7 Principles of Pharmacology	65
<i>Jerry Avorn, Jerry H. Gurwitz, and Paula Rochon</i>	
8 Clinical Strategies of Prescribing for Older Adults	83
<i>Judith L. Beizer</i>	

Part II Changing Contexts of Care in Geriatric Medicine

9 Contexts of Care	93
<i>Laurence Z. Rubenstein</i>	
10 The Long and the Short of Long-Term Care	99
<i>Robert L. Kane</i>	

11	The Geriatrician in the Nursing Home	113
	<i>Wayne C. McCormick</i>	
12	Home Care	121
	<i>Sharon A. Levine and Patricia P. Barry</i>	
13	Acute Hospital Care	133
	<i>Robert M. Palmer</i>	

Part III Clinical Approaches to the Geriatric Patient

14	Clinical Approach to the Older Patient: An Overview	149
	<i>Glendo L. Tangarorang, Gerard J. Kerins, and Richard W. Besdine</i>	
15	Chronic Disease Management	163
	<i>Harrison G. Bloom</i>	
16	Prevention	169
	<i>Harrison G. Bloom</i>	
17	Instruments to Assess Functional Status	185
	<i>Brandon Koretz and David B. Reuben</i>	
18	Comprehensive Geriatric Assessment and Systems Approaches to Geriatric Care	195
	<i>David B. Reuben</i>	
19	Neuropsychological Testing	205
	<i>Marilyn S. Albert</i>	
20	Preoperative Assessment and Perioperative Care	213
	<i>Peter Pompei</i>	
21	Anesthesia for the Geriatric Patient	229
	<i>Jeffrey H. Silverstein</i>	
22	Surgical Approaches to the Geriatric Patient	239
	<i>Ronnie Ann Rosenthal</i>	
23	Rehabilitation	259
	<i>Kenneth Brummel-Smith</i>	

Part IV Palliative Care

24	Old Age and Care Near the End of Life	281
	<i>Diane E. Meier</i>	
25	Doctor-Patient Communication Issues	287
	<i>James A. Tulsky</i>	
26	Care Near the End of Life	299
	<i>Sarah Goodlin</i>	
27	Sources of Suffering in the Elderly	311
	<i>Maria Torroella Carney and Diane E. Meier</i>	

28 Acute and Chronic Pain 323
Bruce A. Ferrell

29 Palliative Care in Early, Moderate, and Advanced Dementia 343
Anna Monias and Diane E. Meier

30 The Value of Achieving a Peaceful Death 351
Daniel Callahan

Part V Medical Care

Section A: Cancer in the Elderly

Cancer in the Elderly: An Overview 361
Harvey Jay Cohen

31 The Science of Neoplasia and Its Relationship to Aging 363
Robert E. Martell and Harvey Jay Cohen

32 Screening for Cancer 375
Eugene Z. Oddone, Mitchell T. Heflin, and John R. Feussner

33 Breast Cancer 393
Ann Partridge and Eric Winer

34 Colon Cancer and Other Gastrointestinal Malignancies 417
Peter C. Enzinger and Robert J. Mayer

35 Lung Cancer 441
Eric B. Haura, Susan A. Blackwell, and Jeffrey Crawford

36 Prostate Cancer 455
Khalid Matin and Donald L. Trump

37 Gynecologic Cancers 469
Angeles A. Alvarez and Daniel L. Clarke-Pearson

38 Hematologic Malignancies 487
Marc Gautier, Elizabeth M. Bengtson, Edward M. Liebers, and Harvey Jay Cohen

Section B: Organ System Diseases and Disorders

39 Cardiovascular Disease 509
Nanette Kass Wenger

40 Hypertension 545
Mark A. Supiano

41 Peripheral Arterial Disease 561
William R. Hiatt and Mark R. Nehler

42 Rheumatologic Diseases 573
Daniel J. Brauner, Leif B. Sorensen, and Michael H. Ellman

43	Skeletal Fragility in the Elderly	621
	<i>Angela Inzerillo, Jameel Iqbal, Bruce Troen, Diane E. Meier, and Mone Zaidi</i>	
44	Orthopedic Problems with Aging	651
	<i>Lawrence A. Pottenger</i>	
45	Medical Aspects of Hip Fracture Management	669
	<i>R. Sean Morrison and Albert L. Siu</i>	
46	Treatment of Diabetes	681
	<i>Kenneth L. Minaker</i>	
47	Thyroid Disorders	695
	<i>David S. Cooper</i>	
48	Changes in Male Sexuality	719
	<i>Thomas Mulligan and Waleed Siddiqi</i>	
49	Sexual Function and the Older Woman	727
	<i>Fran E. Kaiser</i>	
50	Gynecologic and Urologic Problems of Older Women	737
	<i>M. Chrystie Timmons</i>	
51	Benign Prostatic Hyperplasia	755
	<i>Catherine E. DuBeau</i>	
52	Nephrology/Fluid and Electrolyte Disorders	769
	<i>Sharon Anderson</i>	
53	Immunology of Aging	783

Part I

Basics of Gerontology

This page intentionally left blank

1 Evidence-Based Medicine and Geriatrics

Rosanne M. Leipzig

The goal of evidence-based medicine is provision of care guided by the most up-to-date, scientifically sound evidence after careful investigation of the patient's history, physical condition, and expectations. Evidence-based medicine (EBM) is a term coined in 1992 by a group of clinical epidemiologists based at McMaster University in Hamilton, Ontario, to describe their transition from teaching clinicians how to read the medical literature¹ to teaching us how to use the literature in the care of an individual patient (Fig. 1.1).² This change emphasized three basic concepts.

Hierarchy of Evidence

The first concept is that “all evidence is not created equal.” Depending on the type of clinical question—that is, therapeutic, diagnostic, prognostic, etc.—there is a hierarchy among study designs in terms of their ability to provide an accurate, less biased answer. For example, the Hormone and Estrogen Replacement Study (HERS) trial demonstrated in a randomized controlled trial (RCT) that hormone replacement therapy (HRT) given as 0.625 mg conjugated equine estrogens and 2.5 mg medroxyprogesterone acetate did not improve survival or decrease coronary events in women with existing coronary artery disease, even though several prospective cohort trials suggested that it would.³ Results from two other RCTs to support this finding.⁴ In the HRT observational trials, women who were offered and chose to take HRT differed systematically at baseline from those who did not; for example, they were more likely to be upper middle class, to be well educated, and to participate in more health promotion and disease prevention activities, and were therefore less at risk for death and coronary disease. These factors may account for their better outcomes after taking HRT.^{5,6} Randomized controlled trials are superior to prospective cohort studies of the same population because the groups being

compared are at equal risk of the outcome being studied, except for exposure to the intervention being tested. Risk factors associated with an outcome, whether they are known or not yet identified, are randomly distributed in RCTs. An observational trial can only identify known risk factors and then attempt to statistically adjust for discrepancies between them in the study groups.

Most clinical questions fall into one of seven categories: clinical findings, differential diagnosis, etiology, diagnostic tests, prognosis, therapy, or prevention.^{6,2} Table 1.1 provides examples of important criteria that should be met to maximize the ability of clinical research to answer each type of clinical question. Some of these criteria have been used to create the “clinical query” search strategies on PubMed at the NLM's website (<http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.html>) and provide a filter for obtaining high-quality studies relating to therapy/prevention, diagnosis, etiology, and prognosis. Similar criteria have been developed for several other types of clinical questions.⁷ For the past 10 years, studies that meet these validity criteria have been identified and published within the American College of Physicians (ACP) Journal Club, and are available online as well as in the print journal published by the ACP.⁸ Clinical Evidence and the Cochrane Library are two other sources of systematic reviews of high-quality studies designed to answer specific medical questions.^{9,10}

Clinically Meaningful Results

The second concept is that clinical, not statistical, significance is what matters in medicine. Many outcomes that are statistically significant are not clinically important. Some “clinical” outcomes are really intermediate, or surrogate, endpoints, not outcomes that make a difference to the patient. When these intermediate or

1. Convert daily clinical need for information into answerable questions.
2. Find best available evidence with which to answer each question.
3. Appraise the evidence critically and systematically with particular attention to its internal and external validity.
4. Integrate the evidence with the patient's unique biopsychosocial situation and the clinician's own expertise.
5. Evaluate clinical performance as well as the process of acquiring, integrating, and applying the new evidence.

FIGURE 1.1. Five tenets of evidence-based medicine. (From Ref. 62, with permission.)

surrogate outcomes are accepted, the treatment may result in an outcome that harms the patient. For example, before definitive studies using patient-oriented outcomes, suppression of ventricular premature contractions (VPB) was considered beneficial, as was increasing bone mineral density with fluoride. Yet when the studies were done, it was found that suppressing VPBs with certain agents increases patient mortality and increasing bone mineral density with fluoride increases fractures.^{11,12}

Clinical significance also means that the magnitude of the effect is worth the costs of the intervention, including the inconvenience, adverse events, and psychologic or emotional as well as financial costs. The usual way of indicating a benefit, the relative risk reduction (RRR), may be quite large when the absolute risk reduction (ARR), or absolute benefit, is small (Table 1.2), as would be the case when, for example, a treatment reduces the risk of an outcome by 50% for an outcome that only occurs once in every million patients treated. In EBM, a term often used to define the size of the treatment benefit is the number needed to treat (NNT), which is the number of people who would need to be treated with the active intervention, rather than the control, over a specific time period to prevent one additional patient from having the bad outcome the treatment was given to prevent. These terms are illustrated in Figure 1.2, where stroke, the primary outcome of the Systolic Hypertension in the Elderly Program trial, is shown to occur in approximately 8% of control patients and 5% of treated patients.¹³ Here the ARR is 3%, the RRR 36%, and the NNT is 33 over 4.5 years. In other words, treating 33 patients with isolated systolic hypertension (ISH) over 4.5 years will result in one fewer stroke than would have occurred if the ISH had not been treated. Similar terms describe the results of diagnostic tests, including the likelihood ratio, which compares the probability that people with an abnormal test actually have the disease in question to the probability that they have an abnormal test result but not the disease.

Applicability

The third concept is that studies are done on populations but clinicians need to apply them to an individual patient. This approach is relatively easy when the patient sitting in front of you meets the study inclusion and exclusion criteria, but it is far more difficult when the patient resembles those seen in most geriatric practices—old, somewhat frail, with multiple medical conditions and taking multiple medications, possibly with some cognitive, functional, or mood impairment.

In geriatrics, the primary challenge to practicing evidence-based medicine is the lack of high-quality studies that include older adults. There is a paucity of evidence on treating or diagnosing common conditions in relatively healthy elderly, let alone in patients like those just described. For example, how should patients with congestive heart failure (CHF) be treated? The range of mean ages of patients in the systolic CHF clinical trial literature is 58 to 65 years, with the median range being 61,¹⁴ yet one recent population-based study found that almost 50% of new-onset CHF occurred in people age 80 or older and that approximately 50% of these had systolic CHF.¹⁵ Will 80-year-olds be able to tolerate the recent standards for systolic CHF therapy, which include the addition of three to five new medications [i.e., aspirin, beta-blocker, HMG (3-hydroxy-3-methylgluaryl)-CoA reductase inhibitor, angiotensin-converting enzyme (ACE) inhibitor, diuretic, digoxin]? How should the 40% to 50% of patients over 70 whose CHF is diastolic (an ejection fraction $\geq 45\%$)¹⁶ be treated? The answer is unknown, as no large randomized trials have been published to date.

Treatment Studies: Applying Results to Older Adults

Figure 1.3 depicts several of the areas where differences in older adults might impact the benefit/risk ratio of a treatment. Several of these are key principles in geriatric medicine and overlap the specific biologic, social and economic, and epidemiologic issues discussed in the *User's Guide: How to Decide on the Applicability of Clinical Trial Results to Your Patient*.¹⁷ In this chapter, disease, patient, and treatment differences that can influence the application of study results to older adults, as well as the intersections of each of these, are discussed.

Patient–Disease Interactions

Despite the concerns about reduced therapeutic efficacy that follow, it is important to recognize that older adults are often the group most likely to benefit from treatment

TABLE 1.1. Evidence-based medicine (EBM) criteria for evaluating studies.

Criteria	Therapy/prevention	Differential diagnosis	Diagnostic tests	Harm/etiology	Prognosis
Primary validity requirements	<ul style="list-style-type: none"> • Was the assignment of patients to treatments randomized? • Were all patients who entered the trial properly accounted for and attributed at its conclusion? • Was follow-up complete? • Were patients analyzed in the groups to which they were randomized? 	<ul style="list-style-type: none"> • Did the study patients represent the full spectrum of those who present with this clinical problem? • Were the criteria for each final diagnosis explicit and credible? 	<ul style="list-style-type: none"> • Was there an independent, blind comparison with a reference standard? • Did the patient sample include an appropriate spectrum of patients to whom the diagnostic test will be applied in clinical practice? 	<ul style="list-style-type: none"> • Were there clearly identified comparison groups that were similar with respect to important determinants of outcome, other than the one of interest? • Were the outcomes and exposures measured in the same way in the groups being compared? • Was follow-up sufficiently long and complete? 	<ul style="list-style-type: none"> • Was there a representative and well-defined sample of patients at a similar point in the course of the disease? • Was follow-up sufficiently long and complete?
Secondary Validity Requirements	<ul style="list-style-type: none"> • Were patients, health workers, and study personnel “blind” to treatment? • Were the groups similar at the start of the trial? • Aside from the experimental intervention, were the groups treated equally? 	<ul style="list-style-type: none"> • Was the diagnostic workup comprehensive and consistently applied? • For initially undiagnosed patients, was follow-up sufficiently long and complete? 	<ul style="list-style-type: none"> • Did the results of the test being evaluated influence the decision to perform the reference standard? • Were the methods for performing the test described in sufficient detail to permit replication? 	<ul style="list-style-type: none"> • Is the temporal relationship correct? • Is there a dose–response gradient? 	<ul style="list-style-type: none"> • Were objective and unbiased outcome criteria used? • Was there adjustment for important prognostic factors?
Results	<ul style="list-style-type: none"> • How large was the treatment effect? • How precise was the estimate of the treatment effect? 	<ul style="list-style-type: none"> • What were the diagnoses and their probabilities? • How precise are these estimates of disease probability? 	<ul style="list-style-type: none"> • Are likelihood ratios for the test results presented of data necessary for their calculation included? 	<ul style="list-style-type: none"> • How strong is the association between exposure and outcome? • How precise is the estimate of the risk? 	<ul style="list-style-type: none"> • How large is the likelihood of the outcome event(s) in a specified period of time? • How precise are the estimates of likelihood?
Applicability	<ul style="list-style-type: none"> • Can the results be applied to my patient care? • Were all clinically important outcomes considered? • Are the likely treatment benefits worth the potential harms and costs? 	<ul style="list-style-type: none"> • Are the study patients similar to those in my own practice? • Is it unlikely that the disease possibilities or probabilities have changed since this evidence was gathered? 	<ul style="list-style-type: none"> • Will the reproducibility of the test result and its interpretation be satisfactory in my clinical setting? • Are the results applicable to the patient in my practice? • Will the results change my management strategy? • Will patients be better off as a result of this test? 	<ul style="list-style-type: none"> • Are the study results applicable to my practice? • What is the magnitude of the risk? • Should I attempt to stop the exposure? 	<ul style="list-style-type: none"> • Were the study patients similar to my own? • Will the results lead directly to selecting or avoiding therapy? • Are the results useful for reassuring or counseling patients?

TABLE 1.2. Glossary of evidence-based vocabulary included in the fourth edition of *Geriatric Medicine*.

Terms relevant to study design

Case-control study	Case-control studies examine outcomes that are rare or take a long time to develop. Cases are identified in which the outcome occurred; controls are then selected with similar age, sex, and medical conditions excepting the target outcome. Investigators assess the relative frequency of exposure to the alleged harmful agent, controlling for differences in the variables.
Case series	Descriptions of a series of patients; case series lack a control group.
Cohort study	Involves identification of two or more groups (cohorts) of patients, one which did receive the exposure of interest, and one which did not, and following these cohorts forward for the outcome of interest.
Double-blind (DB)	A trial in which neither the patient nor the physician knows whether drug or placebo is being taken, or at what dosage. ⁵⁸
External validity	How well results fit populations other than the one in which the model was generated.
Heterogeneity	In a meta-analysis, results of individual studies suggest that they were performed in different populations. Can compromise the validity of a meta-analysis; significant heterogeneity indicates decreased likelihood that chance alone is responsible for any observed differences in treatment effects between studies.
Internal validity	How well results fit the population in which the model was generated.
Meta-analysis	Quantitative review of systematically chosen literature, the hallmark of which is statistical synthesis of the numerical outcomes of several trials that all asked the same question.
Multicenter	A clinical trial conducted at more than one site, but following the same protocol at all locations.
Placebo-controlled (PC)	A trial in which the effectiveness of the drug is compared to that of a placebo.
Prospective cohort study	An observational study that follows a large group (a cohort) of people forward in time
Randomized controlled trial (RCT)	Experiment in which individual are randomly allocated to receive or not receive an experimental preventative, therapeutic, or diagnostic procedure and then followed to determine the effect of the intervention.
Systematic review	Explicit, structured presentation of results of an unbiased literature review, using predetermined search and appraisal definitions. Based on deductive, rather than inductive, reasoning.

Terms relevant to study results

Absolute risk reduction (ARR)	The difference between the control event rate (CER) and the experimental treatment event rate (EER). Use restricted to a beneficial intervention. $ARR = CER - EER$
95% confidence interval (CI)	An estimate of the precision of a measurement by determining, with 95% accuracy, that the measurement includes the “true” value for the population. The broader the CI range, the more uncertain is the true value of the measurement; CIs that cross zero do not reach clinical significance.
Control event rate (CER)	Rate of the outcome in the control group.
Experimental event rate (EER)	Rate of the outcome in the experimental treatment group.
Intention-to-treat (ITT)	Results that include every individual originally randomized, regardless of whether or not they completed the trial.
Likelihood ratio (LR)	Positive LR = probability of an abnormal diagnostic or screening test result (including clinical signs or symptoms) in patients with the disorder of interest compared to the probability of the abnormal result in patients without the disorder ($Sn/1 - Sp$). Negative LR = probability of a normal diagnostic or screening test result (including clinical signs or symptoms) in patients without the disorder of interest compared to the probability of a normal result in patients with the disorder ($Sp/1 - Sn$).
Negative predictive value	The proportion of patients testing negative for the disorder who are actually disease free, of all the patients testing negative.
Number needed to treat (NNT)	The number of patients who must be treated with this intervention (rather than the control) over a specified time period to prevent one additional bad outcome. $NNT = 1/ARR \text{ (as a decimal)}$
Number needed to harm (NNH)	The number of patients who would need to be treated over a specific time period before one adverse side effect of the treatment will occur.
Odds ratio (OR)	The odds of an experimental patient suffering an adverse event relative to a control patient.
Per protocol analysis	Results that do not take into account all persons originally randomized, only those participants who followed the study protocol.
Positive predictive value	The proportion of patients testing positive for the disorder who actually have the disease, of all the patients testing positive.
Relative risk reduction (RRR)	Percent reduction in “bad” outcome events in the experimentally treated groups relative to the control groups. $RRR = (CER - EER) / CER * 100$
Sensitivity (Sn)	The proportion of diseased patients actually testing positive for the disorder, of all the diseased patients.
Specificity (Sp)	SnNout: When a test has a high Sensitivity, a Negative test rules OUT the diagnosis. The proportion of disease-free patients actually testing negative for the disorder, of all the disease-free patients. SpPin: When a test has a high Specificity, a Positive result rules IN the diagnosis.

of a given disorder. Benefits are almost always greatest in the population most likely to experience the bad outcome that the treatment is intended to avoid or improve. Treatment of hypertension can be used as an example. In Table 1.3, the NNTs over 5 years to prevent one additional death or cardiovascular or cerebrovascu-

lar event are depicted for hypertensive patients. With increasing age, fewer patients need to be treated to obtain benefit, which is not surprising because the prevalence of death and cardiovascular events resulting from hypertension increases with age. In general, older adults have a similar decrease in relative risk and the same or a smaller NNT than middle-aged or younger adults, particularly when risks of treatment are small. Table 1.4 illustrates this concept by summarizing the results of subgroup analyses by age from four RCTs of lipid-lowering agents in patients with known coronary disease.¹⁸

Disease Differences

Age-related differences in disease pathophysiology or in the multifactorial nature of a condition can decrease treatment efficacy. For example, agents effective at treating pneumonia in community-dwelling adults may be less effective when treating nursing home-acquired pneumonia due to differences in the causative organisms and

resistance patterns.^{19,20} Sulfonylureas are effective in treating type II diabetes, but the lack of endogenous insulin makes them of little use in treating type I. The symptom complex of nocturia and leg edema may suggest CHF, yet diuretics will not improve nocturia caused by age-related temporal shifts in fluid elimination that are a result of loss of the circadian rhythm of antidiure-

tic hormone secretion, decreased renin-angiotensin-aldosterone, increased secretion of atrial natriuretic hormone, and diminished renal concentrating and sodium-conserving ability,²¹ or leg edema that is secondary to venous insufficiency.

Classic differential diagnosis teaches us to use Occam's razor; that is, scientists should assume no more causes than are absolutely necessary to explain their observations. A single diagnosis should be sought to account for all the patient's signs and symptoms. Many geriatric disorders, however, are multifactorial in that several different conditions contribute to the symptom complex. With multifactorial disorders, identifying and treating a single condition may result in some but not complete improvement. Intermediate outcomes may be improved, yet patients may not be aware of any improvement. For example, the single diagnoses most responsible for dyspnea on exertion (DOE) are pneumonia, asthma or chronic obstructive pulmonary disease (COPD), angina, or CHF. Specific treatment for the correct diagnosis results in resolution of the symptom. In older patients, a number of chronic conditions may contribute to the complaint of DOE. In addition to the disorders already noted, kyphosis, intrinsic lung disease, deconditioning,

valvular heart disease, left ventricular dysfunction, tachyarrhythmias, and mild anemia may all exacerbate the patient's symptoms. Only some of these can be reversed, and treatment of any one ameliorates only some of the dyspnea, even if the laboratory or radiology results for that condition normalize.

Patient Differences

Older adults are more pathophysiologically heterogeneous than people at other stages of life as a result of the effects of aging itself, disease, lifestyle, and genetics. The concept of applying study results to "older adults" is actually misleading, as there appear to be multiple subsets with significantly different prognostic trajectories: successful agers, usual agers, chronically ill, dementing, or terminally ill agers. Even within each of these groups, the life expectancy trajectory has been shown to differ.^{22–28} Prognostic indexes are better for some conditions than others, but generally even these only provide data on time to death or, occasionally, the need for institutional-type care.

Comorbid and age-related conditions can significantly alter the potential benefits and risks of treatment. The impact of comorbid illness on life expectancy can negate the benefit of treating certain conditions including early prostate cancer, where no outcome difference is seen between treatment and watchful waiting over 10 years,²⁹ and high cholesterol, where benefits are initially seen after 2 full years and reach a maximum at 5 years.³⁰ Other comorbidities allow parsimonious treatment to occur, resulting in an intervention having even greater benefit than usual: examples include anticoagulation in a person with both a deep venous thrombosis (DVT) and atrial fibrillation, or colchicine in someone with gout and significant constipation. Comorbidities can also reduce the effect of treatment by producing a bad outcome through mechanisms not affected by the treatment. For example, cataract removal in older adults may not improve vision substantially if the patient has underlying macular degeneration or diabetic retinopathy, which is less likely to occur in middle-aged or younger adults.

Homeostenosis is a term that reflects the age-related decline in ability to maintain homeostasis and attenuate the impact of stressors. With aging, thermoregulation becomes more difficult, the immune system is not as responsive, and the maximal heart rate is not as high (see Chapter 3). This loss of physiologic flexibility and plasticity means that any intervention might have a more deranging influence than expected. For example, people with structurally abnormal brains due to either dementia or stroke are more likely to develop delirium from a small dose of an anticholinergic drug than age-matched people without these conditions.^{31,32}

Treatment Differences

Patient adherence, and consequently therapeutic effect, can be markedly affected by the social and economic differences discussed in Chapters 6 and 82. In general, people who adhere to placebo in a study do better than study patients who do not adhere,⁵ and many interventions have been found to have less benefit in practice than in an RCT. The ability of older adults to adhere to therapeutic regimens, including preparations for procedures, can be compromised by motivation, finances, social isolation, impaired ADLs (activities of daily living), IADLs (instrumental activities of daily living), and cognition, all of which usually are more common in study nonparticipants than participants. For other types of interventions, including test interpretation, provider and site experience and expertise are key to obtaining results comparable to those obtained in a clinical trial.^{33–35}

Study interventions may be simple, such as a trial of a medication for a specific condition, or complex, for example, the effect of an Acute Care for Elders unit or a Delirium Prevention consultation team on functional change from preadmission to discharge. Complex interventions usually have several components including content variables, such as protocols for preventing and managing urinary incontinence or delirium, and process variables, such as the personnel, administrative structure, and methods for changing staff behavior. When a complex intervention is effective, it is often difficult to replicate and often unclear which components are critical to success and therefore required for replication.^{36,37} Key components might be staff with specific personality traits or a culture that is supportive of change, both of which are more difficult to replicate than the administration of a medication.

Patient–Treatment Interactions

Older adults experience a variety of age-related changes in pharmacokinetics and pharmacodynamics (see Chapter 7), resulting in a need to modify drug dosing regimens from those used in a study. Comorbid conditions and their treatments result in novel drug–drug and drug–disease interactions that are not detected during phase III trials because of the stringent inclusion and exclusion criteria and the relatively small numbers of subjects tested. For example, treatment of atrial fibrillation with rate control agents such as beta-blockers is more likely to result in symptomatic bradycardia requiring a pacemaker in older adults³⁸ because it is more often a manifestation of sick sinus syndrome in this population. Treatment responsiveness may also vary with age, as demonstrated by the decreased immune response and efficacy of the influenza vaccine in nursing home patients.³⁹ The target range for therapeutic or

Question	Supporting evidence and data sources
1. Could the disorder be secondary to a medication that could be tapered or stopped?	Leipzig RM. <i>Drug Prescribing for Older Adults: An Evidence-based Approach</i> . Philadelphia: American College of Physicians; 2003.
2. Has the treatment been shown to be superior to other accepted treatments in its effect on outcomes that matter to patients?	Dukes MNG, ed. <i>Meyler's Side Effects of Drugs</i> , 13th Ed. New York: American Elsevier; 1996. <ul style="list-style-type: none"> • Head-to-head trial against current standard treatment showing <ul style="list-style-type: none"> Better efficacy Fewer adverse events • More likely to be taken as directed (e.g., qd vs. qid) • Costs less In general, do not accept the following: <ul style="list-style-type: none"> Improves disease-oriented outcomes “Me-too” drug that differs chemically or pharmacokinetically but not in any of the above ways Different mechanism of action without head-to-head trials
3. What is the patient's likelihood of a bad outcome if not treated?	<ul style="list-style-type: none"> • Estimation of the patient's life expectancy^{22,25–28} • Studies that: <ul style="list-style-type: none"> Identify prognostic factors and subgroups Provide control group event rates
4. What is the effectiveness of the treatment for older adults?	Hierarchy of evidence <ul style="list-style-type: none"> • Systematic review of RCTs that include subjects similar to the patient • Single RCT that includes subjects similar to the patient • Analyses of the older adults within RCTs <ul style="list-style-type: none"> Individual patient meta-analyses Intentional subgroup analyses (appropriate power to show a difference) Posthoc subgroup analyses • Prospective cohort studies • Retrospective cohort studies • Case-control studies
5. What are the risks of treatment? Is there any type of monitoring that will decrease this risk?	<ul style="list-style-type: none"> • Those identified in the studies (how large were the studies, who was excluded?) • What are the patient's “vulnerable” areas (balance, nutrition, hepatic and renal function, unable to comprehend instructions or report symptoms, etc)? Adverse event literature: <ul style="list-style-type: none"> Goodman LS, Hardman JG, Limbird LE, Gilman AG, eds. <i>Goodman & Gilman's The Pharmacological Basis of Therapeutics</i>, 10th Ed. New York: McGraw-Hill; 2001. Bennett WM. <i>Drug Prescribing in Renal Failure: Dosing Guidelines for Adults</i>, 3rd Ed. Philadelphia: American College of Physicians; 1994. Semla TP, Beizer JL, Higbee MD. <i>Geriatric Dosage Handbook: Including Monitoring, Clinical Recommendations, and OBRA Guidelines 2002–2003</i>, 6th ed.: Lexi-Comp; 2002. Hansten PD, Horn JR. <i>Hansten and Horn's Drug Interactions Analysis and Management</i>. (Updated quarterly.) Vancouver, WA: Applied Therapeutics; 1997–.
6. How important does the patient view avoiding the disorder's bad outcome compared to the risk of treatment?	Patient discussion; family and/or caregivers if patient unable to discuss

toxic drug levels may need to be adjusted due to differences in protein binding²⁵ or in recognition of the types of adverse events, such as delirium or falls, which commonly occur in older but not younger adults. This concern is particularly true for chronically ill or frail older adults, who may have compromised end organs that respond differently or in an exaggerated way to “usual” drug levels.⁴⁰

In summary, it is often possible to identify factors that might change the benefit/risk ratio of an intervention in older adults from that estimated in an RCT performed mainly in younger or middle-aged persons. There are times, especially when the condition or the treatment are “high risk,” when it is important to evaluate data

obtained directly from the treatment's use in older adults themselves. An example of this is thrombolysis for acute myocardial infarction (MI), where RCTs suggest equal benefit up to the age of 75 but provide no data on persons 75 or older. Observational studies concur that 30-day or hospital survival improves up to age 75; however, these studies found that acute MI patients over this age treated with thrombolysis were more likely to die than sicker patients who did not receive thrombolysis.^{41,42} Neither gastrointestinal nor brain hemorrhage in older adults, the major adverse effects of thrombolysis that lead to death, appear to be responsible for this increase. Table 1.5 suggests a series of questions to ask before applying the results of a therapeutic trial to older adults.

Diagnosis Studies—Diagnostic Tests, Differential Diagnosis, Screening, and Clinical Prediction Rules: Applying Results to Older Adults

Prevalence and competing diagnostic possibilities may differ between geriatric patients and the original study population. In a younger population in which a disease has low prevalence, a test may have a low positive predictive value and not be useful for screening; the positive predictive value, however, can increase in an older population where the disease has greater prevalence, making

the same test appropriate as a screening test for older adults.

Differences in the differential diagnosis can affect diagnostic and screening test characteristics such as sensitivity, likelihood ratio, the accuracy of a clinical prediction rule, or the pretest probability of a diagnosis. For example, a clinical prediction rule derived and validated in middle-aged populations (with 20%–30% ≥ 60 years old), found that rales, fever, tachycardia, decreased breath sounds, and the absence of asthma were independent predictors of pulmonary infiltrates;⁴³ confusion and level of consciousness were not. In a similar derivation study conducted in nursing home residents, however,

both acute confusion and somnolence and decreased alertness were independent predictors, along with all the other conditions except decreased breath sounds.⁴⁴ Similarly, a clinical prediction rule for hyperthyroidism or acute myocardial infarction may differ for middle-aged compared to older adults because of the difference in disease presentation in these two groups.^{45–49}

For diagnostic tests, the competing diagnostic possibilities need to be those which are prevalent in the differential for people of that age presenting with a given symptom complex. In older adults, a diagnostic test for dementia due to Alzheimer's disease needs to differentiate this condition not simply from normal cognition or human immunodeficiency virus (HIV) dementia but from dementias due to Parkinson's disease or vascular causes. Younger patients presenting with fever and acute confusion undergo an urgent lumbar puncture and are immediately started on antibiotics because of the concern that they have bacterial meningitis, whereas this is rarely the cause of a febrile delirium in an older adult and a lumbar puncture is not often needed.⁵⁰ If the illness differs pathophysiologically in older and younger adults, diagnostic tests may be far less accurate. Pulse increase is a sensitive sign of orthostatic hypotension in younger adults, but not in older adults, probably because the hearts of older adults are relatively insensitive to the inotropic effects of beta-adrenergic agonists.⁵¹

Conclusion

Time pressures on the clinician make careful critique of individual trials difficult. Evidence-based resources such as those noted in Table 1.6 provide prescrutinized summaries for clinicians and allow one to be more informed of the results of high-quality studies that evaluate outcomes of concern to patients, not just to the disease. Table 1.2 defines some of the terms commonly used both in this chapter and in this edition of *Geriatric Medicine*.

The goal of this fourth edition is to provide, based on currently available sound data, an evidence-based approach to the older patient. We try to provide not only the best evidence available now, but also to set the stage for clinicians to rationally approach evidence that excludes the "real" geriatric patient. Finally, we hope to encourage research in those areas lacking evidence in older adults, with the full understanding that constantly updated editions will be required as new research is conducted.

Molecular and Biologic Factors in Aging

Charles Mobbs

Is “the biology of aging” a misnomer? Are there general principles that may usefully apply generally to senescence, or is senescence simply a collection of degenerative entropic processes that have in common only that they occur over time? Both views are supportable; indeed, the latter is perhaps the more common view among gerontologists and is the most supportable by evolutionary theory.¹

However, gerontology, like geriatrics, has evolved into a discipline in part because senescence entails several general characteristics and because impairments associated with senescence are largely predictable within a species. For example, mortality (and other senescent changes) conform (within limits) to a precise mathematical description, the Gompertz curve, whose parameters are characteristic of each species.² Similarly, dietary restriction dramatically reduces many age-related impairments and increases maximum life span across a wide range of phyla.³

These general characteristics and the specificity of senescence require explanation, and seeking these explanations is the business of gerontology. Furthermore, recent studies have suggested that senescence may entail simpler and more orderly molecular processes than previously assumed. These general molecular processes may have profound consequences for geriatric practice, because far from ascribing age-related impairment merely to “old age,” it may soon be as possible to treat some of these age-related impairments as any other disease.

Thus, some chronic age-related diseases may come to be viewed as symptoms of a more inclusive syndrome of senescence. This integration of geriatrics into the traditional medical model is an outcome of recent progress in gerontology.

Nomenclature

Aging: showing the effects of time; a process of change, usually gradual and spontaneous

Senescence: the loss of the power of cell division and growth (and function with time, leading to death) (*The New Shorter Oxford Dictionary*)

Gerontologists consider the term *aging* insufficiently precise because any process that occurs over time, for example, rusting or development, may be reasonably referred to as aging. Furthermore, although there are reasons to imagine that “aging” is a continuum beginning with development, these two terms are usually used to refer to distinct processes. Specifically, *development* (as in an embryo) refers to a *generative* process over time necessary for (and primarily evident at the beginning of) life, whereas *senescence* refers to a *degenerative* process ultimately incompatible with (and primarily evident at the end of) life. Whether development and aging form, in any informative way, a mechanistic continuum is a hypothesis that is far from proven. (Indeed, bibliographic database searches have been greatly complicated by the assignment of the term *aging* to the process of development, without a concomitant general use of the term *senescence*.) The distinction between aging and senescence is of more than academic interest because many changes that occur during aging may not be deleterious and may indeed be desirable. Thus, for example, the wisdom (or, at any rate, experience that ought to lead to wisdom) that increases with age is not usefully considered senescence, although it may be referred to as part of the aging process. Conversely, impairments in memory that occur during aging are usefully considered a manifestation of senescence. Thus, geriatrics is essentially concerned with senescence, not aging per se, except to promote aging with as little senescence as possible.

Theories of Aging

Is Senescence an Entropic Process?

The essential feature of degeneration as a concomitant to senescence immediately raises one of the most important questions in gerontology: is senescence merely a biologic manifestation of the second law of thermodynamics? An essential feature of life is the low level of internal entropy that characterizes biologic entities compared to the environment. Organisms maintain that low entropy state by conversion of external energy (with the result of a net increase in entropy, of course, when the organism and its environment are considered as a system). Mechanical objects such as automobiles or test tubes are also in a state of low entropy, but without the capacity to reduce internal entropy by converting external energy. Thus it is that mechanical objects accrue increased entropy over time “merely” as a mechanical manifestation of the second law and in that sense can plausibly be said to undergo senescence. Therefore the question arises: is senescence merely the accumulation of random events leading to a level of entropy that is incompatible with life? The key word in this formulation is *merely*. Ultimately, death is always a manifestation of entropy, but the pertinent question is, what is the proximal process that leaves the organism vulnerable to entropy? In short, do organisms senesce in a way fundamentally different from mechanical objects? By the view that senescence is merely a collection of degenerative processes that happen to occur over time, the second law would seem to be the only generally relevant principle operative. On the other hand, by the view that some general principles exist that subserve senescence, organisms would presumably differ fundamentally from mechanical objects.

The role of entropy may seem an abstraction, but an example will demonstrate its pertinence. A famous form of senescence is the death of the Pacific salmon.⁴ After spawning, a predictable pattern of degenerative changes occurs, leading almost always to death. The question is, is this death “merely” the result of entropy? It would be as accurate to posit that death caused by smallpox (or starvation or myocardial infarction) is due to entropy. Such a formulation might be formally true, but it is more informative to ascribe the mechanism of senescence to its proximal biologic substrate—in the case of Pacific salmon, to the hyperactivity of the adrenal gland that accompanies the spawning process.⁴

In most forms of senescence, it has been much more difficult to determine the biologic substrate of the degenerative changes. This difficulty has given rise to the sense that degenerative changes with age are essentially random, for example, a manifestation of entropy. This view has been reinforced by the argument, developed

convincingly by evolutionary biologists, that senescence did not evolve because it bestowed advantage on the species, but rather senescence is essentially an evolutionary by-product and, as such, is probably determined by the complex interaction of many genes with the environment.¹

Evolutionary Theories of Aging

The fact that each species is characterized by a characteristic maximum life span whose value is essentially independent of environment indicates that, among species, senescence is determined genetically. The genetic constraint on maximum life span and rate of senescence has given rise to much speculation concerning the evolution of senescence. Early speculation around the turn of the nineteenth century was that senescence as a trait evolved, similar to most traits, because species that exhibited senescence would be more likely to survive than species which did not senesce. The general tone of such arguments was that species not exhibiting senescence would accumulate ill-adapted older members of the species that would compete with potentially better-adapted younger members of the species, effectively reducing the rate at which potentially adaptive mutations could be introduced into the species, thus slowing the rate of evolutionary adaptation. The lack of rigor of such arguments has long been recognized, and, particularly since Peter Medawar’s landmark monograph in 1952,⁵ there has been a consensus that senescence is not a trait that has been positively selected for but rather is a trait which has not been selected against. In particular, it has been assumed that the force of selection diminishes after reproduction, so that traits that facilitate successful reproduction will be selected for, even if such traits lead to death later in life. This general concept has been formulated mathematically by Charlesworth,⁶ who concluded that even if an immortal species had ever existed, it would have eventually evolved to exhibit senescence.⁷

Although the mathematical formulation of Charlesworth is rigorous, there are challenges to the conclusions that may be drawn from this formulation because of the assumptions on which the analysis is based. For example, several species appear to exhibit extremely low, indeed virtually undetectable, rates of senescence.⁸ Conversely, in some cases such as the Pacific salmon, there would indeed appear to be simple mechanisms that actively initiate and maintain senescent processes. Finally, as discussed below, several individual genes have been found whose continuing activity is by itself limiting to life span; furthermore, across phyla, these genes appear to be impinging on similar physiologic processes. If such a simple set of genes operated similarly in humans, it would be the object of great interest and

perhaps a potential target for drug intervention. The existence of such genes poses a stark challenge to evolutionary analyses that imply that senescence could not be determined by the activity of a few genes or a developmental program.

Entropic Theories of Aging

The bewildering diversity of age-related impairments has led many gerontologists to conclude that no general mechanism is likely to underlie these changes. Furthermore, although there is a general sense that senescence might reflect an orderly unfolding of a genetic program as occurs during development, this view (which never had any real data to support it) has fallen out of favor with the rise of more sophisticated analyses of the evolution of senescence (see following). Nevertheless, gerontology has been a field characterized by a plethora of mechanistic theories. The most influential of these theories generally fall into two categories, which can broadly be referred to “loose cannon” theories and “weak link” theories.

The “loose cannon” theories posit that some entropy-producing agent is slowly wearing away at cellular macromolecular constituents. The most popular candidates have been free radicals^{9,10} and glucose.^{11–13} Free radicals are generated during oxidative phosphorylation and can, in theory, produce a variety of macromolecular modifications, primarily through oxidation. Considerable evidence suggests that oxidative damage increases with age.¹⁴ This evidence includes the oxidation of specific amino acid residues in specific proteins that increases with age (having the effect of decreasing the specific activity of these proteins, a common observation during senescence),¹⁵ and an increase in specific oxidized derivatives of nucleotides derived from DNA.^{16–19} Furthermore, simultaneous overexpression of two different enzymes that attenuate free radical damage, superoxide dismutase and catalase, significantly increases the life span of fruit flies;²⁰ no effect was seen when only one enzyme was expressed. Similarly, exposure of nematodes to small molecules that mimic effects of superoxidase dismutase and catalase also increased life span.²¹ These results are promising, but as yet the contribution of free radicals to senescence remains to be fully clarified.

The other popular candidate for a loose cannon is glucose. The major means by which glucose has been proposed to promote senescence is through nonenzymatic attachment to proteins and nucleic acids through Schiff base formation, followed by an irreversible formation of Amadori products, the same process that produces glycated hemoglobin.¹¹ As with oxidation, glycated proteins increase with age, and chemical blockade of the process of glycation delays at least some age-related

pathologies.²² Furthermore, the fact that dietary restriction increases maximum life span and also reduces blood glucose and rate of glycation has continued to stimulate interest in the possible role glycation may play in the process of senescence.¹² It should also be noted that free radical mechanisms and glycation mechanisms are not mutually exclusive, because glycation can cause free radical production.²³ However, a major difficulty with the free radical and glycation theories, and indeed with all such theories, is that they are of little value in predicting the specific physiologic impairments that characterize the senescence of each species.

The “weak link” theories posit that a specific physiologic system is particularly vulnerable (presumably to entropic processes) during senescence, and when this system fails, it produces cascading effects that accelerate dysfunction of the whole organism. The two most popular candidates for the weak link theories are the neuroendocrine system and the immune system. Both the neuroendocrine system and the immune system exhibit profound and specific functional impairments during aging. Failure of the neuroendocrine system would be expected to produce profound impairments in homeostatic systems, including the loss of reproduction and metabolic regulation that is observed during aging. For example, secretion of growth hormone decreases robustly with age in humans and other species, and replacement of growth hormone has been reported to restore a variety of physiologic functions in aging rats and elderly men.²⁴ Similarly, failure of the immune system would be expected to produce increased susceptibility to infection and decreased ability to reject tumor cells, also observed during aging.

However, in general there is little evidence that failure of either system directly contributes to age-related diseases or mortality. For example, it now appears in fact that, far from the expected relationship between declining growth hormone and age-related mortality, mice with growth hormone deficiency exhibit increased life span compared to wild-type mice, whereas mice with elevated growth hormone exhibit reduced life span.²⁵ Similarly, although autoimmune processes cause type I (juvenile) diabetes, this form of diabetes occurs mainly in young individuals, whereas the form of diabetes that occurs during aging does not appear to involve immune impairments. Furthermore, even though neuroendocrine and immune systems do exhibit impairments with age, little is known about the more primary mechanisms that drive these changes. Therefore, in their current incarnations, none of the entropic theories of aging are complete, and it cannot be said that considerable evidence supports the idea that any of these mechanisms underlie the impairments and death that are associated with aging.

Physiology of Aging

As organisms age, they accrue functional impairments in virtually every physiologic system. In humans, Nathan Shock and his coworkers developed a general rule of thumb that many physiologic systems accrue impairments at a rate of about 5% to 10% per decade after the age of 30 or so.²⁶ A well-known example of this principle is the decrease in maximum tolerable heart rate.²⁷ In aerobic training, the maximum heart rate (Rh) recommended during training is given by the equation $Rh = (244 - \text{age}) * 0.8$.

This equation is based on the general rule of thumb that a heart rate more than 80% of maximum attainable during a stress test is dangerous, and that the maximum heart rate attainable during a stress test reliably decreases by about 1 beat per minute each year during aging. The rate of this decline is reduced by about half in highly trained athletes, but even in such athletes, maximum heart rate and maximum oxygen consumption rate nevertheless decline with age.²⁷ Many other functions change gradually during aging (blood glucose, grip strength, fertility), and with time the death rate from many different causes increases.

The Gompertz Curve

The essential feature of senescence, at least when applied to mortality, is that the rate at which death occurs increases with time. If the rate at which death occurred were constant (e.g., age independent), then the term senescence would not be applicable. In most species, senescence, manifest as an increase in the rate of mortality with age, can be described by a remarkably simple mathematical function. The rate of mortality of most species that have been studied, including flies, nematodes, and rodents, increases exponentially with time, first observed in humans by Benjamin Gompertz after observing actuarial statistics and reported in 1825. The Gompertz equation can be stated succinctly as $Rm(t) = -(1/n) * dn/dt = R_0 e^{(at)}$, where $Rm(t)$ is the mortality rate at time or age t , n = the number of survivors at time t , R_0 is the mortality rate at time $t = 0$, interpreted as a vulnerability factor depending on the hostility of the environment, and a is a rate constant dependent on the species. This equation can be linearized by log transform into $\ln Rm(t) = \ln(R_0) + at$.

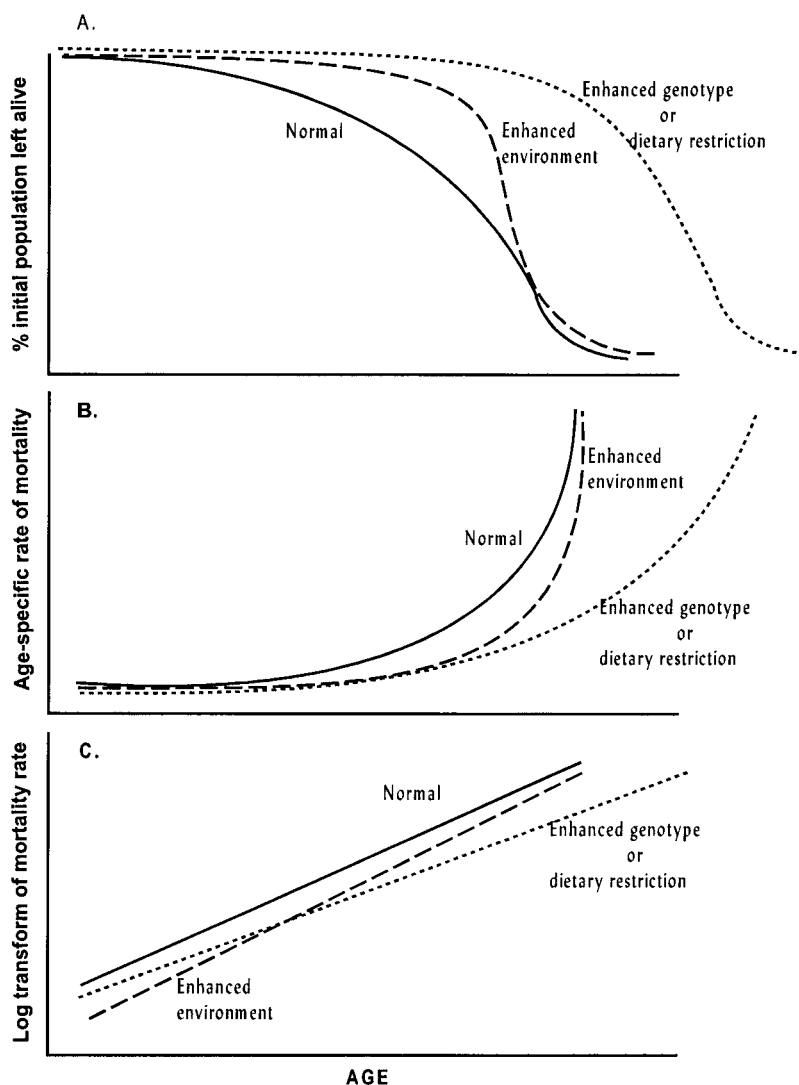

The intercept of this line is generally dependent on the hostility of the environment, whereas the slope is dependent on the genetic background of the population, for example, the species or strain. A goal of gerontology is to be able to derive the constants of the Gompertz curve, especially the slope of the linearized form, from the analysis of the biologic characteristics of the species.

Although this derivation is far from accomplished, simply being able to formulate such a precisely quantitative question is evidence of the state of gerontology as a scientific discipline. Analysis suggests that at least the form of the Gompertz curve may arise from evolutionary effects, involving a decline in the force of natural selection acting on age-specific mortality.²⁸ The extent to which this insight may contribute to a more mechanistic understanding of the process of senescence remains to be determined.

The relationship between the survival curves, rate of mortality, and the Gompertz transform is illustrated in by the idealized depictions of Figure 2.1. In the top panel (A), the survival curve (fraction of initial population left alive as age increases) of a typical (“normal”) population is compared with the survival curve of a genetically similar population placed into an optimum environment (“enhanced environment”) or a population modified genetically or subject to dietary restriction. Note that an enhanced environment can increase average life span by “rectangularization” of the survival curve, but the maximum life span (indicated by the age at which the fraction of the population left alive drops below an arbitrarily small number) is not influenced by environment. In contrast, genetic variance and dietary restriction can increase not only average life span but maximum life span as well. When these same data are plotted in terms of rate of mortality (the number of individuals that have died over an arbitrarily small unit of time), the mortality rate of all groups increases exponentially with age and reaches the same high rate toward the end of life; the groups differ in that environment can delay the exponential increase (although then the rate increases even faster toward the end of life), whereas genotype and dietary restriction can actually change the rate at which mortality rate increases. Because mortality rate increases exponentially with age, these effects are more easily understood by subjecting the rate data to a logarithmic transform. After such a transform, log (mortality rate) increases linearly with time. Normal and enhanced environment groups have similar slopes. If anything, the enhanced environment group may exhibit a slightly higher slope because the intercept is lower, whereas genotype and dietary restriction can actually decrease the slope of this transform.

When the rate of mortality becomes high enough, an arbitrarily small number of individuals will be left alive at time t_m , the maximum life span. In practice, maximum life span is determined empirically, and in humans is generally assumed to be around 125 years (for women; somewhat lower for men). Although the idealization of Figure 2.1 illustrates the case in which the Gompertz relation holds across the entire life span, in actual populations the Gompertz curve actually only applies to the rate of mortality between sometime after puberty and sometime well

FIGURE 2.1. Three views of mortality. (A) Fraction of population left alive as a function of age. *Normal*, standard population dynamics; *enhanced environment*, dynamic pattern as might be observed by idealized optimization of environment, leading to “rectangularization” of the survival curve; *enhanced genotype or dietary restriction*, dynamic pattern observed by single gene mutations that extend maximum life span (such as AGE-1) or by dietary restriction regimens that extend maximum life span. (B) View of the same data as in A, but plotted as rate of mortality. Depicted in this way, rate of mortality increases exponentially with age (Gompertz function). (C) Logarithmic transformation of the data in B. Note that rectangularization of the mortality curve may decrease initial rate of mortality but does not necessarily increase maximum life span and may indeed lead to increased mortality rate during the late period of life, whereas genetic or dietary enhancement of maximal life span is expected to entail decreased rate of mortality but not necessarily a decreased initial mortality rate.

short of maximum life span. In humans, the generally accepted range of applicability is between ages 20 and 80 or so. A particularly interesting recent development is evidence in both humans and other species^{29,30} that the slope of the linearized Gompertz equation (that is, the increase in the rate of mortality, or the second derivative of survival) begins to decrease at very old ages, and possibly the rate of mortality becomes constant (e.g., independent of age) in populations composed of very old individuals. These remarkable results have profound implications for our view of the process of senescence, because senescence necessarily entails an increased rate of mortality with age. Thus under some circumstances (in very old individuals), there is evidence that senescence itself may slow dramatically, possibly even to zero (keeping in mind, however, that even if the rate of mortality does not increase, the high rate of mortality already characteristic of old individuals ensures a fast depletion of the population). The role of selection from within a

population of heterologous individuals in this phenomenon has yet to be determined.

Pathology Versus Senescence

The Gompertz equation applies not only to mortality but also to diseases and may be used to resolve a major and controversial conceptual issue facing gerontologists and geriatricians: is there a valid distinction between pathology, or disease, and what is commonly (although, as we have seen, unrigorously) called normal aging? This distinction is not merely semantic but addresses fundamental questions of mechanism.

As with mortality, the rate of onset of many diseases increases exponentially with age. (In the following analysis, it is essential to keep in mind the difference between incidence, that is, the rate of new cases that occur at a given age, and prevalence, which is the total number of cases in a population of that age; rate equations such as

the Gompertz curve only describe incidence, and thus incidence is the most informative from a mechanistic point of view. With regard to mortality, one generally is inherently referring to incidence, for example, the rate at which death occurs, because the equivalent of prevalence with respect to mortality, such as survival curves, would include the cumulative number of individuals who have died, not a particularly useful statistic with respect to mechanism. However, there is an extremely important difference in the application of rate equations to disease and mortality. As already described, the applicability of the Gompertz equation to mortality begins to break down at about age 85 or so, and the slope of the line (the second derivative of survival) begins to decrease. Nevertheless, the rate of mortality (the first derivative of survival) does not appear to decrease with time; that is, the rate of mortality continues to increase with age, or at least is constant at a very high level in very old individuals.

The incidence rate of diseases increases exponentially up to the age of maximum incidence, the age depending on the disease, but then the incidence of disease begins to decrease. Not only does the rate of increase of incidence begin to fall, but the absolute incidence of new cases declines after some age. For example, the incidence of new cases of type I diabetes increases from around 9 months of age and peaks around 14 years of age (depending on the population);^{31,32} after this age, the incidence of type I diabetes declines³¹ to a lower constant rate. Thus, after the age of peak incidence, the incidence rate decreases to a low rate that is independent of age, a common pattern for age-related diseases. Of course, the prevalence of the disease, representing the total accumulation of patients with the disease, increases over time. Type II diabetes follows a similar pattern, although shifted to much later ages, such that the peak incidence of type II diabetes occurs around 70 years to age, after which the age-specific incidence rate begins to decrease;³³ because the incidence rate falls or becomes constant after the peak age of incidence, it may be said that senescence is no longer operating on this disease after the age of peak incidence. Similarly, the age-specific incidence of Huntington's disease peaks around 40 years of age,³⁴ the age-specific incidence of Parkinson's disease peaks at about 75 years of age,³⁵ and the age-specific incidence rate of Alzheimer's disease appears to peak at about 90 years of age.³⁶

These examples also indicate the important mechanistic implications of incidence rate data. Typically, the incidence rate of familial forms of age-related diseases peaks at earlier ages than the nonfamilial or sporadic forms. Thus, mutations in the *parkin* gene lead to juvenile-onset Parkinson's disease, whose incidence peaks around 20 years of age, and the incidence of Parkinson's disease from mutations in alpha-synuclein peaks around age 50.³⁷ In contrast, the incidence rate of Parkinson's disease in

the population as a whole peaks around age 70.³⁵ Because twin studies have indicated that genotype makes little contribution to the late-onset (and most common) form of the disease, taken together these data imply that the contribution of genotype to Parkinson's phenotype increases with age up until about age 50, then begins to decline, such that by age 70 there is little contribution of genotype to phenotype.³⁷

Gompertz analysis may also clarify the distinction between disease and nonpathologic processes of senescence, because processes whose incidence increases monotonically with age (including mortality) may be usefully considered a senescent process, whereas conditions whose incidences reach maxima before maximum life span are more usefully considered age-related pathology or disease. The mechanistic implications of the distinction between disease and senescence may be clarified by an example. As described, the incidence of Alzheimer's disease continues to increase until late in life. In addition, gradual impairments in memory functions also increase monotonically with age. A major question therefore has been: Is Alzheimer's disease an accentuated form of the more universal impairments in memory function? Were this hypothesis correct, one implication is that if we live long enough, everyone would contract Alzheimer's disease. However, careful analysis of the incidence of Alzheimer's disease has demonstrated that, as in all diseases, the incidence of Alzheimer's disease reaches a peak well before maximum life span. Thus, for example, centenarians exhibit a lower incidence of Alzheimer's disease than individuals between 70 and 80.³⁶ This finding indicates that Alzheimer's disease is not merely an accentuated form of "normal" age-related changes but is a distinct pathologic process (an conclusion supported by detailed analysis of brain tissue); conversely, the more universal (but milder) cognitive impairments observed during aging are not likely to be caused by the same mechanism as that which causes Alzheimer's disease. This conclusion is corroborated by rigorous clinical and pathologic analysis that demonstrates that neither the clinical nor the pathologic profile of Alzheimer's disease is in detail similar to the profile of normal aging.³⁸

Nevertheless, one caveat must be made regarding the distinction between senescence and disease. Age-related diseases do, by definition, exhibit an age dependency, raising the question whether the development of these diseases is, in some fundamental sense, related to the underlying process of senescence, even if diseases can be dissociated from senescence. One reason for suspecting a mechanistic link between many diseases and senescence is that, in animal models, dietary restriction not only increases maximum life span but also dramatically decreases many age-related diseases such as cancer.³⁹⁻⁴⁵ Naturally, much of the interest of gerontology is the possibility of some general principle subserving both senes-

cence and the diseases associated with senescence. The fact that dietary restriction appears to concomitantly delay both senescence and disease suggests that such principles may exist.

Individual Variability

The Gompertz curve for both disease and senescence is essentially a mathematical statement of individual variability. Thus, a few individuals in the population die early, and increasingly more individuals die as the population ages. Similarly, a few individuals contract a disease (type II diabetes) at young ages, and increasingly more contract the disease as the population ages (until rate of incidence begins to decrease again, as discussed previously). Furthermore, a perhaps underappreciated fact is that senescence (in the United States, at least) is not usually accompanied by debilitating illness. For example, only 5.2% of the elderly is in nursing homes (a percentage that has been decreasing in recent years, despite the increase in the average age of the population over 65).⁴⁶⁻⁴⁹ Similarly, recent studies indicate that more than 70% of persons between ages 75 and 84 report no disability, again a number that has decreased in recent years.⁴⁶⁻⁴⁹

These and other studies indicate that despite the fact that the population is growing older, the amount of debilitating illness is actually decreasing. Until recently, it had been assumed that reducing illness would increase average life span but not maximum life span. Thus it was assumed that eliminating disease would in effect increase average life span but increase the rate at which individuals die once advanced old age was attained (the so-called rectilinearization of the survival curve). However, recent evidence suggests that, remarkably, even though individuals are staying healthier longer, the rate of death is not increasing.²⁹ As already discussed, this remarkable and surprising phenomenon may be a reflection of the fact that the Gompertz slope begins to flatten after age 85 or so. If this analysis continues to pertain (and there is evidence from studies in flies that this flattening of the Gompertz curve is a general aspect of senescence), the implication is that very likely the apparent maximum life span of humans will continue to increase (although slowly).

These observations lead to two questions. First, what determines if an individual will contract an age-related disease? Second, what is the basis of the unexpected phenomenon that the incidence of age-related diseases is decreasing while average age (and possibly average life span) is increasing? Better medical technology is probably an important factor in facilitating survival after diseases are contracted, and if the diseases are entirely cured, as occurs with infectious diseases and sometimes cancer, although rarely with chronic diseases such as dia-

betes and cardiovascular disease, there is a higher probability that the individual will live beyond the age of high incidence of diseases. Nevertheless, the more important determinant of longevity is whether the individual contracts a major disease to begin with. The most general determinants of disease risk are hereditary and environment. At least with regard to longevity and average functionality, recent evidence suggests that in humans there is relatively little heritability of longevity.⁵⁰ Therefore, at the moment, it appears that outcome during aging depends largely on what is generally referred to as lifestyle, such as decreased smoking, increased exercise, and better diet. In addition, the apparent increase in healthy (and perhaps maximum) life span is due to the logic of senescence versus pathology: once one has gotten past the age of maximum incidence of most diseases, one can live a relatively healthy life until true senescence becomes the limiting factor in the maintenance of function (which occurs in most humans only at very advanced age).

Aging: Usual Versus Successful

Consideration of individual differences in susceptibility to pathology and the trajectory of senescence has informed a very useful construct, developed by Rowe and Kahn,⁵¹ between “usual aging” and “successful aging” (in this accessible formulation, aging is used as a synonym for senescence). Usual aging refers to the common complex of diseases and impairments that characterizes some of the aging population. However, as just discussed, individuals vary greatly in their manifestation of the diseases and impairments of aging, and some individuals seem to escape these diseases altogether, eventually dying, as former medical practice described it, of “old age,” there not being any particularly more compelling pathology to which to ascribe the death. These individuals would certainly seem to exhibit the trajectory of senescence to which we would all aspire—an active healthy life until the very end. Indeed the very end of such individuals is usually rather late in life, because once one has aged past the time at which the incidence of most diseases is maximum, the probability of life-threatening disease, by definition, decreases.

The concept of successful aging has important implications for the practice of geriatrics. Thus, in the Neolithic period (and in some societies even now) near total tooth loss during aging was not only usual but almost universal; toothlessness was “usual,” but not “successful.” Nevertheless, it is now understood that toothlessness can be largely avoided, and clinicians encourage their patients to make the appropriate changes in personal habits to ensure successful (dental) aging. Although many, or perhaps most, aging individuals have in the past exhibited a range of debilitating diseases, a major and achievable

goal is to decrease the incidence (and prevalence) of these diseases and risk factors in the elderly, rather than simply chalking them up to “old age.” This approach implies that, from a clinical point of view, the temptation to “define deviancy down” during aging should be resisted, and the elderly should be held to the same criteria of health (glycemia, adiposity, etc.) as younger individuals are held. Such a position runs counter to the current practice of following age-adjusted charts for targeting physiologic parameters (such as blood pressure). Although maintaining a youthful profile (for example, with adiposity) becomes more difficult during aging, it is still an appropriate goal for physicians and their patients.

Molecular and Cellular Basis of Senescence

Limits to Cell Division: Role of Telomerase

The great diversity of age-related impairments, combined with the evolutionary arguments already described, have discouraged the idea that senescence could be an outcome of relatively simple and regulated molecular processes analogous with development. However, recent studies have suggested that reductionism is as powerful a strategy in gerontology as in other biologic disciplines.

One of the most important phenomena studied by gerontologists is the process by which cells lose their ability to divide over time unless the cells convert to an abnormal cancerous phenotype.^{52,53} This limit to cellular replicative capacity can even be demonstrated in cell culture after removing the cells from the body. For example, when fibroblasts are removed from the umbilical cord of newborn humans and cultured *in vitro*, they will divide until they are dense enough to contact each other, then stop dividing, due to a phenomenon called contact inhibition. However, if the cells are diluted, they will divide again until a maximum density again occurs. This process can be repeated for about 50 times; each repeated division is called a passage. However, after about 50 passages, the cells cease to divide, regardless of the density. This limit to cellular replicative capacity is called the Hayflick phenomenon or Hayflick limit, in honor of its discoverer Leonard Hayflick. The Hayflick limit demonstrated *in vitro* has been thought to reflect actual processes that occur *in vivo* because fibroblasts removed from older individuals tend to exhibit a decreased number of maximum passages. The loss of replicative capacity is dependent not on the total amount of time that the cells are cultured (chronological age) but rather on the number of divisions (biologic age).⁵⁴

For decades, the Hayflick phenomenon has been considered to be an excellent and experimentally accessible model of organismic senescence. When cells reach their

final stages of division, they do not immediately die, but enlarge and may exist for some time before gradually dying. Cells in these final stages exhibit many differences from either “younger” dividing cells at earlier passages of division or younger cells whose division has been arrested by experimental manipulation. Thus, these “senescent” cells are like senescent organisms by virtue of these numerous differences. Over the years, many mechanisms have been suggested to mediate the Hayflick phenomenon, including free radicals, accumulated mutations, and overexpression of “gerontogenes” secondary to random epigenetic changes in DNA, such as loss of cytosine methylation, or, most likely, a combination of many different processes.

Nevertheless, it has now become clear that replicative senescence may, in fact, be regulated by a relatively small number of genes.⁵⁵ Among these, the gene coding for the enzyme telomerase may be particularly important.⁵⁶ Telomeres are stretches of DNA at the end of chromosome that serve essentially as handles by which the chromosomes are moved during the telophase of meiosis. In transformed cells and during meiosis, the enzyme telomerase is present, which lengthens the telomere after telophase. However, in normal cells after cessation of development, this enzyme is expressed at very low levels, so after each cell division the telomere becomes shorter and shorter.⁵⁶ After about 50 divisions (for human fibroblasts, at least), the telomeres are lost and mitosis is no longer possible. Although this observation by itself does not prove that the loss of the telomeres is the proximal cause of the cessation of mitosis, restoration of telomerase activity by genetic engineering dramatically increases the number of cell divisions of otherwise normal cells well past the Hayflick limit.⁵⁷

This extension of *in vitro* life span by overexpression of telomerase, although dramatic, does not prove that telomerase shortening is the only mechanism by which cells senesce *in vitro*. For example, prior studies demonstrated that mRNA transferred from senescent cells into early passage cells would stop cell division in the young cells.⁵² The normal function of such “gerontogenes” may be similar to that of anti-oncogenes, such as p53.⁵⁸ Mutations in p53 lead to uncontrolled cell division, cancer, and often death of the organism. There appear to be at least two classes of these gerontogenes, both of which must be inactivated to produce cellular immortalization.⁵⁹ It has now been shown that mutations in these classes of gerontogenes extend the number of cells past which cells may divide.^{58,59}

Thus, as for many diseases, it may be said that *in vitro* senescence may be caused by a variety of factors, but on the other hand these factors are enumerable and specific. For example, diabetes may be caused by an autoimmune attack or a mutation in several different genes. However, the number of gene mutations that cause diabetes are

probably small, and the genes whose mutations do cause diabetes are probably involved in a small number of specific metabolic pathways. Similarly, the molecular causes of in vitro senescence, although not confined to a single gene, are probably simpler than was once thought to be plausible.

Senescence in *Caenorhabditis elegans*: Role of Genes in an Insulin-Like Signaling Pathway Acting on Neurons

The relevance of the Hayflick phenomenon to senescence in the whole organism is not entirely clear. Certainly there are some cells that divide more or less continuously throughout life (intestinal epithelia, skin fibroblast), but it is unlikely that such cells approach the limit of 50 cell divisions. Even if they did, most gerontologists agree that the cells most likely to cause functional failure during senescence are cells that either divide very little (immune and endocrine cells) or not at all (neurons and muscle cells). Furthermore, many metazoans are composed entirely of postmitotic cells, yet exhibit senescence that is just as predictable and robust as the senescence of animals which contain mitotic cells.

The nematode *Caenorhabditis elegans* is precisely such an animal, consisting entirely of postmitotic cells that exhibit a reliable trajectory of senescence, including adherence to the Gompertz equation. *C. elegans* has become a useful model for genetic analysis because, owing to its optional hermaphroditic reproductive mode, genetic manipulation is relatively simple. In addition, all its postmitotic cells have been mapped. These properties have made *C. elegans* a dominant model in developmental biology and, beginning about 20 years ago,⁶⁰ *C. elegans* began to be studied as a potential model for aging research as well. One of the early dividends of this work was the establishment of a group of genetic mutations that lead to an extension of maximum life span, for example, genes that when active decrease maximum life span.^{61–63} Particularly striking was the discovery that mutation in a single gene, termed *age-1*, reduces the Gompertz rate of mortality in *C. elegans*.⁶² The existence of such a gene was largely unexpected, given evolutionary arguments implying that senescence is unlikely to be controlled by even a small number of genes.¹ When this gene was cloned, it was discovered to code for a homologue of mammalian phosphatidylinositol-3-OH kinase.⁶⁴ Although this clearly suggested a neuroendocrine mechanism, the ligand pathway mediated by this kinase was initially unclear. Subsequent to the discovery of *age-1*, however, other single genes were discovered that also extended life span in *C. elegans*; among these genes, DAF-2 was subsequently cloned and discovered to code for a homologue of the mammalian insulin receptor.⁶⁵

Further genetic analysis has now conclusively demonstrated that single gene defects extending life span act through an insulin signaling pathway remarkably similar to the mammalian insulin signaling pathway.⁶⁶

In essence, therefore, these studies indicate that senescence (or at least a major component of senescence, as defects in this pathway reduce the Gompertz slope) arises from the activity of an insulin-like pathway. As described below, considerable evidence has suggested that senescence may arise from metabolic activity. Therefore, a logical hypothesis is that an insulin-like pathway drives senescence in *C. elegans* by enhancing metabolic activity. On the other hand, transgenic manipulation has now demonstrated that it is activity of the insulin-like pathway specifically in neurons, not muscle or other highly metabolically active tissue, that regulates life span in *C. elegans*.⁶⁷ Furthermore, the life-extending effects of the insulin-like pathway appear to require activity of an unusual cytoplasmic catalase.⁶⁸ Taken together, these data suggest that reduction of senescence by attenuating the insulin-like pathway entails protection of neurons from free radical damage and that, conversely, integrity of neurons sensitive to this insulin-like pathway constitutes a limiting factor in the life span of *C. elegans*.⁶⁷ The specific nature of these neurons remains to be established, but in mammals the neurons most sensitive to insulin are probably the hypothalamic neurons that regulate metabolism and body weight, destruction of which leads to profound metabolic impairments.⁶⁹ Whether destruction of these neurons by free radical damage is a limiting factor in life span remains to be determined.

Other Single Genes Regulating Maximum Life Span

Single gene defects have now also been shown to increase maximum life span in fruit flies,^{70,71} yeast,^{72,73} and mice.^{74–76} The function of all these “gerontogenes” is not yet completely determined, but it is plausible that, as in *C. elegans*, they all act through pathways that either mediate or are regulated by insulin-like signals. The clearest example would be in mice, in which genetic ablation of growth hormone or the growth hormone receptor extends maximum life span.^{74,75} It is thought that most if not all major effects of growth hormone are mediated through the insulin-like growth factor pathway, whose molecular mechanisms are highly homologous to pathways mediating insulin signaling.⁷⁷ Ablation of p66Shc, which appears to mediate some effects of growth factors including insulin⁷⁸ and may also enhance oxidative damage,⁷⁶ also extends maximum life span in mice.⁷⁶ This latter observation was particularly striking because, unlike the gerontogenes studied in *C. elegans* or mutations in the growth hormone pathway in mice, ablation of

p66Shc had no apparent effect on fertility or other functions,⁷⁶ suggesting that increased life span need not entail reduced functionality in adulthood. Thus, as in *C. elegans*, it appears that in mammals as well activity of an insulin-like pathway (possibly by enhancing oxidative damage) limits life span, and ablation of single genes that mediate this pathway extends life span. In *Drosophila*, ablation of two genes is also known to enhance life span. The first, termed *methuselah*, appears to code for a G-coupled protein receptor,⁷⁰ implying that this gene mediates an endocrine pathway, but the ligand for this receptor has not yet been identified. The second, termed *indy*, appears to code for a dicarboxylate cotransporter.⁷¹ Thus, whereas interference with insulin-like pathways may extend life span by indirectly reducing metabolic function, a similar increase in life span may be obtained with direct interference with metabolism. As with ablation of p66Shc, partial ablation of *indy* increased life span in flies without producing any apparent deficit in fertility or other functions,⁷¹ again indicating that increased life span need not entail impairments in functionality.

Possibly analogous with the effects of *indy*, a single gene, *SIR-2*, has been shown to regulate life span in yeast.^{72,73} In this case, however, enhanced expression of *SIR-2* leads to increased life span, at least as measured in yeast.^{72,73} *SIR-2* has been shown to regulate chromatin state through a histone acetylase activity, leading to a reduction in chromatin fragmentation that constitutes a concomitant of yeast senescence.^{72,73} Although it is questionable if this property of *SIR-2* is relevant to aging in metazoans, a perhaps more pertinent property of *SIR-2* is that its activity is enhanced by the allosteric binding of NAD⁺.⁷² Thus, as glucose is metabolized to produce NADH from NAD⁺, *SIR-2* would become less active, leading to a state more likely to senesce. Indeed, the investigators went on to demonstrate that, by analogy with dietary restriction, reduction in glucose concentration extends life span in yeast, and this effect requires the presence of *SIR-2* and also requires the synthesis of NAD⁺.⁷³ These data suggest, consistent with results from other organisms, that metabolic activity does indeed drive the process of senescence. However, at least in yeast, it is not entropic effects of free radical damage, but the regulation of cellular processes by glucose metabolites (in particular AND⁺), that drives the process of senescence.

Conclusion

Although senescence is undoubtedly a complex phenomenon, and there are sound reasons grounded in evolutionary theory to believe that the process cannot be simply explained in terms of a small number of genes, nevertheless much progress has been made using the same reductionist approach that has been successful in

studying other aspects of biology. The specific examples presented in this brief review are by no means exhaustive. For example, a gene for Werner's syndrome, a progeroid syndrome in humans, has recently been cloned, and has proved to be a gene involved in DNA replication.⁷⁹ Thus, although the complexities of senescence continue to command considerable respect, there is also reason to be optimistic that more powerful simple mechanisms may be elucidated in the near future.

Physiology of Aging

George E. Taffett

Aging, from maturity to senescence, results in an apparent depletion of physiologic reserves that has been termed homeostenosis. This term suggests a narrowing of homeostatic reserve mechanisms. Homeostenosis leads to the increased vulnerability to disease that occurs with aging. Primary aging changes, upon which we focus here, are those that occur as a result of the passage of time and are independent of disease state, although there may be overlap between disease and these changes. The age changes may be accelerated or slowed by lifestyle but are usually evident by the fourth or fifth decade and are gradual and inexorable. Overall, primary aging changes result in little change in function when the older individual (or animal) is assessed in the unstressed state, but these age changes become readily evident when the older individual is stressed or moved away from homeostasis. Because disease produces such stresses, the impact, presentation, and natural history of diseases are modified with age because the substrate, perhaps more than the disease pathophysiology, has been modified.

The concept of homeostenosis—the characteristic, progressive constriction of homeostatic reserves that occurs with aging in every organ system—was recognized by the famous physiologist Walter Cannon in the 1940s.¹ Figure 3.1 graphically displays the traditional thinking about homeostenosis. With aging, the capacity of older persons to bring themselves back to homeostasis after a challenge becomes smaller. All challenges to homeostasis are movements off the baseline, and larger challenges require greater physiologic reserves to return to homeostasis. Aging itself brings the individual closer to the precipice or threshold by the loss of physiologic reserves. The “precipice” may be defined, for example, as death or ill enough to have a cardiac arrest or for hospital admission. The precipice may also be the appearance of common and protean symptoms, such as confusion, weight loss, sleep disorder, or weakness.

Although empirically this paradigm is true, direct evidence for this model may be derived from studying the

physiologic deviation from normal using the APACHE severity of illness scales.² Acute physiologic assessment points are generated by increased deviation from homeostatic values for 12 variables, including vital signs, oxygenation, pH, electrolytes, hematocrit, white count, and creatinine. A normal person at homeostasis will have a zero score. A greater departure from homeostasis is measured by a greater point total.

Figure 3.2 shows young and old patients who experienced a cardiac arrest. The younger group (mean age, 59 years) had significantly higher (by 20%) acute physiologic assessment scores than the older group (mean age, 75).³ The data represent the worst values available in the 24 h prearrest. These data support the concept that the threshold, in this case being “sick” enough to have a cardiac arrest, is closer to homeostasis for the older than for the younger group. In practice, the creators of the APACHE II or III scales recognized that advanced age adds to risk of physiologic impairment with intercurrent illness. Another way to say this is that age reduces reserve capacity and makes us less resilient. APACHE scales give “bonus points” for age so that the total scores are not different between the younger and older groups.³

Despite the summative evidence, there is high variability in these processes. Variation in the age effects on any parameter is large, and the variability appears to increase with age. These variations are present from individual to individual at the same age, within a given individual from organ system to system, and even from cell to cell isolated from the same person. For example, investigators of the Baltimore Longitudinal Study of Aging performed serial measurements of glomerular filtration rate (GFR) measured as creatinine clearance in healthy people. Overall, the mean GFR decreased 1 ml/year; however, almost 30% of patients showed no decrement in function in repeated studies over as long as 30 years. Others showed decreases in GFR of 2 ml/year or more.⁴ Similarly, when lymphocytes are isolated from an older person and then studied *in vitro*, some of the cells func-

FIGURE 3.1. Standard schematic of homeostenosis. As the individual ages, there is no change in homeostasis, but the amount of physiologic reserves available to counter any challenge to homeostasis decreases with aging. Challenges to homeostasis are depicted as *arrows* moving away from the baseline. The “precipice” may be any clinically evident marker such as death, confusion, or cardiac arrest.

tion as well as those from a younger person⁵; of course, others function poorly, and it is the relative ratio of the two groups that impacts overall function. Therefore, as opposed to the pediatrician who can within a few weeks anticipate when a baby will start to walk, the geriatrician has a much harder time predicting when senescent changes will become clinically evident.

Another reason for the variability in the physiologic changes associated with aging is the contribution of behavioral factors such as exercise and diet, both of which are strong influences on healthy aging. Epidemiologists describe the growing rate of obesity, especially among older men, as an increasingly sedentary existence of most people beyond 30 years of age. For many of the variables listed in Table 3.1, exercise or other choices are known to attenuate but not totally abrogate aging effects. Some, such as the decrease in maximum heart rate attained with exercise, appear to be more predictable.

Table 3.1 summarizes many of the major changes in systems receiving further elucidation in respective sections of this volume. Data from the cardiovascular system are expanded here because the data in this area provide ample rationale to justify the necessity to reinterpret the traditional approach to homeostenosis. This reinterpretation helps one understand the phenomenon of frailty, a central concern of geriatrics. Frailty is the state when physiologic reserves are reduced to the point at which susceptibility to disability is increased. Frailty is, therefore, the clinical manifestation of the later stages of homeostenosis, an intolerance of homeostatic challenges. Additionally, the reinterpretation of homeostenosis makes those caring for the elderly appreciate and understand the complexities they face.

In the elderly, as in youth, maintaining homeostasis is a dynamic, active process. The reinterpretation of Figure 3.1 shown in Figure 3.3 is based on the concept that older persons are actively employing some of their physiologic reserves just to maintain homeostasis. Their available reserves appear depleted because they in are already in use by the old heart (or other organ or system) to compensate for primary age-related or other changes. The

physiologic reserves have not “disappeared,” as suggested in Figure 3.1, but they remain unavailable to counter additional challenges. I focus on examples from the cardiovascular system, such as heart rate, cardiac hypertrophy, and diastolic function, because the data in this area provide an ample molecular, biochemical, and physiologic foundation to reinterpret the traditional approach to homeostenosis.

Although resting heart rate is unchanged with age, maximum heart rate attained with exercise or pharmacologic manipulation decreases with age. Baltimore Longitudinal Study data, obtained from healthy, highly screened individuals, give a regression equation of

FIGURE 3.2. Age decreases the level of physiologic derangement associated with cardiac arrest. Acute physiologic assessment (APA) scores (from the APACHE II severity of illness scale) are shown from patients who subsequently experienced cardiac arrest and a resuscitation attempt. The data show the APA scores were significantly higher in the younger patients who arrested than the older ones ($p < 0.05$; Beer et al. 1994³).

TABLE 3.1. Major changes in system.

Endocrine system

Impaired glucose tolerance (fasting glucose increased 1 mg/dl/decade; postprandial increased 10 mg/dl/decade)
 Increased serum insulin and increased HgbA1C nocturnal growth hormone peaks lost, decreased 1GF-1
 Marked decrease in dehydroepiandrosterone (DHEA)
 Decreased free and bioavailable testosterone
 Decreased T3
 Increased parathyroid hormone (PTH)
 Decreased production of vitamin D by skin
 Ovarian failure, decreased ovarian hormones
 Increased serum homocysteine levels

Cardiovascular

Unchanged resting heart rate (HR), decreased maximum HR
 Impaired left ventricular filling
 Marked dropout of pacemaker cells in SA node
 Increased contribution of atrial systole to ventricular filling
 Left atrial hypertrophy
 Prolonged contraction and relaxation of left ventricle
 Decreased inotropic, chronotropic, lusitropic response to beta-adrenergic stimulation
 Decreased maximum cardiac output
 Decreased hypertrophy in response to volume or pressure overload
 Increased serum atrial natriuretic peptide (ANP)
 Large arteries increase in wall thickness, lumen, and length, become less distensible, and compliance decreases
 Subendothelial layer thickened with connective tissue
 Irregularities in size and shape of endothelial cells
 Fragmentation of elastin in media of arterial wall
 Peripheral vascular resistance increases

Blood pressure

Increased systolic blood pressure (BP), unchanged diastolic BP
 Beta-adrenergic-mediated vasodilatation decreased
 Alpha-adrenergic-mediated vasoconstriction unchanged
 Brain autoregulation of perfusion impaired

Pulmonary

Decreased FEV₁ and FVC
 Increased residual volume
 Cough less effective
 Ciliary action less effective
 Ventilation-perfusion mismatching causes PaO₂ to decrease with age: $100 - (0.32 * \text{age})$
 Trachea and central airways increase in diameter
 Enlarged alveolar ducts due to lost elastic lung parenchyma structural support result in decreased surface area
 Decreased lung mass
 Expansion of thorax
 Maximum inspiratory and expiratory pressures decrease
 Decreased respiratory muscle strength
 Chest wall stiffens
 Diffusion of CO decreased
 Decreased ventilatory response to hypercapnia

Hematologic

Bone marrow reserves decreased in response to high demand
 Attenuated reticulocytosis to erythropoietin administration

Renal

Decreased creatinine clearance and GFR 10 ml/decade
 Decrease of 25% in renal mass, mostly from cortex with a relative increased perfusion of juxtamedullary nephrons
 Decreased sodium excretion and conservation
 Decreased potassium excretion and conservation
 Decreased concentrating and diluting capacity
 Impaired secretion of acid load
 Decreased serum renin and aldosterone
 Accentuated ADH release in response to dehydration
 Decreased nitric oxide production
 Increased dependence of renal prostaglandins to maintain perfusion
 Decreased vitamin D activation

(Continued)

TABLE 3.1. *Continued*

Genitourinary (GU)

- Prolonged refractory period for erections for men
- Reduced intensity of orgasm for men and women
- Incomplete bladder emptying and increased postvoid residuals
- Decreased prostatic secretions in urine
- Decreased concentrations of antiadherence factor Tamm–Horsfall protein

Temperature

- Impaired shivering

Regulation

- Decreased cutaneous vasoconstriction and vasodilation
- Decreased sweat production
- Increased core temperature to start sweating

Muscle

- Marked decrease in muscle mass (sarcopenia) due to loss of muscle fibers
- Aging effects smallest in diaphragm (role of activity), more in legs than arms
- Decreased myosin heavy chain synthesis
- Small if any decrease in specific force
- Decreased innervation, increased number of myofibrils per motor unit
- Infiltration of fat into muscle bundles
- Increased fatigability
- Decrease in basal metabolic rate (decrease 4%/decade after age 50) parallels loss of muscle

Bone

- Slower healing of fractures
- Decreasing bone mass in men and women, both trabecular and cortical bone
- Decreased osteoclast bone formation

Joints

- Disordered cartilage matrix
- Modified proteoglycans and glycosaminoglycans

Peripheral nervous system

- Loss of spinal motor neurons
- Decreased vibratory sensation, especially in feet
- Decreased thermal sensitivity (warm–cool)
- Decreased sensory nerve action potential amplitude
- Decreased size of large myelinated fibers
- Increased heterogeneity of axon myelin sheaths

Central nervous system

- Small decrease in brain mass
- Decreased brain blood flow and impaired autoregulation of perfusion
- Nonrandom loss of neurons to modest extents
- Proliferation of astrocytes
- Decreased density of dendritic connections
- Increased numbers of scattered neurofibrillary tangles
- Increased numbers of scattered senile plaques
- Decreased myelin and total brain lipid
- Altered neurotransmitters, including dopamine and serotonin
- Increased monoamine oxidase activity
- Decrease in hippocampal glucocorticoid receptors
- Decline in fluid intelligence
- Slowed central processing and reaction time

Gastrointestinal (GI)

- Decreased liver size and blood flow
- Impaired clearance by liver of drugs that require extensive phase I metabolism
- Reduced inducibility of liver mixed-function oxidase enzymes Mild decrease in bilirubin
- Hepatocytes accumulate secondary lysosomes, residual bodies, and lipofuscin
- Mild decrease in stomach acid production, probably due to nonautoimmune loss of parietal cells
- Impaired response to gastric mucosal injury
- Decreased pancreatic mass and enzymatic reserves
- Decrease in effective colonic contractions
- Decreased calcium absorption
- Decrease in gut-associated lymphoid tissue

TABLE 3.1. *Continued*

Vision

- Impaired dark adaptation
- Yellowing of lens
- Inability to focus on near items (presbyopia)
- Minimal decrease in static acuity, profound decrease in dynamic acuity (moving target)
- Decreased contrast sensitivity
- Decreased lacrimation

Smell

- Detection decreased by 50%

Thirst

- Decreased thirst drive
- Impaired control of thirst by endorphins

Balance

- Increased threshold vestibular responses
- Reduced number of organ of Corti hair cells

Audition

- Bilateral loss of high-frequency tones
- Central processing deficit
- Difficulty discriminating source of sound
- Impaired discrimination of target from noise

Adipose

- Increased aromatase activity
- Increased tendency to lipolysis

Immune system

- Decreased cell-mediated immunity
- Lower affinity antibody production
- Increased autoantibodies
- Facilitated production of anti-idiotypic antibodies
- Increased occurrence of MGUS (monoclonal gammopathy of unknown significance)
- More nonresponders to vaccines
- Decreased delayed-type hypersensitivity
- Impaired macrophage function (Interferon-gamma, TGF-beta, TNF, IL-6, IL-1 release increased with age)
- Decreased cell proliferative response to mitogens
- Atrophy of thymus and loss of thymic hormones
- Accumulation of memory T cells (CD-45+)
- Increased circulating IL-6
- Decreased IL-2 release and IL-2 responsiveness
- Decreased production of B cells by bone marrow

208 - (0.95 × age) for maximum heart rate attained with exercise. It is likely that women have lower maximum heart rates at age 30 and a more gentle fall with aging than this equation predicts. This decrease in maximum heart rate responsiveness results from a combination of factors. First, primary aging decreases the intrinsic heart

rate (the heart rate in the absence of sympathetic and parasympathetic stimulation), as well as invokes reserves just to maintain resting heart rate. Data from Jose,⁶ although regrettably including only a modest number of elders, show a decrease in intrinsic heart rate from 120–130/min to less than 80. There is no difference

FIGURE 3.3. Revised schematic of homeostenosis. In comparison to Figure 3.1, this diagram shows that maintaining homeostasis is a dynamic process. The older person employs or consumes physiologic reserves just to maintain homeostasis, and therefore there are fewer reserves available for meeting new challenges.

in resting heart rate with age, so the extent of parasympathetic tone, slowing heart rate at rest, is decreased. Removal of parasympathetic tone, the first mechanism invoked to increase heart rate with exercise, is then less effective for the elderly because vagal tone is already diminished at rest; this is consistent with the attenuated heart rate response of healthy elders to administration of atropine. The decreased yield from lysis of parasympathetic tone is added to decreased beta-adrenergic chronotropic responsiveness to contribute to the overall decreased maximal heart rate in response to exercise (Fig. 3.4).

Importantly, the same limitation in maximum heart rate with exercise applies to that in response to other stimuli, such as infection or anemia. Therefore, an 80-year-old man with a sinus tachycardia of 120, mounting close to a maximum heart rate response, could be considered as a young man who had a heart rate of 170. In the setting of an infection, although a 120 heart rate would hardly raise eyebrows, a 170 would surely provoke serious concern. For their respective age groups, both values roughly represent an equivalent of 75% of maximum response.

A similar set of observations, that reserves are invoked to maintain homeostasis in the old, are seen following the response to another challenge, pressure overload induced by banding the aorta (Fig. 3.5).⁷ In older male rats (18 months of age), there is only trivial increase in left ventricular mass in response to pressure overload. This same manipulation results in a 40% hypertrophy of the left ventricle in adult (9-month) animals. The molecular response to the pressure overload was markedly attenu-

FIGURE 3.4. Resting and exercise heart rates. There are no differences in resting heart rate between the older and young person, but the extent of the resting vagal tone, slowing heart rate (*dark gray bar*), is decreased in the older person. With exertion, the removal of the vagal tone results in smaller increment in heart rate and the beta-adrenergic chronotropic responsiveness is also decreased (*light gray bar*), all contributing to the decreased maximum heart rate in the old. The straight line represents the intrinsic heart rate (absence of any sympathetic or vagal tone).

ated in the old heart, with little induction of the immediate early response genes *c-jun* and *c-fos*. Skeletal actin, which precedes cardiac actin when new contractile elements are laid down in the heart, was not increased in the older, banded heart. All these molecular markers confirmed the absence of hypertrophic response to banding in the old heart.

FIGURE 3.5. Decreased response to pressure stimulus in the old heart. After aortic banding in the young and old rat, there is a decreased elaboration of RNA for “early immediate response genes” (*fos* and *jun*) in the old heart, followed by decreased contractile protein response (skeletal actin). Ventricular atrial

natriuretic peptide (ANP), a marker for myocyte hypertrophy, is increased in the control and old hearts, suggesting prior invocation of the hypertrophic response (Takahashi et al. 1992⁷ with permission.)

In contrast, atrial natriuretic peptide (ANP), a marker for myocyte hypertrophy when it is expressed by the ventricular myocyte, is increased significantly after banding in the young heart. The ventricular ANP is not detectable in the control young heart. ANP is significantly elevated in the ventricle from both the banded and control older hearts, providing evidence that the old heart has already invoked the hypertrophic response even before the banding is applied.

Morphologic evidence of myocyte hypertrophy in aging is provided by examining myocyte size. Myocytes from the ventricles of older persons and animals are larger than those from young adults, consistent with ongoing myocyte hypertrophy in response to uncertain stresses. Various investigators report 25% increase in myocyte length and 50% or more increases in myocyte width.⁸ There is likely a maximum size for the myocyte; therefore, myocytes in the old heart may be unable to hypertrophy further because they have already responded to prior or ongoing challenges.

With aging in animals and man, there are impairments in early cardiac relaxation, largely caused by alterations in cellular calcium flux. The increased dependence on transsarcolemmal calcium flux (in and out of the cell) seen in the old rat heart maintains adequate calcium availability for contraction. This adaptation appears to be a compensation for decreased transsarcolemmal calcium flux. Therefore, the compensation comes at a cost, the lengthening of contraction by both slowing the development of force and slowing cardiac relaxation. Using gene therapy, a key sarcoplasmic reticulum calcium pump can be restored in old rats to levels found in the young heart, and cardiac relaxation improves significantly.⁹ One manifestation of the impaired relaxation is the decreased effectiveness of early diastolic filling of the left ventricle. As a compensation to maintain ventricular filling, contribution of atrial systole to diastolic filling increases from 10% to 15% at age 20 to almost 50% at age 80.¹⁰ In addition to explaining why atrial fibrillation (and the loss of atrial systole) becomes so devastating in the elderly, the ability to augment the atrial contribution to further increase cardiac output is limited. Therefore, the Frank–Starling mechanism is invoked; filling pressures increase to augment cardiac output.

There are numerous other changes in the cardiovascular system (CVS) that follow the paradigm just described, and the pattern is not at all limited to the CVS, such as the limited heat shock protein elaboration in response to certain stimuli. These changes support rethinking the concept of frailty. Frailty is not a static state of increased vulnerability to stressors; rather, it is a dynamic state in which the older person tolerates additional challenges poorly because reserves are already engaged in battles, seen or unseen. From a therapeutic standpoint, this suggests that efforts to disengage reserves may result

in decreasing vulnerability. To date, evidence for this opportunity to increase reserves remains unproven. Older persons are frailer, more likely to cross a given “precipice” after a stress, not only because they have lost some reserves because of aging, but because they are already utilizing other reserves to compensate for those lost just to maintain homeostasis. Older people are more likely to drown when thrown a brick, not because they cannot swim but because they are already treading water.

It is well known that the mortality associated with myocardial infarction (MI) increases dramatically with age. Although absolute death rates have improved with treatment for all ages, the 10-fold increase in mortality after MI from ages 40 to 80 has not been modified. This age-related increase in mortality has been variously attributed to increased infarct size in the old, comorbid conditions, less aggressive therapy for the old, noncompliance with medical regimens, or increased existence of multivessel coronary artery disease. Some of the points may be true, but in studies where all these factors are controlled, the mortality is still much higher in the older groups. Age is the key component, and I hypothesize that it is the age-related inability to respond to challenge, homeostenosis in the cardiovascular system, that results in the increased mortality.

A similar set of implications can be made relevant to the increased frequency of falls in response to challenge in the elderly. Decreases in baroreceptor sensitivity, arterial compliance, cardiac compliance (and greater dependence on cardiac filling to maintain cardiac output), renal sodium conservation, plasma volume, vasopressin response to standing, and renin, angiotensin, and aldosterone levels all contribute to the propensity to fall with postural change. Many of the problems with medications in the elderly, once attributed to altered pharmacodynamics, may be explained by this apparent depletion of physiologic reserves.

Data from the MacArthur Study of Aging support the concept that healthy elders are actively compensating just to maintain homeostasis and that the presence of invoked compensation is associated with poor outcomes.¹¹ Only 7% of those aged 70 to 79 had no evidence of such compensation, and the lack of compensation was associated with highest level of function. Seeman refers to this activation as “allostatic load,” and while some of the markers, such as elevated cholesterol and systolic blood pressure, are known risk factors for CV events and death, others reflect the activity of sympathetic nervous system or the hypothalamic–pituitary–adrenal axis. Those patients with high allostatic load had decreased physical and cognitive function at 2-year follow-up.

There is some evidence that the inverse may also be true. Masoro believes that one mechanism by which the beneficial, life-prolonging effects of caloric restriction occur is precisely that the decreased availability of calo-

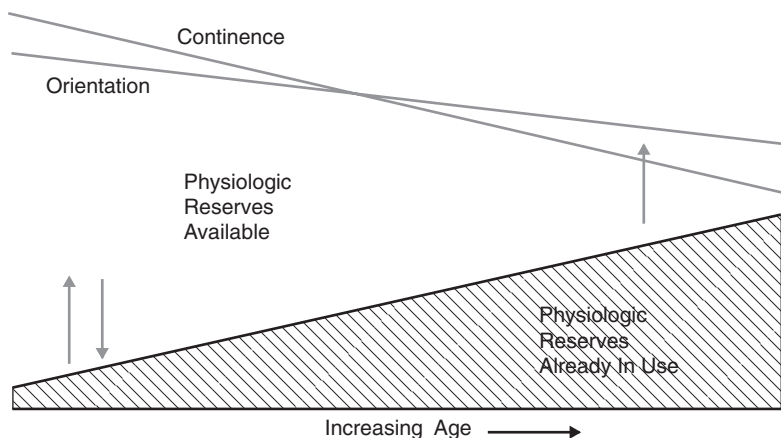

FIGURE 3.6. Altered presentation of illness may be another manifestation of homeostenosis. With age, the precipices may approach homeostasis at differing rates so that modest challenges produce clinically evident events, in this case, new onset of incontinence, and in others, disorientation or confusion.

ries is a low-intensity stress.¹² The beneficial effects of low-dose radiation may also be via this mechanism. Persistent, harmless stresses, such as caloric restriction or radiation, may be good for us; larger stresses may be harmful.

Invoking compensatory mechanisms has the additional effect of constraining the complexity of many variables. Heart rate variability decreases with aging, and this constriction of heart rate may be due to decreased parasympathetic tone and possible activation of the sympathetic nervous system while at rest.¹³ A similar constriction is seen in blood pressure variability. The decrease in variability may correspond with the ongoing activation of compensatory reserves.

The concept of threshold is also useful in understanding the altered presentations of disease in the elderly. The extent that any threshold from Figure 3.1 or Figure 3.3 approaches homeostasis may determine whether that threshold is crossed by a given challenge. For example, delirium is a very common atypical presentation of a wide variety of illness in the elderly, a marker of the uneasy truce that the old brain maintains with its environment. The precarious balance is clearly evident but is not limited to the cholinergic pathways. While it seems strange that a given older person may have the same presentation (confusion) for a urinary tract infection, gastrointestinal bleeding, and a myocardial infarction, this phenomena may be relatively common because the systemic responses to these differing illnesses may be similar, involving cytokines, catecholamines, etc. In these patients, at homeostasis their “anticonfusion reserves” may be exhausted so the distance from homeostasis to the “precipice” becomes minimal and is easily crossed (Fig. 3.6).

Finally, the lines on these schematics (Figs. 3.1, 3.3, 3.6) are straight for convenience’s sake, not because any of the processes described in Table 3.1 are necessarily linear. For example, the loss in muscle mass approaches 40% as one ages from 30 to 80, yet most of that loss happens after

age 60, indicating the rate of loss increases with increasing age. Strength follows mass in this pattern. It is likely that most age-related physiologic changes are not linear functions of age.

In summary, there is an apparent loss of physiologic reserves that leads to an intolerance of challenges to the homeostasis of older persons. One should appreciate that this frailty is, in part, present because the older person is continually expending reserves to compensate for primary age changes and other unseen processes absent or trivial in the younger individual.

The Demography of Aging

S. Jay Olshansky

The demography of aging involves the investigation of trends in, and characteristics of, fertility, mortality, and migration and how these components of population change influence, and are influenced by, the physical and social environments in which people live. It is a relatively new area of scientific inquiry, principally because aging is a demographic phenomenon experienced within the past 200 years for the first time on a population scale by humans and only a few other species. Research on the demography of aging is conducted not only by demographers and actuaries but also by scientists representing a range of disciplines spanning the social and biological sciences from social psychology to evolutionary biology. It is an area of scientific inquiry that has important implications for public policy.

A central distinction exists between *population aging* and *individual aging*. *Population aging* refers to changes in the age structure of a population or, more specifically, an increase in the relative proportion of older persons to the total population alive at a single moment in time. Several measures are used to measure population aging, detect changes across time, and make comparisons between population subgroups. The most common measures include the median age, aged dependency ratio (ratio of the population aged 65+ to those aged 0–64), and the percentage of the total population aged 65 and older.

Individual aging refers to the length of life for individuals or an average length of life for population subgroups or species. Individual aging is measured in chronological time such as days, months, or years. A summary measure of individual aging for a population is most often represented by its expectation of life or life expectancy. Life expectancy is calculated from death probabilities observed throughout the age range over a selected time period, usually one calendar year, and may be estimated for a given birth cohort or for a population reaching any age or age range. The study of secular trends in life expectancy and changes in the underlying causes of death that comprise total death rates is one of many basic areas

of scientific inquiry in the demographic and actuarial sciences. Of particular interest at this time is how high life expectancy at birth and at older ages can increase, and how changes in individual aging influence, and are influenced by, the distribution of diseases and the health status of the population.

It is also important to distinguish between the terms *life expectancy*, *life span*, *average life span*, and *maximum life span potential* because they are often used interchangeably. As previously noted, life expectancy is a summary measure of the expected duration of life calculated from observed death rates for a population. Life span may be defined as the observed length of life for an individual. Average life span may be defined as the average of individual life spans in a population. Maximum life span potential (MLSP) has been used in the biologic literature to define the age of the longest-lived member of a species. The underlying premise behind the concept of average life span is the presumption that there are biologically based limits on the duration of life for individuals, and as the age-specific risk of death declines, the observed life expectancy approaches the average life span. However, because it is not possible to know the maximum duration of life for any individual, by extension it is not possible to know with certainty the maximum average life span for a population.

As individuals in a cohort pass through life from childhood to older ages, the observed probabilities of death take on a characteristic “bathtub” shape (Fig. 4.1). There is high mortality at birth, a rapid decline in the risk of death to its lowest point at sexual maturity, and an exponential rise in the death rate until very old ages (85+), after which the rate of increase in the death rate decelerates. This mortality curve has also been observed for other sexually reproducing species.^{1–3} Although recent studies have documented decelerating increases in death rates at extreme old ages,⁴ this phenomenon has been observed for humans and other species for more than 175 years.⁵ Changes in individuals at the molecular and

FIGURE 4.1. Characteristic “bathtub” shape of mortality.

cellular level that are observed across time and which are believed to bring forth these characteristic mortality patterns among populations are referred to collectively as *senescence*. Senescence may be thought of most appropriately as the passage of biologic time whereas *aging* is colloquially defined as the passage of chronologic time.⁶ Thus, although individuals in a cohort age at exactly the same rate, the random or stochastic nature of damage that accumulates in the DNA, cells, and tissues of living organisms, when combined with genetic variability in inherited mortality risk, leads to different rates of senescence and thus varying mortality risks among individuals in a population across time.

Causes and Consequences of Population Aging

For most of recorded history, and probably dating back to the origin of anatomically modern humans approximately 100,000 years ago, there has been a consistent (stable) pattern of birth rates and death rates (Fig. 4.2, phase 1). Under these “usual” demographic conditions, death rates fluctuated between peaks and troughs largely in response to the episodic influence of infectious and parasitic diseases. Birth rates remained extremely high during most of human history, barely exceeding death rates over the long term, but enough so to produce slow population growth. Death rates at middle and younger ages were so high that survival into what was then thought of as old age (65 years) was a rare event by comparison to today. Survival into extreme old age (85 years and older) was an even less frequent occurrence.

The age distribution of the population during most of human history (i.e., under phase I demographic conditions) resembles the shape of a pyramid (Fig. 4.3). The age pyramid of a population is a snapshot picture of the

number of people alive at all ages during a single moment in time, usually the middle of a calendar year (July 1). In a closed population with no migration, the horizontal bars reflect the number of people surviving to each age range from an original birth cohort based on prevailing death rates. However, with the more conventional interpretation of an open population with internal and external migration and changing vital rates, the age pyramid is a reflection of historical patterns of fertility, mortality, and migration.

During the nineteenth century, a combination of events led to dramatic changes in the stable patterns of birth rates and death rates that had existed for thousands of years. The development of consistent and clean sources of fresh water and refrigeration, the disposal of sewage, temperature-controlled indoor living and working environments, and developments in public health and medicine all contributed significantly to reductions in the transmission of air- and water-borne infectious and parasitic diseases.^{7,8} The pervasive environmental conditions that permitted the easy transmission of infectious diseases which killed early in life had been profoundly altered within an extremely short time period. From a biologic perspective, modifications of this magnitude and importance lead to fundamental changes in the forces of natural selection operating on the human species.⁹

As a result of these advances in public health and medicine, the risk of death at younger ages, particularly among infants, children, and women of childbearing ages, declined rapidly; this eventually led to declines in total fertility rates as the need to replace children lost to early mortality waned. However, the decline in birth rates lagged behind the decline in death rates (Fig. 4.2, phase 2). The result was extremely high rates of population growth, with growth rates reaching as high as 3% to 4% among some population subgroups. A growth rate of 1% leads to the doubling of a population in about 70 years. Every time the growth rate doubles, the time it takes for a population to double in size is reduced by half. Thus, a growth rate of 4% leads to a population doubling time of about 18 years. The transformation of birth rates and death rates to a lower level of equilibrium at approxi-

FIGURE 4.2. Demographic transition.

FIGURE 4.3. Age pyramid for humans before 1900.

mately 10 per 1000 in most of today's developed nations (Fig. 4.2, phase 3) is what set the stage for population aging.

As the human population experienced declines in death rates at younger ages during the past 200 years, the base of the age pyramid expanded and its apex became smaller by comparison to the rest of the population. When the apex of an age pyramid decreases relative to its base, it may be said that a population is becoming younger. Thus, the first demographic consequence of declining early age mortality, at least with regard to a changing age composition, was a younger population.

Within one average human life span (about 85 years), those saved from dying at younger ages reach middle and older ages, thereby altering the population's age composition, with the middle and apex of the pyramid expanding relative to its base. Under conditions where death rates at younger ages have been reduced to extremely low levels (e.g., in populations with high life expectancies), the base of the age pyramid becomes stable, influenced almost entirely by changes in birth rates. With a stable base and a growing middle and apex, the stage is set for a permanent shift in the age structure from its historical pyramidal shape to that of a square or rectilinear form (Fig. 4.4). Although increasing birth rates (such as those that occurred during the post-World War II era) can slow population aging and even temporarily reverse

it, the new rectilinear age structure will eventually reassert itself as the children from the larger birth cohorts survive to older ages. Thus, the transformation from stable high birth and death rates to stable low birth and death rates, experienced only within the last 200 years, has produced fundamental and in all likelihood permanent changes in the age structure of the human species.⁹

The social, economic, health, and political implications associated with rapid changes in a population's age structure are profound.¹⁰ Consider the example of what have become known as the compression and expansion of morbidity hypotheses. As the risk of death at younger ages declines, the proportion of each birth cohort surviving past ages 65 and 85 increases rapidly. For example, in the United States the proportion of the female birth cohort of 1900 that survived to ages 65 and 85 during the twentieth century was 57.8% and 25.5% respectively.¹¹ By comparison, the female birth cohort of 1996 is expected to have 85.7% and 41.6% survival past ages 65 and 85, respectively. These unprecedented patterns of survival into older ages have led scientists to identify the new patterns of mortality that lead to such improved survival chances and to evaluate how the health of cohorts surviving to older ages has already been influenced by these changing mortality patterns and how prospective mortality transitions might influence the future health of the older population.

FIGURE 4.4. Age pyramid of the future.

One school of thought is based on a concept known as the compression of morbidity hypothesis. According to this hypothesis, lifestyle changes and advances in medicine will continue to reduce the risk of death from fatal diseases and simultaneously lead to a postponement in the onset and age progression of the nonfatal disabling diseases.¹² The underlying premise of this theory is that there is a fixed biologic limit to life of approximately 85 years toward which populations are headed. As improved lifestyles simultaneously postpone the onset and expression of fatal diseases and nonfatal but highly disabling diseases and disorders, more people will be pushed toward their biologic limit to life, and morbidity and disability will be compressed into a shorter duration of time before death.

A second school of thought is based on a concept known as the expansion of morbidity hypothesis. According to this hypothesis, the behavioral and biologic forces that are influencing the onset and age progression of the nonfatal diseases associated with senescence are believed to be largely independent of the forces influencing the risk of death from fatal diseases.¹³⁻¹⁵ Thus, further reductions in death rates from fatal diseases are hypothesized to expose the saved population to a longer duration of time during which the nonfatal but highly disabling diseases and disorders of senescence have the opportunity to be expressed. Implicit in this theory is the etiologic

independence of fatal and nonfatal diseases and the premise that there are no active genetic programs for death (i.e., death genes) that evolved under the direct force of natural selection. The rationale supporting the latter premise is that it is not possible for the forces of natural selection to have favored the evolution of death (or longevity) genes that are expressed at older ages because selection does not operate in age ranges where few individuals normally live. That is, selection cannot effectively remove genes carried by those who have already made their genetic contribution to the next generation. The evolutionary explanation for why senescence arose is that it is a by-product of an evolved reproductive pattern and unprecedented survival into an older age range that permits its expression.¹⁶⁻¹⁹

A considerable debate has taken place in the literature regarding these two important hypotheses.²⁰⁻²⁵ It is too early to determine which hypothesis will best characterize the future course of mortality and morbidity because recent studies have provided support for both trends.^{25,26} However, research in this area should be interpreted with great caution because empirical studies addressed to this debate have focused on health transitions observed only during the past 20 years, with an emphasis placed on the decade of the 1980s. It is possible that healthy life expectancy (the proportion of total life expectancy free from disability) could improve at a faster pace in the

short term, only to give way to a more rapid increase in disabled life expectancy at a later date when survival into older, more disabling age ranges becomes common.

Population aging not only has provided an opportunity for most people to survive into older ages, it has also fundamentally altered the age distribution of death, shifted the primary causes of death to chronic lethal conditions associated with senescence, and increased genetic heterogeneity at older ages. In addition to its impact on patterns of health and mortality, population aging has also had profound effects on the funding of age-entitlement programs such as Social Security and Medicare,^{27,28} and in the coming decades it will likely have a profound influence on social institutions such as marriage, age at retirement, and even voting behavior. The social, economic, and health consequences associated with population aging are rapidly emerging as fertile areas of scientific inquiry.¹⁰

Individual Aging

The transformation of birth rates and death rates to their currently stable low levels not only brought forth rapid population growth and aging, it also led to unprecedented increases in life expectancy. It is estimated that during the Roman Empire life expectancy at birth was about 28 years.²⁹ By 1900, life expectancy at birth increased to 45 years in the nations with the lowest death rates of that time.¹¹ In low-mortality populations of the early twenty-first century, life expectancy at birth has now risen to between 75 and 80 years.

Most of the gains in life expectancy during the mortality revolution of the past two centuries are a result of dramatic reductions in death rates at younger ages. In fact, in today's high life expectancy populations of North America, Western Europe, Australia, Scandinavia, and Japan, death rates at younger ages have declined to such low levels that 98 of every 100 babies born will survive past 30 years of age. Deaths that occur among those younger than age 30 result mostly from accidents, homicide, suicide, congenital anomalies, and inherited lethal diseases.

What is perhaps most remarkable about the recent mortality transition is that, during the last third of the twentieth century, the majority of the gain in life expectancy at birth has been attributable to declines in death rates among those aged 50 and older. This latest trend in old-age mortality is so unique that it has been referred to as the fourth stage of the epidemiologic transition.³⁰⁻³² The first three stages are represented by the transition from high unstable mortality to low stable mortality as depicted in Figure 4.2.

Because declining death rates have been observed throughout the age structure, this raises questions about

how much further death rates can decline and how high life expectancy can increase. Interestingly, the belief in a biologically based limit to life has its nonscientific origins in biblical references to a human life span of 120 years (Genesis 6:6). Early scientific studies addressed to a biologically based limit to life were often presented within the context of a fundamental "law of mortality" that would explain why different species have different life spans, and why the risk of death increases in a predictable fashion with the passage of time.³³⁻³⁷

The first scientists to speculate on a biologic limit to life looked to the world of chemistry for answers to why death rates increased predictably with time.³³ These researchers believed that chemical reactions took place within living organisms that resulted in the breakdown of cells and tissues, reactions that in the world of chemistry operated in a time-dependent fashion consistent with the age trajectory of death observed among living organisms. Although these early visions of a law of mortality have remarkable similarities to theories about the mechanisms of senescence that prevail today, scientists early in the twentieth century were unable to measure the chemical reactions that they believed led to increasing mortality with age. Subsequent studies addressed to the question of a law of mortality were focused on interspecies comparisons of mortality,³⁸ and these later gave way to more mathematically oriented models designed to characterize the pattern to the dying-out process of populations.³

The principal scientific basis for a biologic limit to life dates back to the pioneering work of Hayflick and Moorhead,³⁹ where it was shown that normal human fibroblasts have a limited number of doubling times, about 50, after which they die. This limited replicative capacity of fibroblasts has been interpreted as a form of programmed death, as if a death gene evolved that is triggered after a certain amount of elapsed time. In subsequent articles, Hayflick^{40,41} made it clear that his findings should not have been interpreted as a biologic clock designed by evolution for the purpose of causing death. In spite of this clarification, the concept of a biologic limit to life based on these studies remains part of the scientific literature.⁴²

Demographic estimates of how high life expectancy can rise has taken on various forms, from extrapolation and curve-fitting models⁴³⁻⁴⁶ to reverse engineering approaches.⁴⁷ Extrapolating past mortality trends into the future has led some researchers to conclude that period life expectancy at birth in the United States will reach 100 years by the middle to latter part of the twenty-first century^{43,48} and that cohort life expectancy at birth for females born since the early 1980s is already at 100. Other extrapolation models employed by the U.S. Census Bureau,⁴⁴ Social Security Administration (SSA),¹¹ and other researchers⁴⁵ project that life expectancy at birth will rise to between 81 and 87 years by the middle of the next century (based on middle-range assumptions).

The underlying premise behind demographic extrapolation models is that patterns of mortality decline from all causes of death combined that have occurred throughout the twentieth century have remained fairly stable.^{28,45} More recent patterns of mortality decline indicate that, for some older age groups for some nations, mortality declines have even accelerated relative to earlier time periods.⁴⁹ This realization has led some demographers to conclude that extrapolating these mortality trends into the future is warranted and that there is reason to be optimistic that much higher life expectancies can still be achieved.^{28,48–50} In addition, it has been argued that because declines in death rates have been documented reliably for the extreme elderly, if there is a biologically based limit to life it must be beyond the observed longevity horizon.^{49,51–53} Additional support for this line of reasoning comes from research on the hypothetical relationship between risk factor modification and senescent mortality and the changes in behavior required to achieve high life expectancies.⁵⁰

The reverse engineering approach developed by Olshansky et al.⁴⁷ demonstrated that to achieve a life expectancy at birth as high as 100 years for males and females combined, death rates from all causes of death combined would have to decline at every age by approximately 85%. Because mortality reductions of this magnitude require the near elimination of all senescent mortality throughout the age structure, it is difficult to justify assumptions that lead to such high life expectancies.^{54,55} In addition, Olshansky and Carnes⁵⁵ demonstrated that the most optimistic demographic extrapolation models⁴⁸ rely on the underlying premise that dramatic reductions in cancer mortality are forthcoming, a condition that is inconsistent with the historical trend toward increasing death rates from this important cause of death. Furthermore, as death rates from other major killer diseases decline, the population saved from dying of these diseases remains exposed to the risk of developing cancer, a phenomenon known as competing risks (for more details on this concept, see Chapter 5). From the reverse engineering perspective, life expectancy at birth could rise beyond about 85 years only if advances are made in the biomedical sciences that somehow influence the basic rate of senescence itself.⁴⁷

Conclusion

In the past 200 years, the demographic components of population change, principally birth rates and death rates, have been shifted from their “usual” historically high levels to more stable lower levels. This transformation has led to two unprecedented changes in the demography of humans—population aging and increased longevity. The social, economic, health, and political implications

associated with both of these demographic phenomenon are profound.

With regard to population aging, rapid declines in death rates in the twentieth century have occurred throughout the age structure, leading to considerable increases in the proportion of each birth cohort surviving beyond age 65. Changes of this magnitude have undoubtedly led to increased heterogeneity at older ages, the health impacts of which have yet to be fully understood. Scientists involved in the debate on temporal trends in health expectancy are attempting to determine whether recent declines in old-age mortality have had a positive or negative impact on the health status of the older population, an issue directly related to increased heterogeneity. Because there is theoretical and empirical support for both the expansion and compression of morbidity hypotheses, it is premature to draw definitive conclusions about the future course of health and longevity. Many other societal changes are expected to accompany rapid population aging, from changes in patterns of energy usage to the possible emergence of new senescent and infectious diseases at older ages.

Increased longevity among subgroups of the population is the other important demographic consequence of the transformation in death rates from high unstable levels to low stable levels. Although it is recognized that the majority of the rise in life expectancy at birth in the twentieth century is attributable to reductions in death rates at younger ages, reliable evidence has emerged to indicate that death rates are now declining, even among the extreme elderly (over age 85).⁴⁹ Demographic forecasts of human longevity have varied considerably, from optimistic estimates of about 85 years for men and women combined to extremely optimistic estimates of 100 years or higher.

Extrapolating past trends in mortality into the future is the conventional approach, and this appears quite reliable if the forecasts do not extend out too far into the future. Yet, during time periods when mortality rates either remain stable or decline rapidly, even short-term forecasts based on the extrapolation method will lead to substantial underestimates⁵⁶ or overestimates⁵⁵ of longevity. This difference has important policy implications for such agencies as the Social Security Administration or Census Bureau, which rely heavily on population forecasts to formulate public policy. Recently, scientists have questioned the use of statistical methods for speculating on trends in vital statistics that are ultimately determined by biologic phenomenon.⁵⁷ For example, one argument against a purely statistical approach to estimating the upper limit to life expectancy is that a linear extrapolation of past trends in mortality into the future would eventually lead to low death rates that are biologically implausible, which means that either a nonlinear assumption about the future course of

mortality will eventually become necessary or justification for assuming zero death rates at any age must be provided. Because statistical approaches to extrapolating trends in death rates do not have either an implicit or explicit basis in biology, the only theoretical foundation for such assumptions is that the future will be some variation of the past. Determining the extent to which the past can be extrapolated into the future is critical in assessing the plausibility of such an assumption.

The future course of human longevity will be influenced by temporal trends in health practices, changes in the physical environments in which people live, advances in medical technology, and the degree to which humans learn how to modify the time-dependent expression of senescent mortality. The extent to which the expression of senescent mortality for humans can be modified remains uncertain, although there is theoretical and empirical evidence to indicate that low-mortality populations have already reached a point of diminishing returns with regard to future gains in life expectancy, although this is not to say that large declines in mortality at middle and older ages are impossible to achieve. To the contrary, such declines in death rates are anticipated. However, the measure of life expectancy is sufficiently insensitive to declining mortality in developed nations that it would take extremely large reductions in mortality to yield even small increases in life expectancy. Scientific advances that permit further modifications to the expression of senescent mortality may eventually lead to life expectancies for some population subgroups that exceed 85 years. There is reason to be optimistic that advances of this sort are forthcoming—although the social, economic, and health consequences of succeeding in altering the fundamental process of senescence are currently unknown.

Epidemiology and Aging

Tamara B. Harris

The growing numbers of older people and the implications for the health care system, including higher costs of inpatient and outpatient treatments, drugs, and physician care, are inescapable in geriatric medicine. What is the relevance of epidemiology to these issues?

Generally defined, epidemiology is the “science which investigates the causes and control of . . . disease in a community.”¹ However, epidemiology, more specifically, is a methodology by which patterns of risk factors, health behaviors, and environmental and genetic factors are systematically studied for their impact on health outcomes. Application of this methodology to problems of aging has proven useful not only in understanding the relationship of factors contributing to disease but also in gaining insights into the potential age-related biologic processes that underlie these relationships and in defining how these processes are modifiable. This chapter presents an overview of some of the lessons learned from application of epidemiologic methods to problems of old age, highlighting illustrative advances in recognition and treatment of hypertension and new strategies to prevent hip fractures.

The Aging Population

In 2000, there were an estimated 35 million people aged 65 years or older, and this number will increase to 70 million by 2030. The proportion of persons older than age 85 will grow and, if current projections hold, this population will also be increasingly female, with relatively greater numbers of Hispanics and African-Americans. Life expectancy in old age continues to increase, and death rates for heart disease and stroke continue to decline while deaths from cancer are slightly increasing.² Older Americans continue to be more affluent than previous generations and less dependent on Social Security for exclusive income support. This situation will continue to be true in the future, reflecting the demo-

graphic trend for greater current workforce participation by women.³

One of the first lessons from epidemiology, however, is that not all older persons are alike. Chronic health conditions are a major source of heterogeneity in the older population, with hypertension and osteoarthritis among the most common chronic conditions, affecting upwards of 40% of men and almost 50% of women. Other specific diagnoses, such as cancer or heart disease, affect about 20% of the population, with diagnosed diabetes and stroke around 10%. The proportion with cognitive impairment or Alzheimer’s disease is more difficult to estimate, owing to the greater difficulty with disease ascertainment, but estimates by age range from about 4% in those age 65 to 69 to as high as 20% or more in those age 80 and older.⁴ What can be forgotten is that a substantial proportion of the older population remains free of disease and does not even use prescription medication. It is not surprising then that this heterogeneity in health status, coupled with heterogeneity of socioeconomic status and social factors, translates into heterogeneity in functional status.

Functional Status: More Differences Than Expected

The frailest older persons have been the major focus of epidemiologic studies of aging. This group is both the most vulnerable and also the most costly in terms of expenses related to long-term care, medical illness, and medication expenditures. However, it has become clear the frail elderly represent a relatively small proportion of those age 65 and older. A major contribution of epidemiology of aging has been the characterization of the heterogeneity of function in the older population, including the course of disability trajectories and a nascent understanding of factors contributing to these trajectories. In addition, recent studies have emphasized under-

standing how even the most disabled preserve social integrity and provide context in their lives.

In terms of the range of disability in the older population, data suggest that, even accounting for those who are institutionalized or have severe enough disability problems to have difficulty with an activity essential for daily living, only approximately 17% of the population over age 65 have some disability. Furthermore, data from repeated waves of national surveys suggest that this proportion is declining over time.⁵ Even more important, among those age 80 and older, there is a substantial proportion, upwards of a fifth of both men and women, who not only report no difficulty with activities of daily living, but also report that they are fully independent, including meeting criteria established by Nagi for being able to work full-time.⁶ Thus, although the very disabled elderly are most visible in institutions and health care facilities and as users of health care resources, the range of capacities across the spectrum of aging is very large.

These differences have been highlighted by a number of studies targeted to identification of this heterogeneity and to examination of some of the earliest factors contributing to functional decline. These studies have identified new ways to measure disability, including using a wider range of reported items to cover the entire spectrum of function, especially among those with no limitations in activities of daily life; these include drawing on Nagi items to examine mobility-related problems and questions regarding ease of performance or change in performance.⁷ Objective measures involving timed tasks mirroring clinical assessments of daily life tasks have been used to augment the self-report and to provide measures that facilitate comparisons of populations.⁸ These measures, analogous to mental status testing, draw on simple tasks basic to a standard neurologic examination but refined and standardized to be administered and scored by nonmedical personnel. Both sets of measures augment approaches specifically targeted to establishing need for supportive services by self-report of simple, necessary activities of daily living.

Epidemiologic and clinical studies have shown that much of disability reflects a failure of compensatory mechanisms either on an organ-specific physiologic basis, as in the case of congestive failure, pulmonary disease, or renal disease, or on a societal level, where the capacity of the person to be maintained in independent living may be compromised by a lack of ability to obtain the basic necessities of life. Disability trajectories also may reflect the underlying severity of factors contributing to functional decline. Catastrophic disability is associated with irreparable organ failure that cannot be compensated, for instance, from a stroke, whereas progressive disability tends to occur with small decrements which, cumulatively over time, result in failure of compensation, although each insult alone might not result in disability.⁹ Further-

more, in the case of progressive disability, deficits that are quite profound may not be recognizable for some time because individuals may successfully adjust to their deficits either by altering what they do or by altering the manner in which they perform necessary life tasks so that they can continue to function, albeit in a different manner.¹⁰ Last, we have also begun to recognize that disability in one area of function, such as physical function, may not be accompanied by disability in another area of function, such as cognitive or social. For instance, epidemiologists have recently described the phenomenon of emotional vitality, identifying the preserved quality of life experienced by severely disabled older women who continue to maintain an active and supportive social network.¹¹ Religion and religiosity may play a role in this area as well,¹² although social vitality may exist quite apart from the religious community.

Thus, a major contribution of population epidemiology has been to identify the heterogeneity within the older population—developing methods to allow evaluation of the prevalence and causes of disability and to address the question of how people age differently, how aging reflects both biology and life events, and how older people maintain and consolidate their level of independence in the face of major challenges to mind, body, and spirit. These efforts continue to help in identification of new risk factors for disease that will help to further limit loss of independence in old age and in the formulation of preventive interventions appropriate for each level of functioning in old age.

How Heterogeneity Affects Our View of Age-Related Changes and Risk

Epidemiologic tools have been also useful in development of a fundamental principle of gerontologic research: that longitudinal age-related changes are exaggerated by using cross-sectional populations.¹³ Because of the difficulty of performing longitudinal studies across the entire life span, a number of different approaches have been used in studies of age-related changes. The easiest type of study to perform to assess age-related trends involved identification of groups of individuals of different ages, measuring the trait of interest in each of these groups. The results, comparing the older age groups with the youngest group participating, were considered indicative of “normal” trends with age. A number of problems were identified with this approach. There were secular factors that could distort “age” trends, that is, a decrease in cholesterol following major health education campaigns regarding the risks associated with cholesterol.¹⁴ Cohort factors that might change from one generation to another could confound observed patterns. For instance,

although height does decrease with age, this effect is exaggerated if one looks across successive generations because more recent generations enjoy better nutrition and health, which translates into taller maximal heights.¹⁵ Younger individuals have at least two reasons for taller heights. Their generation grew to taller maximal heights because of better nutrition, and they have not yet suffered age-associated height loss, effects that may be difficult to separate. Similar issues are seen for cognitive function, where declines with age are exaggerated by better educational status associated with better test performance in more recent generations.¹⁶ Other investigators identified preagonal patterns affecting the data. For instance, in the years before death, even in seemingly healthier older people, cognitive performance was lower or slower than in those who were likely to survive the same period of time.¹⁷

Even among well-screened volunteers, groups of subjects of different ages were likely to vary by health status, and the trajectories of longitudinal trends might differ reflecting patterns of lifelong contributing factors. For instance, mean creatinine clearance declines with age when comparing subjects of different ages who have been similarly screened. However, at least part of this effect is secondary to the fact that renal function reflects lifelong health factors such as ambient blood pressure. Data from the Baltimore Longitudinal Study of Aging demonstrated that there is little change in renal function among those who have been stable normotensives, whereas among those with poorly controlled hypertension, the trajectory of decline in renal function was very steep.¹⁸ Among people in each age group, the proportion with underlying factors that would contribute to decline in kidney function increases with age, and therefore the mean creatinine clearance appears to markedly decline with “normal” aging. As with renal function, once all these issues were taken into account, many changes in function with age were noted to be much smaller than suggested by either the cross-sectional data or by methodologically poor longitudinal studies.

A second major issue with regard to risk assessment follows from these studies. As the population ages, the proportion of individuals with subclinical illness that could affect the status of other health markers increases. This factor has led to a series of paradoxical findings in elderly populations that have confused efforts to counsel older individuals regarding weight, cholesterol, and other health behaviors and risk factors important in younger populations. For instance, studies of weight and mortality in old age have shown no risk, an increased risk with thinness, an increased risk with heavier weight, and a protective effect of heavier weight, especially in the oldest-old.^{19–21} Although it is biologically plausible that the relationship of weight to mortality could change with age, these disparate findings may also reflect shifts in

weight that occur with age. People in the developed world tend to gain weight over their lifetime, so that by late middle age there are few individuals who have been thin throughout most of life. In old age, many people lose weight, either directly because of illness or to ameliorate weight-related risk, and therefore their thinness reflects risk secondary to poor health.²² Thus, most thin older people have not been thin throughout life but rather have become thin in old age. It is hardly surprising then that this group has an increased risk of mortality that approaches and may even surpass that of the heavier population. Among heavy older persons, most have also not been heavy all throughout their lives but have gained weight in late middle age. This group may have lower risk of mortality secondary reflecting their midlife weight. Consideration of lifelong patterns of risk factors may help to clarify the results of relationships based on a one-point-in-time measurement. This life-course approach, another contribution of epidemiology to aging research, may identify whether the pathophysiology of disease really does differ in old age or whether age-related changes merely obscure a consistent biologic pattern.

Contributions of Epidemiology to Clinical Practice: Hypertension Control in Old Age

Epidemiology has also been important in the “medicalization” of processes previously thought to be a part of normal aging, with conditions once accepted as normal now being identified as associated with risk or as disease states. This reclassification from “normal” to “disease” has allowed formulation of methods of prevention or treatment. Among these conditions is cognitive impairment. Over time, the definition of acceptable cognitive loss with age has become substantially narrower as researchers investigate patterns of cognitive function and risk factors for change. As more “normal aging” becomes understood to represent pathology secondary to disease, health-related behaviors, or environmental factors that change with age, efforts to delineate causal factors increase in parallel with efforts to remediate the condition.

One important example, one of the major successes of aging research, is the recognition and treatment of hypertension, particularly isolated systolic hypertension. As recently as 30 years ago, it was still believed that development of systolic hypertension in old age was “natural” process stemming from atherosclerosis.²³ Autoregulation of cerebral blood flow that reflected hypertension suggested that older people required a “higher head of steam” to perfuse the brain.²⁴ Efforts to treat hypertension, particularly isolated systolic hypertension, were

postulated as not only unlikely to benefit the patient but potentially contributing to risk. These theories did not yield easily to data. Studies began to demonstrate that systolic blood pressure tended to increase later in life and that this increase might represent a distinct physiologic process from diastolic hypertension.²⁵ Although cross-sectional and longitudinal studies showed that blood pressure tended to increase with age in most populations, studies from isolated populations such as lifetime residents of mental hospitals showed that blood pressure did not increase very much at all over the life span.²⁶ These studies called into question whether blood pressure rise with age should be considered as an inevitable consequence of aging. Studies of the outcomes of systolic hypertension demonstrated that this was not a benign condition, but rather, whether in combination with diastolic hypertension or when isolated, resulted in increased risk of stroke and coronary heart disease.^{27,28} Thus, studies of blood pressure change with age showed that these changes were not “normal” with age and that hypertension carried an increased risk of poor health outcomes.

However, demonstration of the poor health risks associated with systolic hypertension was not enough. Clinical trials were needed to demonstrate that there was a benefit to treatment in terms of reduction of risk of cardiovascular complications. The first clinical trials for hypertension did not really address the issue of treatment of systolic hypertension; in fact, the clinical trials focused primarily on diastolic blood pressure, the most common type of elevated blood pressure in middle-aged individuals.²⁹ Even the gradual recognition that treatment of diastolic blood pressure often resulted in lowering of systolic blood pressure was not believed to clearly address the question of whether older persons with isolated systolic hypertension should be treated aggressively to lower blood pressure.

Several major clinical trials were undertaken to address the issue of hypertension in old age. The first was the European Isolated Systolic Hypertension Study, which enrolled 840 older persons in 11 countries throughout Europe.³⁰ In the United States, the Systolic Hypertension in the Elderly Program (SHEP) was established, enrolling 4736 persons in a complicated protocol that involved screening thousands of participants.³¹ Both studies demonstrated conclusively that treatment of systolic hypertension resulted in lower mortality and cardiovascular morbidity in the elderly, and these results were supported by additional studies.^{32,33} Even with a much more limited group of medications than is available today, blood pressure could be treated safely, effectively, and cheaply using a stepped protocol in older persons.

These studies established important principles for research in aging. First, age-related changes that were so common as to seem “normal” can carry risk. Second, medical conditions in the elderly could be successfully

treated to alter the course of health outcomes associated with these conditions. Thus, even in older persons, prevention is important. Third, older persons could be recruited successfully to participate in clinical trials; they would comply with the treatments and provide analyzable data that could help to guide clinical recommendations for other older persons. This realization established the viability of clinical trials in old age; however, even today there remain major barriers to the participation of older persons in clinical trials, primarily based on misconceptions about the compliance of older persons in the trials. Last, results from trials of conditions common in old age could provide important information about the biology of disease in old age and the causes of these conditions and, if not the reversibility of biologic effects, at least the prevention of secondary outcomes.

Population epidemiology continues to provide new information on hypertension risk and the benefits of treatment that could be very important in old age. Although the role of hypertension in cardiovascular disease has been appreciated for some time, the potential contribution of hypertension to other conditions is only beginning to be understood. For instance, recent data on population-based magnetic resonance imaging studies of the brain have suggested that hypertension may make a major contribution to risk of small silent brain infarctions that may contribute to cognitive decline³⁴ and that treatment of hypertension can lower risk of congestive heart failure.³⁵ Other data suggest that even apart from risk of stroke, hypertension in midlife may contribute to cognitive decline in old age.³⁶ This area continues to be one of active research.

Epidemiology and the Geriatric Perspective on Hip Fracture

Epidemiology of aging has contributed a novel perspective on how to attack the problem of fracture risk in osteoporosis. Osteoporosis and associated risk of fracture is a major health problem for both elderly men and women.³⁷ There have been major improvements in understanding of the best techniques and timing for surgery, but outcomes associated with hip fracture are still poor. Risk of mortality in the 6 months postfracture remain high, and odds of full recovery of function are low.

The medical community has gained remarkably in terms of understanding osteoporosis and risk of fracture from clinical research, population studies, and clinical trials targeting osteoporosis and fracture-associated risk. In the course of these studies, a perspective on fracture has emerged that gives weight to both the classical endocrinologic perspective of hormones determining osteoporotic risk and the geriatric perspective, which

suggests that factors associated with frailty and increased risk of falling contribute to fracture risk as well. The benefit has been a comprehensive and integrated approach to fracture prevention.

By the mid-1980s, the role of estrogen decline in women contributing to bone loss was well established. Patterns of change in bone mineral relating to periods of hormonal change over the lifetime had been identified and a threshold for risk of osteoporotic fracture established.³⁸ The primary goal of therapy was to boost women over the fracture threshold so long as possible, with manipulations targeted to increasing peak bone mass and reducing bone loss at critical periods, such as during the perimenopausal period.³⁹

During this same period, a group of geriatricians and general internists began to question whether bone mass alone was the key to the entire risk of fracture. Equally, if not more important, were risk factors that contributed to the fall leading to fracture. Early studies identified those at risk of falling and demonstrated some overlap with known risk factors for fracture.⁴⁰ These studies also established methodologies that could be used to track the frequency and severity of falls in population studies to better prospectively establish the role of falling in relation to risk of fracture.

At the same time, techniques were developed that allowed the measurement of bone mineral density in populations, and several studies were initiated that incorporated a holistic overview of putative risk factors for fracture. The largest of these, the Study of Osteoporotic Fractures, established that bone mineral density and falls were both risk factors for fracture. Furthermore, risk factors contributing to both lower bone mineral density, such as smoking, and risk factors contributing to risk of falling, such as reduced vision and strength, also contributed to risk of fracture.⁴¹ Thus, new avenues for intervention to reduce risk of fracture were identified.

Subsequent clinical trials have addressed the potential modifiability of each of these factors. Tinetti and colleagues identified that risk of falling was modifiable by testing an algorithmic approach to diagnosis and intervention of risk factors for falling.⁴² In addition, Tinetti contributed seminal work defining that the risk factors for falling could be used to identify those most at risk and therefore most likely to benefit from intervention and that the interventions might differ depending on the functional status of the older person.^{43,44} Interventions needed to prevent fracture needed to account for the heterogeneity in the at-risk population, as the goal was to prevent fractures without increasing fear of falling, which could itself lead to decline in functional independence.

Clinical trials have also provided a number of interventions to modify bone mineral. The Fracture Intervention Trial established the efficacy of alendronate first in prevention of vertebral fractures and later for hip frac-

ture.⁴⁵ Other more specific estrogen agonists, such as raloxifene, have also been identified as useful to prevent osteoporotic bone loss.⁴⁶ Most surprising, however, have been the clinical trials of estrogen. Although a staple of therapy for osteoporosis for years, estrogen had not been tested in a randomized clinical trial. Potential biases related to the characteristics of women given estrogen therapy in clinical practice, including the fact that these women were often thinner and healthier than other women, raised questions about whether this therapy would prove as efficacious when tested in a randomly assigned population. The Women's Health Initiative, a multioutcome trial of estrogen use as protective for hip fracture and heart disease and enhancing the risk of breast cancer, is now underway.⁴⁷ Surprisingly, the only finding thus far is a modest increase in risk of cardiovascular deaths in the first several years of the study. This finding, plus options now available with other medications, have opened the question of whether estrogen is the first-line treatment for osteoporosis.

A third potential avenue for prevention of fractures is dietary supplementation with calcium, also part of the Women's Health Initiative. In addition, following the observation that older men are experiencing a major increase in the numbers of fractures, a large population-based study has been initiated to further understand risk factors for fracture in older men, which is likely to add to the already large list of factors that contribute to fracture.

Summing Up

Thus, epidemiologic methods have contributed to a complex and dynamic understanding of risk of disease in old age, identifying factors that are related to "classical" medical disciplines, such as endocrinology, but also a host of new risk factors that could be regarded as "geriatric." These latter risk factors tend to be more holistic in that they relate not to one organ system specifically, but identify how even small deficits in multiple organ systems can contribute to risk of poor health outcomes in old age.

The tools and principles of epidemiology have had an important impact on our view of the capabilities and heterogeneity of the older population, on the differentiation of disease from normal aging, on a life-course perspective for risk, and on the types of interventions available to contend with the problems of old age. Many of these contributions have been incorporated in a variety of evidence-based practice guidelines, and the possibilities for the future are bright. Epidemiology can be an important tool to help researchers who study the problems of old age to learn more about the range of health, social, and psychological problems of the elderly, to identify new avenues for intervention and to test these interventions, and to adapt the interventions to the practical realities of

growing old. In this way, epidemiologic method can function as an important adjunct in the mission of promoting independence and providing evidence-based health care for older people.

6 Psychosocial Influences on Health in Later Life

Elizabeth C. Clipp and Karen E. Steinhauser

Geriatricians face an enormous intellectual and personal challenge in understanding the interactive complexities—physical, psychosocial, functional, and spiritual—of caring for elderly patients. Successful geriatric assessment and treatment depend not only on recognition of pathology but, perhaps more importantly, on understanding how such pathology relates to the “whole person.”

The interactive complexities of geriatric medicine have led geriatricians to consider relatively unique care approaches, most notably the multidisciplinary approach, which utilizes expertise from a number of disciplines in the care of older adults. It is the geriatrician’s challenge to move beyond medical opinion and integrate the observations of multidisciplinary team members before implementing an overall plan of care. Equally important to the recognition of pathologic processes in geriatrics is the impact of disease on function. As such, the practice of multidimensional geriatric assessment focuses heavily on the social, psychological, and environmental factors that influence function, such as the elderly patient’s social milieu.

Several key observations in geriatrics highlight the links between psychosocial factors and patient functioning. First, psychosocial and cultural factors influence differences in illness behavior between older and younger patients. Second, these differences in illness behavior interact with age-related physiologic organ change leading to delayed or altered disease presentation and multiple concurrent pathology. Third, variation in disease presentation and comorbidity profiles gives rise to different trajectories of recovery and clinical outcomes. These observations anticipated the introduction of “non-medical supports” as important to geriatricians’ goals of maintaining and improving patient outcomes. Geriatric assessment often includes patients’ emotional tone and lifelong habits. In some settings, teams expand the social history component in geriatric assessment to include social interaction, support systems, and community

resources, factors likely to influence the future functioning and disability management of the patient in the community.

Now considered the optimal standard of care, a systematic approach to comprehensive geriatric assessment attends to multiple personal domains, including but not limited to physical health, mental health, function, and social situation. This scope of inquiry is significantly broader than other medical specialties and makes performing comprehensive assessment a formidable task within the shorter encounter time frames of most managed care environments. Although early, single-site studies of this approach showed impact on survival and improved functional outcomes, more recent randomized controlled trials have shown little impact on survival but do show benefits in functional outcomes.^{1,2} Tension between managed care time constraints, the geriatrician’s need to integrate multiple data sources, and the potential benefits of applying comprehensive assessment to functionally compromised patients gives rise to two questions. First, what psychosocial aspects of aging are most likely to affect clinical outcomes? And second, how can geriatricians efficiently capture these data in standard clinical encounters?

The clinical focus of this chapter necessitates the omission of many of the more traditional topics usually associated with the psychological aspects of aging (e.g., personality, behavioral processes, memory, learning, perception) and social aspects of aging (e.g., demographic patterns, social structure, housing and living arrangements, work and retirement, economic status). Readers interested in comprehensive reviews on such topics are referred to the recently released fifth editions of the *Handbook of the Psychology of Aging* and the *Handbook of Aging and the Social Sciences*, 2001.^{3,4}

This chapter identifies seven key psychosocial domains that should be part of the geriatrician’s perspective: gender, ethnicity and class; historical influences (i.e., military experience); social relationships; spirituality;

caregiving; elder mistreatment; and successful aging. This list is by no means exhaustive, but rather offers an initial framework for assessment. We present the proposed mechanisms linking these domains to health in later life and conclude with a set of probes that may be used by practicing geriatricians to capture these key psychosocial domains in everyday practice.

The Role of Gender, Ethnicity, and Class

It has long been known that one's position in society—being female or male, richer or poorer, African-American, Caucasian, or Latino—is strongly associated with different levels of health and illness. Beyond differences in physiology, individuals live in psychosocial environments in which health is either enhanced or put at risk. Gender, ethnicity, and socioeconomic status or class are three predominant features of these contexts.

What accounts for these predictable differences in health outcomes? A variety of explanations have been proposed.^{5,6} Demographic categories may function as proxies for inherent physiologic disparities between various population subgroups. Alternatively, demographics may be proxies for other social factors. First, each social location category offers different access to health care. Second, differential socialization affects health behaviors. For example, poorer individuals may be more likely to smoke; men are less likely to formally report health problems; women have higher rates of health care utilization; and persons experiencing discrimination may be less likely to trust physicians of other ethnicities, which may reduce both utilization and compliance. Third, social location may produce varying levels of stress that increase susceptibility to disease. For example, poorer individuals may live in more toxic, crowded, or hazardous environments. Finally, physicians may treat individuals differently on the basis of gender, ethnicity, or class. There are well-documented examples of minorities receiving different cardiac care when presenting the same symptoms as Caucasian patients.⁷ No one explanation is sufficient. Rather, clinicians should be aware of the variety of causal processes—physiologic, psychosocial, environmental—that impact health or contribute to illness.

We offer here a brief general overview of some evidence-based differences in health associated with gender, ethnicity, and socioeconomic status that may be useful in the clinical encounter, highlighting differences in general patterns of chronic disease, functional impairment, self-rated health, depressive symptoms, psychological distress, and mortality. At the end of each subsection, we direct the reader to full reviews, but offer summaries of those reviews.

Gender

For most health indicators, except mortality, women have poorer health than men. Older women report more chronic disease; however, as compared to men, those illnesses generally are less serious or catastrophic.⁸ Women show higher prevalence of functional impairment than men, but there are no gender differences in incidence. This discrepancy is most likely caused by earlier onset and increased longevity for women. Perception of one's own health, or self-reported health, is lower for women than men. However, one study shows a gender and age interaction, whereby gender differences in self-rated health are greatest among young adults and least during old age. Studies show that the onset of depression is more common in younger women than among younger men but equally common in men and women at older ages.⁹

Race and Ethnicity

Chronic diseases are more prevalent among older African-Americans. Functional decline, according to most studies, is also greater among African-Americans; Latino functional status falls between that of African-Americans and Caucasian older adults. However, research has shown a crossover among the oldest-old, where African-Americans over 85 function at higher levels than whites. It has been hypothesized that this crossover represents a "hardiness factor," whereby because African-Americans are at higher risk for mortality and morbidity for the majority of the life course, those who survive to 85 represent a select group in terms of function. African-Americans over 75 have lower mortality than Caucasian older adults. As such, these results represent not an elevated functional status enjoyed by older African-Americans, but rather a remarkable selection effect from a lifetime of poorer health risk.¹⁰ Research shows no differences in self-rated health or depressive symptoms among older African-American and Caucasian adults.^{9,10}

Some have proposed a double-jeopardy hypothesis in that being African-American and older gives double risk for adverse health consequences. Evidence does not support this. However, leading health and ethnicity researchers suggest this hypothesis remains an important part of the theoretical landscape by emphasizing the racial disparity in health outcomes throughout most of the life course.¹⁰

Social Class or Socioeconomic Status

Research shows that, in general, lower socioeconomic status (SES) is related to increased mortality and disproportionate impairment from major diseases, such as cardiovascular disease, diabetes, and cancer.¹⁰ Socio-

economic status is measured in several ways, including education, occupation, and income; conclusions about the effects of SES on health are often dependent on the particular indicator used. Higher levels of education are significantly related to lower prevalence of chronic illness, lower functional impairment, and higher self-rated health. Lower income has been found to predict functional decline among men but not women. Both income and education are inversely related to depressive symptoms. However, SES interacts with ethnicity for this health outcome, such that among highly educated individuals, African-Americans report fewer depressive symptoms and, among lower-education adults, African-Americans report more depressive symptoms. Evidence is not convincing regarding the relationship between SES and depressive disorders.⁹

Socioeconomic status also can mediate the relationship between social factors and health. Education and income have been shown to partially explain functional status differences among blacks and whites and fully explain the relationship between gender and functional decline. These findings suggest that if women had equal socioeconomic resources, they would attain higher functional levels than men. Similarly, data show that SES explains gender differences in self-rated health. Finally, the influence of socioeconomic status on health varies across the life course with differences small in childhood, increasing in middle age, and decreasing again in later life. The lessening effects of SES in late adulthood are hypothesized to be related to policies, such as Medicare, that are aimed at increasing population-wide access to health care resources.^{9,10}

Physician–Patient Relationship and Health

Some discrepancies in health outcomes are associated with ethnic and gender differences between patients and physicians. For example, evidence suggests that gender and ethnicity do influence patient–physician communication and patient decision making.¹¹ In particular, minority patients and those with lower education report less participation with their physicians; women report more participation, receive more information, and ask more questions. Female physicians have been rated as having a higher participatory style and empathy, which is associated with higher patient satisfaction and lower rates of malpractice. These differences may be due to perceived stereotypes, a lack of understanding of cultural differences in disease models, and lack of awareness regarding difference expectation among those with lower education, health literacy, or health care autonomy.¹¹ Some clinician-researchers recommend that physicians may

work to develop their own communication skills, as well as empower patients to increase participation. Furthermore, acquiring “cultural competence” may improve interaction. That competence is developed with three components: knowledge of variation in health-related beliefs and values, disease incidence and prevalence, and differential treatment efficacy.¹¹

Time

It is important to emphasize the role of time in predicting health. Much of gerontologic research focuses on documenting age differences in health. However, we are less clear about the underlying causal processes and whether measurable health differences are age related, age dependent, or time dependent. For example, are the differences we see in older adults the result of an age-dependent process, whereby after 80 years of life, organisms generally function in a relatively predictable way? Or are the observed health differences the result of historical effects, such as the long-term effects of military experience? An entire group or cohort not permitted to attend public school may express the effects of lower education across a lifetime. In fact, no reductionist explanation is sufficient. Individuals, with their unique physiology, move across the life course and through historical time being shaped by and, in turn, shaping their world. Identification of the source of idiosyncrasy apparent in old age is multifaceted and presents researchers with a conundrum, frequently referenced as the age–period–cohort issue in gerontology. Its resolution will appear only as we accrue longitudinal health outcome data on multiple generations across long periods of time that permit us to test the effects of age, controlling for time and generational influences. Until such data are available, clinicians may be reminded of the fluidity of aging processes; aging today will be different from aging tomorrow. A clear example of a cohort or historical effect present in many geriatric patients today is that of military experience.

Historical Influences: The Example of Military Experience

It is well recognized that the entire American population is aging but infrequently acknowledged that the increase of elderly U.S. veterans is even more rapid. Specifically, the number of veterans over age 65 peaked in 2000 at 9 million, making them a majority proportion (63%) of all elderly males in the United States. It is therefore highly likely that currently practicing geriatricians will encounter substantial numbers of older male veterans in

their practices. How does former military experience influence health in later life? Why is knowledge of veteran status important in geriatric assessment?

The majority of studies linking military experience, especially combat exposure, to war and postwar health have concentrated on emotional manifestations, such as psychiatric syndromes and posttraumatic stress disorder (PTSD). Research also has explored veteran postwar and longer-term health trajectories and somatic indicators of war stress, but postwar and long-term pathogenesis (e.g., cardiovascular disease, cancer) has been neglected. Little attention has been given to military experience in the development of health risk factors, and virtually nothing is known about the military precursors of postwar mortality. One model emerging in the behavioral medicine literature that explores potential relationships among war stress, disease risk, and mortality focuses on mechanisms linked to coronary artery disease (CAD), the impairment of immunocompetence, and health risk behaviors. Unfortunately, little work has applied these models to long periods of the life span, as between military service in the twenties and later-life health.

An extensive recent literature now links psychosocial factors (e.g., acute and chronic stress), social isolation, and character traits (e.g., hopelessness) to the pathogenesis of CAD.¹² For each of these factors, behavioral and physiologic mechanisms are implicated in the disease process. Behavioral mechanisms suggest that certain factors (e.g., social isolation) influence the extent to which individuals engage in high-risk behaviors (e.g., consuming high-fat foods, problem drinking, and smoking) that promote CAD. Physiologic mechanisms operate between acute psychologic stress and sympathetic nervous system hyperresponsivity. In the example of social isolation, studies suggest a relationship between lower levels of social support and higher resting heart rates, which suggest altered autonomic arousal.¹³ Blood pressure and cardiovascular responses to stress also may be attenuated by the presence of social support.^{14,15} Our earlier work on the social dislocation hypothesis suggested that men who served overseas, leaving behind families and careers, experienced adverse health effects.¹⁶

War experiences also may engender persistent feelings of hopelessness among aging veterans. In observational studies, hopelessness has been linked to sudden death in humans and prospectively to the development of carotid atherosclerosis and CAD.^{14,17,18} Recent studies using a multi-item measure of fatigue, irritability, and demoralized feelings, termed "vital exhaustion," show that this symptom triad significantly predicts future CAD or cardiac events in both healthy and CAD populations.¹⁹⁻²¹ Early observations of combat exhaustion, indicated by persistent fatigue, irritability, and feelings of inadequacy

led to decades of military studies and clinical case reports of "vital exhaustion" that marked many veterans' lives initially and in the longer term (e.g., shell shock, combat neurosis, battle fatigue, Vietnam syndrome, and, more recently, PTSD). In addition, hostility, an individual attribute and major element of the type A behavior pattern, also has been implicated in the development of CAD.¹²

A CAD model thus links the heightened arousal of war stress to cardiovascular reactivity and an array of other CAD symptoms, including an elevated resting heart rate and hypertension, as well as damaged arteries.²² Excessive cardiovascular arousals can, over time, promote damaged arteries through mechanical injury of the arterial endothelium.²³ Cardiovascular reactivity refers to the duration and magnitude of cardiovascular response to acute stress or change. The greater such reactivity, the greater the CAD risk, as in the prediction of problematic blood pressure.

More specifically, war experiences constitute acute and sometimes chronic levels of stress that stimulate the sympathetic nervous system, leading to a variety of physiologic effects (e.g., heart rate and blood pressure stimulation, direct effects on coronary vascular endothelium). Known clinical consequences of these effects include myocardial ischemia, arrhythmias, more vulnerable vessel plaques, and hemostatic changes. According to Rozanski and colleagues, these changes position the individual for the development of acute myocardial infarction and sudden cardiac death.¹² Combat veterans may thus become increasingly more vulnerable and reactive in cardiovascular symptoms to change and stress as they age.

Finally, war stress has probable consequences for immune system impairments through a complex set of hormonal and neural pathways.²⁴ The biobehavioral pathways described in the CAD model also could act on the cellular and molecular biology of the monocyte-macrophage system to promote arterial lesions that compromise the immune system's ability to disable malignant cells.²⁵ Although the immune system is clearly responsive to changing behaviors and moods, and trauma studies postulate a weakening of previously adequate defenses with age, it is unclear at this time whether altered immune function influences aging changes that can be linked to disease vulnerability.

Given the substantial proportion of veterans in the elderly population and the potential links between war stress and health, veteran status should be ascertained on all geriatric patients. If indicated, patients should be referred for assessment and treatment of posttraumatic stress disorder (PTSD). Even in the absence of formally diagnosed PTSD, current research suggests that military experience can constitute a form of chronic stress that

may be associated with deleterious physiologic processes, including hyperarousal or compromised immune function continuing into old age.

Social Relationships

Military experience illustrates the powerful influence of earlier stress and social dislocation on lifelong risk of illness. The corollary also has received considerable attention, in that health has been shown to be related to one's degree of connectedness or one's social relationships. Research has shown that multiple roles are related to better health, lower functional impairment, and multiple indicators of physical illness and symptoms. For example, unmarried and socially isolated individuals are at risk for higher mortality and morbidity, including tuberculosis, accidents, and psychiatric disorders.^{5,9}

For decades, much of the research on social relationships documented patterns of greater and lesser health and illness associated with social relationships. More recently, researchers are exploring the underlying mechanisms linking social ties and health. Do social relationships prevent people from becoming ill? Do they help in recovery from illness? Do social relationships foster health by improving a sense of meaning or coherence in an individual's life, by promoting healthy behaviors, or perhaps by neuroendocrine response?

Evidence began to accumulate in the 1970s, when researchers such as Cassel and Cobb and Berkman and Syme pioneered the notion that social relationships were protective.^{5,26} Experimental and quasi-experimental research showed that the presence of a familiar member of the species could buffer the impact of experimentally produced stress on ulcers, hypertension, and neurosis in rats, mice, and others. In addition, it was shown to reduce anxiety and physical arousal (via secretion of fatty acids) in humans. Physical contact and the presence of others were shown to modulate cardiovascular activity and reactivity in general and stressful contexts. Handling reduced the arteriosclerotic impact of high-fat diets in rats. Bovard proposed a psychophysiologic theory suggesting social relationships, mediated through the amygdala, activated the anterior hypothalamic zone and, hence, secretion of adrenocorticotrophic hormone, cortisol, catecholamines, and associated sympathetic autonomic activity.²⁷

Similar to socioeconomic status, links between social relationships and health outcomes vary depending on the measurement of this social indicator. Researchers in this tradition have focused particularly on the effects of two types of connectedness: social integration (i.e., the degree to which individuals have formed attachments to social structure) and social support (i.e., the degree to which

individuals have formed attachments to other individuals). Examples of the former include role types, church attendance, and participation in voluntary organizations. The latter contains at least five dimensions: (1) the size of an individual's social network; (2) the type of support they receive (e.g., emotional or tangible assistance); (3) the source (friends or family); (4) the frequency of that support; and (5) the perceived quality referred to as subjective social support.²⁸

Social integration, in the form of church attendance, has been shown to be related to lower functional impairment, better immune function, and reduced depressive symptoms. Among older African-American men, it also has been shown to decrease subsequent mortality. Participation in voluntary organizations also is related to lower mortality. Social support in the form of marriage has been empirically linked to fewer depressive symptoms, decreased psychiatric disorders, and less functional impairment. Some data suggest marriage is more protective against mental illness for Caucasians than for African-Americans. Higher levels of subjective social support have been related to lower functional impairment, better self-rated health, fewer depressive symptoms, and more rapid recovery from depressive disorders. There is no evidence, however, relating this support to mortality.⁹

In general, the data on the influence of social support on health have been mixed. However, based on the evidence to date, leading researchers in the field offer three conclusions. First, social support shows robust direct effects on health outcomes. Second, the most powerful component is subjective social support; "feeling" supported is more important for health than objective levels of support received. Third, support from friends is more strongly related to health outcomes than family support.⁹ It is hypothesized that the voluntary nature of friend support may increase quality. Or friends, as peers, are more likely to offer mutually appealing support.⁹

As researchers continue to identify the mechanisms that link social relationships to health, clinicians should proceed by recognizing the importance of their patients' social integration and support and assess it as part of a normal social history. One may ask what kinds of organizations and activities are important to the patient. A comprehensive assessment of a patient's level of social support should include questions regarding amount, frequency, and kind of support. Gathering such information does not require the physician to resolve support issues. It does, however, offer a window into the social context in which medications or other health regimens are prescribed. If recommending dietary adjustments, increased physical activity, or drug regimens, geriatricians should consider the odds that such recommendations will be taken based on the nature of elderly patients' social rela-

tionships and support. Similarly, when patients are recovering from illness or medical intervention, providers should assess the nature of support that is in place. Perhaps most importantly, physicians should ascertain the extent to which their patients “feel” supported.

Spirituality and Health

One important form of social integration involves the spiritual involvement and religious participation of older patients. In recent years, the medical community has become increasingly interested in the role that religion or spirituality plays in the lives of patients. When patients refer to their faith or spirituality, there are at least three possible aspects of this experience: religion, religious participation, and religiosity. Religion refers to attachment to a formal organization, denomination, or set of formal beliefs. Religious participation involves attendance, particularly its frequency, and is associated with the concept of social integration. Religiosity refers to the personal or intrinsic meaning associated with specific religious or spiritual practices; it can be associated with coping. Patients’ lives may include all, some, or none of these components. Each is hypothesized to have a different relationship to health and illness. In the next section, we provide an overview of the most recent evidence linking religion and spirituality with health.²⁹

Onset of Illness

Research has shown significant relationships between religion and a reduction in the onset of a variety of physical illnesses, including coronary disease and myocardial infarction, emphysema, cirrhosis and other liver disease, hypertension, and disability. Of the multiple dimensions of religion, religious participation is the strongest predictor of prevention practices, longevity, and reduced mortality.²⁹

Recovery from Illness

Research suggests religion can influence the trajectory of illness. It is associated with better recovery patterns among heart transplant patients, reduced risk of heart attacks, reduced mortality among breast cancer patients, increased tolerance of pain, and higher quality of life. Religious coping is the dimension most strongly related to recovery.²⁹

Mental Health and Substance Abuse

Religious involvement has been shown to be associated with reduced likelihood of anxiety disorders, depression,

and alcohol and drug abuse and dependence. It also is associated with increased likelihood of recovery from mental illness and substance abuse or dependence. Religious participation is the dimension most strongly associated with better mental health.²⁹

Evidence linking religion to health and illness proposes three possible mechanisms. First, many religions encourage healthy behaviors. These differences also can be seen between religious denominations. For example, Mormons, Seventh Day Adventists, and members of other religions with strict behavioral prohibitions around health, on average, are healthier and live longer. Second, religious participation may offer a form of social support and thereby be associated with improved health outcomes. Finally, although the studies exploring the mechanisms of religious coping and health are limited, research suggests religion may buffer the effects of stress via an increased sense of coherence or meaning.²⁹

Although it is important to know the evidence regarding religion and spirituality and health outcomes, a more essential clinical question may be what patients want from physicians in relation to their religion or spirituality. A number of recent studies document the overwhelming importance of religion for patients, and most suggest patients would like their physicians to acknowledge its importance in their lives. Specifically, one investigation found that 77% of patients said physicians should consider patient spiritual needs, 37% wanted their physician to discuss religious beliefs with them more frequently, and 48% wanted their physician to pray with them. Interestingly, 68% said their physician had never discussed religious beliefs with them.³⁰ In another study, 70% of patients said they would welcome the question, “Do you have spiritual or religious beliefs that would influence your medical decisions if you became gravely ill?” The large majority of patients (84%) answered affirmatively. However, only 15% recalled ever being asked this.³¹

In one study, an overwhelming majority (more than 85%) of patients rated prayer and coming to peace with God as an important component of end-of-life care; in fact, patients ranked coming to peace with God as equal in importance to freedom from pain.³² There was less consensus, however, about the role of the physician regarding patient spirituality issues: 50% agreed that they wanted to discuss spiritual beliefs with their doctor, and 50% felt otherwise. These results reinforce the notion that spirituality is a highly individual value; cues about its expression must come from the patient. Furthermore, these results imply that resolving the spiritual needs of patients may not be the physician’s responsibility, but that acknowledging the existence of such needs and making appropriate referrals is a way of affirming the whole person.

Caregiver Issues

Many elderly patients presenting to geriatricians for evaluation or follow-up are accompanied by their informal caregivers. These providers are most often related to the older patient, such as a spouse or adult child, but also may be a close personal friend. Geriatricians know that it would be impossible for many of their elderly patients to function in noninstitutional settings, were it not for this occasional or routine assistance. Caregivers provide the critical support that compensates for the older person's limitations caused by chronic illness, disability, or physical or mental frailty. Their dedication stems from deep commitments to their elderly loved ones and because the need for long-term care exceeds formal services and public policy support. Many elderly caregiving spouses take seriously their marital vows, "til death do us part," and adult child providers tend to assume the caregiving role because of desires to reciprocate help that their parents once gave to them. In this section we describe the informal caregivers that geriatricians should expect to meet in their practices, what challenges they face as caregivers, the consequences of meeting those challenges, and why geriatricians should be aware of these informal providers functioning.

Who are the caregivers? The National Academy on an Aging Society recently profiled elderly care recipients and their informal caregivers using Wave 1 data from the NIA-funded study of Assets and Health Dynamics Among the Oldest Old (AHEAD).³³ From this, we learn that some 8.5 million individuals over age 70 are impaired in activities of daily living (ADLs; e.g., using the toilet, eating) or instrumental activities of daily living (IADLs; e.g., taking medications, making phone calls), such that some level of assistance is necessary for them to function in the community. By 2030, this number may be as high as 21 million. For the practicing geriatrician, this translates to approximately two of five older patients in their practices who need assistance with one or more of these routine activities.

AHEAD data suggest that most caregivers are family members (72%), the majority of which are adult children (42%) and spouses (25%), and identifies significant ethnic variation in typical caregiving arrangements. For example, white elderly patients tend to receive help from spouses, Hispanics from adult children, and blacks from informal providers outside the family. Most of the caregivers surveyed provide daily care; about 21% assist several times a week. The large majority (80%) allocates up to 5 h of assistance per day, and a small group, approximately 7%, provides care 24 h a day.

Clearly caregiving can be and usually is time consuming, labor intensive, and stressful. In shouldering this

burden, caregivers often experience substantial levels of emotional distress and physical exhaustion. Caring for an elderly individual with physical impairment involves organizing ADLs and orchestrating medical and home care arrangements. Caring for an elderly person with cognitive impairment requires this same organization of ADLs and health services, plus additional burdens associated with progressive memory loss, complex decisions about health care, legal arrangements and finances, personal control and autonomy issues, challenging behavior problems and communication deficits, and anticipatory grief.

Overall, about 15% of caregivers in the AHEAD study reported experiencing a physical or mental health problem because of their caregiving responsibilities. Among dementia caregivers, links have been found between caregiving and anxiety and depression symptomatology, psychotropic drug use, lower ratings of self-rated health, less optimum health-related behaviors such as getting enough exercise or sleep, and changes in immune function.³⁴ Perhaps the most provocative research to date, from a population-based cohort, suggests that being an elderly spousal caregiver under mental or emotional strain is an independent risk factor for mortality.³⁵

Clearly all caregivers, but especially those coping with progressive dementia disorders in their care recipients, constitute a vulnerable population at high risk for adverse health consequences, including death. Geriatricians attempting to identify caregivers in their practices that may be at risk for adverse health outcomes are aided by two sets of caregiver characteristics identified by Schulz.³⁴ The first set includes characteristics associated with adverse health outcomes in any population, such as being female, low means, high stress, and lower feelings of mastery. Two aspects of caregiving, severity of patient problem behaviors and extent of patient cognitive impairment, complete the risk factor profile.

The wealth of data identifying health risks associated with informal care provision underscores the importance of family assessment in geriatric patient evaluations. Clinicians should inquire about the level (unskilled versus skilled) and intensity (occasional, daily, round-the-clock) of care and the caregiver's needs for additional assistance or services. By identifying at-risk caregivers and referring them to appropriate community resources or to other health care professionals before irreversible health problems arise, geriatricians increase the likelihood that dedicated caregivers continue to provide care and that elderly impaired patients are able to age in place. As most clinicians are acutely aware, however, not all presumably supportive relationships are, in fact, supportive. Some compromise or seriously threaten an elderly patient's health and well-being.

Elder Mistreatment

Caregiving relationships sometimes exacerbate physical violence or other forms of elder mistreatment including verbal, financial, sexual, or emotional abuse, abandonment, or intentional neglect. An in-depth analysis of elder abuse can be found in Chapter 72; the discussion here focuses specifically on elder mistreatment within the informal dementia caregiving relationship. Geriatricians hold key positions to detect such abuse because of the frequency with which they interface with older patients and their family members and are required by statutes in the majority of U.S. states to report suspected abuse to adult protective services. For an in-depth discussion of the physical, emotional, and behavioral indicators of possible elder mistreatment, see Gall and Szwabo in the fourth edition of the *Geriatric Review Syllabus*.³⁶

Among caregivers of elderly persons with dementing disorders, abuse by spouses is more common than abuse by children.^{37,38} Pillemer and Suito suggest that elder mistreatment is more likely to occur when a potential perpetrator has problems, such as mental illness or substance abuse, when the recipient of the abuse is financially or otherwise dependent on the abuser, in socially isolated environments, and in the presence of external stress.³⁸

Research suggests that characteristics of the dementia caregiver, such as older age, being the patient's spouse, and experiencing some form of violence from the cognitively impaired patient, increase the likelihood that caregivers act violently. Geriatricians should be knowledgeable of assessment components of quality care: *physical abuse* (e.g., excessive sedation, restraining to bed or chair, hitting/pinching), *psychologic abuse* (e.g., threats or physical force or to institutionalize, locking in room), *physical neglect* (e.g., failure to provide food, medical care, safe environment), *psychologic neglect* (e.g., failure to provide affection or to include in family celebrations), and *exploitation* (e.g., theft or misuse of resources).³⁹ Asking about the nature of informal care may identify the need to refer caregivers for support services to prevent elder mistreatment from occurring or escalating.

In assessing elder mistreatment, it is important to ask, in separate sessions, the caregiver and the patient about their relationships with each other; this provides an opportunity for each to speak privately and frankly. Geriatricians suspecting mistreatment problems need to consider the safety of sending the older patient back home, the services that may be available to reduce caregiver stress, and the need for closer than usual follow-up. Fortunately, most home care situations involving caregivers and elderly care recipients do not involve abuse. Most informal caregivers are deeply committed to the health

and well-being of their care recipients and work to help them age as successfully as possible.

Successful Aging

Since the publication in 1976 of *The Quality of American Life* by Campbell, Converse, and Rogers, social scientists have understood that definitions of successful aging include multiple domains, including education, income, health, marriage, children, and neighborhood and community life. Gerontologic studies subsequently demonstrated the obvious, that most older adults do not expect to age well at all times across all these domains. Campbell and associates also contributed an important distinction between "satisfaction" with life or the perception that goals have been achieved, and "happiness," a positive affective state. Specifically, they observed that younger persons are more likely than older persons to be happy and that older people are more likely than younger individuals to be satisfied. Over the next several decades, social scientists repeatedly observed that older persons typically want to live well, to age "successfully," adaptively, or in some other way that signifies that living is more than surviving.

Geriatricians have been understandingly hesitant in addressing such concepts as aging well or successful aging, primarily because they observe firsthand the heterogeneity of the older population and know that there cannot be any single pattern of successful aging. In addition, their clinical assessment processes rely largely on objective indicators of health, illness, and function; concepts such as successful aging appear value laden and proscriptive rather than objective and descriptive. From a practical standpoint, the notion of successful aging presents a complexity requiring data about a wide range of parameters that attempt to capture the essence of an elderly person's life. Such breadth is increasingly difficult or impossible to cover in busy practice settings. Yet despite these reasons for not thinking in terms of aging successfully, all geriatricians devote their energies to facilitate aging well.

The most significant articulation of the successful aging concept occurred with the publication of results from the MacArthur Foundation successful aging studies in a recent volume by Rowe and Kahn, entitled *Successful Aging*.⁴⁰ The authors merged their perspectives from geriatrics and social science, rejected the established approach of studying aging in terms of decline, and used data to show that lifestyle choices rather than genetic inheritance are key factors that determine how successfully people age. Basically, Rowe and Kahn point to three tightly interrelated critical components of successful aging: avoidance of disease, lifestyle choices, and engagement with life. Obviously, the avoidance of acute and chronic disease is criti-

cal. However, equally important are certain lifestyle choices that maintain or improve physical and mental function and social engagement with life.

More specifically, the MacArthur studies showed that one of the most statistically significant predictors of maintaining cognitive functioning with age was the older patient's sense of self-efficacy, or the belief in one's own ability to handle various situations. Rowe and Kahn call self-efficacy the "can-do factor."⁴⁰ Other predictors were physical exercise, education, and lung function. People demonstrating this "can do" attitude also demonstrated higher levels of productivity (e.g., gardening, homemaking, volunteering). Physical functioning was more dependent on an elderly person's level of social support, specifically emotional support as opposed to instrumental support or tangible assistance. Elderly with higher levels of emotional support (i.e., expressions of affection, respect, love, encouragement) were more likely to engage in physical activity, such as brisk walking and substantial housework, whereas instrumental support (direct, hands-on assistance, provision of resources) was associated with lower physical performance. These data suggest the importance of providing adequate emotional support to older persons, but at the same time not limiting their autonomy by doing things that they are able to do themselves.

Perhaps the most exciting conclusion of these studies is that lifestyle factors and choices, such as adopting a positive attitude about meeting challenges (i.e., self-efficacy), engaging in routine exercise, and seeking opportunities to engage others are modifiable. With this knowledge, more geriatricians currently are shifting their goals from identifying and managing disease to preventing or delaying disease and promoting health. Because many older individuals have multiple comorbid illnesses, delaying the onset of one condition through lifestyle changes may also reduce risks associated with the development of other medical problems as well. More aggressive attempts to modify risk in elderly patients through exercise, diet, and efforts to detect and prevent disease are important. However, recent data on successful aging suggest that to reduce the total period of disability for any one patient, efforts should be made to enhance patient self-efficacy by promoting their beliefs that challenges can be met and by encouraging close relationships with others. Geriatricians should make their older patients aware that they are more responsible than anyone else for their own health in later life.

Summary

We began this chapter by acknowledging the geriatric perspective as broadly comprehensive with a focus on the "whole person"—biological, philosophical, and psy-

chosocial. Regarding the psychosocial component, we posed two questions. The first sought to identify the psychosocial aspects of aging likely to affect clinical outcomes, and the second challenged us to make recommendations to geriatricians on how best to assess these aspects of their patients during standard clinical encounters. To address the first, we examined the evidence linking seven psychosocial factors to later life health: social characteristics of the older patient (i.e., gender, race, and socioeconomic status); historical influences (i.e., military experience); social relationships; spirituality; caregiving; elder mistreatment; and behaviors linked to successful aging. The potential for each of these domains to affect older patient health and well-being suggests their importance in geriatric assessment practices. The second question asked how best to assess elderly patients along these dimensions. The following questions may assist clinicians in probing these domains with the goal of identifying modifiable areas.

Gender, Ethnicity, and Socioeconomic Status

- Observe gender and inquire about education or years of formal schooling. Assess level of knowledge; do not assume. For example, older patients with lower levels of education have been shown to confuse the concept of a living will with a legal or financial document.
- In the absence of financial information (e.g., income, assets), geriatricians can probe their patients' *perceived* adequacy of financial resources, often a more powerful predictor of well-being than objective income. "Are your bills difficult to meet? Does your money take care of your needs? Can you afford to buy those little extras, that is, those small luxuries?" Such questions may open doors for discussion of unmet needs.

Historical Influences (Military Experience)

- Are you a veteran? Which war? Did you experience combat? If yes, probe into the meaning of that experience in day-to-day life. Consider potential links between chronic stress and CAD. If patient mentions PTSD symptoms (e.g., nightmares, flashbacks, or re-experiencing), make appropriate referral.
- Were you born in the United States? If not, were the circumstances of immigration likely to be traumatic (e.g., Holocaust, revolution)?

Social Relationships

- The structure of a patient's social networks can be appreciated by asking about the people with whom the patient interacts and the assistance, if any, provided by those persons. For example, with whom do you live? One of the strongest predictors of noninstitutionalization is presence of a spouse. How many people are in your support network? What kinds of things do they do for you? How often?
- The adequacy of emotional support can be probed by such questions as the following: "Do you feel supported by and close to those around you?" "Do you feel the need for more assistance than you are currently receiving?" "Is there someone in your life with whom you can discuss your deepest concerns and feelings?"
- Whom would you contact if you needed help?

Spirituality

- What role does faith or spirituality play in your life? This brief question may help the clinician understand for whom spiritual activity (including formal religious participation and private practices) is a critical component in coping with illness, decision making, and general well-being.

Caregiving

- Determine caregiver status by asking patient or family member if they are "providing care for anyone on a routine basis." If yes:
- Ask about the intensity of care provision (primary versus secondary provider, daily basis or less often) and type of care (personal management, household, physical care).
- Identify potential stressors (use of alcohol or drugs to cope) and feelings of helpless and hopelessness that could lead the caregiver to mistreat the patient.
- Ask about the caregiver's needs for assistance—what would help caregiver most (e.g., support group, respite, in-home care, sitter service, chore worker).

Elder Mistreatment

- Ask the patient if problem behavior exists in the family, such as acts of violence or excessive force. "Has anyone tried to hurt or hit you?" "Has anyone made you do things that you did not want to do?" "Has anyone taken your things?"

- The next steps may involve notifying Adult Protective Services or other state-specific agencies and creating a safety plan for the patient.

Successful Aging

- Are measures being taken to avoid disease and maintain optimal cognitive and physical function (e.g., scheduling regular checkups, eating a nutritious diet, engaging in regular, moderate physical activity, and avoiding high-risk behaviors such as smoking)?
- Does the patient cope well with setbacks?
- In general, does the patient have a positive attitude?
- Is the patient socially connected and engaged with life?

Principles of Pharmacology

Jerry Avorn, Jerry H. Gurwitz, and Paula Rochon

It is much easier to write upon a disease than upon a remedy. The former is in the hands of nature and a faithful observer with an eye of tolerable judgement cannot fail to delineate a likeness. The latter will ever be subject to the whim, the inaccuracies, and the blunder of mankind.

William Withering, 1741–1799

The proper use of medications represents one of the most crucial ways in which the practice of geriatric medicine differs from conventional medical care. Pharmacotherapy is probably the singly most important medical intervention in the care of elderly patients, and its appropriate implementation requires a special understanding of the unique pharmacologic properties of drugs in this population, as well as a grasp of the clinical, epidemiologic, sociocultural, economic, and regulatory aspects of medication use in aging.

Pharmacokinetics

Of the four traditional components of pharmacokinetics—absorption, distribution, metabolism, and excretion—only the last three are meaningfully affected by age. In the absence of malabsorptive syndromes, traditional oral formulations of drugs are absorbed as well in old age as in youth. Of course, the same concerns apply in elderly patients as in those of any age concerning the possible adsorption of medications by antacids and the relation between the ingestion of meals and the taking of medications. However, the well-reported changes in gastric motility and blood flow to the gut with aging do not appear to alter meaningfully the efficiency with which medications move from the gastrointestinal tract into the systemic circulation.^{1,2} Nonetheless, many slow-release drug preparations have undergone little or no study of potential age-related changes in their delivery rates. Similarly, data on the kinetics of transdermal, transbuccal, and transbronchial drug administration in the elderly are too limited to allow conclusions regarding age-related

changes in drug absorption via those routes,³ even though the elderly are among the most prominent users of such drug delivery systems.

Another aspect of drug distribution that is likewise not affected by normal aging is the binding of drugs to carrier proteins such as serum albumin. In large populations, clinically meaningful decreases in serum albumin have not been found, although there is a very modest reduction with advancing age.^{4,5} Previous studies that purported to show a large age-related decline in serum albumin levels were probably marred by the problem of confounding illness with aging. Despite these observations on serum proteins in healthy aging, it is crucial to consider that serum albumin levels may be markedly decreased in older patients suffering from malnutrition or severe chronic disease,^{6,7} with important consequences for drug binding.

One of the more important risks of diminished binding proteins is an iatrogenic one, resulting from misinterpretation of serum drug levels. Many assays measure the total amount of drug that is present in serum, both protein-bound and unbound (“free”). The unbound concentration is more clinically relevant than the total concentration because only unbound drug is pharmacologically active. For a patient with hypoalbuminemia or another deficiency in binding protein, any given serum drug level reflects a greater concentration of unbound drug than the same level would signify in a patient with normal protein-binding capacity. A hypoalbuminemic patient with a “normal” total serum drug concentration may actually have an unbound drug concentration that is unacceptably high. By contrast, the same patient with a slightly lower than normal total serum concentration may have an unbound drug concentration that is in a reasonable range. For extensively protein-bound drugs whose binding is reduced as a result of hypoproteinemia, clinicians should expect both therapeutic and toxic events at lower total serum concentrations.⁸ Phenytoin, which is highly bound to albumin, is one example of a drug for

which the interpretation of serum levels reflecting total drug concentration (rather than the free drug concentration) can be difficult in malnourished or chronically ill elderly patients.

In evaluating serum drug levels in the older patient, it is also important to recall that the therapeutic range routinely reported on such assays may not be an accurate guide to either efficacy or toxicity in the geriatric patient. Such ranges have typically been defined in nonelderly subjects and cannot take into account pharmacodynamic differences (see following) or idiosyncratic aspects of specific patients.

One aspect of drug distribution that varies importantly with age is the volume of distribution, which is the theoretical space in a given patient which a particular drug occupies. The volume of distribution is heavily influenced by the relative proportions of lean body mass versus fat. Because the latter increases in the elderly at the expense of the former, lipid-soluble drugs (such as some benzodiazepines) will have a greater volume of distribution in an older patient and water-soluble drugs (such as lithium) will have a smaller volume of distribution.⁹ Combined with changes in clearance (discussed below), these alterations in body composition can have important implications for both the half-life and the steady-state concentration of many medications. Women comprise an increasingly large majority of the aging population, making it important to also consider gender differences in drug distribution and effects. Women have a lower lean body mass compared with men at all ages, and there may be gender differences in other pharmacokinetic and pharmacodynamic functions as well.¹⁰

Drug Clearance and Aging

The liver represents the major site of metabolism for many medications. Hepatic biotransformations of drugs are categorized into phase I (preparative) and phase II (synthetic) reactions. Phase I reactions include oxidations (hydroxylation, N-dealkylation, and sulfoxidation), reductions, and hydrolyses. Phase II reactions involve conjugation of the drug molecule to glucuronides, sulfates, or acetates.

Earlier studies in animals had suggested that normal aging is accompanied by reduced activity of liver microsomal drug-metabolizing enzymes as well as diminished microsomal enzyme induction, but data on hepatic drug metabolism in aging human subjects are much more limited. However, it is clear that normal aging is associated with a reduction in the liver mass, as well as in hepatic blood flow. These changes are likely responsible for the reduction in hepatic metabolism of drugs, which can be as great as 25% over the life span.^{11,12} Autopsy and

ultrasound studies have found a progressive decrease in liver mass after age 50. Regional blood flow to the liver at age 65 is reduced by 40% to 45% relative to that in a 25-year-old; this observation may partially reflect a fall in cardiac output with advancing age. Such changes can also result in reduced clearance rates for drugs exhibiting flow-dependent clearance characteristics ("first-pass effects").¹³

Antipyrine is frequently used as a marker compound to evaluate hepatic metabolizing capacity. Although many studies have reported reduced metabolic clearance of antipyrine in older subjects, as with many age-related differences interindividual variation is substantial.¹⁴ This finding suggests that genetic, environmental, and other patient-specific factors often have a greater important on hepatic drug metabolism than the aging process itself. Therapeutic considerations therefore should be based on individual patient characteristics as well as expected physiologic changes due to aging.

Renal Excretion

Several commonly used drugs are excreted primarily by the kidney, including digoxin, ranitidine, and the aminoglycoside antibiotics.¹⁵ Early cross-sectional studies of renal function in aging suggested that there is a linear decrease in renal function between young adulthood and old age, amounting on average to a reduction in glomerular filtration rate by nearly a third.¹⁶ Although this is true in the aggregate, longitudinal studies indicate that some subjects evidence no changes or only small changes in creatinine clearance with advancing age; another subgroup showed a linear decrease with age; still others appeared to show some improvement in renal function as they became older.¹⁷ Thus, although the aggregate findings have been enshrined in conventional gerontologic wisdom and in nomograms used to calculate drug dosing with age, these longitudinal studies make it clear that the effect of age on renal function (and therefore on the excretion of many drugs) can be quite variable. Here, too, differences among patients often will be as important as the changes attributed to the aging process itself.

Although blood urea nitrogen (BUN) and serum creatinine levels may be useful (albeit crude) markers of renal function, it must be remembered that each is susceptible in its own way to perturbations that can occur with aging but have nothing to do with renal function itself. For example, the BUN reflects the concentration of urea in the blood. However, the origin of much of this urea is ingested protein, so that a malnourished older patient may not consume enough nitrogen to produce an appropriate rise in BUN, even in the face of renal impairment. Similarly, serum creatinine is produced by muscle,

and if a patient has a markedly diminished muscle mass, whether because of chronic illness or any other cause, he or she may not produce enough creatinine to reflect a change in the ability of the kidney to excrete this substance. Thus, overreliance on “normal-appearing” BUN and creatinine in older patients can severely underestimate the degree of renal impairment.

The Cockcroft–Gault formula¹⁸ is sometimes used to estimate renal function in older patients who are to receive potentially nephrotoxic drugs (e.g., aminoglycosides) or drugs that are primarily excreted by the kidneys (e.g., digoxin):

$$\begin{aligned} &\text{Estimated creatinine clearance} \\ &= \frac{(140 - \text{age}) \times (\text{body weight in kg})}{\text{serum creatinine} \times 72} \end{aligned}$$

(for women, multiply $\times 0.85$).

It should be emphasized that these estimates are valid only in patients whose renal function is in steady state and who are not taking medications that directly alter renal function or affect creatinine excretion. This formula has some utility in assessing renal function in healthy ambulatory individuals, but it has limited utility and can be misleading in severely ill, clinically unstable, elderly patients.¹⁹

Drug Elimination Half-Life and Steady-State Concentration

The elimination half-life of a medication ($t_{1/2}$) is determined by the volume of distribution (V_d) for that medication in a given individual, divided by its clearance (Cl) in that subject (generally through metabolism in the liver and/or renal excretion); this can be expressed as follows:

$$t_{1/2} = 0.693 \times V_d / \text{Cl}$$

Thus, the half-life of a medication will increase as the clearance (Cl) decreases if the volume of distribution (V_d) remains constant. If the volume of distribution is also increased (as with a lipophilic drug in an older patient), the half-life will be prolonged still further.²⁰

The clinical implications of these pharmacokinetic relationships are illustrated by the benzodiazepine hypnotic flurazepam. In a study comparing the kinetics of flurazepam in young and elderly subjects, the drug was found to have an elimination half-life of 160 h in elderly men, compared with 74 h in young men.²¹ This difference probably is accounted for by an age-related reduction in the clearance of flurazepam by the oxidative pathways in the liver and an increase in the volume of distribution for this highly lipid-soluble drug. The clinical impact of such massive prolongation of flurazepam half-life is fur-

ther magnified by its biotransformation into the active metabolite desalkylflurazepam, which also has benzodiazepine effects on the central nervous system.

It is frequently assumed that the duration of clinical action of a drug is related to its half-life. Under this assumption, long elimination half-life implies a long duration of action and short elimination half-life implies a short duration of action. Although this presumption is sometimes incorrect,²² some epidemiologic data support an association between use of agents with long elimination half-lives and the occurrence of drug side effects in the elderly.^{23–25} However, other observational studies suggest that dose is a more important determinant of risk than half-life.

Steady-State Drug Concentration

A common goal of long-term pharmacotherapy is to achieve and maintain a therapeutic steady-state serum concentration. The steady-state drug concentration is proportional to the medication dosing rate (dose/dosing interval) and is inversely proportional to drug clearance. Assuming complete bioavailability, the equation for steady-state concentration (C_{ss}) can be expressed as follows:

$$C_{ss} = (\text{dose/dosing interval}) / \text{clearance}$$

This equality has a number of important ramifications for the prescriber. Although drug clearance is a biologically determined characteristic of each patient over which the prescriber has no control, dose and dosing interval are variables that can be modified. To prevent the excessive accumulation of a drug when its clearance is reduced (as is often the case in an elderly patient), one can reduce the dose, increase the interval between doses, or both, depending on the situation.²⁶

Pharmacodynamics

Pharmacodynamic changes with aging (i.e., end-organ effects) have been more difficult to define than pharmacokinetic changes. The study of this phenomenon is complicated by the fact that the effect of many drugs is magnified in the elderly because of reduced drug clearance, resulting in higher serum levels.²⁷ Therefore, in studying the effects of aging on pharmacodynamics, one must control for the age-related changes in pharmacokinetics already discussed. A small but growing number of ingeniously conducted studies are helping to clarify the unique contribution of age-related pharmacodynamic changes to the overall picture of drug response in aging.

One of the first studies describing changes in drug sensitivity with aging involved patients between the ages of 30 and 90 years who underwent elective cardioversion.²⁸ The clinical endpoint used was the patient's inability to respond to voice, with preservation of response to a painful stimulus. The serum level of diazepam at which this effect occurred was significantly lower in elderly patients than in younger ones, suggesting that the older brain was sensitive to smaller concentrations of circulating drug. Analogous findings emerged from a study of the performance of patients given a single dose of another benzodiazepine, nitrazepam.²⁹ Serum levels of the drug were similar in both young and old, but elderly subjects showed a deterioration in performance on psychomotor testing after administration of a single dose of the drug, while comparable deterioration was not seen in younger patients. Similarly, in another study of i.v. midazolam, a lower dose was administered to older patients compared with younger ones, overcoming the expected pharmacokinetic differences between the two age groups. However, elderly subjects still demonstrated greater sedation than younger subjects, probably because of greater central nervous system sensitivity.³⁰ Details of the neuroreceptor explanation for such changes in intrinsic sensitivity to these agents are still obscure. In vitro assessment of benzodiazepine receptor binding and function in brain tissue from young and aged rodents has not revealed clear age-related differences in benzodiazepine receptor number or affinity.³¹ Age-related changes in pharmacodynamics can result in greater therapeutic effect as well as an increased potential for toxicity. Increases in medication sensitivity with age have also been suggested for a number of other medications, including warfarin³²⁻³⁴ and the opioids.

Special care must be taken in drawing conclusions from the results of studies examining age-related changes in pharmacodynamics.³⁵ The interpretation of results of some pharmacodynamic investigations may be complicated by baseline differences between young and elderly study populations, which in turn may confound assessment of drug-associated changes.³⁶ For example, in a study examining the effects of diphenhydramine on psychomotor performance, impairment was reported to be unaffected by the age of subjects when differences were expressed as the percentage change from baseline.³⁷ However, in absolute terms, the elderly demonstrated a greater impairment (expressed as time required to react to a stimulus) than did younger subjects; this yielded a similar percentage change because at baseline younger subjects performed better than older subjects. Thus, the presentation of research data in terms of percentage change from baseline (rather than absolute change) can obscure clinically important differences in pharmacodynamic effects between young and old study groups.

Recognizing and Preventing Adverse Drug Events in Older Adults

Many hospital-based studies have suggested that risk for the occurrence of adverse drug reactions increases with advancing age.³⁸ Unfortunately, this finding is of limited usefulness in guiding medical practice because most investigations have assessed all adverse drug reactions from all medication exposures as a single outcome category. Most studies have not controlled for important variables including the clinical status of the patient, length of hospitalization, and number of medications taken concurrently.

Assessing risk for adverse drug reactions in the individual elderly patient remains a difficult clinical challenge. Patient-specific physiologic and functional characteristics are probably far more important than chronologic age in predicting either the adverse or beneficial effects of specific therapies.³⁹ Nonetheless, from a population standpoint, older patients consume far more medications than younger patients. Taken together with the age-related pharmacologic changes described here, the physiologic declines associated with aging, and the increasing burden of chronic illness in the older population, assessing and reducing the risks for adverse drug effects becomes critically important in the practice of geriatric medicine.

Adverse drug effects can mimic almost any clinical syndrome in geriatrics. Clinicians are most familiar with mental status changes as adverse effects of psychoactive drugs in the elderly;⁴⁰ indeed, one study of reversible dementia found that drug-induced cognitive impairment was among the most common and treatable causes of syndromes that could be mistaken for dementia in the elderly.⁴¹ It is less commonly recognized that some "nonpsychoactive" medications (e.g., anticholinergics) also have the potential to cause central nervous system toxicity in elderly patients.^{42,43}

Equally important are the somatic side effects that can be caused by any drug, including psychoactive medications. Falls can be precipitated by a wide variety of drugs.⁴⁴ Drugs with strong anticholinergic properties run the gamut from antiarrhythmics to antipsychotics, and anticholinergic toxicity can be responsible for numerous symptoms apparently unrelated to the indication for which the drug was prescribed. Because acetylcholine serves as a neurotransmitter in numerous key roles in both the parasympathetic and central nervous systems, its blockade by medications with strong anticholinergic properties can yield a host of problems including dry mouth, constipation, urinary retention, blurred vision, and confusion. Conversely, cholinesterase inhibitors used in Alzheimer's disease, such as donepezil, can have the opposite effect: hypersalivation, diarrhea, nausea.

Another example of drug-induced illness is provided by the neuroleptic drugs often used for the management of behavioral disorders associated with dementia. These drugs can produce extrapyramidal effects including rigidity, bradykinesia, tremor, difficulty swallowing and walking, and loss of facial expression. When they occur, such side effects can be clinically indistinguishable from idiopathic Parkinson's disease. The most common offenders are the high-potency neuroleptic medications (e.g., haloperidol).

If the prescriber does not consider the possibility that neuroleptic therapy could be responsible for the patient's symptoms, additional drug therapy may be started inappropriately. Preferably, the neuroleptic therapy could be discontinued on a trial basis and nonpharmacologic approaches tried. If a neuroleptic therapy is required, it would be critical to choose the drug with the fewest adverse events.^{45,46} Because adverse effects are generally dose related, it is important to choose the lowest dose required for clinical benefit.⁴⁷ Prescribing an additional drug therapy to treat an adverse drug effect should be considered a last resort in the care of older patients.

Adverse Drug Effects Associated with Commonly Used Drug Therapies

A group of drug-related medical problems has been called the "prescribing cascade".⁴⁸ The prescribing cascade develops when a drug complication is mistaken as a new medical problem. Instead, a new drug is prescribed with the patient now placed at the additional risk of developing yet another drug-related problem as a result of the new drug therapy. There are numerous examples of prescribing cascades: the use of nonsteroidal anti-inflammatory drugs and the initiation of antihypertensive therapy,⁴⁹ the use of thiazide diuretic therapy and the initiation of treatment for gout,⁵⁰ and the use of metoclopramide followed by treatment with levodopa therapy.⁵¹ Finally, a patient who develops constipation while taking a strongly anticholinergic antidepressant such as amitriptyline has a resulting dependency on laxatives.^{52,53}

The diagnosis of drug-induced illness in elderly patients is further complicated by lack of awareness of the physiology of normal aging and the tendency by patients, families, and even physicians to mislabel many symptoms as signs of "just growing old." As a result, drug-induced incontinence, confusion, fatigue, depression, and many other problems may be attributed to the human condition, when they may well be amenable to appropriate diagnosis and therapeutic action. A useful antidote to these problems is a very high index of suspicion for drug-induced illness in elderly patients. An overstatement that

is of great clinical use and forms a good starting point for clinical evaluation can be stated as follows: "Any symptom in an elderly patient may be a drug side effect until proved otherwise."

Side Effects of Psychoactive Drugs

Psychotropic drugs have been associated with the occurrence of hip fracture in a number of epidemiologic studies. One study examining risk for hip fracture in older patients exposed to psychotropic medications indicated that a significantly increased risk was associated with use of hypnotic-anxiolytics with long (>24-h) elimination half-lives (odds ratio, 1.8; 95% confidence interval, 1.3–2.4), tricyclic antidepressants (odds ratio, 1.9; 95% confidence interval, 1.3–2.8), and neuroleptics (odds ratio, 2.0; 95% confidence interval, 1.6–2.6).⁵⁴ The long elimination half-life hypnotics-anxiolytics included flurazepam, diazepam, and chlordiazepoxide. More recent studies have suggested that it is the dose of benzodiazepine rather than the drug half-life that is the most important risk factor for drug-induced accidents.^{55,56} Until this issue is resolved, it is prudent to avoid both long-acting drugs and high doses of any benzodiazepine in older patients unless there is a compelling reason to do otherwise.

The tricyclic antidepressants most often implicated in drug-induced injury in the elderly include the older tertiary amines amitriptyline, doxepin, and imipramine. However, more recent findings^{57,58} suggest that risk of falls and fractures is seen as well with selective serotonin reuptake inhibitors (SSRIs) as well as with the older heterocyclic antidepressants. Indeed, one of these studies⁵⁹ found that depressed older patients appeared to be at increased risk of falls even before antidepressant therapy had been started.

Anticoagulants

Ample data exist regarding the benefits of anticoagulation in patients with atrial fibrillation.⁶⁰ Both a substantial increase in the incidence of nonrheumatic atrial fibrillation (AF) with age and an increased association between AF and stroke in the elderly have been found.^{61–63} The proportion of strokes that can be attributed to AF increases consistently with age, after adjusting for the effects of systolic blood pressure.

Long-term oral anticoagulant therapy with warfarin is essential for the management or prevention of many thromboembolic and vascular disorders whose prevalence is increased in elderly patients. In fact, anticoagulation in patients with chronic nonrheumatic AF can reduce the risk of stroke by more than two-thirds. However, willingness to initiate anticoagulant therapy in an older patient is often tempered by concerns about the

risk of bleeding, despite the fact that these patients may have the most to gain from anticoagulant therapy. The extent of anticoagulation, as reflected by the international normalized ratio (INR), is the dominant risk factor for hemorrhagic complications.⁶⁴ Several studies have presented conflicting findings on whether there is a greater risk of anticoagulant-induced hemorrhage in elderly patients, which may be explained to a large extent by differences in treatment setting and in the attention given to monitoring.^{65,66} Specialized anticoagulation consultation services and clinics can assess risks for bleeding, monitor closely for potential warfarin–drug interactions, and pay close attention to target therapeutic ranges. Risk of anticoagulant-related bleeding appears to be reduced when expert consultation is provided at the start of anticoagulant therapy and when patients are monitored in specialized anticoagulation clinics.^{67,68} Careful assessment of the appropriate indications for anticoagulant therapy, the optimal target INR, and the use of potentially interacting medications are the most important strategies for reducing the risk of bleeding complications in older patients.

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are very widely used in the management of arthritis; because the prevalence of degenerative joint disease increases substantially with advancing age, the elderly are among the most frequent users of these medications. The NSAIDs encompass several different chemical entities, each with the common ability to inhibit cyclooxygenase, a major enzyme in the synthesis of prostaglandins. It is important to consider, however, that prostaglandins also mediate a variety of important protective physiologic effects in a number of organ systems. For example, prostaglandins maintain renal blood flow and glomerular filtration in the face of a reduction in the effective or actual circulatory volume (e.g., congestive heart failure, cirrhosis with ascites, volume depletion due to diuretic therapy, and hemorrhage with hypotension). Under such conditions, vasodilatory renal prostaglandins mitigate vasoconstrictive effects on renal blood flow. In this way, renal perfusion is maintained, preventing prerenal azotemia and eventual ischemic damage to the kidney. When this prostaglandin-mediated compensatory mechanism is suppressed by NSAID therapy, impairment in renal function can result. A prospective study of elderly residents of a large long-term care facility who were newly treated with NSAID therapy demonstrated that 13% developed azotemia over a short course of therapy.⁶⁹ Risk factors associated with this adverse effect included higher NSAID dosage and concomitant loop diuretic therapy.

Prostaglandins also mediate a range of effects that protect the mucosa of the stomach and duodenum from injury; these include the inhibition of acid secretion, an increase in mucous secretion and bicarbonate, and enhancement of mucosal blood flow. When the biosynthesis of prostaglandins is impaired by NSAIDs, this can lead to impaired mucosal defense; acid and peptic activity can then produce ulcers. A meta-analysis of epidemiologic studies investigating the association between NSAIDs and severe upper gastrointestinal tract disease indicated that older patient age was associated with a higher risk of gastrointestinal toxicity.⁷⁰

The risks associated with NSAID use in the elderly emphasize the need for careful monitoring of patients with risk factors for NSAID-associated nephrotoxicity and gastropathy. To limit the occurrence of side effects, NSAID therapy should be limited to those clinical situations where it is absolutely required. The lowest feasible dose should be prescribed for the shortest time necessary to achieve the desired therapeutic effect. Because of the iatrogenic nature of these disorders, the best treatment for NSAID-associated nephrotoxicity or gastropathy is discontinuation of the NSAID. Alternative analgesic therapies are available and effective for many patients. For example, nonacetylated salicylates may be a safer alternative to NSAIDs. Another effective analgesic choice is acetaminophen. One study comparing the analgesic effects of acetaminophen (4 g/day) to ibuprofen (1.2 g/day and 2.4 g/day) in patients with osteoarthritis found no difference in pain relief in patients treated with acetaminophen compared to those given NSAID therapy.⁷¹ Although acetaminophen is free of NSAID-related side effects, its use should not exceed 4 g/day in most patients; its toxicity is increased in the presence of hepatic insufficiency, heavy alcohol intake, or fasting.⁷²

Recently, two cyclooxygenase-2 receptors (Cox-2 inhibitors) were approved for use in North America for arthritis treatment: celecoxib and rofecoxib.⁷³ Cox-2 inhibitors are similar to nonselective NSAIDs in terms of efficacy but have a more favorable side effect profile. However, adverse events, including gastrointestinal hemorrhage and reduced renal function, have been associated with use of Cox-2 inhibitors. Relative to nonselective NSAIDs, Cox-2 inhibitors are less likely to produce gastrointestinal ulcers, although ulcers do occur and this complication can be serious and even fatal.⁷⁴ The Cox-2 inhibitors have an effect on renal function similar to that of NSAIDs. A randomized controlled trial compared the effect of rofecoxib relative to indomethacin on glomerular filtration rates in 75 patients between the ages of 60 and 80.⁷⁵ The investigators found that the effect of the Cox-2 inhibitors was similar to that of nonselective NSAIDs in decreasing glomerular filtration rate. These findings indicate the need for caution when prescribing Cox-2 inhibitors for older adults.

The Context of Adverse Drug Effects in Frail Elderly

As the setting of care for more than 1.5 million Americans, the number of beds committed to nursing home care in the United States exceeds the number of acute care beds.⁷⁶ Of all types of therapeutic interventions, medications are the most commonly utilized in the nursing home setting. The average U.S. nursing home resident takes 6 different medications; more than one-fifth use 10 or more different drugs.⁷⁷

The occurrence of adverse drug events that may be preventable is among the most serious concerns regarding medication use in the nursing home setting. Few studies have systematically examined the incidence of adverse drug events in the nursing home population.⁷⁸ A retrospective review of incident reports relating to adverse and unexpected events in one academically affiliated, 700-bed long-term care facility identified 50 reports of adverse drug reactions over a 1-year period.⁷⁹ Skin rashes were the most frequently reported events, and antibiotics were the most commonly implicated medication category. The limited number of periodically documented reports of drug-related events in that study suggested that voluntary reporting systems in the nursing home setting lead to very low reporting rates of only a very narrow spectrum of events. In a recent study of all long-term care residents of 18 community-based nursing homes in Massachusetts over a 12-month observation period, drug-related incidents were detected by stimulated self-report by nursing home staff and by periodic review of all nursing home resident records by trained nurse and pharmacist investigators.⁸⁰ Incidents were subsequently classified by physician reviewers as to whether they represented adverse drug events, their severity (significant, serious, life-threatening, and fatal), and preventability.

During 28,839 nursing home resident-months of observation in the 18 participating nursing homes, 546 adverse drug events were identified (1.89 adverse drug events per 100 resident-months). Of all adverse drug events, 1 was fatal, 31 (6%) were life threatening, 206 (38%) were serious, and 308 (56%) were significant. Overall, 50.5% of adverse drug events were judged preventable. Of the 238 fatal, life-threatening, or serious adverse drug events, 72% were considered preventable, compared with 34% of the 308 significant adverse drug events. Errors resulting in preventable adverse drug events occurred most often at the stages of ordering and monitoring; transcription, dispensing, and administration errors were less commonly identified. Psychoactive drugs (antipsychotics, antidepressants, and sedatives/hypnotics) and anticoagulants were the most commonly implicated drug categories associated with the occurrence of preventable adverse

drug events (Table 7.1). Neuropsychiatric events (confusion, oversedation, delirium), falls, and hemorrhagic events were the most commonly identified preventable adverse drug events (Table 7.2).

Suboptimal prescribing of psychoactive medications in the nursing home setting has long been an issue of substantial concern,⁸¹ leading to federal regulations to control their use in this setting.⁸² Various interventions have been developed and tested to reduce the risks of psychoactive drug use in the nursing home setting.⁸³ “Academic detailing” to educate physicians and nursing home staff about the principles of geriatric psychoactive medication use has been utilized with success to improve the quality of drug prescribing, specifically in regard to antipsychotic medications and long elimination half-life benzodiazepine therapy.^{84,85}

Next to psychoactive drugs, anticoagulants have been found to be the next leading cause of adverse drug events in long-term care facilities. Concerns have been raised regarding the quality of anticoagulant use in the nursing home setting,⁸⁶ with evidence for both undertreatment and poor control of INR. A more systematic approach to decision making regarding the use of warfarin for stroke prevention in the frail elderly is required, as well as a more consistent approach to the management of therapy. More widespread use of specialized anticoagulation clinics to provide coordinated anticoagulation care may offer an option to improve the effectiveness and safety of warfarin therapy in this particularly high-risk group of patients.

If the findings of the study just described are generalizable to all U.S. nursing homes, then one would predict that at least 24 adverse drug events and 8 potential adverse drug events would be identifiable over a 1-year period in the average facility, with half of these adverse drug events being preventable. Thus, in the 1.5 million residents of U.S. nursing homes, as many as 350,000 adverse drug events are likely to occur annually, with more than half preventable. Similarly, almost 20,000 fatal or life-threatening adverse drug events would be expected per year in nursing homes, of which 80% are likely to be preventable.

One flawed approach to preventing medication errors emphasizes seeking out and punishing health care providers who make errors that lead to adverse drug events. However, this ignores the fact that failures in the design of systems of care often contribute to the occurrence of medical errors, as well as the injuries that result from some of those errors.^{87–90} Instead, enhanced surveillance and reporting systems for adverse drug events occurring in the nursing home setting are required, along with continued educational efforts relating to the optimal use of drug therapies in the frail elderly patient population. However, preventive efforts that focus solely on the individual provider or which rely on inspection alone

TABLE 7.1. Frequency of adverse drug events and potential adverse drug events by drug class.^a

have limited impact. As Leape has noted, "Analysis and the correction of underlying systems faults is much more likely to result in enduring changes and significant error reduction."⁸⁹

A systems-based approach to addressing the problem of medication errors emphasizes that the most important cause of error is faulty systems or design. Such approaches include improving information access for health care providers at the time drugs are prescribed,⁹¹ reducing reliance on memory by standardizing approaches to clinical management (e.g., use of protocols when appropriate), and enhancing the education and training of health care professionals around the principles of geriatric pharmacotherapy.⁹² As stated in the recent Institute of Medicine report entitled *To Err Is Human: Building a Safer Health System*, "Errors can be prevented by designing systems that make it hard for people to do the wrong thing and easy for people to do the right thing."⁹³

Ordering and monitoring errors in the nursing home may be particularly amenable to prevention strategies utilizing systems-based approaches. The benefits of such an approach to error reduction in the hospital setting utilizing computerized order entry have recently been reported; such a system could be designed to focus on ordering and monitoring issues in the nursing home.⁹⁴

Successes in the hospital setting pave the way for similar efforts in the nursing home setting aimed at reducing drug-related injuries and disability and improving the quality of care provided to the frail elderly patient population.⁹³

Clinician Initiatives in Preventing Adverse Drug Events

Explicit criteria have been published for determining potentially inappropriate medication use by the elderly,^{95,96} but most drug-related problems for the elderly are caused by medications that are not on any "bad drug" list. Nonetheless, such criteria are increasingly utilized in quality improvement efforts by health care systems and managed care plans. However, it should be recognized that these criteria generally cover a relatively small number of agents, some of which are rarely used in current practice.⁹⁷ Most suboptimal prescribing relates to drugs that are not included on these lists. Common examples include the excessive use of antibiotics for nonbacterial infections,⁹⁸ overuse or misuse of "acceptable" psychoactive drugs in all categories, and suboptimal management

TABLE 7.2. Frequency of adverse drug events by type.^a

Type	Adverse drug events, total (<i>n</i> = 546) <i>n</i> (%)	Preventable events (<i>n</i> = 276) <i>n</i> (%)
Neuropsychiatric	150 (27)	83 (30)
Falls	67 (12)	55 (20)

Hepatic	1 (0.2)	1 (0.4)

^a Adverse drug events could manifest as more than one type.

^b Adverse drug event manifested only as decline in activities of daily living without any other more specific type of event. Other types of events may have been associated with functional decline.

^c Anticholinergic effects include dry mouth, dry eyes, urinary retention, and constipation.

of warfarin therapy in patients with appropriate indications for treatment (e.g., chronic atrial fibrillation).⁹⁹

There are a number of steps that prescribers can take to minimize the risk of adverse drug events in the elderly outside or within long-term care facilities. First, the physician must be aware of precisely what medications the patient is taking, which is best accomplished by a rigorous periodic review (at least every 6 months in a stable patient) of *all* medications taken by each elderly patient. Careful drug regimen review has been said to be one of the most useful interventions available to modern geriatric medicine, yet it fails to receive the attention it merits. Particular attention should be paid to eliciting information about medications that are (1) prescribed by another physician, (2) used only sporadically, (3) obtained over the counter, or (4) taken by some route other than by mouth and hence often not thought of by patients as “drugs” (e.g., eyedrops for glaucoma, estrogen or steroid cream, medications applied via transdermal patch). Periodic drug regimen review makes it possible to identify those medications that are truly enhancing a patient’s clinical status and those which have become accidents of history and pose nothing but an ongoing risk.

Second, consider a “therapeutic un-trial” of a medication of dubious value that is currently in a patient’s regimen. Older patients are at risk of accumulating layers and layers of drug therapy as they move through time, and often from physician to physician, forming the pharmacologic equivalent of a reef with accumulating layers of coral. Medications used for symptomatic relief are fairly easy to “prune,” as their removal is less likely to put the patient at risk. However, even this must be done carefully, as chronic benzodiazepine users who have become habituated to their hypnotic may be at high risk of the serious withdrawal symptoms that can occur after discontinuation of the drug.^{100,101}

More challenging is the reassessment of medications that could be vital to the patient’s regimen or may be presenting the risk of toxicity with no therapeutic benefit; common examples include digoxin, quinidine, thiazides, antihypertensives, and anticonvulsants. Very often, these agents have been prescribed many years previously, for reasons that were either poorly documented or transitory (e.g., digoxin for mild transient congestive heart failure following a myocardial infarction, or phenytoin for a poorly described seizure occurring immediately after a stroke or in the setting of alcohol withdrawal). Some clinicians argue that if a patient is stable and in no overt distress, it is too risky to change the regimen by removing drugs that may not be needed. However, any medication that has the potential for toxicity with no continuing indication can also represent a “time bomb” for the patient. Progressive diminution of renal or hepatic clearance, an acute hypovolemic state accompanying a transient respiratory or gastrointestinal illness, confusion on the part of the patient or caregiver regarding dosing—each of these situations can result in unexpected toxicity from a medication that is not currently producing symptoms.

Another form of risk is the unrecognized diminution in function that may result from the unwise use of a medication. Examples include slight postural instability from excessive diuretic therapy, blunting of affect or cognitive function with psychoactive drug use, and so forth. Often, the presence of these symptoms is clear only in retrospect, when they have disappeared after withdrawal of the offending drug.

A number of investigators have engaged in careful withdrawal of several medications from patients in whom no clear ongoing indication was apparent. In a study of the feasibility of discontinuing potentially unnecessary antihypertensive medications in elderly persons, 105 patients who were normotensive on therapy were withdrawn from their medication. Eleven months later, 41% of them remained normotensive without treatment.¹⁰² However, in a more recent study of withdrawal of diuretic therapy in the elderly, a substantial number of patients randomized to thiazide withdrawal had to have their

regimen restored because of exacerbation of congestive heart failure or uncontrolled hypertension.¹⁰³ A number of studies have suggested that many patients with compensated heart failure in sinus rhythm can be withdrawn from digoxin with no adverse clinical or hemodynamic effects; this may be particularly true of patients receiving concurrent diuretic and vasodilator therapy.¹⁰⁴⁻¹⁰⁶ In a study of nursing home residents (mean age, 87 years) receiving long-term digoxin therapy; three-quarters had normal ejection fractions (50% or greater); and, of these, two-thirds were in normal sinus rhythm. None of the patients in whom digoxin was discontinued had ejection fractions fall below 50%, and none showed signs of clinical deterioration over a 2-month follow-up period.¹⁰⁷ Although these were the first such data from a long-term care setting, they replicated findings from earlier studies conducted in community settings. By contrast, other investigators have reported that withdrawal of digoxin in patients with *impaired* systolic function can be detrimental.¹⁰⁸

When a drug therapy is required, it is vital to use the minimum effective dose. Most adverse drug reactions are dose related. Accordingly, it makes sense to “start low and go slow.” Following this strategy of using titrated dosing may be difficult. For many drug therapies, the low-dose therapy commonly used in clinical practice is not manufactured. For example, thiazide diuretic therapy is widely used in low doses (i.e., 12.5 mg) for the management of hypertension. However, the lowest manufactured dose in Canada is a 25-mg tablet, twice the dose recommended in guidelines for the initiation of this therapy in older patients. In one study of older adults in Ontario, Canada’s largest province, almost 27% were dispensed a low dose of the thiazide diuretic therapy, with low-dose therapy being more common with increasing age. To achieve this low-dose therapy, older adults were required to split their pills.¹⁰⁹

An additional issue is that for many drug therapies the minimum effective dose is not known for older people, particularly those of advanced age. Among commonly used drug therapies, many older people are prescribed doses much lower than were evaluated in clinical trials. For example, beta-blocker therapy is widely recommended for patients for secondary prevention of post-myocardial infarction. However, the minimum effective dose has not been fully determined for older people. Among more than 13,000 myocardial infarction survivors, use of beta-blocker therapy was associated with improved survival and decreased heart failure admissions relative to patients not prescribed beta-blocker therapy. However, among the 4681 older adults prescribed beta-blocker therapy, the risk of rehospitalization with heart failure was greater in the high-dose relative to the low-dose group. This finding suggests that although beta-blocker therapy is beneficial, it may be prudent to start

with low-dose therapy and to slowly titrate upward as tolerated.¹¹⁰

A similar issue of dose, risk, and benefit has recently been identified in relation to thrombolytic therapy in older patients with acute myocardial infarction. Older patients were either excluded from or underrepresented in the initial trials of these agents, even though they are the age group with the highest incidence of heart attack. Years after thrombolysis became the treatment of choice for this condition on the basis of those trials, evidence has emerged that the risk of thrombolytic-induced stroke is greater than expected in older patients being treated for myocardial infarction,¹¹¹ raising the question of whether the benefit–risk relationship for these drugs might be quite different for older patients.

Although almost 50% of older adults report some form of arthritis, randomized control trials of NSAIDs include few older people and hardly any over the age of 85 years.¹¹² Selecting the right dose may therefore be difficult because so little research evidence is available to guide choices. There are, however, a series of studies that suggest that adverse effects, including peptic ulcer disease, renal impairment, and hypertension, associated with the use of NSAID therapy are all dose related. Griffin et al.¹¹³ evaluated older Medicaid enrollees to explore the relation between NSAID use and the development of peptic ulcer disease. Among NSAID users, the relative risk for the development of peptic ulcer disease increased from 2.8 for the lowest to 8.0 for the highest dose group. In a systematic review of epidemiologic studies, Henry et al.¹¹⁴ found that the lower risk of serious gastrointestinal complications associated with the use of certain NSAIDs was attributable mainly to the low doses of those drugs generally used in clinical practice. Gurwitz et al.¹¹⁵ conducted a study of 114 long-term care patients and documented the nephrotoxic effects of short-term NSAID therapy. They found that use of a high NSAID dose was a significant predictor of a greater than 50% increase in serum urea nitrogen level. In a further study, the same investigators studied 9411 patients newly started on an antihypertensive therapy.¹¹⁶ NSAID users were significantly more likely than nonusers to be initiated on an antihypertensive, with the risk of starting up antihypertensive therapy increasing with increasing NSAID dose. These examples illustrate the dose-related development of a range of adverse effects associated with the use of NSAID therapy.

Concerns about preventable drug-induced illness have been amplified in recent years by the increasingly widespread use by older patients of vitamin supplements¹¹⁷ and unproven over-the-counter (OTC) remedies to treat a wide variety of conditions ranging from memory loss¹¹⁸ and depression to erectile dysfunction and arthritis. Following Congressional legislation in 1994 ending the supervisory role of the FDA (U.S. Food and Drug Admin-

istration) over claims made for OTC products, a menagerie of supplements and herbal remedies has sprung up, often marketed directly at the geriatric population, making claims that are completely unsubstantiated. Several related problems have resulted from this proliferation of untested therapies. Their use increases patient health care expenses at a time when it is difficult for many older Americans to afford effective drugs. Further, a growing body of evidence indicates that although most of the newer herbal remedies may lack efficacy, they have a genuine potential for toxicity, with numerous interactions between herbal medicines and conventional drug therapies documented as leading to adverse events.^{119,120} Their presence in the marketplace further increases the need for the physician to take a detailed history of *all* substances the patient ingests in pursuit of health.

Although there is a tendency to focus on the excessive use of medications in the elderly patient population, the underuse of potentially beneficial medications is also a problem. An increasing number of examples suggest that adverse clinical consequences are associated with underprescribing of potentially beneficial drug therapies, including beta-blocker therapy after acute myocardial infarction, drugs for osteoporosis prevention, and the pharmacologic treatment of hypertension.¹²¹

Quality improvement efforts must also focus on underuse of specific classes of drugs and undertreatment of specific medical conditions. Efforts that seek only to reduce the total numbers of drugs prescribed to elderly patients to below an arbitrary threshold have a lower likelihood of providing real health benefits, as compared with carefully considered evidence-based efforts that focus on reducing the use of specific categories of medications that pose a high risk of adverse effects (e.g., long elimination half-life benzodiazepines or highly anticholinergic tricyclic antidepressants).

Clinical Decision Making in the Institutional Setting

Beyond the general aspects of geriatric pathophysiology and pharmacology, the unique situation of the long-term care facility adds another set of influences to prescribing for elderly patients. Drug use in the nursing home occurs in some of the most frail patients in the population, in institutions with the potential for supervised, round-the-clock observation. However, the nursing home environment is also one in which there is sometimes little physician input, particularly in light of the clinical complexity of the patients receiving care.¹²² Nursing homes are complicated social institutions in which physicians, nurses, consultant pharmacists, other health profession-

als, aides, and administrators interact to make drug prescribing and drug administration decisions. Although the physician writes a prescription, this decision is often spurred by a nurse (or an aide) in much closer contact with the resident, who often guides the physician's prescribing decisions by telephone or in brief visits. When a drug is written for prn use (e.g., psychoactive medications, analgesics, and laxatives), it is the nursing staff or their assistants who frequently make the crucial decision as to whether an as-needed drug is actually administered, at what frequency, and often in what dose and by what route.¹²³

For decades, the Health Care Financing Administration has required that a consultant pharmacist periodically review the drug regimens of all residents of skilled nursing facilities.¹²⁴ Thus, the nursing home is the only component of the health care system with required, regular pharmacist involvement in monitoring the appropriateness of specific prescribing decisions. While often dramatic in individual instances, the overall impact of this mandated review has been more modest than originally anticipated and was not successful in controlling the very high levels of psychoactive drug use often reported in such settings.

Adding still another dimension to the influences on drug use in the nursing home is the fiscal situation of such facilities. Although most U.S. hospitals are nonprofit institutions, the majority of long-term care facilities in the United States are for-profit entities. Even those that are not face reimbursement constraints that influence many aspects of care; because Medicaid programs are the main payors for about half the nation's nursing home residents, nonprofit facilities must also confront the limited per diem reimbursement rate provided by these state programs. Although drugs are generally covered separately and in full, limited reimbursement to the institution can constrain the level of staffing in both nonprofit and for-profit homes. Insufficient staffing in turn can influence the incentive for use of psychoactive medications, as well as the capacity to monitor the consequences of drug use, both therapeutic and adverse.

Regulatory changes may have brought about some change, but numerous studies during the 1990s indicated that about half of all nursing home residents were regularly administered one or more psychoactive drugs. Until recently, antipsychotic drugs were taken by a quarter or more of all nursing home residents.¹²⁵⁻¹²⁸ Although a few studies suggest some efficacy of antipsychotics in the treatment of agitation in geriatric patients with dementia,¹²⁹ the literature is both limited and ambiguous in this area. However, there is clear evidence linking the use of such drugs with extrapyramidal symptoms, gait instability, falls, and hip fractures. Benzodiazepines, frequently used for dementia-associated agitation, can also be

troublesome; long elimination half-life benzodiazepines pose their own risks of falls and fractures and other side effects including daytime somnolence, confusion, and ataxia, although not parkinsonian symptoms. Cross-national studies indicate that apparently comparable patients with dementia are managed in long-term care facilities in western Europe and Japan with much less reliance on sedating medications, and apparently with good control of agitated behavior.

In a randomized trial of a comprehensive educational outreach program to reduce the use of psychoactive drugs in nursing homes, the use of antipsychotic drugs was discontinued in significantly more residents in nursing homes receiving the intervention than in control homes (32% versus 14%); these reductions occurred without adversely affecting the overall behavior and level of functioning of the residents¹³⁰ or level of distress among staff.¹³¹ In a similar study, Ray et al. also reported large reductions in antipsychotic drug use.¹³²

Considerably more needs to be learned about the relative clinical efficacy of interpersonal interventions, benzodiazepines, and antipsychotic agents in calming agitated demented nursing home residents. Some studies have found that reliance on sedative drugs was more common in larger nursing homes, facilities with lower staff-to-patient ratios, or by physicians with larger nursing home practices¹³³; however, these findings have not been consistently replicated. The interplay among economic constraints, staffing patterns, and sedative use is a crucial topic for further investigation.

In considering whether pharmacologic intervention is required to manage agitated behavior in an elderly nursing home resident, two basic facts should be considered. The first is that unusual behavior in the elderly is not necessarily an indication for drug intervention. Incoherent babbling or constant repetition of inappropriate requests may merely require a greater level of tolerance on the part of staff members, rather than sedation. Other problems, such as wandering, might be approached by environmental solutions, such as facility designs that enable disoriented patients to move about freely while preventing their escape from the range of staff supervision. If intervention is warranted, the safest therapeutic approach (and one which can be highly effective) is interpersonal attention, which is often preferable to sedation. Whether in the institutional or the ambulatory setting, programs to improve prescribing quality may lead to increased costs in the short term but can lead to long-term improvements in outcome. Such interventions to improve the quality of health care provided to the elderly have been shown to prevent readmission of elderly patients with congestive heart failure,¹³⁴ reduce the risk of falls,¹³⁵ and improve the quality of care in patients requiring chronic warfarin therapy.¹³⁶

Development and Testing of New Therapeutic Agents

Even though many drugs are likely to be used heavily by the geriatric population, progress has been slow toward systematic inclusion of older patients in the drug evaluation and approval process. In the past, it has been advantageous for pharmaceutical manufacturers and clinical researchers to test new drugs before marketing primarily in healthy younger patients, because they are likeliest to yield “clean” results uncomplicated by concomitant therapy with other drugs, comorbidity, or pharmacokinetic abnormalities. However, this leaves open the possibility that one of these “complicating factors” will have a clinically meaningful effect on the new drug once it is marketed and taken by large numbers of elderly persons.

Unfortunately, much time can pass before studies are mounted to address important therapeutic issues in the elderly (e.g., the Systolic Hypertension in the Elderly Program¹³⁷), and clinicians and patients are forced to make pressing clinical decisions in the absence of an adequate knowledge base. Perceptions about the difficulty of involving elderly subjects in research protocols can lead to study designs that prevent a study from yielding the very information necessary to clarify or refute such preconceptions about the drug’s effects in elderly patients. This a priori exclusion of elderly has been particularly problematic in clinical trials in the prevention and treatment of heart disease.¹³⁸ For example, age restrictions excluded older patients from most of the pivotal studies of lipid-lowering drugs in both primary and secondary prevention. Some clinicians and payors then responded to this lack of information with the conclusion that “there is no evidence to justify the use of lipid-lowering drugs in the elderly,” and advocated withholding such therapy from older patients. However, when age-stratified analyses have been performed to determine whether the benefits of cholesterol reduction are attenuated with age (most notably in the CARE trial, which included patients up to age 75),¹³⁹ it was found that the risk reduction afforded by pravastatin remained constant throughout the age range studied.¹⁴⁰ Cost-effectiveness modeling suggested that the intervention remained a “good buy” for older patients as well.¹⁴¹ Definitive results are expected from an ongoing randomized trial of pravastatin in elderly patients, PROSPER.¹⁴²

Over a decade ago, the Food and Drug Administration issued a guideline on the testing of drugs in the elderly.¹⁴³ The guideline was intended to encourage routine and thorough evaluation in elderly populations of the effects of new medications proposed for FDA approval, so that physicians would have sufficient information to use drugs properly in their older patients. The recommendations

state that “there is no good basis for the exclusion of patients on the basis of advanced age alone, or because of the presence of any concomitant illness or medication, unless there is reason to believe that the concomitant illness or medication will endanger the patient or lead to confusion in interpreting the results of the study. Attempts should therefore be made to include patients over 75 years of age and those with concomitant illness and treatments, if they are stable and willing to participate.” The FDA guideline presented a reasonable and practical approach to the study of drugs in the elderly, with implications for the design of future clinical trials of both new and existing drug therapies. However, few data are available to document its effect on the demographics of premarketing trials.

Conclusion

As the most prominent consumers of prescription medications, elderly patients stand to benefit the most and are also at greatest risk of toxicity from our increasingly complex, effective, and costly pharmacopoeia. When pharmacotherapy is indicated, choosing the right drug in the right dose for an elderly patient represents one of the most difficult challenges in all of medicine, but also can yield the most gratifying outcomes. Likewise, few interventions in geriatric practice are as elegant in process, and as “heroic” in outcome, as identifying and treating adverse drug effects. Thorough knowledge of some of the principles outlined here will enable the clinician to wield this powerful double-edged sword with the least possible risk and with the maximum benefit for patients.

Clinical Strategies of Prescribing for Older Adults

Judith L. Beizer

Appropriate prescribing of medication for elderly patients involves more than knowledge of the pharmacology of the medications. Clinical issues, as well as practical and regulatory issues surrounding medication use in the older population, must also be taken into consideration.

Medication History

Before even considering any of the issues involving drug therapy in a given patient, it is essential that the prescriber know exactly what medications the patient is taking, achieved by taking a thorough and accurate medication history. When asking the patient about their medications, it is important to be specific. The interviewer should specifically ask about prescription medications, over-the-counter (OTC) products, as needed (prn) medications, vitamins and minerals, herbal products, and home remedies. The questions can be asked by category of product or as a review of systems. For example, “Do you take anything for your eyes, ears, etc.?” The interview should end with the question, “Do you do anything else for your health?” With the widespread interest in complementary and alternative medicine, this last question may provide some interesting and unusual responses. Another useful technique is to have patients bring in all their medications and medicinal products for review by the physician, nurse, or pharmacist. Ideally the medication history and inventory should be updated at each office visit, and a complete history should be obtained at least every 6 months. Asking what health care providers the patient has seen since their last visit with you often serves as a prompt to remember other medications.

Minimizing Medication

One of the most crucial elements of geriatric pharmacotherapy is not to overmedicate the patient. Polypharmacy, the use of many medications, is a major cause of

noncompliance, adverse effects, and drug interactions. Before adding a new medication to a patient’s regimen, current therapy should be assessed. Questions that should be addressed include: Is the new symptom a side effect of an existing medication, or can the problem be handled by adjusting the dose of current medications or discontinuing a medication? An important point to remember is that it is usually easier to not start a medication that may not be necessary than it is to stop a current medication.

When withdrawing medications thought to be unnecessary, it is crucial to monitor the patient for recurrence of symptoms. Walma et al. conducted a double-blind randomized controlled trial of diuretic withdrawal in elderly patients with no symptoms of heart failure or hypertension.¹ Of the 102 patients in the withdrawal group, 50 patients needed to be restarted on diuretics, 25 of them because of heart failure. Other studies have examined the effect of drug withdrawal in elderly populations. Gerety et al. studied adverse drug events (ADEs) and adverse drug withdrawal events (ADWEs) in a Veteran Affairs (VA) nursing home;² 190 medications were withdrawn and 62 patients experienced 94 ADWEs, 72% of which were minor. The most common risk factors for ADEs and ADWEs were the number of diagnoses, number of medications, and hospitalization during the nursing home stay. The most common medications associated with ADWEs were cardiovascular, central nervous system (CNS), and gastrointestinal (GI) drugs. Of note, 60% of the medications did not need to be reinstated. A similar study was conducted in a VA outpatient setting;³ 238 medications were discontinued in 124 patients, resulting in 62 ADWEs; 74% of the medications were not restarted, and the most common medications involved were cardiovascular and CNS medications.

When choosing the dose of a medication for an older patient, the motto has always been “start low, go slow.” The other half of that statement should be “but don’t stop

too soon.” Although doses of medications used in the elderly should be held to a minimum, the “right” dose in an elderly patient is the dose that is both effective and well tolerated.⁴ Initially, doses should be modified based on pharmacokinetic predictions, but actual pharmacodynamic responses to the medication should then be used to adjust the dose. When pharmacokinetic data are not available, whenever practical, doses can be initiated at one-half the usual adult dose; this can be achieved by splitting tablets or by extending the dosing interval. Some manufacturers, realizing the need for smaller doses in the elderly, have marketed smaller dosage forms or liquid formulations to facilitate dosing.

The scheduling of medications is another important factor to consider when prescribing for the older patient. Minimizing the number of doses per day is easier for the patient and can improve compliance. The use of sustained-release dosage forms or taking advantage of prolonged elimination half-lives in the elderly can decrease the number of doses per day. For example, ciprofloxacin can often be dosed once a day in elderly patients.⁵ Scheduling is also important as to the time of day. Medications that can cause drowsiness should be dosed at bedtime.

Economics

At the time of this writing, Medicare still does not include a prescription drug benefit, and many elderly patients do not have prescription coverage. As the cost of medication soars, elderly patients on fixed incomes may have difficulty affording their drug therapy. Prescribers need to learn the costs of medications, specifically the cost of 30 days at a geriatric dose. It is also useful to be familiar with therapeutic alternatives, and which one is most cost-effective. For example, one angiotensin-converting enzyme (ACE) inhibitor may be less expensive than another.

It is also important to be aware which medications are available generically. There are few data on the use of generic medications in the elderly and whether any significant pharmacokinetic or pharmacodynamic changes are evident. A study of generic verapamil products found that there was a significant amount of variability in the maximum serum concentration and the area under the curve in older adults.⁶ A follow-up study in elderly hypertensive patients found that, despite pharmacokinetic differences, no significant clinical differences were seen when comparing a generic verapamil to the brand product.⁷ It is important to consider that even though the FDA (U.S. Food and Drug Administration) may find that the generic products are bioequivalent, most of these studies are done in younger adults and therefore these products may not actually be bioequivalent in the elderly. Even if elderly subjects are included in the studies, their

data may not be separated from the rest of the study population.

A study comparing generic Warfarin and the brand Coumadin found no significant difference between the two products in respect to average international normalized ratio (INR) values.⁸ The median age of the study population was 79 years (range, 42–96), so it can be inferred that there was no difference between the products in the older patients in the study, but no specific geriatric data were reported.

Patient attitudes about generic medications may influence a physician’s prescribing habits. A survey was conducted to assess patient perceptions of the risk of generic medications versus brand products.⁹ The more serious the condition (e.g., heart disease), the more patients perceived generics as risky compared to the brand. For less severe conditions (e.g., cough), more respondents were willing to accept generic products and perceived them to be the same as the brand product. Patient education about the safety and appropriateness of generics may help improve their acceptance.

Compliance

There is no strict definition of noncompliance, but it can be defined as a patient’s intentional or unintentional deviation from the medication regimen prescribed or recommended by the health care professional. Noncompliance includes omitting doses, adding doses, taking doses at the wrong time, or incorrectly administering the medication, to name only a few noncompliant behaviors.

Studies reporting compliance rates in elderly patients have found that the adherence rate ranges from 26% to 59%.¹⁰ In the elderly, there are numerous causes of noncompliance or barriers to good compliance with medication regimens. Changes in functional and cognitive status are some of the key causes, and creative solutions are sometimes needed to overcome these barriers (Table 8.1).

Specific dosage forms may be particularly difficult for the older patient to manage. For example, in a study by Brown et al., 70% of patients could not adequately instill an ophthalmic preparation into their eyes.¹¹ In another study on eye medications, 21% of patients reported difficulty administering the medication due to the force

TABLE 8.1. Changes in functional status affecting compliance.

Decreased vision
Decreased hearing
Decreased manual dexterity
Dysphagia
Impaired mobility

required to squeeze the bottle, unsteadiness of their hand, difficulty raising their arm, difficulty tilting their head, or difficulty opening the tamper-proof seal on the new bottle.¹² Eyedrop guides, which fit onto the eyedrop bottle, can help steady the hand and direct the drop into the eye. When using the guide, the percent of people who could instill a drop on the first try increased from 20% to 87%.¹²

In all patients, difficulties in properly using a metered-dose inhaler (MDI) can impair the effectiveness of the medication.^{13,14} Assessment of technique and education are essential for compliance and efficacy. Newer versions of MDIs are breath activated, making it easier for the older patient who may not be able to coordinate their breathing with pressing down on the canister. Additionally, there are a variety of devices that can adapt MDIs for patients with arthritis, making it easier to press down on the canister. There are various inhalation aids and spacer devices, such as the InspirEase and Aerochamber, which can improve the delivery of the medication to the airways.

Even child-resistant caps, which have been required on prescription medications in the United States since 1970, can be barriers to compliance in the older patient. In one study, one-third of patients over 60 years of age could not remove tablets from a vial with a child-resistant cap.¹⁵ Of these patients, 91% either left the cap off the vial, changed containers, or did something else to be able to get to their medications; 9% of the patients simply discontinued the medication. Obviously, none of these options is optimal. It is the responsibility of the prescriber and the pharmacist to ask the elderly patient if they need a non-child-resistant cap. The prescriber can note it on the prescription or the patient can tell the pharmacist directly. The pharmacist should document this information on the individual's patient profile for further prescriptions.

Visual problems can affect the patient's ability to read the medication label or patient education material and may even impair their ability to discriminate between colors of tablets. Decreased hearing can make patient counseling challenging for the health professional. When interacting with sensory-impaired patients, it is important to ensure that they are accurately receiving the information.

Besides alterations in functional status, there are other reasons for noncompliance in the elderly patient. Economic issues, as mentioned earlier, can force a patient to compromise their compliance. Attitudes about illness, aging, and even the medications themselves can impair compliance. Medications may be a reminder of illness and growing older, and the patient may resist or ignore the medications. Living alone, with no support system to remind them to take their medication, may also lead to noncompliance.

Cognitive status can also be an impediment to compliance. Simply remembering to take the medication can be difficult for the cognitively impaired patient. Actions requiring judgment, such as recognizing adverse events or self-monitoring their therapy, may be impossible. Simplifying the regimen, reminder aids, and family or caregiver involvement are the best methods to improve compliance in these patients.

It would seem logical that the most significant risk factors for noncompliance are simply the number of medications and the number or severity of illnesses. However, a review of compliance studies found conflicting results.¹⁰ Noncompliance and its reasons are still not well understood. Studies have also examined the relationship between knowledge about the medications or illnesses and compliance.¹⁶ Unfortunately, they do not always correlate, in that educating the patient does not always result in good compliance.

Methods to Improve Compliance

The first step to improve compliance should be to simplify the regimen. The minimum number of medications and doses per day should be the goal. It is advisable to avoid medications that must be given more than twice a day.

Patient Education

Even though knowledge does not always equal compliance, patient education is still important. The National Council on Patient Information and Education (NCPIE) recommends that patients know, at a minimum, the following information about their medications:

1. Name of the medication and its indication
2. Dose and schedule of the medication and how long to take it
3. What to avoid while on the medication
4. Major adverse effects and what to do if they occur
5. Any written information about the medication

With elderly patients, it is advisable to include a family member or caregiver in the education process. Supplementing verbal information with written information is also important. When developing patient education materials, it is important to utilize a large font size and aim for a reading level not greater than sixth grade. Black print on nonglare white or yellow paper can ease the readability.

The effect of an education program on compliance and control of illness was assessed in an elderly population with osteoarthritis.¹⁷ Patients in the intervention group were educated about their disease and their medications via a computer program. The control group was only

exposed to information about osteoarthritis. The intervention group had a significantly higher rate of appropriate use of medication. However, the only difference seen between the groups in regard to the severity of illness measures was in the extent of stiffness. The intervention group also had a greater sense of confidence in their ability to be compliant with the drug regimen.

Another difficulty with compliance lies in the ability of the patient to read and understand the label. Directions should be simple and easy to understand. Ideally the prescription directions for all patients should state exactly how, when, and why to take the medication, for example: "Take one tablet every morning for high blood pressure." Large type should be used when possible, or the patient should be encouraged to use a magnifier.

Medication Administration Skills

One of the simplest ways to assess compliance is to watch the patient take the medication. The patient should be able to open the vial, count out the correct number of tablets or capsules, and swallow them. Assessment of the elderly patient's functional ability to take medication has been reported in several studies.¹⁸⁻²¹ It is important to check their technique for using inhalers, instilling ophthalmic preparations, injecting insulin, and even applying a transdermal patch or creams and ointments. Before prescribing a liquid form of a medication, it should be ensured that the patient can accurately measure liquids. Patients with difficulties with these special dosage forms should be referred to their pharmacist, who can recommend compliance aids. For example, for diabetics, there are magnifiers that fit onto the insulin syringes. For liquid medications, there are a variety of dosing spoons, cups, and oral syringes. Even transdermal patches can present a problem, as an elderly patient with visual problems or arthritis may have difficulty peeling off the protective backing on the patch. For vials, easy-to-open caps are available. It is also important to check the size of the vial. A very small vial may be difficult to manage for a patient with severely arthritic hands or who has hemiplegia. In these cases, a larger vial may be easier to grasp.

Tablet splitters and crushers can be used for those patients who have difficulty swallowing tablets. Before splitting or crushing a tablet, the patient or prescriber should check with the pharmacist or the manufacturer's information to make sure that the medication will not be affected by breaking the tablet. Sustained-release formulations and enteric-coated medications should not be split or crushed.

If despite compliance aids the patient is still having difficulty administering the medication, alternative dosage forms may be necessary. For example, a patient having difficulty with a transdermal nitroglycerin patch may be better managed on isosorbide mononitrate once a day. In

other cases, a family member or caregiver may need to be trained to help with the medications.

One of the medication compliance problems that is often overlooked is the problem of the family caregiver and medication administration difficulties. Travis et al. assessed the difficulties that family caregivers had when giving medications.²² The difficulties were described as scheduling logistics (29.5%), administration procedures (32%), and safety issues (38.5%). The three most common difficulties were (1) giving medications to a confused or uncooperative person; (2) working the medication schedule into the care routines; and (3) recognizing adverse or toxic effects. This study demonstrates that family caregivers must be given proper instructions on how to administer medications and be educated about the medications themselves.

Reminder Aids

A variety of reminder aids can be used to help patients remember to take their medications. The simplest method is to design a calendar that lists the medications and the time of day to take them. The calendar can be posted on the refrigerator or other prominent place in the home. Weekly or monthly calendar cards with boxes to check off each dose can be used and correlated with tablet counts to assess level of compliance.

Commercially available medication boxes can aid in compliance. These boxes hold 1 day or 1 week of medication, and some have compartments for up to four dosing times per day. Electronic aids also have been developed. These devices can be set to beep at the correct times, and some even provide a warning if a dose has been missed. Some systems are locked and tamperproof and actually dispense the medication only at the correct time.

Studies on compliance measures have shown that no one intervention is universally better than another.¹⁶ Rather, a compliance plan should be individualized to the needs of the patient and should include a combination of interventions focusing on behavioral as well as educational interventions.

Utilizing the Pharmacist

Assessing and improving compliance requires a multidisciplinary effort. Prescribers should utilize the patient's pharmacist and keep the lines of communication open. The pharmacist can provide advice on compliance and reminder aids and also can suggest alternative dosage forms, such as sustained-release formulations or smaller tablet sizes. The pharmacist can also track compliance via refill records and note what OTC products the patient is using. The pharmacist is a ready source of drug informa-

tion for both the patient and the prescriber. By federal law, the pharmacist must offer to counsel all Medicaid patients on prescription medications.²³ Many states have expanded this regulation to include all patients. All patients, particularly the elderly, should be encouraged to consult their pharmacist when purchasing OTC medications and other health-related products. Most important, it should be stressed to the patient that it is safer to use only one pharmacy so that all their prescription and OTC medications are entered into one computer profile. This method allows the pharmacist to monitor for drug interactions, duplications, and potential adverse effects.

For the prescriber, the pharmacist can provide information about the availability of new medications, dosage forms, or newly approved indications, as well as drug interactions, adverse effects, and special concerns in the elderly. Since 1997, pharmacists who specialize in geriatrics have had the opportunity to become certified in the area of geriatric pharmacy. The Commission for Certification in Geriatric Pharmacy offers an examination covering various areas of geriatric pharmacy practice. These pharmacists carry the title of Certified Geriatric Pharmacist (CGP), demonstrating their expertise in the area.

Nursing Home Issues

Residents of nursing homes are generally among the frailest of the elderly and are often on many chronic medications. The decision to institute a new medication may be the result of the input of a variety of disciplines. Because the physician may only be making monthly visits to the facility, the nursing staff is the “front line.” The nurses or nursing aides often are the ones to suggest that an intervention is necessary. The consultant pharmacist is another active voice in the drug use process. Since 1974, the Federal government has required that a pharmacist review the drug regimen of all residents in long-term care facilities (LTCF) on a monthly basis.²⁴ This drug regimen review is based on a set of guidelines or “indicators” that are used by the state surveyors when they review medication use in a facility.²⁵ The pharmacist must provide comments about the drug regimen to the physician of record, who must respond to these comments. A recent study assessing the impact of drug regimen review in nursing homes estimated that the pharmacists’ reviews saved \$3.6 billion annually in drug-related costs.²⁶ Despite these savings, it is estimated that for every dollar spent on medications in LTCFs, \$1.33 is spent on drug-related problems.²⁶

Since the implementation of drug regimen review, the nursing home regulations affecting medications have been modified several times. One of the most significant changes was in 1987 with the passage of the Nursing Home Reform Amendments of the Omnibus Budget

TABLE 8.2. Definition of “unnecessary drugs” according to OBRA 1987 guidelines.

An unnecessary drug is any drug when used:

1. In excessive dose (including duplicate drug therapy); or
2. For excessive duration; or
3. Without adequate monitoring; or
4. Without adequate indications for its use; or
5. In the presence of adverse consequences that indicate the dose should be reduced or discontinued; or
6. Any combination of the reasons above.

Source: Omnibus Budget Reconciliation Act of 1987.²⁷

Reconciliation Act (OBRA '87).²⁷ This regulation requires that “each resident’s drug regimen must be free from unnecessary drugs”²⁷ (Table 8.2). The Interpretive Guidelines accompanying this regulation, which were implemented in 1990, focused on the appropriate use of psychotropic medications, most specifically antipsychotics, anxiolytics, and hypnotics.²⁸ OBRA '87 also states that “the resident has the right to be free from any physical restraints imposed or psychoactive drug administered for purposes of discipline or convenience and not required to treat the resident’s medical symptoms.”²⁷ The Interpretive Guidelines include a list of appropriate indications for the use of antipsychotics, anxiolytics, and hypnotics and explain under what circumstances these medications should be used. Nonpharmacologic interventions are considered first-line therapy, and medications should only be used if the interventions fail. Justification for use of psychoactive medication is based on improving or maintaining the resident’s functional status. Emphasis is placed on length of therapy and maximum recommended dosages. For anxiolytics and hypnotics, the guidelines discourage the use of long-acting benzodiazepines and older agents such as meprobamate. They also discourage the use of the antihistamines, diphenhydramine and hydroxyzine, as hypnotics or anxiolytics.

Later modifications to the guidelines focused on antidepressants and their underutilization in nursing facilities. It has been shown that depression is often unrecognized and therefore left untreated in elderly nursing home residents.²⁹ The appropriate diagnosis and treatment of depression are stressed.

In all the psychotropic drug guidelines, the use of the lowest effective dose is emphasized. It must be noted that as new psychoactive medications are marketed, the impact of the guidelines on their use in LTCFs must be established.

Studies assessing the impact of the psychotropic guidelines on prescribing patterns in nursing homes have found significant decreases in the use of antipsychotics.³⁰⁻³² In some cases, reductions in antipsychotics resulted in adjustment in the use of other psychoactive

Prevalence of:

- Symptoms of depression without antidepressant therapy
- Residents who take nine or more different medications
- Antipsychotic use, in the absence of psychotic or related conditions
- Antianxiety/hypnotic use
- Hypnotic use more than two times in the last week

medications, such as an increase in the use of antidepressants.³³ Multidisciplinary and educational interventions were most effective in ensuring appropriate use of psychoactive medications.^{34–36}

Additions to the Interpretive Guidelines in 1999 focused on the choice of medications for elderly nursing home residents.³⁷ The “Beers criteria,” a set of guidelines concerning “potentially inappropriate” medications for the elderly, were incorporated into the nursing home regulations.³⁸ Medications with a high-severity risk were placed under the definition of “unnecessary medications,” and those with a low-severity risk were placed under the drug regimen review regulations. In either case, use of these medications must be justified in the patient’s chart. Department of Health surveyors will scrutinize residents on one of these “potentially inappropriate” medications to make sure that they are not suffering adverse outcomes. Also, 1999 saw the implementation of Quality Indicators for assessing the quality of care in nursing facilities; 5 of these 24 indicators specifically refer to medications (Table 8.3).

A major change in nursing homes that affected medication is the change in reimbursement for Medicare patients. The Prospective Payment System (PPS) provides a per diem rate based on level of care. The payment segment that includes medication is relatively stable across the levels of care. This plan encourages the use of the least expensive medication, which may not necessarily be the best for the elderly patient and, in the end, may not be the most cost-effective. For example, the older tricyclic antidepressants (TCAs) are less expensive than the newer selective serotonin reuptake inhibitors (SSRIs), but the TCAs have more side effects and the outcomes of these side effects may be costly. The effect of the PPS on medication usage and clinical outcomes in LTCFs remains to be seen.

Assisted Living Facilities

At the time of this writing, there are no national guidelines concerning medication use in assisted living facilities. Some states are requiring or suggesting pharmacist drug regimen reviews, and the impact of these interventions is still unknown. Depending on the level of care of

the individual facility, some provide medication administration, some only supervision (reminding the resident to take the medication), and some require that the resident be able to self-medicate. Medication use in assisted living is still an uncharted area in geriatrics.

Conclusion

Appropriate drug therapy in the older patient is the result of assessing all the complexities of the geriatric patient. Factors to be considered are pharmacologic, physiologic, sociologic, practical, and, in the case of nursing homes, regulatory. Once the decision is made to prescribe a medication, the right agent and patient-specific dose must be chosen. Care then must be taken to ensure that the patient will be able to comply with the regimen. Consideration of the patient’s functional and cognitive status and their living environment may influence the choice of medication. By balancing all these factors and being sensitive to the special needs of the elderly, safe and effective medication regimens can be achieved.

Changing Contexts of
Care in Geriatric Medicine

This page intentionally left blank

9

Contexts of Care

Laurence Z. Rubenstein

Geriatric medicine is characterized by multiple levels or contexts of care. The geriatrician and their team typically care for elderly patients along a continuum of these contexts, stretching from hospitalization for an acute problem, such as a stroke, to rehabilitation on a subacute ward, to convalescence in a nursing home, to continued care at home via a home care program, and finally to a return to primary care in the office. (Conversely, one can view this continuum from the opposite direction, beginning in primary and preventive care and spanning to institutional care.) Each of these contexts of care has its own scope of purpose, its own rationale, its own teams of care professionals, and its own financial considerations and incentives, all of which are actively evolving along with changes in the overall health care system and larger society. Proper geriatric care requires familiarity with all these contexts and an understanding of how best to manage patients within them.

In several countries with well-organized health care systems (e.g., Great Britain), the geriatrician serves as the manager/gatekeeper of a variety of geriatric care services, such as hospital geriatric assessment and management units, rehabilitation wards, day hospitals, nursing homes, and home care service. In all these contexts, the geriatrician can function as the primary care provider or as a consultant physician. In other countries with less-developed geriatric care systems, these services, when available, tend to be autonomous, and geriatricians play more consultative roles.

Some common threads shared by most of these programs include their focus on functionally impaired elderly persons, their focus on optimizing functional status and quality of life, and their employment of interdisciplinary teams, comprehensive geriatric assessment techniques, and principles of case management. This chapter provides an overview of these contexts of geriatric care and how they can and should be coordinated, serving as an introduction to the more detailed program-specific chapters that follow.

Use of Services by Older Persons

The population aged 65 and older uses a greatly disproportionate amount of most health services. In developed countries, older persons typically use most services at a rate three to four times higher than their proportion in the general population, which primarily reflects the increased prevalence of most diseases and physical disabilities among older persons.¹ This trend, together with the continual expansion of the older population segment worldwide, has been one of the major factors leading to dramatic cost inflation of health services globally. With medical care responsible for 8% to 14% of the gross national product in most developed countries, public resources have increasing difficulty sustaining these services. Health care cost containment is now an international watchword. The difficulty in attaining this objective without sacrificing the older person's need for adequate care has become a universal and growing challenge. Understanding health services utilization, its determinates, and ways to effectively manage it are major priorities for health services research and policy analysis worldwide.

In 1998, 13.5% of the United States gross domestic product was spent on health care, or \$3632 per capita.² Of this, 33.3% went for hospital services 20.0% for physician services, 10.6% for drugs and other medical non-durables, 7.6% for nursing home care, 4.7% for dental services, 5.8% for other professional services, 3.2% for government public health activities, 1.3% for vision products, 2.5% for home health care, 5.0% for insurance administrative expenses, 3.1% for research and construction, and 2.8% for miscellaneous services. Figure 9.1 shows health care expenditures by older persons in the United States for major service categories by age subgroup and highlights the progressive increase and changing patterns after age 65.³

FIGURE 9.1. United States per capita health care expenditures by older persons, by service type and age group. (Data from 1996 Medicare Current Beneficiary Survey, Older American 2000.)

Hospital Use

Hospital use is by far the largest single health expense category, and it dramatically increases with age, as indicated clearly in Figure 9.2, which shows data on annual per capita hospital discharges in the United States by age group. This age trend is true whether considering discharges, total hospital days per year, or per capita expenditures. Persons age 75 years and over use five times as many annual per capita hospital days as persons 45 to 64 years of age (30.3 versus 6.0 day per year, in 1998 in the United States).²

A number of studies have identified predictors of hospital use that largely explain this disproportionately heavy use of hospital services by older persons. In one study, the most important predictors were hospital use in the previous year, poor perceived health status, more than six physician visits in the past year, and lack of an

informal caregiver.⁴ In a more detailed study using the behavioral model, which subdivided potential predictors of hospital use into the three traditional categories of predisposing, enabling, and need characteristics, significant predictors of hospital use included lower functional status, poorer perceived health, lack of social supports, and health concerns.⁵ In all studies, age has been one of the major predictors of hospitalization.

The most common diagnoses responsible for hospitalization among older persons in the United States in 1996 were, in decreasing order, heart disease, cancer, cerebrovascular disease, injuries, pneumonia, and eye diseases.² Hospitalization rates for all these disorders continue to increase with increasing age, except for neoplastic disease, which tends to decline after age 75. Mean hospital length of stay in 1998 for persons age 65 and older was 6.2 days, down from 10.7 days in 1980. Among the most common diagnoses, mean hospital length of stay was longest for hip fractures (8.2 days), followed by pneumonia (7.1 days), heart disease (5.6 days), and cerebrovascular disease (5.4 days). Over the past two decades, diagnosis-specific length of stay has been dramatically falling, largely in response to economic incentives from the payors. For example, length of stay for hip fracture patients over age 74 has declined from 19.2 days in 1985 to 8.2 days in 1998, and for cerebrovascular disease from 10.0 days to 5.4 days. This shortening of length of stay has been the major factor behind the declining proportion of the health care dollar spent on hospital care—from 42% in 1980 to 33% in 1998—and has been a major factor in the slowing of health care inflation.

A number of studies have looked at factors predictive of hospital outcomes. In an article that reviewed 15 studies, the most commonly found predictors of adverse hospital outcomes (i.e., mortality, nursing home placement, or long length of stay) were advancing age (9 of 11 studies), impaired functional status (8 of 11), impaired

FIGURE 9.2. U.S. hospital discharges by age group, per 100 persons/year. (Data from 1996 U.S. National Hospital Discharge Survey, Health United States 2000.)

FIGURE 9.3. U.S. hospital discharge locations for older adults (1987 data, vs DHHS, 1993).

mental function (7 of 11), and problematic living location (6 of 11).⁶ In a more recent study that was able to include illness severity in the model, severity was an important predictor of adverse outcome, along with impaired functional status.⁷ Figure 9.3 shows the changing patterns of hospital discharge location after age 65, indicating the progressive increase in mortality and nursing home placement and decreasing likelihood of returning home.

Nursing Home Use

Although nursing homes account for only 7.6% of all health care expenditures for the entire U.S. population, the older population expends more than 20% of its health care dollar on nursing home care, and this proportion approaches 46% for the population age 85 and over (see Fig. 9.1).² Between 1974 and 1997, the U.S. nursing home population grew by more than 52%. Currently, about 4.3% of persons age 65 and over reside in nursing homes; however, more than 22% of women age 85 and over live in nursing homes. As discussed in Chapter 11, the nursing home clientele is highly diverse. This diversity presents itself in several areas, including the degree of physical or mental impairment, the type of care required, and the duration of stay. The important distinction has been made between short stayers (less than 6 months) and long stayers (more than 6 months). Short stayers include patients needing rehabilitation or convalescent care after an acute illness and who are expected to go back home, as well as patients who are terminally ill from endstage cancer or dementia and who are expected to die in the nursing home. Long stayers include three large subgroups: those with cognitive impairment; those with physical impairment (largely musculoskeletal, neurologic, cardiac, or pulmonary disease); and those with both cognitive and physical impairments. The proportion of short stayers has increased in the past two decades in

response to fiscal pressures to shorten hospital length of stay.

Several studies have examined predictors of nursing home use. The most common factors that correlate with use include age, diagnostic condition, living alone, functional impairment, being unmarried, white race, weak social support, poverty, hospital admission, bed disability, female sex, and use of an ambulation aid.⁸ Most studies have found that women have a much higher probability of nursing home use. For instance, the lifetime probability of nursing home use in the United States is about 45% for women versus 28% for men.⁹ This gender gap can be partially explained by the greater longevity of women with decreased likelihood of spousal support, their higher prevalence of disabilities, their lower functional status score, and their lower incomes. It has been argued that when the effects of such variables are controlled for, older women may actually have a lower risk of nursing home use than men. Be that as it may, the current prototype of the nursing home dweller is still that of an older woman with multiple pathologies, taking several medications, most likely widowed and incontinent.

Use of Physician Services

A physician contact can take place in the office setting or clinic, in the hospital, in the nursing home, in the patient's home, or by telephone. In 1996, the U.S. population age 65 and over had a mean of 11.7 physician contacts per year²; this included 10.2 annual contacts for persons age 65 to 74 years and 13.7 contacts for persons age 75 years and over. Of these contacts, about 49% took place in the office, 10% in the hospital, 19% in the home or nursing home, 9% on the phone, and 12% in other places such as clinics. Factors shown to correlate with physician utilization include perceived health status, having an active health problem, having a functional impairment, and having a regular primary care physician.¹⁰

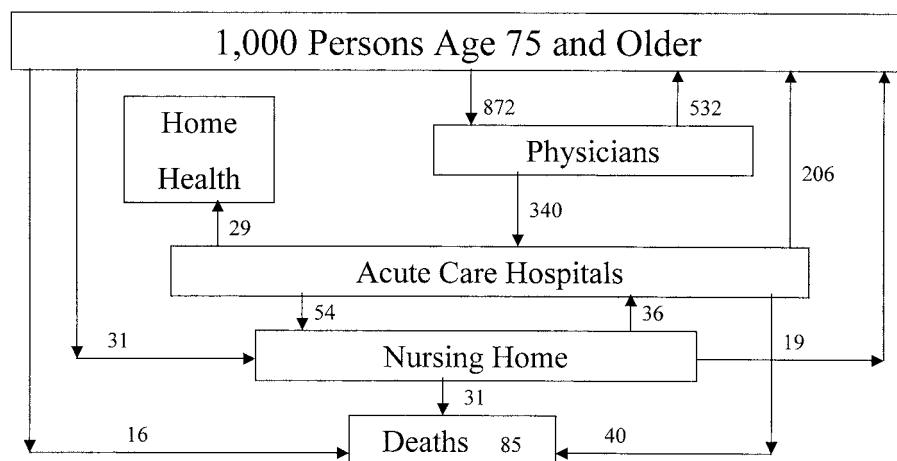

FIGURE 9.4. Movement of the elderly population through the U.S. health care system (US DHHS, 1993).

Use of Community Health Care Services

This category covers auxiliary and support health services and is usually subdivided into the two subcategories of home care services (which include visiting nurses, hot meals, home health aides, or other special care delivered at home) and ambulatory care services (which include rehabilitation, counseling, and speech therapy). Also sometimes considered are services offered by community centers, such as day hospitals and senior citizen centers. Utilization of these services has been traditionally low. In the 1980 National Health Interview Survey, only 4% of respondents had reported using any of these services. However, in more recent years, use of these services has grown faster than for any other type of service. The proportion of the health care dollar paying for home care alone has increased from 0.5% to 3.0% between 1975 and 1997.²

The most important predictor of community services use is a recent discharge from an acute hospital.^{11,12} Age is also a major predictor, largely related to increased needs.¹³ Although community care services are often advocated as “alternatives” to more costly institutional services, most studies have been unable to show a substantial substitution effect. Many people will use community services when offered, as add-ons to their current care rather than as substitutes for more intensive levels of care. In fact, several studies suggest that use of community services may actually lead to increased use of other health care services, albeit often appropriately so. Thus, issues of unproven cost-effectiveness have often been cited as reasons why community care services are not more widely available. However, efforts to contain costs are often influential and may be more important than true effectiveness in determining availability of some of these services.

Interrelationships of Service Use

Utilization of each service in the health care system is inexorably linked to that of other services. These linkages are difficult to analyze because of the complexity of the relationships as well as the lack of accurate information. In a 1991 study of the U.S. Agency for Health Policy Research, Denson attempted to construct a diagrammatic movement pathway for the U.S. population through the health care system,¹⁴ which is shown in simplified fashion in Figure 9.4. One can see that, in a given year, about 87% of the U.S. population age 75 and over will see a physician, 34% will be hospitalized, 8.5% will enter a nursing home, 2.9% will receive home health care, and 8.5% will die. Also shown is the complexity of movement between many of the services. This pattern of movement with its specific rates should be viewed as a snapshot in time because changes in availability in certain types of services and changes in reimbursement systems have dramatic effects on service utilization and on the rates of transition. For example, the prospective payment system of hospital care introduced by Medicare in 1984 led to dramatically shortened hospital lengths of stay and increasing proportions of hospital patients discharged to nursing homes and using home health service.

The Long and the Short of Long-Term Care

Robert L. Kane

Long-term care (LTC) is an amorphous concept. It is more readily defined by what it is not than by what it is. Clinicians tend to view it as what is left over after acute care has been addressed, but in an era of chronic disease, even the concept of acute care is blurred. For many, LTC is synonymous with nonmedical care; but in fact most LTC recipients need active medical care, and close coordination of both types of care is important to obtaining maximum benefit.

It may come as no surprise then that there is no common definition of LTC. One that seems to serve well is the following: Long-term care is assistance given over a sustained period of time to people who are experiencing long-term disabilities or difficulties in functioning because of a disability.

Several implications flow from this definition.

1. Functioning is a central theme of LTC. It serves as the lingua franca (common tongue) that facilitates communication among those involved in planning and delivering care. It is an important basis for assessing the outcomes of such care. For reasons that are not altogether clear, the age-specific prevalence of disability has actually been decreasing slightly.¹ However, the growth in the aging population will far outweigh this modest decrease.

2. LTC is not limited to one age group. Although our attention here is directed at LTC for older persons, people of all ages may need such care. Indeed, especially if one includes chronic mental illness as a cause, those under age 65 far outnumber those above it. Each age group has a different set of goals for the care they receive. Younger persons are more interested in living a normal life, or mainstreaming. For them, the best care is that which supports them in performing their age-appropriate social roles, be it education, employment, or social activities. Many older persons have more modest goals. They seek assistance to help them cope with the disabilities they face. They accept the idea of restricted social roles.

Not surprisingly, leaders of the young disabled movement suggest that older persons are settling too cheap and need to be reeducated to seek more.

3. Even within older clientele, the goals for LTC may vary widely. Some seek active rehabilitation with the expectation of substantial functional improvement. Others seek assistance in coping with their functional deficits, relying on human or mechanical assistance to compensate for losses they have sustained. Still others share the desire of their younger colleagues to maintain an active participation in social affairs.

4. These different goals for LTC can be linked to two fundamentally different conceptual models of this care. One approach can be thought of as “compensatory.” Under this model, activity is focused on assessing functional dependencies and prescribing services to compensate for these deficiencies. Good care is defined as that which matches the needs with appropriate services without creating untoward effects. This approach is often associated with the term social model. The other approach can be thought of as “therapeutic.” Under this model, care should be expected to make a difference. Because the natural clinical trajectory of many people needing LTC is decline, good care may yield simply a slowing of that path. Unfortunately, it may be difficult to detect a positive effect in the absence of good data as to what would have occurred without such care. The ultimate comparison will be actual versus expected course. The therapeutic model is often referred to as the medical model. These two approaches are frequently presented as being in opposition, but it is possible to find common ground by viewing each as necessary but not sufficient. Good care should respond to assessed needs, but it should also make a positive difference. This difference need not be restricted to medically germane concepts; it can include quality of life issues as well.

5. LTC is often linked closely to chronic disease. Much of the disability that underlies it is a result of such disease, often more than one acting simultaneously. Hence,

FIGURE 10.1. Sources of long-term care. Most long-term care is provided by informal caregivers, either alone or in combination with formal care. (From Georgetown University Institute for Health Care Research and Policy. Based on Liu K, Manton K, Aragon C. Changes in home care use by disabled elderly persons: 1982–1994. Washington, DC: The Urban Institute, September 1998, with permission.)

persons needing LTC are also very likely to need aggressive primary care to manage their chronic disease. Attitudes that attempt to categorize people as needing either medical or social care are thus dysfunctional.

6. Nothing about the definition of LTC implies care given at a particular site. Practice has historically confused the site of care with the nature of the services rendered. That artifact has hindered developing more creative and efficient approaches to such care. Indeed, if one looks back on what has happened in delivering acute medical care, there has been a dramatic revolution in how such care is provided. Care that used to be considered as needing a hospital is now provided in an ambulatory setting or even at home. Likewise, LTC can likely be offered in a wider variety of settings than is currently the case.

7. The backbone of LTC is informal care provided by family (and to a lesser extent by others). As shown in Figure 10.1, only about 8% of care provided to persons living in the community comes exclusively from formal (i.e., paid) sources; another 28% is provided by a combination of formal and informal care, and almost two-thirds comes solely from informal sources. This pattern appears to be amazingly stable. It is encountered in countries that have gone through the demographic revolution, including places where universal paid LTC is available. This stability is especially comforting in the face of predictions about the death of the American family. Because informal care has traditionally been a euphemism for care provided by women, the observation that larger numbers of women are entering the labor market, combined with

high divorce rates and smaller family sizes, raises serious concerns about whether this cadre of informal care providers will be available in the years to come. Losing this informal care would place enormous strains on the formal care system. It is, therefore, not surprising to find many policy analysts urging ways to support the informal care system.

Figure 10.2 shows the extent of informal care services provided to frail older people. The proportion of persons receiving assistance increases with their age. Women receive more help than men. The more care given, the more caregivers are involved.

Even with the substantial amount of informal care being provided, many older people still do not receive needed help. Figure 10.3 shows the proportion of persons aged 70 and older who have unmet needs with regard to activities of daily living (ADL) and instrumental ADL (IADL) dependencies. The rates of unmet IADL needs decrease with age among women, while the rates for unmet ADL assistance remain constant.

Figure 10.4 describes the sources of payment for long-term care in general and nursing homes in particular, which are presented together to highlight the differences in funding patterns. Medicare and Medicaid together account for about 60% of LTC expenditures and about the same proportion of nursing home expenditures. However, Medicaid plays a much larger role in the latter, whereas Medicare is major funder of home care (and hence LTC in general). Because a substantial portion of LTC comes from public funds, there is inevitably some

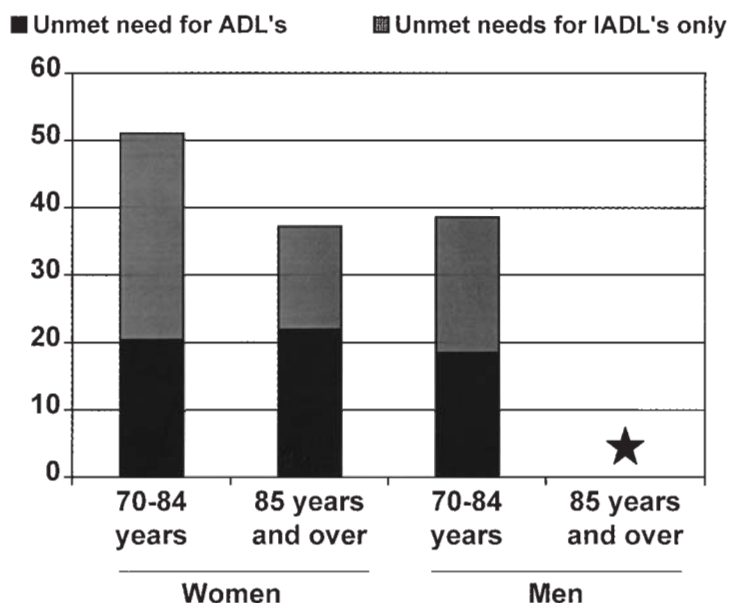

FIGURE 10.2. Proportion of persons 70 years and older with one or more ADL or IADL dependencies receiving informal assistance. The rate of receiving assistance increases with age. The rates for women are consistently higher than those for men. Many older people receive care from more than one person. (From Centers for Disease Control and Prevention, National Center for Health Statistics. 1994 National Health Interview Survey. Second Supplement on Aging.)

degree of age competition, especially with regard to Medicaid. This welfare-based program was designed to provide medical insurance for poor persons, especially mothers and children. An unanticipatedly large proportion of Medicaid funds, however, went to cover the costs of older persons who were in nursing homes. Indeed, a disproportionately large share of Medicaid payments go to older persons. Although the amount spent per recipient is much greater for developmentally disabled children, there are far fewer of them.

Medicare, which is basically a universal health insurance program for persons age 65 and older, was not intended to cover LTC, but it has been used for this purpose by means of two developments. The first was the imposition of prospective payment for hospitals, whereby they were paid a fixed amount based on each Medicare patient's Diagnosis-Related Group. When hospitals were paid for all their costs, there was no incentive to make care more efficient. The Medicare provisions that allowed payment for posthospital care at home or in a nursing

FIGURE 10.3. Percent of persons 70 years of age and over who need help with one or more activities of daily living or instrumental activities of daily living by age and sex, 1995. The overall rate of disability among older women is higher for those 70-84 than for those 85+, but the proportion of those with ADL dependencies increases. Older women are more disabled than older men. (From Health, United States, 1999.)

Long-Term Care Expenditures: \$115 Billion

Nursing Home Expenditures: \$83 Billion

FIGURE 10.4. Sources of long-term care expenditures, 1997. Payments for LTC in general come more equally from Medicare and Medicaid, whereas those nursing homes come more heavily from Medicaid. (From Georgetown University Institute for Health Care Research and Policy, with permission.)

home lay dormant. However, once hospitals were paid a fixed amount, the incentives changed drastically. Patients were discharged “quicker and sicker,” creating a new demand for what came to be called postacute care (PAC).

As the use of Medicare to pay for nursing homes increased, Congress applied prospective payment to them as well. The system used differs from that used in hospitals. Instead of calculating the expected costs of an episode of care, Medicare payments to nursing homes are based on the costs of each day of care. These costs are calculated by estimating the personnel needed to provide various levels of care, called Resource Utilization Groups (RUGs). Linking greater disability to higher RUG payments inadvertently created an incentive to preserve disability.

This care-mix approach is mandated only for Medicare payments to nursing homes. Medicaid payment approaches are left at the discretion of the states. Of the fewer than half the states that use some variant of case-mix-based payments, most have opted to make these payments compatible with the RUGs approach for the sake of simplicity.

The enthusiasm for prospective payment has extended to all forms of PAC. However, each modality is paid separately. Whereas nursing homes are paid on a daily basis, home health care is paid for a 60-day episode and rehabilitation for 30-day episode.

As shown in Table 10.1, 38% of all Medicare-covered hospital discharges in 1995 received one or more forms of PAC. The dominant model was home health care, accounting for more than half of all PAC usage. About 20% of those using PAC used more than one type of service.² The use of PAC, like many other forms of care, varies considerably from one part of the country to another. Table 10.2 shows the extent of the variation across the major census regions for each of four diagnoses associated with substantial PAC use. Several lessons emerge. The likelihood of using PAC varies with both diagnosis and location. Hip fracture patients are more likely to get some type of PAC than are stroke patients, and both use PAC more than congestive heart failure patients. Within a given diagnosis, for example, stroke, the likelihood of getting some PAC varies from

TABLE 10.1. Proportion of hospital discharges using postacute care (PAC), 1995.

Type of PAC service	Use of PAC (%)

63% to 75%. For hip fracture patients, the variation is from 85% to 93%.

One reflection of the impact of the hospital DRG payment system can be seen in Figure 10.5, which compares the payment sources for nursing home care in 1985 and 1995. Over that decade, the proportion of funds covered by private payment decreased, while the contributions of Medicare, and to a lesser degree Medicaid, increased.

The Nursing Home

The nursing home has served as the touchstone for LTC. For better or worse, other forms of LTC are usually considered in relationship to the nursing home. This institution can be said to have a mixed heritage, descended from the almshouse on one side and the hospital on the other. Skeptics would say it has inherited the worst traits from

each parent. Because nursing home care has been closely associated with Medicaid, a welfare program, it carries the welfare stigmata. At the same time, early federal regulations used small hospitals as the template for nursing home standards. What might be tolerable for a brief spell in an acute hospital where one expects to derive substantial benefit becomes unbearable in a longer stay in a nursing home where the expectation of benefit is far less.

Institutional practices that rob patients of their identity and their dignity, which impose rules developed to make care more efficient but less personalized, are never welcome, but they are even less so when the quality of one's environment dramatically affects the quality of one's life. The standard hospital model of multiple persons in a room, fixed hours for eating and being awake, limited choice of food, and a general sense of being driven by a therapeutic philosophy does not jibe well with a sense of creating a more normal living environment. The de facto linking of services and hotel func-

FIGURE 10.5. Changes in the sources of payment for nursing home residents age 65 and older from 1985 to 1995. The proportion of coverage from Medicare and Medicaid increased while that from private pay declined. (From Hing E. (1985). Use of Nursing Home by the Elderly: Preliminary Data from the 1985 National Nursing Home Survey. Advance Data from Vital and Health Statistics no. 135. DHHS Pub. No. (PHS)87-1250. Hyattsville, MD: Public Health Service; 1987, Table 9; and Georgetown University Institute for Health Care Research and Policy, 1995.)

tions, inherent in the notion of a nursing home, may impose a high price on one's lifestyle. In fact, one might argue that the very term "nursing home" is a misnomer, because it provides neither much nursing (on average, about 90 min/day, primarily from nursing aides) nor a very homelike atmosphere.

The plight of the nursing home has been made more serious by asking it to play multiple roles in the lives of very different types of clients. In many instances the nursing home is not the only institution serving this group. Table 10.3 shows the various populations served and some of the alternative sources of care for each group. Trying to fill so many roles makes it difficult to achieve good results.

The use of nursing homes is linked to age. Summary numbers about the average use of nursing home are misleading. As shown in Figure 10.6, the use of nursing homes is much higher among those aged 85 and above. Indeed, it makes much more sense to report nursing

home use rates as a function of the population in this range rather than 65 and above.

For a long time, even though the supply of nursing homes varied greatly across the country, the demand for nursing home care was perceived to be so strong that utilization would rise to meet the supply. However, that situation seems to be changing. As shown in Figure 10.7, the use of nursing homes per capita fell from 1985 to 1995. For the first time, nursing homes are now facing the potential of empty beds. Several factors likely contribute to this shift.

1. Nursing home, are increasingly being used for post-acute care, where the expectation is for a finite stay and discharge to the community. Shorter lengths of stay are inevitably associated with lower occupancy.
2. Nursing homes are facing new competition from assisted living. Private-paying clients especially are attracted to the idea of being able to live in more commodious settings, often at lower costs.
3. People are entering nursing homes later in their medical careers and thus dying sooner, lowering the average length of stay.

Nursing homes entering the postacute care market may find themselves disadvantaged and unable to provide the services they wish. In general nursing homes do not have the nursing staff, especially professional nurses, to meet the needs of patients just discharged from the hospital. Medical attention is often less than that which is needed. Doctors who make hospital rounds are less inclined to make comparable nursing home rounds, certainly not as frequently, nor is Medicare as likely to pay for such care. Ironically, a patient may be covered in a hospital one day and a day later be a nursing home patient, virtually identical clinically, but with much lower

FIGURE 10.6. Nursing home residents among persons 65 years of age and over by age, sex, and race, 1997. The proportion of older persons in nursing home homes increases dramatically with older ages. Women use more nursing home care than men. Black persons now use as much or more nursing home care as do whites. (From Health, United States, 1999.)

FIGURE 10.7. Nursing home residents 65+ per 1000 elderly, 1985 and 1995. The use of nursing home declined from 1985 to 1995. The reasons for this drop are being debated. (From Georgetown University Institute for Health Care Research and Policy, with permission.)

expectations for medical care. Concerned doctors may have to spend considerable effort arguing why they should be paid for their work. Likewise, nursing homes may not be able to provide the rehabilitation needed. Some homes have physical therapists on staff, and others contract for such care, but few have the full gamut of a rehabilitation team.

The nature of medical care in nursing homes has changed. Although nurse practitioners have been shown to improve primary care in nursing homes for some time,^{3,4} they have not been widely utilized. With the emergence of managed care, dedicated teams of physicians and nurse practitioners have been effectively used to follow nursing home residents.^{5,6} Special managed care programs directed specifically at nursing home residents have been created under the belief that aggressive primary care will prove cost-effective by reducing hospitalizations.⁷

Home and Community-Based Care

The nursing home finds itself squeezed at both ends. On the one hand, it must compete with rehabilitation units and hospitals that are turning their new excess capacity into long-stay or subacute care units. At the other end, it must compete for chronic care business with assisted living and home care, both of which may offer more attractive settings in which to live.

This situation is a new one for nursing homes, which have for years served as the touchstone of long-term care. All other modalities were considered in terms of alternatives to the nursing home. This "alternatives paradigm" has persisted for some time. The search for suitable alter-

natives that were both more effective and less costly has proven frustrating, in part because long-term care is, at its base, a social construction. The solution to the problem ultimately was to redefine the needs.

The search for alternatives faced many obstacles.

1. It was hard to target services accurately. Many people who seemed to be eligible for or at risk for nursing home services never used them. Hence, an intervention designed to decrease nursing home use could not show an impressive difference against a low rate in the control group.

2. Calculating comparable costs was a challenge. In one sense, the nursing home is a good buy, as it includes room and board as well as services. Purchasing room and board in the community is an added expense, but one may get much more than in a nursing home, where rooms are not private and little choice of food is offered. Simply adding the costs of room and board to services in the community seems to artificially raise community-based costs, especially if one is, in fact, buying more than would be available in the nursing home. On the other hand, much of the care in the community relies on informal care, which is not charged. Shadow pricing this care implies (1) that the care would be given in the same amount if it were paid for and (2) that the costs would be equivalent to the going wage for an appropriate level of caregiver.

3. The effects of community care may be delayed. The window for detecting a benefit may be too narrow to reflect the effect of delaying institutionalization.

4. The evidence of benefit may extend beyond reduced hospitalizations or nursing home admissions. Getting care in one's own home might be what most people want; there may be intangible benefits.

FIGURE 10.8. Home health care patients among persons 65 years of age and over by age and sex, 1996. The use of home health care increases with age. Women use home health care more than men. (From Centers for Disease Control and Prevention, National Center for Health Statistics. National Home and Hospice Care Survey.)

The most prevalent type of home- and community-based care is home care. Care at home comes in two forms that are often difficult to distinguish. Home health care is usually covered by Medicare and is built around a nursing model, although most of this care is given by home health aids. Homemaking services, usually provided by persons termed personal care attendants, are more likely to be covered from other sources, such as Medicaid. As Figure 10.8 indicates, the pattern of home health care closely resembles that for nursing home care, with a rapid increase in use with age. Home health care has experienced a dramatic growth, spurred by the shortening of hospital stays and the removal of coverage constraints. As a result, home health care, which is presumably treated as a postacute care service under Medicare, was often providing care to persons more than 120 days after discharge from a hospital. Changes in the 1997 Balanced Budget Act and the subsequent revisions in the 1999 Act were introduced to constrain this rapidly growing area. The prospective payment system uses data from the mandated Outcome and Assessment Information Set (OASIS), which is used to track the outcomes of home health care. Table 10.4 shows the effectiveness of the short-term changes in Medicare payment in reducing the numbers of visits per episode. The median number of visits fell from 26 to 28 in 1994 and 1997 to 21 in 1998.

The concept of home- and community-based care conjures up images of care at home, but in some instances housing may be required as well, either because the person's original home has been lost during a period of institutionalization or because the nature of the care required implies a need for frequent brief visits, where the costs of travel time may exceed those of the care itself. Such a situation is best addressed by some form of congregate housing whereby services can be affordably provided to many people living close together.

An emerging form of LTC is assisted living. Although there is no consistent definition of this style of care, most people agree that it includes an opportunity to live alone with quarters that provide their own toilet and bathing facilities and some means to preserve and prepare food. At the heart of this concept is the idea that people are first seen as inhabitants of their space with control over their lives. Services are provided as conditions dictate. Some may be offered as a part of an overall package (e.g., congregate dining, a minimum number of service hours per week); others can be purchased as needed.

Questions have been raised about how well this modality can handle very frail individuals. Although the case mix of assisted living is usually less complex than that of nursing homes, the clinical trajectories seem to be fairly equivalent.⁸ No one has yet probed the limits of such care.

Anecdotal reports feature care of very frail persons, but the wholesale expansion of assisted living has resulted in a proliferation of forms and shapes. The term no longer conveys a clear message. Persons interested in such services must examine carefully just what is promised and for how long. Cost pressures have encouraged many ALs to seek ways to discourage clients once their care needs become heavy or to demand that families hire personal care attendants. States are currently struggling

with how to accommodate AL within their LTC Medicaid programs. The results to date are very varied.

Although the initial efforts to establish the benefits of home- and community-based care were frustrating and the research results proved unconvincing;^{9,10} the press for such care continued. Policies influencing the amount of such care given in proportion to the amount spent on institutional care showed great variation from state to state. Even when demographic and other factors are considered, there continues to be a big national discrepancy.¹¹ Table 10.5 shows the states in 1996 that had the most and the least commitment to home- and community-based care, arrayed by the amount of demographic pressure on them to generate long-term care. Although most of the states with heavy commitments to home- and community-based care have less demographic pressure to develop LTC programs, a few states with high demand have responded creatively.

Until now, LTC has been largely a state responsibility because of the heavy role Medicaid has played. The result has been the wide variety of programs and level of effort reflected here. Some observers view this variation as a positive phenomenon. They see the states as the national laboratory, experimenting to find better programs. Others view this variation as an indication that more federal attention is needed to provide a more equal basis for care. For them, geography should not determine one's destiny.

LTC Policy Dilemmas

Quality

As the population ages and as older people become more affluent, our society faces several conflicting demands. Consumers have long held a preference for receiving care

in the community, preferably in their own homes. Those needing housing, either because they had no shelter or because logistics required some sort of congregate living arrangement to make home care affordable, prefer a livable environment where they have maximal control and autonomy. At the same time, our society continues to view older people as vulnerable and in need of protection.

Heavy regulations dominate the nursing home scene and indeed have shaped the nature of that care. The impetus for active regulation goes back to a series of scandals in the nursing home industry in the 1960s and 1970s that featured both inflated prices and neglectful care.^{12,13} A turning point was the report of the Institute of Medicine,¹⁴ which led to the Nursing Home Reform Act of 1987. In addition to requiring more training and better staffing, the Act mandated a uniform data system. The Resident Assessment Inventory (RAI) is composed of the Minimum Data Set (MDS) and the Resident Assessment Protocols (RAPs), which provides suggestions for further evaluations that should form the basis of care planning. The underlying idea held that collecting more systematic data would improve care planning and could provide the basis for better oversight of the care provided.

The RAI represents an important step forward, although the MDS approach has serious limitations, largely attributable to the plan to collect data from the observations of those who provide the care rather than talking directly to residents, and hence the requirement that many salient domains be inferred or ignored.¹⁵ Although some states had already created strong assessment tools, many states had not. A national standard not only raises the mean performance, it allows comparisons. Whether causal or coincidental, the introduction of the MDS has been associated with improvement in several aspects of nursing home care, including impro-

vements in function,¹⁶ hospitalization,¹⁷ and health conditions.¹⁸

At the same time, the MDS approach has an important limitation. Because its data come exclusively from staff observations, they cannot address the equally important issues around quality of life. Such critical information is highly subjective and cannot be inferred.

Assessing problems is not the same as fixing them. Nursing home regulations have been much better at detecting care deficiencies than correcting them. Such corrective actions involve sanctions and often result in litigation. The threat of litigation and the demand for objective documentation of poor care has led regulators to emphasize those aspects of care that best lend themselves to quantification. Unfortunately, these may not be the ones most closely related to a decent quality of life or even to good care.

Some have argued for a shift in emphasis away from the process and structure of care to a focus on the outcomes of care. In a situation such as LTC, outcomes can be easily misunderstood. Because the normal course favors decline in function, it may be hard to demonstrate a positive outcome. Thus, even good care can appear to create a poor result. The key to understanding LTC outcomes is the recognized need to demonstrate the difference between observed and expected results. Good care may be best portrayed as slowing the rate of decline. Unfortunately, in many instances this favorable result is hard to demonstrate in the absence of any data to show the expected course with such care. Thus, benefits must be expressed as the difference between observed and expected outcomes. Achieving this end requires having access to data that can describe the clinical course associated with typical care and with the care actually being rendered.

This approach is useful beyond regulatory purposes. LTC workers may readily become discouraged and dissatisfied from seeing decline in so many of their clients. Without some means of appreciating the differences their care is making on the lives of those they care for, they may assume a reaction of learned helplessness, feeling that their efforts cannot change the course of their charges. At least some of the high turnover and low prestige of nursing home work may be traceable to this problem.

An outcomes focus also allows comparisons across modalities of care. As new forms of care emerge, such as assisted living, those in the nursing home arena cry foul, claiming that assisted living is allowed to live under a different (i.e., lower) standard. On the other hand, if assisted living is required to meet all the mandates of nursing home care, it will inevitably become nursing home care and any possible benefits will be lost. By shifting the emphasis away from mandating components and methods of care to accountability for case-mix-adjusted

outcomes, it is possible to preserve flexibility and still assure accountability.

One issue that runs through all the discussions about quality is the extent to which frail older people should be placed at risk, or even allowed to take risks. One faction holds that all frail older persons are vulnerable elders and hence must be treated as wards of the state, protected from all potential sources of harm. An alternative formulation suggests that older people should be allowed the right to take risks so long as they do so knowledgeably. This construct, called managed risk, emphasizes the need for responsible decision making and the obligation to provide older persons and their families with better information about the risks and benefits (and costs) of alternative modes of care.

Financing

A continuing issue is how to finance LTC. As noted earlier, a considerable amount of the money is public dollars and many of the costs are hidden as informal care. Despite efforts to push the idea, private long-term care insurance has not really caught on. People seem reluctant to commit their disposable income early in their lives when the risk of LTC seems very remote. As people age and the chances of LTC increase, so do the costs of the policies. Another related problem is that inflation plays a big role in determining the value of such a policy purchased well in advance of needing it. Adding an inflation adjuster raises the cost considerably. From the states' perspective, buying private long-term care can reduce the likelihood of needing Medicaid coverage. Hence many states have tried to create inducements for older people to buy such coverage, usually offering to exclude more assets in determining eligibility for Medicaid. For many people, private LTC insurance is really asset insurance. It offers a means to assure that assets will not be depleted and can be left as a legacy.

The better the LTC coverage offered under Medicaid, the fewer the incentives to purchase LTC insurance. It would be perverse public policy, however, to make Medicaid-covered care so unattractive to induce more people to buy LTC insurance.

One possible way out of this policy dilemma would be to redefine the state's responsibility for providing LTC coverage. So much of these considerations is driven by the nursing home model, which combines room and board with services. An alternative formulation would have public funds cover only the services component of LTC, leaving the responsibility for the housing aspect to the individual. This formulation has several potential advantages. It could lay the groundwork for a universal LTC benefit restricted to services only. It could allow a more even footing for comparing the costs and value of different modalities of LTC. It could emphasize the need

to offer a reasonable living situation as well as the requisite care. In effect, it would end the distinction between institutional and community-based care. All care would offer the same range of services to people living in a variety of settings with varying levels of amenities. The latter would reflect their affluence but would not affect the receipt of care.

Another direction being explored is to translate public obligations for financing LTC into strict accounts. Those eligible for such payments would be given the option of in effect cashing out their benefits by receiving a cash payment in lieu of services. This arrangement has been used in several European countries, most notably Germany, which has a universal long-term care insurance program.¹⁹ A crucial question is, of course, how the conversion rate should be established. Traditionally, it has been quite deeply discounted (paying only about 65% of estimated costs). People's willingness to accept such a deep discount raises interesting questions. Either the cost of LTC is overpriced or many people expect that they can obtain these services less expensively from informal sources, including family members.

These cash and counseling programs raise a number of questions. Historically, public agencies have had a much harder time relinquishing responsibility compared to the relationship between private agencies and clients. Given this vulnerability, public agencies are reluctant to simply cash out benefits. Instead, they prefer to provide some sort of vouchers that would limit the range of services that could be bought or to insist on some sort of counseling to enhance the likelihood of wise decisions. The other large concern is the so-called woodwork effect. Offering home and community care has always raised fears that the availability of such services would induce demand. In the main, these fears have never materialized. However, the offer of cash should prompt more people to demand care (or its cash equivalent) and hence raise the overall costs.

Balancing Long-Term Care

If long-term care is acknowledged as a social construct, then the goal should be to improve the lives of the people served. From this starting point, planning the future would better start from the vantage point of the type of care we want rather than how to revise what we have. We need a wider array of choices that can provide care at varying levels of intensity, combined with housing and supportive services. The housing can be the client's or congregate housing may be needed, either to meet a person's needs for housing or because colocation is necessary to achieve efficiency.

Long-term care is primarily a state-level issue because of the central role played by the Medicaid program. As a result, there is wide geographic variation in the nature

TABLE 10.6. Proportion of total and of Medicaid LTC expenditures going to HCBS, 1996.

	LTC expenditures to HCBS (%)	
	Total	Medicaid
Alaska	47	14

and extent of care. The extent of balance in current long-term care programs varies widely across the states. A few vanguard states, such as Oregon and Washington, have made deliberate efforts to redirect Medicaid expenditures from nursing homes to community care, including institutional options like assisted living, but most states have been hesitant or unable to make such a shift. Table 10.6 illustrates the level of variation in the balance of nursing home and community expenditures for Medicaid and total LTC dollars. The range in expenditures on home- and community-based services (HCBS) as a percentage of total LTC expenditures runs from 47% (Alaska) to 2% (Tennessee). The proportion of expenditures is generally quite similar for Medicaid funds, but there are some exceptions (e.g., Alaska, Idaho, California, Pennsylvania, and Tennessee).

A commitment to a balanced LTC program requires both the creation of options for care and the flexibility to spend money on a variety of services. While one might expect the market to respond to more flexible payment policies, some proactive effort from the state seems to be required to provide assurance of demand as an inducement for innovation.

The debate goes on as to whether LTC should continue to be a state-level issue or should move toward a more national standard. The argument for the latter is one of equity. Geography should not determine services. On the other hand, reality suggests that conditions vary widely across the country, and states have been the primary innovators. No single model that could be adopted as the

national prototype has yet emerged as clearly preferable, nor is there any reason to believe that there will ever be a single best way to deliver such care. At least some consistent set of expectations (beyond the general list of mandatory services that are now part of Medicaid) seems reasonable, leaving the specific modes of implementation to the discretion of states, given that these are publicly funded programs with major federal subsidies.

Integrating Medical and Social Services

Long-term care may be primarily a social service, but many of the people receiving it suffer from serious chronic diseases. At a minimum, these people need close medical attention. Some would advocate merging both long-term and acute care elements into a single program. Others fear that this merger would create an overly medical model that might compromise the quality of life of participants.

One way to provide integrated care is to capitate the total care under a single managed care aegis. The experience with this approach is still preliminary. The best known model of this approach to care is PACE (Program for All-inclusive Care for Elders). This approach places great emphasis on active primary care, provided by a comprehensive care team, with a strong commitment to keeping clients out of institutions, both hospitals and nursing homes.²⁰ Preliminary data suggest that the PACE programs have succeeded in reducing utilization of both types of institutions; however, the overall impacts of the program on health status show little benefits over conventional care.²¹ These results have not impeded PACE in becoming an official option under Medicare + Choice.

It is not yet clear how widely programs like PACE can be replicated, nor whether they really operate within the prescribed budgets they receive.²² Presently, the PACE model has several limitations, which have affected marketing. (1) It serves a select dually eligible (for Medicare and Medicaid) population who are eligible for nursing home care but still in the community. (2) It requires clients to change their doctors to use a PACE physician who is comfortable with the PACE team approach. (3) It requires clients to use adult day health care. Newer forms have been developed that try to adapt the overall PACE philosophy to more flexible models that permit maintaining existing doctor-patient relationships.²³

Quality Concerns

One potential for addressing the quality conundrum posed by the diversity of LTC programs may lie in moving toward establishing accountability on the basis of outcomes in lieu of process and structure. It seems more sensible to hold all providers equally accountable for outcomes adjusted for case mix. However, many advocates

are reluctant to give up the hard-won regulations that have historically emphasized process and structure; they acknowledge the desirability of looking more at outcomes, but they are not yet convinced that outcomes can be used exclusively, or even primarily, as an enforceable tool in regulation.²⁴

Another quality issue addresses the relationship between medical care and other care on behalf of nursing homes. At present, most of the attention is directed at nursing-related items; exceptions include the use of psychoactive medications. It seems likely that future regulation will raise expectations about medical care for nursing home residents, including the failure to track problems with sufficient vigilance to prevent unnecessary hospitalizations. The shared responsibility (leading to an implicit partnership relationship) of hospitals and attending physicians will likely be repeated in the context of the nursing home.

Summary

LTC is changing. Its final form is hard to foresee, but it will inevitably require a close linkage between those providing the supportive services needed to compensate for functional losses and those providing the active medical care needed to manage the underlying chronic conditions. Ironically, although such care is often held in low esteem, it represents an area where a modest input can reap large dividends in terms of both avoiding catastrophes and improving patient quality of life.

The Geriatrician in the Nursing Home

Wayne C. McCormick

Imagine this practice. You arrive to see your patients when it is convenient for you (morning, afternoon, or evening; it does not matter)—sometimes scheduled, sometimes unannounced. The staff is glad to see you, bringing you current information on your patients, as well as documents for your signature, as necessary. Your patients are all present—100% show rate, every time! They are also delighted to see you and will see you when convenient; they are in no hurry—they literally have all day. They are extremely needy of your services; many are quite debilitated, and quite a few have very interesting and challenging medical problems. A substantial diagnostic armamentarium is available to you: standard clinical laboratory tests, radiology, and electrocardiograms; even ultrasound abdominal and vascular studies can be obtained. Reimbursement has steadily improved for your services, as has the knowledge base and quality of care in your practice environment, thanks to a number of national provider organizations and other advocacy groups.¹ And the overhead expenses and hassle factor of your practice are quite low relative to those of other office-based physicians you know.

Welcome to practice in the modern skilled nursing facility (SNF), or nursing home. Many health care providers have poorly conceived prejudices about nursing homes, viewing them as many lay people do—as warehouses for the ill elderly, where care is poor and staff is made up of persons who cannot get a job anywhere else. These prejudices are pervasive because many physicians, like many lay people, have never set foot in a nursing home and are averse to debility and chronic disease. In fact, no two nursing homes are alike. Many are quite fancy; some are highly specialized (catering to patients with head injury, or those with AIDS), whereas others may be more humble physical plants; they are often replete with dedicated and skilled staff with substantial altruism and medical knowledge.

What nursing homes do have in common nationwide is a dedication to care of persons with chronic disease, an

emphasis on patient autonomy, and a daunting regulatory structure that (since an Institute of Medicine report and resultant enactment of federal legislation more than a decade ago²) has standardized patient assessment and quality of care to a large degree. In fact, most nursing homes today deliver good-quality care, and many deliver care that can only be described as outstanding. Certainly, a substantial number need to make quality improvements, which is probably true in any category of medical care. At least assessment of quality of care is more elaborate, codified, and complete, thanks to legislation and a regulatory structure that encourages comprehensive assessment in a uniform manner for all patients.³

In modern times, most nursing homes function in a multidisciplinary manner similar to geriatric evaluation teams or units in other settings. By regulation, most members of a typical geriatric evaluation team are available in the nursing home, including physical therapists, occupational therapists, speech pathologists, social workers, recreational therapists, and, of course, nurses and nurses' aides. It is quite typical for skilled nursing facility nurses to specialize in some aspect of chronic care, such as wound care, dementia, AIDS, or spinal cord injury. This approach is facilitated by the existence of specialized units within many nursing homes, such as high-intensity subacute rehabilitation or ventilator units, or low-intensity dementia or head injury units. It is also common to have team meetings, as is done in geriatric evaluation units, and the family of the patient is often included to help in sharing perspectives and care planning.

Hierarchy of Influence in the Nursing Home

Nursing homes are well named; they are run by nurses. The most powerful and influential administrator in the modern nursing home is not necessarily the executive director, and certainly not the Medical Director or the

attending physicians—it is the Director of Nursing. The language of the clinical staff of nursing homes is the language of nursing, built on the basic needs of persons with chronic diseases. For example, common nursing diagnoses include “alteration in bowel function,” “alteration in nutrition,” or “alteration in cognition.” The underlying medical diagnoses are only of passing interest, whether Alzheimer’s disease, multiple sclerosis, or AIDS: the drivers of care day in and day out are the nursing diagnoses.

Little wonder, then, that all basic assessments are headlined by nursing diagnoses, including the national, mandatory assessment completed on admission and serially (at least quarterly) on all patients admitted to skilled

nursing facilities—the Minimum Data Set (MDS).⁴ This arcane five-page document is becoming more familiar to physicians practicing in nursing homes, who may over time be called upon to verify the data contained in the MDS. The MDS drives nursing home care and reimbursement in an absolute and powerful way nationwide, through severity of illness indices derived directly from the data elements in the MDS.

Figure 11.1 shows a typical portion of a page and section list of the MDS. Debility identified on the MDS “triggers” a Resident Assessment Protocol, or RAP, which is essentially a codified care plan for each triggered problem. The more RAPs that are triggered, the more care plans that are applicable and the more complex the

care of the patient. Progressive debility in basic activities of dally living (ADLs), cognition, behavior, and other realms that translate into higher skilled care needs also translates into higher reimbursement categories, known as Resource Utilization Groups (RUGS),⁵ a classification system analogous to the Diagnosis-Related Group (DRG) system in hospitals and similar in that it dictates prospective payment. The reader will note, however, that the prospective payment in the nursing home is not built on medical diagnoses, but rather on the level of debility implicit in the nursing diagnoses. This fundamental principle highlights the importance of nursing function and lingo in the SNF, and many physicians practicing in the SNF are slow to understand the pervasiveness of this principle; it is much like learning a foreign language while living abroad.

The Nursing Home Medical Record

Physicians are often struck by the volume of the typical nursing home medical record; it is huge. The first reaction of doctors when confronted with the patient record is, “What are all these sections for?” The typical record has two dozen sections. Table 11.1 lists the usual makeup of the record in order; advance directives invariably follow demographic face sheets as the first section. It is nearly impossible to be admitted to the modern nursing home without declaring one’s code status. Admitting history and physical examination, orders, and progress notes usually follow. The progress note section often demon-

TABLE 11.1. Sections of the nursing home medical record.

Miscellaneous

strates a frank economy of space, with all disciplines represented in close succession; typically, 6 to 10 notes can fit on the face of one page. This economy is to account for long stays so the chart can contain a lengthy record without thinning. Most of the sections that follow are nursing driven, with care plans, the MDS, and each discipline (physical therapy, occupational therapy, recreational therapy, social services, medication delivery records, treatment records, etc). Although it is not necessary for the physician to read completely the entire chart of every patient, it pays to do so for a substantial minority to get an impression of the total care rendered. In aggregate, the total nursing home record of patient care captures the comprehensiveness of the experience better than a typical hospital chart, certainly with regard to care rendered.

Patient Autonomy

The second fundamental principle that pervades nursing home practice is that of patient autonomy. The volumes of regulations pertinent to nursing home care (second only to the regulatory burden of the airline and nuclear power industries) has at its core patient autonomy. Every conceivable effort is expended to ensure this principle in the SNF. For example, patients are not to be restrained in any way, whether chemically (via sedatives or neuroleptics) or physically, without extensive documentation and monitoring (Fig. 11.2). Most nursing homes find it far easier to find creative ways to avoid restraint through behavior management than to use restraints. Regarding physical restraints, the rules go beyond what many might consider restraints, not just wrist restraints or waist restraints. For instance, lap trays on wheelchairs and bed rails are considered restraints. Not only are residents not to be restrained; they are also encouraged to participate in as many activities as possible to replicate the day-to-day rights and activities of nondebilitated citizens. By regulation, this autonomy and independence is to be fostered, which implies that it must be assessed in the first place. Residents are strongly encouraged to take meals in groups, to see movies or watch television together, to attend musical events, and to vote. These activities are either brought to them in the facility or arranged in “field-trip” fashion. Again, physicians may be slow to comprehend this fundamental atmosphere of patient autonomy. Physicians are used to meting out admonitions and directives to patients in the office, clinic, or hospital. Patients are referred to as “residents” in the SNF—this is their home, where they are boss. The admonitions and directives are supposed to come from them to the staff and physicians, not the other way around.

Resident behavior and acuity Practices 8

A. Level B requirement: Restraints

1. The resident has the right to be free from any physical restraints imposed or psychoactive drug administered for purposes of discipline or convenience and not required to treat the resident's medical symptoms.
2. Physical restraints are any manual method of physical or mechanical device, material, or equipment attached or adjacent to the resident's body that the individual cannot remove easily which restricts freedom of movement or access to one's body (includes leg and arm restraints, hand mitts, soft ties or vest, wheelchair safety bars, and gerichairs).
3. Psychoactive drugs are covered below, under "Quality of Care."
4. There must be a trial of less restrictive measures unless the physical restraint is necessary to provide lifesaving treatment.
5. The resident or his/her legal representative must consent to the use of restraints.
6. Residents who are restrained should be released, exercised, toileted, and checked for skin redness every 2 h.
7. The need for restraints should be reevaluated periodically.

Drug therapy

Each resident's drug regimen must be free from unnecessary drugs

- (1) "Unnecessary drugs" are drugs that are given in excessive doses, for excessive periods of time, without adequate monitoring, or in the absence of a diagnosis or reason for the drug. An unnecessary drug is a drug for which monitoring data, or undue adverse consequences indicates that the drug should be reduced or discontinued entirely. An unnecessary drug is also one which is prescribed only in anticipation of an adverse consequence of another prescribed drug.
- (2) In deciding whether an unnecessary drug is being used, surveyors are instructed to be very sure that reputable literature and thorough understanding of the resident's clinical condition justifies this judgment. (HCFA is developing additional guidelines for surveyors for determining unnecessary drugs which will include specific drugs and dosages.)

Antipsychotic drugs

- (1) Residents who have not used antipsychotic drugs are not given these drugs unless antipsychotic drug therapy is necessary to treat a specific condition.
- () Antipsychotic drugs should not be used unless the clinical record documents that the resident has one or more of the following "specific conditions":

1. Schizophrenia
2. Schizoaffective disorder
3. Delusional disorder
4. Psychotic mood disorders (including mania and depression with psychotic features)
5. Acute psychotic episodes
6. Brief reactive psychosis
7. Schizophreniform disorder
8. Atypical psychosis
9. Tourette's disorder
10. Huntington's disease
11. Organic mental syndromes (including dementia) with associated psychotic and/or agitated features as defined by
 - Specific behaviors as quantitatively (number of episodes) and objectively (e.g., biting, kicking, and scratching) documented by the facility which causes residents to
 - Present a danger to themselves
 - Present a danger to others (including staff)
 - Actually interfere with staff's ability to provide care
 - Psychotic symptoms (hallucinations, paranoia, delusions) not exhibited as specific behaviors listed above but *hich c e here i e ri h i re*
12. Short-term (7 days) symptomatic treatment of hiccups, nausea, vomiting, or pruritus

() Antipsychotics should not be used if one or more of the following is/are the indication

1. Simple pacing
 2. Wandering
 3. Poor self-care
 4. Restlessness
 5. Crying out, yelling, or screaming
 6. Impaired memory
 7. Anxiety
 8. Depression
 9. Insomnia
 10. Unsociability
 11. Indifference to surroundings
 12. Fidgeting
 13. Nervousness
 14. Uncooperativeness
 15. Any indication for which the order is on an "as needed" basis
- (2) Residents who use antipsychotic drugs must receive gradual dose reductions, drug holidays, or behavioral programming (unless clinically contraindicated) in an effort to discontinue these drugs.

FIGURE 11.2. Summary of new federal regulations relevant to primary physicians and medical directors in nursing homes: 1987 Omnibus Budget Reconciliation Act (OBRA).

Code Status

When physicians enter the nursing home, it is well to remember these two fundamental principles: one, the nursing home is run by nurses and patients, and, two, patients' rights and autonomy rule the day—after all, the nursing home is their home. The lion's share of physician discomfort with nursing home practice might be traced to misunderstanding, and not embracing, these two principles. A sentinel example of this is the typical decision making and ordering regarding cardiopulmonary resuscitation (CPR), or its avoidance [do not resuscitate (DNR)];

this is a "patient order," not necessarily a physician order, in the nursing home. Generally, the patient or surrogate decision maker signs the CPR/DNR order. If the physician is called upon to sign the form as well, it is often merely an acknowledgment, almost an afterthought. Many nursing homes simply dispense with the physician signature. The MD signature merely confuses the issue as they are not the decider; the patient is. On the other hand, if a code status decision is reached that the physician feels is not appropriate, the onus is on the doctor to work with the family and staff to establish goals appropriate to severity of illness and prognosis—an "incorrect" code status is often a good stimulus for such a heart-to-heart discussion. The

physician can and should discuss code status issues with patients; in the nursing home this is primarily to inform, which may or may not influence their decisions.

Physician Visits

Physician participation in the care of nursing home patients is also regulated. By federal law (and as amended in some states), minimum visitation by the physician to nursing home patients includes the initial order and approval for admission in the form of an admitting history, physical, and orders. An annual review similar to the admission work is also prudent. After admission, monthly visits (every 30 ± 10 days) should ensue for at least one quarter, then every other month thereafter. In many states, subsequent visits may be alternated with a physician assistant or nurse practitioner. Some states continue to require monthly visits indefinitely. Again, this is the minimum. So long as medical necessity can be documented, the physician or nurse practitioner can round on the patients (and bill for these services) as often as medically necessary, daily, if need be, as occurs in some high-intensity nursing home wings variously known as rehabilitation or subacute units. Nurse practitioners are highly effective partners in the nursing home because they speak the language of nursing and also have prescriptive authority and diagnostic decision-making skills. Their autonomy and ability to bill effectively for their services have recently been enhanced by federal legislation.

During the physician visit, the doctor must sign all orders (including therapy or telephone orders that have accumulated between visits) and approve the plan of care, usually by signing monthly orders after review, a review that should include review of the MDS. Physicians may also include multidisciplinary care conferences in rounds and, at a minimum, should touch base with nurses and therapists involved in the care of patients, either face to face or by phone. The physician who does not actively interact with nurses and therapists runs the risk of being left out of the picture entirely. Remember, the physician is not running the show, is not present day to day, and needs this interaction to be at all effective in patient care. Communication with staff should take advantage of every available device, including communication logs or books on nursing home units, voice mail, and e-mail, reserving paging for emergencies. Paradoxically, the more available and responsive the physician team is to communications, the fewer calls generated, as the nursing staff feels the confidence of support. Concentrated physician/nurse practitioner presence in the nursing home with good communication can reduce unnecessary readmissions to hospitals by employing the full diagnostic and therapeutic means available in the nursing home (with

attention to patient wishes and directives).⁶ It is not unusual for patients to request “DNH” (do not hospitalize) when they are confident of physician care in the nursing home.

Patient Population Dynamics in the Modern Nursing Home

Most patients admitted to nursing homes in this day and age are rehabilitated over a period of a month or two and discharged alive.⁷ That said, the majority of bed-days are accounted for by long-stayers, patients with slow trajectories of improvement or decline, with chronic illnesses such as Alzheimer’s disease or other debilitating neurologic diseases. These persons can be expected to succumb to their illness in the nursing home setting. A substantial minority of residents, perhaps a quarter to a third, are admitted with a clearly terminal illness, such as advanced carcinoma, amyotrophic lateral sclerosis, or AIDS, and stay only a few weeks for end-of-life care. Small wonder that the staffs of most nursing homes are quite proficient in end-of-life care, with attention to patient and family goals of care first and foremost, with penultimate importance placed on symptom relief, pain management, and smoothness of comfort measure decisions and resuscitation avoidance. This focus of care is considerably easier to arrange (and to attain unanimity of thinking among staff and family) in the nursing home than in the hospital.

Importantly, most nursing homes cannot necessarily provide the full panoply of hospice care, with expert nursing, social services, clergy, and volunteer support all directed toward typical hospice goals. This distinction is highlighted by two phenomena: (1) the common practice of patients receiving care in the nursing home, with the addition of the full hospice team from a home health agency; and (2) the relative lack of family support and bereavement services in nursing home settings. Generally, the nursing staffing ratio in nursing homes may vary from 20:1 to 40:1 (patients: RN or LPN), with nurses’ aide staffing of about 10:1 to 15:1, for an average patient to staff ratio of about 10:1. Nurses are generally occupied with medication passes and wound care; and aides with the physical movement, hygiene, and feeding of patients. This staffing ratio allows enough staff to fulfill the physical, medication, and treatment needs of patients, but not necessarily the time to spend supporting a grieving family. Hence, what appears to be “too many cooks” for a terminally ill patient (i.e., both hospice and nursing home staff) can actually be an excellent team approach in practice. The nursing home staff is free to concentrate on the patient’s comfort, and the hospice team can concentrate on counseling and bereavement, in collabo-

ration with each other. When done well, this nursing home/hospice team collaboration is synergistic; when done poorly, it is indeed “too many cooks,” and the physician is often in the best position to emphasize synergy and discourage the opposite. This attitude implies enough physician input and involvement in the case to manage both the nursing home staff and hospice team effectively.

In fact, this example highlights the certain value of the physician in the nursing home: not as boss, but as manager, consultant, and team player. The physician brings a crucial medical perspective of disease process and medical diagnosis, of medication use and interactions, of prognosis, and of counseling techniques in dealing with patients and families, often at truly the most dire turning point in many patients’ and families’ lives. One cannot imagine a better-trained specialist than the geriatrician to perform this task—a specialist trained and skilled in management of multidisciplinary teams, in rehabilitation and end-of-life care, and in counseling those with chronic illnesses.

Medical Directorship of the Skilled Nursing Facility

Most nursing homes seek out geriatricians to be medical directors of their facilities for these same reasons. Medical directorship enhances the professional experience of physicians in nursing home practice in several ways, not the least of which is the influence, over time, in the overall quality of care of all patients in the facility, not just those being directly managed by that physician. Table 11.2 lists common types of activities of medical directors in skilled nursing home facilities. Excellent courses are now available with certification in medical directorship through national physician organizations.¹ For physicians attracted to a modest administrative role, medical directorship of the nursing home provides a stimulating forum and reasonable reimbursement to enhance the physician’s role in the nursing home. And, the physician’s perspective is truly valued in this role. No one else in the nursing home can provide it. The administration of the nursing home basically wants the medical perspective

from the physician medical director and someone to interact with the physician’s peers, other attending physicians. Geriatricians should not be daunted by this role; it is truly enjoyable and not taxing by any means.

Understanding the Patient Experience of Nursing Home Care

Understanding the experience of the nursing home from the patient’s perspective is perhaps the most challenging exercise in empathy a physician can undergo, at once heartwarming and heartrending. It is hard to imagine a more depressing event than entering a nursing home; a concrete marker of likely permanent debility and disease, joining with many others of the same (or worse) fate, in turn a forced admission of frailty and mortality.

The admission process to the nursing home is also highly regulated. It is a prolonged process involving the signing of stacks of papers and discussions of illness, code status, funeral home choice, relinquishment of belongings, and embracing the frightening and the unfamiliar. Given the multiplicity of legal forms and the lengthy discussions during the admission process, which usually exceeds 2 h, the pervasive feeling is akin to buying a house—a house you do not want. The physical and emotional tolls are sometimes eclipsed by the financial toll. Nearly half of nursing home care is paid for by private funds; that is, the patient or family writes a check every month for several thousand dollars to cover the nursing home daily rate, not to mention medications and doctor visit co-pays. Typical daily cost for nursing home care is of the order of \$100 to \$150, for a monthly cost of about \$4000. The other half of nursing home payment is largely through Medicaid for persons impoverished by fate or illness or by previous medical and nursing home bills (so-called spend down). A small proportion of payment is from Medicare, and an even smaller part from long-term care insurance, the latter still being rare at this point in the evolution of payment for medical services in the United States. The Medicare category of payment is almost entirely for relatively short rehabilitation stays. Medicare was never intended to cover typical long-term care, and legislators have systematically maintained this short-term, rehabilitation focus of the Medicare benefit. Given the daunting costs of typical long-term care for chronic illness, this attitude is unlikely to change in the foreseeable future. The Medicare benefit will cover 100 days per year for a rehabilitation stay after hospitalization, and only fully covers the first 20 days with a substantial co-pay (20%) after that; small wonder that many Medicare stays are less than 20 days. It can only be invoked for skilled services: parenteral therapy (not including insulin), complex wound care, or daily physical,

TABLE 11.2. Potential roles of the medical director in the nursing home.

Participate in medical decision making
Organize and coordinate physician services
Help ensure appropriate high-quality care
Develop and conduct educational programs
Participate in employee health, safety, and welfare
Articulate mission to the physician and wider community
Interact with regulators, government officials, and payors
Assure rights of residents, staff, and volunteers

occupational, or speech therapy. Daily compliance and consistent improvement are necessary to retain the benefit. If patients cannot meet these requirements, the Medicare benefit is terminated, and the remainder of the nursing home stay cost is covered by private pay or Medicaid. This change is a source of consternation for patients and families, and that consternation is often conveyed to the nursing home staff and to physicians. This eventuality cannot be prepared for enough—indeed, much of the staff and physician effort for nursing home patients is in the setting of realistic goals—physical, cognitive, prognostic, and financial. The physician cannot escape participation in all four areas.

Conclusion

For a growing number of physicians, nursing home practice is the most rewarding part of geriatric medicine. Some of the most wonderful and fulfilling experiences of doctoring can be shared with patients and families in nursing homes. Of course, some of the more depressing and occasionally awful experiences also occur, just as they do in hospitals or other clinical settings. In the nursing home, it is often possible to coordinate a compassionate approach to care of persons with chronic or terminal illnesses if the geriatrician knows how to effectively lead the multidisciplinary team and work with nurses. The nursing home is a nursing engine, for nursing-intensive, hands-on care, as opposed to the hospital, which serves more as a diagnostic machine for doctor-intensive workup and intervention. For patients who no longer need the latter, the hospital can be a dangerous

place, filled with iatrogenic pitfalls. The hospital is usually the wrong modality for care of persons with debilitating chronic disease or terminal illness. Often, the nursing home can meet the needs of these patients far better than the hospital. Skilled geriatricians know which type of facility their patients need and can enjoy caring for them in any setting, including the nursing home, to fulfill the primary care bond engendered by the care of older persons with chronic disease.

Home Care

Sharon A. Levine and Patricia P. Barry

Until the 1940s, primary care was often delivered in the home. As medical technology grew more complex and patients became more mobile, care switched to hospitals, clinics, and offices; the prevalence of house calls gradually diminished to less than 1% of practice activity.^{1,2} But while physicians were deemphasizing house calls, home care—providing health and social services in the home—was becoming the fastest growing service industry in the United States. The reasons include the growth of the elderly population, an increase in the number of functionally impaired elders residing in the community, a decline in the number of nursing home beds, and the preference of many elders to receive care at home.^{3,4} There are economic factors, too; prospective payment systems and managed care programs encourage early discharge of patients from hospitals, and Medicare allows home care services without prior hospitalization. From 1990 to 1997, Medicare home care expenditures increased from \$3.9 billion to an estimated \$17.2 billion. However, since then, Congressional initiatives have slowed the growth of the industry. Early in 2000, data from the Congressional Budget Office showed that Medicare spending on home health care dropped to \$9.7 billion in 1999. This sharp decline in spending stems from changes imposed by the Balanced Budget Act of 1997.⁵⁻⁷

There is little formal home care training in most medical schools and residency programs, but many physicians need to understand the basics of health care delivery in the home, including the range of services available and the sources of funding. Most primary care physicians will be responsible for authorizing and supervising complex care plans for homebound patients. They will need to coordinate care among an interdisciplinary variety of service providers. In addition, they must be able to answer patients' and caregivers' questions about home care.

Definitions

The term *home care* includes all health and social services that may be provided in the home, ranging from homemaker, chore, and meal services to nursing and physician care. (The American Medical Association defines home care as “the provision of a wide range of services and equipment to the patient in the home for the purpose of restoring and maintaining the maximal level of comfort, function, and health”).⁸ *Home health care* is the term used for health services provided by health aides, nurses, physical and occupational therapists, and physicians. *Home medical care*, or the *house call*, usually involves a physician or other primary care provider, such as a physician assistant or nurse practitioner.

In 1990, the American Medical Association suggested that medical care at home be categorized as follows:

1. Preventive, including home safety evaluation, patient education, provision of assistive equipment, or monitoring
2. Diagnostic, including home assessment, comprehensive geriatric assessment, or evaluation of functional capacity and the environment
3. Therapeutic, from “high tech” to hospice
4. Rehabilitative, especially with family involvement
5. Long-term maintenance for chronically ill and disabled patients, with supportive care by formal and informal caregivers⁸

Effectiveness of Home Care

Evidence is accumulating that some targeted, home-based interventions are effective in changing clinical outcomes or affecting costs of care. Tinetti and colleagues demonstrated that an in-home fall-reduction program

was successful.⁹ A 1995 randomized controlled trial evaluated the usefulness of annual in-home comprehensive geriatric assessment by a gerontologic nurse practitioner that focused on evaluating problems and risk factors for disability and providing specific recommendations and health education for the intervention group.¹⁰ Three-year results found less disability, fewer nursing home admissions, and more physician visits for the intervention group. A 1998 randomized controlled trial evaluated the utility of a single home visit after discharge from acute hospital care by a nurse and a pharmacist to patients at high risk of readmission to optimize compliance and identify clinical deterioration.¹¹ Six-month results in the intervention group found fewer unplanned hospital readmissions, fewer out-of-hospital deaths, fewer total deaths, and fewer emergency department visits. Another randomized controlled trial has also demonstrated the effectiveness of home interventions in reducing unplanned admissions, out-of-hospital deaths, adverse events, days in the hospital, and overall deaths in patients discharged after hospital admissions for congestive heart failure.¹² An earlier prospective randomized study of patients aged 70 and older who were hospitalized for congestive heart failure used a nurse-directed multidisciplinary intervention that followed Agency for Health Care Policy and Research (AHCPR) guidelines in an effort to reduce readmissions. The trial showed fewer readmissions, better quality of life scores, and lower costs in the intervention group.¹³

These recent trials stand in contrast to older studies that failed to demonstrate the benefits of multiple interventions provided to unselected populations of community-residing elderly. A 1986 critical review of 12 experimental or quasi-experimental studies of home care concluded that there was no evidence of a consistent effect on mortality, hospitalization, physical/functional status, or nursing home placement.¹⁴ Similarly, a 1987 review of 16 waiver-financed demonstration projects, including the well-described Channeling Project, which substituted community care for nursing home care by comprehensive case management, concluded that overall costs were increased by additional case management and community services.¹⁵ Most subjects, apparently, were not actually at high risk of nursing home care. Subsequently, Weissert and Hedrick suggested that targeting might improve outcomes, and that costs must be aggressively controlled and services limited for these programs to be cost-effective.¹⁶

Physicians in Home Care

The role of physicians in home care may include authorization of services, communication with providers, patients, and families, or even actual home visits. However, few physicians provide home visits. In an

TABLE 12.1. The physician's role in home care.

Management of medical problems
Identification of home care needs of the patient
Establishment/approval of a plan of treatment with identification of both short- and long-term goals
Evaluation of new, acute, or emergent medical problems based on information supplied by other team members
Provision for continuity of care to and from all settings (institutions, home, and community)
Communication with the patient and other team members and with physician consultants
Support for other team members
Participation, as needed, in home care/family conferences
Reassessments of care plan, outcomes of care
Evaluation of quality of care
Documentation in appropriate medical records
Provision for 24-h on-call coverage by a physician

analysis of 1993 Part B Medicare claims, Meyer and Gibbons focused on a 5% random sample of more than 1.3 million beneficiaries aged 65 or more who were not in health maintenance organizations.¹ They determined that 36,350 house calls were made to 11,917 patients. Extrapolation from this sample to all Medicare beneficiaries over age 65 suggested that 727,000 house calls were provided to 238,340 patients, which in turn implied that only 0.88% of all Medicare beneficiaries received house calls from physicians, at a cost of \$63 million. Patients who received house calls were noted to be very sick and near the end of life.

In an accompanying editorial, Campion reviewed the disadvantages of house calls: they are time consuming, inefficient, and poorly reimbursed, and there are concerns about safety and lack of equipment.¹⁷ The advantages include patient convenience, support, and reassurance, and the availability of assessment information. He also reported that an elderly patient is significantly more likely to receive a CT scan or a cardiac catheterization than a home visit.

A survey of 389 Virginia primary care physicians found that family physicians and general practitioners were significantly more likely to do home visits than were internists¹⁸; a subsequent national survey of 1161 internists and family physicians found similar results, with physicians noting that, although house calls were important, reimbursement was poor.¹⁹

The American Medical Association has outlined the responsibilities of the physician as a member of an interdisciplinary home care team (Table 12.1).

Home Care Recipients

Homebound patients are community-dwelling individuals who depend on the assistance of others to perform some activities of daily living (ADLs) because of acute

or chronic medical conditions or disabilities. In the absence of this help, they would be at high risk of institutionalization. Nationwide, some 9.5 million people older than 50 receive help with at least one of the ADLs—bathing, dressing, eating, toileting, continence, transferring, and ambulating—or instrumental activities of daily living (IADLs)—management of finances, use of the telephone, organizing transportation, meal planning and cooking, shopping, and taking medications).⁴ The Medical Expenditure Panel Survey findings indicated that 7.2 million individuals received formal home care services in 1996.⁷ Of people receiving home health services in 1996, 72% were aged 65 or older, 67% were female, 65% were white, 29% were married, and 35% were widowed, according to the National Center for Health Statistics.²⁰ These data also showed that 22% of patients discharged from home health agencies in 1995–1996 had as their primary admission diagnoses diseases of the circulatory system, including heart disease and hypertension. Other common admission diagnoses were cancer and diabetes. Medicare data regarding principal diagnoses of home care recipients show a similar profile.²¹

Patients receiving medical care, as opposed to other services, at home have been described in at least two studies. Fried and colleagues described 71 patients cared for in an academic medical house calls program.²² Eligibility included being homebound and residing within a 15-min drive of the academic medical center. Visits were scheduled every 3 months; unscheduled visits were provided on weekdays as needed. Eighty-one percent of patients were female; 52% were age 85 or older; only 23% had independent mobility at home; and 16% had cognitive impairment. Services included an average of five visits per year, 52% of which were for treatment of acute illness; 25% of patients refused hospital care. Social support was provided by children (32%), spouses (21%), or other family members (24%); 14% of patients received no such support. Referral sources included visiting nurses (25%), previous physicians (23%), and the patients themselves or the patient's families (20%).

Barry and colleagues studied the records of 480 patients enrolled in the Home Medical Service of Boston University Medical Center Hospital (now Boston University Geriatrics Services at Boston Medical Center) between January 1, 1992, and October 18, 1994, to better characterize the frail, elderly residents of urban Boston.^{23,24} The study used baseline data from a comprehensive initial assessment that consisted of demographic, social, financial, medical, and functional information. Follow-up data on service utilization and outcome were obtained from Home Medical Service and hospital records. Most patients were female (72%) and elderly (mean age, 80.0 ± 9.1 years); 61% were white; 47% lived alone; and 28% had no informal caregivers. Forty-one

percent had Mini Mental State Examination (MMSE) scores suggestive of cognitive impairment (23%, under 20; 19%, 20–24). One-third reported visual (36%) and hearing (33%) deficits. Many could not independently bathe (53%), ambulate in their own homes (55%), use the toilet (25%), or eat (20%). Only 31% were free of functional impairments; 50% had two or more functional deficiencies. Other characteristics included:

- Women were older than men (59% vs. 46% over 80; $p = 0.03$) and were more likely to have an MMSE score of less than 25 ($p = 0.01$). Women were not significantly more likely to be depressed, live alone, or have two or more ADL deficiencies.
- Age alone was not associated with number of ADL deficiencies or living alone, but age was a risk factor for death or nursing home placement for those over 70 years of age.
- Impaired functional status was associated with several findings, including lower MMSE scores ($p < 0.02$), being unable to live alone ($p < 0.01$), requiring more home visits and more hospital admissions ($p < 0.001$), and increased likelihood of death ($p < 0.01$).
- Subjects who lived alone demonstrated significantly higher MMSE scores and better functional status, and required fewer admissions but did not differ by age or prevalence of depression from those who did not live alone.

Over an average follow-up period of 13 months, patients received an average of 9.6 home visits annually and were hospitalized 0.96 times per year. Increased numbers of home visits were associated with depression ($p = 0.04$) and impaired ambulation ($p = 0.005$) but not with increasing age ($p = 0.48$). Increased frequency of hospitalization was associated with depression ($p = 0.03$) and impaired ambulation ($p = 0.02$) but not with increasing age ($p = 0.70$). Patients who lived alone were less likely to be hospitalized ($p = 0.03$). At the end of the follow-up period, 61% were still being seen in the home, 16% had died, 11% were in a nursing home, and 12% had otherwise been discharged. Dying was associated with being older ($p < 0.01$) and impaired ambulation ($p = 0.01$). Similarly, significant relationships were seen between dying and other impairments in activities of daily living ($p < 0.01$). Living alone was not associated with differences in placement outcomes.

Caregivers

The vast majority of care provided in the home is unpaid, nonmedical, informal care. Data from the Informal Caregivers Survey, which was part of the 1982 National Long Term Care Survey, show that 72% of caregivers are female, mostly wives and daughters, and more than one-

third of all caregivers are 65 or older. One-third of caregivers themselves are in fair or poor health and most are poor or near poor (31%) or low- to middle-income (57%). Because of the competing demands of elder caregiving with child care or employment, 9% have left work and 20% have reduced work hours. These informal caregivers spend approximately 4 h extra on an average day on caregiver tasks; 80% provide this care 7 days a week.²⁵ For people over age 65 who require help with at least one ADL, professional caregivers constitute the largest category of caregivers at 30%.⁴

Services Available at Home

An impressive array of professional, ancillary, diagnostic, and therapeutic services can be provided in the home, including technologically advanced services and telemedicine (Table 12.2). In the United States, the service used most frequently by home care patients 65 and older

is skilled nursing, used by 81% of patients; this is followed by personal care (57%) and homemaker services (23%).²⁶

Funding for Home Care

Funding for home care services comes from a variety of public and private sources (Fig. 12.1). According to the Health Care Financing Administration, Medicare is the largest single payor of home care services, accounting for 39.6% of total estimated home care expenditures in 1997, followed by private out-of-pocket spending (21.7%) and Medicaid (14.9%).²⁷ Other public funding sources include Title XX of the Social Security Act, the Older Americans Act, the Veterans Administration, and the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS). Private sources include research and demonstration grants, charities, and commercial insurers, including managed care plans.

The interim payment system of the Balanced Budget Act of 1997 introduced a new per beneficiary limit designed to slow the growth of Medicare home health expenditures. The results were dramatic. In 1997, home health spending was 9% of total Medicare benefit payments; in fiscal year 2000, home health benefits accounted for only 4% of total Medicare spending. A further 15% reduction in home health payments was scheduled to take effect in October 2001. About 3.5 million Medicare enrollees received fee-for-service home health services in 1997, a twofold increase from 1990. After the enactment of the Balanced Budget Act in 1997, however, utilization of the home care benefit markedly decreased; approximately 500,000 fewer beneficiaries used the benefit in 1998 than in 1997.⁷ Some beneficiaries may have difficulty

FIGURE 12.1. Sources of payment for home care (1997).

gaining access to home care services.²⁸ In a report to Congress, the General Accounting Office states that in response to the changes imposed by the interim payment system, home health agencies may be less likely to care for patients who require costly intensive services.²⁹

Medicaid spending for home health services has also grown enormously in the past two decades, from \$70 million in 1975 to \$12 billion in 1997. Home care services made up 9.8% of Medicaid payments in 1997; payments to hospitals and institutions, by contrast, accounted for nearly half of Medicaid spending.⁷

Medicare

Medicare covers services deemed to be “reasonable and necessary for the treatment of an illness or injury.” To qualify for home care benefits under Medicare, the patient must be *homebound* by Medicare’s definition (Table 12.3), services must be *provided under a plan of care established and approved by a physician*, and the patient must be *in need of reasonable and necessary skilled nursing services* on an *intermittent* or *part-time* basis. In other words, Medicare is not intended to cover long-term care by an individual or a nursing home, nor is it designed to pay for services for patients who leave home regularly for work, recreation, or even social programs such as senior centers. In addition to a home care benefit, Medicare has a home hospice benefit that is reimbursed separately.

Services that are 100% covered under Medicare Part A include skilled nursing, skilled therapy, home health aide services, and social services (Table 12.4). However, the beneficiary must be in need of nursing, physical therapy, or speech therapy to be reimbursed for other services such as occupational therapy, personal care, or social work.³⁰ *Skilled nursing* includes evaluation of the patient’s condition; services and procedures that can only be performed by a skilled professional; assessment or management of the patient’s plan of care; and patient education. *Skilled therapy* includes restorative therapy, which is based on the expectation that the patient will improve in a reasonable amount of time, and maintenance therapy, which consists of activities that the bene-

TABLE 12.3. Medicare definition of homebound.

To qualify for Medicare Home Care benefits, a patient must meet the following criteria:

- A normal inability to leave home
- Medically contraindicated to leave home
- Leaving home requires a considerable and taxing effort
- Inability to leave home except with the aid of supportive devices, special transportation, or the assistance of another person
- Leaves home only infrequently or for short duration of time, or for the purpose of receiving medical treatment

fiary or caregivers will be taught and supervised in carrying out. *Home health aide services* include personal care, dressing changes that do not require the skills of a licensed nurse, assistance with self-administered medication, assistance with exercises not requiring a therapist, and routine care of prosthetic or orthotic devices. *Medical social services* include psychosocial and economic assessment, counseling services for the patient and caregivers, and aid in referring the patient to services in the community.

Medicare services covered under Part B (see Table 12.4), which requires a monthly premium and 20% co-payment, include physician home visits; certain medical equipment ordered by a physician, including hospital beds, wheelchairs, commodes, pumps, tube feeds, and other assistive devices; and diagnostic laboratory studies, electrocardiograms, and portable radiography.

It is important to be aware of exclusions in Medicare coverage, including homemaker services, long-term care nursing, home-delivered meals, transportation that is nonemergent, all bathroom equipment, and patient care for those who do not require skilled nursing services.

Since 1998, physicians providing home health and hospice care have been able to bill Medicare for Care Plan Oversight (Table 12.5). To bill for services, a physician must do at least 30 min or more of documented work per patient within a calendar month. The work can include development or revision of care plans, review of care plans, review of studies and test results, communication with home health agency personnel, coordinating care with consultants, and arranging other services (including by telephone).

Medicaid

Medicaid funding for home care services is provided jointly by the federal and state governments. The regulations are federal, but eligibility is determined on a state-by-state basis. Coverage is designed for those who not only meet state income eligibility guidelines but also are blind or disabled. The majority of states cover nursing and home health aide services, durable medical equip-

ment, and medical supplies. Coverage for diagnostics, medication, transportation, adult day care, social work, personal care, and physical, speech, or occupational therapy varies from state to state. Medicaid payments for home health services fall into three main categories: the traditional home health benefit, which is a mandatory benefit provided by all states, and two optional programs—the personal care option and home- and community-based waivers. Hospice is an optional Medicaid service that is presently offered by 42 states.

Private Insurance and Managed Care

Private insurers and managed care organizations generally follow Medicare guidelines, although benefits and eligibility may vary. There may be caps on the number of visits. Long-term care insurance policies may be purchased privately; eligibility is usually based on functional or cognitive limitations.

Practical Aspects of Home Care

Indications for a Home Care Referral

Indications for a home care referral include advanced age and frailty, multiple comorbidities, recurrent and frequent admissions, homeboundness, impaired psychosocial or functional status, and terminal care. Often the first sign of decline in status is the inability to keep scheduled office or clinic appointments. A single house call, as part of comprehensive geriatric assessment, helps to identify medical, psychosocial, and environmental factors that affect functional ability (Tables 12.6, 12.7). Problems identifiable by house calls include alcoholism (finding bottles or cans), incontinence (by odor), sensory impairment, pain, medical noncompliance, falls (with special attention to environmental factors), elder abuse, and depression.

In a randomized controlled trial with 1-year follow-up, veterans 70 or older were screened by a physician assistant or registered nurse for medical, functional, and social problems. The results included the discovery of four new or suboptimally treated problems in each patient, on average, and an improvement in immunization rate and IADL scores.³¹ In another study of 154 patients, home visits revealed an average of two new problems per patient and from one to eight new recommendations for the treatment plan, when compared with office-based assessment. About 23% of the newly diagnosed problems indicated extreme morbidity and were potentially life threatening.³²

The house call can also be used to find the causes of known problems (e.g., falls or medical noncompliance), to determine whether there is a need for nursing home placement, to make emergency evaluations that otherwise would require a trip to the emergency department, to conduct posthospitalization follow-up, to provide ter-

minal care, or to deliver primary care to the truly home-bound population.

Perceived Barriers to Home Care

Reasons given for the low frequency of home visits by doctors include time constraints, inefficiency, concerns about safety, low reimbursement, concerns about liability, lack of physician training, and institutional barriers. To relieve time constraints and improve efficiency, visits can be carefully planned and clustered geographically. In the Boston University practice, patients or their families are phoned 1 day in advance, and a time for the visit is planned so that family members can be present, which is especially useful in the case of non-English-speaking patients. Practices that employ physician assistants or nurse practitioners can integrate them into the home care team as another way to improve efficiency. Physicians can enhance their safety by traveling with students or other members of the team, scheduling visits early in the day, and carrying cellular telephones.

Current Medicare reimbursement for home visits is higher, in some cases, than outpatient visit reimbursement. For instance, Medicare reimbursement in Massachusetts for the lowest level of care for an established home care patient was \$50.28 in 2000, compared with \$10.67 for a similar ambulatory patient. The highest level of care for a new home care patient was reimbursed at \$205 per visit versus \$135.10 for a new ambulatory clinic patient at the same level of care (see Table 12.5). Physician documentation should be complete, for several reasons: it ensures that physicians will receive compensation; it substantiates the physician oversight that is necessary for other home care providers to receive payment; and it provides important evidence in case of a malpractice suit, although such lawsuits are rare.

What Is in the Doctor's Bag

The old-time doctor's "black bag" is probably not large enough to accommodate the items that most home care physicians might need on a routine or emergent home visit. In the Boston University practice, we use a lightweight diaper bag with multiple pockets. Others use medium-sized overnight bags. A bag on wheels might also be appropriate in the case of a long walk from the car to the patient's home. Table 12.8 shows items that can be included in the doctor's bag.

Interdisciplinary Teams

The home is the ideal location to identify the elder's strengths, abilities, and supports, both formal and informal. These factors are important in developing a care plan that can be put into operation realistically and that

complies with the patient's and family's wishes. An interdisciplinary team approach and the use of a home care coordinator for case management are essential in implementing complex plans that may include numerous referrals and services as well as education for the patient and family (Table 12.9). This approach also allows continuous assessment of outcomes over time so that the plan can be revised as the patient's needs and health status change. The collaborative nature of this practice requires communication among the varied disciplines that provide services in the home. In addition, there may be overlap of shared tasks. In the case of a patient undergoing poststroke rehabilitation, for example, a speech-and-swallowing specialist might work closely with a nutritionist and visiting nurse in providing a patient with a safe plan for eating. A physical therapist must work with the family, patient, home health aide, and visiting nurse on a plan for safe transfers.

Leadership for a given service may be transferred from one discipline to another, depending on the goal being addressed. If communication is adequate, the entire team should be apprised of current and future plans. In small practices where the physician does not have the luxury of an interdisciplinary team, the physician must act as the case manager in concert with a visiting nurse. Although most patients receiving home care services do not receive house calls from physicians, the physician

remains an important member of the team and must remain in close communication with those who provide services. Situations in which a visit by the physician may be required include discrepancies in reports of the patient's status, acute declines in health or function in frail patients, unexplained failure to thrive, unexplained failure of the care plan, request for physician evaluation in the home by another team member, need for a patient/family meeting to make an important decision, and routine medical care for the patient who cannot leave home.³³

Conducting the Home Visit

Before the home visit, the physician or team should gather important data, including the patient's medical diagnoses, current community-based services, formal and informal supports, insurance information, and medications. The doctor's bag should be stocked as already described. Patients should be clustered geographically and the most efficient route planned. The family should be contacted to ensure that key members or significant others are present so that communication can be enhanced. If the patient is non-English-speaking, it is especially helpful to have English-speaking caregivers present to ensure that problems are identified and the plan of care can be carried out. Interpreter services should be employed if available.

The initial home visit to a medically and socially complicated patient who will receive ongoing primary care in the home may pose formidable challenges. It may take several home visits for the physician or team to gather all the information in a comprehensive geriatric assessment. A checklist can be helpful.

Basic elements of the house call should include the history and physical exam, social interaction that solidifies the doctor-patient relationship, assessment of caregivers and their burden, environmental safety assessment, psychosocial assessment, nutritional assessment, financial assessment, cognitive assessment, a medication review (including prescribed and over-the-counter medications), functional assessment, an introduction to a discussion of advance directives and personal preferences, an exploration of spiritual needs, and a discussion of the care management plan.

The physician may have to take into account various environmental barriers when taking the history in the home setting. Families may need to be asked to leave the room for private conversations, and the television or radio may need to be turned off. The physical examination poses its own problems. If lighting is poor, the physician should have a light source available; to avoid self-injury, the physician should use caution when examining patients who are immobile or who are in low, wide beds or chairs. The physician may need to bring disposal containers for needles, syringes, and other instruments. Although the first physical exam must be comprehensive, subsequent exams can be focused on the patient's particular needs. For instance, a look at the feet of a diabetic patient with neuropathy may be more important than weighing the patient.

Social interaction is essential in the development of the doctor-patient relationship. The home environment alters the traditional doctor-patient relationship in that the patient is on his or her own "turf" and therefore has increased autonomy. Some providers may feel uncomfortable about having less control, but the situation sets the stage for more realistic establishment of goals and involvement of the family. As a guest in someone's home, a physician should ask permission to walk through the house, turn off the television, wash hands, use the telephone, or even simply sit at the bedside. Because caregivers provide the bulk of home care, assessment of their level of stress is important. It is also important to identify and enlist the support of potential informal caregivers.

A thorough environmental safety assessment cannot be performed anywhere but in the home. In Ramsdell's study, home safety problems posed great risks to patients.³² The safety of the neighborhood and the patient's access to shopping and other services can be ascertained on the visit. A walk through the home can reveal potential hazards for falls or injury such as loose

wires and tile, poor lighting, and clutter (Table 12.10). The odors of garbage, urine, animal waste, and vermin can point to an unhealthy environment. When alcohol or drug abuse on the part of the patient or caregivers is suspected, bottles or other containers can provide evidence. Faulty wiring, lack of smoke detectors, evidence of burned pots, and lack of heat and hot water are clues to the patient's safety, functional status, or possible impaired cognition or judgment.

The psychosocial assessment can reveal important family ties, depression, or social isolation. A walk through the kitchen will reveal the nutritional status and food preferences of the patient. An empty refrigerator and kitchen cupboards may point to previously undiagnosed functional impairment, such as dementia or decreased mobility, and may show the need for interventions, such as home health aides, transportation, and shopping services. Problems such as malnutrition, vitamin B₁₂ deficiency, and dietary indiscretion in patients on special diets can be addressed and a plan formulated that includes the services of a dietician or nutritionist for patient and family education.

A review of the patient's finances is helpful in determining which services the patient may be eligible for. For instance, in Massachusetts, patients who are Medicaid eligible will qualify for adult day care, which may mean the difference between independent community living and nursing home placement.

The home visit may enhance the physician's ability to conduct cognitive assessment because it may provide evi-

dence of self-neglect, memory impairment, or medication noncompliance. Also, research suggests that in some cases, cognitive assessment in the clinic setting may produce misleading results. In one study, the scores of one-quarter of patients were significantly different when the Mini Mental State Examination was performed at home versus the clinic; of that group, 76% scored higher in the home setting.³⁴ Sometimes the condition of a patient's home environment raises questions about his or her capacity to make decisions, such as whether to remain at home at all. In such situations, the physician can refer to guidelines regarding the complex and nuanced issue of decision-making capacity, an issue discussed in Chapter 85.

A medication review at home can provide more information on medication noncompliance than a drug history in an outpatient clinic. It can reveal that patients are not taking medications they have listed in drug histories at clinics, or, conversely, that they are taking medications they have not listed.³⁵ Dosages, frequency, and modes of medication delivery can be examined more thoroughly in the home. A review of over-the-counter medications, such as analgesics or nonsteroidal anti-inflammatory agents for pain, may point to undiagnosed medical problems. Additionally, such a review may reveal that certain medical problems are caused by adverse drug reactions, drug–drug reactions, or drug–food reactions involving nonprescription drugs. A visit to the home is also the best way to determine which dispensing device—Medi-planner, bottle, or blister pack, for example—would meet the patient's needs.

TABLE 12.10. Elements of home safety assessment.

Areas to be assessed	Questions to consider
Kitchen safety (especially use of gas stove)	Is it easy to tell when a burner or oven gas is turned on or off? Does the patient wear loose garments when cooking?
Bathroom safety	Are handholds in appropriate places? Can the toilet seat be raised, if needed? Does the shower or bathtub have a nonslip surface? Is the floor of the bathroom slick?
Stairs	Are the stairs well lit? If carpeting is present, is it secure?
Gas or electric utilities	Which systems does the home have? Are systems checked and properly maintained?
Heating and air-conditioning	Are the controls accessible and easy to read?
Hot water heater	Is the temperature below 49°C (120°F)?
Water source	Is water from a public service or a well?
Emergency actions and evacuation route	Are emergency numbers on or near the telephone? Is there a means of exit in case of emergency?
Electrical cords	Are cords frayed or lying across walking paths?
Lighting and night lights	Is the wattage sufficient?
Fire and smoke detectors and fire extinguishers	Are fire extinguishers present and accessible? Are fire and smoke detectors present? Are batteries charged or changed regularly?
Loose carpets and throw rugs	Can loose carpets and throw rugs be secured or removed?
Tables, chairs, and other furniture	Is furniture sturdy and well-balanced?
Pets	Are the animals easy to care for and to feed?

Source: Adapted from Unwin and Jerant, with permission.³⁸

Assessment of ADLs and IADLs is readily accomplished in the home setting. The physician can observe bathing, dressing, ambulation, transfers, continence, the distance to the bathroom, and the patient's ability to prepare meals, use a phone, take medications, and manage finances. Further, discussions regarding spiritual needs, the patient's advance directives, surrogate decision making, and personal preferences are accomplished comfortably in the privacy of the patient's home.

On occasion, the physician finds that a patient's needs are inadequately met in the home or discovers a home environment that is unsafe. Often, the physician's first instinct is to recommend placement in a more supervised setting. But we believe that if the patient and the caregivers want the patient to remain at home, all efforts should be made to honor that wish—assuming the patient has the capacity to make such a decision. Physicians should investigate whether maximizing services can help such individuals maintain their autonomy.

Conclusion

Demographics, patient and family preference, insurance reimbursement, and the availability of sophisticated technology in the home guarantee that home health care will continue to grow as an element of community-based long-term care. Care in the home will therefore remain an important aspect of health care policy. Additionally, physicians will continue to be responsible for providing supervision of home care and, when appropriate, making home visits to enhance the well-being of patients. Home care will therefore remain a vital part of the education of physicians. This truly holistic approach to patient care can be among the most rewarding aspects of the doctor-patient relationship for both the physician and the patient.

Acute Hospital Care

Robert M. Palmer

For older patients, hospitalization is a two-edged sword. Hospitalization for acute illness offers older patients the hope of relief of symptoms and cure of disease, but it also exposes them to the adverse risks of hospitalization—functional decline (a loss of independence in activities of daily living), iatrogenic illness, and possible institutionalization. Recent studies have identified risk factors for functional decline in hospitalized elderly patients and opportunities for improving the process of care to improve functional and psychosocial outcomes of hospitalization.

Epidemiology of Hospitalization

Although rates of hospitalization have declined in the past two decades for all age groups, since the introduction of the prospective payment system and Medicare/managed care programs, the proportion of hospitalized patients who are age 65 years and older is increasing. In nonfederal acute hospitals, elderly patients account for 37% of all discharges and 47% of inpatient days of care.¹ Hospitalization rates are more than twice as great for patients 85 years and older compared with patients aged 65 to 74 years. The oldest patients have longer hospitalizations, higher mortality rates, and higher rates of nursing home placement.¹ Among noninstitutionalized adults, patients age 75 years and over have the greatest number of hospitalizations, with nearly 15% being hospitalized yearly and 5.3% hospitalized two or more times per year.² A small portion of older patients consistently make extensive use of hospital services. In the Longitudinal Study of Aging, which followed nearly 7500 patients age 70 years and older for 7 years, 43% had no hospital admissions and another 25% had infrequent hospitalizations.³ Fewer than 5% had consistently higher rates of hospitalization, averaging one or more admissions annually. A prospective cohort study identified eight independent variables that are risk factors for repeated hospital admission among people age 70 years

or older: older age, male sex, poor self-rated general health, availability of an informal caregiver, having ever had coronary artery disease, having had a hospital admission during the previous year, more than six doctor visits, or diabetes mellitus.⁴ The presence of these risk factors more than doubled the risk of hospital admission compared to low-risk patients and was associated with a higher cumulative rate of mortality, hospital days per person-year survived, and higher hospital charges.⁴ The cost of acute hospitalization peaks in the 70- to 79-year-old age group and declines with age, reflecting lower ancillary costs in the oldest patients.⁵

In-hospital mortality rates are age related and increase from 5% among those 65 to 74 years of age to 10% in those 85 years of age and older. In the hospitalized elderly longitudinal project (HELP), a prospective cohort study of seriously ill patients age 80 years and older, major variables predictive of 2-year mortality included weight loss, cognitive dysfunction, impaired functional status, chronic disease class, and adult physiology score (from the Acute Physiology and Chronic Health Evaluation [APACHE]).⁶ Most elderly patients—one-third of patients aged 65 to 74 years and 46% of those 75 years and older—are admitted to the hospital from the emergency department.⁷ Among nursing home residents referred to the emergency department, more than 40% are admitted to the hospital.⁸

Taken together, these data suggest that rates of hospitalization, total cost of hospital care, mortality rates, and nursing home discharges will continue to be greater in the elderly population compared to younger patients.

Risks of Hospitalization

Functional Decline

Hospitalization for an acute illness often results in an older patient's loss of independent self-care (functional

decline). A study of functional morbidity in hospitalized older patients with a mean age of 84 years found that 65% of patients experienced a decline in mobility scores between baseline and day 2 of hospitalization.⁹ By hospital discharge, 67% showed no improvement and another 10% deteriorated further. Recent prospective cohort studies found that 20% to 32% of patients admitted to general medical units lose independence in their ability to perform one or more basic activities of daily living (ADL) at discharge.¹⁰⁻¹²

Risk factors for functional decline, its natural history, and sequelae have been identified. In a study of more than 1200 community-dwelling patients aged 70 years and older hospitalized with acute medical illnesses, 31% lost independence in one or more of five basic ADLs when compared to their baseline status 2 weeks before admission.¹³ A loss of independence in one or more instrumental ADL occurred in 40% of survivors 3 months after hospital discharge. Functional decline occurred more frequently in patients who were over 75 years of age, had some disability in the performance of an instrumental ADL before admission, and had lower mental status scores on admission.¹² Other studies have identified pressure sore, low social activity level, delirium, and depressive symptoms as risk factors for functional decline in hospital.^{10,14} In hospitalized patients aged 80 years and older, independent predictors of functional decline after hospitalization included poorer baseline quality of life, lower serum albumin level, being bedridden, and documented need for nursing home admission.¹⁵

Cognitive impairment and depressed psychosocial functioning are important predictors of posthospital outcomes.¹⁶ Depressive symptoms at hospital admission independently predict mortality in the ensuing 3 years, even when controlling for disease severity and baseline functional status.¹⁷ The loss of independent functioning during hospitalization is associated with serious sequelae, including prolonged hospital stay, nursing home placement, and mortality. Functional measures are strong predictors of mortality and contribute prognostic ability beyond that obtained with combined measures of disease comorbidity, severity, disease staging, and diagnosis-related groups.¹⁸ Three independent risk factors—impairment in the patient's performance of instrumental activities of daily living (IADL), cognitive impairment, and depressive symptoms—predict subsequent mortality in elderly patients adjusted for disease burden and severity.¹⁸

The conceptual basis for functional decline is shown in Figure 13.1.¹⁹ The cause of functional decline is complex and involves the interaction of aging, hospitalization, and comorbid illness. Physiologic impairments, multiple comorbid conditions, impaired homeostatic reserves, and elements of hospitalization interact to predispose the

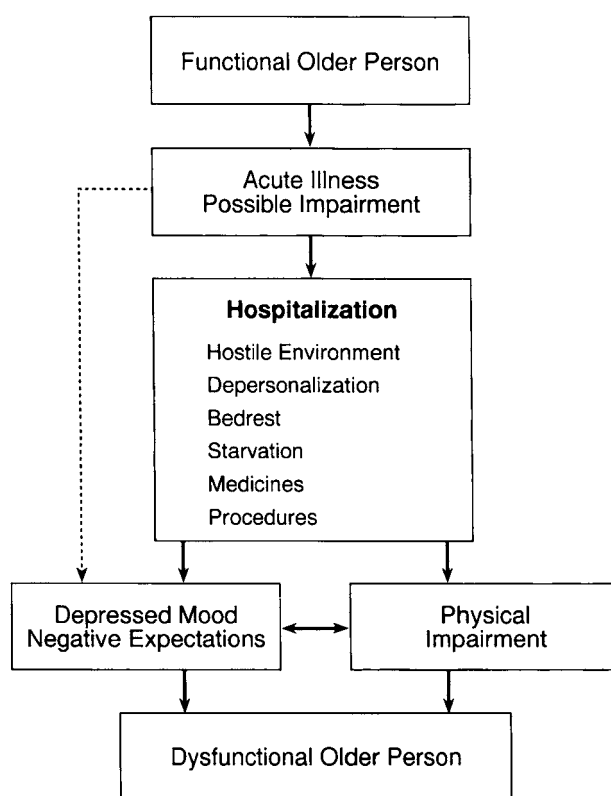

FIGURE 13.1. Conceptual basis for functional decline. (From Palmer RM, Counsell S, Landefeld CS,¹⁹ by permission of W.B. Saunders Company.)

patient to functional decline. The physical features of the hospital may render it a “hostile environment,” structured to meet the needs of professional caregivers rather than patients.¹⁹ Hospitalization is often perceived as depersonalizing, and patients may be subjected to bed rest, undernutrition or starvation, and adverse events resulting from medications and diagnostic or therapeutic procedures. These elements can interact with depressed mood, negative expectations, and physical impairments to result in a dysfunctional older person. Identification of patients at risk for functional decline begins with the recognition of predisposing factors, as accomplished by a comprehensive geriatric assessment conducted by nurses, physicians, or other health professionals.

Iatrogenic Illness

Iatrogenic illness is any illness that results from a diagnostic procedure or therapeutic intervention and is not a natural consequence of the patient's disease.²⁰ Iatrogenesis is often categorized as illness that results from medications, diagnostic and therapeutic procedures,

nosocomial infections, or environmental hazards.²¹ Adverse drug events are the most commonly cited iatrogenic illness in hospitalized patients and are associated with significantly prolonged length of stay, higher costs of care, and increased risk of death. Virtually any class of medication can cause an adverse event, but antibiotics and cardiovascular drugs have been most commonly implicated in studies of hospitalized patients. The increased risk for adverse drug events is also attributable to alterations in drug disposition and tissue sensitivity associated with usual aging and to drug–drug interactions (see Chapter 7). Nosocomial (hospital-acquired) infections are common complications of hospitalization. Common nosocomial infections are those of the urinary tract, pneumonia, and blood (due to intravascular catheters). Colonization or infection with resistant or opportunistic infections may complicate hospitalization.²¹

Guidelines for the potential prevention of iatrogenic illnesses are shown in Table 13.1.

Medical Errors

Medical errors, which have recently received widespread attention, also appear to be more common in elderly hospitalized patients. For example, in one study, patients over age 65 had twice the chance of sustaining injury during hospitalization as younger patients, with most events being judged as potentially preventable.²² Concerns over the reported incidence of medical error led the Institute of Medicine to release a report advocating dramatic systemwide changes in hospitals to reduce these rates.²³ Medical errors can contribute to death or injury of hospitalized patients.

TABLE 13.1. Keys to prevention of iatrogenic illness.

Iatrogenic problem	Common reasons	Keys to prevention
Adverse drug effects	Polypharmacy; drug–drug interactions; altered drug disposition and tissue sensitivity with aging	Rational drug prescribing: review all medications taken before admission; use lower-than-usual maintenance doses when geriatric dose is unknown; limit the addition of psychoactive drugs; avoid whenever possible multiple drugs that inhibit or induce cytochrome P-450 hepatic metabolism or are highly albumin bound
Falls/immobility	Weakness of leg muscles; postural hypotension; deconditioning due to prolonged bed rest; cognitive impairment; sensory impairment	Assess falls risk at admission (multiple chronic diseases, cognitive dysfunction, neuromuscular dysfunction, multiple sensory impairments); avoid physical restraints; order physical therapy for transfer-dependent and gait-impaired patients; prescribe assistive devices (e.g., canes, walkers); modify environment (e.g., add handrails, grab bars to rooms); prophylactic anticoagulation with unfractionated heparin is warranted in immobile patients to prevent deep venous thrombosis
Pressure ulcers	Immobility; sustained point pressure over bones; excess moisture, friction and shearing forces	Pressure ulcer risk assessment: paresis, cognitive dysfunction, incontinence, malnutrition; turn immobile patients at least every 2 h; lubricate skin with cream; correct nutritional deficiencies; order pressurized bed mattresses; use patient lifts
Dehydration/undernutrition	Chronic disease predisposing to protein-calorie malnutrition; poor oral intake due to acute illness; anorexia; preparation for diagnostic studies	Assess nutritional status at admission: low body weight; muscle wasting; low levels of serum albumin, cholesterol, hemoglobin; prescribe and monitor daily calorie and fluid intake; obtain dietitian consult; give intravenous fluids when oral intake is inadequate or prohibited; consider enteral alimentation or peripheral hyperalimentation when oral intake is inadequate or contraindicated
Nosocomial infection	Transmission of resistant/opportunistic microorganisms by caregivers or hardware; use of broad-spectrum antibiotics that eliminate normal flora; instrumentation (e.g., urethral catheters); pulmonary aspiration	Hygienic hand-washing techniques; sterilization of medical equipment; narrowing the spectrum of antibiotics when feasible; aspiration precautions in high-risk patients; disinfection of patient's skin before insertion of intravenous or intra-arterial line; urethral catheterization intermittently rather than continuously when indicated
Contrast-associated nephropathy	Hypertonic contrast agents given intravenously for diagnostic studies; dehydration; renal disease; myeloma	Avoid contrast whenever possible; maintain adequate hydration before and after study; avoid giving contrast to patients with underlying renal diseases, dehydration, multiple myeloma; use noncontrast studies (e.g., renal ultrasound rather than intravenous pyelography); consider <i>N</i> -acetylcysteine prophylaxis

Errors leading to adverse drug events are the most commonly recognized medical error in hospitalized patients. The use of computerized and other support systems is advocated to reduce the rate of errors.²³ Computerized medical information systems can improve the quality of patient care. A computerized decision support program linked to computer-based patient records has been shown to assist physicians in the use of antimicrobial agents and to improve patient care.²⁴ Computer-assisted decision support programs, using practice guidelines, can improve antibiotic use, reduce associated costs, and appear to limit the emergence of antibiotic-resistant pathogens.²⁵ Hospital information systems can be programmed to generate alerts in clinical situations associated with an increased risk for injury resulting from adverse drug events.²⁶ A physician computer order entry system combined with a pharmacist intervention decreases the rate of nonintercepted serious medication errors, thereby providing evidence that information systems can be effective in reducing medical error.²⁷ In addition, computerized databases enable health professionals to access relevant laboratory results, diagnostic studies, and consultation notes, even when they are outside the hospital.

Geriatric Comorbid Problems

Common geriatric problems often complicate the medical management of acute illness during hospitalization.

Immobility

Immobility is associated with functional decline, increased risk of nursing home placement after discharge, medical complications (including deep venous thrombosis, urinary incontinence, pressure sores, joint contractures, cardiac deconditioning, and muscle weakness), and fall.²⁸ Cardiac and muscular deconditioning occur within days of sustained bed rest. Loss of muscle strength is proportionally greater in the lower extremities than the upper extremities. Enforced bed rest and immobility are abetted by high beds, intravenous lines and catheters, and both physical and chemical restraints. Physical restraints include vest, belt, mitten, jacket, wrist, and ankle restraints. Bed rails, geriatric chairs and wheelchairs, and full rails are also often classified as mechanical restraints.²⁹ Restraints are most often used to control problematic behaviors, prevent disruption of treatment, and prevent falls, although their effectiveness is not established.²⁹ Both the Joint Commission on Accreditation of Healthcare Organizations and the Health Care Financing Administration (HCFA) require hospitals to have policies and procedures related to physical restraint of hospitalized patients. Mechanical restraints and drugs used as restraints should be avoided unless they are

medically necessary and less restrictive measures have been deemed ineffective.

To enhance patient mobility, physical therapy or graded exercises should be prescribed on the first hospital day, particularly for bedbound and severely deconditioned patients.²⁸ Exercises should also be prescribed for patients admitted for acute or elective surgery to speed the process of recovery and rehabilitation from the operation. For patients with impaired independence in gait or bed transfers, physical therapy consultation and bedside therapy should be considered. Exercises should include passive and active range of motion exercises to enhance flexibility, low-intensity resistive exercises of the lower extremities, and assisted ambulation. Ideally, patients should be allowed free movement to reduce the risk of physical deconditioning, postural hypotension, venous thrombosis, and joint contractures. Patients often need encouragement to sit up or to get out of bed even when they prefer bed rest.²⁸

Undernutrition

Undernutrition and frank protein-energy malnutrition are common in hospitalized older patients. The importance of undernutrition is underscored by prospective studies that link protein-energy malnutrition evident at admission to increased hospital and posthospital mortality. In one study, the prevalence of malnutrition at admission was 30% in male and 41% in female patients 70 years of age or older.³⁰ In-hospital mortality was associated with low serum albumin and prealbumin levels and decreased midarm circumference and triceps skin fold thickness.³⁰ A prospective cohort study found that 20% of elderly patients consumed an average daily in-hospital nutrient intake of less than 50% of their calculated maintenance energy requirements.³¹ These patients had lower discharge levels of total cholesterol and albumin and prealbumin concentrations and a higher rate of in-hospital mortality.³¹ Patients often had orders for nothing by mouth, and canned supplements often were not consumed.

Malnutrition is suspected in patients with a history of weight loss of 5% to 10% of their body weight over a 6-month period and physical signs of malnutrition such as muscle wasting. The laboratory evaluation of malnutrition is confounded by the effects of inflammation and chronic diseases, associated with the elaboration of cytokines and interleukins, that reduce the serum levels of nutritional markers.³²

The subjective global assessment (SGA), a validated measure of nutritional status based on medical history and physical examination findings, accurately classifies patients as severely, moderately, or well nourished.³³ The SGA combines elements of the patient's nutrition history (weight loss in previous 6 months) and physical exami-

nation (e.g., muscle wasting) to generate a subjective impression of nutritional status.³³ In a study controlling for acute illness severity, comorbidity, and functional status, severely malnourished patients as determined by the SGI had poorer outcomes of hospitalization. They were more likely than well-nourished patients to die within 1 year of discharge; to be dependent in activities of daily living 3 months after discharge; and to spend time in a nursing home during the year after discharge.³³

Acutely ill patients have greater nutritional requirements than well elderly patients. Nutritional consultation is warranted for patients at risk for malnutrition. Oral and enteral alimentation, with a high-protein and calorie-dense diet, are the preferred routes of nutrition. Nutritional supplements have benefits based on studies of elderly patients with femoral neck fractures or chest infections.^{34,35} Food and fluids should be prescribed and monitored daily. Patients at risk for aspiration should be formally evaluated by speech therapist or by a modified barium swallow.³⁶ For patients with dysphagia for liquids, a pureed diet or thickened liquids may restore their ability to safely swallow and to obtain sufficient calories and hydration. Patients with severe oropharyngeal dysphagia or significant risk of aspiration may require enteral or parenteral alimentation. The placement of a nasogastric tube should be considered for a brief duration, with the consent of patient and family for patients with malnutrition and dysphagia. Parenteral alimentation is indicated when there is a contraindication to enteral alimentation. If the patient's dysphagia is severe and unlikely to resolve in the near future, a percutaneous endoscopic gastrostomy tube may be warranted. Active patient and family participation, however, is needed in making the decision to use a feeding tube, with consideration given to the balance between potential benefits, burdens, and limitations in patients with severe irreversible illnesses.³⁷

Delirium

Delirium, an acute disorder of attention and cognition, occurs in 20% to 30% of elderly patients admitted with an acute medical diagnosis. Risk factors for incident delirium in hospitalized elderly patients include baseline dementia, severe underlying illness, sensory impairment, and dehydration.³⁸ Delirium may be precipitated by processes of hospital care, including immobilization of the patient, use of an indwelling bladder catheter, use of physical restraints, dehydration, malnutrition, iatrogenic complications, and psychosocial factors.³⁹ Delirium prolongs hospital length of stay, increases costs of care, and increases the risk of nursing home placement or death.⁴⁰ Delirium can be detected through repeated observations of patients at the bedside and through application of screening instruments and scales. The

prevention and treatment of delirium are discussed in Chapter 77.

Depression

Depressive symptoms are present in 20% to 25% of medically ill elderly patients in hospital.¹⁴ Depression may be difficult to diagnose in patients with critical illnesses or cognitive impairment. Depression may be suspected in patients who appear withdrawn, uncooperative, and intermittently agitated or have a history of functional decline, social withdrawal, and weight loss. Detection for depression is easily performed and aided by screening instruments. Therapy of patients with depression includes environmental, psychosocial, and pharmacologic interventions (see Chapter 80). Environmental changes (for example, a brighter room), physical and occupational therapy, increased frequency of family visits, and psychological counseling may be of immediate benefit to the depressed patient.

Comprehensive Discharge Planning

Comprehensive discharge planning begins on the day of hospitalization. The process of discharge planning often requires an interdisciplinary team, case manager, or advanced practice nurse.^{41,42} The objectives of comprehensive discharge planning are to identify patients at risk of nursing home placement related to nonmedical issues including inadequate social support network or cognitive impairment; to estimate the patient's hospital length of stay; and to identify the need for functional assistance or formal supports at home. Patients and their families may be educated about diagnosis, prognosis, and the need for medications, home safety following discharge, and plans to coordinate posthospital care with physicians and other health professionals.

A "functional trajectory" projects the patient's discharge functional status and disposition from hospital⁴³ (Fig. 13.2). The functional trajectory assesses the patient's current ability to perform activities of daily living, mobility, cognition, affect, and nutritional status. This information is contrasted to the patient's baseline functional status before the acute illness and hospitalization. This review includes the patient's performance of both basic and instrumental ADL, living situation, and the patient's informal and formal support network.⁴³ The functional trajectory predicts nursing home placement in patients with a decline from baseline to admission in their activities of daily living.⁴⁴ Patient-centered interventions, commonly physical therapy, occupational therapy, medication review, and nutritional support, are implemented as required to achieve the anticipated discharge status and disposition.^{11,43,45}

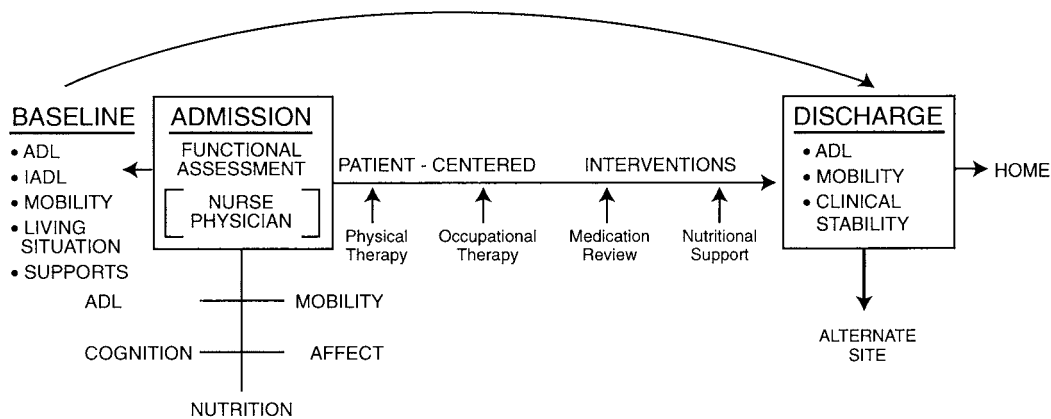

FIGURE 13.2. The functional trajectory. (From Palmer RM,⁴³ by permission of Marcel Dekker, Inc.)

Most medically ill older patients return home after hospitalization, but some patients will require rehabilitation, short-term nursing home care or care at other alternate sites, or home care skilled nursing services (Table 13.2). Patients with a self-limited illness who are able to perform daily activities independently may return to home without the need for formal services. Some patients will benefit from short-term skilled nursing care or other restorative services to assess, treat, or monitor new medical problems. Subacute care units or inpatient rehabilitation hospitals are appropriate options for patients with categorical illnesses, such as hip fracture or stroke, and for patients who require extensive physical therapy and skilled nursing services before their return home.⁴⁶ Home health care is warranted when patients or their families prefer to receive restorative services in the home rather than the subacute care or skilled nursing unit. However, for patients who are dependent in basic ADL, have limited rehabilitative potential, or lack adequate informal supports at home, placement in a long-term care facility may be warranted. Alternatives to hospitalization may include home care for patients with acute but nonlife-threatening illnesses, hospice or palliative care for patients with terminal illness, or direct admissions to a skilled nursing facility for patients who have managed care insurance. Discharge planning that is conducted by Advance Practice Nurses reduces the risk of hospital readmission of patients who are discharged to home.^{41,42}

Patients should not be discharged from the hospital if there is evidence of clinical instability. Signs of instability on the day preceding the planned discharge include (1) a new finding of incontinence, chest pain, dyspnea, delirium, tachycardia, or hypotension; (2) temperature above 38.3°C; or (3) diastolic blood pressure of 105 mmHg or more.⁴⁷ Elderly patients who are sent home in an unstable condition have twice the risk of mortality 30 days after hospitalization compared with those whose condition is stable.

Patient Values and Comfort

The personal values and priorities of patients and the wishes of their families should be addressed early in the course of hospitalization. Hospitals are required to ascertain whether patients have Advance Directives. The patient's Advance Directive should be reviewed with the appropriate family member or power of attorney for health care throughout the hospitalization. A review of the objectives of hospitalization, the diagnostic evaluation, and probable outcome should be discussed early in hospitalization. Periodic conferences with the patient and family will serve to update them about the patient's diagnosis, prognosis, length of stay, and probable disposition.

The value of knowing the patient's values becomes most evident when considering the use of potentially futile but life-extending interventions. One study of health values in very old hospitalized patients revealed that most patients were unwilling to trade much time to live for excellent health.⁴⁸ Discussions with the patient may revolve around end-of-life care, including cardiopulmonary resuscitation, intensive care, or nutritional support in the event of acute or end-stage illness.

Although palliative care is often the most appropriate approach for patients with incurable illness, very few elderly patients with incurable illness receive palliative interventions at the end of life.⁴⁹ In a prospective study, most elderly and seriously ill patients died in acute hospitals and had pain or other troubling symptoms.⁵⁰ Spirituality may be an important predictor of hospital prognosis. In one prospective study of patients aged 60 years and older admitted with depressive symptoms to a medical unit, greater intrinsic religiosity independently predicted shorter time to remission; depressed patients with higher intrinsic religiosity scores had more rapid remissions than patients with lower scores.⁵¹

TABLE 13.2. Discharge disposition of hospitalized patients.

Disposition site	Patient characteristics	Usual source of payment	Example	Comments
Home without formal (paid) support services	Independent in ADL, self-limited acute illness; stable chronic disease; adequate informal (family) supports	Self	Cellulitis; acute gastroenteritis; atrial arrhythmia	Most older patients admitted to hospital from home return to independent living; greater family support often needed for a short time
Home with formal support services	Recovering independence in ADL, or return to stable baseline; good informal supports; skilled nursing care or physical therapy needed	Medicare, third party	New medications (e.g., insulin instructions); pressure ulcer; intravenous antibiotics; gastrostomy tube	Home care needs identified early in hospitalization through process of comprehensive discharge planning; skilled services covered by Medicare for finite time; “custodial” services not included; need to monitor for family caregiver strain or elder mistreatment
Subacute care/skilled nursing unit	Dependence in ADL or ambulation preventing discharge to home; home supports adequate for chronic care, but not subacute; skilled nursing care or physical therapy needed; patient too impaired for rehabilitation hospital	Medicare, third party	Postoperative patients; intravenous antibiotics; heart failure and deconditioning	Often a fine line between patients going to rehabilitation hospital, subacute care unit, or home with formal support services; growth of subacute care is related to the greater severity of illness of hospitalized patients and increasing tendency to discharge patients “quicker and sicker”; short-term (<2 months) placement is typical
Long-term care (intermediate care) facility	Dependent in ADL; unable to return to independent living; ineligible for subacute or rehabilitative services; inadequate informal home supports (e.g., lives alone)	Self, Medicaid	Dementia; end-stage lung or heart disease	Most often needed when informal (family) supports are inadequate or the costs of home care are prohibitive
Hospice (palliative care)	Patients with terminal illness (prognosis ≤ 6 months)	Medicare, third party	Metastatic cancer; terminal heart failure	Provides comfort measures in home (or inpatient unit); palliative, not “curative” interventions covered; provided in hospital, home, or long-term care facility
Rehabilitation hospital	Categorical illness; likely improvement in ADL or ambulation; good home (informal) supports	Medicare, third party	Hip fracture; stroke	Eligible patients must be able to participate in physical therapy ≥ 3 h/day and demonstrate potential for improvement in ADL/ambulation

Personal comfort should be addressed throughout hospitalization. Privacy and quiet at night are important. Family members should be encouraged to visit patients. A normal bowel and bladder regimen is maintained with a toileting schedule, a bedside commode, or urinal for men. Fiber supplements or hyperosmolar laxatives are helpful to prevent fecal impaction in immobilized patients or those taking opiates or anticholinergic agents.

Controlled Clinical Trials Designed to Improve Outcomes of Hospitalization

Models of care designed to enhance patient functioning during hospitalization or immediately postdischarge have emerged in the past decade (Table 13.3). Early studies of

hospitalized patients supported the value of comprehensive geriatric assessment when linked to direct care of selected patients.^{52–54} They demonstrated that geriatric assessment units might be effective for carefully targeted patients. Subsequent clinical trials have been nurse directed or employed the interventions of geriatric consultation and acute care units. The usual objectives of the studies are to improve functional outcomes of hospitalization, reduce hospital lengths of stay, prevent nursing home admissions, or prevent rehospitalization.

The Acute Care of Elders (ACE) Unit intervention includes four main components: a prepared environment to foster patient self-care; patient-centered care, including guidelines for maintaining or restoring patient functioning; interdisciplinary team rounds; and discharge planning and medical care review.^{11,43,45} ACE Units have

TABLE 13.3. Controlled clinical trials to improve outcomes of hospitalization.

Study	Design	Patients	Setting	Intervention	Primary outcome measures	Results	NNT
Inouye et al. 1993 ⁵⁶	Stratified and matched cohort analysis	<i>N</i> = 216; age ≥70 years, targeted conditions	General medicine wards: two intervention, three control; university teaching hospital	Geriatric care program: Geriatric CNS Geriatric resource nurse Geriatricians on one ward Daily surveillance of Frail patients Weekly rounds	Incidence of functional decline (net loss of 1 or more basic ADL) from baseline to discharge	No benefit by stratified analysis: RR = 0.64 (95% CI, 0.43–0.96) by matched analysis (targeted conditions)	4 by matched analysis
Thomas et al. 1993 ⁶³	Randomized clinical trial	<i>N</i> = 132 (analysis on <i>N</i> = 120) age ≥70 years	General medical and surgical wards at nonacademic community hospital	Comprehensive geriatric assessment by interdisciplinary team consultation	Mortality at 6 months	6-month mortality significantly decreased (<i>p</i> = 0.01); hospital readmissions decreased (<i>p</i> = 0.02); no significant differences in functional status	7 to prevent one death
Winograd et al. 1993 ⁶⁰	Randomized clinical trial	<i>N</i> = 197; age ≥65 years; targeted conditions (frailty)	Medical and surgical services at a Veterans Affairs teaching hospital	Comprehensive geriatric assessment by interdisciplinary team consultation; limited direct patient care; limited in-service education	Differences in basic and instrumental ADL, morale, and cognition at discharge and 1 year	No differences in ADL, or morale, at discharge or follow-up for 1 year; cognition better at 1 year follow-up	N/A
Landefeld et al. 1995 ¹¹	Randomized clinical trial	<i>N</i> = 651; age ≥70 years	General medicine wards: one intervention; university teaching hospital	Acute care of elders (ACE): Prepared environment Patient-centered care Planning for discharge Medical care review	Change in 1 or more of 5 ADL between admission and discharge	ACE improved performance of ADL (<i>p</i> = 0.009); nursing home discharges decreased (<i>p</i> = –0.01)	6 to prevent loss of 1 or more ADL; 15 to prevent first-time nursing home discharge
Reuben et al. 1995 ⁵⁹	Randomized clinical trial	<i>N</i> = 2553; age ≥65 years; targeted conditions	General medicine wards, four staff-model HMO hospitals	Comprehensive geriatric assessment by an interdisciplinary team (social worker, nurse practitioner, geriatrician) after hospital admission; daily team conferences; minor changes in therapy made by geriatrician	One-year mortality	No differences in 1-year survival; no differences in functional status at 3 and 12 months	N/A

Rich et al. 1995 ⁶⁴	Randomized clinical trial	<i>N</i> = 282; age ≥70 years; congestive heart failure, risk factors for readmission	General medicine wards, community teaching hospital	Intensive education about CHF by cardiovascular research nurse; dietary instruction by dietitian; social service consultation; geriatric cardiologist recommendations; home care visits; telephone calls	Survival without readmission for 90 days	No differences in 90-day survival (<i>p</i> = 0.09); decrease in hospital readmissions (<i>p</i> = 0.02) and CHF readmissions (<i>p</i> = 0.04); higher quality of life; lower costs	10 to prevent survival without readmission; 8 to prevent ≥1 readmission; 5 to prevent readmission for CHF
SUPPORT Principal Investigators 1995 ⁶⁵	Phase II: randomized clinical trial	Age ≥18 years (median age = 65); advanced states of ≥1 defined illnesses	General medical wards and intensive care units; five university or community teaching hospitals	Physicians given estimates of 6-month survival, outcomes of CPR and 2-month functional disability; elicit/document patient/family preferences and understanding of disease prognosis and treatment	The timing of written DNR orders; patient-physician agreement on DNR preferences; days spent in ICU comatose or on mechanical ventilation before death; pain frequency and severity; hospital resources used	No significant differences in median time to DNR order, DNR agreement, undesirable state, or resource use. No improvement in level of reported pain	N/A
Siu et al. 1996 ⁶¹	Randomized clinical trial	<i>N</i> = 354; age ≥65 years; unstable medical problems, recent functional decline or geriatric problems	Medical and surgical services; university teaching hospital	Geriatric assessment and limited examination before discharge by nurse practitioner; home visits 1–3 days after discharge by NP; home evaluations by health professionals; interdisciplinary team meetings; recommendations to primary physicians	Nursing home admission, hospital readmission, mortality at 30 and 60 days after discharge	No differences in survival, hospital readmission or nursing home placement by 60 days; no benefits on functional status	N/A
Ronning et al. 1998 ⁵⁸	Quasi-randomized clinical trial	<i>N</i> = 570 (analysis on 550); age ≥60 years; acute stroke	General medical ward on stroke unit; Scandinavian community hospital	Stroke Unit: Standardized neurologic and laboratory examination aspirin multidisciplinary stroke team	Death, long-term care placement, ADL, after 7 months	No significant differences in death (OR = 0.87, 95% CI, 0.59–1.28); or long-term care	N/A

Inouye et al. 1999 ⁵⁷	Controlled trial, individual matching strategy	<i>N</i> = 852; age ≥ 70 years; risk factors for delirium	General medical wards; one intervention, two control; university teaching hospital	Elder Life Program, targeted at six risk factors for delirium: Cognitive impairment Sleep deprivation Immobility Visual impairment Hearing impairment Dehydration Interdisciplinary team	Delirium incidence	First episode (incident) of delirium reduced (OR = 0.60, 95% CI, 0.39–0.92); total days of delirium decreased ($p = 0.02$); no difference in delirium severity	20 to prevent a first case of delirium
Naylor et al. 1999 ⁴²	Randomized clinical trial	<i>N</i> -363; age ≥ 65 years; selected common diagnoses, risk factors for poor postdischarge outcomes	Medical and surgical services; one university and one community teaching hospital	Comprehensive discharge planning and home follow-up for 4 weeks by advanced practice nurse	Time to first hospital readmission, 24 weeks after discharge	Time to first readmission was significantly increased ($p \leq 0.001$); readmissions decreased ($p \leq 0.001$); fewer hospital days per patient ($p < 0.001$)	6 to prevent 1 readmission in 24 weeks
Counsell et al. 2000 ⁵⁵	Randomized clinical trial	<i>N</i> = 1531; age ≥ 70 years	General medicine wards; one intervention; community teaching hospital	ACE Unit: Prepared environment Patient-centered care Planning for discharge Medical care review	Change in one or more of 5 ADL from 2 weeks preadmission to discharge	No significant difference in ADL ($p = 0.33$ by intent to treat, 0.07 per protocol); decreased composite outcome of ADL decline or NH placement ($p = 0.027$)	18 to prevent either ADL decline or NH placement

NH, nursing home; NP, nurse practitioner; ADL, activities of daily living; NNT, number needed to treat.

shown the potential to reduce the incidence of functional decline in older patients, the length of hospital stay, and the risk of nursing home admission from hospital.^{11,43,55}

In the Geriatric Care Program, a gerontologic clinical nurse specialist working with trained resource nurses focuses nursing care on patients at high risk for functional decline.⁵⁶ The intervention includes identification and monitoring of frail older patients, twice-weekly rounds of a multidisciplinary "Geriatric Care Team," and a nursing-centered educational program. In a clinical trial, when patients were matched on number of target conditions and risks for functional decline at baseline, the intervention resulted in a significant beneficial effect with a reduction in functional decline.⁵⁶

In the Elder Life Program, patients at risk for incident delirium are identified shortly after hospital admission, using the Confusion Assessment Method.⁵⁷ An array of protocols targeted at specific risk factors serve to optimize cognitive function (reorientation, therapeutic activities), prevent sleep deprivation (relaxation, noise reduction), avoid immobility (ambulation, exercises), improve vision (visual aids, illumination), improve hearing (hearing devices), and treat dehydration (volume repletion). A clinical trial of intervention protocols targeted at risk factors for delirium resulted in a 40% reduction in the incidence of delirium but had no significant effect on the severity of delirium or on recurrence rates.⁵⁷

Several studies demonstrate the effectiveness of specially trained nurses to coordinate discharge planning and reduce the rate of hospital readmissions of at-risk elderly patients. In one clinical trial, an advanced practice nurse-centered discharge planning and home care intervention for at-risk hospitalized elders reduced readmissions, lengthened the time between discharge and readmission, and decreased the costs of providing health care.⁴²

Stroke units appear to reduce rates of patient mortality, institutionalization, and functional dependency in comparison to general medical wards, although long-term benefits are less evident.⁵⁸ The stroke unit interdisciplinary team, including the patient's physician, social worker, physical and occupational therapist, speech therapist, and neurologist, uses a systematic approach to enhance patient recovery after admission and to begin diagnostic and rehabilitative services.

In general, comprehensive geriatric assessment performed by consultation teams fails to improve functional outcomes of hospitalization.^{54,59-61} However, a recent clinical trial found that comprehensive assessment on a geriatric unit reduced hospital length of stay for patients with acute and subacute illnesses.⁶²

These studies in perspective offer hope that the adverse consequences of hospitalization can be attenuated through comprehensive assessment, special units, and comprehensive discharge planning.

Clinical Approach to the Older Patient: An Overview

Glendo L. Tangarorang, Gerard J. Kerins, and Richard W. Besdine

Impact of Aging on Disease

Health and Disease Behavior in Older Adults

Health and disease behavior in older adults refers both to differences in the way diseases behave when occurring in older persons and to differences in the way older persons behave when afflicted with disease.¹ Behavior is the summation of social, cultural, psychological, and clinical influences. Perceived severity of illness, the impact of disease on everyday function, denial, and local resources for help all play into behavior.^{2,3}

Although *self-perception of health* is heavily influenced by an individual's disease burden and its current activity, norms and expectations concerning health in the group against which one measures health and dependence also can be powerful determinants of perceived health.⁴ A robust 80-year-old widow, independent in a community of active and energetic retired persons, self-sufficient in ADL (activities of daily living), IADL (instrumental ADLs), and executive functions, is likely to perceive difficulty walking or remembering which of the 20 identical entrance doors on the street is hers far more seriously than is her cousin living in a nursing home.

Aging is associated with a decline in expectation of healthiness. Those over age 65 generally give more positive evaluations of their healthiness in the face of increasing burden of disease and disability.^{5,6} The older the person, the more likely they are to report very good health status.⁷ However, overestimating healthiness (also called normalization) often results in explaining away symptoms or problems as caused by minor illnesses or even by external events. In either case, late recognition and delayed intervention are the usual outcome. Previous neglect of symptoms by health care professionals is also likely to teach older patients that frailty and loss of independence are normal and to be expected with aging; again, late detection and intervention are likely, resulting in high cost and discouraging outcomes. Perhaps these

attitudes explain the finding of greater pessimism in older persons compared with those middle-aged, even when health status was factored in.⁴

Underreporting of symptoms is a common theme in discussions of illness behavior of older persons. First reported in the 1950s by Scottish geriatricians who screened older individuals and discovered surprising numbers of unrecognized disorders,^{8,9} underreporting has been documented repeatedly. Major burdens of unreported and thus undiagnosed and untreated medical conditions were detected in these investigations. The British studies are doubly noteworthy. First, all patients were served by the National Health Service, which appeared to have requisite features for satisfactory geriatric care. All enrollees had a designated primary care community physician, who received an annual sum to provide care at no cost to the patient. Second, the problems identified were common and usually treatable diseases⁹; congestive heart failure, correctable hearing and vision deficits, tuberculosis, incontinence, anemia, bronchitis, claudication, cancers, malnutrition, diabetes, immobility, oral disease preventing eating, dementia, and depression were frequent.

Shanas reported that 90% of community-dwelling persons had symptoms in the previous 30 days, but only 30% had consulted their physicians about them.¹⁰ When relatives were questioned about their older family members, one-third responded that medical care was insufficient; they further thought that their elderly relatives attributed most of their symptoms to aging, not disease. Brody also demonstrated minimizing of problems¹¹; of 20 potentially serious symptoms (e.g., chest pain, bleeding, shortness of breath, ankle swelling, unsteady on feet), only a slight majority were reported at all, and most of the reports were to a family member rather than a health professional. Explanations were "no big deal; nobody cares; nothing can be done about it" or "don't want to bother people."

Considerable underreporting was also seen among people with chronic diseases. More than half of chroni-

cally ill individuals who were surveyed in one study failed to report at least one disease. "Number of diseases" and age were notable factors that independently accounted for this problem.¹² In another survey of community-dwelling elderly people, the independent influence of age on reporting chronic diseases was again demonstrated. Older people tend to inaccurately report cardiac disease, arthritis, and stroke.¹³

Among patients seen in the emergency room for chest pain due to cardiac ischemia, elderly patients were more likely to wait more than 6 h before going to the emergency room, even though more than half of them had documented coronary artery disease. Among elderly (70–80 years old) and very elderly patients (>80 years old) whose chest pain represented acute myocardial infarction, hospital mortality was double and triple, respectively, when compared to that in younger patients (<70 years old).¹⁴

Morgan et al.¹⁵ emphasized the need for increased health education in older people. Morgan reported that many symptoms classically associated with common diseases were often considered by community-dwelling elderly *to be normal for old people*. Some important symptoms, such as blackouts or paralysis of a limb, were understandably not considered to be normal. However, although nonspecific symptoms of psychiatric disturbances were also frequently considered not normal, they were not considered to represent disease. Whether a doctor would be consulted was often, but not always, related to whether a symptom was thought to represent a disease.¹⁵

In addition to provider-related reasons, failure by older persons to recognize symptoms as abnormal may help explain why depression is frequently underreported and undertreated.¹⁶ Undetected depression in older persons assumes more importance, because it has been shown that, compared with younger suicide cases, older suicides planned more carefully the fatal suicide attempt, *and* they were more secretive about their intent.¹⁷ Even among patients meeting full criteria for major depression, aging is associated with a sharp decrease in self-reported depressive symptoms, as measured by the Beck Depression Inventory.¹⁸ In fact, among older adults, depression is commonly underdiagnosed and undertreated.¹⁹ As a result, clinicians should be cautious in using screening instruments (e.g., Geriatric Depression Scale) or accepting self-report data when trying to exclude depression.

Although the oldest subjects had the highest levels of health-promoting behavior, they were also least likely to take action in response to symptoms of serious illness.²⁰ In one study, older patients with community-acquired pneumonia reported respiratory and nonrespiratory symptoms less commonly than younger patients, even after controlling for increased comorbidity and severity of illness.²¹ Older persons most often attributed symp-

toms to aging and reacted to those symptoms by (1) waiting and watching, (2) accepting symptoms, (3) denying danger, or (4) delaying or rejecting medical care. Although underreporting of symptoms by older persons has been identified as a common illness behavior with dangerous consequences, many clinicians have an image of older patients with infinite complaints whose investigation lead nowhere. As with many "old saws" about older persons, the stereotypical image of hypochondriacal older patients could not be documented.²² Instead, it appears that hypochondriasis is less common among older people than among the middle-aged. In addition, among nonhypochondriacal patients, complaints in older adults are more often "validated" by the identification of disease than in younger persons.²³

The riskiness of underreporting of symptoms by older patients is obvious; late identification of disease leads to late initiation of treatment, usually after substantial morbidity associated with advanced pathology has already occurred and caused major functional losses. Rehabilitation to independence from these losses is difficult; permanent dependence in spite of "successful" treatment may occur. The message to clinicians is clear: aggressive case-finding and surveillance of at-risk older persons is necessary to prevent perpetuation of the discouraging and expensive pattern of late discovery of disease resulting from insufficient symptom reporting by older patients.²⁴ This aggressive approach must include the patient, and family when appropriate, in the decision process when surveillance uncovers the need for more intensive investigation and intervention. It may be that underreporting is a cohort phenomenon, likely to abate as contemporary generations of Americans age, aware of the benefits of medical intervention and having heightened consciousness of wellness. For the present, clinicians should expect symptom underreporting by their older patients.

The Role of Cultural Diversity

Cultural beliefs and factors exert important influences on provision of medical care to older adults. Social supports, perceptions of wellness or illness, and health expectations are all influenced by one's cultural beliefs. Use of alternative and nontraditional therapies may also be culturally based and must be considered when providing medical care. Recent data suggest that African-American and Hispanic women use complementary and alternative medicine for a wide range of health conditions.²⁵ Social supports that may affect health care utilization and use of long-term care can be influenced by culture and tradition, which vary greatly among different ethnic and socioeconomic groups. Accordingly, appreciating the influence of cultural diversity and beliefs on health and

health care demands that physicians and other providers understand diversity and its relationship to care.²⁶

Goldstein and Griswold²⁷ point out that the challenge to acquire competence and sensitivity in dealing with patients of diverse cultures is especially important for health professionals in gateway cities, in urban communities along the U.S. border, and in rural areas with migrant workers or Native Americans. The broad categories commonly used to define ethnic minorities—African-Americans, American and Alaskan Natives, Asian-Americans, and Hispanics—do not capture the wide array of cultural differences that can affect definition of illness and selection of treatment. It is important to view elders with multicultural sensitivity and to understand that there may be great heterogeneity within cultural or ethnic groups.²⁷ Clinicians should always consider the epidemiology of diseases in various cultures, the acculturation process, and the potential for misdiagnosis resulting from cultural differences. Another unique challenge is presented by the care of persons who have come to the United States in late life, often to join sons and daughters who previously emigrated.²⁷ Continuing research is addressing these issues.

Multiple Pathology

Multiple pathology, or concurrence of diseases, is common among older persons. An early Scottish study of community-dwelling persons over age 65 reported 3.5 major problems per person⁹; for those being admitted to hospitals, 6 disorders were documented per patient.²⁸

Multiple pathology poses multiple risks to older patients and their physicians.²⁹ The first hazard is that active medical problems frequently interact with one another to the detriment of the patient—*disease-disease interactions*. The more frail and delicately compensated the patient, the more quickly unattended disease produces major functional losses; these can be permanent in spite of subsequent detection and treatment.

Illustrative is the story of a 70-year-old community-dwelling widow who walks slowly and limps because of left knee pain, who chews incompletely because of gum pain, who sees poorly, and who has urinary urgency and “a touch of diabetes.” She develops lethargy and fever over several days, and oral intake declines; one night, on her way to the bathroom to urinate, she is incontinent of a large volume of urine. Stepping into the puddle, she slips, falls backward onto her right greater trochanter, and sustains a hip fracture. In the hospital, preoperative evaluation identifies hyperosmolar dehydration resulting from out-of-control diabetes and right intertrochanteric hip fracture. Bacteremia is discovered; it and fever are attributed to periodontal abscess. Treatment is initiated for all these conditions and, on the 5th day, the hip fracture is successfully repaired with a compression screw.

That night, she develops atrial fibrillation; evaluation reveals transmural myocardial infarction. Over the next 5 days, although hemodynamically stable, she is in and out of atrial fibrillation; she is found hemiplegic and aphasic on the 6th postoperative day. Evaluation reveals mural thrombus and left ventricular clot. After a 2-week hospitalization, she is discharged to a nursing home, doubly incontinent, confused, aphasic, and requiring total nursing care.

Her prefracture problem list of (1) degenerative osteoarthritis of the knee causing slow gait, (2) atrophic vaginitis causing urinary urgency, (3) osteoporosis, (4) cataracts, (5) periodontal disease, (6) type II diabetes mellitus, and (6) coronary insufficiency had never been assembled or considered by her physician, who thought of her as a “delightful old dear.” Her root caries and gingivitis had never been treated, nor had her difficulty with chewing been considered as a risk factor for dehydration. Her gait had not been evaluated, either for primary treatment of the underlying arthritis nor for support with a walking aid. Her cataracts had not been considered, nor had her vaginitis been identified or treated with estrogens for comfort or reduction of urinary urgency; her osteoporosis had not been addressed. Late detection of treatable problems whose neglect and interaction have led to functional decline is common in older patients and can be one of the few discouraging features of geriatric care. Preventive dental and medical care could have avoided the sepsis, worsening of diabetes, fall, hip fracture, postoperative heart attack, stroke, and loss of independent living.

A second risk is that unidentified multiple pathologies can interact with diagnostic studies or treatment undertaken to manage a diagnosed problem and produce iatrogenic harm, or *disease-treatment interaction*. An 82-year-old man with coronary heart disease and impaired systolic function presents to an urgency-center for shortness of breath; treatment is begun with furosemide and digoxin, resulting in reduced symptoms and improved physical findings. Diabetes mellitus (type II, diet-controlled), prostatism, and early Parkinsonian gait are not considered. Dehydration is precipitated by furosemide and exacerbated by poor oral intake resulting when his already loose upper denture falls out and breaks. The intense diuresis also results in urinary retention with overflow incontinence. Blood sugar rises and further exacerbates dehydration. Now confused, dribbling urine, and unsteady, he falls, hits his head on the toilet, and sustains a subdural hematoma. The clinical outcome is dismal; no longer able to walk, confused, and afflicted with three pressure sores and a urethral catheter, he requires permanent nursing home residence. Ignoring his (1) poorly fitting dentures, (2) diabetes, (3) prostatism, and (4) gait difficulty has transformed a well-intentioned intervention into an iatrogenic catastrophe.

Functional Loss

Functional loss is a final common pathway for most clinical problems in older persons, especially in persons over age 75.³⁰ Additionally, it may be the only sign or symptom of important underlying disease when more specific and typical symptoms of a particular disease are absent. Functional impairment means decreased ability to meet one's own needs and is easily measured by assessing activities of daily living (ADL) and instrumental activities of daily living (IADL). In addition, objective assessments of cognition and behavior and of social, economic, and emotional state are required to document health-related function of older persons^{31–35} (see Chapter 17). A systematic literature review³⁶ identified risk factors highly correlate with functional decline, including cognitive impairment, depression, comorbidity/disease burden, increased and decreased body mass index, lower extremity functional limitation, low frequency of social contacts, low level of physical activity, no alcohol use compared to moderate use, poor self-perceived health, smoking, and vision impairment. Among the very old (85 years and older), impaired functioning and cognition predict institutionalization.⁶

Presentation of illness in older persons less often is a single, specific symptom or sign, which in younger patients, announces the organ with pathology. Older persons often present with nonspecific problems that are in fact functional deficits.^{29,37} Stopping eating and drinking, or the new onset of falls, confusion, lethargy, dizziness, or incontinence in older patients may be the primary or sole manifestation of diseases with classic signs and symptoms in the young (e.g., pneumonia, myocardial infarction, pulmonary embolus, alcoholism or myxedema). These deficits have been named *geriatric syndromes*; they devastate independence without producing obvious or typical indications of disease. Geriatric syndromes may be defined as a set of lost specific functional capacities potentially caused by a multiplicity of pathologies in multiple organ systems. For example, dizziness among community-dwelling elderly people was shown to be associated with seven characteristics: anxiety; depressive symptoms; impaired hearing; use of five or more medications; postural hypotension; impaired balance, and past myocardial infarction.³⁸ Comprehensive evaluation is usually required to identify and treat underlying causes. Although in many instances a geriatric syndrome has several contributing causes, remedying even one or a few may result in major functional improvement.

Nonspecific Presentation of Disease

The most likely explanation for nonspecific presentation is that the additive effects of aging restrict capacity to

maintain homeostasis. Perturbation of homeostasis by disease, trauma, or drug toxicity will be manifest in the most vulnerable organ, or weakest link, resulting from interactions of biologic aging and chronic disease. The locus of deficit, which reliably identifies the root of pathology in younger patients (immobility originates in musculoskeletal or neurologic disorders, confusion arises from brain disease, incontinence stems from urinary tract problems, and undernutrition is gastrointestinal), is a less reliable guide in older patients. Instead, especially vulnerable systems are likely to decompensate from systemic impact of disease anywhere in the body. The lesson for physicians and for older persons and their families is that functional loss, especially if abrupt, is a reliable sign of disease; rapid and comprehensive evaluation is the only appropriate clinical response.

Altered Presentation of Disease

In addition to nonspecific presentation, disease in older patients can present in other atypical ways. Blunting or absence of typical or classic symptoms and signs is well described in many conditions.^{39–44} In a study of 55 elderly patients presenting to the emergency room with suspected hypovolemia, seven signs correlated best with dehydration: confusion; extremity weakness; non-fluent speech; dry mucous membranes; dry tongue; furrowed tongue; and sunken eyes. None of these findings is particularly helpful when present in isolation.³⁹ Painless myocardial infarction^{41,42} is well documented as more common in older patients. Hypothyroidism has been shown in a prospective study to occur with fewer symptoms and to be more difficult to diagnose in older patients.⁴³ Likewise, among patients 70 years and older, hyperthyroidism *infrequently* presented with tremor, hyperactive reflexes, increased sweating, heat intolerance, nervousness, polydipsia, and increased appetite. More commonly found in the older hyperthyroid patients than in younger patients were anorexia and atrial fibrillation. Only three signs occurred in more than half the older patients: tachycardia, fatigue, and weight loss. Goiter, seen in 94% of younger patients, presented in only 50% of the older subjects.⁴⁴ Osler first drew attention to the muted picture of lobar pneumococcal pneumonia: "Pneumonia in the aged may be latent and set in without a chill; the cough and expectoration are slight, the physical signs ill-defined and changeable, and the constitutional symptoms out of all proportion to the extent of the local lesion."⁴⁵ Finally, a few diseases have specific presentations usually found only in older patients; diabetes out of control presents as hyperosmolar state,^{46,47} hyperthyroidism presents as apathetic thyrotoxicosis,⁴⁸ and depression presents as blunted cognition.^{49–51}

Evaluating the Patient

Much of what has been written on evaluation of the older patient is simply attention to the details of careful clinical assessment. Contemporary emphasis on efficiency and effectiveness of clinical care requires thoughtfulness about any extension of the already lengthy evaluation of complex chronic medical problems that commonly cluster in older persons. Brief screening questions rather than elaborate instruments are appropriate for first encounters⁵²; more detailed assessment should be reserved for patients with demonstrated deficits.³⁵ Even at its most parsimonious, the initial evaluation of older patients with multiple disorders and treatments will generally be prolonged, as compared with time needed for younger persons. Dividing the new patient assessment into two sessions can spare both patient and physician an exhausting and inefficient 2-h encounter. Other office personnel can collect much information by questionnaire before the visit, from previous records, and from patient and family before the physician's contact. It is essential that good care, fully informed by current geriatrics knowledge, be delivered within a reasonable time allocation consistent with contemporary patterns of primary care. One hour for a new visit and 30 min for a follow-up are an absolute maximum in most environments.

Completing a home visit may also provide valuable insight into a patient's environment and daily functional status. How mobility may affect function in a particular environment, real insight into nutrition, medication use and compliance, and social interactions and support can all be assessed quickly by a home visit. In one well-designed trial, in-home comprehensive geriatric assessment delayed onset of disability and reduced future need for skilled placement.⁵³ Medicare now provides appropriate reimbursement for a home visit with the proper code (CPT code 99341–99350, depending on the various conditions). Comprehensive geriatric evaluation and management by an interdisciplinary team in selected populations may improve overall health outcomes, maintain function, and possibly reduce health care utilization^{54,55} (see Chapter 18).

The Setting

Ambulatory Office Care

The common occurrence of physical frailty among older persons demands particular attention to providing both a comfortable and safe environment for evaluation. Autonomic dysfunction, reflected by the occurrence of accidental hypothermia and hyperthermia, is commonly encountered in older persons and increases vulnerability to excessively cool or warm settings, especially when the

patient is dressed appropriately to the outside temperature. Accordingly, examining rooms should be kept between 70°F and 80°F. Brighter lighting is required for adequate perception of the physician's facial expression and gestures by the older patient, whose lenses admit less than half the light they did in youth, due to cross-linking of lens proteins.

Presbycusis (present in >50% of older persons) makes background noise more distracting and interferes with the patient's hearing. Even in a quiet setting, the high-tone loss of presbycusis makes consonants most difficult to discriminate; speaking in a lower-than-usual pitch will help the patient hear, and facing the patient directly will improve communication by allowing lip reading. The patient's eyeglasses, dentures (to enhance the patient's speech), and hearing aid (with a functional battery) should always be brought to and used at the physician visit. Chairs with a higher-than-standard seat or a mechanical lift to assist in arising are useful for frail older persons with quadriceps weakness, and a broad-based step stool with handrail can make mounting and dismounting the examining table safe. Drapes for the patient should not exceed ankle length so as not to be a risk for tripping and falling.

The Acute Hospital or Nursing Home

The patient room is commonly the site of evaluation for the nursing home resident or hospitalized older adult. Little is different in evaluating older persons in the hospital; the patient is usually confined to bed, so that safety and comfort are dictated by the hospital amenities. All other considerations relevant in the ambulatory setting apply. Respect demands either drawing the privacy curtain or, in the nursing home, asking a roommate to leave if possible. In the nursing home, a good strategy, if space allows, is to do everything except emergency evaluation and treatment in set-aside office space rather than in the resident's room. The room is home for the resident; using that space for clinical purposes risks implying that the resident has no personal space and that the room and bed are part of the medical care environment. Privacy and identification of the nursing home room as living space, rather than medical care space, are important issues for the nursing home resident and staff.

The History

Although it is important to discover the patient's "reliability" as soon as possible, one should not simply dismiss patients with dementia as unreliable and confine data collection to other informants or previous records.⁵² Dementia produces a spectrum of cognitive function loss, ranging from detectable only on exhaustive neuropsychologic testing to mutism or gibberish. Beginning

history taking with questions whose answers will illuminate mental status (e.g., time and place orientation, reasons for the visit, previous health care contacts, biographic data, problem solving) can quickly establish credibility of responses.⁵⁶ Even in cases of severe impairment, questions concerning current symptoms may still give useful information,⁵⁷ and interaction at any level is an essential part of conveying a caring and respectful attitude.

Regardless of mental status, it is common for older patients to be accompanied by family members. Always give the patient the option of being interviewed and examined alone; including family members or companions during the visit should only occur at the patient's request. Certain older adults may be more comfortable meeting the physician with others present, but this decision should be left to the patient.

Generally, it is best to ask if the patient wants a relative or other concerned person present for history or physical examination; getting *some* time alone with the patient is essential for the patient to communicate any information he or she regards as confidential for the physician.⁵⁸ If the relative is present during the history, it is critical to make clear that *the patient* is to answer all questions; the relative should answer only if the physician asks for clarification. In cases of cognitive impairment or simply a long and complex history, family members, previous medical records, and other providers can provide supplementary data.

Structuring the History

A single or chief complaint is less common among older patients; more often, multiple diseases and problems have multiple symptoms and complaints associated with them. Accordingly, trying to structure the history in the standard format of "chief complaint," "history of present illness," and "past medical history" usually results in frustration for the clinician. More useful is the enumeration of a comprehensive problem list, followed by complaints, recent and interval history, and remote information for each of the active problems being considered at a visit. The first evaluation, regardless of setting, requires creating a complete database; its future utility justifies the initial time allocation. It may be easiest to commence the history with an open-ended question, such as "What do you feel interferes most with your day-to-day activities?" Such a question is usually very helpful in focusing the clinical evaluation.

Another common finding in older patients is that the law of parsimony, or Occam's razor, is not valid—multiple complaints and abnormal findings arise from multiple diseases; discovering a diagnosis that unifies multiple signs, symptoms, and laboratory data is uncommon and, although welcome in patients of any age, should not be

expected in older persons. The classic paradigm in which clinical findings lead directly to a unifying diagnosis has been found to operate in fewer than half of older patients studied; other models, which included major roles for comorbidities, for functional status, and for psychosocial factors, were found to operate in 60% of patients evaluated.⁵⁹

Medications

The importance of collecting and inquiring about each and every medication taken by or in the possession of the older patient cannot be overemphasized.⁶⁰ Older adults often take duplicate, overlapping, and conflicting drugs,⁶¹ usually acquired from multiple prescribing physicians and over-the-counter sources. All drugs owned by the patient, including supplements, herbals, vitamins, laxatives, sleeping pills, and cold preparations, should be gathered from bathroom cabinet, bedside table, purse, kitchen drawer, and relatives and brought to the office visit. Ask patients specifically about food and vitamin supplements and the use of any other alternative medications or remedies they may take. A national survey of alternative medicine use in the United States documented that 42% of 2055 adults used alternative therapies during the previous year, mostly for chronic conditions such as back pain, anxiety, depression, and headache. In addition, a sizable number of people who are taking alternative medicines fail to inform the clinician, emphasizing the need for the clinician to specifically inquire about nonprescription drug use.⁶² All containers should be placed on a table and the patient asked how often each drug is taken and for what, if any, symptomatic indication.⁶⁰ Consider review of all types of medications every 3 months. Ascertaining pneumococcal, influenza, and tetanus vaccination status can be conveniently done as part of the medication history.

In the hospital, caution should be exercised in ordering all drugs that have been prescribed; toxic accumulation of one or several agents is common, usually because the patient has not been taking prescribed medications as instructed. "Self-protective nonadherence" to the regimen, often in response to adverse reactions when drugs were taken as ordered, has led to reduction in dosage or frequency by the patient. Return to originally prescribed schedules produces toxicity.

In the nursing home, the major additional caution concerns the continued administration of unnecessary drugs that were initiated for transient problems arising during hospitalization. Sedative, antipsychotic, diuretic, antiarrhythmic, and anti-infective drugs are often continued indefinitely at the nursing home on the incorrect assumption that they are needed.⁶³ Careful winnowing of the medication list is indicated at least every 3 months and following any hospitalization.

Social History

Crucial information for developing a coherent and feasible care plan at home includes detailed knowledge of any change in living arrangements, who is available at home or in the local community, and what plans if any exist for coverage in times of illness or functional decline. Although a home visit is the best way to evaluate risks or limitations, inquiring about stairs, rugs, thresholds, bathing facilities, heating, and crime can increase the care plan's utility. Stable and durable plans for care at home both fulfill the patient's goal to remain at home and the system's goal to control costs of institutional care. Extent of social relationships is a powerful predictor of functional status and mortality for older adults⁶⁴; accordingly, determining the patient's friendship network and recommending ideas for increased socialization can be an appropriate clinical role. Even social and productive activities that involve little or no physical exertion may lower the risk of all cause mortality as much as fitness activities do.⁶⁵ Encouraging older persons to become involved with local senior center activities may be one mechanism to enhance social relationships, reduce isolation, and improve daily functioning.

Nutrition History

Although independent elders in the community are generally adequately nourished, the prevalence of under- and overnutrition increases in older persons. Undernutrition is most often unrecognized.⁶⁶ Most of the undernutrition occurs in those with chronic diseases that directly or indirectly interfere with nutrition. Oral or gastrointestinal disorders, drug effects on appetite, systemic illness, and psychiatric disease increase the risk of undernutrition. Screening questions include a diet history (within the past few days), pattern of weight during recent years, and shopping and food preparation habits.⁶⁷ Other questions should include any recent intentional efforts to gain or lose weight or any history of eating disorders. Sites of eating, companionship, and skipped meals are also relevant. Serum albumin is a good marker of nutritional status over the preceding 3 months and is correlated with mortality rates.⁶⁸ The prealbumin reflects nutrition during the past 20 days.

Although it is not strictly part of the nutritional history, this is a convenient time to inquire about alcohol and tobacco use. Alcohol misuse by older persons is often overlooked in all but florid situations, in part because symptoms and signs are often attributed to other problems common in older persons.⁶⁹ However, alcohol-related hospitalizations are more common than expected, as frequent as for myocardial infarction.⁷⁰ Alcohol can dramatically affect health status and function. Furthermore, alcoholism increases the older patient's risk of

dying within 2 years.⁷¹ Accordingly, it is important to include routine questions in the history⁷²; the CAGE (*Cut down, Annoyed, Guilty feelings, Eye-opener*) questionnaire has been validated in older persons.⁷³ In a study of 120 elderly male veterans, the MAST-G (Michigan Alcoholism Screening Test—Geriatric Version) and the CAGE had comparable sensitivity and specificity (70% and 81%, respectively, for MAST-G score ≥ 5 , and 63% and 82% for CAGE score ≥ 2). The CAGE is more useful, as it requires only four easily memorized questions.⁷⁴ A positive response to two of four questions has traditionally been considered a positive screen. However, in a patient population with high prevalence of drinking problems, even a score of one should trigger appropriate investigation.⁷⁵ In elderly medical outpatients, the CAGE may miss half the cases of alcohol abuse or dependence.⁷⁶ Occult alcohol ingestion contributing to cognitive deficits, falls, depression, and exacerbation of diabetes or heart disease is common; specific questions are required for detection. Smoking cessation at any age, even beyond 80, rapidly improves health^{77,78}; a minority of physicians counsel older persons to quit.

Family History

Although causes of mortality among relatives are usually irrelevant, history of Alzheimer's disease or nonspecified dementia appears to be important. Likewise, certain psychiatric disorders, such as depression and dysthymia, appear to cluster within families. From a mental health perspective, the medical family history also can identify caregiving by the older person. Caregiving of a disabled spouse and its attendant stress confer substantial mortality risk for the caregiver. Persons who were providing care and who were experiencing strain have a 50% greater risk of dying within 4 years, compared to non-caregiving controls.⁷⁹

Sexual History

Older persons continue to be sexually active unless inhibited by the absence of a partner or the occurrence of a disease that reduces libido, makes intercourse painful, or prevents it mechanically.⁸⁰ Discomfort or awkwardness may result from physician rather than patient attitudes; a simple open-ended question, such as "Tell me about your sex life" or "Are you satisfied with sex?" may encourage the older person to give information not spontaneously reported.

Miscellaneous History

Routine questions should be asked regarding driving habits, seatbelt use, recreational activities, and gambling history. The Lie/Bet questionnaire⁸¹ may be a useful screening tool. A positive response to either of two ques-

TABLE 14.1. Brief screening instrument for common problems in older persons.

Problem	Screening measure	Positive screen
Vision	Two parts: Ask: "Do you have difficulty driving or watching television, or reading, or doing any of your daily activities because of your eyesight?" If yes, then: Test each eye with Snellen chart while patient wears corrective lenses (if applicable)	Yes to question and inability to read greater than 20/40 on Snellen chart
Hearing or	Use audioscope set at 40 dB	Inability to hear 1000 or 2000 Hz in both ears
Leg mobility	Test hearing using 1000 and 2000 Hz Time the patient after asking: "Rise from the chair; walk 20 feet briskly, turn, walk back to the chair, and sit down"	either of these frequencies in one ear Unable to complete task in 15 s
Urinary incontinence	Two parts: Ask: "In the last year, have you ever lost your urine and gotten wet?" If yes, then ask: "Have you lost urine on at least 6 separate days?"	Yes to both questions
Nutrition/weight loss	Two parts: Ask: "Have you lost 10 lb over the past 6 months without trying to do so?"	Yes to the question or weight <100 lb
Memory	Weigh the patient Three-item recall	Unable to remember all three items in 1 min
Depression	Ask: "Do you often feel sad or depressed?"	Yes to the question
Physical disability	Six questions: Are you able to: "Do strenuous activities like fast walking or bicycling?" "Do heavy work around the house like washing windows, walls, or floors?" "Go shopping for groceries or clothes?" "Get to places out of walking distance?" "Bathe, either a sponge bath or shower?" "Dress, like putting on a shirt, buttoning and zipping, or putting on shoes?"	No to any of the questions

Source: Modified with permission from Moore AA, Siu AL.⁸⁵

tions: (1) "Have you ever felt the need to bet more and more money?" and (2) "Have you ever had to lie to people important to you about how much you gambled?" is highly sensitive and specific for a gambling problem.

Functional Status

Data support the validity of self-reported physical functional status. The patient should be asked screening questions about independence and self-care—ability to get out of bed, dress, shop, and cook.^{82,83} Any reported or observed difficulty should provoke more elaborate questions concerning dependence in activities of daily living (ADLs: mobility, bathing, transferring, toileting, continence, dressing, hygiene, and feeding⁸⁴) and in instrumental activities of daily living (IADLs: shopping, cooking, cleaning, managing money, telephoning, laundry, and travel out of house²⁸). Questions should also be asked about vision, hearing, continence, and depression; deficits should be followed up. A brief screening instrument for common impairments,⁸⁵ administered by trained non-medical personnel, was found to be inexpensive and clinically useful (i.e., good validity and reliability). Appropriate use of such an instrument may help identify

specific problems and issues that can then be addressed in a more detailed manner by the clinician (Table 14.1).

Preferences for Care

Although not classically part of the history, before discussing end-of-life decision making and advance directives, it is wise to take a values history: the patient's beliefs about technologic interventions to prolong life, what defines life quality for the patient as an individual, and with what decrements the patient would still think life were worth living. Documenting discussions, executing a living will, and designating a proxy decision maker and durable power of attorney for health care are part of this process of helping the patient have a voice in decisions that may need to be made when the patient, by reason of illness, cannot participate.⁸⁶

Physical Examination

General appearance of the older patient should include any noteworthy features; vitality, markedly youthful or aged appearance, and any indicators of frailty or clinical

problems (e.g., odor of urine or stool; signs of abuse, neglect, or poverty; hygiene and grooming) deserve mention. Merely observing how long it takes for the patient to get ready for examination and the extent and nature of help that may be required remains a useful and reliable tool to measure functional capacity.

Vital signs do not change with age. Hypothermia is more common, and reliable low-reading thermometers are essential, especially for emergency room and winter-time use. Blood pressure should be taken in the supine position after at least 10 min rest, and immediately and 3 min after standing. Orthostatic hypotension, defined as either 20 mmHg drop in systolic pressure or any drop accompanied by typical symptoms, occurs in 11% to 28% of individuals older than 65 years.^{87,88} In acute moderate blood loss, postural hypotension is a fairly specific but poorly sensitive sign of hypovolemia.⁸⁹ Blunting of the baroreflex mechanism with age makes cardioacceleration with the upright position a late and unreliable sign of volume depletion in older persons.

Although pseudohypertension is often mentioned as a consideration when blood pressure is refractory to treatment, the condition is extremely rare. Osler's maneuver, widely recommended in the past, is not reliable in older people.⁹⁰ Tachypnea at a rate of more than 25 per minute is a reliable sign of lower respiratory infection, even in very elderly patients.⁹¹ Weight is the most reliable measure of undernutrition in older outpatients and should be carefully recorded under comparable conditions at each visit. Specific assessment of general or localized pain should be considered as the fifth vital sign and should be recorded using a uniform scale (e.g., 0–10).⁹²

Skin undergoes many changes with age, including dehydration, thinning, and loss of elastic tissue. Wrinkling is more powerfully predicted by sun exposure and cigarette smoking than by age. Most proliferative lesions, benign and malignant, are related to sun exposure; accordingly, basal and squamous cell cancers and melanomas should be most aggressively hunted on exposed skin. Because of skin aging, turgor is not a reliable sign of hydration status. All skin should be examined, exposed to sun or not, for evidence of established or incipient (nonblanching redness) pressure sores. Ecchymoses should also be noted, whether due to purpura of thin old skin or trauma; the possibility of abuse should be considered.

Head and neck examination begins with careful observation of sun-exposed areas for premalignant and malignant lesions (as above). Palpation of temporal arteries for pain, nodularity, and pulse is recommended, but asymptomatic temporal or giant cell arteritis or polymyalgia rheumatica is not common,⁹³ and palpation is an insensitive test. Arcus ocularis, or cornealis, a white-to-yellow deposit at the outer edge of the iris, along with xanthelasma, predicts premature coronary disease in young

adults. Beyond age 60, these signs do not identify increased risk.

Visual acuity and hearing screening are necessary, given the high prevalence of impaired vision and auditory acuity among older persons. Impairment in either sense predicts subsequent functional loss. Measured visual impairment was found predictive of mortality in 10 years, whereas combined impairment confers the highest risk of 10-year functional dependence.⁹⁴ For most clinical situations, a pocket Snellen chart, held 14 in. from the eye, is more practical than a wall-mounted chart. The whispered voice is as sensitive as an audioscope for detection of hearing loss,^{95,96} but the latter is, to date, the best objective measurement of hearing and more accurate at following changes over time. Inspecting the ear canals and drums using an otoscope is especially necessary if hearing loss is detected; removing impacted cerumen is a common quick-fix intervention for many older patients.

Oral examination for denture sores, tooth and gum health, and oral cancers is essential and should include inspection and palpation with dentures out.⁹⁷ The earliest detectable malignant oral lesion is red and painless; if persistent beyond 2 weeks, biopsy is mandatory. Although on the decline, oral cancers are most common in older persons with long-standing alcohol or tobacco use or poor hygiene.

Vascular sounds in the neck usually arise from vessels other than the carotid artery;⁹⁸ true carotid bruits confer more risk for coronary events and contralateral stroke than for ipsilateral stroke, and may cease unpredictably.⁹⁹

Breast examination is generally simpler in older women. Fat diminished, making breast tissue and the tumors that arise from it more easily palpable. Routine screening mammograms annually or every other year should be continued lifelong or until a decision is reached that a discovered cancer would not be treated¹⁰⁰; age-specific breast cancer incidence increases at least until age 85, and no evidence indicates that treatment is not effective in older women.^{101,102} Current recommendations for breast cancer screening suggest yearly mammography until age 69, but there has been much discussion about revising the age to 74, 79, or removing an upper age limit entirely. Routine screening mammography annually is part of the Medicare benefit, and age cutoffs or stopping screening on the basis of age alone is controversial (see Prevention, Chapter 17). Routine screening mammograms should be continued with the understanding that the patient and/or family are aware that an abnormal result will provoke more aggressive evaluation. Many elderly women experienced considerable anxiety concerning more testing when their mammographies appeared suspicious, even though the vast majority did not have breast cancer.¹⁰³ Accordingly, discussions as to how the information will be utilized should take place before testing is initiated.

Lung examination is little different in the older patient. Rales are abnormal at any age; evanescent crackles of atelectasis are the most common cause of rales in the absence of pathology.

Cardiac examination has several special features in aged patients. Both atrial and ventricular ectopy are common at baseline without symptoms or ominous prognosis.^{104,105} Although S_4 is common among older persons free of cardiac disease, S_3 is associated with congestive heart failure. The ubiquitous systolic ejection murmur is less reliable as a sign of hemodynamically significant aortic stenosis in older individuals. A loud murmur ($>2/6$), diminution of the aortic component of S_2 , narrowed pulse pressure, and dampening of the carotid upstroke suggest aortic stenosis, but each may be absent and be falsely reassuring.¹⁰⁶ Although not specific to older patients, true aortic stenosis may be detected by the simple bedside maneuver of simultaneous palpation of brachial and radial arteries and noting a delay between their pulsations.¹⁰⁷ Absence of a murmur over the right clavicle rules out moderate or severe aortic stenosis, whereas the presence of three of the following four associated findings makes moderate to severe aortic stenosis likely: slow carotid artery upstroke, reduced carotid artery volume, maximal murmur intensity at the second right intercostal space, and reduced intensity of the second heart sound.¹⁰⁸ In the absence of typical symptoms, a systolic ejection murmur lacking any of the features of stenosis may be followed without cardiac imaging. Although for decades aortic sclerosis was considered benign, it has recently been associated with increased risk for myocardial infarction, congestive heart failure, stroke, and death from cardiovascular causes, even without evidence of significant outflow tract obstruction.¹⁰⁹

Abdominal and rectal examination have few additional or special components for the older patient. Unsuspected fecal impaction is common and, despite no complaint of constipation, should be treated with a bowel regimen that includes fiber and scheduled toileting. Evidence of fecal or urinary incontinence is usually obvious to the alert examiner. A chronically overfilled and distended bladder should be suspected in men who are incontinent. Although part of the screen for prostate cancer, prostatic masses detected on digital rectal examination may also reflect granuloma, calcification, or hyperplasia, and benign causes outnumber malignant ones; differentiation by imaging is thought not to be reliable unless calcification is present. Prostatic enlargement of benign hyperplasia (because cell proliferation occurs, hypertrophy is an incorrect term) correlates poorly with both urethral obstruction and symptoms of prostatism; anterior periurethral encroachment causes symptoms, but it is the posterolateral portions of the gland that are accessible on digital examination. The need for and utility of screening

for fecal occult blood in the early detection and reduction of mortality and morbidity of colon cancer is established in patients of all ages.^{110,111}

Musculoskeletal examination, often a source of abundant complaints and pathology in older adults, begins with simple screening. In the absence of complaints or loss of function, brief tests of function are adequate to reveal unsuspected limitations. For upper extremity, "Touch the back of your head with your hands" and "Pick up the spoon" are sensitive and specific.⁵² Gait and mobility can be assessed by the timed "up and go" test¹¹² (arise from a chair, walk 3 m, turn, walk back, and sit down); requiring that each foot be off the floor in the "up and go" yields a test that is a better predictor of functional deficits than standard detailed neuromuscular examination.¹¹³ Neuromuscular abnormalities may not identify persons with mobility deficits and demonstrable difficulties in the "up and go." Simple physical-diagnostic tests, such as stance and balance assessments, timed walking of 8 feet at a normal pace, and timed rising from a chair and sitting back down five times in succession identified patients with increased risk of disability in 4 years.¹¹⁴ When deficits are detected in any screening test, more detailed evaluation, including neuromuscular exam and longer standard objective tests,^{35,115} and likely inclusion of a physical therapist in evaluation and treatment, are indicated.

Pelvic examination in older women often is neglected. Atrophic vaginitis, with associated urinary incontinence, or itching or dyspareunia, is remarkably easy and gratifying to treat. Topical (often difficult for the elderly woman with arthritis to manage) or oral conjugated estrogen may often be discontinued after a few weeks without return of symptoms. Ovaries or uterus palpable more than 10 years beyond the menopause usually indicate pathology, often tumor. Any adnexal mass in a woman over 50 years is considered malignant until proven otherwise.¹¹⁶ If arthritis or frailty makes stirrups uncomfortable for the patient, examination in bed or on a table with the patient positioned on her side with knees drawn up will allow speculum exam and Papanicolaou smear. The bimanual exam can be done with the patient supine, again avoiding use of stirrups. Signs of abuse may only be apparent on pelvic examination.

Neurologic examination of older patients is confusing for many physicians. Abnormalities are thought to be common and their clinical importance is sometimes uncertain, because of either lack of data or existence of conflicting data. Odenheimer¹¹⁷ has approached the problem rationally; in an age-stratified (65–74, 75–84, >85) random sample of nearly 500 community-dwelling older persons, comprehensive physical, psychiatric, neuropsychologic, and neurologic examinations were performed. In addition, medical histories, functional status, and medication use were inventoried. Data were used to

determine whether neurologic abnormalities could be attributed to identifiable disease or existed in the absence of detectable medical or neurologic conditions.

The most important principle found in this study is that although abnormalities are common in the neurologic examination of the older patient, one-third to one-half the abnormal findings have no identifiable disease causing them. Abnormalities were classified as (a) attributable to a disease or an isolated abnormality; and (b) more common with increasing age or not. Abnormalities occurring in the absence of detectable disease and more common with increasing age are the best current definition of “changes of aging” in the nervous system. Abnormalities attributable to disease and more common with increasing age simply reflect diseases that are more common in older persons and have nervous system findings. Abnormalities occurring in the absence of detectable disease but not more common with increasing age are most likely individual variations not attributable to aging; the unlikely possibility also exists that lack of progression occurs following changes that developed before age 65.

Analysis of previous reports of abnormal neurologic signs in older persons helps explain sources of confusion. Most studies include subjects screened inadequately or not at all for diseases that can be expected to produce the abnormal findings. Accordingly, caution must be used in interpreting reports of very high prevalence of abnormalities in older persons. On the other hand, the considerable prevalence of neurologic abnormalities in older persons carefully evaluated and found to have no disease explaining the finding demands even greater caution in attributing predictive significance to the abnormality. For example, frontal release signs (also called “primitive” reflexes)—snout, palmontal, root, suck, grasp, glabellar tap—have been reported to identify patients with dementia^{118–120} or with Parkinson’s disease. Because these signs appear in 10% to 35% of older adults screened to exclude disease,^{117,121,122} it is difficult to accept reports of these signs as identifiers of disease, at least in older persons. Ankle jerks, reported to be absent among many otherwise healthy older persons, turn out to be just a bit more difficult to elicit. Using a high-quality, round neurologic hammer rather than a lightweight, red triangulated hammer and striking briskly will improve accuracy. It appears that reports of loss of ankle jerk with age may be a result of the care and expertise with which the reflex is elicited, rather than an aging effect.^{117,123}

Peripheral neuropathy, which is common in older adults, increases risk for falls by causing impairments of proprioception and strength that hinder balance. Suggestive of functionally significant neuropathy are absent heel reflexes, reduced vibratory sense, impaired position sense at the great toe, and inability to maintain unipedal stance for 10 s in three attempts.^{124,125} Unipedal stance time is

particularly helpful in assessing the severity and functional importance of peripheral neuropathy. Persons with healthy peripheral nerves are generally able to stand for more than 10 s, while patients with significant peripheral neuropathy rarely keep the stance for more than 5 s. The precise prevalence of peripheral neuropathy in elderly persons is yet unknown (estimates vary from 10% in the nondiabetic population to around 50% among diabetic patients older than 60 years), but the presence of disease, particularly diabetes, accounts for the majority of cases.

Chronic Disease Management

Harrison G. Bloom

The term *disease management* has evolved within the past decade to become defined as a systematic, population-based approach to identify persons with a given disease or persons at risk for that disease, followed by implementation of therapeutic or preventive interventions, finally followed by measurement of clinical and other (e.g., utilization of services, costs) outcomes.^{1,2} Chronic disease management places an emphasis upon coordination and comprehensiveness of care along the continuum of disease, not just the acute episode or exacerbation, and across health care delivery systems.³ Promotion of high-quality, better coordinated, and appropriately utilized care, coupled with control of costs, are its major goals. Components of disease management programs include the following³: presence of an integrated health delivery system that has the capability to coordinate care along the continuum; a thorough understanding of the disease in question, including approaches to prevention, diagnosis, treatment, and palliation; information systems for clinical and administrative data that allow for continuing analysis of practice patterns and outcomes; and a philosophy and active program for continuous quality improvement. Developing an evidence-based disease management program requires a series of steps as outlined in Table 15.1.³ Schematically, the disease management process would encompass a process illustrated in Figure 15.1.⁴

Overall objectives of disease management programs include the following⁵:

- Encourage disease prevention
- Promote correct diagnosis and treatment planning
- Maximize clinical effectiveness of interventions
- Eliminate duplication of effort and activity
- Utilize only cost-effective diagnostic and therapeutic strategies
- Maximize the efficiency of health care delivery while maintaining appropriate standards of quality
- Continually improve the outcomes of the process, and the process itself

The proliferation of managed care has given great impetus to the establishment of disease management programs with considerable help from pharmaceutical companies. A push by insurers and employers to measure clinical and other outcomes has also contributed to its growth. Indeed, some would argue that such programs are simply marketing and packaging devices, yet there is a small but growing literature indicating significant value for properly designed and implemented programs.⁶

A significant majority of individuals over 75 years of age suffer from chronic medical conditions. The prevalence of congestive heart failure, hypertension, diabetes mellitus, depression, osteoarthritis, Alzheimer's, and other dementias are high among the older population. There are, therefore, unique aspects of chronic disease management that apply to programs aimed at older individuals. These aspects include attention to syndromes, not just diseases; the frequent presence of accompanying comorbidities; cognitive impairment as a frequent complicating factor; the high prevalence of functional dependencies; the involvement of family caregivers; and the realization that self-care may or may not play a significant role.

Although emphasis may vary among programs, most comprehensive chronic disease management programs include care in the patient's home, office-based care, and care in the acute hospital setting. Additionally, careful attention to the transition between these settings (e.g., hospital to home in the community) can be a key component as well. Interventions can range from very "low-tech" patient-focused steps (e.g., providing educational materials about a disease) to specialized units with sophisticated monitoring (e.g., inpatient stroke units).⁷

A variety of examples of chronic disease management programs that have had some degree of success follow.

For patients requiring lifelong oral anticoagulation therapy, a program utilizing a structured educational approach to patient self-management of anticoagulation resulted in improved accuracy of anticoagulation control

TABLE 15.1. Steps for developing an evidence-based disease management program.

Formulate a clear definition of the disease, its scope, and its impact over time using a multidisciplinary team
Develop comprehensive baseline information to understand current health care delivery and resource utilization
Generate specific clinical and economic questions and search the literature
Critically appraise and synthesize the evidence
Evaluate the benefits, harms, and costs
Develop evidence-based practice guidelines, clinical pathways, and algorithms
Create a system for process and outcome measurement and reporting
Implement the evidence-based guidelines, pathways, and algorithms
Complete the quality improvement cycle

and improved treatment-related quality of life.⁸ Other programs targeting older patients with chronic non-valvular atrial fibrillation have utilized expert nurses as teachers and managers to assist physicians by helping educate patients about the condition, its potential complications, and the rationale and method of medication

management with attention to dietary interactions with anticoagulants.⁹

A number of programs and studies have targeted congestive heart failure.¹⁰⁻¹³ Most were multidisciplinary approaches implemented in the patient's home immediately after a hospitalization for congestive heart failure (CHF). The major goals of the programs were to improve patient adherence with therapeutic recommendations, increase patients' understanding of their disease, allow for and provide easy access for communication during careful follow-up surveillance, decrease unplanned hospital readmission, improve functional status, and reduce overall medical costs. Most studies were at least 3 months in duration, with 6- to 18-month follow-up periods. One randomized controlled trial enrolled patients (mean age, 79) at a large urban teaching hospital in the Midwest.^{10,11} Protocols emphasizing education about CHF and careful clinical follow-up were carried out by a nurse managed multidisciplinary team including a geriatric cardiologist, dieticians, social workers, and home health professionals. The control group received usual care and follow-up. Positive outcomes included improved quality of life measures, a 56% reduction in hospital admission

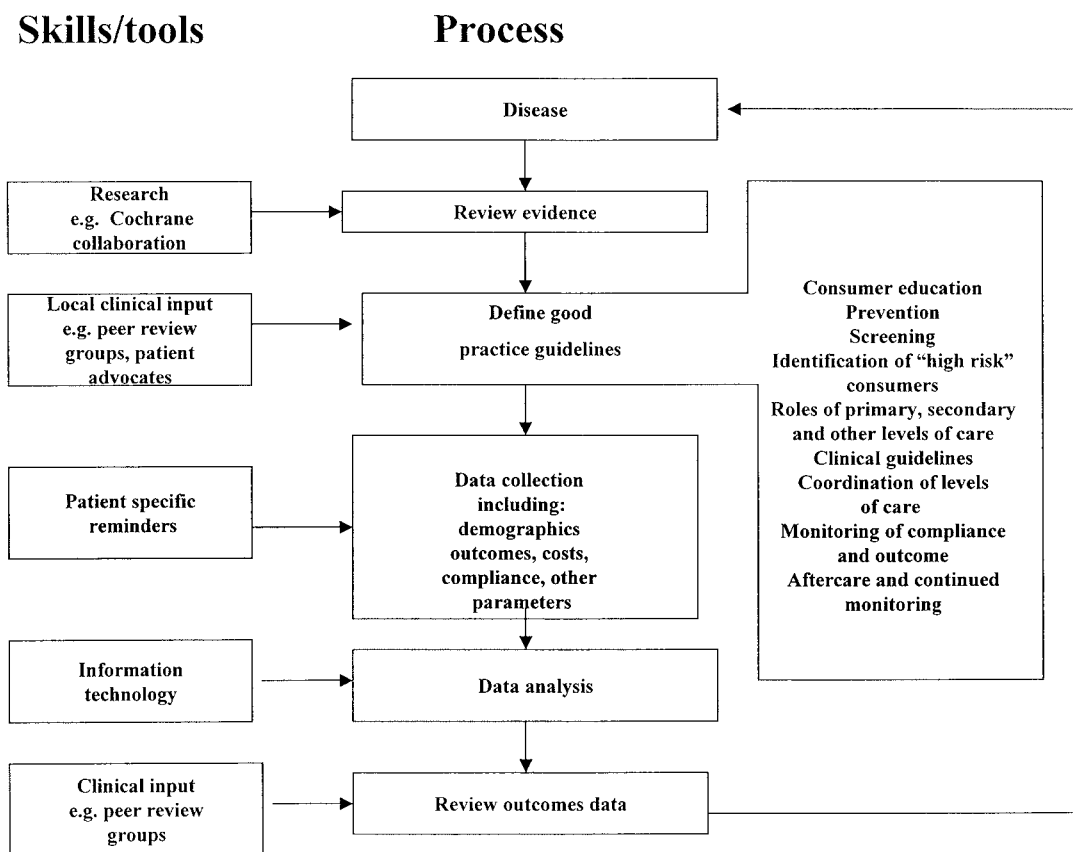

FIGURE 15.1. Disease management process.

rate, and a savings of \$1,058 per patient in health care costs. Another study with 97 individuals whose intervention was a single home visit by a nurse and a pharmacist 1 week after hospital discharge for acute heart failure resulted in a significant reduction in unplanned hospital readmissions, hospital-based costs, total hospital stay, and mortality.¹³

With Alzheimer's disease, any chronic disease management program must involve caregivers because patient self-directed care and self-help are, at best, limited. Because the prevalence of Alzheimer's disease is increasing dramatically as the population ages and because the natural course of the disease often can be over 10 years, programs attempting to work with patients and caregivers are potentially important and helpful. One randomized controlled intervention study carried out in a large urban area with 206 spouse-caregivers of Alzheimer's disease patients utilized counselors (clinicians with master's degrees or doctorates in social work, gerontology, or psychiatry) whose primary goal was to help caregivers better cope with caring for their Alzheimer's spouse.¹⁴ A series of individual and family counseling sessions, support groups, and additional counseling availability were provided to the intervention group. The control group received usual care. The major positive outcome was a significant increase in time that Alzheimer's patients, especially those with mild to moderate disease, were able to continue living at home rather than being placed in a long-term care facility.

Accidental falling is not a disease, nor are those at risk for injurious falls a homogeneous group. The morbid sequelae of injurious falls in older people are well known, hip fracture being one of the most common. Prevention of falls, however, is a good example of a variation of chronic disease management applicable to the older population. By identifying individuals at risk, a falls prevention program can theoretically thwart the acute and chronic complications of falls by preventing them from occurring. One study of 301 community-dwelling individuals utilized a multifactorial intervention for the study group and usual care plus social visits for the control group.¹⁵ To be enrolled, individuals had to be at least 70 years old and have at least one risk factor for falling. The risk factors identified were postural hypotension; use of sedatives; use of four or more prescription drugs; impairment in arm or leg strength or range of motion; problem with balance or gait; and difficulty with transfer skills (e.g., bed to chair). The study group received some or all of the following in their homes from a nurse practitioner and a physical therapist: medication adjustments, behavioral instructions, and exercise programs, all aimed at modifying their risk factors. Outcomes resulted in a significant reduction in the risk of falling, as well as reduction in the number of actual risk factors for falling. Another study of 530 older individuals (mean age, 77

years) demonstrated that home visits by occupational therapists making environmental modifications could prevent falls among those at risk of falling by both home environmental modifications and subsequent behavioral changes in those at risk.¹⁶

Some chronic illness management programs are less disease specific. A randomized controlled study examining a heterogeneous group of patients (mean age, 65 years) demonstrated that a community-based self-education course could result in positive outcomes for those participating in this chronic disease self-management program.¹⁷ Participants included 952 patients with a diagnosis of heart disease, lung disease, arthritis, or stroke, most also having comorbidities. The self-education course addressed the following issues: use of cognitive symptom management techniques; nutrition; fatigue and sleep management; use of community resources; medication use; dealing with fear, anger, and depression; communicating with health care professionals; problem solving; and decision making. The intervention group demonstrated improved health behaviors, improved health status, fewer hospitalizations, and fewer days of hospitalization. This study showed that, for individuals able to learn and self-manage, a multifaceted educational program could be effectively utilized for those with a variety of chronic conditions and comorbidities.

A somewhat similar randomized controlled study of 201 chronically ill adults (mean age, 77 years) paired community primary care providers with managed care organization nurse practitioner-led interventions.¹⁸ The multicomponent disability prevention and disease self-management program addressed risk factors for disability such as inactivity, smoking, misuse of alcohol, use of psychoactive drugs, depression, and poor nutrition. The program also taught self-management of chronic illness. The geriatric nurse practitioner met individually with each participant from one to eight times (median, three) during the 1-year study period. Participant chronic conditions included heart disease, hypertension, arthritis, cancer, stroke, and diabetes. Significant outcomes in the study versus control group were as follows: less functional decline, less hospitalization and fewer total inpatient days, greater levels of physical activity, and less use of psychoactive medications. Another 1-year randomized study of 200 older individuals utilizing an approach integrating social and medical care along with case management also demonstrated less functional decline, less hospitalization, and less nursing home placement, as well as considerable cost savings in the intervention group.¹⁹

An additional variation of chronic disease management is sometimes called high-risk case management. High risk could refer to susceptibility to or a specific disease syndrome, or it could refer to an individual's overall health status. For example, hazards of hospitalization for older adults have been well documented.²⁰

Also, the hospital readmission rate for a subset of older patients is high, especially during the first month after hospital discharge. A study to examine the effectiveness of intensive pre- and posthospital care, the transitional care period, by interventions by experienced advanced practice nurses with at-risk older patients, demonstrated significant reductions in unplanned hospital readmissions and overall health care costs.²¹ The advance practice nurses coordinated and actively participated in hospital discharge planning, made regular posthospital discharge home visits, which included thorough clinical assessments, and were available 24 h per day, 7 days per week, by telephone.

Chronic disease management programs have been implemented and utilized far more often in the Medicare managed care sector than in the regular Medicare fee-for-service arena. Managed care organizations view such programs as an opportunity to significantly decrease health care costs while maintaining or even improving quality of care. Also, because managed care companies deal with large populations and often have the capability of collecting and tracking large volumes of data, they are much better positioned than individual physicians or small physician groups to implement and evaluate disease management programs. Additionally, they can distribute educational materials and flexibly fund, as well as quickly modify or cancel programs, if necessary. Until the Center for Medicare and Medicaid Services (CMS) endorses and funds chronic disease management programs in the traditional system, this discrepancy will persist.

Nevertheless, in spite of the advantages managed care organizations have in creating, implementing, and evaluating chronic disease management programs, significant barriers to success exist even within managed care. Such barriers include the cost of program development and implementations, limited data systems, resistance by physicians to participate in or support programs, and the difficulty in measuring any dollar savings. Additionally, overlapping programs can interfere with the coordination of care. If, for example, a managed care organization has programs in both diabetes and congestive heart failure, which program will be primarily responsible for a member with both conditions?²²

Chronic disease management programs implemented in the older adult population hold promise for better quality care and decreased costs. The systematic and evidence-based approach to specific at-risk populations, not just individual patients, has the possibility to improve overall health care status. It is, however, still a relatively new and very heterogeneous field that will require many additional methodologically sound studies, especially in the nonmanaged care arena where most Medicare beneficiaries are still insured, before it can be accepted as a standard of treatment for chronic diseases.

Prevention

Harrison G. Bloom

Disease prevention and health promotion are important aspects of health for older individuals. Between 40% and 70% of all diseases are partially or totally preventable through lifestyle modification, risk factor management, and primary or secondary preventive practices.¹⁻³ Despite a lack of definitive data regarding preventive interventions for a number of diseases and occasional disagreements among organizations publishing preventive guidelines, there is consensus on the value of many preventive measures. However, the underutilization of recommended preventive services remains a major challenge in medicine, including geriatric medicine.

Because significant barriers preventing the implementation of recommendations exist for both clinicians and individuals, creative ways to deliver preventive services have become increasingly important. Offering and incorporating such services at worksites, schools, senior centers, and churches could significantly help improve the numbers of older people receiving preventive care. Using nonphysician assistants, nurses, technicians, and others can also greatly facilitate the delivery of preventive services.

Primary, secondary, and tertiary prevention are all important. Primary prevention is the avoidance of a disease before it can begin. Secondary prevention, or screening for occult disease, is looking for early markers of a disease before it becomes symptomatic and then intervening early enough to positively affect outcomes. Tertiary prevention emphasizes rigorously treating established disease to prevent adverse outcomes and complications from the natural course of that disease.

Important criteria for deciding upon which diseases to apply primary or secondary preventive interventions are addressed here and apply to all age groups, including individuals 65 and over. Differentiating recommendations for the general population of older adults as opposed to a high-risk group within that population is also important. For example, yearly influenza vaccination is recommended for all adults age 65 and older. Regular

Papanicolaou smears to detect early cervical cancer, on the other hand, are recommended after age 65 mainly for women with high-risk sexual behavior or those without a previous Pap smear. Additionally, life expectancy and quality of life are especially important considerations for older individuals when deciding upon preventive interventions. Table 16.1 outlines typical life expectancies.

Criteria for screening tests include the following:

1. *The disease must have a significant effect on the quality and quantity of a patient's life.* Screening for common warts, for example, may be simple and inexpensive, but there are no adverse health effects from their presence and hence no reason to screen.

2. *Acceptable methods of treatment must be available.* Discovering a potentially serious condition at an early stage via screening is only useful if there is a treatment available to cure or significantly decrease morbidity from that condition. If effective treatment does not exist or if any individual is unable to access treatment after screening, screening is not indicated.

3. *Early treatment should yield a therapeutic result superior to that obtained by delaying treatment.* If early treatment does not lead to a better outcome, detecting a condition earlier by screening is not warranted.

4. *The disease must have an asymptomatic period during which detection and treatment significantly reduce morbidity or mortality.* By definition, screening is performed on individuals asymptomatic for the condition. If symptoms are present, any testing is diagnostic. Not only must an asymptomatic period exist, but finding and treating the condition at that earlier time must significantly reduce morbidity or mortality.

5. *Tests must be available at a reasonable cost to detect the condition in the asymptomatic period.* This criterion is more of an administrative or policy consideration. Individuals may be willing to pay for a screening test that their insurance company will not cover. Before Medicare covered screening mammography, women had to pay for

TABLE 16.1. Life expectancy, United States, 1997: additional years of life.

Age (years)	All races (years)
65	17.7
70	14.3
75	11.2
80	8.5
85	6.3
90	4.5
95	3.3
100	2.5

the test. More recently, some groups have advocated utilizing helical computerized tomography to screen for lung cancer in smokers. The test is costly, and to date there is only limited evidence of its efficacy as a screening tool.

6. *The incidence of the condition must be sufficient to justify the cost of screening.* This point is also an administrative consideration. A physician may decide that if a patient can afford it, screening for a condition with an extremely low incidence is worthwhile. Conversely, the medical director of a health center, managing a limited budget, would likely not want to spend scant resources screening for a condition that would very likely never occur in that health center's population.

Influenza Prevention

Yearly vaccination against influenza is one of the most important primary preventive practices readily available for older individuals. Influenza and pneumonia together rank as the sixth leading cause of death in persons aged 65 to 74, the fifth leading cause between the ages of 75 and 84, and the fourth leading cause in persons 85 years of age or older.⁴

Inactivated influenza virus vaccine is strongly recommended for all persons 65 and older.⁵ Vaccination is safe and cost-effective, particularly for individuals at high risk for influenza infection.^{6,7} Medicare covers the cost of the vaccine and its administration. The vaccine needs to be given annually because of antigenic drift (variation in infectious strains) and antibody levels that wane with time.⁸ October to mid-November are usually the best times to administer influenza vaccine, but any time from September to the end of flu season is appropriate.

Among community-dwelling older adults, one randomized controlled trial (RCT) found a 58% reduction in relative risk of clinically and serologically confirmed influenza infection for those who received an annual

influenza vaccination compared to those receiving a placebo.⁹ An intranasal live attenuated influenza vaccine has recently undergone several clinical trials and is nearing approval.¹⁰ Like the inactivated vaccine, it will be useful preventively for influenzas A and B.

In nursing homes, vaccination of both patients and staff reduces patient morbidity and mortality. A large meta-analysis of cohort studies in nursing homes demonstrated the effectiveness of annual influenza vaccination in reducing relative risk of respiratory illness, pneumococcal pneumonia, hospitalization, and death compared to unvaccinated controls.¹¹ A resident vaccination rate of at least 80% should be met to establish herd immunity in institutionalized populations during active influenza outbreaks.¹² Staff vaccination in long-term care facilities provides additional protection to older institutionalized patients and in two RCTs was associated with a 40% reduction in relative risk for patient mortality.^{13,14}

During institutional influenza outbreaks, chemoprophylaxis in combination with timely annual influenza vaccination has been shown to be highly effective in preventing influenza complications in small cohort studies.^{15,16} M2 channel inhibitors (amantadine or rimantadine) and the neuraminidase inhibitor oseltamivir are approved for chemoprophylaxis in older adults with known or anticipated influenza A exposure. For influenza B prophylaxis, only neuraminidase inhibitors are effective. Unfortunately, there are very few randomized trials assessing efficacy of these agents in older adults, and the data are hampered by limited population size and low influenza incidence in control groups. Zanamivir, an inhaled neuraminidase inhibitor recently approved by the U.S. Food and Drug Administration (FDA) for influenza prevention, has demonstrated a nonsignificant trend toward efficacy against clinical and laboratory-confirmed influenza in a nonblinded randomized nursing home trial.¹⁷ Persons with underlying airway diseases should not be given zanamivir.

Chronically ill or immunodeficient older persons, those who have not received the yearly influenza vaccination or received it too late to be of use in an active outbreak, and those who received a vaccine poorly matched to the outbreak antigen are particularly likely to benefit from chemoprophylaxis during influenza outbreaks. In institutional outbreaks, 14-day chemoprophylaxis for residents and staff, (with dosage adjusted for renal function) is warranted, continuing at least 7 days past the onset of the last case.¹⁸ For community-dwelling older patients and their close personal contacts, 10-day prophylaxis is usually sufficient. Drug resistance is a concern with the M2 channel inhibitors, and the side effect profile of these agents appears slightly worse than the neuraminidase inhibitors. Both drug classes can also be used for treatment of acute influenza infection if begun within 48 h of symptom onset.

Handwashing, isolating infected persons, and restricting ill visitors and staff also reduce infection transmission in nursing homes.^{19–21} Because of the very significant morbidity and mortality associated with outbreaks of influenza, both community surveillance and rapid diagnosis are important. Community surveillance can alert health care workers as to whether an outbreak is influenza A, B or both, as well as when influenza entered and exited the area.

Other Immunizations

Vaccines recommended for older individuals include influenza, pneumococcal, and tetanus. Influenza A and B and pneumococcal disease are common diseases frequently associated with significant morbidity and mortality. Tetanus, although rare, is a serious disease often resulting in death.

The 23-valent pneumococcal vaccine is between 50% and 80% effective in preventing invasive pneumococcal disease, but not pneumococcal pneumonia, in older adults who are immunocompetent.^{22–25} The vaccine is safe, has only rare serious adverse effects, is inexpensive, and is covered by Medicare. There are no definite data on whether the vaccine should be given only once in a lifetime or repeated every 5 to 6 years. Although its efficacy in high-risk groups, particularly immunocompromised patients,^{26,27} is questionable, the U.S. Preventive Service Task Force and the CDC's Advisory Committee on Immunization Practices recommend its use in this population because of the low risk of harm. The vaccine can be administered at any time during the year, including the same time influenza vaccine is given (in a different extremity).

Although tetanus is rare in the United States, it is a serious disease and more than 60% of tetanus infections occur in older individuals.^{28,29} Current recommendations call for booster vaccinations every 10 years, although 15 to 30-year intervals are probably adequate in the United States for those properly vaccinated in childhood. If never previously vaccinated, older adults can be given a primary series that includes doses at 0, 2, and 8 to 14 months.³⁰ The vaccine is safe, effective, and covered by Medicare.

Colorectal Cancer Screening and Prevention (See Chapters 32 and 34)

More than 55,000 deaths yearly with 140,000 new cases per year place colorectal cancer as the second most common form of cancer, as well as the cancer with the second highest mortality rate, in the United States. The incidence of both invasive colorectal cancer and mortal-

ity increase sharply with advancing age (see Chapter 32).

Early detection in the asymptomatic period is associated with better prognosis. For patients at average risk of colon cancer, the American Cancer Society (ACS) recommends screening with fecal occult blood tests (FOBT) annually in combination with flexible sigmoidoscopy (FSIG) every 5 years (either test alone is sufficient, but the ACS prefers the combination), or a total colon exam with either a double-contrast barium enema every 5 years or colonoscopy every 10 years. As with other cancers, older adults at higher risk for colorectal cancer (e.g., those with inflammatory bowel disease or a strong family history of colorectal cancer, adenomatous polyposis, and nonpolyposis colorectal cancer) should be screened more frequently than the general older population.³¹ The ACS does not impose an upper age limit at which to discontinue screening, suggesting instead that continued screening is of benefit to older patients with continued good health. The most frequently studied form of screening, fecal occult blood testing, has been shown to significantly reduce the rate of death from colorectal cancer.^{32–34} There is also evidence that fecal occult blood testing done annually reduces the actual incidence of colorectal cancer by detecting premalignant adenomatous polyps.³⁵ Adding fecal occult blood testing to sigmoidoscopy improves the sensitivity of sigmoidoscopy, although recent studies suggest that the combination may miss as many as 50% to 60% of advanced proximal lesions.^{36,37} Double-contrast barium enemas are less useful in older adults, as uninterpretable results occur because many patients cannot move as required while on the radiography table^{38,39} and biopsy cannot be done at the time of the exam, making a second bowel prep necessary. Colonoscopy is the most accurate of the available tests and is becoming the modality of choice for many physicians.^{40–42} “Virtual colonoscopy,” three-dimensional computed tomographic colography, is a new technique promising fewer complications than endoscopic colonoscopy, does not require sedation, and requires less time. However, a number of improvements and more controlled studies are necessary before it can be recommended for population-based routine screening.⁴³ Although very uncommon, serious complications do occur with screening sigmoidoscopy and colonoscopy, making the choice of screening tests, especially for older persons, an individual choice as much as a clinician preference.⁴⁴

Primary prevention of colorectal cancer with diet remains controversial. Observational data have yielded conflicting results,^{45,46} and there are no randomized controlled trials (RCTs) on the efficacy of fiber in primary prevention of colon cancer. In an RCT, neither a wheat bran-supplemented diet nor a low-fat, high-fruit and -vegetable diet were found to affect the incidence of new colorectal adenomas (which can then progress to

cancers).⁴⁷⁻⁴⁹ It is important, however, to encourage measures to reduce known risk factors for colorectal cancer through weight control, smoking cessation, regular exercise, and less red meat intake.⁵⁰

There has been increasing interest in chemoprevention of colorectal cancer utilizing one or a combination of substances. Although future research may prove utility, there is currently no evidence from double-blind, placebo-controlled, randomized studies that aspirin, other NSAIDs, supplemental folate and calcium, or postmenopausal hormone replacement therapy are efficacious in the primary prevention of colorectal cancer.⁵⁰ Cohort and other studies of observational design do suggest a beneficial association, and the reader is referred to Chapter 34 for a summary of these studies.

Screening for Breast Cancer (See Chapters 32 and 33)

Approximately one in eight women will develop breast cancer during her lifetime. There are more than 176,000 new cases of breast cancer yearly, making it the most common cancer in women and the second leading cause of cancer death in women.⁵¹ Advanced age is an important risk factor both for developing breast cancer and for death from breast cancer.⁵²

The use of screening mammography has been highly recommended for women aged 50 to 69, with a decrease in the rate of late-stage disease detection correlating well with an increase in the use of mammography.⁵³⁻⁵⁵ Recently a Cochrane Review of the randomized controlled trials upon which these recommendations are based strongly questioned the validity of five of the seven trials, only "accepting" two which together suggested that mammography does not save lives.⁵⁶ The National Cancer Institute's independent panel of experts, the PDQ, reviewed this evidence and concurred.

Most completed clinical trials have not included women over age 70 and therefore the effectiveness of screening mammography is not known in women 70 and older. Additionally, mortality is not the only endpoint of interest to women who may develop breast cancer; the effect of breast cancer diagnosis at a later stage on function and quality of life is not known. There is some evidence from a retrospective cohort study that screening mammography is effective in women at least up to age 79.⁵⁷ In fact, if women 70 and older are cognitively and functionally intact with a life expectancy of 5 or more years, there is little reason to exclude routine mammography at any age in spite of there being no definitive evidence yet that this decreases breast cancer mortality. The American Geriatrics Society recommends annual or

biennial screening mammography until age 75, and every 1 to 3 years after that with no upper age limit for nondemented women with life expectancies of at least 4 years.⁵⁸ For women with family history of breast cancer or ongoing or previous long-term exposure to hormone replacement therapy, screening should be more frequent.

Fewer than half of all women over age 65 undergo regular screening mammography. Primary care physicians are encouraged help older patients overcome physical, economic, or other barriers to receiving screening. Medicare covers annual mammography screening for all female beneficiaries 40 and older, with patients paying 20% of approved charges but no deductible.⁵⁹

Other modalities used to screen for breast cancer include clinician breast exam and teaching breast self-examination. There is not sufficient evidence at this time to recommend in favor of or against including these in periodic screening exams.⁶⁰ Nevertheless, long-standing clinical practice habits usually include periodic breast exams, and there is little reason to exclude performing these exams.

Regarding primary prevention of breast cancer, raloxifene and the antiestrogen tamoxifen have been recommended for women at increased risk of developing breast cancer, but not for the general risk population.⁶¹ In a large RCT in which 30% of the participants were over age 65, tamoxifen was associated with as much as a 50% reduction in invasive breast cancer incidence, particularly estrogen receptor-positive cancers, compared to placebo. Use of the drug in older women, however, was associated with a 4-fold increased risk of endometrial cancer, however (RR 4.01).⁶² In an RCT in which breast cancer development was a secondary outcome, raloxifene use over 3 years effectively reduced incidence of invasive breast cancer compared to placebo by as much as 40% and was not associated with elevated risk of endometrial cancer. Again, protective effects were mainly observed against the development of estrogen receptor-positive cancers.⁶³

Physical activity may also reduce the risk of cancer. A review of 13 mostly observational studies found lower incidence of breast cancer among physically active adults than in sedentary adults.⁶⁴

Screening for Prostate Cancer (See Chapters 32 and 36)

Routine screening for prostate cancer using prostate-specific antigen (PSA) remains very controversial in older men. Although prostate cancer is common in older men and it can be aggressive and lethal, there are currently no reliable ways to distinguish small early cancers

that will become aggressive from those that are slow growing and non-life-threatening even if left untreated. Additionally, false-positive PSA tests are frequent, and treatment is associated with the potential for significant complications.^{65,66} For these reasons, a number of organizations advise that an individual patient be educated about the potential benefits and risks of routine screening PSA testing followed by diagnostic confirmation and treatment and decide for himself whether or not to pursue testing.

Digital rectal exam by itself is not effective as a screening test for prostate cancer.⁶⁷ In one study, the most valid screening results were obtained when suspicious digital rectal exam was combined with PSA values greater than 4 ng/ml (sensitivity, 95%; positive predictive value, 62%).⁶⁸ Medicare covers annual digital rectal exams as well as annual PSA screening test without deductibles or coinsurance payments or male beneficiaries aged 50 and over.⁶⁹

Screening for Cervical Cancer (See Chapters 32 and 37)

Positive Pap smears are more often associated with invasive disease in older women.^{70,71} A significant percentage of women over age 65 have never had a Pap smear. There is some debate as to what age to discontinue Pap screening. For women who have a cervix, the U.S. Preventive Service finds no solid evidence to impose an upper age limit, but suggests testing be discontinued after age 65 for those who have up until that time had regular and normal screenings.⁷² For women at higher risk of cervical cancer (including older patients with a personal or family history of cervical cancer, previous abnormal smears, or high-risk sexual behavior), testing should continue annually.⁷³ Medicare covers annual cervical cancer screening for women at higher risk for cervical cancer; screening for all other female beneficiaries is covered every 3 years.

The validity of the Pap test as a screening instrument varies with the technique of the individual physician, sample method used, and laboratory interpretation; sensitivity ranges from 30% to 87% while specificities range from 86% to 100%.⁷⁴ Obtaining a proper specimen can sometimes be difficult in older women for a number of reasons, including vaginal atrophy and narrow cervical os. Musculoskeletal disorders can make lying in the usual supine position with legs in stirrups quite difficult. Using the left lateral position may be preferable. For these reasons, if a primary care clinician is not experienced in performing Pap smears in older women, referral to a gynecologist is appropriate.

Screening: Other Cancers (See Chapter 32)

There are currently no reliable screening modalities for cancers of the lung, ovary, thyroid, kidneys, brain, skin, pancreas, or hematologic system.

Screening for High Blood Pressure (See Chapter 40)

Hypertension is a chronic, highly prevalent, generally asymptomatic condition that is safely and effectively treatable in older adults. Treatment of hypertension in older persons has played a key role in leading to a significant reduction in morbidity and mortality from congestive heart failure, myocardial infarction, and stroke.⁷⁵⁻⁷⁷ Controlling hypertension can also decrease risks for renal disease, retinopathy, and ruptured aortic aneurysm.⁷⁸

All forms of hypertension, including isolated systolic, isolated diastolic, and mixed systolic/diastolic, should be screened for at least every 2 years and treated.^{33,79} Annual screening is appropriate for patients whose most recent diastolic blood pressure was between 85 and 89 mmHg and/or systolic blood pressure was 130 to 139; higher measurements should provoke more immediate evaluation.⁸⁰ Proper cuff size and technique are especially important in older individuals, and, as with younger adults, hypertension should only be diagnosed if present at more than one reading on three separate visits.^{81,82}

Screening for Lipid Disorders (See Chapter 39)

Whether to routinely screen older individuals for high cholesterol and other lipid abnormalities remains controversial. The American College of Physicians guidelines neither recommend nor discourage cholesterol screening in patients 65 to 75 years of age and find it unnecessary in patients older than 75 years with no evidence of coronary disease. However, the evidence upon which these recommendations were based, that is, studies showing no association between coronary heart disease (CHD) mortality and high cholesterol in old age, may have been confounded by inclusion of frail elderly persons with low cholesterol. A study of 4066 older persons, after adjustment for frailty, found an association between total cholesterol and increased risk for CHD mortality.⁸³ Older age (>45 years for men, >55 years for

women) is itself an accepted risk factor for coronary artery disease.

After reviewing evidence on whether identification and treatment of asymptomatic people with abnormal lipid levels can substantially reduce the risk of coronary heart disease, the U.S. Preventive Services Task Force recently extended its recommendations to include routine lipid screening for older and middle-aged persons. Neither an optimal screening interval for older adults nor an upper age limit at which to discontinue screening has been set, but the Task Force has suggested that repeated screening may be less important in older people because lipid levels are less likely to increase after age 65 years. Five-year intervals have been suggested as a benchmark for the general U.S. population, with longer or shorter intervals dictated by patient risk; intervals longer than 5 years may be sufficient for older persons who have had low-risk results on previous lipid tests whereas elderly patients showing higher-risk lipid levels should be screened more frequently. Older individuals who have never been screened should be.⁸⁴

The U.S. Preventive Services Task Force strongly recommends measurement of total cholesterol (TC) and high-density lipoprotein cholesterol (HDL-C), but finds insufficient evidence to recommend for or against triglyceride measurement. The American College of Physicians has set ranges for total cholesterol (>240 mg/dL), LDL-C (≥ 160 mg/dL), and triglycerides (>400 mg/dL) that it considers associated with high risk for coronary heart disease. The National Cholesterol Education Program sets a high-risk range for HDL-C (<40 mg/dL) levels.⁸⁵⁻⁸⁹ The Canadian Task Force on the Periodic Health Exam is in the process of revising its earlier screening recommendations.

Diabetes (See Chapter 46)

Noninsulin-dependent diabetes mellitus (NIDDM) is an increasingly common disease in older adults. Weight loss and increased physical activity are simple lifestyle changes that significantly reduce the risk of diabetes. At least three studies have found marked benefits from lifestyle modifications in preventing the development of diabetes in middle-aged adults with impaired glucose tolerance,⁹⁰⁻⁹² and the latter of these studies showed benefit for older patients as well. Even relatively modest weight loss (mean, 7.7 lb) over 2 years is associated with significant reductions in risk in persons already at high risk for diabetes. These studies are summarized in Chapter 46.

For screening purposes, the American Diabetes Association lowered its normal fasting glucose level for adults over age 45 to less than 126 and suggested screening occur every 3 years.^{93,94} Although the value of rigorous

glucose control in older diabetics to prevent end-organ damage (tertiary prevention) has not been definitively demonstrated, consensus expert opinion believes it will be equally beneficial in older as well as younger (insulin-dependent) individuals.⁹⁵⁻⁹⁷ Medicare covers home glucose monitoring kits for its beneficiaries.

Prevention and Screening for Osteoporosis (See Chapter 43)

Even in asymptomatic older women, the prevalence of low bone mineral density (BMD) is widespread. The National Osteoporosis Risk Assessment study, a longitudinal observation of 200,160 postmenopausal women, offered bone mineral density screening at primary care sites and revealed previously undiagnosed osteoporosis in 7.2% of those screened and a further 36.9% with undiagnosed osteopenia. The consequences of undiagnosed low bone mineral density (BMD) in the year following testing, compared to those with normal BMDs, were a 4-fold-greater incidence of fracture with osteoporosis and a 1.8-fold-greater rate of fracture with osteopenia.⁹⁸ History of smoking or cortisone use was associated with significantly elevated risk of fracture.

As a primary preventive measure, discussing and offering hormone prophylaxis to perimenopausal and postmenopausal women is recommended. Fracture and bone mass decline is most effectively prevented when hormone replacement therapy begins close to menopause and is continued for longer than 5 years. Benefits are observed only while estrogen use is continued, and a history of past estrogen use provides little or no current bone mass protection for women over age 75. No upper age limit to stopping prophylaxis has yet been established.⁹⁹

Hormone prophylaxis carries its own set of risks, including risk of cardiovascular events during the initial period of treatment and of breast or endometrial cancer with long-term use. Lifestyle changes are viable alternatives to HRT in the prevention of bone loss for most older women, and include adequate calcium intake, routine exercise, and cessation of smoking.^{100,101} Adequate intake of Vitamin D is also prudent.

Bone densitometry to screen for osteopenia in asymptomatic women at risk for osteoporosis is recommended, and if osteopenia is present, prophylactic treatment to avert frank osteoporosis should be recommended utilizing estrogen, raloxifene, or alendronate.¹⁰² National Osteoporosis Foundation (NOF) guidelines, issued in 1998, recommend testing for women over age 65 regardless of risk factors. (NOF recommendations are summarized in Chapter 43, Table 43.4.) Although the efficacy of osteoporosis screening in men is unproven, longevity is a risk factor in itself, and a one-time

screening can establish which men need preventive treatment.

Malnutrition (See Chapter 68)

Obesity, malnourishment, and failure to maintain adequate fluid intake are all common, significant problems in older adults, associated with increased mortality and morbidity, including cognitive dysfunction, depression, and delayed wound healing. Up to 15% of community-living elders may be considered malnourished if the term is defined as a decrease in nutrient reserves.¹⁰³ Among hospitalized or institutionalized patients the prevalence is much higher. Chronically ill persons, cognitively impaired elderly, and those with excessive alcohol intake are particularly prone to malnourishment;¹⁰⁴ malnourishment can in turn exacerbate these same problems. Vitamin D deficiency is common in elderly populations with limited exposure to sunlight. Protein-energy malnourishment is common among older persons following elective surgical procedures or minor infections. Physicians should maintain a high index of suspicion for nutritional deficiencies in these patients, as well as in patients with low incomes, social isolation, multiple medication use, malabsorption syndromes, or chronic myocardial, renal, or pulmonary illnesses.

The U.S. Preventive Services Task Force recommends that all patients, regardless of age, be administered periodic height and weight measurements. Body mass index (BMI) is the recommended gauge, although obtaining accurate height measurements may be difficult in bedbound elders. BMI below 22 or above 29 should raise red flags. Use of the single question: "Have you lost 10 pounds over the last 6 months without trying to do so?" in combination with measurement of BMI or use of height/weight charts is an effective and simple screen for malnourishment. Persons weighing less than 100 lb (45.5 kg) are more likely to be malnourished, and involuntary weight loss may indicate elevated risk of death. Older patients of normal weight or who are overweight can also be malnourished. The Nutrition Screening Initiative Checklist, with 10 yes/no questions, can also help physicians identify older persons at risk for malnourishment. Scores of 6 points or higher warrant concern. Nearly one-quarter of a noninstitutionalized Medicare population surveyed with this tool was found to be at risk.¹⁰⁵ Other nutritional screening tools validated among older adults in various settings are reviewed by Reuben et al.¹⁰³

A thorough physician assessment of patient access to nutritious foods with counseling on daily multivitamin use and adequate water intake can prevent or alleviate many problems. Chapter 68 details management of nutritional deficiencies common in older adults.

Screening for Depression and Dementia (See Chapters 74 and 79)

Depression is a common and treatable condition in older individuals. Early diagnosis (case finding) and appropriate treatment with medication or psychotherapy are critical to management; unfortunately, however, it is both underdiagnosed and undertreated once diagnosed in the elderly population. The U.S. Preventive Services Task Force recommends that physicians maintain a high index of suspicion for elderly patients, especially those with a family or personal history of depression, chronically ill or homebound elders, and those with recent personal loss, sleep disorders, and memory impairment.

A "yes" response to the question "Do you often feel sad or depressed?" has a sensitivity of 83% and specificity of 79%,¹⁰⁶ and should provoke a more thorough assessment. The Geriatric Depression Scale (GDS 15 or 30) is even more sensitive. In a random sample of community-living persons over the age of 75 in the United Kingdom, a GDS 15 cutoff score of 3 had 100% sensitivity and 72% specificity in detecting cases of depression, more than three-quarters of which had been undiscovered by the primary care physicians at least as long as the year before the clinical interview.¹⁰⁷ The GDS, however, is a screening instrument and does not make the diagnosis. Fewer than one in five of those testing positive with the GDS 15 in this study reached the diagnostic threshold for depression upon further testing by researchers blinded to GDS score.

Dementia, particularly Alzheimer's disease, increases in prevalence as the population ages. It is a chronic, progressive disease whose etiology is not yet known and for which there is currently no effective curative treatment. A systematic review of studies by the American Academy of Neurology indicates that individuals classified as having mild cognitive impairment (but not meeting clinical criteria for dementia) have a high risk of progressing to dementia or Alzheimer's disease (estimated rate, 6%–25% per year, compared to incident dementia in the overall population of older persons of 0.2% in the 65–69 age range to 3.9% in the 85–89 age range).¹⁰⁸ For the purposes of the systematic review, criteria for mild cognitive impairment included objective memory impairment as well as patient memory complaint, preferably corroborated by an informant, but normal general cognitive function and activities of daily living.

Early diagnosis (case-finding) is increasingly important as potentially helpful palliative treatments are available, but as yet there is insufficient evidence to screen elderly adults in whom there is no suspicion of cognitive impairment. When patients or family informants reporting memory difficulties, the U.S. Preventive Task Force advises screening; recommended instruments include the

Mini-Mental Status Exam (MMSE), the Short Portable Mental Status Questionnaire, and the Clock-Drawing Test. A very simple three-item recall test has a sensitivity of 90% for patients unable to remember all three items after 1 min.¹⁰⁹ In general, mild to moderate cognitive impairment is indicated by scores between 18 and 24 on the Mini-Mental Status Exam. The MMSE must be adjusted for high education or intelligence levels. The Clock-Drawing Test, despite multiple scoring systems, has a mean sensitivity and specificity of 85% and a likelihood ratio greater than 10.¹¹⁰ Abnormal entries in the fourth quadrant of the clock alone are almost diagnostic of dementia.¹¹¹ For an excellent review of studies on the sensitivity and specificity of the various instruments, the reader is referred to Petersen et al.¹⁰⁸ It is important to note that depression, language differences, hearing impairment, and aphasia can affect the accuracy of cognitive screening tests. In addition, because dementia cannot reliably be screened in the presence of delirium, differentiating between the two must be a priority. The Confusion Assessment Method has a high specificity for delirium.^{112,113}

Screening for Visual Acuity and Glaucoma (See Chapter 59)

Routine vision screening utilizing Snellen acuity testing to detect diminished visual acuity is recommended for older individuals although there have not been any trials in older individuals that primarily assessed vision per se.^{114,115} Analysis of multiphasic assessment trials where visual acuity testing was included has not revealed a benefit.¹¹⁶ Despite a lack of evidence supporting routine screening for glaucoma, screening older persons can be justified but is best done by eye specialists, not primary care physicians.¹¹⁷

Screening for Hearing Impairment (See Chapter 60)

A very common problem in older adults, hearing impairment is most easily and reliably screened for by periodically asking individuals whether they are experiencing any problems with their hearing.¹¹⁸ If yes, referral for formal hearing evaluation is indicated. Even those already wearing hearing aids can benefit from routine screening: in one study, 10 of 11 older hearing aid users were discovered upon testing in a screening clinic to require major readjustment or complete replacement of the device.¹¹⁹ Hearing aids are often helpful in appropriate persons and are smaller and cosmetically more appealing than in the past.

The audioscope and the self-administered Hearing Handicap Inventory for the Elderly—Screening Version

(HHIE-S) are both valid screening tools with similar specificities and likelihood ratios, but audioscope testing is the more sensitive test in both older^{120–122} and younger¹²³ adults and is considered to be the gold standard. The majority of older adults receiving both these screening tests in one primary care setting preferred audioscope testing (60%) to the HHIE-S (13%) because they believed it to be more “reliable,” an important consideration as many older adults are reluctant to follow through on recommendations to get further testing and fitting for amplification devices. Depending on whether a cutoff score of 8 or 24 is used, the HHIE-S has a sensitivity ranging from 29% to 63%, specificity ranging from 75% to 93%, and positive likelihood ratio ranging from 2.42 to 4.27. The audioscope, depending on reference standard used, has a sensitivity range of 64% to 96%, specificity of 80% to 91%, and positive likelihood ratio of 4.86 to 7.52.¹²⁴ Another simple screening test, the whisper test, may be inadequate in the primary care setting due to broad variation in outcomes between examiners.¹²⁵ For more details on screening for hearing impediments, the reader is referred to Chapter 60.

Incontinence (See Chapters 50 and 63)

Patients are often reluctant to mention or seek help for urinary or fecal incontinence, yet both are common problems with aging, affecting independence and quality of life. In a cross-sectional survey conducted in Minnesota, the age-adjusted prevalence of any episode of fecal incontinence in 1540 community-living adults over the age of 50 was 11.1% for men and 15.2% for women; for urinary incontinence, 25.6% of men and 48.4% of women reported problems. Approximately 6% of men and 9.4% of women reported dual incontinence.¹²⁶

In addition to the significant social and emotional toll, incontinence may be both a marker for and a contributing cause of frailty in elderly patients. Frequent urinary incontinence (weekly or more often) is associated with an increased risk of falls and nonspinal fractures in older women.¹²⁷ Onset of incontinence after age of 65 has also been associated with increased risk of functional impairment in one elderly Hispanic population.¹²⁸

Screening is simple. All older patients should be asked, “Do you ever lose your urine and get wet?” Affirmative answers should be followed up with the question, “Have you lost urine on at least 6 separate days?” Chapter 63 provides follow-up questions regarding frequency, quantity, and situations under which incontinence occurs and management of the problem. Fecal incontinence can be screened for in a similar manner. Few trials have evaluated the outcomes of screening for either condition on function or quality of life, but incontinence is a common and potentially treatable cause for nursing home admissions.

Exercise (See Chapter 69)

Regular physical activity has been shown in numerous studies to be an extremely important preventive intervention for older adults. Exercise promotes health and stimulates a sense of well-being. Included among the many benefits of regular exercise for older people are the following: an increase in lean body mass and strength; a reduction in risk for coronary artery disease, hypertension, and diabetes; a diminished risk for falling; a delay in overall functional decline; a decrease in depression; a reduction in pain from arthritis; and improved longevity.^{129,130} Of all the benefits, perhaps the most important are those gleaned from preventing age-associated functional decline and the reversal of effects of adverse health episodes.¹³¹⁻¹⁴⁰

Exercise, if approached properly, is safe even into advanced age.¹⁴¹ Jogging may be one exception: in a randomized trial of 70- to 79-year-old men and women, injury rates were 57% for those who jogged during weeks 14 to 26 and had walked during the first 14 weeks compared to 5% to 9% injury rates for walking and strength training groups in the first 14 weeks.¹⁴² Both resistance training and aerobic exercise are important and efficacious. Resistance training is most helpful for improving balance and muscular strength. Aerobic exercise is most helpful for improvement in cardiopulmonary fitness and stamina.¹⁴³

Giving permission to older patients and encouraging regular physical activity are more important than the exact exercise program undertaken. Regular activity along with the older individual's preference and adher-

ence are key factors for success. Appropriate exercise can include regimens easily integrated into a routine day such as walking, climbing and descending stairs, swimming, gardening, and bicycling (mobile or stationary). For individuals unable to ambulate or transfer independently, exercises can be done in bed or in a chair. Regular exercise is therefore appropriate for people at any age and almost all stages of functional status.

Functional Decline and Frailty (See Chapters 17 and 73)

Frailty, loss of function, and disability are common among older individuals. Preservation of as much independence as possible is a major goal in caring for older individuals, especially the older old. Prevention of disability is a multifaceted task encompassing all the preventive measures reviewed in this chapter plus very careful and thorough generalized overall physical and cognitive assessment. Interventions must be individualized. Ultimately, geriatric medicine strives to limit functional loss and disability to the extent possible, thereby improving quality of life.

Table 16.2 provides likelihood ratios and sensitivities for several common in-office geriatric screening instruments. Tables 16.3 through 16.5 summarize evidence-based recommendations for inclusion or exclusion of preventive measures for the older adult population. How often to perform various preventive measures and at what age (chronologic or physiologic) to stop certain

TABLE 16.2. Sensitivity and specificity of common screening instruments by blinded assessment ($\pm 95\%$ CI).

Condition	Description of screening test	Sensitivity	Specificity	Likelihood ratio
Nutrition	Ask: Have you lost 10 lb, over the past 6 months without trying to do so? Weigh the patient.	0.65 (0.56, 0.74)	0.87 (0.81, 0.93)	5.0
Vision	Ask: "Do you have difficulty driving, watching TV, or reading, or doing any of your daily activities because of your eyesight?" If yes, test each eye with Snellen chart while patient wears corrective lenses (if applicable).	0.67 (0.58, 0.76)	0.86 (0.79, 0.93)	4.8
Hearing	Set audioscope to 40 dB. Test hearing using 1000 and 2000 Hz.	0.93 (0.88, 0.98)	0.60 (0.51, 0.69)	2.3
Cognition/ memory	Three-item recall test.	0.90 (0.84, 0.96)	0.64 (0.55, 0.73)	2.5
Incontinence	Ask: "In the last year, have you ever lost your urine and gotten wet?" If yes, ask: "Have you lost your urine on at least 6 separate days?"	0.89 (0.83, 0.95)	0.95 (0.91, 0.99)	17.8
Depression	Ask: "Do you often feel sad or depressed?"	0.83 (0.76, 0.90)	0.79 (0.71, 0.87)	4.0
Physical disability	Ask six questions: Are you able to: Do strenuous activities like fast walking or bicycling? Do heavy work around the house like washing windows, walls, or floors? Go shopping for groceries or clothes? Get to places out of walking distance? Bathe, either a sponge bath, tub bath, or shower? Dress, like putting on a shirt, buttoning and zipping, or putting on shoes?	0.91 (0.86, 0.96)	0.50 (0.41, 0.59)	1.8

interventions, with few exceptions (e.g., influenza vaccine yearly), has not been well studied. Until better evidence is available, common sense should prevail.

Conclusion

As the quantity of prevention-related information increases and dissemination becomes quicker and more widespread, shared decision making between clinician and patient will become increasingly important. Availability of sites beyond the physician's office—the Internet, the workplace, senior centers, and schools, for example—will facilitate broader access to disease prevention and health promotion measures. As more individuals live longer and more active lives, attention to lifestyle habits, quality of life issues, risk factors for diseases, and genuine health promotion activities will demand more attention in the disease prevention/health promotion arena. The medical community, however, will need to be vigilant in its surveillance of “new breakthrough prevention measures” to guard the general older public from the unscientific claims of those purporting to practice “anti-aging” medicine (see Chapter 62).

Instruments to Assess Functional Status

Brandon Koretz and David B. Reuben

Geriatric assessment refers to an overall evaluation of the health status of the elderly patient. The well-being of any person is the result of the interactions among a number of factors, only some of which are medical. In the geriatric population, these various factors may have become impaired at different rates. Thus, an overall functional assessment is more holistic than the traditional medical evaluation. The ultimate goal of these evaluations is to improve or maintain function.

Frequently, assessment instruments are used to evaluate the various components of patients' lives that contribute to their overall well-being. These components, or domains, include cognitive function, affective disorders, sensory impairment, functional status, nutrition, mobility, social support, physical environment, caregiver burden, health-related quality of life, and spirituality. The instrument itself can take many forms: it can be a structured interview, a self-reported questionnaire, a physical or mental task, or a blood test. Assessment instruments usually produce scores that can be compared to established normal ranges. The results from an individual patient assessment can be used to establish a baseline for future comparisons, form diagnoses, monitor the course of treatment, provide prognostic information, and screen for occult conditions. This last application is the most common use for instruments that are employed in the outpatient setting.

This chapter provides an overview of geriatric assessment instruments. We begin by briefly describing some of the basic psychometric attributes that should guide the use of any instrument. Next, we discuss the strengths and weaknesses of different types of instruments. Finally, we end with a review, arranged by functional domain, of some useful instruments. The emphasis is on those instruments that are easy for a single healthcare provider to apply in the outpatient setting. A list of some suggested instruments appears in Table 17.1.

Psychometric Attributes of Instruments

As there are a wide variety of assessment instruments, it is important for practitioners to choose those that have been appropriately evaluated for validity, reliability, and, if possible, responsiveness.

Validity

Validity is the extent to which an assessment instrument accurately measures the quality it is intended to measure. Usually, validity is the relationship between an instrument's performance and a "gold standard," another instrument, or a future event.

Sensitivity and specificity are both components of validity. Sensitivity is the extent to which a test is able to detect persons with a disorder.¹ Specificity is the extent to which those with a negative test result do not have a disorder.¹ Both these characteristics refer to the intrinsic qualities of the instrument itself and are not dependent upon disease prevalence in the population being examined. However, they are frequently combined with prevalence rates to estimate positive and negative predictive values. For screening purposes, it is appropriate to maximize sensitivity at the expense of specificity to capture as many patients with the condition as possible.

Reliability

Reliability is the ability of a test to arrive at the same result with repeated measurements. The two most important types are interrater and test-retest. Interrater reliability refers to the degree of similarity between two scores obtained by two simultaneous observers. Test-retest reliability refers to the similarity between two scores obtained serially by the same observer over a time period when change is not expected.

TABLE 17.1. Suggested brief geriatric assessment instruments.

Domain	Instrument	Sensitivity	Specificity	Time (min)	Cutpoint	Comments
Cognition Dementia	MMSE ⁷	79%–100% ^a	46%–100%	9	<24 ^b	Widely studied and accepted
	Timed time and change test ²⁰	94%–100%	37%–46%	<2	<3 s for time and <10 s for change	Sensitive and quick
Delirium	CAM ²³	94%–100%	90%–95%	<5		Sensitive and easy to apply
Affective disorders	GDS 5 question form ³³	97%	85%	1	2	Rapid screen
Visual impairment	Snellen chart ⁴	Gold standard	Gold standard	2	Inability to read at 20/40 line	Universally used
Hearing impairment	Whispered voice ^{4,40}	80%–90%	70%–89%	0.5	50% correct	No special equipment needed
	Pure tone audiometry ^{40,41}	94%–100%	70%–94%	<5	Inability to hear ≥ 2 of 4 40-db tones (0.5, 1, 2, and 3 kHz)	Can be performed by trained office staff
Dental health	DENTAL ⁴⁶	82%	90%	<2 (estimated)	Score ≥ 2	
Nutritional status	Weight loss of >10 pounds in 6 months or weight <100 lb ³	65%–70%	87%–88%		Yes to either	
Gait and balance	Timed Get Up and Go ^{3,70}	88%	94%	<1	>20 s	Requires no special equipment

^a Some studies have found lower sensitivities, but most studies of dementia subjects fall in this range.⁷

^b Cutoff is dependent on a number of variables including age, education, and racial or ethnic background.⁷

Responsiveness

Responsiveness refers to an instrument's ability to detect clinically significant changes over time, even if these changes are small.² Tests demonstrating a high sensitivity to small changes may have an increased rate of false positives. Although in general reliable measurements are likely to be responsive, the two terms are not interchangeable.

Strengths and Weaknesses of Instruments

Assessment instruments are simply tools to begin an evaluation process. It is easy to overestimate their value and make their application an end unto itself. The crucial step in the use of assessment instruments is the interpretation of their findings. Knowing how to proceed based on positive or negative results is one of the most important duties of the clinician.

The choice of which assessment instrument to use is based on a careful consideration of its relative strengths and weaknesses as they apply to a given clinical situation. For instance, comprehensive but lengthy interview-based questionnaires may be appropriate for research settings but not in clinical practice. Patients are usually unwilling to submit to prolonged interviews, and practitioners are

unlikely to have enough time to conduct them. Thus, clinically useful assessment instruments must be concise. This criterion does not mean, however, that they must be administered by the primary clinicians. The costs and utilities of administering various instruments in clinical settings by nonphysician office staff are reasonably inexpensive and effective.^{3,4} Furthermore, patients can complete self-administered surveys at home.

The mode of administration (i.e., who performs the rating) can affect a test's results. The rater can be the patient, a proxy, or an interviewer. Self-administered questionnaires, although efficient and inexpensive, may introduce elements of underreporting or overreporting because of lack of motivation or denial of dysfunction. Furthermore, elderly patients may require or request assistance from family members when completing the questionnaire, thus introducing the biases of a second reporter; this may be especially true for those with cognitive impairments. However, even trained interviewers can introduce their own biases during the information-gathering process.⁵

Another element to consider is the contrast between measures of capacity and those of performance. There are advantages and disadvantages to each approach. Capacity refers to what patients report they are able to do. As the task or skill at issue is not actually performed in an observed setting, the rating process can be completed quickly. Similarly, there is no need for any special

equipment. The chief disadvantage of capacity assessment is the reliance on patients' subjective estimates of their abilities. Thus, clinicians frequently ask what patients actually do instead of what they can do. Because some patients function substantially below their capacity, this approach may underestimate their functional ability. Performance-based measures are direct observations of particular actions. Advantages include an increase in objectivity as patients' biases and those of their proxies are minimized. Disadvantages include the need to train the observer and the costs for specialized equipment to create the task being observed: an audiometer to create a tone, stairs to climb, etc. Some tasks (e.g., role functions), however, cannot be measured in clinical settings.

Patient factors may also affect the performance of the instrument in clinical settings; these include educational level, social background, gender, and ethnicity.⁶⁻⁸ An additional element—patient fatigue—can affect scores on cognitive or performance-based measures.

Finally, each test has a limited range in which it is sensitive, commonly referred to as ceiling and floor effects. A ceiling effect describes limited usefulness of an instrument because virtually everyone scores at the top. Conversely, a floor effect is when everyone scores at the bottom of the scales. For example, in a population of healthy community-dwelling older persons, the ceiling effect would apply if one measured basic activities of daily living (BADL, discussed below); almost all the patients are able to complete all the relevant tasks. Similarly, in a nursing home population, almost all patients will be dependent in all items of the instrumental activities of daily living scale (IADL; discussed below); thus, the instrument does not capture a range of function—a floor effect. Practitioners must be aware of the range of sensitivity of the tools they employ and select tests that are appropriate for the population.

Screening

Many assessment instruments applied in the outpatient setting are used to detect asymptomatic conditions. The principles of screening derive from preventive services research. Screening has been defined as using “a test or other standardized examination procedure ... to identify patients requiring special intervention.”⁹ There are at least five requirements for screening: (1) a screening test must have acceptable sensitivity and specificity; (2) the test must detect a condition in a presymptomatic stage; (3) there must be a proven treatment for this condition; (4) there must be additional benefit derived from receiving the treatment in the presymptomatic stage; and (5) the condition that the screening is targeting must be common and be associated with a significant burden.¹⁰ Although geriatric assessment instruments usually do not

fulfill all these requirements, these principles should be considered when deciding whether it is worth assessing a particular dimension.

Dimensions of Geriatric Assessment

Cognitive Function

Assessment of the cognition of elderly patients generally focuses on detection of dementia and delirium. Although these two conditions can be distinguished by time course, pathophysiology, and clinical features, they may coexist. In fact, the presence of dementia is a risk factor for the development of delirium in elderly hospitalized patients.¹¹

Cognitive Impairment

The prevalence of dementia, an acquired, progressive impairment of multiple cognitive domains, is age dependent. Therefore, the yield of screening for cognitive impairment increases as the population ages. Because the initial phases of impairment can be quite subtle, it can be difficult for a clinician to make the incidental discovery of cognitive impairment. Structured examination techniques may be helpful in detecting early dementia. Such detection has become increasingly important because a number of pharmacologic and behavioral interventions have been shown to slow the progression of symptoms and delay nursing home placement for patients with moderate Alzheimer's disease.^{12,13} Additionally, early detection of cognitive impairment allows family members and caregivers to plan for the future.

The most widely used assessment tool for cognitive status is the Mini-Mental State Exam (MMSE).¹⁴ Originally developed to detect delirium, dementia, and affective disorders in inpatient settings, it has since been validated in a number of other settings.¹⁵ In a 5- to 10-min period, the MMSE tests a number of cognitive domains: orientation, registration, attention and calculation, language, recall, and visual-spatial orientation. It is easy to apply and interpret. In fact, the instrument can be given by office staff after minimal training. The Short Portable Mental Status Questionnaire¹⁶ is similar in design but has a more narrow focus. It requires that the patient answer many of the same orientation questions as the MMSE but also asks for the name of the current and past president, the patient's mother's maiden name, and his or her birthday, address, and phone number. As the questionnaire is shorter, it takes less time to administer. A disadvantage to both these performance tests is that they measure functions that are not particularly relevant in everyday life, such as drawing intersecting pentagons and performing serial subtraction.

Other useful and rapidly administered tests are the Clock Drawing task and the Time and Change test. Both are performance-based tests. The former assesses executive function and visuospatial skills by having the patient draw a clock face and place the hands at 10 min after 11 o'clock. There are standardized scoring methods¹⁷ for the drawing, and the test has been shown to have a high negative predictive value for Alzheimer's disease.¹⁸ The latter is a brief performance based test in which a patient must read a clock face set at 11:10 and separate \$1.00 in change from a collection of coins totaling \$1.80.^{19,20} It has been shown to be accurate in both inpatient and outpatient populations.^{19,20} To improve sensitivity, time thresholds may be applied—taking longer than 3 s to correctly tell the time and longer than 10 s to correctly make change indicate the need for further evaluation.

A very different type of cognitive assessment is the Set Test.²¹ As originally described, the patients are given four categories (colors, fruit, towns, and animals) and an unlimited amount of time to list as many members of that category as possible. The maximum score in each category is 10. A score under 15 is considered abnormal,²² although there are concerns about its sensitivity even at higher cutpoints. In one trial, 17% of demented patients demonstrated a perfect score.²³ Patients are not exposed to any lists of relevant words before the test begins and are expected to create their list *de novo*. This test examines a number of cognitive domains including language, executive function, and memory. Unimpaired older persons should be able to generate a list of 10 items within 1 min.

Delirium

Delirium is an acute, fluctuating alteration in level of consciousness and attention. It is a common occurrence, particularly in hospitalized elderly patients. Because its manifestations can be variable, it is often overlooked. Delirium is associated with increased morbidity and cost of care.

Several assessment instruments can facilitate the detection of delirium.²⁴ The most commonly used is the Confusion Assessment Method.²⁵ When using it, the examiner diagnoses delirium based on the demonstration of (1) an altered mental status with an acute onset and fluctuating course, (2) impaired attention, and (3) either disorganized thinking or a change in level of consciousness. Its high sensitivity and brevity make the Confusion Assessment Method a clinically useful instrument. Other cognitive tests that have been used to detect delirium are the MMSE, the Dementia Rating Scale,²⁶ and the Mental Status Questionnaire.²⁷ All have adequate reliability.²⁸ Disadvantages of these latter instruments include their substantial false-negative rates and their inability to distinguish delirium from dementia. Clinical tests of

attention, such as digit span or stating the months of the year backward, may also help detect delirium at an early stage. Because of the temporal variability that is the hallmark of delirium, a patient may seem entirely lucid at the time of evaluation. For this reason, it is important to seek out reports from collateral informants, family or nurses.

Affective Disorders

Depression is one of the most common psychiatric disorders affecting older persons. It is associated with significant morbidity and mortality.²⁹ The earliest depression scales relied heavily on the presence of somatic symptoms.^{30,31} Hence, the scales may be less useful in geriatric populations with a high prevalence of such symptoms caused by other comorbid medical illness.³² The Geriatric Depression Scale (GDS) was specifically designed for elderly patients.³³ Initially validated in a 30-question format, 15- and 5-question versions have been described.^{34,35} The threshold scores for a positive depression screen are 11, 7, and 2, respectively.^{33,34,35} An even more concise approach, a single question screen, "Do you often feel sad or depressed?" has been suggested.³⁶ If answered affirmatively, it should be followed by the 30-question form of the GDS. The single question may be as accurate in identifying depression as the long version of the GDS,³⁷ although this technique identifies too many false positives to be useful as a screening instrument.³⁸

Visual Impairment

Although the treatment of visual impairment is beyond the scope of the primary practitioner, the leading causes of visual loss in older adults—cataract, glaucoma, age-related macular degeneration, and diabetic retinopathy—are prevalent and treatable. One accepted method of screening is having patients read the letters from the handheld Jaeger card at a distance of 14 in. from their eyes. Decreased visual acuity is defined as the patient begin unable to read the 20/40 line. The wall-mounted Snellen chart, generally considered to be the gold standard, can be similarly employed. Visual acuity tests do not assess the functional impact of visual impairment, but three self-report instruments have been developed. The Activities of Daily Vision Scale,³⁹ the VF-14,⁴⁰ and the National Eye Institute Visual Function Questionnaire,⁴¹ although not typically used in the primary practice setting, each assess the patient's perceptions of impairments of their visual function.

Hearing Impairment

Hearing impairment can result in social isolation, depression, and decreased functional status. Treatment by amplification with a hearing aid has been demonstrated

to improve quality of life. Analogous to the visual impairment screens, both performance-based and self-reported measuring tools are used to determine hearing loss.

Performance tests include the whispered voice, finger rub, and tuning forks. Of these, the whispered voice test has been shown to have acceptable sensitivity and specificity to be useful as a screen.⁴² The examiner performs it by initially asking the patient to repeat a series of words. Then the examiner stands out of sight of the patient, occludes one of the patient's ears, and whispers one of the previously spoken words at a minimum of 6 cm from the patient's ear. A passing score is the ability to correctly repeat at least 50% of the whispered words. Screening can also be accomplished with the Welch–Allyn audioscope, a handheld otoscope with a built-in audiometer capable of delivering a 40-dB tone at frequencies of 500, 1000, 2000, and 4000 Hz. Patients fail the screen if they are unable to hear at least two of the four tones. Compared to pure tone audiometry, the audioscope has a sensitivity of 94% and a specificity of 72% for detecting hearing impairment. Its positive predictive value in the elderly is 60%.⁴³

The Hearing Handicap Inventory for the Elderly—Screening version is a self-reported questionnaire designed to evaluate the effects of hearing loss on the social and emotional well-being of elderly patients.⁴⁴ A newer scale, developed from an analysis of data from the National Health and Nutrition Examination Survey, also accurately predicts hearing loss.⁴⁵ It incorporates age, gender, and education, in addition to specific questions about decreased hearing. However, because it was developed using data from a relatively young population, aged 50 to 74, its value in those who are older remains uncertain. Neither questionnaire is commonly used in primary care settings.

Dental Health

Dental disease, similar to visual or hearing impairment, requires a specialist for management. Nevertheless primary care providers should recognize dental problems and the resulting functional impact so that they can make appropriate referrals. Two of the assessment instruments available are the Geriatric Oral Health Assessment Index (GOHAI) and the DENTAL instrument. The GOHAI⁴⁶ is a 12-item self-report measure that assesses the impact of oral disease in three domains—physical function, psychosocial function, and discomfort. It is sensitive to the change of function and symptoms that occur after the subject receives dental care.⁴⁷ The DENTAL instrument, on the other hand, is used for screening purposes and to provide dental referrals from primary care practices.⁴⁸ It is composed of a list of six conditions: dry mouth, oral pain, oral lesions, difficulty eating, altered food selection,

and no recent dental care. The presence of one of the first three or two of the latter three conditions should trigger a dental referral.

Functional Status

Functional status has been defined as “a person's ability to perform tasks and fulfill social roles associated with daily living across a broad range of complexity.”⁴⁹ Measures of functional status are used for a wide variety of purposes. Clinicians apply them to establish baselines, to monitor the course of treatment, or for prognostic purposes. These assessments can also be used for screening. For instance, health maintenance organizations may use them to identify frail elderly who can be targeted for case management efforts.

Examinations of function may be divided into three levels: basic activities of daily living (BADL),⁵⁰ instrumental activities of daily living (IADL),⁵¹ and advanced activities of daily living (AADL).⁵² BADL refer to those functions that are necessary, but not sufficient, for maintaining an independent living status. Katz described basic functional tasks: feeding, maintaining continence, transferring, toileting, dressing, and bathing. Individuals with multiple dysfunctions at this level will require significant in-home support, such as 24-h care, or nursing home admission.

IADL are more complicated levels of activity that are necessary to maintain an independent household; these include tasks such as paying bills, taking medications, shopping, and preparing food. People with several deficiencies in these areas usually require an assisted living situation, extensive community services, or some in-home support. At this level, opportunity and motivation are important contributors to maintaining function.⁵³

The highest level of activity is represented by the AADL. These are tasks such as working, attending religious services, volunteering, and maintaining hobbies. These pursuits, because they are the most complex and require the highest levels of multiple abilities to complete, are likely to be the most sensitive to changes in health status.

Self-reported measures of functional status can be administered by questionnaire or by interview. As the scales tend to follow a hierarchical ordering,⁵⁴ the clinician can efficiently assess a patient's level of function by asking about more advanced items first. Performance-based measures of functional status provide useful prognostic information. Several instruments have been developed including those that focus on lower extremity function (e.g., standing balance, gait speed, and rising from a chair⁵⁵) and those that include upper extremity function.⁵⁶ These instruments predict functional decline, institutionalization, and mortality.

Nutritional Status

Malnutrition occurs frequently among elderly patients, particularly those residing in nursing facilities. It has been associated with increased mortality, morbidity, and admission to nursing homes.⁵⁷ Nutritional status can be evaluated by self-report screens, biochemical markers, and anthropometric measures. The most widely used self-report screen is the 10-question, self-administered checklist portion of the Nutrition Screening Initiative.^{58,59} A score of six or more indicates that a patient is at risk for malnutrition. If patients score at this level, they are prompted to see health care providers for more in-depth evaluations. Checklist scores can predict future disability and persons at high risk for hospitalization.⁶⁰ The checklist has been criticized for being no more accurate as a multi-item instrument than some of the individual component items and for having poor predictive value in general.^{61,62}

Biochemical markers, although not specific for malnutrition, can be used as prognostic indicators. The most studied serum marker is the serum albumin, which predicts morbidity and mortality in community-dwelling, hospitalized, and institutionalized patients.⁶³ Hypocholesterolemia is also associated with increased mortality.⁶⁴ The combination of hypoalbuminemia and hypocholesterolemia can be used to predict long-term mortality and functional decline.⁶⁵

Anthropometric tools have been used to assess nutrition. The easiest one for the primary practitioner to employ is the body mass index (BMI), which is calculated by dividing the body weight in kilograms by the square of the height in meters. BMI less than 22 indicates undernutrition and predicts future mortality.⁶⁶ Measurements of skin folds assess nutritional status. However, these measurements require specialized equipment and training and may not be reliable in elderly patients.⁶⁷

Assessment methods employing combinations of these approaches can be used to determine nutritional status. The Mini Nutritional Assessment (MNA)⁶⁸ creates a composite score from the results of anthropometric measurements, general assessment, dietary factors, and patient self-report. Subjects are then classified as either well nourished, at risk of malnutrition, or malnourished. The Subjective Global Assessment also uses information from the history and physical examination to categorize patients into one of three groups—the same three as the MNA—which can be used to predict major postoperative complications.⁶⁹

Gait and Balance Impairment

Falls are a major cause of morbidity and mortality in geriatric patients. Assessments of gait and balance impairment should begin with the clinician asking patients

about their histories of falls, including frequency, resulting injury, and circumstances surrounding each incident. However, because many patients do not recall previous falls,⁷⁰ self-report measures alone may not be sufficient. Performance-based assessment instruments can be more useful. For example, the Performance-Oriented Assessment of Mobility⁷¹ employs a series of simple tasks: sitting and standing balance, turning, standing without the use of upper extremities for a push-off, and gait. Five other common maneuvers—head turning, reaching, bending over, back extension, and standing on one leg—can be added for a further assessment of balance. All these simulate real-life situations in which the patient may be at increased risk for falls. Although an impairment in these activities is not diagnostic of a particular pathologic process, clinicians can use this information to identify those in need of further diagnostic evaluation.

Other screening instruments include the Timed Get Up and Go Test⁷² and the Functional Reach.⁷³ In the Timed Get Up and Go Test, patients arise from a seated position, walk 3 m, turn around, return to the chair, and sit down. A healthy, elderly individual should be able to complete this task in less than 10 s; any score greater than 20 s should prompt a more in-depth evaluation. This test may also be useful to follow patients over time for functional decline. The Functional Reach is a measure of patient ability to stretch forward without moving their feet. Limited ability to reach forward predicts the occurrence of future falls.

Although falls themselves create disability, even the fear of falling can produce functional limitation. The Survey of Activities and Fear of Falling in the Elderly is an instrument designed to evaluate how this fear contributes to the restriction of physical activity.⁷⁴

Social Support

There is a strong association between patients' social functioning and health status. Clinicians should be familiar with their patients' levels of social interaction. During times of physical or emotional stress, these social networks may mean the difference between remaining independent in the community or requiring nursing home care. Although there are a number of scales to assess social well-being and interaction, they are too detailed to be useful when applied by a primary care practitioner in interview form.⁷⁵ As part of the social history, the health care provider should ask about who lives with the patient, who provides meals and transportation if the patient is unable to do so, and if the patient provides care for anyone else. These questions are particularly important because any subsequent absence of a caregiver, if present, would have major implications for the patient's well-being. For example, if the caregiver becomes ill, the patient may need to find an alternative source of food

and transportation. Simple ways to assess a patient's social supports are to ask if there is someone whom the patient could call for help or if there are friends or relatives with whom the patient has contact more than once a month.⁷⁶

Environment

Physicians rarely perform home safety evaluations themselves, but many home health providers are trained to do so. These evaluations are covered by Medicare for those who are eligible for home health services. Environmental hazards that may lead to falls are common in community-based housing and in retirement communities.⁷⁷ The most common hazards are poor lighting, pathways that are not clear, and loose rugs or other "slip and trip" threats.

Caregiver Burden

Because dementia and other chronic illnesses affecting the elderly are prevalent, older persons are frequently caregivers for their spouses or other relatives. The psychologic, physical, and economic burden associated with caregiving can be substantial. Moreover, such stress also has effects on patients who are recipients of care. Increased caregiver burden independently predicts use of medical services and nursing home placement.⁷⁸ Interventions to decrease the stress of caregivers may delay nursing home placement.⁷⁹

Scales to assess caregiver burden are primarily used for research,⁸⁰ but some may have clinical applications. The Screen for Caregiver Burden,⁸¹ which evaluates spouse caregivers of patients with Alzheimer's disease, is a 25-item self-administered questionnaire that is sensitive to changes over time. The Caregiving Hassles Scale also evaluates the stress experienced by the caregivers of family members with Alzheimer's disease.⁸² This 42-item self-administered instrument focuses on the minor irritations associated with providing care on a daily basis.

Quality of Life

Many elderly patients have chronic diseases that result in discomfort and disability. As it is impossible to cure these problems, the goal is to ameliorate suffering and improve patients' perceptions of their lives. Measurements of health-related quality of life provide feedback to researchers and clinicians so they can better target their efforts. Unfortunately, there is not yet any brief, widely accepted quality of life scale specifically targeting the geriatric population. The Geriatric Quality of Life Questionnaire (GQLQ) was designed to measure the health-related quality of life of community-dwelling elderly. However, in spite of being specifically designed for a frail

elderly population, the GQLQ is neither more responsive nor more valid than other generic scales with regard to measurement of ADL function and emotional function.⁸³ The Medical Outcomes Short Study Form-36, a brief questionnaire, has been extensively studied and is widely used.⁸⁴ It is more appropriate for healthier community-dwelling older persons rather than the frail or institutionalized population.

Spirituality

For many older patients, spiritual beliefs are very important components of quality of life. Furthermore, attendance at religious services has been associated with decreased mortality.⁸⁵ The SPIRIT mnemonic provides a structure for taking a patient's spiritual history.⁸⁶ The interview covers personal spirituality and beliefs, involvement in a spiritual community and rituals, as well as the implications of these beliefs and practices on medical care and advanced directives. These issues may be particularly important for patients who are approaching death. As with problems in other domains, clinicians should not hesitate to involve specialists. Clergy members can be helpful, especially during times of health crisis.

Incorporating Assessment Instruments

The biggest challenge for clinicians with regard to assessment instruments is incorporating them into a busy practice. The particular combination of self-reported and performance instruments that will result in the best yield, highest accuracy, and most efficient use of time will vary from practice to practice. Similarly, how to best utilize trained ancillary staff to maximize the amount of useful information obtained during each office visit will depend on the patient populations and resources of each practitioner. Finally, assessment instruments are valuable only if the practitioner can respond to abnormal findings. Hence, clinicians should be knowledgeable and skilled in the management of the conditions detected, including having available referral resources (e.g., rehabilitation therapy).

Comprehensive Geriatric Assessment and Systems Approaches to Geriatric Care

David B. Reuben

During the past quarter century, the health care delivery of older persons has evolved from a traditional medical framework to a broader recognition of the relationship between an older person's health and their environment, beliefs, support system, and societal roles. Accordingly, new systems of care have been developed that recognize the complexity of this health-related ecosystem and attempt to organize and enhance it to improve the overall health and well-being of the individual. The initial attempts at organizing this care focused on the frail elderly population, based upon the belief that this population was most needy and most likely to benefit from a geriatric approach. Early descriptive studies indicated that among many institutionalized older persons, treatable problems could be uncovered by systematic evaluation of multiple dimensions of health. These dimensions and specific approaches to evaluation are covered in Chapter 17. Because of the frailty of the population initially considered and because physicians had little training or skill in many aspects of this broader evaluation, teams of health care professionals were assembled to provide comprehensive geriatric assessment (CGA). A 1987 National Institutes of Health Consensus Development Conference defined CGA as a "multidisciplinary evaluation in which the multiple problems of older persons are uncovered, described, and explained, if possible, and in which the resources and strengths of the person are catalogued, need for services assessed, and a coordinated care plan developed to focus interventions on the person's problems."¹

Over the past two decades, research on the effectiveness of CGA has led to changes in both the target population for geriatric assessment and the approaches employed. Simultaneously, the overall health care system has evolved in response to financial, technologic, and cultural forces. This chapter first describes traditional comprehensive geriatric assessment and then traces the evolution of the next generation of health service delivery innovations that are derived from CGA. Finally, I speculate on the future of CGA-like interventions.

Comprehensive Geriatric Assessment

Overview

The premise behind comprehensive geriatric assessment is the belief that a systematic evaluation of frail older persons by a team of health professionals can uncover treatable health problems and lead to improved health outcomes. Early randomized clinical trials provided convincing evidence that such programs conducted in hospital-based and rehabilitation units, which typically required several weeks of treatment, could lead to better survival rates, improved functional status, and more desirable placement (e.g., home rather than nursing home) following discharge from the hospital. Since these first trials were published in the early 1980s, the health care delivery system in the United States has changed and there has been an increased focus on the costs of delivering care. Such emphasis on controlling costs has led to a shift from hospital to outpatient care, growth in managed care, and case management of frail older persons. In response to these changes, many programs have attempted to retain principles of CGA yet streamline the process of care, frequently relying on postdischarge and community-based assessment. Furthermore, most of the early programs focused on restorative or rehabilitative goals (tertiary prevention) whereas many newer programs are aimed at primary and secondary prevention. Finally, many of the principles of CGA are being incorporated into the practices of individual clinicians (both physicians and nurse practitioners), whereas in CGA the assessments are conducted by a team of health care professionals rather than by one solitary clinician. As a result, most of today's CGA programs bear little resemblance to the traditional models of the 1980s. Nevertheless, reviewing the basic principles of CGA provides an understanding of both the evolution of this method of health care delivery and the framework for CGA-like interventions that are currently available or are in development.

Process of Care

Conceptually, comprehensive geriatric assessment is a three-step process: (1) screening or targeting of appropriate patients; (2) assessment and development of recommendations; and (3) implementation of recommendations, including physician and patient adherence to recommendations. Each of these steps is essential if the process is to be successful at achieving health and functional benefits. Within this broad conceptualization, CGA has been implemented using many different models in various health care settings.

Screening and Selection of Appropriate Patients

Most CGA programs have used some type of identification (targeting) of high risk patients as a criterion for inclusion in the program. The purpose of such selection is to match health care resources to patient need. For example, it would be wasteful to have multiple health care professionals conduct assessments on older persons who are in good health and have only needs for preventive services. Rather, the intensive (and expensive) resources needed to conduct CGA should be reserved for those who are at high risk of incurring adverse outcomes. Such targeting criteria have included:

- Chronologic age
- Functional impairment
- Geriatric syndromes (e.g., falls, depressive symptoms, urinary incontinence, functional impairment)
- Specific medical conditions (e.g., congestive heart failure)
- Expected high health care utilization

Each of these criteria has been shown to be effective in identifying patients who may benefit from some type of geriatric assessment and management. However, none of these criteria are effective in identifying patients who would benefit from all geriatric assessment and management programs. Accordingly, the specific targeting criteria should be matched to the type of assessment and intervention that is being implemented. For example, a geriatric evaluation and case management program might focus on persons at high risk of health care utilization. Conversely, a preventive program might rely solely on age (e.g., >75 years) as the entry criterion.

Assessment and Development of Recommendations

Once patients have been identified as being appropriate for CGA, the traditional model of CGA invokes a team approach to assessment. Such teams are intended to improve quality and efficiency of care of needy older persons by delegating responsibility to the health professionals who are most appropriate to provide each aspect

of care. Appropriateness in this case indicates both special expertise (e.g., social workers have unique knowledge about community resources) and costs of providing care (e.g., a nurse may be able to conduct some medical assessments as well as a physician). Such team care requires a set of operating principles and governance. Otherwise, it can result in uncoordinated, redundant, or dysfunctional care. First among these principles is an understanding of the roles of each member of the team and mutual respect among the different professions. The team must also establish rules for process of care including the conduct of team meetings, communication, and follow-up on each professional's assigned responsibilities and tasks. Although such teams have been embraced in principle by health care systems, in practice they often run counter to the training of health professionals. In particular, physicians have had little training in working with health care teams, and their basic training emphasizes a medical model.

The composition of the CGA team has traditionally included core and extended team members. Core members evaluate all patients; whereas extended team members are enlisted to evaluate patients on an "as-needed" basis. Most frequently, the core team consists of a physician (usually a geriatrician), a nurse (nurse practitioner or nurse clinical specialist), and a social worker.

The extended members of the team include a variety of rehabilitation therapists (e.g., physical, occupational, speech therapy), psychologists or psychiatrists, dietitians, pharmacists, and other health professionals (e.g., dentists, podiatrists). Frequently, the constituency of the team is determined more by the local availability of professionals with interest in CGA than by programmatic needs.

To increase efficiency, the concept of a core and extended team is gradually yielding to a strategy that relies on flexibility in team composition so that patients are assessed by only those providers who are likely to benefit the patient. In this model, the only consistent member of the team would be the primary care provider. Brief screens, as described in Chapter 17, might identify which providers need to conduct further assessment and therapy. Thus, team members would only assess the patient briefly to determine whether a more in-depth evaluation is necessary. The overriding approach of this strategy is that each patient receives the only the amount of assessment that is necessary.

Regardless of the composition of the team, a key element is the training of the team. Such training should serve several purposes: (1) to ensure that team members have an adequate understanding of the CGA process; (2) to raise the level of expertise of team members in their specific contribution to the team; (3) to develop standard approaches to problems that are commonly identified through CGA; (4) to define areas of responsibility of indi-

vidual team members; and (5) to learn to work effectively as a team. Such training can begin as a retreat or through a series of in-service seminars and should be reinforced periodically. When new members of the team are added, they should receive the basic components of the initial team training.

If CGA is to be effective, the following six components of the process of care must be addressed:

1. Data gathering
2. Discussion among team members
3. Development of a treatment plan
4. Implementation of the treatment plan
5. Monitoring response to the treatment plan
6. Revising the treatment plan as necessary

The approach to gathering clinical data is changing. Traditionally, data gathering for outpatient-based comprehensive geriatric assessment has been conducted by all team members during the course of one long visit, often lasting 3 to 4 h. This scheduling has traditionally been to accommodate the health care providers schedules but must be balanced with considerations of potential patient fatigue. As a result, there has been increasing flexibility in scheduling outpatient CGA so that is more convenient for patients and their families. In inpatient and home settings, different providers usually conduct their assessments over the course of several days before convening as a team.

The content of clinical data that are collected is also evolving. Although health care professionals receive broad and patient-specific training in their discipline that is relevant to assessment of older persons, what actually happens in the clinical encounter is highly variable. Therefore, many CGA programs have turned toward structured professional evaluations so that each patient receives a similar evaluation. Of course, when appropriate, health professionals may depart from the standard evaluation to pursue problems in greater depth. These structured evaluations may take the form of assessments that the team has developed and believes to be clinically relevant for their population or may rely on validated instruments. The latter allows comparisons of assessments with those conducted in other programs but, because these instruments are usually developed for research purposes, they may be less useful for clinical decision making.

With increased flexibility in team structure and scheduling, team discussions in outpatient and home settings are increasingly changing from face-to-face meetings to conference calls or conferencing via Internet. In this manner, discussions can occur at convenient times, even though team members may be in geographically disparate locations. However, in inpatient settings, where discharge planning is an exceptionally important role for the team, most meetings still occur face to face.

The process of management of clinical disorders can also be structured (e.g., protocols for managing geriatric syndromes). However, as discussed next, the implementations of such protocols have frequently met with considerable resistance or have been ignored in clinical settings. Nevertheless, common approaches to these problems that span across providers participating in the CGA team are important to ensure that a similar intervention is being rendered to all patients.

Implementing Recommendations from CGA

In inpatient settings where the assessment team has primary care of the patient, generally implementation of recommendations is not a problem, provided that there are adequate resources (e.g., sufficient number of rehabilitation therapists available at the hospital). However, patients may refuse to participate in diagnostic or therapeutic plans. When the CGA team is providing consultative services, the link between recommendations and implementation is less certain. In outpatient settings, the implementation of CGA recommendations is particularly tenuous because the process can fail at several points, including lack of implementation of CGA recommendations by primary care physicians (in consultative CGA models) and poor adherence to CGA recommendations by patients. The latter can range from patients choosing not to see recommended consultants or refusing to undergo recommended tests to choosing not to adhere to prescribed exercise, nutrition, or rehabilitation regimens.

Successful strategies to increase adherence to CGA recommendations have included geriatrician-to-referring-physician telephone calls with follow-up patient-specific recommendations by mail, and patient and family education including empowerment techniques. Newer technologies, including fax and e-mail, are increasingly being used to communicate recommendations. Even when primary care physicians and patients are in agreement with CGA recommendations, access barriers to receiving indicated services may limit the effectiveness of outpatient CGA. These access barriers include lack of transportation, fragmented services, and gaps in insurance coverage. For example, patients may not be able to get to needed physical therapy three times a week because they do not drive, have no nearby family, or are too disabled to use public transportation. In community-based settings, needed referral services may not be available or, more commonly, are not covered by Medicare. A potential solution to some of these obstacles is use of home health agencies, which can provide a wide range of services to those who are homebound. Similarly, establishing a network of health professionals in the community is essential in developing CGA programs in office-based practices.

Outcomes of Traditional CGA

In virtually all studies of CGA, the process itself has resulted in improved detection and documentation of geriatric problems. However, such identification of problems has not always led to improved outcomes. A 1993 meta-analysis of five models of CGA (geriatric evaluation and management units, inpatient geriatrics consultation services, home assessment services, home assessment services for patients who had recently been discharged, and outpatient assessment services) summarized the evidence to date on traditional models of CGA.² The principal findings of the meta-analysis indicated that the hospital or rehabilitation unit model of CGA had the strongest and most consistent benefits on mortality, living at home, and functional status. Home assessment programs, all of which were implemented and tested in Europe, demonstrated survival benefit at 36 months. None of the other models demonstrated consistent benefits across studies, outcomes, and time points.

Further studies of these traditional models have supported these findings including negative randomized clinical trials of inpatient geriatric assessment consultation,³ in-home assessment by a geriatric nurse practitioner for patients who had recently been discharged from the hospital,⁴ and outpatient geriatric consultation.⁵ Even the most robust traditional CGA model, the geriatric evaluation and management unit, may no longer confer the same benefits in the current environment. A recently completed multisite randomized clinical trial within the Department of Veterans Affairs demonstrated little benefit of such units when compared to usual care, which may have improved considerably since the early 1980s.⁶ Nevertheless, many CGA programs continue despite the lack of strong supporting evidence from clinical trials. Reasons include perceptions among teams and health systems that this is a better way to deliver care to frail older persons, regardless of whether clinical or cost benefits can be demonstrated, and a sense that traditional outcome measures employed in previous research do not adequately capture the benefits of CGA.

New Models of CGA

In light of the potential benefits that CGA can provide when physician implementation and patient adherence are high, new strategies have focused on geriatric management with continuity by the geriatrics team⁷⁻⁹ and CGA consultation coupled to an adherence intervention that emphasizes patient empowerment.¹⁰ Recently, some of these models have achieved health benefits in randomized clinical trials. Geriatric evaluation and continuity management has resulted in better perceived health, life satisfaction, affective health status, and quality of health and social care.^{7,8,11,12} Another type of continuity

geriatric evaluation and management assumes primary care of older persons who are at high risk for high health care utilization for an average of 6 months and then returns patients to the care of their primary care physicians. When evaluated in a randomized clinical trial, this approach prevented functional decline and reduced the likelihood of depression at a modest cost.¹³ A model of geriatric preventive services for unselected community-dwelling older persons utilized a geriatric nurse practitioner to provide periodic in-home assessments that were subsequently discussed with a multidisciplinary team.¹⁴ This intervention delayed functional decline and reduced nursing home placement in a randomized clinical trial. In a replication study, however, the benefit was confined to persons who were at low risk for nursing home admission.¹⁵ Finally, a model that combines CGA with an adherence intervention has been developed and tested. This program provided single outpatient comprehensive geriatric assessment for community-dwelling older persons with functional impairment, urinary incontinence, falls, or depressive symptoms. The team consisted of a geriatrician, nurse practitioner, social worker, and physical therapist (when needed). The assessment was then linked to an adherence intervention that was designed to empower the patient to take action and to educate the physician. In a randomized clinical trial, this strategy was associated with less functional decline, less fatigue, and better social functioning¹⁶ and was cost-effective when compared with many commonly used treatments.¹⁷

New Models of Care That Have Roots in CGA

As traditional models have been tested and modified, several new models of care have been developed and tested that could be considered the progeny of CGA. These models differ from traditional and modified CGA in some important characteristics. First, they are increasingly being developed outside of academic settings. This shift is noteworthy because of the increased difficulty of conducting studies in such settings where change is so rapid. Nevertheless, these studies are exceptionally valuable because they frequently test effectiveness rather than efficacy (i.e., the ability to work under “real-world” circumstances as well as in the “idealized” research settings). As a result, when successful, these interventions are frequently retained. Second, there has been increasing emergence of nursing-based interventions, both in hospital and community-based settings. Third, many new interventions have focused on self-management and increased patient empowerment in caring for their diseases. Such approaches, including those using volunteer

FIGURE 18.1. Functional and clinical outcomes.

lay class leaders, have demonstrated improvement in health status among person with chronic diseases.¹⁸ Fourth, there has been an emphasis, perhaps a predominance, of the importance of cost savings as an outcome. However, reliance on costs as a sole outcome may result in programs that improve health care delivery but do not benefit patients directly. Although the argument that a financially secure health care system will be able to afford to provide other benefits to its patients, improved patient health outcomes should not be forgotten as an important goal of these interventions. Finally, many programs have begun adopting more of a systems approach to providing care that also includes the community and patient as well as the health care system.

One example of such a model of health care for chronic diseases is provided in Figure 18.1.¹⁹ Within the health care system, information support is used (e.g., to identify patients through a registry), the manner in which health care is provided is changed to meet the needs of both patients and providers (e.g., group visits or condition-specific visits), and decision support for providers is readily available (e.g., through telephone or on-line consultants or ready references). This model focuses on self-management as a major philosophic tenet and practical approach (e.g., through self-management classes or other methods of empowering patients to assume responsibility for their diseases). In the best cases, there is partnership with community agencies and resources to provide complementary education and services.

An important caveat in interpreting these new CGA-like interventions is that their effectiveness may be dependent upon the health care system where they are implemented. Variations in health care delivery and

financing systems across nations and within the United States may override the effectiveness of these interventions. As a result, the same intervention may be effective in one setting yet ineffective in another. Even within the same health care system, effectiveness may vary between experimental and practice conditions and may diminish with changes in the environment (e.g., downsizing or merging). Finally, as health care evolves, the concept of a "shelf life" of clinical interventions must be recognized. In other words, health services delivery innovations may be effective for a time and then no longer retain the same value when the entire health care system and reimbursement system change. Examples include the inpatient geriatrics evaluation and management units and hospital-based postacute units; in these instances, economic forces have rendered effective interventions untenable.

Outpatient Models

Several new models of outpatient care for older persons modify the basic structure of care; these adopt various components of CGA including targeting, assessment, and interventions. One approach has been to utilize gerontologic nurse practitioners who are based at senior centers and develop a targeted health management plan that addresses risk factors for disability.²⁰ This health management plan emphasizes physical activity and chronic illness self-management, including attending a 7-week course. Although the intervention did not demonstrate functional or health status benefits, total hospital days were reduced.

Another approach that focuses on older persons who have high predicted health care utilization is the Chronic

Care Clinics developed at Group Health Cooperative of Puget Sound. These clinics are actually special sessions within the primary care physicians practices in which a team of health providers (including a nurse, social worker, and pharmacist) are convened to care for patients who have similar health problems. In one randomized clinical trial, significant benefits on health, functional status, or costs could not be demonstrated at 24 months.²¹

Another comprehensive care model that uses an interdisciplinary team of health professionals is the Cooperative Health Care Clinics developed at Kaiser-Permanente, Colorado, and widely replicated elsewhere. This model of care focuses on older persons who have at least one of four chronic conditions (heart, lung, or joint disease, or diabetes) and high outpatient utilization. However, the intervention is unique, consisting of monthly group visits led by a physician, a nurse, and a guest speaker. Typically, 20 to 25 members attend the group. At the end of these 90-min sessions, 30 min are set aside for brief one-on-one visits with the physician, if necessary. In a randomized clinical trial, such care was associated with increased visits and calls to nurses but fewer emergency room and subspecialist visits and fewer hospitalizations. Although there were no differences in health and functional status measures, participants were more satisfied with their care and the overall costs of care were less.²²

In-Hospital Settings

Several interventions have incorporated CGA principles into hospital care of older persons. Acute care of the elderly (ACE) units have been developed and widely replicated. The care of elderly patients in these units focuses on environmental changes, patient-centered care, discharge planning, and intensive review of medications and procedures (including protocols) to minimize the adverse effects of medications and procedures. The initial randomized clinical trial of these units demonstrated their effectiveness in reducing functional decline and discharge to nursing homes among unselected older hospitalized persons.²³ In a subsequent replication study at a community hospital, the benefits were less dramatic.²⁴

More recently, programs have been developed to identify hospitalized older persons who are at risk for functional and cognitive decline and intervene regardless of where the patient is located in the hospital.²⁵ Such an approach obviates the need for a dedicated unit. The intervention includes geriatric assessment and interdisciplinary involvement as needed, as well as specific interventions to address the multiple dimensions of geriatric syndromes. A prototype program has demonstrated

reduction in new cases of delirium and hospitalized costs.²⁶

Disease Management

A major trend in the management of chronic illness has been disease management in which health care delivery has been focused around a single disease (target condition) with the goal of optimizing the care of this disease. These programs adopt the assessment and intervention approach of CGA, frequently using an interdisciplinary team. The prototype condition has been congestive heart failure. A multidisciplinary program (geriatrics cardiologist, nurse, dietitian, and social worker) for elderly patients with heart failure who were at risk for readmission has been demonstrated to reduce readmission rates and cost of care.²⁷

More recently, this concept has been extended beyond a disease-specific model. A nursing-led program of comprehensive discharge planning and home follow-up has been developed and tested. It uses series of targeting criteria, a program of comprehensive discharge planning (including multidimensional assessment), and home follow-up with advanced practice nurses who visited the patients at least every other day during the hospitalization and at least twice during the 4 weeks following discharge; these visits were supplemented by telephone calls.²⁸ In a randomized clinical trial, this intervention was associated with reduced hospital readmissions and costs (both reduced by approximately 50%).

Case/Care Management

Case management has been defined as a process designed to allocate services appropriately and organize them efficiently.²⁹ This innovation was initially implemented in managed care settings, which were free to allocate funds to support such services, and is beginning to be integrated into fee-for service Medicare where it has traditionally been excluded as a benefit. However, the practice of case management varies considerably in terms of types of health care professionals and their responsibilities.²⁷ Some programs have relied on nurse case managers and others have used social workers; some have used both interchangeably. Similar to CGA, case management virtually always begins with some method of screening to identify high-risk older persons (case selection). Usually, these targeting criteria have been functional impairment or predicted high health care utilization. Following identification, the roles of case managers differ, though components frequently including problem identification, planning, coordinating or implementation, monitoring, and evaluation.^{27,30} However, within this broad frame-

work, there is considerable variation especially with respect to caseload, how services are provided (e.g., face to face versus on the telephone), assessment, and provision of specific services (e.g., home visits, education, counseling).²⁷

Research support for health benefits or cost savings of case management has been limited by both the paucity of studies and methodologic issues in some studies. In randomized clinical trials and pre–post studies, case management has had variable success in providing health or functional status benefits or reducing costs. In an Italian study of persons who were already receiving conventional home health services, case management in conjunction with a geriatric evaluation unit resulted in improved physical function, less cognitive decline, and reduced health care costs.^{31,32} A Kaiser-Permanente of Northeast Ohio study demonstrated attenuation of functional decline³³ but at higher cost than conventional care. Another trial of nurse case managers assigned to frail older persons discharged from a hospital emergency department failed to demonstrate health or economic benefits and resulted in higher readmission rates to emergency departments.³⁴ A social work model of case management for health maintenance organization enrollees at high risk of using health care services heavily in the future did not demonstrate cost savings in a randomized clinical trial.³⁵

The Future

The place of traditional comprehensive geriatric assessment in future health care delivery is likely to be quite limited. Although some programs remain, usually at academic health centers, the expense and logistics of such programs preclude their widespread proliferation. Such programs may be largely confined to teaching settings where they provide excellent environments for teaching geriatrics and team care. Rather, new generations of programs will need to be created that draw upon the lessons learned from these well-studied programs. These programs will need to be efficient yet comprehensive. The best of these programs will adopt the chronic illness care model similar to that described in Figure 18.1 that relies on partnerships between health care systems and the community.

Under the current system of health care reimbursement, such major restructuring of health care for older persons is extremely difficult. Within fee-for-service health care delivery, there is no financial incentive to make health care more efficient. In fact, many of the innovations that have been most successful are not covered benefits under traditional Medicare. With managed care, such global changes are equally difficult to

implement in independent provider models despite the incentive to reduce costs. Logistic and reimbursement difficulties usually preclude such innovation. Such change is easier within group or staff managed care models but still requires vision, leadership, and willingness to overcome inertia.

Nevertheless, future models of geriatric care are likely to be guided by the following principles:

- Comprehensive provision of preventive services (including lifestyle modification) and basic and episodic care for older persons who have few health care needs. These services will likely be provided as inexpensively as possible, using community educational and preventive care resources and trained health care providers who are mostly not physicians.
- Increased use of technology (e.g., Internet) for delivery of health care information to both professionals and patients.
- Systematic identification of older persons who have more extensive health care needs and design of systems to meet such needs on an ongoing basis. Such care is likely to be best provided by teams of health care providers, but such teams must reflect more efficient care rather than simply more care. Communication among teams will be increasingly electronic.
- Increased patient (and family) participation in management of diseases and health care decision making.
- The traditional distinction of roles among health care professionals will become increasingly obscured. Nurses will be increasingly responsible for care management and continuity for older persons who have chronic illnesses.

Such changes will not come easily; they reflect departures from the traditional health care delivery system, and resistance and inertia will be formidable barriers. As noted by the Institute for the Future, “There has been little real change in the way physicians practice medicine since the invention of the telephone.”³⁶ Nevertheless, there is enormous incentive to make basic changes in health care delivery. Even in times of economic prosperity, health care in the United States and other countries has remained under continued pressure to reduce costs. Such pressures are unlikely to abate, and “smarter” systems of care that improve patient outcome within cost constraints will be the only systems that survive.

Neuropsychological Testing

Marilyn S. Albert

A variety of cognitive disorders occur with increasing frequency as people age; these include progressive dementing disorders, acute confusional states, and cognitive disorders secondary to psychiatric syndromes. Epidemiologic studies indicate that approximately 15% of the population over 65 years of age suffers from some form of dementia.¹ However, the probability of having a dementing disorder increases dramatically with age. Data concerning the prevalence of dementia in a community-dwelling population indicate that between the ages of 65 and 74 years the prevalence of dementia ranges from 2% to 3%; this increases to 22% to 23% among those persons 75 to 84 years and to 47% to 48% among those persons aged 85 years and older.² Similarly striking figures pertain to the incidence and prevalence of acute confusion in hospitalized elderly patients. Several studies have reported that 25% to 35% of hospitalized geriatric patients on a general medical service who are cognitively intact at admission develop acute confusion. The incidence of acute confusion in younger subjects is approximately 3%, whereas among individuals 70 and older the prevalence has been estimated to be at least 10 fold higher.^{3,4} There are few systematic studies of the prevalence of cognitive disorders secondary to psychiatric syndromes, but numerous clinical reports state that their prevalence is greater among elderly patients than young patients.⁵

These cognitive disorders produce considerable morbidity and mortality, and although only some of them can be completely reversed with treatment, appropriate management can substantially improve the quality of life and reduce the development of secondary conditions. Thus, it is in the best interests of the patient if one can become increasingly attuned to the possible presence of cognitive dysfunction in older individuals and to be knowledgeable about procedures for workup and referral. This chapter focuses on the role of neuropsychologic testing in the assessment of cognitive dysfunction in elderly patients, particularly as it applies to the geriatrician, because there

is much that a geriatrician can do to identify the presence of cognitive dysfunction and see that it is properly assessed.

Interview with Patient

There are two sources of information concerning the cognitive status of patients: (1) patients themselves and (2) patients' families. Unless a family member has approached the physician with concerns about the patient's cognitive function, it is not likely a family member will be routinely involved in a geriatric assessment. Therefore, the physician is initially limited to information that is obtainable from the patient. This information can be most easily gathered in two ways: (1) from an interview of the patient in the course of conducting a medical evaluation and (2) from brief mental status testing.

Observation During the Medical Examination

In the course of a routine medical examination, there is ample opportunity to converse with patients and gather information about their cognitive status. Because the most common causes of cognitive decline in elderly patients produce a memory disorder (specifically a difficulty with learning and retaining new information), greatest emphasis should be placed on ascertaining information about the memory function of the patient. This may be accomplished by a discussion of current events. Appropriate subjects will differ according to the educational and socioeconomic background of the patient. For one patient; it may be politics, for another, sports, and for another, the stage of the planting season. If there is a particularly dramatic event in the news that most people

are likely to have heard of (e.g., a presidential election, a plane crash), this may be useful for persons of diverse backgrounds. In any case, the task is to determine whether the person is familiar with the event in question and, if so, if it is familiarity that is more than general. Many patients in the early stages of dementing disorder can make general all-purpose remarks that appear to be appropriate while obscuring the fact that they do not have any substantive knowledge of the subject at hand.

In the course of conversing, one can also listen to the nature of the patient's linguistic output. Language problems are important to assess because they are common in both cerebrovascular disorders (e.g., stroke) and dementing disorders. The patient's comprehension ability can be evaluated during a medical examination with relative ease because the patient is generally asked to perform tasks (e.g., open your mouth; life up an arm), and the ability to comprehend these simple directions can be ascertained. Speech fluency also is relatively easy to observe. Patients who are nonfluent have an effortful and halting quality to their speech. Substantive words, such as nouns and verbs, are present, but small connective words (e.g., "if," "and," "but") are generally missing. Disturbances in speech fluency and problems with comprehension often are indicative of a stroke, unless the patient has a long-standing dementing disorder.⁶

Naming ability also can be assessed in the course of conversation. A person with naming problems frequently hesitates over names of objects or persons and may attempt to circumvent the difficulty in a variety of ways (e.g., giving a lengthy description of the object or person; substituting associated words). If naming problems are suspected, a further evaluation can be carried out by using common objects at hand. Very familiar objects, such as a watch or a door, are easy to name. Thus, only a person with a relatively severe naming problem will have difficulty with them. In general, however, parts of objects are harder to name (e.g., the stem of a watch; the knob on a door). The use of both common objects and parts of objects as stimuli will assess a range of naming ability.

Thus, with little additional expenditure of time, memory and language, that is, the two aspects of cognitive function most frequently affected by cerebrovascular disease and common dementing disorders, can be briefly assessed. The goal is not to undertake a detailed or thorough evaluation, but to determine whether any problems are present that suggest an underlying abnormality.

Mental Status Testing

It should, however, be pointed out that it takes a considerable amount of experience to become skilled in drawing sound clinical conclusions from a conversational

approach to the assessment of cognitive function. Therefore, it is ideal if this can be supplemented by a brief test of mental status.

The most widely used tests are the Mini-Mental State Exam (MMSE),⁷ the Blessed Dementia Scale (BDS),⁸ and the Short Portable Mental Status Questionnaire (SPMSQ).⁹ In addition, a test known as the 7-Minute Screen was recently developed for use by the practicing physician.¹⁰ These tests all take approximately 10 min to administer and have high test-retest reliability.

Of these, the MMSE has most commonly been used in clinical settings. Its strength is that it assesses a broad range of cognitive abilities (i.e., memory, language, spatial ability, set shifting) in a simple and straightforward manner. In addition, the wide use of the MMSE in epidemiologic studies has yielded cutoff scores that facilitate the identification of patients with cognitive dysfunction. The other screening tests have been used in a variety of experimental settings, but epidemiologic data are limited. Finally, the extensive use of the MMSE has produced widespread familiarity with its scoring system, facilitating communication among clinicians. Until additional data are available on newer tests, such as the 7-Minute Screen, the MMSE still seems most appropriate for inclusion in the standard clinical evaluation of a patient.

Scores on the MMSE range from 0 to 30. In general, scores greater than 26 are considered to be excellent and reflective of normal cognitive function. Mildly impaired patients typically obtain scores of 18 to 26, moderate impairment is reflected by scores of 11 to 18, and severe impairment by scores of 10 or lower. A cutoff score of 23 is generally recommended as indicative of cognitive dysfunction; however, the application of this cutoff value must be modified by knowledge of the educational level of the patient. For example, patients with a substantial amount of education can experience a considerable amount of cognitive decline before a score of 23 is achieved. On the other hand, persons with little education may obtain a score of 23 at baseline. The rigid use of cutoff scores is difficult because some items on the MMSE, or other comparable screening tests, require minimal educational background. For example, serial sevens, which contribute heavily to the score on both the MMSE and SPMSQ, can be difficult for most elderly persons with limited education. This difficulty may lower the total score such that, with a few other minor errors, the result falls below the cutoff point on the test.

Several studies have examined subjects of varying educational levels, racial backgrounds, and age to identify some guidelines for adjusting MMSE cutoff scores according to the premorbid level of the patient.¹¹⁻¹³ Their findings suggest that a cutoff score of 17 is appropriate for persons with 8 or fewer years of education. The standard cutoff score of 23 was optimal for subjects with 8 to 15 years of education. For persons with higher educa-

tional levels (i.e., 16 or more years), a cutoff score of 27 appeared more appropriate. No consistently significant differences were found between black and white subjects with equal education, suggesting that education, not race, is the important factor that influences test performance. Moreover, persons with little or no formal education may vary in terms of literacy; those who report that they never learned to read and write will perform more poorly on cognitive tests than those who learned these skills outside the normal education channels.¹⁴

It is also important to note that screening tests, such as the MMSE, by their very nature were not designed to measure subtle aspects of behavior. In addition, because there is less redundancy in a brief screening test and it is brief, its measurement error may be close to the amount of decline one might expect with a dementing disease, such as Alzheimer's disease (AD). Thus, the scores may show little or no decline over time in patients whose conditions can be shown, by other measures, to have declined substantially.¹⁵

Despite these shortcomings, mental status screening tests are extremely useful tools. In a brief period of time, one can administer a standardized series of questions that have proved to be helpful in identifying persons with cognitive dysfunction. Most of the tests are effective in screening memory ability. Thus, they are useful in identifying persons with dementing disorders, such as Alzheimer's disease, or acute confusion, conditions that are particularly difficult to diagnose. If used repeatedly over time, they are helpful in establishing a numerical baseline against which future performance can be compared. And, if clinicians use the same test with frequency, they will begin to learn how to use test results to formulate referral questions. It is, for example, much more useful for a patient to be referred for further neuropsychologic testing with a statement such as "the patient has declined four points on the Mini-Mental State Exam over the last year and appears to have particular difficulty with memory testing" rather than "referral for question of dementia."

Obtaining a Cognitive History

If cognitive dysfunction is suspected, it is extremely important to obtain a good history of the cognitive changes that have occurred over time. As the patient's self-report may be unreliable, it is important to obtain a cognitive history from one or more family members (or equivalent caregivers).

When obtaining this information, it is often helpful to begin by asking about the nature of the patient's personality and cognitive skills many years before the onset of the symptoms (e.g., "Can you tell me whether, 15 years ago, the patient was outgoing or quiet, organized or dis-

organized; did he/she have a good memory or a bad memory?"). This type of information helps to provide an anchor against which reports of the onset and progression of symptoms can be judged, because the issue at hand is whether there has been a true change and what the nature of the change has been.

Obtaining a good cognitive history is one of the most difficult and yet important aspects of an evaluation for cognitive dysfunction. A comprehensive history should include information concerning the onset, nature, and progression of behavioral change. Cognitive histories are difficult to obtain because most patients and family members are not attuned to subtle behavioral symptoms. They do not know how to isolate important aspects of the medical history or how to focus on individual cognitive functions in isolation from one another. For example, the family may state that the first symptom of disease was the patient's anxiety and depression about work and, only when asked, may remember several episodes that preceded the onset of work-related anxiety in which the patient could not remember how to handle a complex situation or how to use new equipment in the workplace.

Family members also may have difficulty in understanding why certain subtle distinctions are important for diagnosis. For example, a family member may say that the patient's first symptom was forgetfulness, but when asked to provide instances of forgetfulness, the family member may explain that the patient had trouble installing a new drawer pull in the kitchen or had trouble knowing how to find a familiar location, both of which would suggest spatial difficulty more than memory difficulty. In addition, an unwillingness to admit that certain impairments exist can prevent family members from providing accurate information.

Finally, family members can sometimes misinterpret even fairly direct questions. For example, a history of a gradually progressive disorder is essential to the diagnosis of Alzheimer's disease. Yet, frequently family members say that a disorder came on suddenly when it did not. The realization that the patient is having cognitive problems often coincides with an unusual external event, such as a trip to an unfamiliar place. An unfamiliar environment generally prevents persons from employing overlearned habits and routines and thus exposes their cognitive problems. As family members notice these difficulties suddenly, they may conclude that the disease onset is sudden. Likewise, an illness or hospitalization can exacerbate an underlying cognitive impairment that suddenly makes the family aware that a problem exists. If either of these situations appear to be the case, it is necessary to determine whether any symptoms of cognitive change preceded the external or precipitating event. Most commonly, family members then recall episodes of an earlier change in cognitive function.

Time Since Onset

As mentioned earlier, a good cognitive history must first establish the time at which cognitive changes became apparent. This background will provide important clues regarding the nature of the disorder because some diseases are well known for their particularly rapid rate of decline (e.g., Creutzfeldt–Jakob disease). It will also enable the clinician to give the family some tentative feedback regarding the course of the illness. If the point at which the disorder began is known, the rate of decline can be determined by seeing how long it has taken the patient to reach the present level of function. Although estimates of the rate of progression can be only roughly approximated, it is extremely helpful for the family to have an estimate in making plans for the future. Repeated cognitive testing can provide further help in establishing the course of disease.

Initial Symptoms

Second, it is important to determine the nature of the cognitive or behavioral changes that were evident when the disease began; this also will provide essential information regarding the diagnosis. For example, an early symptom of frontotemporal dementia or Pick's disease is often a change in personality (e.g., inappropriate behavior), whereas the most common early symptom of Alzheimer's disease is a gradually progressive decline in the ability to learn new information.¹⁶ Several years after the disease has begun, which is when most patients' conditions are actually diagnosed, the cognitive symptoms of the two disorders may be very similar, so that information regarding the initial symptoms may be critical to accurate diagnosis.

Type of Onset

Third, it is important to determine whether the initial symptoms came on suddenly or gradually. If the onset of illness is gradual and insidious, as in Alzheimer's disease, it is often only in retrospect that the family realizes that a decline has occurred. In contrast, a series of small strokes, even if not evident on computed tomographic or magnetic resonance imaging scans, generally produce a history of sudden onset and stepwise progression. There may, for example, be an incident (e.g., a fall or a period of confusion) that marks the beginning of the disorder. Acute confusional states generally have an acute onset as well, although if they are the result of a condition such as drug toxicity, this may not be the case.

The manner in which the symptoms have progressed over time also provides important diagnostic information. A stepwise deterioration, characterized by sudden exacerbations of symptoms, is most typical of multi-

infarct dementia. However, a physical illness in a patient with Alzheimer's disease (e.g., pneumonia, hip fracture) can cause a rapid decline in cognitive function. The sudden worsening of symptoms in a psychiatric patient (e.g., depression) also can produce an abrupt decrease in mental status. Careful questioning is therefore necessary to determine the underlying cause of a stepwise decline in function.

It is also important to determine the patient's current functional status. This information is most easily elicited by asking about what the patient does during the course of a usual day. A substantial discrepancy between the functional and cognitive status of the patient suggests the presence of a psychiatric illness. For example, a report that the patient tends to sit all day doing very little in an individual with an MMSE score of 20 suggests a level of functional impairment that is substantially beyond what would be expected. If physical limitations, such as difficulty in walking, are not present, then careful questioning for evidence of depression is warranted.

Detailed Neuropsychologic Testing

If one suspects the presence of cognitive deficits and is going to refer a patient for neuropsychologic testing, it is helpful to know that there are two basic approaches to the selection of a neuropsychologic test protocol. Some neuropsychologists use a predetermined battery, such as the Halstead Reitan Battery¹⁷ or the Luria Nebraska Battery.¹⁸ Other neuropsychologists select a set of tests from among a group that seems to be particularly relevant to the diagnostic question. Even in the latter case, however, there tends to be a core set of tests that are relied on more heavily than others. However, regardless of the approach of the neuropsychologist, it is reasonable to expect the neuropsychologist's report to be formed in terms of the following major areas of cognitive ability: attention, language, memory, spatial ability, executive function, and general information.

Attention is important to consider because simple attentional abilities must be preserved for any other task to be performed adequately. If the subject has difficulty in keeping his or her mind on a task for 1 to 3 min at a time, it will not be possible to assess other areas of function. Commonly used tests of simple attention are digit span,¹⁹ reaction time,²⁰ and the continuous performance test.²¹

In the digit span test, the individual is asked to repeat a series of numbers of increasing length, first in order forward and then a similar series backward. Reaction time is generally tested on a computer, where the individual is asked to press a key in response to a specific stimulus (e.g., pattern, sound, etc). The continuous performance test generally asks the subject to identify a par-

ticular letter (“A”) or series of letters (“I before X”) in a continuous series of letters; the series can be written or spoken out loud.

If aphasia is not suspected, the language evaluation is likely to be limited to an assessment of confrontation naming because decreases in naming ability are a prominent symptom of a number of cognitive disorders common in the elderly (e.g., Alzheimer’s disease). The most common method for assessing naming is to present drawings of common objects or the actual objects to be named. The Boston Naming Test²² and the Alzheimer’s Disease Assessment Scale²³ include such assessments of naming.

Verbal fluency is also commonly assessed, as it is a reflection of both linguistic and executive function skills. Both letter fluency and category fluency are generally evaluated. In both these tests, the individual is asked to generate within 1 min all the words they can think of within a particular category (e.g., the letters F, A, S; or animals; or vegetables).²⁴

If a more extensive language evaluation seems desirable, then it will generally include an assessment of naming, fluency, grammar, comprehension, repetition, vocabulary, reading, and writing. This step can be done briefly with a short screen for each of these areas²⁵ or with a lengthy and more comprehensive assessment of language, with such batteries as the Boston Diagnostic Aphasia Exam²⁶ and the Western Aphasia Battery.²⁷

A careful evaluation of memory is perhaps the most essential to the cognitive workup of an older person. Memory dysfunction occurs in almost all the cognitive disorders common in the elderly, and the nature and severity of the memory impairment can serve as one of the major guidelines in the diagnosis. The neuropsychologic assessment of memory should at least distinguish between the patient’s immediate and delayed memory function, because the difference between immediate and delayed recall is strikingly impaired in early Alzheimer’s disease and, if present, can be diagnostic. By contrast, normal aging individuals typically take longer to learn something new, but retain that information well over brief delays.²⁸ Moreover, patients with other dementing disorders, such as frontotemporal dementia and psychiatric disorders (e.g., major depressive disorder) can have difficulty with memory, but the loss of information over a brief delay is less severe than in AD.^{29,30} Commonly used tests of memory include the California Verbal Learning Test,³¹ Wechsler Memory Scale,³² and Cued Selective Reminding Test.³³

The assessment of visuospatial ability should, if at all possible, include figure copying. Such figures can be chosen to span a great range of difficulty and to include both two-dimensional and three-dimensional figures. If the patient has visuosensory deficits, the visual stimuli to be used for copying can be adapted (by using enlarge-

ments of drawings or making figures with a felt-tipped pen). A number of shorter test batteries that have been developed for use with dementia patients contain an array of figures that are easy to use; these include the CERAD Battery³⁴ and the Alzheimer’s Disease Assessment Scale.²³ Other tests of spatial ability can be used that employ blocks, sticks, or design recognition; these include the Benton Visual Retention Test³⁵ and the Block Design subtest of the Wechsler Adult Intelligence Scale—III (WAIS).¹⁹

Tasks that examine executive function ability evaluate a variety of functions, including set formation, set shifting, self-monitoring, and abstraction. These abilities are affected in most of the major dementing disorders (such as Alzheimer’s disease and frontotemporal dementia), as well as in psychiatric disorders such as depression. Therefore, executive function should be carefully assessed. Examples of such tests that can be used include the Trail Making Test,³⁶ Stroop Test,³⁷ Self-Ordering Test,³⁸ Proverbs Test,³⁹ and the Similarities subtest of WAIS.¹⁹

Individuals who are having trouble performing tasks with multiple steps that must be integrated with one another, such as cooking or balancing a checkbook, will usually demonstrate impairments on tests that evaluate set shifting, such as the Trail Making Test. Individuals who have trouble understanding complex ideas or planning for the future, such as required for planning a trip or deciding how to handle one’s finances, will often have problems on tests of abstraction, such as the Similarities subtest of the WAIS.

Tests of general intelligence are also useful to administer, if time permits; this will allow one to determine whether the individual has access to previously acquired knowledge. For example, early in the course of Alzheimer’s disease, some patients have a normal IQ although they have a striking memory deficit and difficulty with executive function. A relatively preserved IQ in a patient with Alzheimer’s disease often relates to higher levels of functioning at home and tends to be a good prognostic sign.

Full-scale IQ tests are, however, very lengthy. It is therefore likely that the neuropsychologist may administer a brief test that provides a good estimate of general intelligence. One such test is a reduced version of the WAIS.⁴⁰ Alternatively, one can use a brief test that estimates IQ, based on the ability to read irregular words.⁴¹

The referring physician should encourage the neuropsychologist to formulate their clinical report in terms of the six broad areas of cognitive function described here. A neuropsychologic report organized in this fashion will make it easier for an individual with less neuropsychologic expertise to interpret the results. It will also be easier to determine whether the patient has spared areas of cognitive function. This understanding is important, because knowing the patient’s pattern of spared and

TABLE 19.1. Strengths and weaknesses in mildly and moderately impaired patients with Alzheimer's disease (AD).

Mild AD

- Memory: very defective new learning, relatively preserved recall of remote events
 Conceptualization: defective ability to plan and execute complex activity, problems switching from one task to another, impaired ability to form conceptual generalities, and preserved ability to understand concrete ideas
 Language: word-finding deficits, preserved conversational abilities
 Visuospatial skills: difficulty with complex spatial tasks, relatively preserved figure copying and spatial skills needed for activities of daily living (dressing, bathing, sports, etc.)
 Personality: less interest in usual activities, occasional irritability, paranoia in some patients, preserved general personality profile

Moderate AD

- Memory: severely defective new learning, moderately affected remote memory, preserved recall of most distant remote events
 Conceptualization: difficulty with anything requiring abstract thinking, can understand only simplest concrete ideas
 Language: increased word-finding deficits, difficulty with comprehension of complex language, relatively fluent speech
 Visuospatial skills: difficulty in copying simple drawings; problems with spatial skills needed for activities of daily living (dressing, bathing, sports, etc.); can engage in physical activity, such as walks and simple exercise
 Personality: increased likelihood of behavioral disturbances, such as hallucinations, delusions and agitation; can enjoy simplified and restructured activities

impaired abilities can provide an important guide to diagnosis. For example, patients with Alzheimer's disease have an approximately equal impairment in both verbal and nonverbal memory. Therefore, a patient whose verbal memory skills are disproportionately deficient relative to nonverbal testing is unlikely to have Alzheimer's disease.

The description of a patient's major cognitive impairments and major cognitive strengths also can be used to maximize function. For example, early in the course of Alzheimer's disease, most patients have striking difficulty in retaining new information during a brief delay and have problems with conceptualization that make it hard for them to integrate a number of individual tasks into a complex whole or to plan activities in the future. However, mildly impaired patients with Alzheimer's disease frequently have spared spatial abilities and a preservation of well-learned skills; therefore, they can be encouraged to carry out a wide variety of sports and leisure activities with the knowledge that they will be successful. Table 19.1 provides a summary of the major strengths and weaknesses in mild and moderately impaired patients who have typical symptoms of Alzheimer's disease.

The number and nature of the patient's impairments will also enable the skilled clinician to formulate a reasonable prognosis. For example, even though a patient with Pick's disease might have only a mild memory deficit, early evidence of severe conceptualization difficulties and inappropriate behavior suggests that the patient will need to be in a supervised environment relatively soon and the family needs to plan for that eventuality. On the other hand, a patient with Alzheimer's disease with a striking memory deficit who has some preservation of conceptualization skills and shows good judgment by, for example, not cooking when food has been repeatedly burned, or not going for a long walk if

this has previously led to being lost, is likely to be able to remain in a relatively unsupervised environment for a long period of time.

The assessment of cognitive function in an older person can thus serve many useful purposes if it is well focused and integrated into the general evaluation of the patient. A geriatrician who understands the potential utility of neuropsychologic testing can substantially contribute to its appropriate application.

Acknowledgments. This chapter represents a revision and expansion of the one that appeared in the 3rd edition of *Geriatric Medicine*. The preparation of this chapter was supported in part by funds from NIH grant P01-AG04953.

Preoperative Assessment and Perioperative Care

Peter Pompei

The increasing number of older persons undergoing surgery stems from both our aging population and important recent advances in surgical and anesthetic techniques. Currently, about one-third of all operations are performed on persons 65 years of age and older, compared to about 20% in 1980.¹ The types of surgical procedures commonly performed on older persons reflect the prevalence of chronic diseases: intraocular lenses for cataracts, resections of hypertrophied prostate glands, colorectal procedures for cancer, arthroplasties for osteoarthritis and fractures, and arterial reconstruction for vascular disease. The introduction of neuroleptic anesthesia, sophisticated perioperative monitoring technology, and effective prophylaxis against deep venous thrombosis have contributed to lower surgical mortality for older adults.² Endoscopic and other minimal access techniques have added to the ease and safety of operative therapy and have led to reduced mortality, increased ambulatory surgery, and shorter-stay hospitalizations.^{3,4} Returning patients quickly to their usual environment and functional status can reduce complications so commonly related to medications and immobilization associated with hospitalization. The lowered risk of operative morbidity and mortality has encouraged physicians and patients to consider surgical therapy more readily.

With the increasing rate of operative therapy among older patients, there is an increasing demand by surgeons for medical consultation in the perioperative period. Although the request is often for “preoperative clearance,” both the unstated expectations of the requesting physician and the responsibilities of the consultant are much more specific. The purpose of a preoperative assessment is to identify factors associated with increased risks of specific complications related to the anticipated procedure and to recommend a management plan that would minimize these risks. The consultant must give careful attention to the extent and severity of comorbid conditions, the current and anticipated pharmacologic therapy, and the functional and psychologic state of the

patient. These patient-specific risk factors are only part of the required assessment; the type and technical difficulty of the procedure, the skill of the surgeon, and the anesthetic management all contribute to the risks of complications.² The most common postoperative medical complications include respiratory problems, congestive heart failure, delirium, and thromboembolism.⁵ This chapter reviews the risk factors for and management of these and other common perioperative problems of older persons.

Perioperative Risk Stratification

Assessing a patient’s risk for postoperative complications is an important aspect of preoperative evaluation. This process allows physicians to focus treatments on modifiable factors, anticipate specific problems, and provide patients and families with more precise, individual-specific, prognostic information.

Since 1941, anesthesiologists have stratified patients according to a physical status classification system that has been modified over the years and now consists of the five classes shown in Table 20.1.⁶ Although developed to describe the preoperative condition of patients in a subjective but standardized way, several reports indicate an important relationship between the American Society of Anesthesiologists (ASA) score and operative mortality.^{7,8} The ASA status has become a useful global index of operative risk despite institutional differences in death rates and the subjective nature of the ratings.

In a large study of complications associated with anesthesia done in France, the rate of complications, although rising with advancing age, was largely dependent on the number of associated diseases per person.⁹ Among patients 75 years of age and older, those with three or more associated diseases had a complication rate 10 times greater than those with no associated diseases. This observation supports the hypothesis that physiologic

reserve and ability to regain homeostasis is affected partly by changes associated with aging but, more importantly, by the deleterious consequence of accumulating disease among older persons. To determine predictors of 30-day mortality among 92 patients undergoing pneumonectomy, investigators examined the contribution of the following comorbid conditions: cardiac disease, diabetes, hypertension, respiratory disease, pulmonary cancer, peripheral vascular disease, liver disease, renal insufficiency, and inflammatory bowel disease.¹⁰ The presence of one or more of these conditions was associated with an increased risk of 30-day mortality. Similarly, in a study of about 100 patients undergoing total knee arthroplasty, comorbidity was quantified by counting how many of the following conditions were present: hypertension, diabetes mellitus, coronary artery disease, atherosclerotic heart disease, peripheral vascular disease, chronic renal failure, and asthma.¹¹ Patients with four or more of these comorbid conditions were found to have longer hospital stays and a worse functional status at 3 months compared to those with fewer than four of the conditions. These results indicate that a simple count of selected diagnoses can help identify patients at risk for untoward outcomes such as decreased survival, functional recovery, and longer duration of hospitalization.

A tool commonly used to measure comorbidity is the Charlson index,¹² an empirically derived prognostic taxonomy of comorbid conditions relevant to short-term survival. It was derived from a cohort of about 600 patients admitted to the medical service of New York Hospital during a 1-month period in 1984. Comorbid conditions judged cogent to short-term prognosis were included in the index. Weights were assigned to each condition based on the association with 1-year mortality of the patients enrolled. The specific conditions considered and their associated weights are shown in Table 20.2. The index has proven useful in many clinical studies, including predicting 5-year mortality among older men undergoing prostatectomy for benign prostatic hypertrophy¹³ and estimating the risk of 30- and 90-day mortality in more than 21,000 cases of open cholecystectomy among older persons.¹⁴

Two patient-specific factors other than comorbidity associated with poor surgical outcomes are hypoalbuminemia and severely limited physical activity level. Two

reports from a study of more than 200,000 patients treated at Department of Veterans Affairs Medical Centers highlight the importance of a low serum albumin in predicting poor surgical outcomes. Among about 54,000 cases of major noncardiac surgery, a low serum albumin level was the strongest predictor of morbidity and 30-day mortality when compared to 61 other preoperative patient risk variables.¹⁵ In the subset of patients undergoing proctectomy for rectal cancer, presurgical hypoalbuminemia was associated with an increased 30-day mortality rate.¹⁶ It is not yet known whether preoperative correction of hypoalbuminemia will alter patient outcomes. Similarly, an impaired physical functional status has been associated with poor postoperative outcomes. In a study of 474 male veterans (mean age, 68 years) undergoing noncardiac surgery, the risk of death was significantly increased among those patients with severely limited preoperative activity level, defined as bedridden or bed-to-chair movement.¹⁷ Awareness of patient-specific factors associated with a high risk of poor surgical outcomes is useful in providing realistic prognostic information to patients and their families.

Assessing the Risk of Cardiac Complications

Because cardiac complications are among the most common and most serious postoperative problems, significant attention has been focused on estimating the risk

of cardiac complications, especially in noncardiac surgical procedures. Goldman and associates pioneered the association of preoperative factors with the development of cardiac complications among patients over 40 years of age.¹⁸ In their initial work, nine independent predictors of cardiac complications after noncardiac surgery were identified, the most important of which included recent myocardial infarction, uncompensated congestive heart failure, electrocardiographic evidence of a rhythm other than sinus or premature atrial contractions, and more than five premature ventricular contractions per minute. The usefulness of the multifactorial index of cardiac risk that was developed has been repeatedly confirmed.¹⁹⁻²³ Most recently, Goldman and others have revised and validated a simple index for predicting cardiac risk of noncardiac surgery.²⁴ Stable patients undergoing nonurgent, major, noncardiac surgery were assessed for the presence or absence of the following six factors: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative

serum creatinine greater than 2.0 mg/dL. The rates of major cardiac complications among patients with zero, one, two, and three or more of these factors were 0.5%, 1.3%, 4%, and 9%, respectively. This index performed better than the original Goldman index and several other risk prediction indices.

Beyond the identification of groups of patients at increased risk for developing cardiac complications are management algorithms that can guide the physicians beyond the assessment phase.^{25,26} The guideline for assessing and managing the risk of perioperative cardiac complications in noncardiac surgery from the American College of Physicians is shown in Figure 20.1. The algorithm begins with an assessment of the patient's risk for cardiac complications using the Modified Cardiac Risk Index. Patients in the low-risk category can proceed to surgery without additional evaluation or treatment. Patients in the intermediate-risk category not undergoing a vascular procedure can also proceed to surgery. Patients in the intermediate-risk category undergoing vascular surgery are advised to have a cardiac stress test.

FIGURE 20.1 Assessing and managing risk of cardiac complications of nonemergent, noncardiac surgery.

If negative, they can proceed to surgery; if positive, they are treated like patients who fall into the high-risk category based on the Modified Cardiac Risk Index.

Patients in the high-risk category and those in the intermediate-risk category with an abnormal cardiac stress test should have a further evaluation of the nature of their risk. If the risk is due to ischemic heart disease, eligibility for coronary revascularization should be considered before proceeding with elective noncardiac surgery. If the risk is due to congestive heart failure, dysrhythmias, or other modifiable factors, these should be optimally managed before proceeding to surgery. If the risks are nonmodifiable, consideration should be given to canceling or altering the anticipated surgery. The stepwise approach of this guideline provides the clinician with an organized, systematic approach to assessment and management. The clinical outcomes to be expected by following this approach are still being studied. Results of some large studies support the recommendation that preoperative stress testing be done in selected patients undergoing vascular surgery.^{27,28}

Management of Selected Problems

In addition to identifying and quantifying the risks older patients face when surgery is being planned, geriatricians are also called upon to assist in minimizing these risks by managing specific medical problems. A comprehensive review of the management of all possible medical problems in surgical patients and of the specific problems related to particular operations is beyond the scope of this chapter. The reader is referred to other publications that address many of these important issues.²⁹⁻³³ The remainder of this chapter focuses on the management of selected perioperative medical problems commonly faced by medical consultants.

Hypertension

The prevalence of hypertension among Hispanic and non-Hispanic white Americans aged 60 years and older was found to be about 60%; in non-Hispanic African-Americans of the same age group, 70% had hypertension.³⁴ Uncontrolled hypertension is a well-established risk factor for stroke, myocardial infarction, and renal dysfunction. In the preoperative period, when the blood pressure is 180/110 mmHg or greater, elective operations should be postponed until better control of the hypertension is achieved.²⁵ An increased incidence of myocardial ischemia is seen not only among patients with preoperative hypertension, but also in those patients who have major fluctuations in blood pressure during a

surgical procedure.^{35,36} This variability is more common in patients with established hypertension: significant elevations in blood pressure were observed in 25% of hypertensive patients during the perioperative period, irrespective of the control of their blood pressure preoperatively.³⁷

The causes of variability in blood pressure among older persons perioperatively include anesthetic agents and other medications, age-related changes in the cardiovascular system, changes in intravascular volume, and pain or other stimuli to the nervous system. The work of Prys-Roberts³⁶ has demonstrated some of the expected changes in blood pressure during surgery. Induction of anesthesia usually results in a reduction in systemic vascular resistance. The normal compensatory responses of increased heart rate and increased stroke volume may be limited in older persons; this limitation may result in a reduced cardiac output and a fall in blood pressure. Endotracheal intubation generally causes significant stimulation of the sympathetic nervous system and a sharp rise in blood pressure. Changes in intravascular volume and depth of anesthesia contribute to fluctuations in blood pressure during the operation.

Although the anesthesiologist attends to the variability of blood pressure in the immediate perioperative period, the geriatric consultant is more likely to have a role in preoperative assessment and the management of the patients once they have left the recovery room. Patients with chronic hypertension undergoing elective operations are probably at no increased risk for cardiac complications so long as the preoperative diastolic pressure is stable and less than 110 mmHg and large fluctuations in the mean arterial pressure can be avoided intraoperatively.³⁷ For this reason, and because of the potential for untoward responses to newly introduced antihypertensive agents, it generally is not advisable to begin a new drug regimen for blood pressure control in the few days before surgery. When therapy needs to be initiated or adjusted, it is preferable to postpone the procedure until the patient's response to a new regimen can be observed and a steady state achieved. Oral medications used to control hypertension preoperatively should be given on the day of surgery with a sip of water and restarted as soon as possible postoperatively.³⁸ The risks of severe hypertension from withholding antihypertensive medications far outweigh the potential adverse effects of giving these medications preoperatively. Clinicians must be alert to the negative chronotropic and inotropic effects of some beta-adrenergic blockers and calcium channel antagonists that may exacerbate similar pharmacologic effects of inhalation anesthetics.

In the postoperative period, patients with significant elevations in blood pressure should be fully evaluated. Occasionally, uncontrolled pain or a distended bladder is

the cause of the hypertension, and treatment is directed at these precipitating factors. If secondary causes of hypertension are excluded, antihypertensive drug treatment is indicated. Parenteral calcium channel antagonists, beta-blockers, and drugs that block both alpha- and beta-adrenergic receptors have been very useful in controlling postoperative hypertension in older patients. Intravenous angiotensin-converting enzyme inhibitors, such as enalaprilat, have been used for postoperative hypertension and hypertensive crises and may be appropriate for patients with congestive heart failure and hypertension. The ability to quickly titrate the dose of parenterally administered medications to blood pressure response is a significant advantage. Beta-blockers must be used cautiously in patients predisposed to congestive heart failure because of negative inotropic effects. The negative chronotropic effects of this class of drugs can blunt the normal compensatory response of increased heart rate to a sudden loss of intravascular volume, such as a major postoperative bleeding episode. Other relative contraindications to beta-blockers include a history of bronchospasm, claudication, and diabetes mellitus. Orally administered calcium channel antagonists have been successfully used to control postoperative hypertension in older patients undergoing cataract surgery.³⁹ Potent vasodilators, such as hydralazine, can be hazardous in the subset of patients with hypertensive, hypertrophic cardiomyopathy who have a small left ventricular chamber and good contractile function; these patients depend heavily on adequate diastolic filling that can be compromised by rapid vasodilation and reflex tachycardia. Nitroprusside can effectively control significant hypertension, but its use requires careful monitoring of the patient, usually in an intensive care unit with an intra-arterial catheter to continuously measure the blood pressure response.

Atherosclerotic Disease

Many older surgical patients can be expected to have atherosclerosis. The identification and management of occlusive coronary disease in the surgical patient is especially important because the mortality of perioperative myocardial infarction has been estimated to be about 40%.⁴⁰ Useful guidelines for the assessment and management of patients with coronary artery disease have been developed, and one has been outlined in the previous section on Assessing the Risk of Cardiac Complications.^{25,26,41} Management of patients with known or suspected coronary artery disease should include the perioperative use of beta-blockers. The use of these medications has been shown to significantly reduce the risk of postoperative cardiac complications among patients undergoing non-cardiac surgery, including vascular procedures.⁴²⁻⁴⁴

Carotid occlusions and peripheral vascular disease are prevalent among older persons and raise important management questions. The presence of a carotid bruit has been judged to be supportive evidence of atherosclerosis but has not been shown to increase the risk of postoperative stroke.⁴⁵ Clinical factors that have been shown to increase the incidence of perioperative stroke include cerebrovascular disease, chronic obstructive pulmonary disease, and peripheral vascular disease.⁴⁶ Patients experiencing transient ischemic attacks for whom carotid endarterectomy is recommended should have this procedure done before elective noncardiac surgery. Peripheral vascular disease very commonly coexists with significant atherosclerotic coronary artery disease. If the peripheral vascular disease is serious enough to limit the patient's activity, exertional angina may be masked. Symptoms or signs of arterial disease should prompt the consultant to evaluate the patient for the presence of ischemic heart disease.

Congestive Heart Failure

Congestive heart failure is an important complication of ischemic heart disease, but it can also result from other cardiomyopathies or valvular heart disease. In the original Goldman index of cardiac risk factors in noncardiac surgery, the preoperative conditions associated with the most points predictive of an adverse outcome are the presence of an S₃ gallop and jugular venous distension, two of the classic signs of uncompensated congestive heart failure. In the management of surgical patients with congestive heart failure, it is important to optimize their medication regimen and to monitor carefully their volume status and cardiac output. The standard treatment of systolic cardiac dysfunction includes the use of diuretics, positive inotropic agents, and medications to reduce afterload. Heart rate and rhythm contribute significantly to cardiac output and may require special interventions; this is especially true in patients with diastolic dysfunction, often caused by hypertensive cardiomyopathy, in which the left ventricular end-diastolic volume is so dependent on atrial contraction and adequate filling time. Swan-Ganz catheters have significantly improved our ability to monitor accurately the volume status of patients and optimize ventricular filling pressures. The intraoperative transesophageal echocardiogram has become popular in some centers, especially for cardiothoracic procedures.⁴⁷ The advantages of this device over the Swan-Ganz catheter are that continuous estimates of left ventricular end-diastolic volumes can be made, changes in regional wall motion can be monitored, and the observed ejection fraction area can be used to assess contractility. The disadvantage is that the device is only used intraoperatively, and unless a right heart catheter is

also placed, management of postoperative volume status must rely on imprecise clinical measures.

Valvular Heart Disease

The primary perioperative risks associated with valvular heart disease are congestive heart failure and bacterial endocarditis. It has been estimated that 20% of surgical patients who have significant valvular heart disease will develop new or worsening congestive heart failure perioperatively.⁴⁸ Critical aortic stenosis has been identified as the valvular lesion most commonly associated with complications. Preoperative identification of this lesion by history and physical examination alone may be difficult. Clinical findings include a harsh systolic murmur radiating to the neck, occurring late in systole, that is prolonged and may obscure the second heart sound; diminished carotid pulses; and left ventricular hypertrophy on the electrocardiogram and radiographic evidence of aortic valvular calcification. A bedside clinical prediction rule has been proposed to detect moderate or severe aortic stenosis. The absence of a murmur over the right clavicle is a useful sign that significant aortic stenosis is unlikely. When such a murmur is heard, the presence of three of the following four associated findings is useful to confirm the presence of aortic stenosis: reduced carotid artery volume, slow carotid artery upstroke, maximum murmur intensity at the second right intercostal space, and reduced intensity of the second heart sound.⁴⁹ If significant aortic stenosis is suspected, an echocardiogram can confirm the diagnosis. It has been suggested that patients with angina, heart failure, or syncope who have significant aortic stenosis established by echocardiography should undergo cardiac catheterization to assess the need for valve replacement before elective operations.⁵⁰ Other types of valvular heart disease are not absolute contraindications to elective surgery. Nevertheless, patients with stenotic or incompetent valves require careful hemodynamic monitoring during perioperative fluid management.

Certain valvular and other cardiac conditions predispose the patient to endocarditis, and prophylactic antibiotics should be used in selected operative settings. Patients with a high risk of endocarditis are those with prosthetic cardiac valves, previous bacterial endocarditis, complex congenital heart disease, and surgically constructed systemic pulmonary shunts or conduits. Patients considered to be at moderate risk for endocarditis are those with most other congenital cardiac malformation, acquired valvular dysfunction, hypertrophic cardiomyopathy, and mitral valve prolapse with valvular regurgitation and/or thickened leaflets.¹⁵ The procedures for which prophylactic antibiotics are indicated are listed in Table 20.3;⁵¹ the recommended antibiotic regimens are summarized in Table 20.4.⁵¹

TABLE 20.3. Procedures for which endocarditis prophylaxis is recommended.

Dental procedures
Dental extractions
Periodontal procedures including surgery, scaling and root planning, probing, and recall maintenance
Dental implant placement and reimplantation of avulsed teeth
Endodontic (root canal) instrumentation or surgery only beyond the apex
Subgingival placement of antibiotic fibers or strips
Initial placement of orthodontic bands but not brackets
Intraligamentary local anesthetic injections
Prophylactic cleaning of teeth or implants where bleeding is anticipated
Respiratory, gastrointestinal, and genitourinary tract procedures
Tonsillectomy and/or adenoidectomy
Surgical procedures that involve respiratory mucosa
Bronchoscopy with a rigid bronchoscope
Sclerotherapy for esophageal varices
Esophageal stricture dilation
Endoscopic retrograde cholangiography with biliary obstruction
Biliary tract surgery
Surgical procedures that involve intestinal mucosa
Prostatic surgery
Cystoscopy
Urethral dilation

Rhythm Disturbances and Heart Block

A cardiac rhythm other than sinus rhythm is associated with an increased risk of cardiac complications, most commonly myocardial ischemia or congestive heart failure.⁵⁰ If a patient is on an antiarrhythmic medication, this should be given on the day of surgery and restarted as soon as possible postoperatively. Parenteral forms of many of these drugs are available and can be used until the patient can tolerate oral medications. Supraventricular tachycardia is commonly encountered in older persons undergoing noncardiac surgery. A recent study of more than 4000 patients undergoing major, nonemergency, noncardiac procedures who were in sinus rhythm at the preoperative evaluation identified 12 risk factors for developing perioperative supraventricular arrhythmia: male gender, age 70 years and older, significant valvular disease, history of a supraventricular arrhythmia, asthma, congestive heart failure, premature atrial complexes on preoperative electrocardiogram, ASA class III or IV, abdominal aortic aneurysm repair, and abdominal, vascular, or intrathoracic procedures.⁵²

Efforts to restore sinus rhythm often begin with an infusion of adenosine; for patients who do not convert with this intervention, intravenous infusion of a beta-blocker or calcium channel blocker has been shown to accelerate the conversion to sinus rhythm.⁵³ Ventricular dysrhythmias during the perioperative period occur in

TABLE 20.4. Regimens of prophylactic antibiotics for patients at risk for bacterial endocarditis.

Drug	Dosing regimen
Dental, oral, respiratory tract, or esophageal procedures:	
Standard regimen	
Amoxicillin	2 g orally 1 h before procedure
Amoxicillin-/penicillin-allergic patients	
Clindamycin or Cephalexin or cefadroxil or Azithromycin or clarithromycin	600 mg orally 1 h before procedure 2 g orally 1 h before procedure 500 mg orally 1 h before procedure
Patients unable to take oral medications	
Ampicillin	2 g intravenously (i.v.) or intramuscularly (i.m.) within 30 min before procedure
Penicillin-allergic patients unable to take oral medications	
Clindamycin or Cefazolin	600 mg intravenously (i.v.) within 30 min before procedure 1 g intravenously (i.v.) or intramuscularly (i.m.) within 30 min before procedure
Genitourinary and gastrointestinal (excluding esophageal) procedures:	
High-risk patients	
Ampicillin and gentamicin	Intravenous (i.v.) or intramuscular (i.m.) administration of ampicillin 2 g, plus gentamicin 1.5 mg/kg (not to exceed 120 mg), 30 min before the procedure; followed by ampicillin 1 g i.m./i.v. or amoxicillin 1 g, orally 6 h after initial dose
High-risk patients allergic to ampicillin/amoxicillin	
Vancomycin and gentamicin	Intravenous administration of vancomycin 1 g, over 1–2 h, plus gentamicin 1.5 mg/kg i.m./i.v. (not to exceed 120 mg); complete injection/infusion within 30 min of starting procedure
Moderate-risk patients ^a	
Amoxicillin or ampicillin	Amoxicillin 2 g orally 1 h before procedure, or ampicillin 3 gm i.m./i.v. within 30 min of starting procedure
Moderate-risk patients allergic to ampicillin/amoxicillin	
Vancomycin	1 g i.v. over 1–2 h; complete infusion within 30 min of starting procedure

^a Patients with prosthetic heart valves and those with a previous history of endocarditis are considered to be in a high-risk category and should not be considered for this regimen.

almost half of older men with known or suspected coronary artery disease undergoing noncardiac surgery, but unless they occur with other symptoms or signs of myocardial ischemia, they may not require monitoring or treatment.⁵⁴ The indications for a pacemaker are not influenced by an anticipated operative procedure. Patients with an asymptomatic chronic bifascicular block or left bundle branch block rarely progress to complete heart block in the perioperative period. Bradyarrhythmias can occur but are successfully managed with medications so that prophylactic insertion of a temporary pacemaker in such patients should be questioned.⁵⁵

Pulmonary Disease

Pulmonary problems are among the most common postoperative complications.⁵⁶ Older persons may be particularly prone to pulmonary complications because of the age-related changes in the respiratory system. At the alveolar level, there is a decrease in elasticity due to alterations in collagen content and structure. Functionally, this leads to an increase in the closing volume, that lung volume at which airway closure is first detected. As the

closing volume approaches the functional residual capacity, the risk for atelectasis increases. There is also increased chest wall stiffness due to calcification of cartilage, arthritic changes, and diminished intervertebral space combined with insufficient respiratory muscle strength to match the added work load of breathing imposed by the increased chest wall stiffness.⁵⁷ These structural changes can increase residual volume and reduce the expiratory flow rates in older persons.

There are also important changes in respiratory function resulting from anesthesia and surgery that are superimposed on the age-related changes. The combination of the supine position, general anesthesia, and abdominal incisions leads to a significant reduction in functional residual capacity and an associated increase in airway resistance.⁵⁸ The decline in functional residual capacity is most severe on about the fourth postoperative day but can persist for more than a week.⁵⁹ The combination of a reduced functional residual capacity and an age-associated increase in closing volume predisposes patients to atelectasis with the attendant risks of hypoxemia and infection. Vital capacity can be decreased as much as 25% to 50%, especially after upper abdominal incisions.⁵⁹ Postoperative pain and analgesics both con-

tribute to a reduction in tidal volume and impaired clearing of secretions through normal cough mechanisms.

The geriatric consultant can be most helpful by anticipating patients at high risk for complications and then recommending strategies to reduce these risks. In addition to the well-recognized risk for pulmonary complications, such as significant lung disease and type and duration of operation, a patient's functional level should be taken into account. Patients with better exercise tolerance by self-report or by the measured distance during a timed walk have fewer pulmonary complications than those with poorer exercise tolerance.⁶⁰ Other patient characteristics used to identify those at increased risk for pulmonary complications include dementia, recent cigarette smoking, age of 60 years or more, a history of cancer or angina, location and length of the incision, and ASA class of 3 or greater.⁶¹ Continued research is needed to establish a valid risk index for pulmonary complication for older persons undergoing noncardiac surgeries.

Considerable attention has been focused on pulmonary function tests to identify patients at high risk for respiratory complications.^{59,62} Functional and anatomic tests have proven helpful to clinicians in managing patients facing pulmonary resections. In such patients, the quantitative ventilation-perfusion scan can accurately predict postoperative flow rates; when the predicted postoperative forced expiratory volume in 1 s is 0.8 L or greater, the operative risk is often considered acceptable.^{63,64} In contrast, the predictive value of pulmonary function tests for patients undergoing abdominal procedures is unproven.^{65,66} Additional studies are needed to address whether pulmonary function test results contribute significant additional information to what is known from the clinical examination and whether this information has a beneficial effect on patient outcomes.

Prospective studies in high-risk patients have identified specific interventions that reduce morbidity and mortality from respiratory problems. Stein and Cassara found that "poor-risk" patients treated with a regimen of preoperative smoking cessation, antibiotics "when indicated," perioperative bronchodilator therapy, inhalation of humidified gas, postural drainage, and chest physiotherapy had fewer pulmonary complications, lower mortality, and shorter hospital stays than nontreated patients.⁶⁷ Data on the impact of cigarette smoking suggest that as much as 6 weeks of abstinence may be required before there is improvement in small airways disease, hypersecretion of mucus, tracheobronchial clearance, and immune function, although cardiovascular function can be enhanced through the elimination of carbon monoxide and nicotine for even 12 to 24 h.⁶⁸ Benefits of antibiotics, chest physiotherapy, and incentive spirometry have been reported,⁶⁹⁻⁷¹ but more information is needed regarding these interventions, especially which patients to target and for which operative procedures.

There is little consensus about the benefit of other treatments, such as instruction in respiratory maneuvers, bronchodilators, minimization of postoperative narcotic analgesics, and early mobilization of the older patient.⁷² In the absence of an evidence-based practice guideline for the perioperative management of an older person at increased risk of pulmonary complications, a pragmatic approach is required. Preoperatively, it is important to encourage abstinence from cigarettes, eradicate tracheobronchial infections, relieve airflow obstruction, and instruct the patient in lung expansion maneuvers. Intraoperative goals would include limiting the duration of the operation to less than 3 h using limited access surgical procedures when possible, and considering spinal or epidural anesthesia. Postoperatively, deep-breathing exercise and incentive spirometry should be encouraged, and consideration should be given to continuous positive airway pressure devices and regional analgesia via epidural or local nerve blocks.⁷³

Thromboembolic Disease

Thromboembolic complications are prevalent in the perioperative period. It has been estimated that between 20% and 30% of patients undergoing general surgery develop deep venous thrombosis, and the incidence is as high as 40% in hip and knee surgery, gynecologic cancer operations, open prostatectomies, and major neurosurgical procedures.⁷⁴ Although fatal pulmonary embolism occurs in 1% to 5% of all surgical patients, it accounts for a larger proportion of operative deaths in middle-aged and older individuals.⁷⁵ Because venous thrombosis and pulmonary emboli can be difficult to diagnose and treat, considerable effort has been focused on prophylaxis. Various regimens to reduce deep venous thrombosis and pulmonary emboli, including heparin, warfarin, aspirin, dextran, and leg compressive devices, have been used. The recommendations for prevention of venous thromboembolism of the Sixth American College of Chest Physicians Consensus Conference on Antithrombotic Therapy related to older surgical patients are summarized in Table 20.5.⁷⁶ Clinical risk factors identified by this group include: increasing age; prolonged immobility, stroke or paralysis; previous venous thromboembolism; cancer and its treatment; obesity; varicose veins; cardiac dysfunction; indwelling central venous catheters; inflammatory bowel disease; nephrotic syndrome; and estrogen use.

Renal, Fluid, and Electrolyte Disorders

The kidneys play a critical role in drug metabolism and fluid and electrolyte balance during the perioperative period. The age-related changes in kidney structure and

TABLE 20.5. Prevention of venous thromboembolism.

Clinical setting	Recommended prophylaxis
General surgery	
>40 years old, nonmajor surgery, no other risk factors	LDUH, LMWH, ES or IPC
>40 years old, major surgery or >60 years old, nonmajor surgery, with other risk factors	LDUH, LMWH, or IPC
Higher risk patients with a greater than usual risk of bleeding	ES or IPC
Very high risk patients with multiple risk factors	LDUH or LMWH combined with ES or IPC
Orthopaedic surgery	
Hip replacement	LMWH or adjusted dose warfarin (INR 2-3)
Knee replacement	LMWH or adjusted dose warfarin (INR 2-3)
Hip fracture repair	LMWH or adjusted dose warfarin (INR 2-3)
Neurosurgery	
Intracranial operations	IPC with or without ES

LDUH, low dose unfractionated heparin; LMWH, low molecular weight heparin; ES, elastic stockings; IPC, intermittent pneumatic compression

function, combined with the effects of anesthesia and surgery, can have important consequences in the management of the older surgical patient. With aging, there is a loss of renal mass, primarily in the cortex, that results in a 30% to 50% decrease in the number of glomeruli by the seventh decade.⁷⁷ This loss of filtering surface is associated with a fall in renal blood flow and reduction in glomerular filtration rate (GFR). The decrease in GFR is generally coincident with a decline in muscle mass so that the serum creatinine levels may remain normal. Accurate measurements of glomerular filtration rates can be very helpful to the clinician but may not be readily available. Estimates of GFR can be calculated using the following equation proposed by Cockcroft and Gault⁷⁸:

$$C_{Cr}(\text{ml}/\text{min}) = \frac{[140 - \text{age}(\text{yr})] \times [\text{weight}(\text{kg})]}{[72 \times \text{serum Cr}(\text{mg}/\text{dL})]}$$

where C_{Cr} indicates creatinine clearance and Cr is the serum creatinine level. (This formula is for men; the estimate is adjusted for women by multiplying the result by 0.85.) The estimates obtained from this formula have been shown to correlate with measured creatinine clearance in older patients.^{79,80} This measure, although not precise, is sufficiently accurate for appropriate medication dose adjustments when $\text{Cr} < 5 \text{ mg/dl}$ and relatively stable.

Diminished preoperative renal function increases the risk of postoperative acute renal failure. Renal blood flow can be compromised intraoperatively because of a decline in cardiac output secondary to the negative inotropic effects of inhalational anesthetic agents, the effects of positive pressure ventilation, and loss of intravascular volume. These factors and nephrotoxic medications can result in postoperative acute reversible intrinsic renal failure.⁸¹ Oliguria, isosthenuria, and a rising serum creatinine are early clinical signs of this syndrome.

When acute renal failure is suspected, the urine sediment should be examined for epithelial cell casts, granular casts, and tubular epithelial cells. The urine sodium is generally greater than 40 mEq/L, and the urine to plasma creatinine ratio is generally less than 10:1. In contrast, prerenal azotemia is associated with a urine sodium of less than 40 mEq/L and a urine to plasma creatinine ratio of greater than 10:1. Management of acute intrinsic renal failure includes discontinuing potentially nephrotoxic drugs and carefully monitoring volume status. Dialysis is occasionally necessary to manage hypervolemia, hyperkalemia, metabolic acidosis, or uremic encephalopathy. Even with appropriate treatment, acute postoperative renal failure has a mortality rate between 40% and 80%.⁸² Obstructive nephropathy is a concern in older patients because of sensitivity of the bladder to anticholinergic medications and the prevalence of associated problems such as prostatic hypertrophy and detrusor and urethral sphincter dysfunction from a variety of causes.

The ability of the kidneys to regulate body osmolality and fluid volume can be compromised by both aging and surgery. With aging, the loss of functioning nephrons increases the solute load per nephron, and renal blood flow patterns favor the medulla; these changes adversely affect the normal countercurrent concentrating mechanism⁷⁷; this can lead to volume depletion through a reduction in renal concentrating capacity and excessive losses of free water. Older individuals also have a diminished thirst perception that compromises their ability to respond to significant free water loss and hyperosmolality.⁸³ This change is particularly important postoperatively, when third-space losses of fluid and bleeding may cause severe intravascular volume depletion. Conversely, volume overload sometimes results from the delayed response to sodium restriction and salt wasting observed in older individuals,⁸⁴ which can be exacerbated by the elevated levels of vasopressin seen in the postoperative

state. Sodium and water retention after surgery may last for several days. These physiologic changes are compounded by the difficulties in the clinical assessment of volume status in older persons. Postural hypotension is an important sign of intravascular volume depletion but can be observed in euvoletic older patients and may be difficult to assess properly in the immediate postoperative period. When the assessment of volume status becomes critically important, it is often necessary to measure pulmonary capillary wedge pressure using a Swan–Ganz catheter.

Intravenous fluid administration must be adjusted for the older surgical patient because there is a decline in both total body water and intracellular water with advancing age. For men between 65 and 85 years of age and weighing between 40 and 80 kg, the intracellular volume represents 25% to 30% of body weight.⁸⁵ For women of the same age and weight ranges, the intracellular volume is approximately 20% to 25% of body weight. In the absence of acute stress and conditions known to affect salt and water balance, the daily metabolic requirements per liter of intracellular fluid are as follows:

Water, 100 mL
 Energy, 100 kcal
 Protein, 3 g
 Sodium, 3 mmol
 Potassium, 2 mmol

For example, an 80-year-old woman weighing 40 kg has an estimated intracellular volume of 10 L. Daily maintenance requirements would be 1 L water, 1000 kcal, 30 g protein, 30 mmol sodium, and 20 mmol potassium. Fluid and electrolyte status must be closely monitored and adjusted according to the response of the patient and the development of other pathophysiologic conditions.

Endocrine Disorders

Diabetes mellitus, usually type II, is common among older persons. It has been estimated that of diabetic patients undergoing surgery, more than 75% are over the age of 50.⁸⁶ Diabetes not only complicates the management of surgical patients but also predisposes the patient to an increased risk of morbidity and mortality from cardiovascular and infectious complications.^{87,88} Several predictable perioperative metabolic changes can exacerbate hyperglycemia. With the stress and tissue injury of surgery, there is an increase in many of the counterregulatory hormones: cortisol, epinephrine, glucagon, and growth hormone. These changes stimulate gluconeogenesis, and the catecholamines can directly depress the release of insulin from the pancreas and blunt insulin activity at the cellular level.

In all diabetic patients undergoing surgery, it is important to monitor blood sugar frequently. Values should be obtained preoperatively, during the procedure, and in the recovery room. Afterward, the frequency of monitoring will be determined by the treatment regimen, the patient's condition, and glucose control. For patients whose blood sugar can be maintained in the normal range by diet and exercise therapy, no special preoperative preparation is required. Hyperglycemia can be effectively treated with supplemental short-acting insulin preparations given subcutaneously. The patients receiving oral hypoglycemic medications should have these held on the day of the operation. Hyperglycemia can be treated with short-acting insulin. For patients receiving insulin, several management regimens are possible. Constant insulin infusions can be used successfully but require careful monitoring because of the rapid changes in glucose and potassium levels. More commonly, for patients normally treated with a single dose of insulin each day, one-half to two-thirds of the usual dose of insulin is given on the morning of surgery, and a glucose-containing intravenous solution is administered at a rate of 5 to 10 g glucose per hour.

For patients who are normally managed with multiple doses of insulin throughout the day, one-third the usual morning dose is administered on the morning of surgery, and a glucose-containing solution is infused intravenously.⁸⁹ Blood sugar control is easier if a constant rate of infusion of the glucose solution is maintained while nonglucose-containing intravenous fluids are used to adjust for changes in intravascular volume. Additional doses of regular insulin should be administered to control blood sugar levels; a 6-h interval between glucose measurements is commonly used. In addition to meticulous attention to blood sugar levels, it is important to monitor diabetic surgical patients for infections and impaired wound healing.⁹⁰ Cardiovascular complications are also common because diabetes is an important risk factor for atherosclerosis. Myocardial ischemia can be silent and may be detected unexpectedly on postoperative electrocardiograms.

Thyroid disease is not as prevalent as diabetes but, if undetected, can result in major complications perioperatively. The prevalence of hypothyroidism in hospitalized older patients has been reported to be 9.4% and the prevalence of hyperthyroidism 0.8%.⁹¹ It is well known that older persons may have nonspecific or atypical manifestations of thyroid illness, so it is important to maintain a high index of suspicion for thyroid illness in this population. The consequences of operating upon a patient with unsuspected hypothyroidism can be significant. These patients metabolize medications more slowly, and their increased sensitivity to central nervous system depressants can result in respiratory insufficiency. In addition, cardiac reserve is diminished and the response

to pressors may be blunted. While the potential for these complications should be suspected and preventive measures instituted, hypothyroidism should not be considered an absolute contraindication to necessary operative procedures.⁹² Emergency surgery and trauma are indications for rapid replacement of thyroid hormone. When hypothyroidism is severe, an intravenous dose of 300 to 500 µg L-thyroxine will significantly improve basal metabolic rate within 6 h. Corticosteroids should also be given in the perioperative period because the acute rise in basal metabolic rate can exhaust adrenal reserves.

The increased perioperative risks associated with hyperthyroidism include hyperpyrexia, arrhythmias, and congestive heart failure. Older persons may be particularly prone to iodine-induced hyperthyroidism from non-ionic contrast radiography.⁹³ Elective operations should be delayed until treatment with thionamide medications render the patient euthyroid. When an emergency operation is necessary, the patient can be treated with 1000 mg propylthiouracil by mouth and a beta-blocker to control the increased catecholamine effects. Sodium iodide is often given to inhibit the release of thyroid hormone and transiently inhibit organification. Iodide can be given either by mouth or intravenously; administration should be delayed until at least 1 h after the propylthiouracil to allow time for the latter to block organification. Supplemental corticosteroids are also recommended for hyperthyroid patients undergoing emergency operations. These supplements are given to protect against the possibility of adrenal insufficiency related to the chronic hyper-metabolic state and because corticosteroids may lower serum thyroxine and thyroid-stimulating hormone levels.

Nutrition

Surgery and wound healing cause increased energy demands. Patients who are malnourished preoperatively are likely to quickly deplete their body's carbohydrate stores, which will lead to protein catabolism and a negative nitrogen balance. In some malnourished or high-risk patients, preoperative total parenteral nutrition has been shown to reduce morbidity and mortality rates.^{94,95} Whenever possible, preoperative nutritional supplements should be delivered via the gastrointestinal system. Total parenteral nutrition should be reserved for those patients in whom the gastrointestinal tract cannot be used.

Especially for older patients, there is no consensus on the best method for assessing nutritional status.^{95,96} In addition, it is not clearly established that improvements in commonly used nutritional indices are associated with reduced perioperative morbidity; hence, the optimal duration of nutritional support is unknown. Additional studies are needed in patients most likely to benefit from

perioperative nutritional supplements: those who are severely malnourished before major surgery; and those who undergo operations resulting in prolonged periods of inadequate enteral intake. Until more is known, it is common to provide postoperative enteral tube feedings to patients with a functioning gastrointestinal tract who were malnourished preoperatively and who are unable to consume adequate calories orally. Total parenteral nutrition is indicated for malnourished patients who have a nonfunctioning gastrointestinal tract or for whom enteral feedings are contraindicated.⁹⁷ (See Chapter 68 for a more complete discussion of nutrition.)

Neuropsychiatric Disorders

Neuropsychiatric problems are common among older persons and can be associated with an increased risk of perioperative complications. The prevalence of dementia is about 5% among persons aged 65 years; it increases to about 25% in those 80 years of age and older. A study of older patients admitted for repair of hip fractures in Sweden reported a prevalence of dementia of 15%.⁹⁸ Depression also is prevalent among older persons and can be exacerbated by any acute illness or hospitalization. Anesthesia and surgery can have profound effects on mental functioning. The metabolic changes associated with surgery along with the previously discussed effects on all the vital organ system can compromise cerebral function and exacerbate or precipitate neuropsychiatric disorders. The physiologic and behavioral manifestations of neuropsychiatric disorders can significantly complicate perioperative care and often lead to prolonged hospital stays.

The most common psychiatric problem in the postoperative period is delirium. The major manifestation of this condition is an alteration in consciousness, and it is, by definition, a transient disorder.⁹⁹ One prospective study reported delirium in 44% of older patients undergoing repair of hip fractures.¹⁰⁰ The presence of depression, use of anticholinergic medications, and hypoxemia were associated with delirium. Neither the duration of the procedure nor the type of anesthetic used (halothane versus epidural) were predictors of an acute confusional state. In another study of older patients undergoing elective noncardiac surgery, 9% of patients developed delirium postoperatively. Risk factors included age 70 years and older; self-reported alcohol abuse; poor cognitive status; poor functional status; markedly abnormal preoperative serum sodium, potassium, or glucose level; noncardiac thoracic surgery; and aortic aneurysm surgery.¹⁰¹

The differential diagnosis of delirium is very broad. A careful clinical assessment of the patient should focus on the possibility of infection, metabolic derangements, central nervous system events, myocardial ischemia, sensory deprivation, or drug intoxication. Lidocaine,

cimetidine, atropine, aminophylline preparations, antihypertensives, steroids, and digoxin are medications commonly associated with delirium, but all drugs should be considered as possible causes. The best management strategy is prevention; the incidence of delirium can be significantly reduced by meticulous attention to precipitating factors. A multicomponent intervention that addressed the six risk factors—cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration—was successful in reducing the incidence of delirium from 15% to 9%.¹⁰² When it cannot be prevented, it is important to recognize the syndrome early, then identify and treat the underlying cause. When medications are necessary to protect the patient and others from agitated behaviors, 0.5 mg haloperidol can be given parenterally and repeated every 30 min as necessary. The minimum dose sufficient to control symptoms is recommended, and doses exceeding 6 mg over a 24-h period are rarely indicated. Frequent assessment of patients suffering from delirium is mandatory to monitor both response to therapy and potential drug toxicity. It is important to ask patients about their hallucinations and illusions, to discuss and clarify these frightening experiences, and to reassure them if the underlying cause is reversible.

Alcoholism is another serious and common problem among older persons; it has been estimated that there are at least 1.5 million alcoholics in this country who are 65 years of age or older.¹⁰³ The geriatric consultant should carefully explore current ethanol use with all patients, and a screening tool such as the Michigan Alcoholism Screening Test may be useful in identifying alcohol abuse preoperatively.¹⁰⁴ When there is suspicion of alcoholism, the patient should be evaluated for symptoms or signs of physiologic dependence and organ damage.

Chronic alcohol use can cause important metabolic derangements, as well as cardiac, hepatic, hematologic, and neurologic dysfunction. Liver disease has a variable effect on drug metabolism. The rate of metabolism of many drugs is slowed, but microsomal enzyme induction may result in increased dose requirements of many anesthetic agents. The patients for whom a withdrawal syndrome seems likely should be treated with thiamine and short-acting benzodiazepines, and elective surgery should be delayed. The consultant is commonly called to assist in the management of delirium tremens or alcohol withdrawal seizures occurring postoperatively. Withdrawal seizures are effectively treated with benzodiazepines and often do not require long-term antiepileptics. Delirium tremens usually occurs 24 to 48 h after the last drink but can occur after 7 to 10 days of abstinence. The classic signs are fever, tachycardia, confusion, and visual hallucinations. Oxazepam or lorazepam are given in sufficient doses to sedate the patient. The other principles of treating patients with delirium also apply.

Summary

Operative therapy is an important option for many of the health conditions experienced by older persons. Although the risks of perioperative complications are increased in individuals with multiple chronic conditions and impaired functional status, with careful preoperative assessment and perioperative management, these risks can be minimized and successful outcomes can be achieved.

Anesthesia for the Geriatric Patient

Jeffrey H. Silverstein

Anesthesia is a reversible state that permits procedures to be performed on the human body. Based principally on the early experience with ether, the anesthetic state was thought to be a single entity as described by the unitary theory of narcosis. In recent years, it has become clear that various physiologic phenomena that can be controlled independently combine to produce the anesthetic state. These phenomena are analgesia, hypnosis or amnesia, control of the physiologic responses to surgical stimuli, and maintenance of adequate operating conditions, primarily muscle relaxation.

In the first third of the twentieth century, surgery was considered a desperate measure for patients over 50 years of age, who were believed to be incapable of sustaining the rigors of even an inguinal hernia repair.¹ Advances in anesthesia have allowed surgeons to develop an extraordinary array of procedures with excellent outcomes in an increasingly aging population. The number of patients over age 65 who undergo noncardiac surgery are now projected to increase from 7 million to 14 million over the next three decades.² Geriatric patients are becoming an increasing part of the anesthesia workload.³

Because intraoperative mortality is now rare and intensive care can prolong short-term survival, the current standard for comparing rates of perioperative complications is 30 days from the time of surgery. Current estimates of 30-day perioperative mortality for properly prepared surgical patients over age 65 are 5% to 10%.⁴⁻⁶ These figures are less than half the mortality recorded a few decades ago but are still higher than for younger patients. Denney and Denson reported on 272 nonagenarians undergoing 301 operations.⁷ Their initial belief was that surgery was not justified in such old patients; however, they reported that in more than 70%, the benefit justified the risk they underwent. Only serious small bowel obstruction was associated with prohibitive perioperative mortality (63%). Studying 500 patients over age 80 who had undergone surgery in the Harvard

System, Djokovic and Hedley-Whyte found that the American Society of Anesthesiologists (ASA) physical status classification (see p. 213–214) predicted mortality.⁵ This finding is consistent with an earlier large French study by Tiret et al., in which age is seen to be an important modifier of comorbid conditions⁸ (Fig. 21.1).

Lawrence and colleagues studied 372 patients undergoing elective abdominal surgery in San Antonio, Texas.⁹ Patients were evaluated preoperatively and postoperatively at 1, 3, and 6 weeks and at 3 and 6 months using a battery of instruments to capture multiple dimensions of functional health. Figure 21.2 shows the recovery status for activities of daily living (ADLs) across the follow-up assessments. Using ADL and instrumental activities of daily living (IADL) summary scores, patients were dichotomized as not recovered or recovered/improved at each assessment point. Mean change scores were significantly different from preoperative assessment at 1, 3, and 6 weeks. For IADLs (Fig. 21.3), mean scores were significantly below baseline at 1, 3, and 6 weeks and 3 months. At 3 months after surgery, 14% of patients had disability in ADLs; for IADLs, 20% had persistent disability at 6 months after surgery. Thus, although surgery is feasible for elderly patients, it remains an important and potentially debilitating experience.

General Anesthesia and Anesthetic Agents

Anesthesia generally consists of analgesia, control of the physiologic responses to surgical stimuli, hypnosis or amnesia, and maintenance of adequate operating conditions, primarily muscle relaxation. Analgesia, the absence of pain, is the cornerstone of the anesthetic state. Pain pathways have been described in great depth and can be altered by a variety of different methods.¹⁰ Other integrated systems also respond to surgical stimuli. The most

FIGURE 21.1. Major anesthesia complications per 1000 as a function of age and associated disease (Modified from Tiret et al. *Can Anaesth Soc J.* 1986;33:336,⁸ with permission.

important clinically is sympathetic nervous activity, which manifests principally as increased pulse and blood pressure. Blood pressure and pulse are the principal endpoints by which adequacy of anesthesia is gauged. Hypothalamic-pituitary-adrenal and acute-phase reactions also occur. Anesthesia does not completely block all these reactions, but they are reduced orders of magnitude from what would occur in the absence of anesthesia. Hypnosis or amnesia is a state in which conscious awareness is suppressed. Awareness under anesthesia is considered an adverse event. The amnesia produced by various hypnotic agents is not necessarily complete in that, even under deep general anesthesia, it is possible to demonstrate learning. Finally, it is important to maintain adequate operating conditions to facilitate surgery.

FIGURE 21.2. Patients aged 60 and greater ($n=372$) on average return to baseline levels of activities of daily living by approximately 3 months following elective abdominal surgery under general anesthesia. (From Ref. 9, with permission.)

FIGURE 21.3. Patients aged 60 and greater ($n=372$) on average return to baseline levels of independent activities of daily living by 3 months following elective abdominal surgery under general anesthesia. (From Ref. 9, with permission.)

Aside from a lack of movement, muscle relaxation is frequently required to facilitate surgery, for example, on the abdominal cavity. In addition, the anesthesiologist is responsible for maintenance of the patient's homeostasis during and immediately following surgery.

The spectrum of activity of the drugs available to the anesthesiologist varies tremendously (Fig. 21.4). Agents are chosen to produce the desired effect and minimize side effects. In this chapter, I first describe the agents and techniques used to produce anesthesia. Selection of different anesthetic techniques for elderly surgical patients and their advantages and disadvantages follow.

Volatile Anesthetics

The commonly used volatile anesthetic agents are isoflurane, ethrane, halothane, sevoflurane, and desflurane. They are administered by inhalation as part of the gas mixture used to ventilate patients under general anesthesia. All agents are principally agonists of the GABA_A chloride channel.¹¹ Volatile agents have a broad spectrum of action and are capable of producing a complete anesthetic state. Induction of anesthesia can be accomplished simply by breathing a mixture of a volatile agent in air or oxygen. Certain of the volatile agents (isoflurane, ethrane, and desflurane) are considered too pungent (produce gagging and coughing) to accomplish an inhalation induction; however, halothane and sevoflurane are commonly used for this purpose. This type of induction is reserved almost exclusively for young children who will not allow an intravenous catheter to be placed before anesthesia; it is essentially never done for an adult.

FIGURE 21.4. Spectrum of activity for anesthetic drugs. Physiologic aspects of the anesthetic state are displayed in the vertical boxes. The ability of various medications to provide all or parts of that state are displayed in horizontal bars. Volatile anesthetic agents can produce a complete anesthetic state, but their use alone is limited by side effects.

The pharmacologic equivalent of an ED₅₀ (median effective) dose for volatile anesthetics is defined as the minimum alveolar concentration (MAC),¹² the concentration of an agent at which 50% of subjects no longer produce purposeful movement in response to a skin incision. Anesthesia can be maintained with any of these agents at 1.25 to 1.3 times MAC. Relatively lower concentrations are usually employed in combination with other agents in a standard general anesthetic. Halothane has been associated with hepatitis and is rarely used in adult patients. Anesthetic requirements decrease progressively with advancing age, a phenomenon thought to be primarily a pharmacodynamic alteration¹³ (Table 21.1).

Sedative Hypnotic Agents

Induction of anesthesia is most commonly undertaken with intravenous hypnotic agents, which have the

TABLE 21.1. Alteration in volatile anesthetic doses for the elderly.

Agent	Young adults	Elderly adults

Desflurane	6	5.2 ^b

^a Age 64 years.

^b Age 80 years.

principal advantage of a rapid induction of unconsciousness. The old adage to count backward from 99 is rarely employed because a patient almost never gets beyond 97. The principal agents are the barbiturates thiopental (Pentothal), thiamylal (Surital), and methohexital (Brevital), and an agent of a unique class called propofol (Diprivan). Ketamine, etomidate, and benzodiazepines may also be employed. Apart from ketamine, the sedative hypnotic agents do not provide analgesia. The barbiturates are antianalgesic; that is, on their own, they make pain worse.

Following the introduction of barbiturates, a lack of understanding of their pharmacokinetics led to their use for induction and maintenance of general anesthesia in the manner of diethyl ether and chloroform, with frequently disastrous results, including prolonged sleeping times and hypotension. Administration of thiopental to the casualties at Pearl Harbor resulted in large numbers of deaths and the statement that intravenous anesthesia was “an ideal method of euthanasia.”¹⁴ A subsequent understanding that the effects of small doses of barbiturates were terminated not by metabolism but rather by redistribution from their sites of actions to other body tissues set the groundwork for thiopental to become the standard drug for induction of anesthesia. This experience is an important example of the importance of an in-depth understanding of the pharmacology of anesthetic agents.

The most likely site of action for the barbiturates is the γ -aminobutyric acid (GABA) receptor complex. GABA is the principal inhibitory neurotransmitter found in mammalian central nervous systems. Barbiturates both enhance and mimic the action of GABA on the ion channels.¹⁵ Studies on the effect of aging on the pharmacodynamics and pharmacokinetics of thiopental suggest that the principal effect is based on a reduction of volume of distribution in the elderly, resulting in a higher concentration of the drug at the effect site for any given dose. There is considerable interindividual variation in the dose of thiopental required to induce anesthesia. A healthy 80-year-old requires approximately 85% as much drug as a 20-year-old. It appears that the elderly brain is not more sensitive to the effects of thiopental. A more complete description of the pharmacology of barbiturates in the elderly is provided by Shafer.¹⁶

Propofol (diisopropylphenol) is the newest intravenous anesthetic, one that has become very popular for the induction and maintenance (by continuous infusion) of anesthesia and for sedation. The exact mechanism of action of propofol has not been completely elucidated. There is evidence that it acts through activation of the GABA_A β_1 -subunit, as well as by inhibition of the *N*-methyl-D-aspartate (NMDA) subtype of the glutamate receptor.

The induction dose varies from 1.0 to 2.5 mg/kg. Premedication with a benzodiazepine and/or an opiate substantially reduces the induction dose of propofol. A dose of 1 mg/kg (with premedication) to 1.75 mg/kg (without premedication) appears to be appropriate for patients over age 60.¹⁷ Side effects associated with the induction of anesthesia with propofol include a decrease in arterial blood pressure, pain on injection, myoclonus, apnea, and rarely thrombophlebitis of the vein where the propofol is injected. Apnea is very common, with an incidence similar to thiopental or methohexital; however, the apnea is likely to last longer.¹⁸

Propofol has been used for sedation during surgical procedures and in the ICU for sedation during mechanical ventilation. The level of sedation is readily titratable and recovery occurs rapidly on termination of the infusion, regardless of the duration of infusion.^{19,20} Infusion rates must be markedly reduced in elderly and sicker patients.

Etomidate is an imidazole derivative that was introduced into practice in the United States in 1972. Its properties include minimal respiratory depression, cerebral protection, rapid recovery, and hemodynamic stability. Reports that the drug can temporarily inhibit steroid synthesis and hence decrease adrenal activity,^{21,22} along with a side effect profile that includes myoclonus, pain on injection, and high incidence of nausea and vomiting, tremendously decreased the enthusiasm for this drug.²³ In recent years, the drug has regained some of its popularity, particularly for sick and elderly patients. Increasing age is associated with a smaller initial volume of distribution and decreased clearance of etomidate.²⁴

Ketamine is the one phencyclidine currently available for clinical use. Although phencyclidine, the prototype of this class of drugs was a promising anesthetic agent, it was associated with an unacceptably high incidence of psychologic effects, including hallucinations and delirium. Phencyclidine is currently available only for illicit recreational use ("angel dust"). Ketamine (Ketalar) was released for clinical use in humans in 1970 and is still used for a variety of clinical circumstances. Ketamine is unique among the injectable hypnotic agents because it provides significant analgesia. In addition, it does not depress the cardiovascular system (i.e., does not produce hypotension) or the respiratory system.²⁵ Indeed, ketamine manifests both sympathomimetic and bronchodi-

lating effects. Nonetheless, it does possess some potential to create the same adverse psychologic effects found with other phencyclidines. Poor-risk (ASA IV) patients with respiratory and cardiovascular disorders represent the majority of candidates for ketamine. The drug is used with some frequency for sedation of children outside the operating room and for dressing changes in settings such as burn units. When used in combination with a benzodiazepine, emergence delirium is considerably less frequent, and this combination has recently been advocated for routine use in the elderly (R. Roy, personal communication).

The principal benzodiazepines utilized for anesthetic care are midazolam, diazepam, and lorazepam. Midazolam (Versed) is the only water-soluble benzodiazepine and thus causes considerably less irritation of the vein at the site of infusion and less thrombophlebitis. It has a faster onset of action. These properties have made midazolam the benzodiazepine of choice for most anesthetic use. Midazolam may be used for the induction of anesthesia. Awakening times following a benzodiazepine induction are much longer than for either thiopental or propofol, and thus benzodiazepines are rarely used for the induction of anesthesia. As an adjunct to general anesthesia, benzodiazepines provide better amnesia than thiopental. Elderly patients require lower doses of midazolam than younger patients.²⁶ This phenomenon was well illustrated in a series of 800 cases of sedation for upper gastrointestinal endoscopy in which the dose decreased from an average of 10 mg for a 20-year-old patient to 2.4 mg in 80-year-old patients²⁷ (Fig. 21.5).

FIGURE 21.5. The influence of age on the intravenous dose of midazolam required to produce sedation in 800 patients undergoing endoscopic procedures. (Adapted from Bell GD, Spickett GP, Reeve PA, Morden A, Logan RF. Intravenous midazolam for upper gastrointestinal endoscopy: a study of 800 consecutive cases relating dose to age and sex of patient. *Br J Clin Pharmacol.* 1987;23:241–243.²⁷)

Anecdotal evidence suggests that some elderly patients manifest a paradoxical reaction to benzodiazepines, becoming agitated rather than sedated.

Flumazenil is the only available competitive antagonist for the benzodiazepine receptor. In the absence of a benzodiazepine, flumazenil has little discernable effect. When administered to patients who have benzodiazepine-induced CNS depression, flumazenil produces rapid and dependable reversal of unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction.²⁸ There is little substantial information concerning alteration of flumazenil pharmacology for elderly patients. It should be emphasized that flumazenil is rarely used by experienced anesthesiologists, who greatly prefer to titrate the initial drug effect carefully rather than depend on functional antagonism. Repeated doses of flumazenil may be necessary because the effect of the initial benzodiazepine is likely to last longer than that of flumazenil and re sedation may easily occur.

Opioids

The opioids are those endogenous and exogenous substances that bind to the opiate receptors. The principal use of opioids is to provide analgesia, and the primary downside is respiratory depression.

Pain perception is altered with aging, but this does not mean that pain is either less common or less important in the elderly. There is a dramatic decrease in myelinated and unmyelinated nerve fibers in older patients.^{29,30} Elderly patients report pain primarily following activation of C fibers, whereas younger patients require A δ fiber activation before reporting pain.^{31,32} These types of alterations in pain perception, with alterations in pharmacokinetics of analgesics, provide direction for both the anesthesiologist and physicians involved in postoperative pain management.

The most used opioid in modern anesthetic practice is fentanyl, a synthetic opioid with a short half-life. Using EEG, Scott and Stanski observed a 50% decrease in the concentration at which 50% inhibition occurs (IC_{50}) from age 20 to age 85.³³ However, unlike many drugs, the pharmacokinetics of fentanyl are not altered by age, except for a small change in rapid intercompartmental clearance. Thus, the dose of fentanyl is decreased for pharmacodynamic reasons.

Remifentanyl was recently introduced to clinical practice under the new FDA guidelines that require pharmacodynamic and pharmacokinetic evaluation of special populations, including the elderly. Minto et al. reported on the age-adjusted pharmacology in two manuscripts that formed the basis for age-adjusted dosing in the remifentanyl package insert.^{34,35} In addition to a similar pharmacodynamic alteration, the volume of the central compartment decreases about 20% from age 20 to 80,

FIGURE 21.6. The influence of age and weight on remifentanyl dose. The bolus dose should be reduced by 50% in elderly patients, and the infusion rate should be reduced by two-thirds. The dose adjustment for age is considerably larger than the dose adjustment for weight. (Adapted from Minto CF, Schnider TW, Shafer SL. The influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanyl. II. Model application. *Anesthesiology*. 1997;86:24–33, with permission.³⁴)

and the clearance concurrently decreases about 30%. Figure 21.6 presents a series of nomograms that may be used to calculate remifentanyl doses for elderly patients.

Muscle Relaxants

To facilitate endotracheal intubation and provide an optimal surgical field, an anesthesiologist must frequently control muscle tone, which may be accomplished with high concentrations of volatile anesthetic agents. The concentrations necessary to produce an adequate effect are frequently associated with hemodynamic instability. A regional anesthetic technique will provide muscle relaxation for operations amenable to this approach (see following). The third, and by far most common, approach is to utilize agents that disrupt neuromuscular transmission. The available agents are either depolarizing agents, such as succinylcholine, or competitive antagonists such as pancuronium, vecuronium, or atracurium. Depolarizing agents exert the same effect at the neuromuscular junction as acetylcholine, depolarizing the endplate and causing muscle contraction; this is

seen clinically as fasciculation, an uncoordinated contraction of muscle. Because succinylcholine is not eliminated as rapidly as acetylcholine, depolarization of the endplate persists and the muscle remains flaccid for a relatively short period of time (about 2 min). This short-acting phenomenon is frequently used for facilitation of endotracheal intubation and for muscle relaxation during electroconvulsive therapy. Patients frequently complain of muscle soreness following succinylcholine, and it has been associated with rapid, sometimes fatal, increases in serum potassium levels, particularly in patients with recent trauma, extensive burns and possibly hemi or paraplegia.

The competitive antagonists combine with the acetylcholine receptor but do not activate them. Their presence on the receptor prevents access of the transmitter. At sufficient concentration, muscle relaxation occurs. Many different agents have become available in recent years. All manifest a minor increase in duration with age, but doses are not significantly altered. None of these agents should ever be used in the absence of both the equipment and expertise necessary to maintain adequate ventilation.

Regional Anesthesia

A different method of allowing a procedure to proceed without pain and its sequelae is to block the nerve fibers that subserve pain to the region of interest. Neural blockade is produced by local anesthetic agents. All currently available clinically useful agents are either aminoamides or aminoesters. When applied in sufficient concentration at a site of action, these drugs prevent conduction of electrical impulses by the nerve. When these drugs are administered systemically, the function of cardiac, skeletal, and smooth muscle, as well as peripheral and central nerves, is altered. Care must be taken to prevent toxicity that may occur either locally or systemically. The principal forms of acute toxicity affect the CNS (seizures) and cardiovascular system (arrhythmias and sudden death).

Local anesthetics are thought to act by blockade of neural sodium channels that block the conduction of signals along the nerve. The clinically observed rates of onset and recovery from local anesthetic blockade are governed by the relatively slow diffusion of local anesthetic molecules in and out of the nerve, rather than by their binding and dissociation from ion channels. For many years, the prevailing dogma was that minimal alterations in the pharmacokinetics or pharmacodynamics of local anesthetic occurred with aging.³⁶ In recent years, increasing knowledge has refined our understanding of the effects of age on local anesthetic agents; however, the effects are not as prominent as for many of the general anesthetic agents.³⁷

Local anesthetic agents may be used for infiltration anesthesia where the agent is injected into the area

required for a procedure; this is commonly done for small dermal surgeries but may be used for larger areas. Toxicity limits the total dose and therefore the area that may be anesthetized by this method. Intravenous regional anesthesia involves the intravenous infusion of local anesthetic into a tourniquet-occluded limb, almost always the arm; this procedure is called a Bier block. The anesthetic agent diffuses from the vascular space to the surrounding nerve endings. Peripheral nerve blockade techniques inject local anesthetic around specific nerves or nerve trunks that innervate particular areas of the body. Central neural blockade techniques encompass primarily epidural and spinal or subarachnoid anesthesia. Some local anesthetic preparations are available for topical administration. These techniques provide relatively short lived anesthesia for a very circumscribed area of limited depth. Finally, a relatively new technique, called tumescent anesthesia, applies a large volume of dilute local anesthetic into the subcutaneous tissue; this has been used by plastic surgeons for liposuction procedures.

Regional anesthesia is frequently advocated for the elderly patient because of the presumed advantage of reduced stress and less mental confusion in the perioperative period. Unfortunately, no large study has been able to confirm this perception.³⁸ A large international study examining neurocognitive function in patients randomized to regional versus general anesthesia is currently underway, and results should be available in 2003.

Neuraxial Anesthesia

Neuraxial anesthesia involves blockade of nerves within the spinal cord, which may be accomplished by injecting agents into the cerebrospinal fluid that surrounds the spinal nerves in the subarachnoid space. This technique is referred to as spinal or subarachnoid anesthesia. Epidural anesthesia involves the placement of drug in the epidural space, which is the area outside the dural sac but inside the vertebral canal (Fig. 21.7). Despite the apparent similarities, there are significant pharmacologic and physiologic differences between these two techniques. Spinal anesthesia utilizes a small volume of concentrated anesthetic that produces profound anesthesia and very low systemic levels of drug. Although continuous techniques exist, for the most part spinal anesthesia is a one-shot process. Epidural anesthesia requires a larger volume of anesthetic that produces pharmacologically significant blood levels of anesthetic. Epidural techniques are usually associated with the placement of an indwelling catheter, thus permitting long-term anesthesia and analgesia. A recent trend toward combined spinal epidural anesthesia tends to blur the difference.

Spinal anesthesia is the most easily mastered technique and is frequently selected for elderly patients. However,

FIGURE 21.7. Cross-sectional anatomy of the lumbar spine. Needles for neuraxial anesthesia are usually inserted at the lumbar levels, seeking to place medication outside the dura mater, in the epidural space, or directly into the cerebrospinal fluid that is contained in the intrathecal space.

the high incidence of osteoarthritis in the spinal column frequently diminishes flexion and impairs positioning of the patient that is necessary to institute spinal anesthesia. Alterations of the technique are available to facilitate placement of the needle into the subarachnoid space.³⁹ Spinal anesthesia is frequently associated with profound decreases in cardiac output and blood pressure. Young patients may be relatively resistant to hypotension, but patients over 60 years of age frequently manifest 30 to 40 mmHg decrease in blood pressure with anesthetic levels up to the T5 dermatome.^{40,41} Another important complication of spinal anesthesia is the development of a postspinal headache; this can be a severe and debilitating headache that requires that placement of an epidural blood patch, 10 to 20 ml of the patient's blood that must be acquired sterilely and injected into the epidural space near the site of the previous spinal puncture. Fortunately, spinal headache is principally a complication of younger patients and is relatively rare in the elderly.

Epidural techniques require similar modifications to cope with the anatomic alterations of age.³⁹ Dosage may be slightly decreased to compensate for increased permeability of the dura mater, and the onset of anesthesia may be somewhat more rapid.

In addition to local anesthetics, opioids are frequently administered into either the subarachnoid or epidural space as a means of pain control.

TABLE 21.2. Types of operations undertaken with nerve blocks.

Nerve or trunk	Area of operation
Cervical plexus	Carotid endarterectomy
Brachial plexus	Shoulder operations
Optic nerve	Eye surgery
Axillary nerve	Lower arm surgery
Femoral nerve ^a	Upper leg
Popliteal nerve	Below-knee surgery
Ankle block ^b	

^a Sometimes combined with sciatic and obturator blocks for leg surgery.

^b Ankle block involves the deep and superficial peroneal, saphenous, sural, and posterior tibial nerves.

Nerve Blocks

Blockade of specific nerves or nerve trunks may be accomplished by injecting local anesthetic agents around the nerve. Examples of operations of the area subtended by specific nerves are listed in Table 21.2.

Sedation

"Sedation and analgesia describes a state that allows patients to tolerate unpleasant procedures while maintaining adequate cardiorespiratory function and the ability to respond purposefully to verbal command and tactile stimulation."⁴² Sedation is a frequent accompaniment to regional anesthetic techniques or may be used to facilitate minor procedures that do not require full anesthesia, such as endoscopy. Sedation/analgesia is preferred to the more common term "conscious sedation," which is difficult to define. The American Society of Anesthesiologists supports a practice guideline development process based on evidence linkages from exhaustive literature reviews and expert opinion from 60 to 150 external consultants. The Task Force on Sedation and Analgesia published their work in 1996.⁴²

Recommendations for sedation/analgesia include a patient evaluation and preprocedure preparation, including fasting. The patient should be monitored, and a record of the monitored parameters should be maintained. The patient's level of consciousness may be assessed using spoken responses. Patients whose only response is reflex withdrawal from painful stimuli may be approaching a state of general anesthesia. Sedation/analgesia is expertly performed by many medical practitioners; however, general anesthesia should be administered by trained anesthesia personnel. Respiratory activity can be monitored by observation of spontaneous respiration, auscultation of breath sounds, but other methods, such as detection of exhaled carbon dioxide, may be required if access to the patient is limited, such as in a CAT scan bay. Although there are insufficient data to support regular monitoring of blood pressure and heart rate or electro-

cardiogram (ECG), most experts suggest vital sign monitoring for patients undergoing sedation/analgesia. ECG is recommended only for patients with cardiovascular disease. Acknowledging that patients at the extremes of age or with severe cardiac, pulmonary, hepatic, or renal disease are at increased risk for developing complications related to sedation/analgesia, no specific recommendations were advanced by the expert panel to address sedation/analgesia in the elderly.

Choice of Anesthetic Technique

The choice of anesthetic techniques for any given patient is the province of the anesthesiologist. Notations in a medical chart indicating that a patient should undergo one or the other type of anesthesia are inappropriate and place the practitioner in the unfortunate position of conducting an argument in a medical record. An excellent review of the issues associated with choosing anesthetic techniques for elderly patients was recently compiled by Roy.⁴³ Although there are theoretical considerations and clinical perceptions that regional anesthetics should be safer for elderly patients than general anesthetics, most major studies fail to support this idea. A recent meta-analysis, not focused on elderly patients, concluded that, "Neuraxial blockade reduces postoperative mortality and other serious complications. The size of some of these benefits remains uncertain, and further research is required to determine whether these effects are due solely to benefits of neuraxial blockade or partly to avoidance of general anaesthesia."⁴⁴ There is a developing consensus that overall perioperative care, as opposed to the choice of anesthetic technique, is more likely to have a positive impact on the elderly surgical patient.⁴³

Indications for Intraoperative Monitoring

Blood pressure, ECG, and oxygen saturation should be monitored in all elderly patients undergoing any procedure. Automated blood pressure cuffs are common and accurate. The measurement should be made at least every 5 min. Accurate reading may be difficult in patients with highly irregular cardiac rhythms. Application of the cuff should be done with care in frail individuals, who may require a thin layer of webril padding to protect the skin. The ECG should be configured to observe both p waves and the lateral wall of the left ventricle (i.e., II and V5, or MCV1). The pulse oximeter measures oxygen saturation of arterial blood using a probe that is typically placed on the finger. Frequently, signal quality is inadequate due to a decrease in pulsatile flow. The probe can be repositioned, or other forms of probes can be used on other

anatomic sites, such as ear lobes. Anesthesia or sedative drugs should not be administered in the absence of a satisfactory pulse oximeter reading. For lengthy procedures, a urinary catheter is usually needed to monitor urine output. If the operative field involves the pelvis, draining the bladder often aids operative exposure.

Temperature should be measured and recorded during all major operations because significant hypothermia is a common sequela of a long procedure, particularly when the viscera are exposed. After a complicated operation, a core temperature of 32.2° to 35°C (90°–95°F) can occur. Many elderly patients begin with lower core temperatures. The importance of maintaining temperature is due to the metabolic cost of rewarming the body. Elderly patients do not maintain temperature as well as young patients, and the mechanisms used to increase body temperature, such as shivering, can require excessive portions of a patient's oxygen consumption. Severe hypothermia [$<31.5^{\circ}\text{C}$ (89°F)] is associated with cardiac dysrhythmias. Core temperature is commonly measured with either an esophageal or rectal temperature probe. During large operations, measures to maintain a reasonable body temperature are essential. Convection warming systems operate like a large hair dryer, inflating a blanket that directs warm air over the patient's body. Intravenous fluids can be warmed, the operating room can be maintained at a reasonable ambient temperature, the abdominal viscera can be maintained in the abdominal cavity as long as possible, and lavage fluids can be warmed. In spite of these attempts, patients may lose significant body heat. Elderly patients emerging from general anesthesia should not be extubated until body temperature is within 0.5°C of their baseline core body temperature. End-tidal carbon dioxide measurement is used to evaluate ventilation and should be used whenever intubation is required.

For larger or prolonged surgeries, invasive monitoring should be considered. Continuous peripheral arterial blood pressure measurement may be taken by placing an intra-arterial catheter in the radial artery and connecting it to a transducer. Other arterial sites include the axillary and femoral arteries. Both radial arteries should be palpated before selecting a cannulation site to be sure that they are equal. If blood flow to one limb is diminished, the arterial monitor should be placed elsewhere. The advantages of continuous monitoring include beat-to-beat blood pressure information and the ability to acquire multiple blood samples without further venipuncture.

Central venous pressures can be monitored with a catheter placed in an intrathoracic vein, such as the superior vena cava. With major limitations, these pressures reflect intravascular volume, which is very important when the cardiovascular system responds primarily to Starling forces, rather than altering heart rate and contractility (see Chapter 39). The normal pressure is 8 to 10 mmHg. Lower pressures generally indicate the need for blood or fluid

replacement; elevated pressures may occur with right ventricular or biventricular heart failure. Pulmonary arterial hypertension secondary to pulmonary disease, high bronchial airway pressure, and right ventricular failure may elevate central venous pressure out of proportion to the left ventricular end-diastolic pressure and volume. Such an elevation suggests adequate blood volume when, in fact, blood volume is inadequate. If major blood loss or fluid shifts (e.g., major peritoneal dissections) occur, central venous pressure should be instituted from the outset of surgery. If a patient shows signs of hypovolemia, tachycardia (which may not occur), hypotension, or decreased urine output, isotonic fluid should be administered in bolus form (250–500 ml in ≤ 10 min, as tolerated). If signs fail to resolve with one or two bolus infusions, placement of a central venous catheter is indicated. In addition, a central catheter may be indicated for venous access if irritating medications need to be administered or if the patient has difficulty maintaining a peripheral intravenous line for multiple days.

The next level of monitoring is the use of balloon-tipped pulmonary artery catheter (PAC), which is passed through the right ventricle into the pulmonary artery. Occluding a small pulmonary artery with the flotation balloon allows measurement of the pulmonary capillary wedge pressure (PCWP). This measurement removes any right ventricular and most pulmonary artery contribution to the pressure measurement. Normal PCWP is 4 to 12 mmHg. PACs also allow measurement of cardiac output and mixed venous blood gas analysis, which can be useful in managing hemodynamics. Patients with severe cardiac dysfunction and patients in whom the CVP is high when other signs suggest hypovolemia should be considered for PAC monitoring. In left ventricular failure, wedge pressures may rise to 40 mmHg or more. These measurements are particularly valuable guides to intraoperative management of fluid replacement therapy and management of cardiac inotropic activity and peripheral vascular resistance when vasopressor support is used in patients with cardiac dysfunction. When available, this level of monitoring can be supplemented or replaced by the use of transesophageal echocardiography.

Intraoperative fluid replacement should be carefully considered, providing maintenance fluids and replacing lost blood and fluids. The elderly may have difficulty eliminating any excess fluid because of exaggerated or prolonged aldosterone and antidiuretic hormone (ADH) responses postoperatively.

Conclusion

Anesthesiology has followed the general specialty of geriatrics in developing a wealth of information that can be brought to bear on the care of elderly surgical patients. This chapter provides an overview of some of the issues

associated with anesthetic care of the elderly. Interested readers are referred to a number of recent publications that expand greatly on the knowledge presented here.^{45–47}

Surgical Approaches to the Geriatric Patient

Ronnie Ann Rosenthal

Operative Outcomes

Surgery, as a therapeutic alternative, has an essential role in the medical care of the geriatric patient. Certain types of cancer, coronary artery disease, and arthritis, common diseases that accompany aging, can be effectively treated and often cured by operation. Yet concern about the risk of surgery in patients with diminished reserves and multiple comorbid illnesses, although sometimes warranted, may prevent the appropriate referral of older patients for this care. With careful attention to detail and an understanding of how elderly patients differ from younger patients, many of these hazards can be at least partially avoided (see Chapter 13 and 20).

Changing Patterns of Surgical Care

It should be emphasized that reluctance to offer surgical treatment at a point in time when elective operation can be conducted with minimal risk leaves the patient vulnerable to progression of the disease. As a consequence, emergency surgery may become necessary at some point in the future when reserves are further compromised. Operative mortality and morbidity increase at least threefold when surgery is performed under emergent rather than elective conditions, almost regardless of the type of procedure. In a series of 42 operative procedures in 31 men and women over age 100 years, all the perioperative deaths occurred in patients requiring emergency operation.¹ However, the percent of operations done on an emergent basis in patients over age 85 is twice that of patients under age 65.

As the size and general health of the population over age 65 has increased, attitudes toward surgery in older patients have become more liberal. Discharge data from acute care hospitals in the United States² show that the portion of all operations performed in which the patient is over age 65 has increased from 19% in 1980 to 36% in

1998. When obstetric procedures are excluded, the percentage increases to 43%. The distribution of common operations performed on the elderly in 1998 is shown in Table 22.1: 38% of cholecystectomies, 56% of coronary artery bypass grafts, 60% of bowel resections, and 67% of total joint replacements. It is now estimated that at least 50% of patients in most general surgical practices are over age 65.

The pattern of surgical management of malignant disease in the elderly is an example of the changing views on surgery in this age group. Using data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program, Farrow et al.³ compared operative percentages for various cancers by age in three time periods: 1973–1978, 1979–1985, and 1986–1991. With increasing age, there was a persistent decline in the percentage of patients receiving surgical treatment for cancer. However, the gap between younger and older patients narrowed over the three time periods for certain cancers. The likelihood of receiving surgery when indicated for cancers of the breast, ovary, uterus, colon, and rectum increased more rapidly among patients over age 75 than in those younger than 55 (Fig. 22.1). For cancers that required extensive surgery and for those from which survival is poor even with surgery, there was less of a change, even for early-stage disease (Fig. 22.2). At present, it is still unclear whether this is the result of appropriate decision making based on the overall health of the patient and the patient's preference for treatment or a consequence of unfounded age bias.

The increased willingness to consider surgery in the elderly patient is also a reflection of the improvements in surgical and anesthetic techniques that presently allow us to operate safely on even the oldest patient. With the question of "can we operate?" less of an issue, the question "should we operate?" becomes the principal concern. To answer this question, we must understand the goals and expectations of treatment in the context of the individual patient.

TABLE 22.1. Common operations performed on elderly patients.

Operation	Total patients ($\times 1000$)	Patients of age >65	Percent (%)
Coronary bypass	553	304	55
Total joint replacement	426	286	67
Open reduction and Internal fixation	416	184	44
Cholecystectomy	438	165	38
Large bowel resection	242	146	60
Lysis of adhesions	310	87	27
Appendectomy	278	16	5

Mortality and Morbidity

For surgeons, the traditional measures of outcome have always been postoperative mortality and morbidity, with mortality used as the endpoint in the determination of “operative risk.” For the elderly patient, however, restoration of functional capacity to at least the preoperative level and quality of life may be far more important considerations than survival alone. It is shown that when the perioperative course in an elderly patient is uncomplicated, results are nearly indistinguishable from those of younger patients. However, when a complication occurs, the elderly are far less able to muster the reserves to overcome the complication without significant overall decline. Strategies to improve surgical care for the elderly, therefore, should be designed to identify and address concomitant diseases that predispose to complications, thereby minimizing the influence of these factors on all outcome measures. Chapter 20 details the essential considerations in the preoperative assessment and perioperative care of the aged patient. With careful attention to the details described therein, surgical care can

be provided with excellent results in a cost-effective manner.

In the recent debates over containing rising health care costs, this latter consideration has gained attention. The efficacy and cost-efficiency of major surgery as a treatment modality for the elderly is demonstrated in a recent study of coronary artery bypass surgery versus medical management in octogenarians. Outcome was assessed in terms of cost and quality life-year survival.⁴ The cost of surgical care per quality life-year saved was only \$10,424, less than the cost for many common procedures such as screening mammography. The survival in the surgery group was 80% and 69% at 3 and 4 years, respectively, whereas in the medical group, comparable survival was 64% and 32%. Using a validated health status assessment tool, the EurQol Questionnaire,⁵ the authors assessed the quality of life in five domains: pain, activity, mobility, self-care, and depression/anxiety. In all areas, quality of life was better in the surgically treated than in the medically treated groups. Quality of life in the group of 80-year-old patients who selected Coronary Artery Bypass Grafting (CABG) was found to be equal to that of an average 55-year-old in the general population.

Unfortunately, data on functional outcomes for surgical procedures that are not specifically designed to improve functional outcome, as are coronary revascularization and joint replacement, are not yet abundant. Where available, these data are included with the more traditional data on operative outcomes of mortality and morbidity.

Reviews of several series of operative procedures in elderly patients have reported a decline in overall operative mortality over the past several decades, from 10% to 25% in the 1960s to less than 5% in 1990s.⁶ The reason for this is unclear. Series of this kind are primarily retrospective with a wide variety of procedures from a wide

variety of institutions and without standardized methodology to allow comparison among of the patient groups for comorbidity and severity of illness.

Prospective data on declining postoperative morbidity and mortality over the past decade, adjusted for the risk imposed by comorbidity and other pre- and intraoperative factors, can be found in the National VA Surgical Quality Improvement program (NSQIP).⁷ Since 1991, this program has been prospectively collecting data on patient risk and surgical outcome from 44 Veterans Affairs Medical Centers across the country. The study was designed to provide risk-adjusted mortality and morbidity figures for the comparison of surgical care across institutions in the VA Hospital system. At present, there are more than 1 million cases enrolled in the database. Although this study was not designed to look at older patients specifically, nearly half the patients are over age 65 because of the nature of the VA population. Interrogations into the data to obtain age-specific data are presently underway.

From 1991 to 1999, overall postoperative mortality in the NSQIP population has fallen from 3.1% to 2.4%, and overall morbidity has decreased from 17.6% to 9.6%, while the mean age of the patients has increased slightly from 60.1 to 60.6 years.⁸ Complication rates in this study appear to increase as a function of age, from 7.1% in patients less than 65 years of age to 17.6% for those over age 85. Risk-adjusted complications rates as a function of age are not yet available; however, it is likely that this increase in morbidity is in great part related to patient comorbidity rather than chronologic age alone.

Better data on the effect of age specifically on mortality can be found by looking at the results of a single type of

operation. In one such study⁹ examining the results of open cholecystectomy in the prelaparoscopic era in 21,000 elderly patients, mortality clearly increased with increasing age, from 0.7% in patients aged 65 to 69 years to 7.5% in those over age 85 (Table 22.2). However, increasing comorbidity with age, rather than chronologic age alone, was shown to be responsible for this effect. Similar results can be found in studies of other procedures.

Pathophysiologic Considerations

Aging influences surgical outcome in two major ways: first, because of the increased incidence of comorbid disease, and second, because of changes in the presenta-

tion and natural history of the primary surgical disease. Although the latter is far less well characterized, each plays an extremely important role.

Effect of Aging on the Surgical Patient

A thorough review of the importance of comorbid conditions on surgical outcome can be found in Chapter 20. Here, however, we address four general factors that are of particular importance because they are either sensitive predictors of outcome (functional capacity and nutritional status) or are subtle and difficult to quantitate (cognitive status and wound-healing capacity).

Functional Status

For decades, the American Society of Anesthesiologists (ASA) Physical Status Classification has been one of the most reliable and accurate predictors of surgical mortality. This simple classification ranks patients according to the functional limitations imposed by coexisting disease (see Chapter 20). Curves for mortality versus ASA class in older patients are nearly superimposable on those of younger patients¹⁰; even in patients over age 80, ASA classification has been shown to accurately predict postoperative mortality.¹¹ Data from the NSQIP study indicate that ASA classification ranks as either the first or second most predictive factor for mortality and among the top three for morbidity for all types of surgical procedures combined.¹²

Other standard measures of functional status have also proven to be predictive of postoperative outcome. The ability to perform the activities of daily living (ADL) has been correlated with postoperative mortality and morbidity.¹³ In one study, patients identified as inactive were

shown to have a higher incidence of all major surgical complications (Fig. 22.3).¹⁴ Inactivity was defined as the inability to leave the home by one's own efforts at least twice a week. In another study of noncardiac surgical cases, mortality in patients with severely limited activity was 9.7 times higher than in active patients.¹⁵ In this study, limited activity was defined as confined to bed or, at maximum, able to transfer from bed to chair. Of the risk factors studied, inactivity was found to be the strongest single predictor of death.

Preoperative functional deficits contribute to postoperative immobility, with associated complications such as atelectasis and pneumonia, venous stasis and pulmonary embolism, pressure ulcers, and multisystem deconditioning. Deconditioning is an important clinical entity characterized by depression and lethargy; anorexia and dehydration; neuromuscular instability, decreased bone density, muscular weakness, and incoordination; altered bladder and bowel function with retention and constipation; and urinary and fecal incontinence. Deconditioning leads to further functional decline despite improvement in the acute illness.¹⁶ The recovery period from deconditioning after surgery can be three or more times longer than the period of immobilization that led to the decline (see Chapter 13).

Even for patients with less obvious limitations, functional capacity as demonstrated by exercise tolerance is the single most important predictor of cardiac and pulmonary complications following noncardiac surgery. In a study comparing ASA criteria, several other objective clinical risk measures, and exercise tolerance, Gerson et al. demonstrated that the inability to raise the heart rate to 99 beats/min while doing 2 min of supine bicycle exercise was the most sensitive predictor of both postoperative cardiac and pulmonary complications and death.^{17,18}

TABLE 22.3. Estimated energy requirements for various activities.

1 MET	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2–3 mph or 3.2–4.8 km/h? Do light work around the house like dusting or washing dishes?	4 METs	Climb a flight of stairs or walk up hill? Walk on level ground at 4 mph or 6.4 km/h? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football? Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

A recent study in which oxygen consumption was quantitated during exercise demonstrated that subjects unable to increase oxygen delivery by threefold over basal levels during exercise were unable to meet the metabolic demands of surgical stress and therefore had much higher rates of postoperative cardiac ischemia and death.¹⁹ Energy requirements for many types of activities have already been determined in terms of metabolic equivalents (METs), with one MET being equal to the basal oxygen consumption of a 40-year-old, 70-kg man at rest.²⁰ Using a simple questionnaire about activity level,²¹ a quantitative estimate of the ability to meet the metabolic demands of surgery can be determined (Table 22.3).

Nutritional Status

Nutrition is an extremely important factor in surgical care, so much so that surgical nutrition is a topic in the curricula of all surgical residency training programs. In fact, the scientific basis and clinical development of total parenteral nutrition (TPN) was largely the work of one famous surgeon, Dr. Stanley Dudrick. Yet, the presence and importance of preoperative malnutrition in the elderly surgical patient is often not appreciated. Surgeons rarely perform more of a nutritional assessment than querying weight loss.

Physiologic dysfunctions, comorbid conditions, and a variety of psychosocial issues common to the elderly place this population at high risk for nutritional deficits. Malnutrition occurs in approximately 0% to 15% of community-dwelling elderly persons, 35% to 65% of older patients in acute care hospitals, and 25% to 60% of institutionalized elderly.²² Factors that may lead to inadequate intake and utilization of nutrients include the ability to get food (e.g., financial constraints, availability of food, limited mobility), the desire to eat food (e.g., living situation, mental status, chronic illness), the ability to eat and absorb food (e.g., poor dentition, chronic gastrointestinal problems such as gastroesophageal reflux disease or diarrhea), and medications that interfere with appetite or nutrient metabolism (Table 22.4).²³

Although complete assessment and specific markers are necessary to identify deficits and direct correction, simple measurement of the body mass index [BMI = weight in kilograms/(height in meters)²] is a useful guide. It is generally accepted that a BMI between 24 and 29 is appropriate for persons over age 65. The Subjective Global Assessment (SGA) is one relatively simple, reproducible tool for assessing nutritional status from the history and physical exam.²⁴ SGA ratings are most strongly influenced by loss of subcutaneous tissue, muscle wasting, and weight loss. In a study of patients undergoing elective gastrointestinal surgery, both SGA and serum albumin were predictive of postoperative nutrition-related complications.²⁵

In the face of stress from either illness, injury, infection, or even elective surgery, in nutritionally compromised elderly patient quickly develops protein-energy malnutrition. This metabolic response to the release of cytokines and hormones is characterized by increased requirements for energy and protein. The increased catabolism, however, is not matched by increased intake because of anorexia or other limitations to ingestion imposed by the disease process. When exogenous energy is not provided, endogenous protein stores are mobilized

TABLE 22.4. Historical findings associated with an increased risk of nutritional deficiency.

Recent weight loss
Restricted dietary intake
Limited variety, food avoidances
Psychosocial situation
Depression, cognitive impairment, isolation, economic difficulties
Problems with eating, chewing, swallowing
Previous surgery
Increased losses due to GI disorders such as malabsorption and diarrhea
Systemic disease interfering with appetite or eating (chronic lung, liver, heart and renal disease, abdominal angina, cancer)
Excessive alcohol use
Medications that interfere with appetite or nutrient metabolism

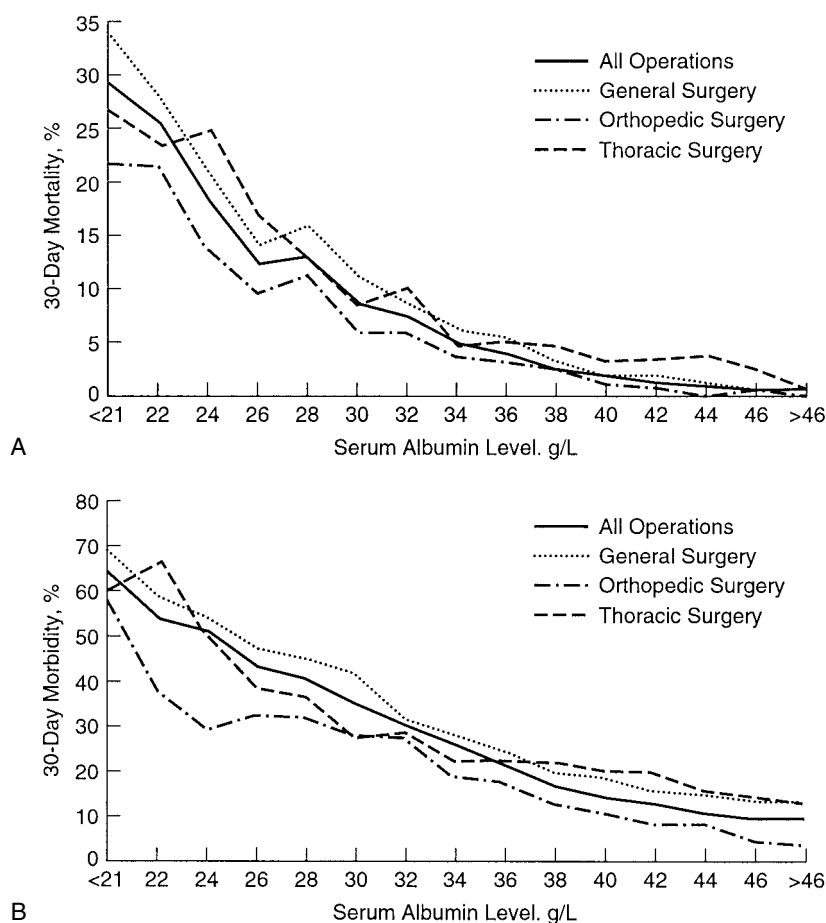

FIGURE 22.4. Thirty-day mortality rate (A) and morbidity rate (B) as a function of serum albumin for all operations combined and for three sub-specialties. (From Gibbs et al.,²⁸ with permission.)

and depleted to meet the metabolic demands. Serum albumin levels fall and hepatic function declines, further impairing endogenous protein synthesis. Dysfunction in those tissues with high cell turnover (the skin, the hematopoietic and immune system, and gastrointestinal organs) leads to breakdown in barrier function, increased susceptibility to infection, and further impairment of absorption of essential nutrients.²⁶ This cycle of worsening nutrition is compounded by dehydration, as the thirst drive declines with advancing age as well.

In the elderly surgical patient with protein-energy malnutrition, these changes are further aggravated by the increased energy requirements for wound healing. Additional deficits in vitamins, particularly A and C, and in trace minerals such as zinc can adversely affect enzyme systems necessary for wound repair. Further, major tissue injury and sepsis is associated with large fluid shifts and sequestration of extracellular water in the interstitial space. Compared to a younger patient, the mobilization of this fluid is delayed following large-volume resuscitation in the elderly. It is postulated that this prolonged sequestration is related to alterations in the structural elements of the interstitium with age and sepsis, which are exacerbated when endogenous

protein stores are depleted and protein synthesis is impaired.²⁷

It should not be surprising that low serum albumin is a very sensitive predictor of complications and deaths for the hospitalized elderly whether hospitalization is the result of medical or surgical illness. In a subgroup of data from the NSQIP study mentioned earlier, both 30-day operative mortality and overall morbidity clearly rose as a function of declining serum albumin for a variety of different types of operations (Fig. 22.4A,B).²⁸ The incidence of several major infectious complications, including pneumonia and systemic sepsis, were approximately four times higher in patients with albumin levels below 3.5 g/dL when compared to those with higher albumin levels.

Cognitive Function

The importance of cognitive status as a determinant of surgical outcome is also underappreciated. Most surgeons do not perform tests of cognition before surgery, even when cognitive decline is a reported consequence of the procedure, as it is in cardiopulmonary bypass. Yet, a change in mental status postoperatively is frequently the first clinical sign of other serious complications, and

TABLE 22.5. Association of postoperative delirium with other surgical outcomes.

Outcome	Delirium		<i>p</i>
	Yes (<i>n</i> = 117)	No (<i>n</i> = 1124)	
Major complication	18 (15%)	28 (2%)	<0.001
Death	5 (4%)	3 (0.2%)	<0.001
Mean length of stay (days)	15	7	<0.001
Discharge to long-term care or rehabilitation facility	43 (36%)	136 (11%)	<0.001

Source: From Marcantonio et al.,²⁹ with permission.

the occurrence of delirium in the postoperative period has a significant negative effect on all the markers of outcome. In one study,²⁹ mortality was increased 17 fold, major complications were increased 7 fold, length of stay was doubled, and patients returned to independence only one-third as often (Table 22.5). In another subgroup of patients from the NSQIP study undergoing operations for rectal cancer (mean age, 66 years), acute confusion was also associated with a number of other complications. Postoperative pneumonia, unplanned intubation, and failure to wean from the ventilator were 14.3, 15, and 5.7 times more likely to occur, respectively, in patients with cognitive changes than in those without. The chance of death within 30 days was 8.1 times higher in patients with delirium.

The impression that the cognitive consequences of surgery and anesthesia are transient recently has been disproven; deficits can persist for months, even years, after the operative event. One prospective study of non-cardiac surgery patients over age 60 years demonstrated that cognitive deficits persisted in nearly 10% of patients for more than 3 months after hospital discharge.³⁰ In another study of coronary artery bypass patients of mean age 61 years, the incidence of cognitive decline was 53% at discharge, 36% at 6 weeks, 24% at 6 months, and 42% at 5 years.³¹

Postoperative delirium may be the manifestation of unrecognized preexisting disease or the result of intra- or postoperative events. Over the past several years, several studies have attempted to identify risk factors for delirium in hospitalized elderly surgical and medical patients. Although the results vary somewhat with the reasons for hospitalization, type of surgery, and the variables studied, age, polypharmacy, preoperative cognitive impairment, and poor functional status are among the most frequently associated factors.

A “predictive rule” for postoperative delirium has been developed from a large prospective study of major elective noncardiac surgery patients over age 50 years.²⁹ Independent correlates for postoperative delirium in this study included age over 70 years; self-reported alcohol

abuse; poor cognitive function; poor functional status; markedly abnormal serum sodium, potassium, or glucose; aortic aneurysm surgery; and noncardiac thoracic surgery. A point system was devised to quantify these factors. Postoperative delirium developed in 2% of patients with 0 points; 8% with 1 point; 13% with 2 points; and 50% with more than 3 points.

Intraoperative and postoperative factors have also been studied. No association has been found with the route of anesthesia, epidural versus general,^{32,33} or the occurrence of intraoperative hemodynamic complications. Intraoperative blood loss, the need for blood transfusion, and postoperative hematocrit below 30%, however, are associated with a significant increased risk of postoperative delirium.³³ Alteration in the sleep-wake cycle following surgery has also been associated with delirium.³⁴ In nonsurgical hospitalized elderly patients, independent precipitating factors for delirium include malnutrition, the use of physical restraints, the use of bladder catheters, the need for more than three medications, and any iatrogenic event during hospitalization.³⁵ These factors no doubt have similar influence on the incidence of delirium in elderly postoperative patients.

Specialized hospital programs designed to maintain functional status and minimize delirium in the elderly with medical illness have had a positive effect on outcome. In one such program entitled Hospital Elder Life Program, Inouye and colleagues³⁶ used a multicomponent strategy with standard protocols to manage six risk factors for delirium in hospitalized medical patients: cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration. With this strategy, they were able to reduce the number of episodes of delirium and prevent cognitive and functional decline in at-risk older patients. This strategy, with minor modification, is presently under investigation as a method for reducing delirium and related complications among elderly postoperative patients.

Wound Healing

Wound healing is a complex constellation of coordinated events requiring adequate nutrition, adequate perfusion, and immunocompetence to support the cellular mechanism of tissue repair. Many of the processes involved in normal wound healing are susceptible to the changes of aging. Although it is generally thought that wounds in the elderly heal more slowly, this impression is largely unsubstantiated. Actual clinical differences in wound healing have been difficult to demonstrate because of myriad interacting and uncontrollable factors. Certain changes in the skin, subcutaneous tissue, muscle, and bones are documented,³⁷ but the effect of these changes, and others, on the orchestrated process of tissue repair is more

elusive. Although tissue friability and easy inadvertent injury are observed in the elderly, as they are in infants and small children, the quantitation of these observations is lacking. A brief review of normal wound healing and the changes observed in the elderly is presented. It is more likely, however, that comorbidity with poor perfusion, poor nutrition, and immunosuppression rather than physiologic decline alone is responsible for most clinically relevant wound problems seen in elderly surgical patients.

Normal wound healing is described in three overlapping phases: inflammation/coagulation, proliferation, and remodeling. In large healing wounds, fibrinous exudate and eschar represent the inflammatory phase; granulation tissue, the proliferative phase; and contracting edges, the remodeling phase.³⁸

The initial response to tissue injury is hemostasis and inflammation. When endothelial disruption occurs, platelets exposed to collagen adhere, aggregate, and release coagulation factors, vasoactive amines, and many of the cytokines essential for coordination of ensuing events. A fibrin mesh is formed that traps platelets, RBCs, and inflammatory cells and seals the wound. Increased capillary permeability from histamine, serotonin, and bradykinin release from platelets and mast cells facilitates diapedesis of lymphocytes, macrophages, and neutrophils in response to chemotactic factors such as interleukin-1 (IL-1), transforming growth factor-beta (TGF- β), and platelet-derived growth factor (PDGF) produced by platelets and macrophages. By 24 h, activated neutrophils predominate; they scavenge debris and phagocytize and kill bacteria. In the process, however, oxidative bursts and release of proteases may further damage surrounding uninjured tissue. Removal of as much nonviable tissue as possible limits the extent of neutrophil migration and subsequent inflammation and scarring. When there is extensive bacterial contamination, macrophages process necrotic material and bacteria for presentation to lymphocytes. These, in turn, proliferate and release cytokines, including interferon- γ and IL-2, which stimulates the antimicrobial activities of monocytes and inhibits their migration out of the wound. Lymphocytes have a smaller role in less-contaminated wounds.³⁸

By 48 h, macrophages progressively replace neutrophils. In response to debris, fibrin, low tissue oxygen tension, and high lactate levels, macrophages release the large array of cytokines and growth factors essential for repair; these include IL-1, IL-6, IL-8, tumor necrosis factor-alpha (TNF- α), TGF- β , insulin-like growth factor (IGF-1), fibroblast growth factor (FGF), and epidermal growth factor (EGF), which stimulate migration and proliferation of fibroblasts and endothelial cells.³⁹ As TGF- β increases, fibroblasts are stimulated to synthesize

collagen and proteoglycans, and the proliferative phase begins.

The proliferative phase is characterized by fibroplasia, angiogenesis, and epithelialization. By 72 h, fibroblasts have begun to proliferate and synthesize collagen and proteoglycan elements of the extracellular matrix. FGF stimulates the angiogenesis cascade and hypoxia, and TNF- α , among other growth factors, stimulates the migration and proliferation of endothelial cells. Extracellular matrix materials such as fibronectin, hyaluronic acid, laminin, and fibrin form the framework on which new vessels can form. Epithelial cells migrate from the margin of the wound or from the bottom of epithelial-lined skin appendages as an intact sheet, facilitated by matrix material and endogenous proteases. Reepithelialization restores the barrier function.

Remodeling is the prolonged phase characterized by collagen synthesis, remodeling, and wound contraction. By 9 days, collagen synthesis declines as fibroblasts begin to disappear, neovascularity regresses, and mature scar is formed. Wound strength continues to increase from 1 to 6 weeks as collagen is cross-linked. Although this cross-linking increases strength and contraction, it renders the scar less elastic than unwounded skin.

Changes in wound healing with aging have been identified in each phase, but the translation of these changes into consistent clinical findings is not clear. Changes in coagulation and immune function with age might be expected to have a detrimental effect on the early events in wound healing. In a study of experimental human wounds, there was an exaggerated peak of neutrophils early in the inflammatory phase with a delay in the appearance of macrophages and lymphocytes.⁴⁰ In young mice, 7-day-old wounds showed mature granulation tissue and few inflammatory cells while those of older animals were still in the inflammatory phase.⁴¹ Platelet and macrophage adherence to substrate seems to increase with age, whereas there is a decline in macrophage function in mice and humans.^{42,43} In other experiments, the addition of macrophages from young animals to the wounds of old animals accelerated the healing rate.⁴⁴

In addition, T-cell-mediated functions decline with age; there is a decreased proliferative capacity, decreased cytotoxic activity, and a decreased release of IL-2. This decreased release of IL-2 may further impair monocyte efficiency.³⁹

In the proliferative phase, there is a deficit in the cellular responsiveness to certain cytokines, with decline in motility and proliferation of fibroblasts.^{45,46} The rate of epithelialization of open wounds has been shown to be delayed in older patients compared to younger patients.^{47,48} A few studies have demonstrated changes in angiogenesis, and there is a consensus that aged endothelium has a reduced proliferative capacity. The expression

of endothelial adhesion molecules is also delayed with increasing age in human wounds.⁴⁰

There are contradictory data on changes in collagen synthesis in the remodeling phase with age. In one study of experimental human wounds, the collagen content of wounds appeared equal regardless of age, but the accumulation of noncollagenous proteins was decreased in the older group.⁴⁷ Others report variations in collagen content, and there is no consensus. The breaking strength of some wounds may be lower in older animals,⁴⁹ but age alone does not suppress experimental anastomotic healing in the intestines.⁵⁰

Improving wound healing in the elderly is not primarily directed at the cellular events identified above but at the comorbid conditions that cause hypoperfusion and subsequent tissue hypoxia, immunosuppression, and inadequate nutrition. Sufficient tissue perfusion to allow appropriate delivery of nutrients and oxygen to the wound is of paramount importance. In the elderly, conditions such as diabetes, congestive heart failure, arteriosclerosis, and venous insufficiency commonly compromise this perfusion.

Growing evidence supports the importance of adequate tissue oxygenation for the biochemical and cellular aspects of wound healing and infection control. Collagen synthesis requires oxygen as a cofactor, and the rate of collagen deposition is directly proportional to oxygen tension in the wound.⁵¹ The enzymatic hydroxylation of proline and lysine residues on forming collagen chains also requires oxygen. Inadequate hydroxylation of proline results in instability of the collagen molecules and decreased strength of the resulting scar.⁵² Collagen content in subcutaneous test wounds of general surgery patients has been shown to correlate with tissue oxygen tension during the first 48 h after surgery.⁵¹ In animals, angiogenesis⁵³ and the rate of epithelialization⁵⁴ are accelerated in hyperoxic environments. In addition, the rate of healing of ischemic wounds in old animals is impaired by 40% to 65% compared to that of younger animals.⁵⁵

Local wound infection is the most significant cause of impaired wound healing. The inflammatory response to infection further increases the inflammatory phase of wound healing and disrupts the balance toward collagen degradation rather than synthesis. Bacterial control in wounds is also an oxygen-dependent process. The ability of leukocytes to effectively kill bacteria requires local tissue oxygen tension of 30 mmHg or more.⁵⁶ In a study of general surgery patients, wound infections occurred in 43% of those with measured tissue oxygen tension of 40 to 50 mmHg compared to 0% in those with tissue oxygen tension over 90 mmHg.⁵⁷

Systemic sepsis, in addition to local infection, can also interfere with proper wound healing. In one study, experimental systemic sepsis impaired collagen synthesis,

resulting in defective healing of bowel anastomoses and reduced anastomotic bursting strength.⁵⁸ Transient bacteremia from instrumentation of the oropharynx, trachea, and urinary tract in the perioperative period may seed newly created wounds. Eliminating possible sources of local wound contamination and eradicating all treatable infections before any elective disruption of tissue can decrease the incidence of wound complications. The high prevalence of bacteriuria in the elderly (approximately 20% in men and 20%–50% in women over age 80 years), most of which is asymptomatic, mandates preoperative microscopic exam of the urine followed by culture/sensitivity and treatment if positive.⁵⁹ The colonization of the oropharynx with gram-negative bacteria may predispose to gram-negative pneumonia postoperatively, although the clinical relevance to postoperative infection is not well established.

Adequate tissue perfusion and oxygenation require appropriate hydration. Increasing volume resuscitation as a therapy to improve wound healing has recently been studied in patients undergoing abdominal operations. Patients randomized to receive modest fluid supplements showed higher tissue oxygen tension on the 1st postoperative day and higher hydroxyproline content of test wounds on the 7th postoperative day.⁶⁰

In the elderly, maintenance of adequate hydration may be difficult. Preoperative bowel preps and periods of forced abstinence from oral intake combined with age-related decline in thirst drive may quickly result in dehydration, which is often unrecognized. In elderly patients with compensated congestive heart failure, overzealous hydration will decrease tissue perfusion. However, in those with diastolic rather than systolic failure, the maintenance of adequate preload is essential for optimum cardiac output.⁶¹ Finding the appropriate balance may be challenging for the anesthesiologist, particularly when the procedure is long and there are large volume losses.

Cold ambient temperatures may exacerbate the effects of underhydration on tissue perfusion by causing vasoconstriction. In the elderly, the declining metabolic rate and decreased function of the hypothalamic thermal regulatory centers lead to rapid decreases in core and peripheral temperature. Studies have shown that wound infection rates,⁶² as well as cardiac-related complications,⁶³ go up if temperatures are allowed to fall intraoperatively. Higher room temperature, warmed infusions, and forced-air warming devices are useful in maintaining body temperature and limiting vasoconstriction. Radiant heat, which has been shown to increase blood flow to wounds, is being studied with regard to effects on actual wound healing.

Pain and stress with the release of catecholamines have also been shown to induce vasoconstriction and decrease tissue perfusion. Activation of the sympathetic nervous

system during the stress response shunts blood away from the periphery to support the heart and brain. Sympathetic blockade with epidural anesthetic has been shown to improve wound healing in vascular surgical procedures.⁶⁴ Although epidural anesthesia is an excellent method for decreasing postoperative pain without the sedation of systemic agents (see pain, following), its utility in improving wound healing in other settings remains to be determined.

The benefit of supplemental oxygen in routine clinical practice to improve tissue oxygenation and thereby improve wound healing has not been well established. Tissue oxygen levels fall as a result of surgery alone,⁶⁵ but tissue perfusion depends on many factors in addition to the oxygen saturation of the blood. It makes sense, however, that in patients at risk for tissue hypoxia either because of preexisting diseases or the length, contamination level, and location of the operation, supplemental oxygen might be of benefit.⁵²

The importance of adequate nutrition for wound healing was mentioned earlier. The incidence of major complications and death in a variety of settings increases as a function of falling serum albumin.²⁸ Experimental wounds in elderly surgical patients show delayed wound-healing response, even with a mild degree of protein-calorie malnutrition (mean weight loss, 9%; mean albumin, 3.9 g/dL).⁶⁶ Nutritional supplements given both pre- and postoperatively have been shown to improve wound healing. One study demonstrated that healing was better when both preoperative and postoperative nutritional supplementation were given.^{67,68}

In patients with significant preoperative deficits, several weeks of supplementation to reverse these deficits before the operation would be ideal, but this is rarely feasible. In one study, wound healing as assessed by hydroxyproline accumulation increased in surgical patients receiving only 1 week of intravenous alimentation.⁶⁹ In another study, recent preoperative food intake was found to be more important than overall nutritional status.⁷⁰ A short course of enteral supplements is worthwhile in patients with moderate deficits who can tolerate the delay in operation. For those who cannot, enteral or parenteral nutrition should be started immediately postoperatively. A recent randomized trial of postoperative enteral supplementation showed a decrease in morbidity and an improvement in nutritional status and quality of life.⁶⁷

Replacement of specific nutrients is also important. Vitamins A, B, C, and possibly E and trace elements such as zinc are essential for wound healing. Vitamin C is a cofactor for the enzymes involved in proline and lysine hydroxylation during collagen synthesis, and it is also important in leukocyte function and production of growth factors such as IGF-1. Vitamin A promotes the early inflammatory phases of wound healing and is par-

ticularly important in reversing the wound-healing deficits that accompany the use of steroids and chemotherapeutic agents. Zinc is involved in at least 300 enzyme reactions and is essential for DNA synthesis, cell division, protein synthesis, and lymphocyte proliferation. Although replacement of these nutrients is essential for wound healing, supplementation beyond replacement has not been shown to improve healing.³⁹

Other specific nutrients including the amino acid arginine have recently generated significant interest as a stimulant of both wound healing and immune function. In animals, wound breaking strength and collagen synthesis have been shown to improve with arginine supplementation.⁷¹ In healthy humans, oral arginine increased wound collagen deposition and lymphocyte response to mitogens.⁷² Supplemental arginine has also been shown to increase IGF-1 and improve nitrogen balance.⁷³ The effects of arginine may be the result of stimulation of growth hormone secretion or increased T-cell recruitment and activation of fibroblasts.⁷⁴ Alternatively, arginine is converted to citrulline and nitric oxide (NO) by nitric oxide synthase. NO in low concentration stimulates collagen synthesis. The impaired wound collagen synthesis seen in protein-energy malnutrition may reflect low NO synthesis in the wound. The deficit may be corrected by the addition of exogenous arginine.⁷⁵

Growth hormone (GH) has also been studied as a stimulant to wound healing. In animal models, GH has been shown to increase collagen content in wounds and bowel anastomoses.^{76,77} It has also been shown to accelerate the rate of donor site healing in pediatric burn patients.^{78,79} GH effects are exerted through the induction of synthesis of endogenous growth factors such as IGF-1. IGF-1 is secreted early in the inflammatory phase and stimulates fibroblast and endothelial proliferation and collagen synthesis; there are no studies documenting its clinical utility specifically in wound healing in the elderly. Other growth factors, such as PDGF and PDGF, have been shown in prospective randomized studies to accelerate the rate of closure of chronic wounds such as diabetic ulcers, venous status ulcers, and pressure sores. The cost of these therapies, however, is prohibitive.³⁸

Effect of Age on the Presentation and Natural History of Disease

With age, there are changes in the pattern of presentation of certain diseases. Although these changes are not well characterized, they are real and frequently observed. For example, surgical disease in the elderly is often described as atypical and acute because the signs and symptoms tend to be less severe early in the course of the disease and a complication is often the presenting finding.⁸⁰ With gallbladder disease, for example, the

classic pattern of worsening biliary colic leading to elective cholecystectomy is replaced by acute cholecystitis, cholangitis, or pancreatitis at presentation without antecedent symptoms.⁸¹ Even when acute inflammatory changes are present, as many as one-half of elderly patients with acute cholecystitis fail to have signs of peritoneal inflammation in the right upper quadrant, one-third have normal white blood cell counts, and one-third are afebrile.⁸² In the previously mentioned study of open cholecystectomy, more than 60% of operations on the elderly were performed as emergencies, as compared less than to 20% in the general population. With appendicitis, more than 50% of elderly patients are found to have perforation at the time of operation, compared to less than 25% in younger patients.⁸³

This advanced progression of disease at the time of surgery occasionally makes the technical execution of the operation more difficult. With biliary tract disease, for example, older age is associated with a higher rate of conversion from laparoscopic to open technique because of the technical difficulties encountered due to the long-standing inflammation.⁸⁴ At operation for perforated appendicitis, inflammatory changes may be so severe that right hemicolectomy rather than appendectomy is required to rule out the possibility of perforated cecal cancer.

Even when the presentation of disease is similar in the elderly, there may be a delay in diagnosis because the symptoms are attributed to other diseases found more commonly in old age. Such is the case with Crohn's disease, in which the basic symptoms of diarrhea, pain, and weight loss occur with about equal frequency in the elderly; the correct diagnosis, however, is initially made in only 64% of patients over age 65 years compared to 96% of younger patients.⁸⁵

The natural history of surgical disease in the elderly is also not well defined in many cases. In both Crohn's disease and ulcerative colitis, for example, there are conflicting reports about the relative frequency of disease location, the need for surgery, the response to treatment, and the prognosis.⁸⁶ The characteristics of tumors may vary also with age. In elderly women, for example, breast cancers are found more often to be moderately to well differentiated, have estrogen receptors, and have a low thymidine labeling index.⁸⁷ The biologic behavior of tumors in the elderly may also be different. In a series of patients with gastric cancer, for example, 5-year survival was 23% for older patients compared to 11% for younger patients.⁸⁸ In those with stage IV disease, no younger patient survived 3 years, while several elderly patients were alive at 5 years.

Great care must be taken, however, to avoid inappropriately treating cancer in the elderly because of the impression that the disease may have a less virulent course. Although there have been improvements in the

SEER database about the approach to surgery for cancer treatment in the elderly over the past two decades, patients in this age group are still often excluded from many types of treatment trials. Data from the 1990 SEER database, for example, indicated that 47.7% of breast cancer occurred in patients over age 65, but only 17.3% of women treated in National Cancer Institute-sponsored trials were in this age group.⁸⁹ Until more elderly patients are included in treatment trials, conclusions about the safety and efficacy of these treatments in the elderly will continue to be made without firm evidential support.

Minimizing the Impact of Surgery

Many of the negative consequences of surgery in the elderly are the same as those of hospitalization for any reason in this age group (see Chapter 13), although the additional stress of tissue damage, blood loss, and anesthesia is not insignificant. Table 22.6 lists the most common and potentially preventable hazards of hospitalization for both medical and surgical patients.⁹⁰ The use of prophylactic measures, monitoring devices, and alternate approaches to operation can minimize the risk of many of these adverse outcomes.

Prophylactic Measures

Anticoagulation

The annual incidence of deep venous thrombosis (DVT) and pulmonary embolism (PE) at ages 65 to 69 is 1.3 and 1.8 per 1000, respectively. At ages 85 to 89, this incidence rises to 2.8 and 3.1 per 1000.⁹¹ In the elderly surgical patient, the factors favoring the development of DVT and PE abound: included are surgery-induced hyper-

TABLE 22.6. Hazards of hospitalization and surgery.

coagulability; stasis from postoperative immobility and decreased lower extremity musculature; frequent operation for malignancy or injury; and age-associated coagulation changes, with hypercoagulable states particularly involving factor X_a, decreased vascular wall fibrinolysis, and decreased antithrombin levels.⁹² In spite of these risks, the incidence of clinically significant postoperative DVT and PE is lower than that of many other operative complications overall. In the VA NSQIP study mentioned earlier, the overall incidence DVT is 0.3% and PE is 0.1%. The incidence of PE is twice as high in orthopedic procedures⁸ and five times as high for patients over age 85. In certain operations such total hip replacement, the risk of thromboembolic complications has been reported to be as high as 20% to 50%.⁹³ The mortality for PE in the hospitalized elderly exceeds 20%.⁹⁴

Prophylaxis for DVT and PE is now a standard part of perioperative care for a variety of moderate- and high-risk procedures. Regimens include adjusted-dose subcutaneous heparin, low molecular weight heparin, or warfarin, combined with sequential compression devices (see Chapter 20). DVT and PE still occur, however, even when prophylactic measures are properly employed. Newer regimens using synthetic oligosaccharides that are selective, antithrombin-dependent indirect inhibitors of factor X_a have recently been reported. These agents potentiate the neutralization of factor X_a, inhibiting the generation of thrombin from prothrombin and thus preventing clot formation. In a recent report comparing one of these agents, Org3150/SR90907A, with low molecular weight heparin in patients undergoing total hip replacement (median age, 66 years), the oligosaccharide was shown to increase the risk/benefit ratio for the prevention of DVT; at a dose that produced bleeding rates equivalent to the standard dose of low molecular weight heparin, there was an 82% reduction; the risk of thromboembolism was 82% less.⁹⁵

Antibiotics

As already mentioned, a leading cause of wound-healing failure is infection. Older persons are potentially more susceptible to wound infection because of the changes in the nutrition, perfusion, and immunocompetence that accompany aging and the high prevalence of comorbid conditions, such as diabetes mellitus. Appropriate utilization of methodology to decrease wound infection is, therefore, particularly important when operating on elderly patients. The Centers for Disease Control and Prevention provide excellent guidelines for the prevention of surgical site infection.⁹⁶ While the recommendations for skin preparation and operating room environment are important, they are well accepted and uniformly employed. The importance and correct use of antibiotic prophylaxis, however, is less well understood and less uniformly applied.

According to the CDC guidelines, antibiotic prophylaxis is “a critically timed adjunct used to reduce the microbial burden of intra-operative contamination to a level that cannot overwhelm the host.” Four basic principles guide the use of antibiotic prophylaxis⁹⁶:

1. *Prophylaxis should be used for all operations in which it has been shown to reduce the incidence of surgical site infections, or where the risk of infection would be catastrophic.* This condition includes all operations in which there is controlled entry into a hollow viscus (clean-contaminated) and clean operations in which a prosthetic material, particularly an intravascular graft or prosthetic joint, is being implanted. Cardiac, neurosurgical, and certain operations on the eye also meet this criteria because of the catastrophic consequences of infection in these organs (Table 22.7).

2. *The agent used should be safe, inexpensive, and bactericidal with an in vitro spectrum that covers the organisms that are likely to be encountered with that specific procedure (see Table 22.7).*

3. *The agent should be given before the skin is incised so the tissue and serum levels of the agent are adequate at the time the potential contamination might occur.*

4. *Therapeutic levels should be maintained throughout the operation by redosing until a few hours after the procedure is over and the skin is closed.* The frequency of redosing depends on the tissue levels normally achieved, serum half-life of the drug, and the MIC₅₀ of the agent for the organisms likely to be encountered.

TABLE 22.7. Guidelines for antibiotic prophylaxis.

Operation	Likely pathogen
Placement of prosthetic	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci
Cardiac	<i>S. aureus</i> , coagulase-negative staphylococci
Neurosurgery	<i>S. aureus</i> , coagulase-negative staphylococci
Breast	<i>S. aureus</i> , coagulase-negative staphylococci
Ophthalmic ^a	<i>S. aureus</i> , coagulase-negative staphylococci Streptococci, Gram-negative bacilli
Orthopedic	<i>S. aureus</i> , gram-negative bacilli, coagulase-negative staphylococci
Noncardiac thoracic	<i>S. aureus</i> , coagulase-negative staphylococci <i>Streptococcus pneumoniae</i> , gram-negative bacilli
Vascular	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci
Appendectomy	Gram-negative bacilli, anaerobes
Biliary tract	Gram-negative bacilli, anaerobes
Colorectal	Gram-negative bacilli, anaerobes
Gastroduodenal	Gram-negative bacilli, streptococci Oropharyngeal anaerobes (peptostreptococci)
Head and neck	<i>S. aureus</i> , streptococci Oropharyngeal anaerobes (peptostreptococci)
Urologic	Gram-negative bacilli

^a Limited data but used for anterior segment resection, vitrectomy, scleral buckle.

Special note should be made about controlling infections during operations in which the colon may be resected. Oral nonabsorbable antibiotics are usually given as part of the mechanical bowel preparation before all such procedures, in addition to parenteral prophylactic antibiotics. Although there is some controversy about the need for both, most colorectal surgeons use oral and parenteral prophylaxis.⁹⁷

In colon surgery, however, the most important part of the preparation is the mechanical cleaning of the bowel to decrease the enormous bacterial load, not the antibiotics alone. Mechanical preparation is accomplished with cathartics or gastrointestinal lavage solutions containing polyethylene glycol and electrolytes. Lavage solutions are commonly used in the elderly because they are isosmotic and the risk of dehydration is less than with the effective saline cathartics. Nausea and vomiting from lavage can still lead to dehydration. Monitoring of the preparation is extremely important because the large volume (4 L) required for lavage to be effective can lead to compliance problems in elderly patients, particularly those who have mobility constraints. In the past, bowel preparation was usually performed in the hospital where patients could be observed. With present health insurance mandates for same-day admission for surgery, preparation is now routinely done at home the night before operation. In the frail or compromised elderly, home nursing support should be used if preoperative hospitalization is not possible because of the high rate of infection if preparation is inadequate.

Swallowing Dysfunction: A Less Well Appreciated Risk

The most common and one of the most resource-intensive complications in the elderly in the postoperative period is pneumonia. In the NSQIP study for 1998, the incidence of postoperative pneumonia was nearly 5% in patients more than 85 years of age compared to 1% for those aged less than 65 years. Although the explanation for this increase is multifactorial, one factor that has only recently been studied is the effect of swallowing dysfunction on the incidence of postoperative aspiration.

The majority of community-acquired bacterial pneumonias in the elderly are the result of microaspiration of oral flora.⁹⁸ Alterations in deglutition secondary to stroke and other central nervous system disease, dementia, medications, and generalized decline predispose to the aspiration of oral contents. In the postoperative period, nausea and vomiting from anesthetic medications combined with the decline in level of consciousness and the further pharyngeal dyscoordination caused by endotracheal, nasogastric, and transesophageal echocardiogra-

phy (TEE) probes exacerbates the risk for aspiration of gastric, as well as oral, contents.

Most surgeons are aware that the incidence of swallowing dysfunction following endotracheal extubation in postoperative and critically ill patients correlates with the length of intubation.⁹⁹ It is less well appreciated that other tubes that traverse the oropharynx can alter swallowing function in the elderly and also cause postoperative aspiration. TEE has gained great favor as a less-invasive method to monitor intravascular volume and cardiac performance during operation. The safety and efficacy of this form of monitoring is generally accepted. The utility of TEE in cardiac surgery has been particularly impressive. However, in a study of swallowing dysfunction after cardiac surgery,¹⁰⁰ the two independent predictors by multivariate logistical regression analysis were length of endotracheal intubation and the use of TEE. Swallowing dysfunction in this study was documented in 4% of patients, 90% of whom had documented aspiration. The incidence of pneumonia, need for tracheostomy, length of ICU stay, and length of hospital stay were all significantly increased in the TEE group. In another study of cardiac surgery patients,¹⁰¹ the relative risk for dysphagia in the postoperative period was 7.8 times greater for TEE than for non-TEE patients.

Similar negative consequence of pharyngeal intubation occur with nasogastric (NG) tubes. In a meta-analysis¹⁰² of all published trials comparing routine versus selective use of nasogastric tubes after elective laparotomy, fever, atelectasis, and pneumonia were significantly less common in patients managed without an NG tube. There was, however, significantly more abdominal distension and vomiting in the group managed without the NG tubes, but these episodes did not translate to a higher incidence of aspiration pneumonia. Caution should be exercised when reviewing these data because the study was for elective operation only and results are not reported as a function of age. However, there are putative advantages and disadvantages with either method of management in this age group. If gastric distension is unrecognized in the sedated elderly patient, vomiting and aspiration is a serious risk. If an NG tube is functioning properly, gastric decompression will prevent vomiting, but aspiration of oral secretions may still occur. If the NG tube is functioning improperly, the risk of aspiration is probably higher than without an NG tube because the normal protective mechanism of the lower esophageal sphincter is disturbed by the presence of the tube. The data seem to firmly support the use of NG tubes only when specifically indicated for control of distension and vomiting in selected cases. The NG tube is still an important adjunct to treatment for procedures on the esophagus or stomach, where they are placed for technical reasons, and in emergencies when the likelihood of prolonged distension is high.

Minimal Access Surgery

Over the past decade, the growing applications of minimal access techniques to a large number of disciplines has allowed surgeons to perform a wide variety of complex major operations through small incisions. Smaller incisions are associated with less postoperative pain, less atelectasis, less postoperative ileus, fewer wound complications, and quicker return to normal activities. It is logical that the elderly patient with marginal reserves would benefit most from this minimal invasive approach. However, the extent to which the traumatic response to surgery is moderated by minimal incisions in the elderly is a subject of active investigation. It is still unclear whether the hemodynamic and cardiorespiratory consequences of pneumoperitoneum are completely offset by the benefits of decreased inflammatory, hormonal, and metabolic stress.¹⁰³

The cardiorespiratory consequences of pneumoperitoneum are attributable both to the use of CO₂ as the insufflating gas and to mechanical forces associated with increased intra-abdominal pressure. Although hypercarbia and respiratory acidosis from CO₂ absorption are common, pH can usually be well controlled with adequate mechanical ventilation. Hypercarbia becomes a serious problem only when there is preexisting pulmonary disease. The consequences of increased intra-abdominal pressure, although not insignificant, are usually easily controlled with adequate volume loading and mechanical ventilation as well. Although the overall consequences of laparoscopy and pneumoperitoneum are not inconsequential, with adequate preload and careful mechanical ventilation laparoscopic procedures can be safely performed in most elderly patients. In those with severe cardiac and or pulmonary compromise, invasive monitoring to maintain adequate volume loading and alternate gas sources or gasless techniques may eliminate most of the negative sequelae of CO₂ insufflation.¹⁰⁴

The largest amount of data on the outcome of laparoscopic surgery in the elderly is found in the biliary literature, although a wide range of other major intra-abdominal and intrathoracic procedures are being reported.¹⁰⁵ Laparoscopic cholecystectomy is associated with fewer complications and shorter length of stay than open procedures. Results of one study comparing laparoscopic to open cholecystectomy in patients over 65 years of age is shown in Table 22.8.¹⁰⁶ However, when compared to younger patients, the elderly still experience more postoperative complications. In addition, operative times are longer in elderly patients with complicated cholelithiasis and in those classified ASA 3 or 4. Both age greater than 70 years and ASA 3 or 4 are also associated with higher rates of conversion from laparoscopic to open procedures.¹⁰⁷ In one study comparing patients with acute cholecystitis, the conversion rate to open operation

TABLE 22.8. Prospective randomized trial of laparoscopic versus open cholecystectomy in the elderly.

Factor	Open	Laparoscopic	<i>p</i>
Number of patients	131	133	ns
Age	72 (65–88)	71 (65–87)	ns
Acute cholecystitis (%)	29.7	32.3	ns
Operative minutes	70.9	75.0	ns
Hospital days	9.9	3.7	<0.05
Complications	31 (23.6%)	18 (13.5%)	<0.05

Source: From Brunt and Soper,¹⁰⁵ with permission.

was 23.3% in older patients compared to 2.5% in younger patients.¹⁰⁸

As with open cholecystectomy, the mortality rate for laparoscopic cholecystectomy is largely a function of comorbidity and acuity of the disease. Mortality rates are reported from 0% to 2.0%. Two studies comparing mortality of laparoscopic versus open operation by logistical regression analysis indicated reduced odds of death from the laparoscopic approach.¹⁰⁵ Present comparisons are less meaningful because conversion to open procedure usually indicates complicated disease.

The presence of common bile duct (CBD) stones requires additional intervention by either minimal access or open procedure. Although laparoscopic CBD explorations are successful in more than 90% of reported cases,¹⁰⁵ the technical skills to do this procedure are greater than those required for routine cholecystectomy. Many surgeons, therefore, address CBD stones with endoscopic techniques either preoperatively or postoperatively.

The laparoscopic technique for colon resection has also been reported in the elderly, although fear of port site implantation of tumor during laparoscopy for malignant disease slowed the development of this technique for that indication. In a matched control study of laparoscopic versus open colectomy in patients over age 75, the morbidity rate in the open group was 33.3% compared to 14.3% for the laparoscopic group. There were no deaths in either group. Narcotic use, return to normal bowel function, and length of hospital stay were all also significantly shorter in the laparoscopic group. Of the 37 laparoscopic patients and 38 open patients documented as independent in ADLs on admission, 35 in the laparoscopic group and 29 open group ($p < 0.025$) were independent at discharge.¹⁰⁹ These data indicate that laparoscopic colectomy is not only safe but is associated with a better outcome in terms of morbidity and maintenance of function.

As mentioned earlier in the chapter, surgical options for malignant disease in the elderly are not offered when the surgery is high risk and the chance of survival even with surgery is low; this was the case with lung cancer in the past. With careful patient selection, mortality for tho-

racotomy in elderly patients over the past decade has ranged from 3% to 5%. Recent experience with video-assisted thoracic surgery (VATS) suggests that this technique may result in much lower morbidity and mortality and should be evaluated in more rigorous clinical trials. VATS procedures use small incisions and preserve respiratory muscle function by not spreading the ribs and by avoiding rib fractures. In a study from the Brigham and Women's Hospital,¹¹⁰ there was no mortality when VATS was used to perform 32 lobectomies or segmentectomies in patients over age 65 and only one death when used in 156 other thoracic procedures. Length of stay was 4 days for patients aged 65 to 79 and 5 days for those aged 80 to 89. Of particular note is that the incidence of delirium in the postoperative VATS patients was 2.7% compared to 13% to 19% for elderly patients undergoing traditional thoracic procedures.

Similarly encouraging results have been reported for retroperitoneal laparoscopic radical nephrectomy and nephroureterectomy in patients over age 80.¹¹¹ In a small series, laparoscopically treated patients had quicker return to oral intake, lower narcotic requirements, and shorter hospital stay. In addition, total convalescence time was 14 days in the laparoscopic group compared to 42 days in the open group.

The laparoscopic approach has also been studied for splenectomy, antireflux procedures, staging of malignancy, and the diagnosis of acute abdominal pain. Although the series are few and the number of elderly patients studied is small, results in these areas also appear favorable when compared to open procedures.

Postoperative Pain Management

Untreated or undertreated postoperative pain can have significant negative impact on the recovery of the elderly patient following surgery. Pain causes tachycardia, increases myocardial oxygen consumption, and may lead to myocardial ischemia. The anticipation of pain after major abdominal and thoracic procedures leads to splinting and poor inspiratory effort with subsequent atelectasis and increased risk of pneumonia. Because pain is exacerbated by moving, untreated pain results in immobility with all the sequelae of prolonged bed rest including pressure ulcers, thromboembolic disorders, and the declines associated with deconditioning; depression and lethargy; anorexia and dehydration; neuromuscular instability, decreased bone density, muscular weakness, and incoordination; altered bladder and bowel function with retention and constipation; and urinary and fecal incontinence.

Several clinical observations suggest pain perception is altered with increasing age: the incidence of silent myocardial infarction rises from less than 20% in patients aged 45 to 54, to more than 40% in those aged 75 to 84¹¹²;

more than 35% of elderly patients with duodenal ulcer disease report no epigastric pain compared to only 8% of younger patients.¹¹³ However, experimental data do not support changes attributed to aging alone. Therefore, pain must be actively assessed and treated in the elderly as it would in any other postoperative patient.

Pain assessment should be based on the patient's perception of pain, not on the assumptions of the caregivers. Simple tools such as a numerical rating for severity of pain or a visual analogue scale are usually adequate to document the patient's perceived level of pain. In the cognitively impaired or acutely delirious patient, this assessment is much more difficult. Patients with chronic dementia can often respond to direct questioning about the presence and intensity of pain, although concern about inducing or exacerbating acute confusion with opioids may result in inadequate treatment of the pain. This undertreatment itself may be a cause of worsening agitation and confusion. When coherent verbal communications are not helpful, other verbal cues such as groaning and nonverbal signs such as facial expressions and body language can be used to guide treatment.

Opioids are the ideal agents for treating the acute postoperative pain because they have no ceiling to the analgesic effect.¹¹⁴ However, the side effects of confusion and sedation are rate limiting in the elderly patient. Of the opioids used outside the operating room, morphine is the most commonly used and most predictable. The previous enthusiasm for meperidine is unfounded for the treatment of pain in the elderly: it is associated with CNS excitatory effects, particularly in patients with renal insufficiency, and its metabolites can cause grand mal seizures.

Parenteral nonsteroidal anti-inflammatory drugs (NSAIDs) when first introduced were widely accepted because of their excellent analgesic effects without the sedation associated with opioids. However, the incidence of gastrointestinal bleeding in the elderly with parenteral NSAIDs has greatly limited their usefulness.

The route of administration of the analgesic agent is extremely important. For elderly patients the epidural infusion of opioids combined with local anesthetic agents is an excellent intra- and postoperative method of pain control, providing excellent analgesia with less sedation.¹¹⁵ The local anesthetic agents also provide sympathetic blockade, which ameliorates some of the negative sequelae of sympathetic activation associated with general anesthetics. Local anesthetics, however, can cause orthostatic hypotension, urinary retention, and muscle weakness, while the opioids cause urinary retention and itching.¹¹⁴ Overall, however, the improved risk/benefit profile of the epidural route more than justifies the additional invasive procedure.

Patient-controlled analgesia (PCA) is also an important improvement in the way pain medications are now

delivered. The patient is given a button to push to deliver a fixed dose of drug when needed. A lock-out interval between doses prevents overdose, which is also unlikely because the patient must be conscious enough to push the button. Low-dose continuous infusion can run simultaneously when the pain is most severe in the first few days after surgery. PCA allows for a much more constant level of analgesia without the peaks and troughs associated with conventional intramuscular (i.m.) injections. In a randomized study comparing PCA with conventional i.m. injections in elderly men, PCA gave better pain control with few complications, less sedation, and better patient satisfaction.¹¹⁶ The only caveat for using the PCA is that the patient must be able to understand the instructions and must be encouraged to use the button before the pain becomes intense to maintain the effective level of pain control.

Rehabilitation

Kenneth Brummel-Smith

Rehabilitation is a process of care directed at restoring or maintaining a person's ability to live independently. Interventions are directed at helping the patient to recover from and adapt to the loss of physical, psychologic, or social skills lost as a result of illness or trauma. This chapter primarily considers rehabilitation from physical illnesses, but geriatrics always involves attention to the psychologic and social aspects of care.

Disability is a common problem among older Americans. Kunkel and Applebaum estimated that by the year 2020, between 9.7 and 13.6 million older people will have moderate to severe disability, an increase of 85% to 167% over current levels.¹ Clinical geriatrics emphasizes the "functional approach" in the care of the patient. By enhancing the person's functional abilities, the impact of a disability can be lessened. Rehabilitation is a basic foundation of geriatric care. All health care providers should promote a rehabilitation orientation when caring for older persons.²

Ultimately, those receiving rehabilitation hope to live in personally satisfying environments and maintain meaningful social relationships. In geriatrics, rehabilitation shifts from a goal of returning the patient to gainful employment to helping the older person live more independently. This type of care can be provided in any health care setting, including the home, office, acute or rehabilitation hospital, and long-term care facility. An interdisciplinary team approach is required because of the complex nature of the various interventions. Patients and their families must be involved in decisions regarding rehabilitation treatment.

Rehabilitation is a philosophic approach to the patient that recognizes that improvement in functional abilities is an important goal of medicine, that having a disability does not diminish one's social worth, and that the psychosocial aspects of care are at least as important as its medical aspects. Rehabilitation is an essential component of quality geriatric care that should be available to all those who might benefit. The American Geriatrics

Society has recognized the importance of rehabilitation in a position statement.³ The Society has also proposed training guidelines in rehabilitation for geriatric fellows.⁴ All persons caring for older patients should have some knowledge of rehabilitation.⁵

Functional disability had been on the rise for a number of years but appears to be decreasing.⁶ The 1994 National Long Term Care Survey showed the overall prevalence of disability (21.3%) to have fallen by 3.6% from 1982. However, the rate of disability in individuals increases markedly with age. In 1995, among noninstitutionalized persons over the age of 70, 32% had difficulty performing and 25% were unable to perform at least one of nine physical activities, such as dressing or bathing.⁷ Activity limitations increase with age and are more prevalent in females and in African-Americans. Those persons over age 85 are 2.6 times as likely to be unable to perform physical activities.

Disability is costly, consuming more than \$170 billion per year.⁸ Rehabilitation services are but one part of that cost. Equipment use in disabling conditions is common and expensive. Most elderly patients with disability require assistance from family members or special community services. At higher levels of disability [>3 activities of daily living (ADLs) impaired], either personal assistance only or equipment use only appeared insufficient to support the patient remaining in the community.⁹ Disability measures strongly predict cost of Medicare services.¹⁰

Definitions of Disability

The World Health Organization's classification system is useful when discussing geriatric rehabilitation¹¹ (Table 23.1). In this system, *disease* refers to intrinsic pathology that may or may not be evident clinically. *Impairment* refers to alterations of function at the organ level. Older persons may have many impairments. Some physiologic

TABLE 23.1. World Health Organization definitions of disability.

-
- Disease—an intrinsic pathology or disorder . . . [which] may or may not make [itself] evident clinically
 - Impairment—a loss or abnormality of structure or function at the organ system level
 - Disability—a restriction or lack of ability to perform an activity in a normal manner, a disturbance in the performance of daily tasks
 - Handicap—a disadvantage resulting from impairment or disability that limits or prevents fulfillment of a role that is normal
-

decline in organ function is seen in almost all systems. These declinations, however, may not affect the person's ability to perform daily activities. An impairment severe enough to affect the person's daily functioning is a *disability*. When persons with disability have received appropriate rehabilitation training and have adapted to the change in functional status, they often can be fully independent. However, if subjected to policies that limit rehabilitation interventions or services because of age, these persons become *handicapped*. Therefore, by this definition, there are no handicapped persons; there are only handicapping societies. Unfortunately, there is evidence that such factors as race and hospital size can affect whether older people receive rehabilitation interventions.¹² Although this chapter is devoted to the problems of aged persons with a disability, the sociopolitical implications of rehabilitation must not be forgotten.

Demographics of Disability

A large percentage of persons with a disability are elderly. Conditions for which rehabilitation interventions are beneficial disproportionately affect the elderly population. Arthritis is the most common condition affecting older persons and the most common cause of disability.¹³ The incidence of stroke peaks in the seventh and eighth decades.¹⁴ The average 80-year-old white woman has a 1% to 2% risk of hip fracture per year.¹⁵ Most amputations are performed in the geriatric age group.¹⁶ Even without such catastrophic diagnoses, the prevalence of limited activities due to chronic conditions is very high, particularly in those over age 75.

The type of disability also is important in the way it affects the caregiving system. A decreased ability to walk, feed, or toilet indicates greater dependency and increases the burden on caregivers. The decision to institutionalize an older family member is very much related to the level of disability, in that a greater burden of illness creates greater needs for care. Interventions designed to enhance functional abilities and support caregivers have been shown to be cost-effective and lead to fewer hospitalizations, greater levels of independence, and lower mortal-

ity.¹⁷ Access to rehabilitation for older persons, however, is sometimes restrictive. The prospective payment systems for reimbursement for acute care and short hospital stays provide disincentives for physicians and hospitals to offer rehabilitation interventions while the patient is in the hospital. A study of attitudes and knowledge of a large sample of policy makers in the federal and state governments indicated that comprehensive rehabilitation programs were widely unavailable because few of these officials considered it a priority need.¹⁸

Rehabilitation Principles

Components of Rehabilitation

Rehabilitation comprises a number of components of care, as summarized in Table 23.2. Each of these components requires special attention in geriatric patients. With older persons, it is not always possible to completely stabilize the primary problem. Furthermore, there often is more than one "primary problem." An 80-year-old man with a recent amputation may have underlying cardiac disease, diabetes, and mild renal failure, necessitating close supervision by the geriatric provider during an inpatient rehabilitation stay. He also may be more prone to secondary complications than a younger person. Preventing such complications is crucial in geriatric populations because of the remarkable ease with which such events develop and the great risks involved. Secondary complications are frequently seen in older patients, including such conditions as falls, pressure sores, deep venous thrombosis, contractures, deconditioning, malnutrition, incontinence, family discord, and depression.

These complications also disproportionately affect older patients. Decreased subcutaneous fat, poor capillary function, and low blood volumes increase the risk of developing pressure sores. Besides adding great costs to the care of the patient, a sacral pressure sore may delay wheelchair training after a stroke. The enforced lack of exercise may then increase the risk of other secondary complications, such as deconditioning or psychologic dependence. Contractures, that is, muscle shortening causing a decrease in the functional range of motion, begins to develop within 24 h of the cessation of activity. Some contractures may lead to permanent disability,

TABLE 23.2. Components of rehabilitation.

-
- Stabilize the primary disorder
 - Prevent secondary complications
 - Treat functional deficits
 - Promote adaptation:
 - Adaptation of the person to their disability
 - Adaptation of the environment to the person
 - Adaptation of the family to the person
-

TABLE 23.3. Tools for activities of daily living.

-
- Bathing—handheld shower hoses, bath seats and benches, long-handled scrubbers, grab bars
 - Ambulation—canes, walkers, special shoes, wheelchairs
 - Toileting—raised toilet seats, arm attachments, grab bars
 - Transfers—side rails, sliding boards, trapeze bars
 - Eating—large-handle utensils, rocker knives, plate guards, plate holders, hand braces
 - Dressing—button hooks, Velcro closures, sock-donners, clothes hooks
-

while others may require months of intense physical therapy and serial casting to recover the full range of motion. Muscle strength rapidly declines with acute immobilization or chronic decreased physical activity.¹⁹ Recovery of lost strength occurs at a much slower rate. Last, the quality of “help” given may contribute to the development of secondary complications. Patients encouraged to maintain activities of daily living may lose abilities less rapidly than those who are helped with all such activities.²⁰ A conscious effort by all members of the team, including the patient, is required to prevent the development of secondary disabilities.

The foundation of rehabilitation is the restoration of lost functional abilities. By using directed exercises, with the assistance of physical, occupational, and often communication therapists, the patient can “relearn” how to carry out daily activities. Various adaptive equipment, such as rocker knives, sock-donners, and dressing sticks have been shown in randomized trials to enable a person to function independently and reduce health care costs²¹ (Table 23.3).

Another key component in geriatric rehabilitation is adaptation of the environment to the disabled person. The older person may be less able than a younger person to maintain an activity that is extremely demanding physiologically. For instance, a 20-year-old paraplegic may be able to walk using canes and braces. An 80-year-old with spinal stenosis and diminished cardiac reserve most often needs to learn wheelchair mobility skills. Similarly, the evaluation of the home environment plays an important

role in geriatrics. Financial concerns and personal preferences may limit opportunities for obtaining new housing or for modifying the home.

Finally, the family must be assisted in the adaptation and support of the older person with a disability. The family provides 85% of all health care for dependent elders.²² Often the caregivers themselves are elderly (spouses and older children). Families play a vital role in determining rehabilitation outcomes. Families may perceive the disability as a threat, or as a challenge, or be overwhelmed by it. They will cope using the preexisting rules and roles that existed before the disability.²³ In a study of outcomes in a geriatric rehabilitation unit, 78% of the patients who had family members that participated in the inpatient program returned home, whereas only 54% of those patients whose families did not participate returned to the home setting.²⁴ Rehabilitation in the home prevents hospitalizations and nursing home use.²⁵ The approach to the training of family caregivers is similar to that used with other students. Their knowledge regarding the disabilities and caregiving needs must be assessed and enhanced, their skills in providing care should be evaluated, and their attitudes toward the caregiving role should be elicited.

In summary, each component of rehabilitation must receive attention from a team of clinicians to ensure that the greatest level of functional independence is achieved.

Rehabilitation Teams

Both multidisciplinary and interdisciplinary teams are used in rehabilitation (Table 23.4). Geriatric providers and psychiatrists (specialists in physical medicine and rehabilitation) are often involved in interdisciplinary teams, while most primary care physicians function in a multidisciplinary setting. A multidisciplinary team works in a consulting relationship, each person seeing the patient individually and communicating with other team members by written notes or telephone calls. The decision to involve other team members usually is made by the physician. An interdisciplinary team functions in a

TABLE 23.4. Roles of selected team members.

-
- Psychiatrist—provides consultation regarding complex functional limitations and interventions to improve function; conducts diagnostic tests such as nerve conduction studies and may perform invasive interventions such as nerve blocks
 - Physical therapist—deals with problems in mobility and transfers, gait training, use of braces for mobility; involved in training in the use of canes, walkers, and wheelchairs
 - Occupational therapist—works with patient to improve skills in activities of daily living, uses a variety of interventions, and teaches the patient how to use assistive devices for ADL; may also produce or train in the use of splints
 - Recreation therapist—helps the patient to recover or learn new skills in vocational activities (many older adults continue to have vocational activities, extending from volunteer work to income-generating activities)
 - Speech and language pathologist—helps the patient to improve communication skills; trains patient to use alternative forms of communication if needed; may be involved in swallowing programs
 - Orthotist—fashions braces and splints
 - Rehabilitation nurse—in addition to providing nursing care, assists the patient in utilizing new techniques learned from the above-mentioned therapists; involved in family training
-

setting where all team members can meet periodically to discuss the patient's problems and progress. Although each team member has a specific area of expertise, often there is considerable overlap in roles. With more complex cases, such as those seen in inpatient or long-term care rehabilitation, an interdisciplinary team is usually required.

Different team members address specific areas of functioning. Speech and language pathologists or communication disorders specialists do much more than help people talk. In addition to training patients in a wide variety of communication techniques and helping the family adapt to the patient's communication needs, they assess cognitive skills. Occupational therapists are primarily concerned with assessment and treatment of the patient's deficits in basic and instrumental activities of daily living. Cognitive retraining programs, as well as perceptual and sensory evaluations, are also provided by occupational therapists. Some occupational therapists can assist the geriatric provider by providing driver training and by making recommendations for automobile modifications.²⁶

Physical therapists assess strength, range of motion, coordination, balance, and gait, but these are only a few of the services they provide. Some also assess bulbar function and provide swallowing training programs. The use of electrical stimulation for functional activities and pain control often is managed by physical therapists. Retraining in ambulation, the use of walking aids (canes and walkers), general strengthening, and wheelchair mobility are within the province of physical therapists. As there are hundreds of types of wheelchairs, these are best prescribed by physical therapists. Many of these activities are also conducted by kinesiotherapists, particularly in Veterans Administration hospitals.

Recreation therapists serve an important role in geriatric rehabilitation. The ability to resume one's favorite leisure activity can be a powerful force encouraging participation in the rehabilitation program. The quality of life can be greatly enhanced by the resumption or learning anew of hobbies and enjoyable activities.

Each of these specialists has specific requirements for certification or registration. Most have certified aides, assistants, or technicians who provide some portion of the therapeutic program under the supervision of the registered therapist. In some states, physical and occupational therapists are in private practice and available for outpatient consultation and referral. When this is not the case, consultation can be obtained by referral to the appropriate hospital department.

Rehabilitation nurses play a crucial role in promoting the gains made by all the other therapists. Besides attending to the patient's nursing needs, they help the patient practice activities of daily living, make transfers in and out of bed or to the toilet, and learn new medication

regimens. They also train family members in caregiving skills and encourage patients and their families to bring up questions, discuss concerns and fears, and learn to cope with disability.²⁷

Ideally, team members should meet periodically to discuss their assessments, establish goals, provide updates on progress toward those goals, and estimate the length of the program needed to meet the goals. A written summary of the meeting is placed in the patient's record. Some teams also provide a copy to the patient and the family.

Every attempt should be made to incorporate the patient and family into the rehabilitation process. Patients often find attendance at team meetings to be stressful. Many teams regularly report the patient's and family members' views of the course of rehabilitation and facilitate a discussion after a team meeting.

The role of the physician on the team is to provide medical expertise and often to serve as facilitator of the team process. Physicians must be extremely careful in this dual role as both the "expert" and the "facilitator." Hierarchical relationships are common in medical settings, and the physician-expert may inhibit the functioning of other team members. If that happens, the flow of information necessary to make critical decisions may be impeded. Although the final responsibility of the clinical decision rests with physicians, they must always promote the reasoned deliberation of other team members. Group communication skills and knowledge of team dynamics, attributes often ignored in medical school training, are important for efficient and mutually satisfying teamwork.

Rehabilitation in Different Care Sites

Rehabilitation interventions can be provided in a variety of continuing care sites (Table 23.5). Medicare covers most of these services, but Medicaid's reimbursement policies vary from state to state. Medicare and most third-party reimbursement requires that there be documenta-

TABLE 23.5. Sites for rehabilitation.

-
- Home—requires a committed in-home caregiver, reasonably accessible (or modifiable) environment, and access to home health services
 - Outpatient facility—requires a dependable means of transportation, enough medical stability to tolerate outings into the community, reasonable cognition to retain newly learned information between visits
 - Nursing home—best if a rehabilitation-oriented facility, needs dependable access to therapists, burden of documentation by physicians and therapy staff is high
 - Acute hospital—limited time available for providing rehabilitation; even small amounts of therapy may be beneficial; attention should be paid to limiting functional decline
 - Rehabilitation hospital—intensive services (minimum 3 h/day) may limit ability of frail elders to participate; evidence that greatest gains in stroke rehabilitation happen in this setting
-

tion that the patient is progressing toward goals and that therapy must not be used for “maintenance” of function only. Algorithms have been developed for determining the proper site of rehabilitation for older persons with functional decline⁵ and for stroke.²⁸

An ideal site for providing rehabilitation is the patient’s home.²⁹ The problem of transportation is relieved, and services can be rendered at lower costs than in hospitals. In a small, randomized trial in England, patients with stroke who received rehabilitation at home had similar outcomes, at lower costs, than those treated in the hospital.³⁰ The patient’s ability to function in a familiar environment with available equipment can be assessed, the family is usually supportive, and carryover of techniques taught during therapy can be monitored. In one study, patients cared for at home obtained the greatest degree of functional improvement from home modifications, the next best improvement from instruction in the proper use of assistive aid devices, and the least from exercises.³¹ For the patient thought to be able to benefit from rehabilitation in outpatient settings but unable to attend clinics because of transportation difficulties, limited endurance, psychologic reasons, or personal choice, home care is a valuable option.

Outpatient centers provide a large proportion of rehabilitation services. These centers may be found in physicians’ offices, private physical (and occupational) therapy practices, Certified Outpatient Rehabilitation Facilities (CORF), day health centers, specialized senior clinics,³² and hospital-affiliated facilities. Their advantages are (1) access to a wider variety of practitioners and technology, (2) the stimulation for patients of being around other people (a disadvantage to some patients with cognitive deficits), and (3) their ability to serve more patients with fewer practitioners. Transportation to the clinic often is a major problem with the very old.

Perhaps the greatest unmet need for rehabilitation is in the acute hospital. The potential negative effects of acute hospitalization have been well documented.³³⁻³⁵ Many elderly patients have difficulties with activities of daily living, and the hospital environment itself may interfere with functional recovery. With the advent of prospective payment, patients are being discharged “quicker and sicker.” It is essential to obtain early allied health consultation and discharge planning. When possible, patients should be kept out of their beds, walked to the bathroom or diagnostic studies, and encouraged to dress and feed themselves.

The classic site for providing rehabilitation is the specialized rehabilitation unit. Such facilities may be free-standing or affiliated with an acute hospital. A full complement of rehabilitation specialists is on site. Usually, a physiatrist (or, in the case of geriatric rehabilitation units, a geriatrician) coordinates the team. To receive Medicare reimbursement, patients must undergo

3 h per day of physical, occupational, or speech therapy and must make regular progress toward specific goals. Periodic team meetings are held at least biweekly, and progress must be documented in the chart. Because of these criteria, older persons may have restricted access to inpatient programs. In one study, only 21% of patients who met criteria for rehabilitation actually received rehabilitation services. At follow-up, those participants in rehabilitation had lower mortality, spent less time in skilled nursing care, and were less frequently hospitalized.³⁶ With the expansion of the use of health maintenance organizations (HMOs), there has been a decrease in the use of hospital-based rehabilitation units.^{37,38} In part, this change is based upon there being little evidence from randomized controlled trials that specialized units provide added benefits. In fact, although the Agency for Health Care Policy and Research (AHCPR) algorithm for choice of a rehabilitation unit appears to function reasonably well,³⁹ the factors that guide choices were all based solely upon expert opinion.

Some hospitals have developed specialized geriatric rehabilitation units. Patients at moderate, rather than high, risk for nursing home placement appear to do the best in geriatric rehabilitation units. In a randomized trial, such patients had improved function, fewer nursing home placements, and a trend toward reduced mortality when compared to older patients cared for in traditional hospital units.⁴⁰ Geriatric-orthopedic units⁴¹ have shown similar success, as have stroke rehabilitation units,⁴² although there is controversy whether they offer benefits over traditional rehabilitation units. Geriatric rehabilitation has been shown to be effective,^{43,44} and age need not be a deterrent to providing rehabilitation. In a prospective evaluation of factors that may predict rehabilitation outcomes, Rondinelli et al. were able to show that age was not a good predictor of outcomes (length of stay or functional improvement).⁴⁵ Preadmission functional status and social supports were strong predictors, as would be expected.

The nursing home is another important site for providing rehabilitation.⁴⁶ For patients in a skilled facility requiring physical, occupational, and speech therapy, Medicare reimbursement is available. With implementation of the Balanced Budget Act of 1997, changes in Medicare reimbursement have led to an increase in the number of nursing homes providing rehabilitation services.^{47,48} In fact, the highest rate of Medicare reimbursement is provided for the most complex rehabilitation patient. Some community-dwelling elderly persons may be able to use the nursing home as a primary site of rehabilitation because of the slower pace allowed. However, in the fee-for-service setting, current Medicare regulations require a 3-day stay in an acute hospital before allowing reimbursement. This requirement is waived for HMOs, so direct admission to a nursing home can be

arranged. Outcomes from nursing home rehabilitation are beginning to be demonstrated with various studies showing improvements in mobility and the use of assistive devices,⁴⁰ muscle strength and gait velocity,⁵⁰ and general activity levels.⁵¹

It is possible, however, that nursing home-based rehabilitation is less effective than hospital-based programs. A recent study compared patients admitted either to a skilled nursing facility or to a rehabilitation facility for treatment of stroke or hip fracture. Patients were matched according to seven groups of patient characteristics: basic demographics; social support measures; pre-morbid functional status, using the ADL index; acute medical or surgical characteristics; conditions at admission to rehabilitation, derived from nursing staff or patient record; functional status at rehabilitation admission, using the number of ADL dependencies and the Barthel index; and cognitive and psychologic status, assessed using Mini-Mental State Exam and Geriatric Depression Scale (GDS) scale scores. Enhanced outcomes were found for elderly patients with stroke who were treated in rehabilitation hospitals, but not for patients with hip fracture. Rehabilitation-oriented nursing homes were more effective than traditional nursing homes in returning patients with stroke to the community, despite comparable functional outcomes.⁵²

Assessment for Rehabilitation Potential

The first step in the assessment for rehabilitation potential is awareness that rehabilitation interventions may be of benefit. Once that idea is entertained, a number of features must be considered. Factors associated with a better prognosis include recent (rather than long-term) health changes, less severe deficits, an assertive personality, a supportive family system, and adequate economic resources. A poorer prognosis exists for patients with low motivation, more severe health problems (especially if associated with cognitive impairments), and inadequate economic resources or support systems. However, because of the great variability seen in older persons, no single factor should automatically exclude a person from a trial of rehabilitation interventions.

When there is doubt, the patient should undergo a comprehensive assessment before a final determination is made. The assessment should identify what demands the patient will encounter in the expected living environment and whether he or she has the ability to meet those demands. A complete assessment includes evaluation of the patient's physical impairments, cognitive and psychologic functioning, the social environment, and economic resources.⁵³ The patient's prior levels of functioning and present capabilities should both be determined.

Two scales have been widely used to measure progress in rehabilitation. The oldest is the Barthel index⁵⁴ (Table 23.6). Using this 100-point scale, some investigators have

TABLE 23.6. Barthel index.

Activity	Score
Bowels	0 = incontinent (or needs to be given enemas) 5 = occasional accident 10 = continent
Bladder	0 = incontinent, or catheterized and unable to manage alone 5 = occasional accident 10 = continent
Grooming	0 = needs help with personal care 5 = independent face/hair/teeth/shaving (implements provided)
Toilet use	0 = dependent 5 = needs some help, but can do some things alone 10 = independent (on and off, dressing, wiping)
Feeding	0 = unable 5 = needs help cutting, etc., or requires modified diet 10 = independent
Transfers (bed to chair and back)	0 = unable, no sitting balance 5 = major help (one or two people, physical), can sit 10 = minor help (verbal or physical) 15 = independent
Mobility (on level surfaces)	0 = immobile or <50 yards 5 = wheelchair independent, including corners, >50 yards 10 = walks with help of one person (verbal or physical), >50 yards 15 = independent (but may use any aid; for example, stick), >50 yards
Dressing	0 = dependent 5 = needs help but can do about half unaided 10 = independent (including buttons, zips, laces)
Stairs	0 = unable 5 = needs help (verbal, physical, carrying aid) 10 = independent
Bathing	0 = dependent 5 = independent (or in shower)
Total (0–100)

shown that discharge to home is unlikely with scores below 29 and very likely with scores above 60. The most widely used scale in rehabilitation at this time is the Functional Independence Measure (FIM)⁵⁵ (Table 23.7).

Rehabilitation of Common Geriatric Conditions

Stroke

Stroke is one of the most common conditions for which older people receive rehabilitation. (Risks, prevention, and early treatment of stroke are covered in Chapter 78.) Rehabilitation interventions begin during the acute hos-

pital phase, primarily directed at preventing secondary complications. The geriatric provider will need to be involved in many aspects of the patient’s care, in reducing ongoing risk factors, minimizing medications, providing the family with information, and care planning.

Although impairment and disability depend on the size, location, and nature of the offending lesion(s), functional return is to some degree dependent on chance. However, even in the case when the patient is fortunate to have significant return of motor or sensory function, the occurrence of a secondary disability may limit the maximum independence the patient may achieve. Hence, rehabilitation should be considered in all patients as they progress.

Most of the return of function is seen in the first month. In some cases, however, motor function may return as late as 6 months after the stroke. Sensory deficits or swallowing problems may improve later. In spite of these endogenous improvements, rehabilitation efforts following stroke are

cost-effective and lead to higher functional levels.⁵⁶ A meta-analysis of rehabilitation research determined that the average person in treatment functioned better than 66% of the participants in the control group. ADL performance and visual-perceptual function improved the most consistently. Younger patients fared better than older, but gains were seen among the older subjects.⁵⁷ Age, by itself, does not affect rehabilitation outcome.⁵⁸

Patients and their families need accurate prognostic information soon after the stroke to make informed decisions about care. They should be told that most patients survive infarcts and that the highest mortality is in the first week. Many survivors will have residual deficits longer than 6 to 12 months after the acute event (Table 23.8). Rehabilitation interventions help survivors adjust to these disabilities even if they cannot be eliminated through therapy.

Acute Care Phase

Initially, rehabilitation efforts are geared toward preventing secondary disabilities and identifying patients who need more intensive rehabilitation. Prevention of secondary disabilities should begin soon after admission. The patient must be turned regularly to prevent the development of pressure sores. Sitting up, daily range of motion of the extremities, and exercise of the uninvolved limbs to prevent deconditioning should be provided. Constipation or dehydration must be avoided. Although most have some urinary incontinence initially, patients with persistent problems should receive appropriate investigation for treatable causes (see Chapter 63).

Immediately after the stroke, the patient’s affected limbs are often flaccid. The arm needs to be properly positioned to prevent subluxation of the shoulder, so that

when motor function returns the arm will be more functional. Shoulder-hand syndrome (a form of reflex-sympathetic dystrophy) may be prevented by regular range of motion exercises (“ranging”), close attention to proper bed positioning, and protecting the shoulder when moving the patient. Systemic corticosteroids may be helpful in its treatment.⁵⁹ Proper body positioning will usually prevent nerve palsies from developing. The use of a footboard to prevent plantar flexion contractures is controversial and should not take the place of active ranging of the patient’s ankles.

Predictions of eventual recovery are difficult during the acute phase. Factors associated with a poor prognosis include flaccid hemiplegia of more than 2 months duration, dementia, persistent bowel or bladder incontinence, severe neglect or sensory deficits, and global aphasia.⁶⁰ Certain features, such as a depressed caregiver, those caregivers not married to the patient, and family dysfunction have been shown to predict which patients may not benefit from home rehabilitation.⁶¹

The choice of which site, whether inpatient unit, nursing home, or the patient’s home, to provide rehabilitation is complex. Recently, the algorithm provided in the Post-Stroke Rehabilitation Guidelines²⁸ has been evaluated and revised slightly⁶² (Fig. 23.1). Rehabilitation “services” refer to a single discipline or type of therapy, whereas a rehabilitation “program” refers to multidisciplinary, coordinated services. The algorithm was found to have good reliability for home and nursing facility placement with rehabilitation services but with no multidisciplinary rehabilitation program. In fact, more than one type of placement was appropriate for 65% of patients. Hence, the most appropriate choice must often be negotiated between the clinician and the patient based upon patient-specific desires and available resources.

Rehabilitation Phase

Once the patient’s condition is reasonably stable, intensive rehabilitation can begin. Total stability is elusive in the older person, and risks of an intervention must be weighed against risks of continued bed rest and deconditioning. Motor return follows a fairly predictable pattern. Initially, the limbs are flaccid with hyperactive reflexes. The next stage is mass flexor synergism; that is, the limb will flex at multiple joints when movement is attempted. A mass extensor synergism usually occurs next. Once the patient has an extensor synergy pattern, even with poor control, ambulation may be possible with a brace and adequate physical training. If the motor return progresses, selective flexion of individual joints usually follows, and finally selective extension with decreased flexor tone returns. Unfortunately, the return of sensory function is much less predictable. Although the return of motor function most affects ambulation (a value held

highly by patients), sensory return often determines upper extremity function and ability to accomplish activities of daily living. There are many interventions that can be used to accommodate for weak muscles. However, patients who are oblivious of their deficit due to perceptual neglect will have a much more difficult time learning new techniques.

It is in this phase that rehabilitation therapists play crucial roles. Physical therapists work with patients to develop strength, augment balance (first while sitting, then when standing), enhance transfer ability, and increase endurance. When being tested for strength, patients should attempt to stand (with assistance if necessary), because supine testing may give falsely weak results. When the lower extremities have “good strength” (4/5) and the patient can balance on the uninvolved side, gait training can be initiated.

For those patients with difficulty advancing the limb or maintaining stability, the patient should be evaluated for a brace and walking aid. For instance, a platform cane or hemiwalker may be required (Fig. 23.2). Ankle-foot orthoses (AFO) are most commonly used in the elderly stroke patient (Fig. 23.3). Two types are commonly employed: the double adjustable upright metal ankle-foot orthosis, used to stabilize a spastic ankle and provide some proprioceptive feedback to the knee; and the posterior plastic AFO, which prevents footdrop but requires a more stable ankle. Seventy-eight percent to 85% of patients are able to walk after 6 months.²⁸

The occupational therapist works with the patient to provide training in daily self-care activities. Occupational therapy has been shown to significantly reduce functional deficits in a randomized trial of stroke survivors.⁶³ Perceptual deficits are commonly seen, particularly in right hemispheric strokes. The patient’s deficits may go undetected until the patient’s ability to organize motor tasks in sequence is evaluated. Simple remedies may provide great self-care benefits. For instance, spasticity sometimes can be controlled with the use of weighted utensils. Other types of special utensils, such as rocker knives, plate guards, and reachers, enable persons with hemiplegia to function more independently. A cognitive retraining program also may be provided by occupational therapists or sometimes by speech therapists. Early assessment for aphasia is critical to providing other team members with recommendations regarding communication needs. Approximately 24% to 53% of stroke survivors are partially or totally dependent 6 months after their strokes.⁶⁴

Special attention must be given to two common, and often related, problems. Poststroke depression is very common, affecting about 30% of survivors. It is especially likely with left hemisphere damage. Depression is often recognized 2 to 3 weeks after the stroke. Depression retards functional recovery and may be misinterpreted as “poor motivation.”⁶⁵ Treatment of depression facilitates

the gains made in rehabilitation. Psychotherapy and the judicious use of antidepressant medication are usually needed. The choice of an antidepressant medication is usually made based on the side effect profile because all have more or less the same response rate. However, because most agents require at least 2 weeks to produce a response, some have advocated early use of methylphenidate to accelerate the response.⁶⁶ Depression must be distinguished from uncontrolled crying, which is also common after a stroke. This condition, thought to be caused by “disinhibition,” responds to selective serotonin reuptake inhibitors.⁶⁷

Malnutrition is another problem seen too often in rehabilitation. A bedside swallowing evaluation by a speech and language pathologist has been shown to be valuable,⁶⁸ and early dietary consultation should occur on all persons after stroke. In some cases, short-term use of enteral feedings may be required.

Attention to premorbid problems must be especially vigilant in geriatric patients. Having access to one’s dentures, eyeglasses, and clothing promotes self-esteem and

may enhance the ability to participate in the rehabilitation program. The patient’s family should be involved in the treatment program through training in caregiving skills. A bedside graph to document progress made by the patient and a chart that specifies goals to be achieved can also be helpful.

Chronic Phase

The chronic phase begins when the person who has suffered a stroke returns to society as a person with a disability. The home, especially the bathroom, will usually need modifications. Raised toilet seats with arm frames, grab bars, and a bathtub bench with a handheld shower hose will often be required (Fig. 23.4). Kitchen modification also may be necessary. Before discharge, the home should be assessed for door widths to assure passage of walkers or wheelchairs, the presence of steps and stairs, the need for ramps, the adequacy of lighting, and safety features that may need modifications.

Because the adjustment process to a major disability may take up to 2 years, ongoing psychologic support often is necessary. The patient may benefit from individual or group psychotherapy, a day health center, or a stroke recovery group. Frank information should be provided regarding the fact that sexual activities following a stroke are quite safe, although new techniques are often needed.

Social activities should be strongly encouraged. A vocational rehabilitation counselor can assess and help with the return to employment if appropriate. Arrangements for transportation are particularly important, as many geriatric patients stop driving after a stroke. For patients with right hemisphere lesions and neglect, driving is inadvisable unless the neglect resolves.

The question of whether patients should receive further evaluations by rehabilitation therapists 1 to 2 years after the stroke is controversial. In a randomized trial, physical therapy was offered to study patients with mobility problems seen more than 1 year after their stroke. Therapy was provided in the home, with most patients seen one to six times. Follow-up was for 6 months. The intervention group showed an improvement in their gait speed (while the controls declined). This benefit was lost, however, if patients stopped having therapy.⁶⁹ In another study, intensive rehabilitation was provided in a stroke clinic to 40 patients who were, on average, 3 years poststroke. Patients received 2 h of therapy, four times a week, for 4 weeks. Significant improvements in balance and ADL performance were achieved. Three months following the intervention, the patients' skills in balance and weight shifting, as well as their ADL scores, were maintained.⁷⁰

Hip Fractures

Many patients with hip fractures can benefit from rehabilitation. Unfortunately, since the advent of prospective payment in hospitals, more patients with hip fracture are sent to nursing homes for longer periods of time.^{71,72} Rehabilitation in the home and nursing home setting has been shown to be cost-effective,^{73,74} but inpatient rehabilitation has not.⁷⁵ Early surgical repair and more than five physical therapy/occupational therapy (PT/OT) sessions per week postoperatively are associated with better health outcomes.⁷⁶ Unfortunately, in this age of short hospital stays, many patients may not be afforded adequate hospital-based physical therapy, in spite of evidence showing that such interventions decrease the number and the length of nursing home stays.⁷⁷ Certain features predict more successful outcomes with hip fracture, which include intact mental orientation, younger age, independence in bathing and transfers, family involvement, and the number of hours received in physical

therapy.⁷⁸ Other features, such as being over age 85 and poor prefracture functional status, predict poor outcomes.⁷⁹ Mild to moderate dementia should not preclude providing the patient with rehabilitation.⁸⁰

Weightbearing after surgery is often a source of confusion. The ideal surgical result would promote maximum independence and allow early ambulation to prevent deconditioning and prevent venous thrombosis. Many orthopedists order weeks of nonweightbearing after the placement of pins or nails, the most common type of surgery used in elderly patients. It is very difficult for older persons to bear weight with only touching their foot on the ground ("toe-touch" weightbearing) during ambulation, owing to general deconditioning and weak upper extremities. There is no evidence that this practice is needed, and early weightbearing according to the patient's tolerance of pain is recommended.^{81,82} It does not appear that hip replacement facilitates better functional outcomes over other surgical approaches.⁸³

Two types of hip fractures, femoral neck and intertrochanteric, are most common. The distinguishing feature is the high rate of avascular necrosis of the femoral head seen in subcapital fractures. Impacted and nondisplaced fractures are often treated with internal fixation, using nails or pins. As already noted, weightbearing can begin usually by the 3rd day. In osteoporotic patients, subcapital fractures may be treated with installation of an Austin-Moore (or similar) prosthesis. Weightbearing to tolerance is allowed by the 2nd or 3rd day. Trochanteric fractures are treated using open reduction and internal fixation, often using a compression screw. With this procedure, the patient usually can bear weight as tolerated by the 2nd day. In the patient with a femoral neck fracture who has preexisting joint disease, a total hip prosthesis also may be indicated.⁸⁴

Rehabilitation efforts should begin as soon as the patient is admitted to the hospital. Stabilization of life-threatening medical problems should occur before surgical repair. If the patient is alert, preoperative evaluation by physical and occupational therapy and training in the exercises to be performed in bed can begin immediately. The patient can begin quadriceps contractions and, on the 1st postoperative day, can sit up and perform isometric exercises as well as gentle flexion and extension at the hip. Adduction, excessive flexion, and abduction at the hip should be avoided if the joint has been replaced.

The patient can begin supervised ambulation with parallel bars by the 2nd or 3rd postoperative day, advancing to the use of a walker or cane. A properly fitted cane should have a 1-in. (or 2–3 cm) rubber tip and be long enough to allow 20° to 30° of flexion at the elbow when held at the side (Fig. 23.5). The patient should support no more than 20% to 25% of total body weight on a cane. The patient should hold the cane in the hand opposite the

FIGURE 23.5. Proper cane length. The elbow is flexed 20° to 30° when holding the cane at the side.

injured hip. Stair training begins during the second week and consists of going up stairs with the uninvolved leg first and coming down with the involved leg first (“up with the good, down with the bad”).

If the patient lacks upper body strength or is unstable with a cane, a pick-up walker should be prescribed (Fig. 23.6A). Patients need to practice advancing the walker about 20 to 30 cm, then advancing the weak leg, and then the good leg. Some older persons may find it easier to advance the good leg first, but this practice increases the risk of falls. Crutches are very difficult for most older persons to use. It must be remembered that special walkers are needed for going up stairs and that it is very difficult to carry objects while using a walker. New walkers with three or four wheels are available that are much easier to negotiate and have carrying baskets⁸⁵ (Fig. 23.6B). Patient acceptance of these walkers is better than for the standard issue models.

Depending on the preexisting health and social support status of the patient, the site for rehabilitation

after hip fracture will vary. Early discharge and home rehabilitation should be considered for those with (1) good health (the absence of significant medical problems), (2) strong social supports (someone who can provide assistance), and (3) adequate performance of ambulation and activities of daily living within 2 weeks of surgery. The remainder may require more intensive therapy that can be effectively provided in a rehabilitation nursing facility.

Lower Extremity Amputation

Although most patients who experience a lower extremity amputation (LEA) are between 51 and 69 years old, the age-related incidence of LEA in persons over age 80 has increased significantly.⁸⁶ More than 1.5 million people in the United States live with some form of major limb amputation.⁸⁷ Of the 127,000 limb amputation procedures done in acute care, nonfederal hospitals in 1993, 98,000 involved the lower extremity. The direct medical cost for a single LEA procedure is approximately \$46,900.⁸⁸ Below-the-knee (BK) amputations are used in two-thirds of patients and above-knee (AK) in one-third.⁸⁹ The predominant cause is peripheral vascular disease. The older person's care is more complex after amputation because of upper extremity weakness, underlying cardiovascular problems, skin that is prone to breakdown, and poor balance mechanisms. Older persons are more likely to have subsequent amputations on the contralateral side.⁸⁶ The geriatric provider plays a crucial role in managing these problems and in helping to determine the most appropriate surgical intervention.

In frail older persons, the decision as to level of amputation is often difficult. An ankle-brachial Doppler index ratio of greater than 0.5 is associated with a greater than 90% success rate for healing a transtibial amputation.⁹⁰ Others believe that a transcutaneous oximetry measurement provides better determination of the appropriate level of surgery.⁹¹ Sometimes the surgeon cannot determine the best level until the amount of blood flow to the tissues can be observed during surgery. Above all, attempts should be made to avoid serial amputations (e.g., partial foot, followed by transtibial, followed by transfemoral) because prolonged bed rest and its attendant complications are more likely.

There are three major types of lower extremity amputations: partial foot, transtibial (also called a below-the-knee or BK amputation), and transfemoral [above-the-knee (AK)]. Partial foot amputations generally do not require postoperative rehabilitation. The older person with a BK amputation has a much greater chance of achieving independent ambulation. With a BK procedure, there is a lower postoperative mortality rate, the energy costs of using a prosthesis are less, and the chance of walking without the use of canes or walkers is better.

FIGURE 23.6. Types of walkers. (A) Standard pick-up walker is very stable. Patient is able to put full weight on handholds. Promotes a slow and abnormal gait. Useful in early rehabilitation

of hip fractures. (B) Rolling four-wheeled walker is very mobile, easy to maneuver in tight spaces. Patient must have good balance and control to use safely.

Indeed, the energy cost of walking with bilateral BK amputations is lower than that of walking with a single AK amputation (Table 23.9). In a younger person such energy costs may be insignificant, but in the older patient they may precipitate angina when there is underlying coronary insufficiency.

Barriers to successful use of a prosthesis include hip or knee contractures, preexisting joint disease of the affected knee, contralateral sensory deficits (e.g., periph-

eral neuropathy), and significant comorbid disease (congestive heart failure, angina, chronic lung disease).⁹² Those patients with cognitive deficits that interfere with learning may have difficulties learning to use a BK prosthesis.⁹³ If the patient has contralateral vascular disease, a prosthesis may be contraindicated. However, this is a very individual decision, and the motivated patient still may benefit from a prosthesis trial. It has been shown that measurements of transcutaneous oxygen tension on the

TABLE 23.9. Lower extremity amputation (LEA) in the elderly patient.

stump skin may be valuable in predicting success at prosthesis fitting. Levels above 40 mmHg are associated with successful fitting, while below 15 mmHg there are often complications.⁹⁴

Even if a prosthesis is not going to be used, patients can benefit from rehabilitation. Training in the use of a special amputation-style wheelchair should be provided. Bed, chair, and toilet transfers also must be learned. Home modifications will be needed. Because the energy costs of using a wheelchair are higher than those of walking, patients with chronic obstructive pulmonary disease and cardiovascular insufficiency must be stabilized.

All geriatric patients should be considered for the fitting of a prosthesis. Age should not be a determinative factor in this consideration. The decision should be based on the patient's medical state, motivation, and mobility needs. As in the case of hip fractures, rehabilitation should begin before the surgical procedure.⁹⁵ Exercise training, including strengthening of the upper body, quadriceps, and hip extensors and practice lying prone, should begin as soon as the amputation is considered. Upper extremity bicycle ergometry is particularly useful for this purpose.⁹⁶ Contractures of the hip and knee are the most common complications of amputations and must be prevented by active and passive ranging daily. The bed should be kept flat, and pillows should not be placed under the knees.

Following the operation, the patient must be trained in care of the stump. Massage techniques, wrapping with an elastic bandage or stump shrinker, inspection for skin integrity, and hygiene should receive attention. Semirigid dressings may also be used and appear to accelerate the time to prosthesis fitting.⁹⁷ The patient should begin transfers with and without the prosthesis immediately postoperatively. Many geriatric patients will use a wheelchair for longer distances, so they also must receive training in its use. Sitting and single-limb balance training also are important.

A permanent prosthesis is usually fitted 6 to 8 weeks postoperatively to allow for stump shrinkage and wound healing. A temporary pylon prosthesis is often employed in the meantime. Some surgeons have used casts placed at the time of the operation to promote early ambulation.⁹⁸ The experience of using casts or prostheses in older persons is limited. A physiatrist or orthotist usually prescribes and fits a prosthesis. A patella-tendon supracondylar socket with a solid-ankle, cushioned heel (SACH) foot is often used in elderly patients because it is lightweight and easy to use.

The outcome of prosthetic training in elderly persons is good, with between 60% and 80% of unilateral BK amputees achieving independent ambulation. Unfortunately, only 50% of bilateral BK amputees and less than 50% of unilateral AK amputees will walk with a pros-

thesis.⁹⁹ Most amputees will have some residual sensations long after surgery. In one study, 79% reported phantom limb sensations, 72% reported phantom limb pain, and 74% reported residual limb pain. However, most described their phantom limb and residual limb pain as episodic and not particularly bothersome.¹⁰⁰ Massage and physical therapy, along with small doses of antidepressant medication, usually suffice to treat such pain. The older person also may experience a change in the socket size with large weight changes (weight loss affects size more than weight gain), and neuroma formation and local skin problems can occur.

Parkinson's Disease

The peak incidence of Parkinson's disease is between the ages of 60 and 69 years, with as many as 40,000 to 50,000 new cases per year. Drug treatment has led to significant improvements in the care of patients with Parkinson's disease (see Chapter 78). Physical therapy, including passive and active mobilization exercises, walking, and range of motion exercises, when combined with medication treatment, may be superior to medication treatment alone.¹⁰¹ Many rehabilitative therapies, such as speech therapy and music therapy, have been studied in Parkinson's patients.^{102,103} All have shown improvements in functioning during treatment, but many report that the positive gains are not maintained once the treatment concludes. There have been no randomized, controlled trials showing long-term, sustained effects on function from rehabilitation alone. Hence, the physical treatment of Parkinson's disease can be considered an example of "preventive" geriatric rehabilitation.

The patient should be trained in techniques used to counter the effects of the disease. Strengthening and endurance training and proper use of assistive equipment also are important. Such training is best provided early in the course of the illness as an outpatient. Involvement in a support group may help to maintain newly learned skills.

Gait and balance training emphasizes a safe gait and improved balance. The patient should be taught to keep the head up, to counter the flexed posture consciously, and to lift the toes during the swing phase of the gait.¹⁰⁴ It also may help to take longer steps and widen the base. The therapist often prescribes a home program of regular exercises to maintain or improve strength, range of motion, and flexibility. Other patients find singing to be helpful. In a recent 3-month randomized, controlled, single-blinded study, researchers explored the efficacy of active music therapy (MT) on motor and emotional functions in Parkinson's patients. The MT group showed significant improvements in their bradykinesia, as measured by the Unified Parkinson's Disease Rating Scale.¹⁰³

Canes should be avoided when walking aids become necessary. Due to the posture of Parkinson's disease, protraction and internal rotation of the shoulder may place the tip of the cane between the legs, causing a fall. When the walker is prescribed, it should be fitted with front wheels, as pick-up walkers may induce a backward fall. In the home, shag or throw rugs should be removed, rails should be installed on all steps, and bathroom equipment (including a raised toilet seat or arm frames and grab bars) should be prescribed.

Deconditioning and Immobility

Deconditioning, which usually can be traced to excessive bed rest in the home or institution, is a common geriatric phenomenon. With modern medical therapies, there are few diseases for which absolute bed rest is indicated. Conditioning reflexes can be maintained by simply sitting in a chair for 1 to 2 h. Following hospitalization, some patients may be unable to return home because of deconditioning, in spite of having had their admitting diagnoses "successfully" treated. Therefore, the mainstay of treatment is prevention. In the acute hospital, patients should have orders for regular out-of-bed activities, be encouraged to walk to diagnostic studies if possible, and be taught bed and chair exercises if activities are limited. In some cases, group exercise programs may be better tolerated and less costly.

If patients do not stress their cardiopulmonary or muscular systems, the presence of deconditioning may go unnoticed. This disorder can be recognized by a rise in the resting heart rate or an exaggerated blood pressure response to exercise, decreased muscle power, decreased endurance, and fatigue during simple activities of daily living. Measurements of a person's "capacity" for exercise should be based on the expected demand in the anticipated living environment. One does not need to achieve total cardiovascular fitness to improve skills in independent living. Gait velocity and safety, not cardiovascular fitness, determine how well the person functions in community settings.

Rehabilitation is directed at enhancing strength, gait stability, and velocity in building endurance.¹⁰⁵ In severely deconditioned patients, the time required to recover lost strength can be estimated to be three times as long as they were immobilized. Patients with premorbid cardiac or pulmonary disease may need inpatient rehabilitation to regain independence. Over the long run, low-intensity, low-frequency (two times per week) walking exercise is associated with improvements in cardiovascular fitness in older women. After 26 weeks of training in a supervised walking program, the experimental group had lower heart rates, both at rest and during exercise.¹⁰⁶ Regular exercise also improves gait stability in disabled elders.¹⁰⁷

Arthritis

A wide variety of other problems are amenable to rehabilitation interventions. The most common chronic illness in the geriatric age group is arthritis. Rehabilitation techniques are used to maintain function of arthritic joints, enhance mobility, and prevent deterioration. In one study, an 8-week course of comfortable walking enabled walkers to improve 70 m over their maximum distance achieved, while controls decreased 17 m. Improvements in functional status (as measured by the Arthritis Impact Measurement Scale) were observed in the walking group but not in the control group ($p < 0.001$); patients assigned to the walking program improved 39%. Walkers used fewer medications and had a 27% decrease in arthritis pain.¹⁰⁸ A longer randomized trial in patients with osteoarthritis using either an aerobic or a resistance exercise program showed improvements in walking speed, pain, stair climbing, and lower rates of disability.¹⁰⁹ Regular exercise should be encouraged in all elders with osteoarthritis to prevent deconditioning and promote independence. The Arthritis Foundation has an extensive array of educational materials for patients.¹¹⁰

Joint replacement surgery is being used increasingly in older populations, and rehabilitation is very important following these procedures. The cornerstones of arthritis rehabilitation are the use of adaptive equipment and training in joint protection and energy conservation techniques.

Conclusion

Rehabilitation should be considered in all geriatric patients with functional losses. Every intervention provided to older persons has the potential for enhancing functional abilities or limiting disabilities. A rehabilitation approach can be adopted in any care setting, including the acute hospital. The patient's premorbid functional status, cognitive capabilities, and support system are strong predictors for success in rehabilitation interventions.

Old Age and Care Near the End of Life

Diane E. Meier

Popular images of death and dying are a jumble of gun violence; young and middle-aged adults on television fighting for life; with the help of tubes, ICUs, and other modern machinery, and nineteenth-century images of feverish mothers or children attended at home by their grieving families and helpless physicians. In reality, these media visions bear little relationship to the actual human experience of dying in the United States.¹ In our society, the overwhelming majority of people who die are elderly. Typically, they die slowly of chronic diseases, over long periods of time, with multiple coexisting problems, progressive dependency on others, and heavy care needs met mostly by family members. They spend the majority of their final months and years at home but, in most parts of the country, actually die in the hospital or nursing home surrounded by strangers. Many of these deaths become protracted and negotiated processes, with health care providers and family members making difficult, often wrenching, decisions about the use or discontinuation of life-prolonging technologies such as feeding tubes, ventilators, and intravenous fluids. There is abundant evidence that the quality of life during the dying process is often poor, characterized by inadequately treated physical distress, fragmented care systems, poor to absent communication between doctors and patients and families, and enormous strains on family caregiver and support systems.

Demography of Dying and Death in the United States

The median age at death in the United States is now 77 years, associated with a steady and linear decline in age-adjusted death rates since 1940. In 1900, life expectancy at birth was less than 50 years, but a girl born today may expect to live to age 79 and a boy to age 75. Those of us reaching 75 years can expect to live another 10 (men) to 12 (women) years, average. By the year 2010, life expectancy is projected to increase to 86 years for women and 79 years for men.^{2,3} This dramatic and unprece-

dent increase in life expectancy (equivalent to that occurring between the Stone Age and the year 1900) is due primarily to decreases in maternal and infant mortality, resulting from improved sanitation, nutrition, and effective control of infectious diseases. The result of these changes in demography has been an enormous growth in the number and health of the elderly, so that by the year 2030, 20% of the United States population will be over age 65, as compared to less than 5% at the turn of the last century. One of the results of this growth in the numbers of older adults is the financial impact of their medical and health care needs. Not only does the Medicare budget absorb much of these costs, but the out-of-pocket expenses for patients and their family caregivers themselves are enormous, and increase with longevity. It has been estimated that about half of all bankruptcies in persons over age 65 are attributable to high medical expenses.⁴ Because of the growth in both numbers and longevity of older persons, the Centers for Medicare and Medicaid Services (formerly the Health Care Financing Administration)⁵ and others⁶ have projected a 73% increase in Medicare and long-term care expenditures in the next several decades.

Although death in the early part of the twentieth century was largely attributable to infectious diseases, today the leading causes of death are heart disease, cancer, and stroke. Advances in treatment of atherosclerotic vascular disease and cancer have turned these previously rapidly fatal diseases into chronic illnesses with which people often live for many years before death. In parallel, deaths that occurred at home in the early part of the twentieth century now occur primarily in institutions (53% in hospitals and 24% in nursing homes). The reasons for this shift in location of death are complex, but are related both to financial incentives, primarily Medicare reimbursement for hospital-based care, with the subsequent rise in the availability of hospitals and hospital beds, and to the care burdens of chronicity and functional dependency typically accompanying life-threatening disease in the elderly. The older the patient,

the higher the likelihood of death in a nursing home or hospital, with an estimated 58% of persons over 85 spending at least some time in a nursing home in the last year of life.⁷

These statistics, however, hide the fact that the majority of an older person's last months and years is still spent at home in the care of family members, with hospitalization or nursing home placement occurring primarily near the very end of life. Additionally, national figures such as these hide the substantial regional variation in location of death. In Portland, Oregon, for example, only 35% of adult deaths occur in hospitals as compared to more than 50% in New York City,⁸ a disparity associated at least in part with differences in regional hospital bed supply and availability of adequate community supports for the seriously ill and dying. Finally, national statistics also obscure the variability in the experience of dying that characterizes our highly diverse nation. For example, need for institutionalization or paid formal caregivers in the last months of life is significantly higher among the poor and women. Similarly, persons suffering from cognitive impairment and dementia are much more likely to spend their last days in a nursing home compared to cognitively intact elderly persons dying of nondementing illnesses.

The fiscal and care system incentives promoting an institutional death, as opposed to home death, persist despite evidence that many (although not all) patients prefer to die at home and despite the existence of the Medicare Hospice Benefit. The hospice benefit was designed to provide substantial professional and material support (medications, equipment) to families caring for the dying at home for their last 6 months of life. Reasons for the low rate of utilization of the Medicare Hospice Benefit (serving about 20% of adult deaths) vary by community but include the inhibiting requirements that patients must choose to give up disease-modifying treatments to access hospice services, that physicians must certify a prognosis of 6 months or less "if the disease follows its usual course," and that very few hours (usually 4 or less) of personal care home attendants are covered under the benefit. In addition, the fiscal structure of the Medicare Hospice Benefit lends itself well to the relatively predictable downward trajectory of late-stage cancers or AIDS, but not so well to the unpredictable, multiyear chronic course of other common causes of death in the elderly, such as congestive heart failure, chronic lung disease, stroke, and dementing illnesses.²

Experience of End of Life in Older Adults

Although death occurs far more commonly in the elderly than in any other age group, most research on the experience of dying has been done in younger populations.

Remarkably little is known about how death occurs in the oldest old, those over age 75. The largest and most detailed study of adult hospital deaths in the United States⁹ focused on a relatively young population (the median age at death in the United States is 77 whereas the median age in the SUPPORT study was 66 years) and demonstrated a high rate of untreated pain in the last few days of life, poor doctor-patient communication about the goals of medical care, and frequent use of ventilators and intensive care.⁹ There is some evidence that costly "aggressive" and potentially burdensome life-prolonging interventions are less frequently used among the oldest patients, independent of baseline functional measures,^{10,11} which may represent a form of implicit rationing based on age. Others have shown consistently high levels of untreated or undertreated pain in the elderly. In one study of elderly cancer patients in nursing homes, 26% of patients with daily pain received no analgesic at all and 16% received only acetaminophen, a percentage that rose with increasing age and minority status.¹² Another study comparing pain management in cognitively intact versus demented elderly with acute hip fracture also found a high rate of undertreatment of pain in both groups, a phenomenon that worsened with increasing age and cognitive impairment.^{13,14} Similarly, Cleeland's study of outpatients with cancer found that age and female sex were predictors of undertreatment, a disturbing observation given the dramatic rise in cancer prevalence and proportion of women with increasing age.^{15,16} Finally, chronic pain caused by arthritis, other bone and joint disorders, and low back syndrome is probably the most common cause of distress and disability in the elderly, affecting 25% to 50% of community-dwelling older adults and, similar to cancer pain, consistently undertreated.¹⁷ These data suggest that the time before death among elderly persons is often characterized by significant physical distress that is neither identified nor properly treated.

Impact of Serious Illness on Patients and Families

Aside from pain and other sources of physical distress, the key characteristic that distinguishes the dying process in the elderly from that experienced by younger groups is the nearly universal occurrence of long periods of functional dependency and need for family caregivers in the last months to years of life. SUPPORT, focusing on a younger age cohort, found that 55% of patients had persistent and serious family caregiving needs during the course of a terminal illness,¹⁸ a figure that rises exponentially with increasing age. Estimates based on 1996 data suggest that more than 25 million Americans deliver care to a seriously ill relative at home, on average about 18 h per week. Assuming a conservative hourly rate of \$8 for

such services, this amounts to \$194 billion in uncompensated care annually.¹⁹

Although the vast majority of caregiving is done by unpaid family members (transportation, homemaker services, personal care, and more skilled nursing care), paid care supplements or provides the sole source of care for 15% to 20% of patients, especially among poor elderly women living alone. Most family caregiving is provided by women (spouses and adult daughters and daughters-in-law), placing significant strains on the physical, emotional, and socioeconomic status of the caregivers.²⁰ More than 87% of caregivers say they need more help with transportation (62%), homemaking (55%), nursing (28%), and personal care (26%) for the patient. Caregiving in itself is a risk factor for death, major depression, and associated comorbidities.²¹ Those ill and dependent patients without family caregivers, or those whose caregivers can no longer provide or afford needed services, are placed in nursing homes where 20% of the population over age 85 resides.^{22,23} Thus, the dying process in the oldest old is characterized by a high prevalence of untreated pain and other symptoms due to chronic conditions, associated with progressive functional dependency, unpredictable disease course, and extensive family caregiver needs.

Mismatch Between Our Health Care “System” and the Needs

The current payment system is poorly matched to the needs of the chronically ill and dying elderly. Medicare fee-for-service promotes use of procedure-based payments, hospitalization, and associated specialization and discontinuity of care. Capitated managed care systems attempt to avoid seriously ill or dying patients with high-intensity service needs, focusing instead on healthier, lower-cost patient populations. The Medicare hospice benefit was designed for patients with cancer and predictably short (less than 6-month) life spans who are willing to give up efforts to prolong life and whose families can provide for the majority of their care needs at home. None of these payment systems addresses the long-term care needs (whether at home or in a nursing home) of chronically ill and functionally dependent individuals whose prognosis is uncertain and whose medical care usually requires simultaneous efforts to prolong life, palliate symptoms, and provide support for functional dependency. Neither paid personal care services at home nor nursing home costs for the functionally dependent elderly are covered by Medicare, but instead are paid for approximately equally from out-of-pocket and from Medicaid budgetary sources originally intended to provide care for the indigent. Even in nursing homes, standards of care focus on improvement of function and

maintenance of weight and nutritional status, and evidence of the decline that accompanies the dying process is typically regarded as a measure of substandard care. Thus, a death in a nursing home is often viewed as evidence, particularly by state regulators, of poor care rather than an expected outcome for a frail, chronically ill older person. Similarly, quality indicators required in long-term care settings fail to either assess or reward appropriate attention to palliative measures, including relief of symptoms, spiritual care, and promotion of continuity with concomitant avoidance of brink-of-death emergency room and hospitals.²⁴

Good News and Bad News

Because of unprecedented improvements in maternal and infant mortality and successes in the control, if not cure, of common chronic diseases, most people who die in the United States are old and frail. They die of chronic, progressive illnesses (such as end-stage heart and lung disease, cancer, stroke, and dementia) with unpredictable clinical courses and prognoses. They have unrecognized and untreated symptoms and an extremely high prevalence of functional dependency and associated family caregiver burden. Current reimbursement systems are unresponsive to this patient population and their families, failing to provide primary care with continuity, support for family caregivers, and home care services, and instead promoting fragmented specialized care tied to procedures and hospitals for lack of any other coherent alternative financing mechanism. This phenomenon has prompted widespread calls^{25,26} for change and reorganization that would ensure accountability for outcomes, processes, and costs of care for the growing population of frail, functionally dependent, and chronically ill elderly in their last phase of life.²⁷

Because care for a dying person typically includes preventive, life-prolonging, rehabilitative, and palliative measures in varying proportion and intensity based upon the individual patient's needs and preferences, any new model of care must be responsive to this range of service requirements. For example, an 88-year-old woman with congestive heart failure and deconditioning after hospitalization for pneumonia typically requires life-prolonging measures (treatment of heart failure, oxygen, and antibiotics), preventive measures (annual influenza vaccination), rehabilitation (home physical therapy to restore independent bed-to-chair mobility), and palliative care (advance care planning, appointment of a health care proxy, treatment of depression, diuretics, oxygen, and low-dose opiates for dyspnea). Because her daughter works during the day, this woman also needs a 12-hour-a-day home health aide because she is unable to care for herself independently. Thus, the model of care needed provides

simultaneous life-prolonging, palliative, and personal care (in this patient they are nearly one and the same) and, given the difficulty of prognosticating time of death in heart failure, will have to continue to do so for the remainder of the patient's life. This so-called mixed management model of care for the frail elderly has been tried in the PACE Demonstrations,²⁸ a capitated Medicare waiver program of full-service primary care for the elderly focusing on continuity, avoidance of hospitalization, and bringing needed services to the patient.

Another promising model, developed by Joanne Lynn and colleagues, is undergoing pilot evaluation in a chronically ill veterans' population with lung and heart disease. The MediCaring model will (1) define eligibility in terms of chronic disease severity (e.g., congestive heart failure with an ejection fraction of less than 30% and two hospitalizations in the last year), *not* by predicted time of death; (2) provide services that span the range of patient and family needs through use of interdisciplinary teams, consistent primary care providers across all care settings, and delivery of as much care as possible in the home setting, whether the focus be on life prolongation, palliation, rehabilitation, or, as is typical, all three; and (3) organize payment through a Medicare waiver combination of capitation (for team services, equipment) and fee-for-service or salary for participating physicians.²⁵⁻²⁷

Substantial change using approaches such as these will be necessary if the health care system is to bear any relationship to the needs of the patients seeking care: patients who are predominantly old and chronically ill and in urgent need of help truly fitted to their needs. Although the problem is daunting, the increase in attention to medical education, research, and clinical service delivery for patients near the end of life are indicators that the recognition necessary to begin the process of change has occurred. The next steps, testing new models and seeing what works, will define the new structure of health care services for future generations.

A century ago, virtually everyone died at home, surrounded by family and cared for by physicians whose primary role was the relief of suffering, whereas today the majority of Americans die within hospitals and nursing homes, surrounded by medical technology and physicians who believe there is nothing else that they can offer. Although the past 100 years have seen tremendous advances in the treatment of disease such that previously fatal illnesses (e.g., diabetes, congestive heart failure) have become chronic conditions, this progress has come at some substantial cost. We have transformed the culture of the dying process from an accepted part of life's experience to an unfamiliar and much-feared event. The majority of Americans have never witnessed a loved one die (a common experience at the turn of the century) and physicians are ill trained, ill equipped, and uncomfortable taking responsibility for the care of dying patients. It is

clear that the time has come to restore the balance so that "relief of suffering and cure of disease are seen as twin obligations of a medical profession that is truly dedicated to the care of the sick."²⁹

A New Section

This edition of *Geriatric Medicine* introduces a new section on palliative care. Palliative care is interdisciplinary medical care focused on the relief of suffering and achievement of the best possible quality of life for patients and for their family caregivers. It involves formal symptom assessment and treatment; aid with decision making and establishing goals of care; practical and moral support for patients and their family caregivers; mobilization of community supports and resources to assure a secure and safe living environment; and collaborative models of care (hospital, home, nursing home, hospice) for persons living with serious, complex, and eventually terminal illnesses.

These fundamentals bear a strong resemblance to the core precepts of geriatric medicine, and while it is true that not all older people suffer from multiple complex chronic illnesses that will ultimately lead to their death, most do, and all eventually will. As a result of the successes of modern medical care, dying and death is now a geriatric phenomenon—therefore, sophisticated management for patients and families entering this stage of their lives is the province of the geriatrician as well as all primary treating physicians. In this new section are chapters on practical approaches to communicating with older adults about prognosis, about the likelihood of death, and about patient preferences for how to use their remaining time; on management of diverse sources of suffering in older adults, including distress associated with transfer from home to a nursing home, with being dependent on others, and with being confused; on palliative approaches to caring for persons with dementia at all stages of the illness and regardless of how long the patient may have to live; and on the importance of the value of achieving a peaceful death and why physicians should care about and know how to help their patients ensure it. We hope our readers find these chapters useful as they accompany their patients and their families through one of the most difficult and important stages of late life.

Doctor–Patient Communication Issues

James A. Tulsky

Why Worry About Communication?

Whether patient suffering is caused by pain, nausea, unwanted medical intervention, or spiritual crisis, the common pathway to treatment is through a provider who is able to elicit these concerns and is equipped to address them. In patients with cancer, the number and severity of unresolved concerns has been shown to predict high levels of emotional distress and future anxiety and depression.^{1–3} Eliciting concerns requires skillful communication with the patient. Unfortunately, physicians and nurses tend to underestimate patients' concerns.⁴ Even in a hospice setting, one study revealed that only 40% of concerns were elicited.⁵ As elderly patients are less likely than younger patients to be proactive in the medical encounter, clinicians working with these patients must be particularly vigilant to elicit concerns and promote patient-centered care.⁶

A central goal of palliative care is to meet the disparate needs of patients and families. Everyone defines a good death differently.⁷ Good communication is indispensable to uncovering these needs through empathic exploration and individually negotiated goals of care. Among the frequently articulated goals of patients at the end of life is the use or avoidance of particular medical treatments. Although patients generally wish to discuss even these most difficult issues, such discussions occur infrequently and late.^{8–11} When they occur, the quality of communication has been found to be lacking.^{12–18} Good communication is necessary to meeting patients' needs and to achieving good deaths.

Finally, considerable evidence suggests that improved physician–patient communication correlates with improved health outcomes, patient satisfaction, and emotional well-being.^{19–23} In fact, primary care patients are more satisfied with their physicians if they discuss advance care planning.²⁴ The mechanisms for this impact are likely twofold. First, improved communication increases the likelihood that patient's needs will be rec-

ognized and addressed. Second, the communication itself may be therapeutic. Simply telling one's story may improve objective health outcomes.²⁵

General Rules of Good Communication

Whether one is explaining the implications of hypertension or talking about impending death, the physician must adhere to basic principles of good communication. The primary difference between these communication tasks is the meaning of the conversation to the patient and the attendant level of emotional significance. When the situation is more likely to make the patient feel vulnerable, one should focus extra attention on the task.

Considerable data exist from the medical and psychological literature to support certain general skills. For example, more accurate assessment of anxiety and depression is associated with good eye contact, clarifying of disclosures, responsiveness to cues of emotional distress, supportive comments, and explicit questions about psychologic content.²⁶ Disclosure of concerns is promoted by open-ended questions, focusing on psychologic aspects of illness, summarizing, educated guesses, and demonstrations of empathy. Likewise, disclosure is inhibited by closed-ended or leading questions, focusing on physical aspects of illness and offering of advice and premature reassurance.²⁷ Furthermore, short demonstrations of empathy can reduce patient anxiety.²⁸ Training programs that emphasize these sorts of skills have been able to demonstrate improvement in physician communication behaviors and decreased patient distress.^{23,29,30}

The following sections identify and elaborate on general skills that are useful in all encounters with elderly patients. Practical advice for specific situations that arise in geriatric and palliative care follows.

Advance Preparation

A little effort spent on advance preparation can have a tremendous impact on the quality of the encounter with the elderly patient. Whenever possible, important medical information, particularly bad or sad news, should be delivered during a scheduled meeting. This plan allows patients to prepare themselves for the type of information they will hear and to ensure that appropriate family members or friends are present. It also allows the physician to allocate the necessary time to the encounter.

Communication best occurs face to face, particularly with elderly patients. Telephones accentuate physical communication difficulties, such as hearing loss and speech problems. There is no opportunity to employ the benefits of nonverbal communication. And, if the topic is emotionally threatening, it is more difficult to assess and ensure the patient's safety at the other end of the telephone.

If one is anticipating an emotionally charged conversation with a patient, as when expecting results of a biopsy of a suspicious lesion, it is best to schedule an office visit. Frequently, however, the physician is caught off guard, and unexpectedly discovers a bad result. In such cases, it is still best to try and schedule a time to discuss the results face to face. For example, one can call the patient and say, "I have received the results of your blood tests, and I would like to discuss these results with you in person. Can you come in tomorrow at lunchtime?" Most patients will understand that all is not well, however, will not ask further questions, and will come in for the visit where everything can be discussed. In effect, they have received a "warning shot" about the bad news and have begun to prepare themselves. Some patients, however, will respond by requesting to know the facts—"Is it cancer?" Even though it may seem evasive, it is worth trying to avoid delivering the news, even at this point, with a statement such as, "I can imagine that you are concerned about the results, and I will answer all your questions. There are a number of things we need to talk about, and I think I can help you better if we speak face to face." If the patient continues to insist on hearing the information, then one is obliged to answer directly, employing all the appropriate skills for delivering bad news. In such a case, it is valuable to inquire directly about the patient's support at home and their immediate plan of action.

One also needs to approach all such conversations prepared with basic medical information and anticipating the most likely questions regarding treatment options, prognosis, and resources for support and guidance. Finally, to the extent possible, such conversations are best held when both the physician and patient are well rested.

Sensory Issues and Control of the Environment

When speaking with older adults, choose a quiet, private room with good lighting to enhance the patient's ability to comprehend. The physician should sit at eye level and within reach of the patient. If possible, one's pager or cellular phone should be turned off, or at least on a quiet mode, and one should avoid interruptions. As presbycusis first affects higher sound frequencies, it is helpful to speak slowly in a clear, loud, low voice.³¹ If patients wear hearing assistive devices, these devices should be in place.

Increasingly, we encounter non-English-speaking patients. One absolutely must employ the assistance of an interpreter in such settings. However, it is equally important to avoid using family members as interpreters. Not only does this run the risk of faulty translation or reinterpretation of the physician's statements, but it also places family members in the uncomfortable position of being both the physician's and patient's spokesperson. The common practice of using bilingual young children as translators is particularly problematic. Most hospitals and health care facilities in regions with high numbers of immigrants employ professional translators or maintain lists of language skills among facility staff members.

The Role of Affect in Communication

Most difficulties in communication are the result of inattention to affect. Affect refers to the feelings and emotions associated with the content of the conversation. Feelings such as anger, guilt, frustration, sadness, and fear modify our ability to hear, to communicate, and to make decisions. For example, after hearing bad news, most patients are so overwhelmed emotionally that they are unable to comprehend very much about the details of the illness or a treatment plan.^{32,33} Conversations between doctors and patients often transpire only in the cognitive realm. Emotion is frequently not acknowledged or handled directly, and physicians miss opportunities to do so.^{34,35} Consider the following conversations observed in a study of empathic communication and missed opportunities³⁶:

- MD: Does anybody in your family have breast cancer?
 PT: No.
 MD: No?
 PT: ... After I had my hysterectomy. I was taking estrogen, right?
 MD: Yeah?
 PT: You know how your breasts get real hard and everything? You know how you get sorta scared?
 MD: How long were you on the estrogen?

PT: Oh, maybe about 6 months.
 MD: Yeah, what, how, when were you, when did you have the, uh, hysterectomy?

In this exchange, the doctor ignores the patient's fears and proceeds with factual questions. Not only is this patient unlikely to feel supported, but she may also fail to give detailed information about her symptoms and hinder treatment. In contrast, in the following conversation, the physician recognizes the patient's expression of affect and delivers an empathic response. This is likely to continue the conversation in the realm of the emotions and leave the patient feeling supported.

MD: How do you feel about the cancer—about the possibility of it coming back?
 PT: Well, it bothers me sometimes, but I don't dwell on it. But I'm not as cheerful about it as I was when I first had it. I just had very good feelings that everything was going to be all right, you know. But now I dread another operation.
 MD: You seem a little upset; you seem a little teary-eyed talking about it.

It is important, as well, to be attentive to the physician's affect. When caring for dying patients, physicians are likely to experience many emotions; these include guilt (“If only I'd convinced him to get that screening colonoscopy”), impotence (“There's nothing I can do for her”), failure (“I messed up, I'm a bad doctor”), loss (“I'm really going to miss this person”), resentment (“This patient is going to keep me in the hospital all night”), and fear (“I know they're gonna sue me”).³⁷ Such feelings are normal and common. However, they can affect one's ability to interact successfully with the patient. For example, feelings of failure may motivate one to avoid the patient, while feelings of loss may make discussions about dying too difficult. The first step toward managing such feelings is to acknowledge that they exist. The next step is to discuss them with colleagues or confidants. In most cases, however, patients do not benefit from hearing such thoughts. When considering sharing such feelings with a patient, a good rule of thumb is to ask oneself, “Am I doing this for me or for the patient?” If the answer is truly the latter, then it may be appropriate to share.

Emotion-Handling Skills

One barrier to eliciting patient affect is the fear of being unable to manage the patient's emotional response. This section describes an approach to handling emotions that is also likely to further elicit the sorts of concerns described earlier. The primary goal of emotion handling is to convey a sense of empathy. Empathy is the sense that “I could be you” and is what patients are usually

TABLE 25.1. NURSE-ing an emotion.

Name the emotion
Understand the emotion
Respect or praise the patient
Support the patient
Explore what underlies the emotion

Source: Fischer GS, Tulsy JA, Arnold RM. Communicating a poor prognosis. In: Portenoy RK, Bruera E, eds. *Topics in Palliative Care*, vol. 4. New York: Oxford University Press; 2000,⁴¹ with permission.

feeling when they comment about a physician that really cared for them.³⁸ Robert Smith has created a useful mnemonic to recall four basic techniques to use when confronted by patient emotions: NURS (Name, Understand, Respect and Support).³⁹ This discussion adds a final “E” for Explore (Table 25.1).

Naming the emotion serves to acknowledge the feeling and to demonstrate that it is a legitimate area for discussion. Statements such as “that seems sad for you” can serve this purpose well, although one needs to be careful not to inappropriately label the patient. Therefore, naming is often best done in a quizzical fashion that does not presuppose the emotion (e.g., “Many people would feel angry if that happened to them. I wonder if you ever feel that way?”).

Expressing a sense of *understanding* normalizes the patient's emotion and conveys empathy. However, expressing understanding must be done cautiously to prevent a response such as, “How can you possibly understand what I'm going through—have you ever had a stroke?” A typical statement might be, “Although I've never shared your experience, I do understand that this has been a really hard time for you.”

Respect reminds us to praise patients and families for what they are doing and how they are managing with a difficult situation. Offering respect defuses defensiveness and makes people feel good about themselves and more capable of handling the future. A useful statement might be, “I am so impressed with how you've continued to provide excellent care for your mother as her dementia has progressed.”

Support is essential to helping people in distress not feel alone. Simple statements, such as “I will be there with you throughout this illness,” can be tremendously comforting. Health care providers ought not feel the entire support burden on their shoulders—support offered can include other members of a team. For example, “We will send a nurse to your home to check in on you in a couple of days, and if you'd like, I could ask the chaplain to pay you a visit.”

Finally, patients will frequently make statements that deserve further *exploration*. For example, a patient may say, “After you gave me the results of the test, I thought that this is gonna be it.” A simple response, such as “Tell me more,” may help reveal the patient's fears and

concerns about cancer that will be helpful in planning future treatment.

Communicating Bad News

Communicating bad news draws upon the skills discussed previously. Many protocols exist for the delivery of bad news; however, the behaviors tend to be grouped into several key domains that include preparation, content of message, dealing with patient responses, and ending the encounter (Table 25.2).^{40,41} The primary elements of preparation (getting the setting right, getting needed information) have already been addressed.

Content of Message

Knowledge of what the patient already knows or believes is extremely valuable to have before revealing bad news to a patient.⁴¹ This understanding allows the physician to begin their explanation from the patient's perspective, aligning oneself with the patient and making communication more efficient and effective. The time that a test is ordered is a good time to assess this. One might ask, "Is there anything that you are particularly concerned about?" If the patient mentions a serious illness that might be present, the physician can follow up by asking what the

TABLE 25.2. Key elements of delivering bad news.

<i>Preparation</i>	
Find out what patient knows and believes	
Find out what patient wants to know	
Suggest a supportive person accompany the patient	
Learn about the patient's condition	
Arrange the encounter in a private place with enough time	
<i>Content</i>	
Get to the point quickly	
Fire "warning shot" (example: "I have bad news")	
State the news clearly, simply, and sensitively	
Allow silence	
Avoid false reassurance	
Make truthful, hopeful statements	
Provide information in small chunks	
<i>Handle patient's reactions</i>	
Inquire about meaning of the condition for the patient	
NURSE (Name, Understand, Respect, Support, Explore) expressed emotions	
Assure continued support	
<i>Wrap-up</i>	
Set up a meeting within the next few days	
Offer to talk to relatives/friends	
Suggest that patients write down questions	
Provide a written appointment and contact information and how to be reached in emergencies	
Assess suicidality	

Source: Fischer GS, Tulsky JA, Arnold RM. Communicating a poor prognosis. In: Portenoy RK, Bruera E, eds. *Topics in Palliative Care*, vol. 4. New York: Oxford University Press; 2000,⁴¹ with permission.

patient's specific fears and concerns are. Consider, for example, an elderly woman with a breast mass. Her doctor is concerned that it might be breast cancer. Here is how the physician might approach the patient⁴¹:

MD: Is there anything that you are particularly worried that this might be?

PT: I guess anyone would be scared that it is cancer.

MD: I'm afraid that it might be cancer. There are other things that it might be too, however. That's why we are going to do the biopsy—to find out. What worries you most about cancer?

PT: My mother died of colon cancer. She suffered terribly with it. In the end, she was so weak and thin . . . she had to "do her business" in a bag—you know? And she always seemed to be in pain . . .

At the end of this exchange, note how the physician begins to find out what the patient's fears are in an effort to anticipate the patient's reactions to the news if the test result does turn out to be bad.

When prepared to deliver the content of the message, the physician should begin by firing a brief "warning shot" and then stating the news in clear and direct terms. One should avoid spending any time "beating around the bush" before sharing the news. For example:

MD: We have the test results back, and I'm afraid they don't look good.

PT: Oh no, what is it?

MD: The biopsy shows you have cancer.

Perhaps most important is what follows this exchange. The clinician should remain silent and allow the patient an opportunity for the news to sink in. One can strike an empathic stance, maintain comfortable eye contact, and perhaps use a nonverbal gesture, such as reaching out and touching the patient's hand. However, silence is imperative to allow the patient an opportunity to process the information, formulate a response, and experience his or her emotions. The clinician who feels uncomfortable during this silent phase needs to appreciate that the discomfort is rarely shared by the patient, who is engrossed in thought about the meaning of the news and thoughts about the future. Furthermore, very little that is said by the physician at this time will be remembered by the patient, so it is best not to say it at all. If the patient makes no verbal response after perhaps 2 minutes, it can be useful to check in: "I just told you some pretty serious news. Do you feel comfortable sharing your thoughts about this?"

Dealing with the Response

The remainder of the conversation should be spent primarily dealing with the patient's response, including using the NURSE skills to legitimize and empathize with the

patient's experience. It is also important to explore the meaning the news has for the patient and to achieve a shared understanding of the disease and its implications. For example:

MD: What is most troubling to you about having cancer?

PT: It's a death sentence—my mother died from cancer; my brother died from cancer. I guess it's my turn now.

MD: Given your experience, I can see how this is really scary for you. And cancer can be very serious. However, in your case, there are a lot of treatment options, and you have a good chance of surviving with this disease.

PT: So this won't kill me?

MD: I certainly hope not. And I'll be there with you every step of the way fighting this illness.

The preponderance of literature stresses the importance of maintaining hope while remaining truthful.⁴⁰ Hopeful messages need to be tailored to patients' specific concerns, particularly addressing patient misconceptions and fears. Once patients' concerns have been explored, patients can be reassured more effectively. When effective treatment is available, this fact should be explained. When the treatment options are poor, hope may be found by alleviating patients' worst fears. Doctors may reassure patients that they will not be abandoned during their illness, that the doctor will remain available if things get worse, that everything will be done to maintain the patient's comfort, and that they will continue to watch for new treatment developments.⁴² Often people find hope and strength from their religious or spiritual beliefs, from having their individuality respected, from meaningful relationships with others, and from finding meaning in their lives.⁴³ Exploring these with the patient over time may help to foster realistic hope. Although physicians may have a desire to make an overly reassuring statement to the patient right after revealing the diagnosis, hopeful statements that are truthful and that are made after taking the time to explore the patient's concerns first are more likely to be accepted by the patient.⁴⁴ One can offer a realistic sense of hope, whether biomedical ("We'll keep our eyes open for new treatments and discuss them as they become available") or psychosocial ("I look forward to talking with you more about how we can help you live every day as fully as possible, despite this illness").

Patients may have specific questions about further tests, treatment options, and prognosis. It is important to respond to these seriously. However, many patients suffer comprehension difficulties in such emotionally challenging situations. Give simple, focused bits of information, use nonvague language that patients can understand, carefully observe the patient's verbal and nonverbal reactions to what you say, and most importantly, avoid information-packed speeches.

Ending the Encounter

The clinician must end the encounter in a way that leaves the patient feeling supported and with some sense of hope. Support can be provided through meeting patients' immediate health needs and risks. One must treat pain and palliate other symptoms. Patients should be asked how they plan to cope with the news, and if their response raises any concerns about suicide, this should be asked about directly and addressed. One should try to minimize aloneness through statements of nonabandonment and referral to other resources, such as support groups, counselors, or pastoral care.

Last, one should provide a specific follow-up plan: "I'd like to you to keep a list of questions so I can answer them for you on our next visit this Tuesday. We'll talk about all your options again at that time . . . Okay? And please feel free to call me." A legibly written phone number and date and time for the next appointment will provide concrete evidence of the ongoing connection to the physician and help a distressed patient to remember the plan. The physician needs to remember that the goal of this conversation is not to leave a happy patient. That is rarely possible (or even desirable) after delivering bad news. Instead, one hopes to leave a patient who feels supported and cared for and who can look forward to a specific plan of action.

Advance Care Planning

Discussions about advance care planning encompass many goals. These aims include preparing for death and dying, exercising control, relieving burdens placed on loved ones, helping patients make decisions consistent with their values, and leaving patients feeling supported and understood.⁴⁵ Unfortunately, frequently many of these goals are not met. Audiotape studies of actual discussions about advance care planning demonstrate that information is frequently presented in ways that may not be understood by patients, uncertainty is addressed insufficiently, empathic opportunities are missed, and the scenarios and treatments discussed do not reflect the most challenging situations confronted in real medical settings.^{15,16} These data are not surprising. Patients struggle to understand the issues underlying hypothetical future treatment decisions while confronting the emotional impact of discussing their own mortality. Clinicians must respond to patients' cognitive and affective demands, yet few providers receive formal training in such communication.^{46,47}

The first step in preparing to discuss advance care plans is deciding on the appropriate goals for the discussion.⁴⁸ What one hopes to accomplish will vary depending on the clinical situation.⁴⁹ Advance care planning includes

many different tasks: informing the patient, eliciting preferences, identifying a surrogate decision maker, and providing emotional support. Frequently, one cannot accomplish all this in one conversation, and focusing on the goals of the discussion allows the physician to tailor the encounter. Advance care planning is completed as a process over time that allows patients and providers an opportunity for thoughtful reflection and interaction with others.

For a healthy, older patient, physicians might establish whom the patient would like to appoint as a health care surrogate. They might ask whether the patient already has a written advance directive and explore the patients' thoughts about dying and the general views about life-sustaining treatments. For an elderly patient with a serious chronic illness, the doctor might also discuss the patient's attitudes about specific interventions that are likely to occur. For example, the physician might ask about attitudes toward mechanical ventilation in a patient with severe chronic obstructive pulmonary disease (COPD). Finally, if the illness has progressed to the point where it seems that the patient will soon die, the doctor will shift the focus from future treatment in hypothetical scenarios to establishing what the goals should be for care provided in the present. In all cases, advance care planning can help patients prepare for death, discuss their values with their loved ones, and achieve a sense of control.⁴⁵ It can help build trust between doctors and their patients, so that when difficult treatment decisions arise, doctors, patients, and their loved ones can communicate openly and achieve resolution.

Despite considerable recent attention to the issue of advance care planning, advance directive discussions and completion rates remain low. Doctors may be uncomfortable discussing death because it evokes feelings of their own impotence and it calls to mind their own mortality. Doctors may also be concerned that the discussion will shock or trouble their patients.

Nevertheless, ample data demonstrate that many patients want to have discussions about advance directives with their physicians,^{10,50} that they believe these discussions should occur before the onset of serious illness, and that they believe that physicians ought to initiate the discussions.^{11,51} Most patients are not overly disturbed by these discussions and may actually have a positive emotional response to them because of increased sense of control.^{10,52} Although some may have negative feelings of anxiety or sadness, patients who experience these emotions still want to discuss advance care plans.

Initiating the Conversation

There are a number of ways to begin the discussion.⁴⁸ Often physicians can relate the topic to a recent serious illness. For example, if the patient had been previously

hospitalized for COPD, the doctor may begin an advance directive discussion this way:

MD: How have you been doing since you were discharged from the hospital?

PT: Pretty well. The breathing is pretty much back to normal . . . you know.

MD: Good. You know, I was pretty worried about you when the medics brought you to the ER.

PT: So was I. I was never that bad before. I really felt like I was suffocating.

MD: That sounds like it must have been awful.

PT: Yeah.

MD: Well, I realized that you and I have never had a chance to talk about what we should do if you were sicker, say so sick that you couldn't tell me what you wanted, and we had to do things like put you on a breathing machine . . .

Another way to begin is to ask about experiences with relatives or friends who have died. Elderly patients are no strangers to death. They have been to many funerals of family members and friends. They are likely to have observed serious illness closely and perhaps have had loved ones in some of the situations that the physician is describing. They are likely to have much information and misinformation about end-of-life care, and are likely to have thought about their own deaths. Opening a discussion in this manner can naturally lead to a discussion about how decisions were made and what the patient thought of that particular death. This will provide valuable insights into the patient's own values. Finally, when there is no such event to tie the discussion to, doctors can simply note that they discuss the topic with all their patients. One can reassure patients, when true, that one is not bringing the topic up because one believes that the patient's death is imminent or because the physician has information about the patient's condition that is not being shared.

Providing Information

Patients must have adequate information to make informed decisions. It helps to start by asking patients what they understand about their medical illness. ("Tell me what your understanding so far is of your illness. What have your other doctors told you?") If the patient's condition is more serious than he or she realizes, then the physician will need to shift focus. The physician will want to put off discussing advance care plan, focusing the discussion instead on explaining to the patient the seriousness of their condition.

Studies indicate that patients are more interested in what the expected health outcome will be than in details about the interventions themselves.^{53,54} ("Many patients tell me they would not want their lives medically pro-

longed if they could not expect to recover to a point where they could recognize and interact with loved ones. Others say they want everything possible done to lengthen their life, no matter what. Which kind of person are you?") Furthermore, when elderly patients are provided with evidence-based outcome data about the prognosis after requiring CPR, they change their preferences for the intervention.^{55,56} The primary reason for patients to consider withholding treatments is to avoid an outcome judged by them to be worse than death.⁵⁷ The other reason is that the burden of the treatment, on themselves or their loved ones, outweighs the potential benefit. Therefore, patients should achieve an understanding of the impact of common life-sustaining interventions on one's quality of life. In contrast, vivid descriptions of the nature of the treatments themselves (e.g., intubation, cardioversion, ICU care) may alarm patients but be less helpful.

Eliciting Preferences

Patients state preferences after learning about potential options and evaluating these in light of their personal values. Values refer to deeply held beliefs, such as a desire for personal independence or the importance of a religious practice. By exploring patients' values and goals, clinicians can help them clarify their specific preferences. Sometimes one can ask explicitly about such values (e.g., "What makes life worth living for you?"). Alternatively, values may be elicited in the process of asking about specific treatment preferences. For example, after a patient makes a statement about end-of-life care (e.g., "I'd never want to be on one of those machines."), the clinician may respond by simply asking, "Why?" The answer to this question (e.g., "Because I never want to be a burden on my family or society") may uncover a patient's core values that will impact greatly on treatment decisions.

Identifying what conditions the patient would find unacceptable can also help clarify a patient's preferences. A useful question is, "Can you imagine any situations in which life would not be worth living?"⁵⁸ Typically, patients mention persistent vegetative state or similar dire scenarios. This question can be followed by asking what the patient would be willing to forgo to avoid such states.

For many patients, dealing with uncertainty comprises the most difficult aspect of decision making. When doctors ask patients if they would want a particular treatment, like a ventilator, patients will often state that the treatment should be provided "if it will help me, but if it won't help me, don't do it." Statements like this ignore the reality that physicians are often uncertain about the outcome. Everyone responds to uncertainty differently, and the patient's approach to this issue should be discussed explicitly as well. For example, one may ask,

"What if we are not sure whether we will be able to get you off the breathing machine?" Depending on the patient's answer to this question, the doctor can explore what the chance of success needs to be to pursue aggressive treatment. Some patients will state that any possibility of recovery is worth pursuing, whereas others will refuse curative treatment when the likelihood of recovery drops below a particular threshold.⁵⁹ Some patients are comfortable using numbers talking about probabilities, others are less quantitatively facile.^{60–62} The patient's preferences should dictate the extent to which numbers are used in this discussion. Many patients will be satisfied leaving it to the judgment of the physician and family members, with only general instructions. The option of a time-limited treatment trial is also a useful way to provide reasonable alternatives and clarity in the face of uncertainty.

It is impossible to elicit meaningful preferences for every intervention in every possible situation. By focusing on a patient's values and goals, the physician can then help the patient make decisions about future or current treatments that are consistent with those goals. Discussions should move back and forth from preferences to reasons and values to information and back again, ensuring that the patient understands the implications of their stated preferences and that the doctor understands the patients' values. In this way, when the physician is faced with an unanticipated clinical situation, he or she can use the patient's stated values and goals to help determine the appropriate course of action. In such discussions, it is frequently worthwhile to inquire specifically about some controversial treatments such as artificial nutrition and hydration; this is particularly true in states that require the patient's specific directive to withhold these treatments.

Patients and physicians often use vague terms that ought to be avoided. For example, a statement that a treatment should be continued so long as "quality of life is good" begs further clarification. How does the patient (or the surrogate or the physician) define a good quality of life? In fact, it is always important to ensure that the patient and physician have a shared understanding of the conversation and its implications. Similarly, medical jargon should be avoided, one should always define technical terms, and patients must be encouraged to ask questions.

Choosing Surrogate Decision Makers

Identifying who is to act as the patient's health care proxy may be the most important outcome of a conversation about advance care planning. Does the patient wish this to be a single individual or an entire family? Given the literature demonstrating poor concordance between patient preferences and surrogate perceptions

of those preferences, the clinician would be wise to stress the need for the patient to communicate with the selected proxy decision maker.⁶³ Patients should also be asked how much leeway their proxies should have in decision making.⁶⁴ Should proxies adhere strictly to patients' stated preferences, or should they have more flexibility when making actual decisions?

These discussions can be emotionally difficult, even when they are welcome. It is important to draw upon the emotion-handling skills described earlier and to acknowledge the patient's feelings of sadness, fear, or anger when they arise and to validate those feelings by stating your understanding of their reaction. The physician can admit that the discussion can be difficult and support the patient by stating how helpful he or she has been in helping to understand his or her preferences. Another way doctors can provide support to the patient is to assure the patient that they will do whatever they can to meet their goals (such as comfort) and to articulate what some of those things might be. In this way, doctors can assure patients that they will continue to care for them, even if they are in a condition in which they would not want life-sustaining treatment.

Communicating about the Transition

It is possible that the greatest communication challenges face physicians and patients as they discuss progression of disease, the transition from a primary focus on life-prolonging therapy to a primary focus on palliation and the referral for hospice care. Such times of transition involve the recognition of loss, redefinition of self-concept and social role, and great emotional stress. Patients are likely to feel sadness, anger, and denial. Physicians frequently have difficulty with such discussions because they feel a sense of failure or are worried that patients will feel abandoned or that they will be overcome in the conversation by anxiety or despair.⁴¹ Furthermore, they may have their own unresolved issues about mortality or fear the patient's anticipated emotional response.

Again, it is useful to identify the goals of these conversations, which include eliciting emotional, psychological, and spiritual concerns and providing empathic and practical support. Of course, it is also important to help patients acknowledge their illness and to make appropriate health care decisions, such as enrolling in hospice. However, conversations should not be dominated by the physician's agenda, and patients must be given ample space to make decisions according to their own timetables. According to a recent study, patients facing terminal illness desire a physician who will talk in an honest and straightforward way, be willing to talk about dying, give bad news in a sensitive way, listen, encourage questions, and be sensitive to when they are ready to talk about death.⁶⁵ They also wish for physicians to maintain hope

TABLE 25.3. Open-ended questions to initiate conversations about dying.

“What concerns you most about your illness?”
“How is treatment going for you (your family)?”
“As you think about your illness, what is the best and the worst that might happen?”
“What has been most difficult about this illness for you?”
“What are your hopes (your expectations, your fears) for the future?”
“As you think about the future, what is most important to you (what matters the most to you)?”

Source: Lo B, Quill T, Tulsky J. Discussing palliative care with patients. *Ann Intern Med.* 1999;130:744–749, with permission.⁶⁹

while being truthful. Easier said than done. As a general rule, it is important for physicians to employ behaviors that promote the sharing of concerns by patients and to avoid behaviors such as reassurance that inhibit such sharing. Table 25.3 provides useful open-ended questions with which one can initiate such conversations.

As patients respond to these questions, the physician should continue to focus on the psychosocial and spiritual aspects of their illness and not allow the biomedical issues to dominate. It is important to avoid false reassurance.⁶⁶ A particular form of response that can be extremely effective at these times is the “wish statement.”⁶⁷ These are particularly effective in response to statements that appear to demonstrate significant denial of the severity of illness. For example:

- PT: I'm going to get better. I know that this new chemotherapy they're offering at the university will make the difference.
- MD: I wish that there was a treatment that would make this cancer go away.
- PT: You mean that you don't think it will work.
- MD: It's hard to come to terms with this, but unfortunately I don't believe it would help you overcome your cancer.
- PT: I was afraid you might say that. What do we do now?
- MD: There's a lot that we can do. Let's talk about what goals are most important for you right now.

The wish statement allows the doctor to demonstrate empathy toward the patient and to align herself with the patient's hopes. Yet, at the same time it implicitly conveys the message that certain goals are unrealistic. In this way, the physician can address the patient's denial without losing the therapeutic alliance.

Dreaded Questions

Finally, it is useful to consider several of the questions that many physicians find most difficult to answer. Responding to such questions draws upon the many skills

described in this chapter, and it is useful to keep several additional points in mind.⁶⁸ Check the reason for the question (e.g., “Why do you ask that now?”), show interest in the patient’s ideas, and empathize with their concerns. It is also important to be prepared to admit that you do not know.

Having anticipated replies can be useful, and several examples follow⁶⁹:

PT: How long do I have to live?

MD: I wonder if it is frightening not knowing what will happen next, or when.

This response acknowledges that underlying such a question is tremendous emotion, most likely fear. It will be important for the physician to give a factual response to this question. However, the patient will not be prepared to hear this response until the doctor has addressed their emotional concerns. The suggested answer above allows patients to speak about their fears and worries. When the physician needs to use a more factual response, the following is a way of being honest while maintaining hope: “On average, a person in your situation lives 3 to 4 months, but some people have much less time, and others may live longer. I would take care of any practical or family matters now that you wish to have completed before you die but continue to hope that you are one of the lucky people who gets a bit more time.”

FM: Does this mean you’re giving up on him?

MD: Absolutely not. But tell me, what do you mean by giving up?

Suggesting that a patient receive palliative care risks conveying a sense of abandonment. Physicians must be emphatic that palliative care and hospice are active forms of care that meet patients’ varying goals at the end of life. However, further exploration of a patient’s or family’s concerns about abandonment are important to understanding their perceptions and attitudes toward care at the end of life.

PT: Are you telling me that I am going to die?

MD: I wish that were not the case, but it is likely in the near future. I am also asking, how would you want to spend the remaining time if it were limited?

This wish statement helps the physician identify with the patient’s loss. The following sentence is an attempt by the physician to reframe the patient’s understanding of the situation. He has acknowledged that the patient is dying, but now he seeks to understand what the patient’s goals might be in light of this new information. Creating new goals in this way provides an outlet for the patient’s hope.

Bereavement

Caring for elderly patients means caring for bereaved patients. The loss of spouses, siblings, other family members, and close friends is extremely common among older persons. A full discussion of bereavement is beyond the scope of this chapter; however, it is useful to review several key elements of communication with patients after loss.⁷⁰ Patients should be encouraged to tell their stories of loss, including describing details of the days and weeks around the death of their loved one. Similarly, patients benefit by recalling earlier positive memories of the person. Physicians can explore how the patient has responded to the grief (“How have things been different for you since your husband died?”) and identify the patient’s social support and coping resources (“Has anyone been particularly helpful to you recently?” “What helps you get through the day?”). Last, one should not overlook the frequently enormous practical ramifications of loss, such as financial difficulties or the possible loss of a home and transportation.

Good communication skills provide the pathway to excellent care for elderly persons. The fundamentals of such communication are listening, attending to the patient’s emotional needs, and achieving a shared understanding of the concerns at hand. Specific tasks such as delivering bad news, discussing advance care planning, helping patients through the transition to hospice care, and responding to bereavement require using these skills to ensure that patients’ concerns are elicited and addressed, that they are informed, and that they feel supported.

Care Near the End of Life

Sarah Goodlin

Advances in medical science during the past half century allow people to survive many acute illnesses that previously would have resulted in death. Yet, rather than curing illness, most medical interventions permit us to manage chronic disease. Most Americans age with one or more degenerative or disabling diseases and require daily assistance toward the end of life. It is difficult or impossible to identify a point at which a gradually worsening patient begins “dying” in many chronic disease states. In the process of ongoing care, physicians and patients often become aware that the likely benefits of certain treatments or diagnostic tests may be outweighed by their discomfort or other burdens. For some patients, no treatment offers hope for prolongation of life or restoration of function, and their care becomes focused on palliation of symptoms and enhancing the quality of their remaining life. Other patients with advanced illness may prefer to attempt to prolong life, but they will also benefit from efforts to reduce symptoms and address social, existential, and spiritual needs.

Because of the multitude of therapies and interventions available in current medical practice, caring for dying patients has been too often viewed as withdrawing or withholding treatment. Care near the end of life is better viewed as “shifting the emphasis” of treatment to an intensive focus on maintaining dignity, enhancing quality of life, supporting the family, and lessening the burden of illness. All patients with advanced illness will benefit from this focus, even when they are still receiving treatment directed at prolonging life. The provision of palliative care in settings such as the hospital or intensive care unit, associated with the acknowledgment that patients have a high likelihood of dying, will ease transition from life-prolonging efforts to palliation alone when such treatments are no longer appropriate.

Three-quarters of the 2.3 million deaths in the United States annually occur in persons over the age of 65 and 26% are in persons age 85 years or older.¹ The median age at death in the United States is 77 years. Hence, all

physicians who care for elderly patients should know how to care for patients at the end of life. The interdisciplinary approach to patients with multiple medical, social, and functional problems utilized in all of geriatrics applies equally to all seriously ill and dying patients. This chapter reviews available data about death in elderly Americans and presents an approach to care for those nearing the end of life.

Dying in the United States

National data from 1998 death certificates indicate 33% of deaths were from heart disease, 23% from cancer or malignant neoplasm, and 7% from stroke. Evaluation of Medicare claims data for the last year of life shows multiple diagnoses in the majority of decedents. In that analysis, heart diseases are present in 66%, neoplasm in 31%, pneumonia and influenza in 29%, chronic obstructive pulmonary disease in 26%, cerebrovascular disease in 23%, and dementia in 14% (dementia is likely underrepresented, as Alzheimer’s disease prevalence is 19% of individuals aged 75–84 years and up to 45% in those 85 years old and older²). Among Medicare beneficiaries receiving hospice care, 40% had malignant neoplasm, 10% had congestive heart failure, and 6% had other heart disease.³ Only 23% of individuals dying in the United States received hospice care in 1998; more than 80% of those were white or Caucasian. Medicare was the source of hospice payment for two-thirds of individuals. Referrals from physicians to hospice programs often come very late in the course of the illness.⁴ The median length of care in hospice in the United States in 1999 was 29 days and mean enrollment 48 days, suggesting that hospice services are not invoked until death is imminent for many patients.

In the United States, 50% to 60% of individuals die in hospitals, 25% in nursing homes, and 20% at home. After initiation of the “Diagnosis Related Group” prospective

payment system for Medicare in the mid-1980s, the site of death for Medicare recipients shifted from the acute hospital toward nursing homes.⁵ Predictors of death in the home include cancer or AIDS diagnosis, a caregiver or spouse in the home, younger age, type of health insurance, physician experienced in home death,⁶ and geographic location. The regional number of hospital beds is inversely related to the likelihood of death at home. A fivefold difference among five geographically distinct hospitals in the rates of death at home correlated with hospital beds per capita when controlled for age, disease, income, preference for site of death, and family support.⁷ The Dartmouth Atlas of Health Care documented wide geographic variation for Medicare recipients in location of death and care in the final 6 months of life. Death in the hospital varied for hospital referral region from 17.29% in Bend, Oregon, to 49% in Nevada in 1995 to 1996. In 1994 to 1995, the number of days in the hospital in the final 6 months of life was 4.4 days at the low end of the spectrum and 22.9 at the high end, with longest lengths of stay observed in the northeast and south. Similar variation was observed in intensive care use, visits by medical specialists, and visits to 10 or more physicians in the last 6 months of life.⁸

Death in the hospital often occurs without specific plans to meet patient and family needs and is frequently accompanied by interventions of uncertain value.⁹ Inpatient palliative care and hospice units have been developed in several institutions¹⁰ but are not the norm. Intensive care unit (ICU) deaths typically involve decisions to withhold or remove life-prolonging therapies.¹¹ The ICU brings unique challenges, including the dilemmas of attempting to prolong life for patients at high likelihood of dying and the obligation to ensure comfort in noncommunicative patients.¹²

Costs of care in the last year of life are greatest for those who die in the hospital, and Medicare payments for hospital care are five times the amount paid for home health and hospice care in the last year of life. Medicare annual reimbursement for decedents averaged \$26,300, in contrast to \$4400 for survivors.¹³ The Dartmouth Atlas Project documented a bell-shaped curve by geographic region in Medicare-reimbursed inpatient care in the last 6 months of life. Very old persons receive less costly and less resource-intensive care than younger individuals.^{14,15} Medicare expenditures in the final 2 years of life decrease with age above 75 and are significantly less for the oldest old.¹⁶ Other costs may increase, however; individuals incur significant out-of-pocket expense for institutional and community-based long-term care services (unless they qualify for Medicaid) or receive nonreimbursed care from family.

Perversely, the reimbursement system for medical services favors in-hospital highly technical acute care and does not ensure payment for in-home supportive care.

Reducing highly technical or life-sustaining interventions for those who are very near death may yield only small effects on health care costs.^{17,18}

The Process of Care

Care for patients near the end of life can be viewed as a series of steps. While each individual progresses toward death in his or her own way, the process of providing care should include certain fundamental steps, which are depicted in Figure 26.1.

Clarifying and Making Explicit the Goals of Care

Perhaps because of heterogeneity in disease course and patterns, physicians identify life expectancy and prognosis poorly in seriously ill persons.¹⁹ Nonetheless, the clinician should employ relevant medical knowledge and experience to inform patients of their status, the likely course of their disease (including the fact that they will die of this disease at some point), and the benefits and burdens of interventions and treatments (Table 26.1). Physicians must talk with patients and their families about what is medically possible and reasonable in a given situation and elicit patients' values and preferences for care. Medical options and patient values and preferences should be integrated to form explicit goals of care. As disease and care progress, the goals may change; hence, decision making will be a dynamic process. The goals for care should be the foundation for planning and delivering care. Patients' status, their needs, and their family's needs should be continuously reevaluated relative to the goals.

Decision making about care near the end of life should occur as a shared process between the physician and patient. Family and other providers should be made aware of the decisions and included whenever appropriate. When the patient lacks decision-making capacity, an appointed proxy or surrogate can speak for the patient. A plan to meet the goals should follow. The plan should address interdisciplinary holistic care for the patient and family.

On occasion, patients or caregivers may request interventions for which the potential benefits would be significantly outweighed by probable burdens. Although a patient's right to refuse treatment is well established, patients have very limited legal or ethical authority to demand interventions that are not medically sound. Physicians are not obligated to provide futile therapy or treatments that are not medically appropriate.²⁰⁻²² Evaluating the interventions requested in relation to the goals of care can provide helpful insight for the patient or family.

FIGURE 26.1. Care for patients near the end of life: core process.

Patient Preferences for the End of Life

Understanding what is and what was most important to the person facilitates a conversation about preferences for end-of-life care. Values help clarify how to structure goals and what interventions are acceptable. Discussion should review the potential desirable and undesirable outcomes and alternative approaches as they relate to the goals of care for the individual. Patients should be specifically asked if they wish life-prolonging treatments under circumstances of permanent loss of mental ability severe enough to keep them from recognizing and interacting with loved ones. For example, the alternative to attempted cardiopulmonary resuscitation (CPR) is to be kept comfortable and be allowed to die naturally when the heartbeat or breathing stop. As with other care decisions, conversations about preferences should involve the patient directly. Both physicians and surrogates do little better than random chance when predicting the patient's wishes about CPR.^{23,24} Discussion with patients about preferences should ideally occur in advance of significant decline in cognitive status, although psychiatric or neurologic illness should not preclude a discussion with

the patient. Capacity is decision specific. Even patients who are mildly to moderately demented can usually state what they value and whom they trust to make decisions on their behalf. Mild to moderately impaired patients with Alzheimer's disease have the capacity to appoint a health care proxy and should be counseled to do so.²⁵ Depression does not mean that a patient has lost decisional capacity, although depressed persons may be more likely to decline life-sustaining interventions than others.^{26,27}

Preferences and plans about attempted resuscitation must be integrated into the plan of care. Informing patients about their rights to make choices about treatment and about the use of advance directives, as required by the Patient Self-Determination Act (PSDA), has not been demonstrated to alter patient outcomes.^{28,29} For hospitalized patients with serious illness, rates of attempted CPR varied significantly with geographic location and with diagnosis; CPR rates were more than threefold greater for patients with congestive heart failure than other diagnoses.³⁰ Orders to not attempt resuscitation (DNR) are more common for patients with more functional compromise and with increased age and vary by diagnosis, gender, race, and location.³¹ In nursing homes³² and in the community,³³ physicians, patients, and surrogates often choose to limit diagnostic and therapeutic interventions, limit hospitalization, and maintain comfort rather than prolong life. In one geriatric practice, a discussion of probability of survival reduced by approximately 50% the number of elderly patients who

The patient's values, concerns, and preferences
Alternative approaches that are possible to manage expected events
The good and bad effects likely from each alternative

stated that they wished CPR attempted for a cardiac arrest.³⁴

The topics of physician-assisted suicide and euthanasia are discussed in detail in Chapter 86. Requests for physician-assisted suicide center around patient fears of decline in function, suffocation, pain, suffering, and the desire to not be further dependent on others or to be a burden to others.³⁵ Aggressive management of physical and emotional symptoms and support for family caregivers may reduce fears of pain and suffering and obviate the demand for suicide. Allowing patients to refuse food and water in concert with pharmacologic treatment of any symptom distress has been proposed as an alternative to active physician aid in dying.³⁶

Planning and Providing Care

The physician's willingness to listen to a patient's or family member's concerns and to discuss plans for care may be critical to satisfaction with their care.³⁷ Plans for the patient's care should address management of symptoms currently experienced and anticipated, likely medical events in the course of the illness, social and caregiver issues, existential issues, functional problems, and bereavement. An interdisciplinary team—either established or virtual (brought “together” via telephone or other communication for the specific patient)—can best address these varied issues based upon the explicit goals for the patient.³⁸ Specific issues confronted in care near the end of life require a perspective that may differ from general medical care.

Artificial Nutrition and Hydration

Artificial nutrition and fluids and the risks and benefits associated with them should be addressed with patients and their families, and specific plans should be made for the management of decreased oral intake in advance of its occurrence whenever possible.^{39,40}

Dehydration and inadequate nutritional intake are typically not associated with discomfort when appropriate oral care is provided. Thirst decreases with advancing age. Elevated levels of tumor necrosis factor (TNF) that suppress appetite and may reduce the sensation of hunger are present in older persons in general, as well as in persons with advanced illness.⁴¹ Other changes with age, such as decrease in growth hormone and vasopressin levels, may decrease sensations of hunger and thirst, and ketosis is believed to reduce the sensation of pain and other noxious stimuli. Concerns of patients and families about “starving” can often be assuaged by the knowledge that thirst and hunger are unusual during terminal illness and can be easily managed.⁴² Understanding that the process of gradual dehydration leads to comfortable sleep and coma can ease fears about discomfort when the patient is not artificially supported. Often patients and

family more easily accept decreased intake of food and fluids when they understand that comfort may be adversely effected by artificial or forced feeding. Several excellent patient and family guides may help with weighing the burdens and benefits of artificial nutrition and hydration and other treatments.^{43,44} Hospice studies suggest that patient decisions to forego artificial nutrition and hydration do not lead to suffering.⁴⁵

Nasogastric feeding tubes, restraints, and intravenous catheters are associated with moderate to severe discomfort⁴⁶ that may outweigh any benefits of improved hydration and nutritional status. In patients with progressive dementia, families can anticipate the loss of ability to eat and drink in the natural progression of advanced-stage illness. Decisions about tube feeding and other interventions can be made in advance, in the context of the goals of care (comfort and safety versus maximal possible life prolongation). When a decision is made not to employ artificial nutrition and hydration, patients should be offered food and fluids freely, and careful attention should be given to keeping the mouth and lips moist. Aspiration should be accepted as a consequence of late-stage dementia, with or without feeding. When aspiration is likely, the diet can be modified and caregivers can be coached in appropriate techniques (such as sitting up at 90°, tipping the chin forward), as there is not evidence that tube feeding reduces the risk of aspiration. Physically frail persons or those with advanced dementia frequently demonstrate aversion to food. Observing distress associated with feeding by mouth can help family reframe concerns about food and understand that forcing food may not be the most compassionate approach.

Functional Issues

Although the course toward death varies in length from hours to several years, most patients can benefit from efforts to maximize functional status. Improved function may enhance the patient's, and often the caregiver's, mood, sense of self-esteem, and quality of life. Aids in ambulation such as a walker, cane, or wheelchair make it possible for patients to interact in the community or move about in their environment as long as possible. Pain control should be directed at maintaining mobility. Analgesia before movement, other interventions such as nerve blocks, or a short course of palliative radiation therapy for cancer metastatic to bone may enhance mobility. Except in the final stages of life or when pain exacerbated by movement would require more sedation than desired, a range-of-motion program will prevent painful contractures. Occupational therapists can be particularly helpful in providing adaptive equipment to facilitate hygiene. When death is near, bathing and grooming should be directed at maintaining comfort.

Site of Care

The location of care while the person is ill and the place of death should be planned. Decisions may depend on resources available to the patient and family, their feelings about death in the home, and time available to organize care. Family caregivers suffer significant financial, psychologic, and health problems due to the stresses of providing care for their ill family member.⁴⁷ Volunteer hospice workers and other volunteer organizations may provide intermittent caregiver respite. Other emotional support and resources for family members are found through national programs run by the Alzheimer's and Related Disorders Society for patients with dementia, and Strength For Caring for patients with cancer.⁴⁸

Care at Home

Home care services through visiting nurse agencies may provide "intermittent" care for up to 28 h per week or more under Medicare Part A, including skilled nursing, home health aide, physical, occupational, and speech therapy, and social work. The patient must be homebound and have a clear medical indication for skilled care. Health care providers in home care agencies do not have specific training in pain and symptom management or care for patients near the end of life. Home health agencies linked with hospice agencies may provide "prehospice" care.

The Medicare Hospice Benefit

The Medicare hospice benefit, available through certified visiting nurse agencies, allows patients to elect palliative care rather than usual (life-prolonging) care under Medicare Part A. Patients must sign a consent (drafted by each agency) to enroll in hospice care. The patient's attending physician and hospice medical director must sign a statement that life expectancy is 6 months or less, although hospice care may be recertified and provided indefinitely once a patient has enrolled. The National Hospice and Palliative Care Organization published guidelines for estimating prognosis in noncancer illnesses, although some Medicare intermediaries unfortunately apply these as criteria to determine appropriateness of hospice referral and reimbursement.

The Hospice benefit provides home care to meet patients' needs and covers the cost of all palliative medications (except a \$5.00 co-pay), durable medical equipment, and any treatments and medical services (except for a 5% deductible) pertaining to the patient's terminal illness. Acute hospital stays are minimized (usually limited to periods of up to 5 days for acute symptom management or respite for caregivers). The "Continuous Care" level benefit provides intensive hospice services for a minimum of 8 h and up to 24 h per day for brief periods. Intravenous medications, transfu-

sions, artificial nutrition, radiation therapy, chemotherapy, and dobutamine infusions and other treatments may be provided in hospice care when the treatment is intended to palliate symptoms. In practice, such treatments are too expensive for all except for large hospice agencies to cover, given their Medicare per diem reimbursement of approximately \$102 per day. (Reimbursement rates are higher for Continuous Care and for inpatient stays.) Hospice care under the Medicare Benefit may be provided to patients residing in nursing homes when the daily nursing home care is paid for privately or by Medicaid. Medicaid reimburses hospice care in 43 states and Washington, D.C. An individual may revoke hospice care and return to usual Medicare coverage at any time.

Symptom Management

A careful assessment of pain and other symptoms is crucial to good care of elderly dying patients. Patients may underreport symptoms, either because they assume symptoms are to be expected as they approach the end of life or because they wish to be a "good patient" and avoid "complaining" or admitting current treatment is not effective. Physicians should inquire about pain, dyspnea, constipation, nausea, insomnia, anxiety or worries, depression, and existential or spiritual concerns for all patients. An assessment should include the frequency, severity, character, duration, and location of the symptom, precipitating or exacerbating factors, and response to interventions or treatment. Numerical scales (e.g., a scale of 1 to 5)⁴⁹ help to assess severity of symptoms and to assess response to interventions. The particular scale or instrument chosen is less important than that symptoms are assessed routinely and reassessed in response to interventions.

Evaluation of symptoms will direct their management. For example, recognition that a patient with dyspnea has bronchospasm results in the use of inhaled bronchodilators to reduce shortness of breath. Excellent physical diagnosis skills may obviate the need for other diagnostic evaluation. In some locations, portable x-rays and other studies may be obtained at home without significant discomfort for the patient. The ability of diagnostic evaluations to change the plan of care should be weighed against the inconvenience and discomfort of the tests (Table 26.2). The effect or outcome of a treatment or intervention should be continuously reevaluated, and the intervention should be modified based on the ongoing assessment of symptoms.

Pain

Many people approaching death fear pain and physical suffering. Significant pain during cancer illness ranges from 50% to 75%.^{50,51} Pain also accompanies advanced

TABLE 26.2. Approach to symptom management.

Identify symptoms through regular assessment
Evaluate the cause
Treat readily reversible causes
Address social, emotional, and spiritual issues
Weigh treatment options, including nonmedical interventions, with the patient
Prescribe around-the-clock palliative medications for constant symptoms and as-needed medications for episodic symptoms

neurologic illness, such as Parkinson's disease, or may be unrelated to the primary disease yet significantly impair quality of life, as with osteoarthritis or a compression fracture in patients with heart or lung disease. Primary care physicians can manage the majority of pain experienced by patients. Cognitive impairment should not deter providers from assessing pain, as even markedly impaired patients can describe pain and alternative assessments and standards can be applied to patients unable to communicate.⁵² Sadly, nursing home residents with end-stage cancer and other serious illness often are not prescribed appropriate analgesia.⁵³ Appropriate treatment of pain demands that health care workers anticipate and aggressively try to reduce pain. The assessment and evaluation of pain in the elderly patient is addressed in detail in Chapter 29.

Respiratory Symptoms

Dyspnea or difficulty breathing is a subjective symptom and should be distinguished from tachypnea (increased rate of breathing), hyperpnea, and hyperventilation (increased ventilation).⁵⁴ Measurement of dyspnea relies on patient report of the sense of difficulty breathing using verbal descriptors, visual analogue scales, or numeric scales. One study of elderly dying patients found 50% experienced respiratory distress and fearfulness.⁵⁵ The prevalence of dyspnea in dying cancer patients is as high as 70%.⁵⁶ An underlying cause for dyspnea should be identified and treated specifically whenever possible. Oxygen may help alleviate symptoms of dyspnea even in those patients who are not significantly hypoxemic.⁵⁷ Benzodiazepines effectively relieve dyspnea, possibly by depressing the ventilatory response to carbon dioxide,⁵⁸ and relieve anxiety associated with dyspnea. Opioids relieve the sensation of air hunger and are the most effective and most commonly employed medications to treat shortness of breath.⁵⁹ Often patients with chronic dyspnea from congestive heart failure, lung disease, or degenerative neurologic disease can be well managed with moderate doses of sustained-release opioids. Parenteral opioids (morphine 0.5–1 mg i.v. or s.q., increasing by 1–2 mg q 10 min, then continuous dose at 50% of bolus dose or fentanyl beginning with 2–10 µg i.v. or s.q.,

increasing with 2 µg q 10 min, then continuous infusion) or sublingual opioids (morphine 2–10 mg s.l., or the fentanyl 200–800 µg Actiq “lollipop”) are appropriate for patients who are otherwise unrelieved.⁶⁰ Respiratory suppression from opioids is rare when doses are begun low and titrated gradually to relieve dyspnea.

Suctioning may not decrease pulmonary congestion or increased secretions (“death rattle”). Glycopyrrolate (.1–.2 mg IV or SQ q 6–8 h) reduces secretions rapidly and effectively in most patients. Scopolamine (Transderm Scop 1–2 patches q 72 h or scopolamine 0.4 mg s.c. q 4 h) is also effective in reducing secretions.

Psychiatric Symptoms

Anxiety

Anxiety occurs commonly in dying patients, either independently or as a result of symptoms such as pain or dyspnea. Associated symptoms should be controlled whenever possible, but it may be necessary to initiate treatment for anxiety simultaneously. Identification of specific concerns and counseling by social workers, or by spiritual counselors, may effectively reduce anxiety. When anxiety relates to fear of being alone, it can be addressed by the companionship of family or volunteers.

The cornerstones of anxiolytic medication are the short- to moderate-acting benzodiazepines, such as lorazepam (Ativan) or oxazepam (Serax). Occasionally, buspirone (Buspar) or antidepressants [including paroxetine (Paxil), mirtazapine (Remeron), nortriptyline (Pamelor), nefazodone (Serzone), trazodone (Desyrel), or doxepin (Sinequan, Adapin)] may be employed to relieve anxiety. Some elderly individuals respond paradoxically to psychoactive medications, so medication effect must be closely monitored. Antipsychotic agents should be avoided as treatment for anxiety because of their side effect profiles, except in the case of terminal restlessness, apathetic or agitated delirium, paranoia, or hallucinations.

Depression

Approximately 25% of dying cancer patients are depressed.⁶¹ In one study, more than half of terminally ill patients with a pervasive desire for death were depressed.⁶² Depression is common in the elderly and is addressed in detail in Chapter 80. Patients may not have classic vegetative symptoms, yet they or their family will give a history of persistent sadness, guilt, or withdrawal from usual activities. Antidepressant therapy should be tried for these patients, with careful assessment of mood and status during the trial. Dysphoria, particularly when it relates to sadness or anticipatory grief, may also respond to counseling. Antidepressant medications are

appropriate, even when the depressions “appropriate” to the related loss of function or when approaching the end of life. Methylphenidate (Ritalin) and other psychostimulants are effective in improving mood, alertness, and appetite and in reducing apathy in some patients and have the advantage of rapid onset of action. Antidepressants and psychostimulants have an adjuvant analgesic effect, and their use can lead to reduction in analgesic requirements. The tricyclic antidepressants have a lag to onset of action and significant anticholinergic side effects but may be quite effective for patients who need the anxiolytic or soporific effects or who have neuropathic pain. Doxepin and mirtazapine may also have the advantage of stimulating appetite.

Confusion and Delirium

Most individuals fear the loss of mental capacity. Except in cases of intractable symptoms, an effort should be made to titrate therapies to maintain alertness. Confusion and delirium are common at the end of life and should be considered whenever there is a change or decline in a patient’s mental status. (The diagnosis and management of delirium are addressed in detail in Chapter 77.) Medications are often at fault. A patient may develop confusion with an increased or continued dose of an opioid, despite having done well previously, or develop a delirium on an H₂ blocker or other agent they previously tolerated. When caused by opioid analgesics, delirium may resolve with dose reduction change to a different opioid or addition of an antipsychotic agent.^{63,64} Careful physical examination may reveal simply treated causes of delirium such as fecal impaction, hypoxemia, bladder outlet obstruction, or a urinary tract infection. When no clear etiology of delirium is identified, antipsychotic therapy (haloperidol, olanzapine, or risperidol) is appropriate to control distressing symptoms. Apathetic delirium is characterized by somnolence or decreased level of consciousness and is as distressing to the patient and family as an agitated delirium. Antipsychotic therapy is effective and is indicated in both apathetic and agitated delirium.

Dementia

Dementia may be the primary disease from which patients die or a problem in addition to the terminal illness.⁶⁵ Patients with late or end-stage dementia are at increased likelihood of dying following hospitalization for pneumonia or hip fracture compared to patients without cognitive impairment.⁶⁶ In one community, dementia patients with family caregivers most commonly died at home (42%) and in nursing homes (32%), with only 26% dying in the hospital. Of those at home, only a quarter had physician home visits and less than half had skilled nursing visits.⁶⁷ Recommendations for end-of-life care in dementia include advance care planning at the time of

diagnosis of dementia and coordinated interdisciplinary care for patients and their families across the continuum.⁶⁸ Specific palliative care programs to care for severely demented individuals reduce measures of discomfort in these patients and reduce overall costs of care when compared with traditional long-term care.⁶⁹ The focus of care in Dementia Special Care Units is maintaining comfort, avoiding tube feeding and restraints, and minimizing the use of antibiotics and diagnostic testing.

Gastrointestinal Symptoms

Anorexia

Early in the course of the disease, encouraging adequate nutrition may enhance strength and a sense of well-being. Many dying patients become profoundly anorexic (92% of patients in one small series),⁷⁰ and the goal of feeding may shift to satisfying appetite and avoiding hunger, rather than providing adequate nutritional support. Allowing patients to eat preferred foods and relaxing dietary restrictions may help increase intake. Identifying and, when possible, treating causes of decreased oral intake, such as mouth pain from thrush or other processes, odynophagia, or dysphagia, can be helpful. Medical illnesses may present as anorexia or be associated with decrease food intake. For example, peptic ulcer disease may present as anorexia or nausea, and abdominal vascular disease or biliary disease may be associated with decreased food intake. Pharmacologic appetite stimulants such as megestrol (Megace) 40 to 400 mg qid, dronabinol (Marinol 2.5–10 mg before lunch and dinner), or cyproheptadine (Periactin 2–4 mg p.o. q 8 h) may be effective.

Nausea and Vomiting

Nausea is mediated through the chemoreceptor trigger zone (CTZ) on the floor of the fourth ventricle and the vomiting center (VC) in the medulla. Dopamine (D₂) receptors are the principal receptors in the CTZ, and muscarinic and histamine-1 are the most common receptors in the VC. Serotonin (5-HT₃) receptors are present in both locations, and in vagal afferents. Metaclopramide (Reglan) speeds gastric emptying and has antidopaminergic action on the CTZ but rarely cause delirium, depression, and parkinsonism, so as low a dose as effective should be used, and side effects should be closely monitored. Prochlorperazine (Compazine) 5 mg i.v. or 25 mg p.o. or p.r. up to three times a day or other phenothiazines and butyrophenones (haloperidol 0.5–1 mg p.o. or i.m. q 8 h) act on the CTZ, but extrapyramidal and anticholinergic effects should be monitored. Serotonin antagonists such as ondansetron (Zofran) 8 mg p.o. or i.v. up to every 6 h are effective antiemetics, which do not have the antidopaminergic toxicity of the benzamides,

TABLE 26.3. Selected medications to treat nausea and vomiting.

Medication	Site of action	Dosage	Side effects
Prochlorperazine	Chemoreceptor trigger zone (CTZ)	5 mg p.o. or i.v./i.m. q 6–8 h	Anticholinergic ^a and extrapyramidal
Haloperidol		0.5–1 mg p.o./s.l./i.m. q 8 h	
Metaclopramide	Stomach (forward peristalsis), gastroesophageal junction (tone) at higher doses also CTZ	5–10 mg p.o. or i.v. 1/2 h before meals	Delirium, depression, and extrapyramidal
Cyclizine	Vomiting center in medulla	50 mg p.o. or i.m. q 4–8 h	Anticholinergic ^a
Dexamethasone	Unclear	4–10 mg p.o. or i.v. q 6–12 h	Hyperglycemia, delirium, and all common corticosteroid effects
Ondansetron	4HT ₃ receptors on vagal nerve and in CTZ	4–8 mg p.o. or i.v. q 6 h	Expense

^a Dry mouth, orthostatic hypotension, constipation, urinary retention.

but they are very expensive (\$20 per tablet). Antihistamines (diphenhydramine or hydroxyzine PO or IV) act on the VC and may be quite effective with fewer potential side effects. Corticosteroids are also potent antiemetics.

Remediable causes of nausea or vomiting such as peptic disease and obstipation should be identified and treated (Table 26.3). Doses of H₂ blockers should be halved in the elderly, as they may precipitate delirium. Sucralfate (Carafate) or antacids may be effective in relieving dyspeptic symptoms. The proton pump inhibitors [omeprazole (Prilosec), lansoprazole (Prevacid), and others] are the most potent agents for decreasing gastric acid secretion and do not alter cognition.

Bowel Management

Constipation results in a myriad of other symptoms, including urinary retention, nausea and vomiting, delirium, and, if severe, intestinal perforation. Decreased mobility and bed rest predispose to constipation, so a bowel regimen should be initiated as patients become less mobile. Constipation occurs uniformly with opioid

analgesics. Any patient placed on opioids should simultaneously be started on stimulant laxatives. Osmotic stool softeners, such as lactulose, and milk of magnesia may be effective in maintaining bowel function for patients at bed rest (Table 26.4). A bowel regimen should be identified for all patients and followed routinely. Patients who develop constipation should be treated with saline, or mineral oil retention, or tap water enemas as needed to relieve the blockage in the lower gastrointestinal (GI) tract. Impaction should be resolved from below before giving oral laxatives. Bowel stimulants can be used once any lower GI tract obstruction is resolved. Patients often respond to regularly scheduled glycerin or bisacodyl suppositories (1–4 per rectum), after breakfast, daily.

Diarrhea

Although less common than constipation, diarrhea can be a particularly distressing symptom in dying patients, especially if mobility is impaired. When possible, the etiology of the diarrhea should be clarified, and processes amenable to treatment, such as *Clostridium difficile* colitis, or fecal impaction, should be treated aggressively.

TABLE 26.4. Selected agents to treat constipation.

Type of agent	Medication	Dose	Onset	Comments
Stimulant/ contact agents	Senna	1–3 tabs p.o. qd	6–12 h	Act by increasing fluid and electrolyte secretion in distal ileum and colon
	Bisacodyl	5–15 mg tabs p.o. or 10 mg suppository p.r.	6–8 h immediate	
Lubricants	Docusate salts		3–5 days	Also have emollient action Avoid p.o. in patients at risk for aspiration; can decrease absorption of fat-soluble vitamins
	Mineral oil	15–45 mL p.o. or 60–150 mL p.r.	6–8 h	
Osmotic agents	Polyethylene glycol (Miralax)	1–2 capsules q 8–12 h		
	Lactulose	15–60 mL p.o.		
	Magnesium citrate	mL		
	Milk of magnesia	15–60 mL p.o.		
	Sorbitol	15–60 mL p.o.		

First-line therapy for diarrhea should be Kaolin-pectin 60 mL p.o. q 2–3 h or bulk agents, such as cholestyramine (Questran) 4 g p.o. qid, because these agents may control diarrhea without systemic effects. Antispasmodic agents may be indicated to decrease frequency of bowel movements. Loperamide (Imodium) is preferable to diphenoxylate-atropine (Lomotil) combination, as the latter has greater potential for systemic and CNS toxicity.

Oral Care

As patients near death, they may increasingly need assistance moistening or lubricating mucous membranes (with moistened swabs or artificial saliva) and lips (with petrolatum or lip balm). Even when the patient is unresponsive, the mouth should be cleaned and moistened at regular intervals for patient comfort and to lessen family distress.

Urinary Symptoms

Urinary incontinence, dysuria, and frequency can be particularly disturbing symptoms for patients, especially if mobility is impaired. A urinalysis should be checked to identify an infection that could be treated. For symptoms of incontinence and frequency, a postvoid residual (PVR) volume should be documented. If the PVR is greater than 150 mL, an indwelling catheter should be left in place or intermittent catheterization performed regularly. Indwelling catheters may be used for easing caregiver burden or avoiding moving patients with severe pain; however, they are associated with urinary tract infections in all patients in whom they are in place for more than about 1 week. Some patients with urinary retention may respond to bethanechol (Urecholine) 5 to 10 mg bid to tid. In the absence of elevated PVR, tolterodine (Detrol) 1 to 2 mg daily or oxybutinin (Ditropan) 2.5 to 5 mg p.o. bid to tid may be effective in reducing frequency, urge symptoms, and incontinence. These agents may cause urinary retention, constipation, and changes in mental status. Dysuria can sometimes be reduced with a bladder anesthetic, such as pyridium 100 to 200 mg p.o. tid. Women with atrophic changes of the urethral meatus and external genitalia may have improved bladder function and reduction in irritative symptoms with small amounts of topical estrogen cream applied to the urethral meatus daily or several times per week.

Skin Care

Skin should be kept clean and dry and decubitus ulcers prevented, particularly in cachectic or malnourished patients. Prophylaxis includes avoiding friction, reducing prolonged pressure by turning every 2 h, or using an air or water mattress when patients become bedbound; however, in some situations, these interventions need to

be weighed against the discomfort of frequent movement. Ulcers that develop should be treated to keep the area soft and clean to reduce discomfort. (See Chapter 66 on pressure ulcers and wound healing.)

Infectious Processes

Pneumonia and other infectious processes may still be “the old man’s friend.” In some dying patients, pneumonia or other infection is appropriately treated by relieving dyspnea and suppressing fever and discomfort, rather than administering antibiotics. Fever may be suppressed by round-the-clock acetaminophen orally or per rectum, or with cooling techniques such as bathing with cool water. When a decision is made to give antibiotics, a broad-spectrum oral antibiotic or once-daily injection will allow treatment at home. Other symptoms such as dyspnea associated with pneumonia, or dysuria and urinary frequency associated with urinary tract infection, should be addressed to relieve physical distress.

Bereavement

Anticipatory grieving, or sadness about the expected death, should be acknowledged and support offered to patients and family members. Communication before death between the patient and friends and family is important when possible. Hence, patients and their family members need to understand that death is likely, have adequate time to process that information, and spend time with each other. Information about what to expect as disease progresses and death approaches may dramatically reduce patient and family anxiety. When death seems imminent, the patient and family should be advised and given the opportunity to “say good-bye.” Acknowledgment of our lack of precision in estimating the time course of what will transpire is imperative when counseling the patient and family about what to expect.

After death, the physician and other members of the caregiver team should participate in bereavement activities. Often a simple letter or telephone call may be adequate for the family to know that the physician recognizes their sense of loss. Some physicians maintain tickler files to call or to send a note to the patient’s family on the anniversary of the patient’s death. Hospice programs and clergy often open grief or bereavement programs or support groups to members of the community, and families should be made aware of these resources.

Conclusion

Care near the end of life focuses on optimizing quality of life for the patient and their family and minimizing symptoms. Excellent communication, management of

symptoms, and maximizing patient function are essential. The process of caring for patients near the end of life should be learned by all health providers and improved within health systems.

Sources of Suffering in the Elderly

Maria Torroella Carney and Diane E. Meier

The relief of suffering is one of the primary aims of medicine. The nature of suffering and what physicians can do to prevent or relieve it is poorly understood. Suffering is a global concept that must be distinguished from pain or other physical symptoms with which it may be associated. Although physicians, patients, and medical literature tend to link pain with suffering, these are distinct phenomena.¹

Cassell describes suffering as it relates to personhood.² Personhood includes personality and character, the individual's past, the family's past, associations and relationships with family and others, work and social roles, body image, the unconscious mind, political affiliations, the secret life, the perceived future, and the transcendent or spiritual dimension. Suffering with sickness occurs when the illness or its symptoms not only threaten interference with some aspect of personhood, but when it destroys or is perceived to destroy the integrity of the person, as just define.¹

Suffering often goes undiagnosed and unrelieved. Identification of suffering requires a high index of suspicion in the presence of serious disease and distressing symptoms.³ Clinicians should ask both themselves and their patient whether there is suffering. Ask directly, "Are you suffering?" "I know you have pain, but are there things that are even worse than the pain?" "Are you frightened?"³ The questions are purposely open-ended, telling patients that they have permission to talk about things that no one is likely to have wanted to hear before and conveying a sense of compassion and a willingness to listen from the person asking the questions. Intervening to try to relieve distress or suffering can only be accomplished once it has been identified, heard, and named.

The elderly often suffer from multiple acute disease processes superimposed on chronic and progressive illness, accompanied by an increased risk of sensory and cognitive impairment, and functional dependency.⁴ This

chapter attempts to address both physical and psychosocial sources of distress in elderly patients, as well as other factors associated with suffering often found in the elderly patient population.

Goals of Care

As symptoms are often interrelated with multiple concurrent medical problems, management can be challenging. As with any illness, the approach to treating symptoms requires a thorough history, physical examination, and laboratory or radiologic investigations appropriate to gain the best understanding of etiology and underlying pathophysiology. Once the cause and pathophysiology are known, intervention ideally includes therapy to relieve the symptoms as well as to treat underlying causes.

The goals of care may involve weighing the benefits and risks of treatments aimed at relief of suffering versus those aimed at prolongation of life. This approach is particularly important when symptom relief measures may either cause (or are perceived to cause) a higher risk of impairment or death. Many physicians fear that medications used to manage symptoms have an unacceptably high risk of an adverse event that may cause intolerable side effects or even shorten life, especially in the elderly. The fear of such consequences generally far outweighs their actual prevalence. It is extremely rare for opiate analgesics given at doses sufficient to relieve pain to simultaneously lead to respiratory depression. Nonetheless, the intent of the practitioner when offering a treatment is what determines whether it is ethical medical practice.⁵ Education and involvement of the patient and family as partners in care are key to successful management of symptoms.

Symptoms and Their Treatment

Formal Assessment

Symptom control is an essential component of medical care. For most patients, physical pain is only one of several sources of distress. Symptom relief encompasses physical, psychologic, social, and spiritual aspects of suffering. Physical aspects of pain cannot be effectively treated in isolation from the emotional and spiritual components that contribute to it, nor can these sources of suffering be addressed adequately when patients are in physical distress. The various components of suffering must be addressed simultaneously. Many sources of distress and suffering are not visible and frequently are not spontaneously reported by patients. Formal and regular assessment is therefore critical to identification and appropriate treatment of diverse symptoms.⁶

Physical and psychologic symptoms have been assessed most frequently using simple, validated measures, often in the form of symptom checklists. The Edmonton Symptom Assessment Scale (ESAS) evaluates eight symptoms on visual analogue scales and has been extensively used in palliative care research.⁷ The Memorial Symptom Assessment Scale (MSAS) is a validated patient-rated measure that provides multidimensional information about a diverse group of common symptoms.⁸ It characterizes 32 physical and psychologic symptoms in terms of intensity, frequency, and level of distress.⁸ Other frequently used symptom assessment instruments may be found on the web at www.stoppain.org, www.growthhouse.org, or www.chcr.brown.edu/pcoc/toolkit.htm.

Distressing symptoms addressed in this chapter include dyspnea, cough, nausea and vomiting, constipation, diarrhea, bowel obstruction, mouth symptoms, skin symptoms, odors, and dizziness. In addition, suffering caused by spiritual distress, developmental tasks faced at the end of life, the trauma of transferring or moving to hospital or nursing home, and the experience of being cared for by others is discussed. Pain is discussed separately in Chapter 29.

Respiratory Symptoms

Dyspnea

Dyspnea is a subjective sensation of shortness of breath⁹ that is described in 70% of cancer patients during the last 6 weeks of life and in 50% to 70% of patients dying of other illnesses.¹⁰ It is a common symptom associated with pneumonia, congestive heart failure exacerbations, and chronic obstructive pulmonary disease—all illnesses common to elderly adults. Nevertheless, dyspnea may be a subjective symptom that may not match any objective

TABLE 27.1. Dyspnea drug treatment.

Morphine 2.5–5 mg p.o. q 4 h while awake (opiate-naïve patient)
Morphine infusion 0.5 mg/h; titrate to relief of respiratory distress
Once dose requirement established, switch to long-acting opiate or fentanyl patch
Nebulized morphine or hydromorphone:
Injectable morphine 2.5–10 mg in 2 mL NS
or
Injectable hydromorphone 0.25–1 mg in 2 mL NS
Plus or minus
Albuterol 0.083% (3 mL)
Plus or minus
Solumedrol 10 mg
Corticosteroids:
Dexamethasone 16 mg initial, then
8 mg bid × 2 days, then 4 mg bid × 2 days, then 2 mg bid
Prednisone pulse
40 mg po bid × 5–7 days
Oxygen

Source: From Ref. 13, with permission.

signs of respiratory function,⁹ and its management can be challenging. It is important to diagnose and treat the underlying reversible causes of dyspnea when possible. When therapy specific to the underlying cause is unavailable or ineffective, several techniques may alleviate breathlessness. Simple techniques include pursed-lip breathing and diaphragmatic breathing, leaning forward with arms on a table, cool air ventilation (fan or open window), and nasal oxygen. Opiates have been shown in numerous studies to be highly effective in the amelioration of dyspnea.^{11,12} In one study of the effect of opiates on dyspnea and respiratory physiology, opiates sufficient to relieve dyspnea had no measurable adverse effect on respiratory rate, effort, oxygen saturation, and carbon dioxide concentration.¹¹ Along with treating the underlying cause, steroids and oxygen therapy may be of benefit. A list of some medications and dosages to alleviate refractory dyspnea can be found in Table 27.1.¹³

Cough

Cough is a normal but complex physiologic mechanism that protects the airways and lungs by removing mucus and foreign matter from the larynx, trachea, and bronchi. Cough is under both voluntary and involuntary control.¹⁴ Management of cough should be determined by the type and the cause of the cough, as well as the patient's general condition and likely diagnosis. When possible, the aim should be to reverse or ameliorate the cause, combined with appropriate symptomatic measures. Exacerbating factors should be defined, and simple measures such as a change in posture can be very helpful. Breathlessness can trigger cough and vice versa. Persistent cough can also precipitate vomiting, exhaustion, chest or abdominal pain, rib fracture, syncope, and insomnia.

Cough suppressants are usually used to manage dry cough. The most effective antitussive agents are the opioids. Codeine is a mild antitussive, while other opioids (morphine, oxycodone, hydrocodone, hydromorphone) have a more pronounced effect. Methadone can be particularly effective at night, but due to its prolonged half-life, the risk of accumulation exists. Other useful measures include decongestants, antihistamines, and corticosteroids.

Gastrointestinal Symptoms

Nausea and Vomiting

Nausea and vomiting are present in up to 62% of cancer patients.¹⁵ There are multiple potential causes for both nausea and vomiting, yet symptomatic relief is relatively easy to achieve with the appropriate use of medications. A thorough assessment is crucial to understanding the underlying etiology and, in turn, to providing the most beneficial form of treatment.

Two organ systems are particularly important in nausea and vomiting: the central nervous system and the gastrointestinal system.¹⁶ The gastric lining, the chemoreceptor trigger zone in the base of the fourth ventricle, the vestibular apparatus, and the cortex are all involved in the physiology of nausea. Stimulation of the vomiting center from one or more of these areas is mediated through the neurotransmitters serotonin, dopamine, acetylcholine, and histamine. Serotonin seems to be important in the gastric lining and central nervous system, whereas acetylcholine and histamine are important in the vestibular apparatus. Cortical responses are mediated via neurotransmitters as well as through learned responses (e.g., nausea related to anxiety).

Table 27.2 describes the major causes of nausea and vomiting, classified by the mechanism's principal site of action. Dopamine-mediated nausea is probably the most common form of nausea and is the type most frequently targeted for initial symptom management. These medications are phenothiazines or butyrophenone neuroleptics (metoclopramide, prochlorperazine) and

TABLE 27.2. Management of nausea and vomiting.

Etiology	Pathophysiology	Therapy
Metastases		
Cerebral	Increased intracranial pressure Direct chemoreceptor trigger zone	Steroids, mannitol Antidopamine, antihistamine
Liver	Toxin buildup	Antidopamine, antihistamine
Meningeal irritation	Increased intracranial pressure	Steroids
Movement	Vestibular stimulation	Antiacetylcholine
Mentation (e.g., anxiety)	Cortical	Anxiolytics
Medications		
Opioids	Chemoreceptor trigger zone, vestibular effect, gastrointestinal tract	Antidopamine, antiacetylcholine, prokinetic agents, stimulant cathartics
Chemotherapy	Chemoreceptor trigger zone, gastrointestinal tract	Antiserotonin, antidopamine, steroids
Others	Chemoreceptors	Antidopamine, antihistamine
Mucosal irritation		
NSAIDS	Gastrointestinal tract	Cytoprotective agents, antacids
Hyperacidity, gastroesophageal reflux		
Mechanical obstruction		
Intraluminal	Constipation, obstipation	Manage constipation
Extraluminal	Tumor, fibrotic stricture	Surgery, manage fluids, steroids, octreotide, scopolamine
Motility		
Opioids, ileus, other meds	Gastrointestinal tract	Prokinetic agents, stimulant laxatives
Metabolic		
Hypercalcemia	Chemoreceptor trigger zone	Antidopamine, antihistamine, rehydration, steroids
Hyponatremia		
Hepatic/renal failure		
Microbes		
Local irritation	Gastrointestinal tract	Antibacterials, antivirals, antifungals, antacids
Systemic sepsis	Chemoreceptor trigger zone	Antidopamine, antihistamine, antibacterials, antivirals, antifungals
Myocardial		
Ischemia	Vagal stimulation	Oxygen, opioids, antidopamine, antihistamine, anxiolytics
Congestive heart failure	Cortical, chemoreceptor trigger zone

TABLE 27.3. Medications for Nausea and Vomiting.

Oral medications:	
Dexamethasone	2–8 mg q 6–12 h
Diphenhydramine (Benadryl)	25–50 mg q 4–6 h
Haloperidol (Haldol)	0.5–5 mg q 6–8 h
Hydroxyzine (Atarax)	25–50 mg tid-qid
Hyoscyamine (Levsin)	0.125–0.25 s.l. q 4 h
Lorazepam	1–2 mg q 2–4 h
Marinol	2.5–10 mg bid, tid
Meclizine (Antivert)	12.5–25 mg bid-qid
Metoclopramide (Reglan)	10–40 mg qid
Ondansetron (Zofran)	8 mg p.o. tid-qid
Prochlorperazine (Compazine)	5–10 mg q 4–6 h
Prochlorperazine (Compazine)	s.r. 10–15 mg bid
Promethazine (Phenergan)	12.5–225 mg tid-qid
Thiethylperazine (Torecan)	10 mg q d-tid
Trimethobenzamide (Tigan)	250 mg tid-qid
Suppositories:	
Prochlorperazine (Compazine)	25 mg q 6 h
Promethazine (Phenergan)	12.5, 25, 50 mg tid-qid
Trimethobenzamide (Tigan)	200 mg tid-qid
Continuous infusion:	
Dexamethasone	8–100 mg/24 h
Haloperidol	2.5–10 mg/24 h
Hyoscyamine (Levsin)	1–2 mg/24 h
Scopolamine	0.8–20 mg/24 h
Metoclopramide (Reglan)	20–80 mg/24 h
Ondansetron	0.45 mg/kg/24 h
I.V. medications:	
Dexamethasone	2–8 mg q 4–6 h
Diphenhydramine (Benadryl)	25–50 mg q 6 h
Dronabinol	5 mg/m ² q 4 h; max, 6 doses/day 5 mg/m ² (meter squared)
Granisetron (Kytrel)	10 µg/kg q d
Haloperidol	0.5–2 mg q 4–6 h
Lorazepam	1–2 mg q 6–8 h
Metoclopramide (Reglan)	10–20 mg q 6 h
Ondansetron	4–8 mg q 8 h
Prochlorperazine (Compazine)	5–10 mg q 4–6 h

have the potential to cause drowsiness and extrapyramidal symptoms. Haloperidol is a highly effective antiemetic agent and may be less sedating. Antihistamines such as diphenhydramine can be used to control nausea but may cause sedation. Antihistamines also have anticholinergic properties covering two mechanisms of nausea. Serotonin has been implicated in chemotherapy-associated nausea. Serotonin blockers are effective but expensive. Other agents are listed in Table 27.3.

Nausea can also be caused by a slow gastric/intestinal motility, “squashed” stomach syndrome due to mechanical compression of the stomach or constipation, and thus prokinetic agents such as metoclopramide should be considered as therapeutic modalities. Hyperacidity and mucosal erosion may be associated with significant nausea. Consider the use of antacids, H₂ blockers, proton pump inhibitors, and misoprostol.

Constipation

Constipation can be defined as the passage of small hard feces infrequently and with difficulty.¹⁷ Constipation is a common complaint among elderly patients. One study found 54% of its community-based elderly to report constipation.¹⁸ Risk factors include immobility, depression, female sex, and polypharmacy.^{19–23} Constipation also tends to be associated with illnesses and/or conditions such as diabetes mellitus, hypothyroidism, diverticular disease, irritable bowel syndrome, and hemorrhoids²⁴ (Table 27.4).

Inquiry should be made about the frequency and consistency of stools, nausea, vomiting, abdominal pain, distention and discomfort, mobility, diet, and any other symptoms.¹⁷ As with any symptom, evaluation of a reversible cause is initial and paramount. A plain x-ray can be useful. Invasive evaluation with colonoscopy should be considered in difficult, refractory, or complicated cases. Many medications can contribute to constipation. First and foremost are opioid agents; many other medications, including beta-blockers, calcium channel blockers, anticholinergic agents, and diuretics, are also contributors²⁵ (Table 27.5).

Constipation is a universal side effect of opioid analgesic therapy, especially in the terminally ill and elderly, this can lead to serious, if not life-threatening, complications including bowel obstruction, ulceration or perforation, and delirium. Prevention of constipation must be accomplished by using stool softeners, rectal

TABLE 27.4. Constipation causes and risk factors.

Idiopathic
Dietary factors: low residue, poor nutrition
Motility disturbances: colonic inertia or spasm
Sedentary living, weakness
Depression
Poor fluid intake
Confusion
Inability to reach the toilet
Change in setting, travel
Structural abnormalities
Anorectal disorders: fissures, thrombosed hemorrhoids
Strictures
Tumors
Adhesions
Endocrine/metabolic
Hypercalcemia
Hypokalemia
Hypothyroidism
Neurogenic
Cerebrovascular events
Spinal cord tumors
Trauma
Smooth muscle/connective tissue disorders
Amyloidosis
Scleroderma

suppositories, laxatives, and hyperosmotic agents, before and during opiate therapy. A multiple agent bowel regimen must be begun coincident with the initiation of opiates. Table 27.6 describes a seven-step suggested bowel regimen to avoid constipation in a patient receiving opioid therapy.⁴ This regimen could also be utilized for anyone complaining of constipation once intestinal obstruction is ruled out. Operative management of severe constipation may be required in refractory cases.

Fecal impaction is stool impacted in the intestines, often causing “overflow” diarrhea. This disorder must be treated from below utilizing digital disimpaction and rectal laxatives (rectal suppositories, and/or enemas) before any forms of oral treatment are used.¹⁷

Various forms of laxatives exist. Rectal laxatives are available as suppositories or enemas. Table 27.7 lists stimulant, osmotic, and detergent laxatives, along with prokinetic agents, lubricant stimulants, and large-volume enemas. Clinicians should dose escalate a particular modality to a maximum therapeutic dose.

Polyethylene glycol solution (Golytely) or powder (Miralax) is often used as a precolonoscopic regimen but may be an effective means to treat constipation. It offers advantages over other laxatives in that it may cause less cramping. Mineral oil, is usually avoided in the elderly, as it may predispose to aspiration pneumonitis in people with swallowing problems.

Diarrhea

Diarrhea, potentially caused by fecal impaction, antibiotic-associated colitis, gastrointestinal bleeding, malabsorption, medications, or even stress, is a particularly distressing and exhausting symptom.¹⁷ A general approach is to determine the patient’s normal bowel habits. Once diarrhea is confirmed, the underlying cause must be evaluated and treated if possible. Initial therapy

for transient or mild diarrhea may respond to attapulgite or bismuth salts.¹⁷ For persistent and bothersome diarrhea, kaolin-pectin of psyllium, loperamide, or tincture of opium may be effective. Octreotide is also an effective means of reducing gastrointestinal secretions.²⁶

Bowel Obstruction

Symptoms of bowel obstruction include anorexia, confusion, abdominal distension, nausea and vomiting, constipation, and pain. Obstruction may be the presenting symptom that heralds the diagnosis of cancer or may occur later in the course of disease. Bowel obstruction can be caused by multiple and often coexisting etiologies, including intraluminal obstruction, infiltration of the bowel wall, external compression of the lumen, dysmotility, fecal impaction, and intra-abdominal adhesions. The prevalence of bowel obstruction is as high as 40% in bowel and pelvic cancers. Gastrointestinal obstruction can be particularly challenging to palliate if the cause of the obstruction cannot be removed. Therefore, investigation of the underlying cause of the obstruction is the first step in alleviating the distress. Furthermore, aggressive measures to prevent or treat constipation and impaction as previously described may be necessary. Treatment of bowel obstruction may involve the surgical relief of obstruction, nasogastric suction, and pharmacologic measures. Colicky or cramping pain may respond to dicyclomine, opiates (parenteral or rectal), and warm soaks to the abdomen. The obstruction and associated nausea and vomiting may respond to metoclopramide, haloperidol, or dexamethasone. Parenteral octreotide is also

TABLE 27.6. Bowel regimen.

With few exceptions, all patients on opioid therapy need an individualized bowel regimen. Start with the step 1 regimen. When an effective regimen is determined, it must be continued for the duration of the opioid therapy. If fecal impaction is present or suspected, rectal evacuation must occur (before any laxative agents are given orally), using digital disimpaction, enemas, high colonic enemas, and bisacodyl suppositories (2–4 at a time).

Step 1: Docusate 100 mg tid plus senna 1 tab q d or bid

Step 2: Docusate 100 mg tid plus senna 2 tab bid, plus bisacodyl rectal suppository 1–2 after breakfast

Step 3: Docusate 100 mg tid plus senna 3 tab bid, plus bisacodyl suppository 3–4 after breakfast

Step 4: Docusate 100 mg tid, senna 4 tab bid plus lactulose or milk of magnesia or polyethylene glycol powder or sorbitol 15–30 mL bid, plus bisacodyl suppository 3–4 after breakfast

Step 5: Sodium phosphate or oil retention enema; if no results add a high colonic tap water enema,^a and continue until results

^a High colonic enemas are given by warming 2-L bags of saline or water to body temperature, hanging bag at ceiling level, and infusing rectally over 30–60 min. May repeat continuously or until results.

Source: From Ref. 4, with permission.

TABLE 27.7. Treatments for constipation.

Stimulant laxatives: irritate the bowel and increase peristaltic activity

- Prune juice, 120–240 mL qd or bid
- Senna, 2 p.o. q h, titrate to effect (up to 9 or more per day)
- Casanthranol, 2 p.o. q h, titrate to effect (up to 9 or more per day)
- Bisacodyl, 5 mg p.o., p.r. q h, titrate to effect; bisacodyl suppositories
 - may be given per rectum, up to 4 at a time, preferably after breakfast

Osmotic laxatives: draw water into the bowel lumen, increase overall stool volume

- Lactulose or sorbitol, 70%, 30 mL p.o. q 4–6 h, then titrate
- Milk of magnesia, 1–2 tablespoons 1–3 times per day
- Magnesium citrate, 1–2 bottles prn
- Polyethylene glycol (Golytely), 1–4 L p.o., drink 8 ounces every 10 min until consumed
- Polyethylene glycol powder (Miralax), 17 g (1 tablespoon) powder q d in 8 ounces of water; 2–4 days may be required to produce a bowel movement; may increase dose as needed

Detergent laxatives (stool softeners): increase water content in stool by facilitating the dissolution of fat

- Sodium docusate, 1–2 p.o. q d-bid, titrate to effect
- Calcium docusate, 1–2 p.o. q d-bid, titrate to effect
- Phosphosoda enema prn

Prokinetic agents: stimulate bowel's myenteric plexus and increase peristaltic activity and stool movement

- Metoclopramide, 10–20 mg p.o. q 6 h

Lubricant stimulants: lubricate the stool and irritate the bowel, increasing peristaltic activity and stool movement

- Glycerin suppositories
- Oil: mineral, peanut

Large-volume enemas: soften stool by increasing its water content, distending the colon, and inducing peristalsis

- Warm water (addition of soap suds irritates bowel wall to induce peristalsis)

High colonic enemas

- Utilize gravity to bring fluid to more proximal parts of bowel; use 2-L bags of water or saline warmed to body temperature, hang on intravenous pole at ceiling level and run in over 30 min, repeat q 1 h

Source: From Refs. 5 and 25, with permission.

useful in this setting to decrease the volume of bowel secretions.²⁶

Mouth Symptoms

A patient's oral problems can be kept to a minimum by good hydration, brushing the teeth with a fluoride toothpaste twice daily, and daily observation of the oral mucosa. Oral problems can reduce intake of food and fluid due to altered taste, pain, and difficulty swallowing. The first step is managing local problems. Key questions to ask concerning mouth care include the following: Is the mouth dry? Is infection present? Is the mouth dirty? Is the mouth painful? Are oral ulcerations present?

Dry Mouth

The presence of saliva is hardly ever noticed, but the lack of it can seriously damage the quality of life for those experiencing a sensation of oral dryness. Xerostomia describes the subjective complaint of dry mouth. Xerostomia may have both salivary and nonsalivary causes.²⁷ More than 50% of elderly have been reported to have noticed oral dryness.^{28–30} Table 27.8 lists principal causes of salivary gland dysfunction and xerostomia. Table 27.9 lists medications that have the potential to reduce salivary flow rates.

Almost all forms of xerostomia require symptomatic therapy irrespective of etiology. The goal of therapy is to moisten the oral mucosa, and the best, simplest aid is to sip water frequently. However, several mouth moisteners or artificial salivas have been designed that contain mucin

and may be preferred by patients.^{31,32} Pilocarpine tablets (Salagen) may be used (5–10 mg q 8 h) if these measures fail. Side effects may include nausea, diarrhea, urinary frequency, and dizziness.

Oral Ulcers/Mucositis

Oral infection can be due to multiple etiologies. Aphthous ulcers are common and can be helped by topical corticosteroids or tetracycline mouthwash. Oral candidiasis usually presents as adherent white plaques but can also present as erythema or angular cheilitis. Nystatin suspension is the usual treatment, but a 5-day course of oral ketoconazole 200 mg can be used as well. Severe viral infection (herpes simplex or zoster) requires acyclovir 200 mg every 4 h for 5 days. Malignant ulcers are often associated with anaerobic bacteria and may respond to metronidazole at 400–500 mg orally or rectally every 12 h or as a topical gel.³³ Table 27.10 lists other local measures.

Skin Symptoms

Pressure Sores

Pressure sores result from immobility, moisture, friction, shear (sliding movement), and pressure. Prevention and treatment require reduction in pressure (frequent turning and repositioning, foam or low-pressure mattresses), maintaining dryness and cleanliness, avoidance of shear, and friction. Patients at risk of pressure sores should be monitored regularly with daily visual inspection of pressure areas. How a patient moves or is moved by caregivers needs to be assessed and monitored. Even with regular turning and careful lifting and positioning, special

pressure surfaces or mattresses are sometimes needed.³³ Good hydration, high-protein and -carbohydrate diets, and vitamin C supplements encourage healing.

Gel or colloid dressings that keep the area moist reduce pain and can be left in place for several days. Painful changing of dressings can be eased by extra analgesia before each change.³³

Encourage family and caregivers to keep skin clean and dry. Absorbent surfaces, urinary catheters, and rectal tubes may be of assistance.⁵ Cover fragile skin that is at risk for breakdown with clear, occlusive dressings. Cover pressure points with thin, hydrocolloid dressings.

Pressure ulcer management should be consistent with goals of care. If overall maintenance or improvement of function is the goal and prognosis is weeks to months, then treat the ulcer with expected management guidelines. If prognosis is limited, then the intent is to optimize quality of life.

For uncomplicated malignant ulcers, pain relief and wound care are managed in the same way as pressure sores. However, malignant wounds present special problems such as bleeding, odor, and disfigurement. A bleeding malignant ulcer should be treated with radiation therapy, topical sucralfate, or topical tranexamic acid. Dirty ulcers should be debrided, which can be accomplished chemically. Altered body image can be lessened with cavity foam dressings. Furthermore, empathetic listening is often therapeutic in itself, but anxiety, anger, or depression will need specific support.³³

Foul-Smelling Wounds

Odors may be very distressing to patients, families, and caregivers and may lead to poor-quality care, as even professional caregivers avoid sickening smells. Odors are usually caused by anaerobic infections or poor hygiene or both. Treat superficial infections with topical metronidazole or silver sulfadiazine.⁵ For soft tissue infections, add systemic metronidazole to topical management.

To control odors, place open kitty litter or activated charcoal in a pan under the patient's bed, provide adequate room ventilation, place an open cup of vinegar in the room, or burn a candle. Special charcoal-impregnated dressings placed over the odorous wound may also be helpful.⁵

Dizziness/Dysequilibrium

Dizziness is a well-recognized problem among older persons. The reported prevalence ranges from 13% to 38%.^{34–38} Dizziness has been associated with increased risk for falls and with syncope, functional disability, nursing home placement, stroke, and death.^{34,35,37,39–41} Dizziness and associated fear of falling often lead to progressive immobility and deconditioning. Given the fre-

quency of dizziness and its associated morbidity, much attention has focused on identifying its causes.

In past studies, authors assumed that dizziness was a symptom of one or more discrete diseases. Investigators typically assigned the cause of the dizziness to specific diagnostic categories on the basis of clinical judgment or diagnostic algorithms. Vestibular disease, cerebrovascular disease, psychiatric disorders, and cervical spondylosis have all been identified as contributing causes^{41,42} (Table 27.11). No diagnosis could be made in 8% to 22% of cases, and multiple diagnoses were assigned in 0% to 85% of cases.⁴³⁻⁴⁵

Due to the great variability in the prevalence of specific diagnoses and the frequency with which no diagnosis or multiple diagnoses were made, Tinetti et al. suggested the hypothesis that dizziness in elderly may result from multifactorial causes rather than being solely a symptom of a discrete disease, henceforth considering it a geriatric syndrome.⁴⁶ Dizziness is associated with an increased likelihood of self-reported worsening health, depressive symptoms, less involvement in social activities, and less participation in the activities of daily living.⁴⁷

Treatment may be better directed toward strategy aimed at ameliorating the multiple contributing factors rather than focusing on diagnosing and treating discrete diseases.⁴⁶ Preliminary evidence suggests that factors including anxiety and depressive symptoms, hearing impairment, balance impairment, postural hypotension, and the use of multiple medications were additively associated with the likelihood of reporting chronic dizziness.⁴⁶ Chronic dizziness should be approached similarly to falls and amelioration of the symptoms—the physical, psy-

chologic, and social disability should be paramount. (See Chapter 68 for a more detailed discussion of dizziness.)

Spiritual Suffering

Patients who are living with life-threatening illness are frequently distressed by hopelessness, meaninglessness, remorse, anxiety, being worried, and disruption of personal identity.² These worries are universal and may result from past, present, or future concerns, independent of religious background or beliefs.⁴⁸ Facing a life-threatening illness brings to surface questions as to what life is all about.⁴⁹ People may suffer from an inability to find meaning in this last chapter of their lives, from an abbreviated future, from inability to relate meaningfully with family and loved ones at their final opportunity, from anger about being ill, and from isolation because of the reluctance of the healthy to broach the subject of dying.⁴⁹ These are all spiritual issues.

Yet patients do not suffer alone. Families and caregivers suffer, too. Family members may have to reshape their identities and redefine their basic commitments when their loved one is ill or dying. Long-unresolved family issues threaten to become permanently unresolvable. The family may suffer from guilt and a sense of abandonment.⁴⁹ Many turn to religious or spiritual beliefs for decision-making guidance and support when threatened by serious illness.^{50,51}

Physicians are participants in their patient's life and have a distinctive role and responsibility to minimize patient and family suffering. Patients and families should be afforded the opportunity to explore issues relating to the nature of death and issues of afterlife.⁴⁸ Discussion of religious or spiritual beliefs might enhance physician-patient understanding and communication. Some patients may want to share their religious convictions with physicians.^{52,53} In one study, two-thirds of patients surveyed would welcome a carefully worded inquiry about their spiritual or religious beliefs in the event that they became gravely ill. However, 16% would not. Therefore, spiritual guidance may be desired. When applicable, an appropriate religious chaplain or minister should be consulted for both patient and family.⁴⁸ Some appropriate questions for a physician to ask⁵⁴ are given in Table 27.12.

TABLE 27.12. Physician questions to explore patient's spiritual needs.

1. Are you a member of a faith community?
2. Does your community know you are ill?
3. Would you like them to be contacted?
4. Would you like me to call the priest (rabbi, minister, etc.) to come visit you?

Developmental Tasks at End of Life: Barriers and Associated Suffering

Throughout a person's life, the sense of who one is changes in the process of responding to the challenges and crises that define the developmental stages of infancy, childhood, adolescence, midlife, and late life. During each major life transition, there may be suffering. At times people may feel broken and never fully recover a sense of self, but most find a way to grow through these turning points. Many persons describe an experience of enhanced awareness and growth in the last stage of life. People who can be said to have grown in their dying are those who express satisfaction in personal change that occurred in response to the stresses of a disabling illness and for whom an enhanced subjective sense of self emerges during the process. Dying is surely among the most profound of life's challenges.⁵⁵

Progressive illness offers an opportunity to reconcile previously strained relationships and achieve closure or resolution of unfinished tasks.⁵⁵ Byock describes developmental landmarks and tasks for the end of life that serve as diagnostic tools enabling clinicians to anticipate issues with which patients may struggle and from which struggling may arise (Table 27.13).

One of the central tenets of hospice care has been the need to discuss death openly with the patient; however, that is not possible for some individuals and in many cultures. Physicians, families, and perhaps patients from Native American, Asian, and other cultures may be reluctant to discuss the prospect of death openly. In the United States, there is more openness and emphasis on patient autonomy and the right to make decisions. The hospice movement, the work of Dr. Kubler-Ross, and the aging of the baby boom population have combined to cause a marked change in attitudes over the past two decades, so that it is now considered ethically appropriate for the patient to be given the news about a terminal illness directly. This approach increasingly tends to be the pattern in the United Kingdom. In Italy, a belief against

TABLE 27.13. Developmental landmarks and tasks for the end of life.

Sense of completion with worldly affairs
Sense of completion in relationships with one's community
Sense of meaning about one's individual life
Experienced love of self
Experienced love of others
Sense of completion in relationships with family and friends
Acceptance of the finality of life—of one's existence as an individual
Sense of a new self (personhood) beyond personal loss
Sense of meaning about life in general
Surrender to the transcendent, to the Unknown: "Letting Go"

Source: From Ref. 55, with permission.

speaking of cancer or terminal illnesses to the patient is strong, but this may be changing.⁵⁶ A reluctance to discuss death also seems to be prevalent in areas where there is no strong religious belief or ritual.⁵⁷ Traditional customs, religious beliefs, and ceremonies have typically helped patients come to terms with death and helped survivors deal with their loss. Cultural and religious variations should be explored and understood to optimally serve patients and their families.

Suffering Associated with Moving or Transferring to or from a Hospital or Nursing Home

Transfer anxiety is a term generally used only by nurses or social workers to describe anxiety experienced by the individual when he or she moves from a familiar, secure environment to an environment that is unfamiliar.⁵⁸ The nursing diagnosis of relocation stress syndrome was accepted in 1992 by the North American Nursing Diagnosis Association.⁵⁹ It is defined as a syndrome of physiologic or psychosocial disturbances as a result of transfer from one environment to another. The defining characteristics include increased confusion in the elderly, depression, anxiety, apprehension, and loneliness.⁵⁹ Relocation stress syndrome has been used to describe the experience of patients transferred from intensive care units to general hospital units and geriatric patients transferred from home or the hospital to a long-term care facility. Studies do not exist that demonstrate how to best limit the suffering associated with transfer, but common sense dictates that making the patient aware of possible location changes early, allowing for questions or preliminary visits, and having the family available for support and present during the transfer process may help to minimize the inevitable suffering associated with dislocation.

Suffering Associated with Being Cared for by Others

Physical disability is a substantial adverse outcome associated with aging.⁶⁰ Disability is reported by up to 40% of adults aged 65 and older and increases significantly after age 85.^{61,62} Chronic disease is the major cause of long-term disability.⁶³⁻⁶⁶ One of the major concerns patients repeatedly express with old age and end of life includes fear of being a burden on loved ones. Included in that fear may be not wanting to be cared for by others (family or strangers), being totally dependent, having loss of independent capabilities, being turned from a contributor into a burden on others, the humiliation and indig-

nity of being unable to take care of even basic bodily functions, and feeling a sense of abandonment.⁴⁹ Patients often fear losing independence, living with disability, or dying without dignity. Such changes may interrupt an individual's sense of personhood. Approaches to the relief of suffering associated with humiliation and dependency include asking the patient how they feel about it, reminding patients that family members and other caregivers want to give care, and identifying and strengthening remaining areas of intact function.

Conclusion

Alleviation of suffering is the central tenet of the practice of medicine. However, because of multiple technical advances, medicine today—in its zealous striving to cure illness and prolong life—may, in fact, contribute to a patient's suffering.⁶⁷ It is critical to question patients about their sources of suffering, ranging from physical and psychosocial to spiritual. Regular formal assessment leads to identification of sources of suffering, and identification, in turn, leads to treatment and intervention trials.

Even when a patient's suffering admits of no cure, the act of listening and accompanying the patient on his journey is healing in itself. A physician's ability to hear about the patient's experience assures patients of their connection to a concerned physician who is not frightened to hear the truth and will not abandon them.

Acute and Chronic Pain

Bruce A. Ferrell

Pain is one of the most common symptoms of disease in older persons. Second only to symptoms of upper respiratory tract infections, it is one of the most common complaints in physicians' offices. The intensity of pain often correlates with the severity of disease and indicates the intensity of treatment needed for pain relief. Unrelieved pain, pain that persists, or pain out of proportion to tissue damage often results over time in complications that include physical disability and serious psychologic distress.

Pain assessment and management have reached a high level of sophistication over the last several years. The publication of clinical practice guidelines, the focus of quality review organizations, and moral outrage over suffering and unrelieved pain, especially in those near the end of life, have fueled rapid development of new strategies, products, and technology to improve pain management. Discovery and description of pathophysiologic mechanisms of pain have helped target existing pain management strategies more effectively and suggested new drugs and interventions with lower side effect profiles. Unfortunately, substantial barriers still exist, and pain often remains underrecognized and undertreated. Zealous regulation of opioid drugs and prejudicial attitudes about the patients who need them, health systems that still emphasize cure over care, and financial incentives that favor high-tech pain management strategies over other conventional approaches to pain management remain all too common.

The approach to pain assessment and management is different in elderly versus younger persons.¹ Older persons may underreport pain for a variety of reasons,² despite functional impairment, psychologic distress, and needless suffering related to pain. They often present with concurrent illnesses and multiple problems, making pain evaluation and treatment more difficult. Elderly persons have a higher incidence of side effects to medications and higher potential for complications and adverse events related to many treatment procedures.

Despite these challenges, pain can be effectively managed in most elderly patients. Moreover, clinicians have an ethical and moral obligation to prevent needless suffering and provide effective pain relief, especially for those near the end of life.³

Taxonomy of Pain

Pain is defined as an unpleasant sensory and emotional experience.⁴ It is derived from complex physiologic processes that include elements of neural sensation and nerve transmission integrated with central nervous system processing of memory, expectations, and emotions. Unfortunately, there are no objective biologic markers of pain. There are no measurements in blood, or by electroencephalographic or other imaging devices that accurately reflect the intensity or character of pain experiences. The most accurate and reliable evidence for the existence and intensity of pain is the patient's description.⁵ Pain complaints are quite variable in description, character, and intensity. For the purpose of understanding, predicting, and treating pain, a variety of classification schemes have been used. For clinical purposes, it may be helpful to categorize pain as acute or chronic.

Acute Pain

Acute pain is often defined by its distinct onset, obvious cause, and short duration. Trauma, burns, infarction, and inflammation are examples of pathologic processes that can result in acute pain. Acute pain is often associated with autonomic nervous system signs including tachycardia, diaphoresis, or elevation in blood pressure.⁶ The presence of acute pain often indicates an acute injury or acute disease; and the intensity of acute pain often indicates the severity of injury or disease. Thus, acute pain should trigger an urgent search for an underlying cause that might be life-threatening or require immediate intervention.

The effective management of acute pain is important. The relief of acute pain can facilitate diagnostic tests by helping patients cooperate with prolonged radiographic or other procedures. Preoperative pain management makes anesthesia easier and postoperative pain control better. In some cases, management of acute pain can help prevent development of chronic pain syndromes.

Chronic Pain

Chronic pain is usually defined by its persistence beyond an expected time frame for healing. The International Association for the Study of Pain defines chronic pain as lasting more than 3 months.⁵ Intensity of chronic pain is often out of proportion to the observed pathology and often associated with prolonged functional impairment, both physical and psychological. Autonomic signs are often absent or exhausted. Underlying causes of chronic pain are often associated with chronic disease and are less curable.⁵

Chronic pain is often more difficult to manage because the underlying cause is less remedial and many treatment strategies are either short lived, difficult to maintain, or associated with long-term side effects. Chronic pain usually requires a multidimensional approach to treatment, including use of both analgesic drug and nondrug strategies with attention to sensory, emotional, and behavioral components of the pain experience.

Classification Based on Pathophysiology

The classification of pain by pathophysiologic mechanisms may help clinicians choose and target pain management strategies more effectively. Treatment aimed at specific pathophysiologic pain mechanisms may be more effective. The American Geriatrics Society Panel on Chronic Pain identified four basic pathophysiologic pain mechanisms that have important implications for choosing pain management strategies (Table 28.1).⁷ Pain problems that result largely from stimulation of pain receptors are called nociceptive pain.⁸ Nociceptive pain may arise from tissue injury, inflammation, or mechanical deformation. Examples include trauma, burns, infection, arthritis, ischemia, and tissue distortion. Pain from nociception usually responds well to common analgesic medications. Neuropathic pain results from pathophysiologic processes that arise in the peripheral or central nervous system.^{9,10} Examples include diabetic neuralgia, postherpetic neuralgia, and posttraumatic neuralgia (postamputation or “phantom limb” pain). In contrast to nociceptive pain, neuropathic pain syndromes have been found to respond to nonconventional analgesic medications such as tricyclic antidepressants and anticonvulsant drugs. Mixed pain syndromes are often thought to have multiple or unknown pathophysiologic mechanisms. Treatment of

TABLE 28.1. Pain classification based on pathophysiology.

these problems is more problematic and often unpredictable. Examples include recurrent headaches and some vasculitic syndromes. Finally, psychologically based pain syndromes are those with psychologic factors that play a major role in the pain experience.¹¹ Examples include somataform disorders and conversion reactions. These patients may benefit from specific psychiatric intervention, but traditional pain strategies are probably not indicated. It is important to remember that the pathophysiologic basis of pain may be multifactorial for many diseases. Cancer, for instance, may cause pain from tumor distension and deformation of surrounding tissues, invasion of peripheral nerves, or chronic inflammation. Arthritis may cause pain from inflammation, joint distortion with associated strain on muscles and connective tissue, and microfracture from eroded cartilage or bone. Unfortunately, for many diseases, the pathophysiologic basis of pain is only partially understood.

Age-Related Changes in Pain Perception

Age-related changes in pain perception have been a topic of interest for many years. Elderly persons have been observed to present with painless myocardial infarction

TABLE 28.2. Age-related changes in pain perception.

Component	Age-related change	Comments
Pain receptors	50% decrease in Pacini's corpuscles 10%–30% decrease in Meissner's/Merkle's disks Free nerve endings: no age change	Few studies, largely limited to skin
Peripheral nerves	Myelinated nerves Decreased density Increase abnormal/degenerating fibers Slower conduction velocity Unmyelinated nerves Decreased number of large fibers (1.2–1.6 μm) No change in small fibers (0.4 μm) Substance P content decreased	Evidence of change in pain function is lacking; findings are not specific to pain
Central nervous system	Loss in dorsal horn neurons Altered endogenous inhibition, hyperalgesia Loss of neurons in cortex, midbrain, brainstem 18% loss in thalamus Altered cerebral evoked responses Decreased catecholamines, acetylcholine, GABA, 5HT Endogenous opioids: mixed changes Neuropeptides: no change	Findings not specific to pain

Source: Adapted from Gibson SJ, Helme RD. Age differences in pain perception and report: a review of physiological, psychological, laboratory and clinical studies. *Pain Rev.* 1995;2:111–137, with permission.

and painless intra-abdominal catastrophes. The extent to which these observations are attributable to age-related changes in pain perception remains uncertain.^{12,13} Table 28.2 summarizes anatomic and neurochemical changes associated with pain perception in aging. Unfortunately, most of these findings are not specific to pain, and changes in pain perception related to these findings remain poorly defined. Studies of pain sensitivity across the life span have shown mixed results. A substantial number of studies of induced pain in normal volunteers have reported both increased and decreased pain threshold, as well as no change in pain threshold across the life span. Decreased pain sensitivity (increased threshold) with aging can be supported by evidence of decreased numbers of receptors and changes in nerve conduction. Increased pain sensitivity (decreased threshold) with aging can also be supported by evidence of alterations in spinal cord and central nervous system processing (poorer endogenous analgesia). If these observations are correct, overall pain perception may not change much with aging. Clearly, additional studies are needed to define age-related changes specific to nervous system function and pain perception.

Epidemiology of Pain Complaints in Older Persons

The precise incidence and prevalence of pain in older populations is not known. Pain is a universal sensation. Every individual has an occasional experience of pain,

such as a headache or muscle or joint pain from overexertion. Epidemiology studies of pain in general populations have suffered from the lack of standard definitions for what might be considered “significant” pain. Nonetheless, studies have suggested that the prevalence of pain in community-dwelling older persons may be as high as 25% to 56%.¹⁴ Sources of pain also vary from study to study. Prevalence of back pain has been reported from 21% to 49.5%; joint pain 20.5% to 71%; and headache 1.2% to 50% in persons over the age of 65 years.¹⁵

In 1997, a Louis Harris telephone poll reported 18% of elderly people take analgesic medications on a regular basis (several times a week or daily).¹⁶ Of those who took analgesic drugs regularly, more than 70% reported taking over-the-counter analgesics, and more than 70% took prescription analgesics, suggesting that most patients took both sources of medication simultaneously. The study reported that most patients complained of musculoskeletal pain.

In general, the most common cause of pain in elderly persons is probably related to musculoskeletal disorders such as back pain and arthritis. Neuralgia is common, stemming from common diseases, such as diabetes or herpes zoster, and trauma, such as surgery, amputation, and other nerve injuries. Nighttime leg pain (e.g., cramps, restless legs) is also common, as is claudication. Cancer, although not so common as arthritis, is a cause of severe pain that is distressing to patients, families, and staff. The distress of cancer pain has brought attention to the moral, ethical, and recently legal obligation of clinicians to provide effective pain management near the end of life.³

Pain is also common in nursing homes. It has been suggested that 45% to 80% of nursing home residents may have substantial pain.¹⁷ Many of these patients have multiple pain complaints and multiple potential sources of pain. Our studies have suggested that for 70% of nursing home patients pain results from arthritis and other musculoskeletal causes.^{2,18}

Pain is associated with a number of negative outcomes in elderly people. Depression, decreased socialization, sleep disturbance, impaired ambulation, and increased health care utilization and costs have all been associated with the presence of pain in older people. Other outcomes less thoroughly explored include gait disturbances, slow rehabilitation, and adverse effects of analgesic medications.¹⁹ Older patients rely heavily on family and other caregivers near the end of life. For these patients and their caregivers, pain can be especially distressing. Pain can have a substantial impact on caregiver strain and caregiver attitudes.²⁰

Assessment of Pain in Elderly People

Pain assessment is the most important part of pain management. Accurate pain assessment is important to identify the underlying source and associated physiologic pain mechanisms to choose the most effective treatment and maximize patient outcomes. Pain management is most effective when the underlying cause of pain has been identified and treated definitively. Inherent in pain assessment is the need to evaluate acute pain that may indicate life-threatening injury and distinguish this from exacerbations of chronic pain. For chronic pain in which the cause is not reversible or only partially treatable, a multidimensional or multidisciplinary evaluation may be required. Among those with cognitive impairment or difficulty reporting pain, other clinicians, family, and caregivers may be helpful in providing a more accurate description.

Compared to younger patients, older persons often present with unique challenges to pain assessment. Elders may tend to underreport pain, despite substantial functional impairment. Multiple concurrent medical problems and multiple sources of pain make assessment more difficult. Finally, cognitive impairment, impaired sensory function, and denial and avoidance behaviors may all contribute to underreporting.

Pain History and Physical Examination

Assessment of pain should begin with a thorough history and physical examination to help establish a diagnosis of underlying disease and form a baseline description of pain experiences. The history should include questions to elicit: *when* the pain started; *what* events or illnesses coin-

cidated with the onset; *where* does it hurt (location) and *how* does it feel (character); *what* are the aggravating and relieving influences; and *what* treatments have been tried. Past medical and surgical history is important to identify coexisting disease and previous experience with pain and analgesic use. The review of systems should focus on the musculoskeletal and nervous system. Any history of trauma should be thoroughly investigated because falls, occult fractures, and other injuries are common in this age group. In this setting, care must be taken to avoid attributing acute pain to preexisting conditions. Complicating pain assessment is the fact that chronic pain does fluctuate with time. Injuries from minor trauma and acute disease, such as gout or calcium pyrophosphate crystal arthropathy, can be easily overlooked. Finally, many older persons do not use the word "pain" but may refer to their problems as "hurting," "aching," or some other description. It is important to probe for and identify pain in the patient's own words so that references for subsequent follow-up evaluations are clearly established.²¹

A physical examination should confirm any suspicions suggested by the history. Because of the frequency with which problems are often identified, the physical exam should concentrate on the musculoskeletal and nervous systems. Tender points of inflammation, muscle spasm, and trigger points should be sought. Observation of abnormal posture, gait impairment, and limitations in range of motion may trigger a need for physical therapy and rehabilitation. Evidence of kyphosis, scoliosis, and abnormal joint alignments should be identified. A systematic neurologic exam is also important to identify potential sources of neuropathic pain. Focal muscle weakness, atrophy, abnormal reflexes, or sensory impairments may indicate peripheral or central nervous system injury. Mottled skin in a denervated extremity, presence of a Charcot joint, orthostatic hypotension, impaired gastric emptying, or incontinence may indicate autonomic nervous system dysfunction that can imply sympathetically mediated pain or a complex regional pain syndrome.

It is important to assess functional status to identify self-care deficits and formulate treatment plans that maximize independence and quality of life. Functional status can also represent an important outcome measure of overall pain management. Functional status can be evaluated from information taken from the history and physical examination, as well as the use of one or several functional status scales validated in elderly people (see Chapter 17, Instruments to Assess Functional Status).

A brief psychological and social evaluation is also important. Depression, anxiety, social isolation, and disengagement are all common in patients with chronic pain. There is a significant association between chronic pain and depression, even when controlling for overall health and functional status. Therefore, assessment should include

routine screening for depression. Psychologic evaluation should also include consideration of anxiety and coping skills. Anxiety is common among patients with acute and chronic pain and requires extra time and frequent reassurance from health care providers. Chronic pain often requires effective coping skills for anxiety and other emotional feelings that can be learned.²² For those with significant psychiatric symptoms, referral for formal psychiatric evaluation and management may be required. In these patients, specific counseling, supportive group therapy, biofeedback, or some psychoactive medications may be necessary for developing and maintaining effective coping strategies as well as management of major psychiatric complications. Social networks should also be explored for availability and involvement of family and other caregivers. It has been shown that the family's and informal caregivers' involvement can have a substantial impact on overall pain management.²³ Evaluation of caregivers is particularly necessary when complicated or high-tech pain management strategies are contemplated, such as continuous analgesic infusions. Need for frequent transportation, administration of pain treatments, and technical training may result in substantial stress for non-professional caregivers that can result in work absence or emotional and physical illness.

Pain Assessment Scales

A variety of pain scales are available to help categorize and quantify the magnitude of pain complaints. Results of these scales are also helpful in documenting and communicating pain experiences. It is helpful to evaluate pain using an appropriate pain scale initially and periodically to maximize treatment outcomes. Results can be recorded in flow chart or graph, making it easy to identify stability or changes in pain over time. Because there are no objective biologic markers or "gold standards," the validity of pain scales relies largely on face value, correlation with other known scales (concurrent validity), correlation with pain-related constructs (convergence), and experience in many populations over several years.

Pain scales can be grouped into multidimensional and unidimensional scales. In general, multidimensional scales with multiple items often provide more stable measurement and evaluation of pain in several domains. For example, the McGill Pain Questionnaire has been shown to capture pain in terms of intensity, affect, sensation, location, and several other domains that are not evaluative with a single question. At the same time, multidimensional scales are often long, time consuming, and can be difficult to score at the bedside, making them difficult to use in a busy clinical setting. Table 28.3 provides a description of several multidimensional scales for pain. Unfortunately, few data are available on the use of many of these scales specifically in elderly populations.

Unidimensional scales consist of a single item that usually relates to pain intensity alone. These scales are usually easy to administer and require little time or training to produce reasonably valid and reliable results. They have found widespread use in many clinical settings to monitor treatment effects and for quality assurance indicators. Table 28.4 describes some unidimensional scales that are commonly used, but a large number of variants are available that have similar characteristics and produce similar results. It is important to remember that unidimensional pain scales often require framing the pain question appropriately for maximum reliability. Subjects should be asked about pain in the present tense (here and now). For example, the interviewer should frame the question, "How much pain are you having right now?" Alternatively, the interviewer can ask, "How much pain have you had over the last week?" or "On average, how much pain have you had in the last month?" The latter questions require accurate memory and integration of pain experiences over time. Recent studies in those with cognitive impairment have shown that pain reports requiring recall are influenced by pain at the moment.³⁴ Thus, it may be more useful to use unidimensional scales to assess pain at the moment while evaluating changes in pain reports over time, much the way vital signs are used; this is especially true for those with some cognitive impairment.

Pain Assessment in Persons with Cognitive Impairment

Cognitive impairment, Alzheimer's disease, stroke, or dementia can present substantial challenges to pain assessment. Fortunately, it has been shown that pain reports from those with mild to moderate cognitive impairment are no less valid than other patients with normal cognitive function.³⁵ Weiner and associates have shown that these reports are also usually reliable (stable over time).³⁴ Our experience has shown that commonly available instruments, such as those in Table 28.5, are feasible for use in most patients with cognitive impairment.¹⁸ Thus, most elderly patients with mild to moderate cognitive impairment appear to have the capacity to report pain accurately and reliably using commonly available methods.

Of particular interest is the Hurley Discomfort Scale.³¹ This instrument was developed for the assessment of discomfort in patients with profound dementia. The scale consists of nine items scored by a trained examiner after observation of a noncommunicative patient. Behavioral observations such as breathing, vocalization, facial expression, body language, and restlessness are scored on Likert scales. Testing of the scale has demonstrated reasonable reliability and stability over time.^{31,36} The scale

TABLE 28.3. Multidimensional scales for pain measurement.

Instrument	Description	Target	Validity	Reliability	Advantages	Disadvantages	References
McGill Pain Questionnaire	Subjects asked to identify words descriptive of individual pain from 78 words grouped in 20 categories; plus 4 other items (including a 5-point word descriptive scale of pain intensity at the moment [PPI] scored separately)	All pain	Good	Good	Multidimensional, extensively studied over a long time; may discriminate between types of pain	Long, difficult to score	Melzack ²⁴
Short-Form McGill Pain Questionnaire	15 words scored on Likert scale, plus a visual analogue and PPI scales	All pain	Good	Good	Shorter than original McGill; not studied as deeply as original	May not discriminate between pain types	Melzack ²⁵
Wisconsin Brief Pain Inventory	16-item scale; items scored separately	Cancer pain	Good	Good	Multidimensional	Studied largely in cancer pain	AHCP ^R Cancer Pain Guidelines ²⁶
Memorial Sloan–Kettering Pain Scale	Four word descriptor scales	Cancer pain	Good	Good	Multidimensional	Studied largely in cancer pain	Fishman et al. ²⁷
Geriatric Pain Measure	24-item questionnaire; 22 items scored dichotomously; 2 items scored 0–10	Ambulatory elderly	Good	Good	Multidimensional; tested in elderly	Limited experience; sensitivity to change unknown	Ferrell et al. ²⁸
Neuropathic Pain Scale	10 items each scored 1–10	Neuropathic pain			Specific for neuropathic pain	Individual item analysis may be more helpful than changes in total score	Galer and Dworkin ¹⁰
WOMAC	41 items in 5 domains; pain, stiffness, physical function, social function, emotional function	Arthritis	Good	Good	Specific for arthritis	Difficult to use clinically	Bellamy et al. 1988 ²⁹
Roland and Morris Disability Questionnaire	24 items scored yes or no	Back pain	Good	Good	Specific for back pain	May not be generalizable to other pain syndromes	Waddell et al. ³⁰
Hurley Discomfort Scale	Designed to score discomfort behaviors in patients with severe Alzheimer's disease	Acute pain	Probably fair	Reasonable	Does not rely on self-report	Relies on behavioral observation	Hurley et al. ³¹
Osteoarthritis Pain Behavior Observation System	Designed to score position, movement, and behavior among adults	Osteoarthritis of knee	Compared to 0–10 scale, $r = 0.45$	Test–retest over 10 weeks, $r = 0.53$	Does not rely on verbal ability	Limited to osteoarthritis of knee	Keefe et al. ³²

requires some training and experience to administer, which may be problematic for some clinical settings.

Patients with severe cognitive impairment present substantial challenges for pain assessment. Although it has been assumed that those in deep coma do not experience pain, it is not clear that such brain damage necessarily results in complete anesthesia. Patients with “locked-in syndrome” (having intact perception and cognitive function but no purposeful motor function and no means of communication) may suffer severely. Unfortunately, no reliable methods exist to assess pain in these individuals. Health care providers must be aware of these situations and provide analgesia empirically, especially during procedures and conditions known to be uncomfortable or painful. More often, the majority with moderate to severe cognitive impairment can and do make their needs known in simple yes or no answers communicated in various ways. For example, those with profound aphasia can often provide accurate and reliable answers to yes and no questions when confronted by a sensitive and skilled interviewer. For these patients, it is important to be creative in establishing communication methods for the purpose of pain assessment.

Although pain is an individual experience, the use of family and caregivers in the assessment of pain can sometimes be helpful.³⁷ For patients with cognitive impairment, the history is often only obtainable from family or close caregivers. Family and caregivers are an excellent source of qualitative information about general behavior,

medication usage, actions that seem to reduce pain, and actions that seem to aggravate pain. It is important to remember, however, that family and caregivers are limited in their interpretation of events and behaviors. In fact, evidence has suggested that when it comes to estimating pain intensity, proxies are not always very

TABLE 28.5. Acute pain control options.

Mild pain	Administration of acetaminophen or NSAIDs Cognitive-behavioral strategies (relaxation, distraction, etc.) Physical agents (cold, heat, massage, etc.) Combined strategies
Moderate pain	Low-dose or low-potency opioids Combinations of acetaminophen or NSAIDs with low-dose or low-potency opioids Combined strategies
Severe pain	Potent opioid analgesics (intermittent or around the clock) Continuous infusions of opioid analgesics (e.g., PCA) Neural blockade (intermittent or continuous) Spinal anesthesia (e.g., epidural anesthesia, intermittent or continuous) Combined strategies

Source: Adapted from Acute Pain Management Guideline Panel. *Acute Pain Management: Operative or Medical Procedures and Trauma. Clinical Practice Guideline*. AHCPR Pub 92-0032. accurate or reliable. Our studies of elderly cancer patients suggest that caregivers may overestimate pain intensity and distress,²³ and both physicians and nurses have been found to underestimate pain, as well as provide inadequate pain medication.^{38,39} In the final analysis, family and close caregivers can be valuable sources of qualitative information, but they probably should not be relied on entirely for quantitative assessment of pain intensity or distress, especially among those patients able to communicate their pain experiences.

Acute and Perioperative Pain Management

The treatment of acute pain relies largely on short-term use of analgesic medications and resolution of the underlying cause. A variety of nondrug strategies have also been shown to be helpful. The choice of analgesic medications and other strategies to be used may depend on the severity of pain, availability of technical equipment and expertise, expectations for resolution of underlying injury, and individual patient characteristics. Table 28.5 lists some options available for acute and postoperative pain control.

The most common approach to treating acute pain relies on the World Health Organization recommendations for choosing the intensity of treatment based on the intensity of pain.^{6,40} Pain of mild intensity usually responds to nonopioid drugs used alone or in combination with other physical and cognitive-behavioral interventions. Pain of moderate intensity often requires more intensive efforts, such as weak opioids or low doses of more potent opioid drugs. Many of these drugs are compounded with NSAIDs or acetaminophen to achieve enhanced relief, with only modest exposure to the side effects of opioids. Severe pain usually requires potent opioid analgesic medications given alone or in combination with other analgesic strategies. For severe trauma or postoperative pain, intermittent intravenous, continuous intravenous, or spinal anesthesia may provide faster and more continuous pain relief. Table 28.5 provides an outline of acute pain control options for mild, moderate, and severe pain.

Although initially designed as a stepwise approach to cancer pain management, the WHO approach has become an acceptable approach to all pain with a few caveats. First, it is important to remember that the model does not require that strong opioids be withheld until after other treatments have failed. When patients present with severe pain, they should be treated initially with strong medications. Second, when pain rapidly escalates from mild to severe, analgesia should be rapidly escalated to strong opioids, with or without other combined strate-

gies. Third, adjuvant drugs and combined treatments should be used early for mild to moderate pain, especially those of the neuropathic type. Finally, when patients present with acute pain, even though establishing a diagnosis is a priority, symptomatic pain treatment should be initiated while investigations are proceeding. It is rarely justified to defer analgesia until a diagnosis is made. In fact, a comfortable patient is better able to cooperate with diagnostic procedures.

Acute and postoperative pain is dynamic. Without treatment, sensory input from damaged tissue causes alterations in spinal cord neurons that result in enhanced responses. Pain receptors also become more sensitive after injury. Studies have demonstrated long-lasting changes after brief painful stimuli.⁵ These observations may explain why long-standing pain is more difficult to suppress. Thus, patients should be encouraged to take pain medications continuously or to prevent pain before it becomes severe and requires higher doses of medication to suppress. In general, it may be helpful to provide continuous analgesics initially, with intermittent or “prn” rescue doses reserved for breakthrough or intermittent pain as the injury resolves.

Aggressive pain prevention and control before, during, and after surgery can have both short- and long-term benefits. Good preoperative pain control has been shown to make postoperative pain easier to control.⁴¹ Postoperative patients who use analgesia via a continuous infusion pump with self-administered boluses for breakthrough pain report less pain and are more satisfied with their pain control. These patients also use less medication, have fewer postoperative complications, and tend to be discharged earlier compared to similar patients who are given similar drugs on an intermittent or “as-needed” basis.^{5,42}

The importance of preoperative patient education cannot be overemphasized. Studies have shown that preoperative patient education and preparation dramatically enhance postoperative outcomes and improved pain management.⁴³ Patients given complete information about specific procedures including detailed descriptions of expected discomfort postoperatively often have less pain, use less pain medication, and have earlier discharges.⁵ Table 28.6 summarizes important preoperative information for patients and families.

Chronic Pain Management

Chronic pain management often requires a multimodal approach of drug and nondrug pain management strategies.⁷ Although analgesic medications are the most common strategy employed, the concurrent use of cognitive behavior therapy and other nondrug strategies may be helpful to reduce long-term reliance on medications

TABLE 28.6. Preoperative patient education for pain control.

Discuss the patient's previous experiences with pain, beliefs, and preferences for pain control
Give detailed information about postoperative pain expectations
Give patient information about pain management strategies available
Develop with the patient a plan for pain assessment and management
Select a pain assessment method and teach the patient how to use it
Inform patients of the importance of pain prevention
Provide patient with suggestions and training for non-drug pain management activities such as breathing and relaxation techniques

Source: Adapted from Acute Pain Management Guideline Panel. *Acute Pain Management in Adults: Operative Procedures. Quick Guide for Clinicians*. AHCPR Pub 92-0019. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services; 1995.

alone. It is important to consider that chronic pain management is often a labor-intensive effort. Not unlike the effort required during warfarin anticoagulation, pain management requires frequent monitoring and adjustments. Indeed, elderly patients with chronic pain benefit particularly from physicians, nurses, and restorative personnel who are able to employ an interdisciplinary approach to complex problems.

In general, chronic pain is often more difficult to relieve than acute pain. Patients should be given an expectation of pain relief, but it is unrealistic to suggest or sustain an expectation of complete relief for some patients with chronic pain. The goals and trade-offs of possible therapies need to be discussed openly. Sometimes a period of trial and error should be anticipated when new medications are initiated and titration occurs. Review of medications, doses, use patterns, efficacy, and adverse effects should be a regular process of care.⁷ Ineffective drugs should be tapered and discontinued.

Economic issues are also important in the management of chronic pain. It is appropriate to consider economic issues and make balanced decisions while basic principles of assessment and treatment are followed. Health care professionals should be aware of the costs and economic barriers patients and families may encounter with the strategies often prescribed. These issues include lack of Medicare reimbursement, limited formularies, delays in referrals in some managed care environments, delays from mail-order pharmacies, and limited availability of opioid medications in some pharmacies.

Analgesic Medications

Any patient who has pain that impairs functional status or quality of life is a candidate for analgesic drug therapy.⁷ Analgesic medications are safe and effective in elderly people. As with all pharmacotherapy, all analgesic interventions carry a balance of benefits and burdens. For

some classes of pain-relieving medications (opioids, for example), elderly patients have been shown to have increased analgesic sensitivity.⁴⁴ Dosing for most patients requires beginning with low doses with careful upward titration, including frequent reassessment for optimum pain relief and management of side effects.

The least invasive route of drug administration should be used. Some drugs can be administered from a variety of routes, such as subcutaneous, intravenous, transcutaneous, sublingual, and rectal. Most drugs are limited to only a few safe routes of administration, but new delivery systems are being created each year. The oral route is preferable because of its convenience and relatively steady blood levels produced. Significant effects are often seen 30 min to 2 h after an oral dose, which may be a drawback in acute, rapidly fluctuating pain. Intravenous bolus provides the most rapid onset and shortest duration of action, which may require substantial labor, technical skill, and monitoring. Subcutaneous and intramuscular injection, although commonly used, has disadvantages of wider fluctuations in absorption and rapid falloff of action compared to oral routes. Transcutaneous, rectal, and sublingual routes are also more difficult to predict but may be essential for those with difficulty swallowing.⁷

Timing of medications is also important. Fast-onset, short-acting analgesic drugs should be used for episodic pain. Medications for intermittent or episodic pain can usually be prescribed as needed. For continuous pain, medications should be provided around the clock. In these situations, a steady-state analgesic blood level is more effective in maintaining comfort. Long-acting or sustained-release preparations should only be used for continuous pain. Most patients with continuous pain also need fast-onset short-acting drugs for breakthrough pain. Breakthrough pain includes (1) end-of-dose failure as the result of decreased blood levels of analgesic with concomitant increase in pain before the next scheduled dose; (2) incident pain, usually caused by activity that can be anticipated and pretreated; and (3) spontaneous pain, common with neuropathic pain that is often fleeting and difficult to predict.⁷

The use of placebos is unethical in clinical practice, and there is no place for their use in the management of acute or chronic pain. Placebos, in the form of inert oral medications, sham injections, or other fraudulent procedures are only justified in certain research designs in which patients have given informed consent and understand that they may be receiving a placebo as a part of the research design. In research, placebos help identify and measure random or uncontrollable events that may confound results of some research designs.⁴⁵ In clinical settings, placebo effects are common, but they are neither diagnostic of pain or indicative of a therapeutic response. The effects of placebos are short lived, and most patients

eventually learn the truth, resulting in loss of patient trust and more needless suffering.

Acetaminophen

Acetaminophen is the drug of choice for elderly persons with mild to moderate pain, especially that of osteoarthritis and other musculoskeletal problems.⁷ As an analgesic and antipyretic, acetaminophen acts in the central nervous system to reduce pain perception. Despite the lack of anti-inflammatory activity, studies have shown that acetaminophen is as effective as ibuprofen for chronic osteoarthritis of the knee.⁴⁶ It has also been suggested that acetaminophen may have deleterious effects on renal function (dose related over many years)⁴⁷ and may interfere with the concomitant administration of warfarin.⁴⁸ Nonetheless, given in a dose of 650 to 1000 mg four times a day, it remains the safest analgesic medication compared to traditional NSAIDs and other analgesic drugs for most patients. Unfortunately, acetaminophen overdose can result in irreversible hepatic necrosis. Therefore, the maximum daily dose should never exceed 4000 mg/day.⁷

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have analgesic activity both peripherally and centrally. They are potent inhibitors of prostaglandin synthesis, which have effects on inflammation, pain receptors, and nerve conduction and may have central effects as well.⁴⁹ It is now known that there are two major NSAID-sensitive cyclooxygenase enzymes (COX-1 and COX-2) synthesized in a variety of organs. COX-1 is present in most organ systems and plays a role in normal organ function such as gastric mucosal blood flow and barrier function, renal blood flow, hepatic blood flow, and platelet aggregation. COX-2, normally present in lower concentrations, is an inducible enzyme in response to injury or inflammation. It is now known that selective inhibition of COX-2 gives rise to analgesic and anti-inflammatory activity with less organ toxicity compared to the nonselective inhibition of both enzymes. These findings have resulted in new NSAIDs reaching the market that have substantially less gastric and platelet toxicity compared to older NSAID medications. In fact, clinical trials have found COX-2 inhibitors to be similarly effective to traditional NSAIDs in terms of peak pain relief, total pain relief, and in indices of joint inflammation in patients with arthritis. Safety profiles of these agents have been impressive in reduction of gastrointestinal injury and bleeding diathesis.⁵⁰ However, it is important to note that, like other NSAIDs, these drugs have ceilings to their effects and limited potency for patients with moderate to severe pain problems.

Nonspecific inhibitors of COX enzymes (most older NSAIDs) are still appropriate for short-term use in inflammatory arthritic conditions such as gout, calcium pyrophosphate arthropathy, acute flare-ups of rheumatoid arthritis, and other inflammatory rheumatic conditions. They have also been reported to relieve the pain of headache, menstrual cramps, and other mild to moderate pain syndromes. These drugs can be used alone for mild to moderate pain or in combination with opioids for more severe pain. They have the advantage of being nonhabit forming. Individual drugs in this class vary widely with respect to anti-inflammatory activity, potency, analgesic properties, metabolism, excretion, and side effect profiles. Moreover, it has been observed that failure of response to one NSAID may not predict the response to another. A disadvantage of NSAIDs is that, unlike opioids, they all demonstrate a ceiling effect, that is, a level at which increase dose results in no further increase in analgesia. A large number of NSAIDs are now available; however, there is no evidence to support a particular compound as the NSAID of choice. Several are available over the counter without a prescription. Table 28.7 lists COX-2 and other selected NSAIDs for pain.

High-dose NSAIDs for long periods of time should be avoided in elderly patients.⁷ Of major concern is the high incidence of adverse reactions, including gastrointestinal bleeding,⁵¹ renal impairment,⁵² and bleeding diathesis from platelet dysfunction. The concomitant use of mesoprostol, high-dose histamine-2 receptor antagonists, and proton pump inhibitors is only partially successful at reducing the risk of significant gastrointestinal bleeding associated with NSAID use.⁵³⁻⁵⁵ Also, the side effect profiles of gastroprotective drugs in this population must be weighed against their limited benefits.⁵⁶ These gastroprotective medications do nothing to prevent the renal impairment and other side effects. For those with multiple medical problems, NSAIDs are associated with increased risk of drug-drug and drug-disease interactions. NSAIDs may interact with antihypertensive therapy.⁵⁷ Thus, the relative risks and benefits of NSAIDs must be weighed carefully against other available treatments for older patients with chronic pain problems. For some patients, chronic opioid therapy, low-dose or intermittent corticosteroid therapy, or other nonanalgesic drug strategies may have fewer life-threatening risks compared to long-term NSAID use.⁷ (Also see Chapter 7, Principles of Pharmacology.)

Opioid Analgesic Medications

Opioid analgesic medications act by blocking receptors in the central nervous system (brain and spinal cord), resulting in a decreased perception of pain. Many opioids also act similar to local anesthetics and have recently found widespread use in epidural anesthesia.⁵⁸ Selected

TABLE 28.7. Selected nonsteroidal anti-inflammatory drugs for pain.

Drug	Maximum dose	Description	Comments
Celecoxib (Celebrex)	200 mg bid	Selective COX-2 inhibition; pain and anti-inflammatory activity similar to other NSAIDs	Less gastric toxicity; less platelet inhibition
Refocoxib (Vioxx)	50 mg q 24 h	Selective COX-2 inhibition; pain and anti-inflammatory activity similar to other NSAIDs	Less gastric toxicity; less platelet inhibition
Relafen (Nabumetone)	2000 mg/24 h (q 24 h dosing)	Partially COX-2 selective; gastric toxicity may be less; occasionally requires q 12 h dosing	Avoid maximum dose for prolonged periods
Aspirin	4000 mg/24 h (q 4–6 h dosing)	Prototype NSAID	Salicylate levels may be helpful in monitoring
Salsalate (Disalcid)	3000 mg/24 h (q 6–8 h dosing)	Hydrolyzed in small intestine to aspirin	Elderly may require dose adjustment downward to avoid salicylate toxicity; salicylate levels may be helpful in monitoring
Ibuprofen (Motrin by prescription; Advil, Nuprin, and others OTC)	2400 mg/24 h (q 6–8 h dosing)	Gastric, renal, and abnormal platelet function may be dose dependent; constipation, confusion, and headaches may be more common in older persons	Avoid high doses for prolonged periods of time
Diflunisal (Dolobid)	1000 mg/24 h maximum dose Loading = 1000 mg, then 500 q 12 h; or 750 mg then 250 mg q 8 h in small patients or frail elderly	Relatively good analgesic properties, but requires loading dose	Dose may need downward adjustment for small patients or frail elderly
Sulindac (Clinoril)	400 mg/24 h (q 12 h dosing)	Same as ibuprofen	Same as ibuprofen
Naproxen (Naprosyn by prescription; Aleve and others OTC)	1000 mg/24 h (q 8–12 h dosing)	Same as ibuprofen; may require a loading dose	Same as ibuprofen
Choline magnesium trisalicylate (Trilisate)	5500 mg/24 h (q 12 h dosing)	Lower effect on platelet function	Salicylate levels may be helpful to avoid toxicity
Indomethacin (Indocin)	200 mg/24 h (q 8–12 h dosing)	Extremely high toxicity in frail elderly; should be reserved for acute inflammatory conditions (e.g., gout)	Keep dose to a minimum (25 mg q 18 h) and for short-term use only; avoid use for osteoarthritis or other noninflammatory problems
Ketorolac (Toradol)	i.m., 120 mg/24 h (30–60 mg loading dose; followed by half the loading dose (15–30 mg q 6 h, limited to not more than 5 days) p.o., 60 mg/24 h (q 6 h dosing limited to not more than 14 days)	Substantial gastrointestinal toxicity as well as renal and platelet dysfunction; relatively high postoperative complications have been documented	Duration of treatment limited because of high toxicity; reduce dose in half for those <50 kg or >65 years of age

OTC, over the counter or available without prescription; i.m., intramuscular (injection); p.o., per oral route (by mouth).

Limited number of examples are provided. For comprehensive lists of other available NSAIDs and a host of brand names, clinicians should consult other sources.

opioid analgesic medications are listed in Table 28.8. Opioid drugs have no ceiling to their analgesic effects and have been shown to relieve all types of pain. Short-term studies have suggested that elderly people, compared to

younger people, may be more sensitive to the analgesic properties of these drugs; this has been shown for acute postoperative pain, as well as chronic cancer pain.^{59–61} One study noted enhanced analgesia in elderly women

TABLE 28.8. Selected opioid analgesic medications for pain.

Drug	Starting dose (oral)	Description	Comments
Morphine (Roxanol, MSIR)	30 mg (q 4 h dosing)	Short–intermediate half-life; older people are more sensitive than younger people to side effects	Titrate to comfort; continuous use for continuous pain; intermittent use for episodic pain; anticipate and prevent side effects
Codeine (plain codeine, Tylenol 3, other combinations with acetaminophen or NSAIDs)	30–60 mg (q 4–6 h dosing)	Acetaminophen or NSAIDs, limit dose; constipation is a major issue	Begin bowel program early; do not exceed maximum dose for acetaminophen or NSAIDs
Hydrocodone (Vicodin, Lortab, others)	5–10 mg (q 3–4 h dosing)	Toxicity similar to morphine, acetaminophen, or NSAID combinations; limit maximum dose	Same as above
Oxycodone (Roxicodone, Oxy IR; or in combinations with acetaminophen or NSAIDs such as Percocet, Tylox, Percodan, others)	20–30 mg (q 3–4 h dosing)	Toxicity similar to morphine, acetaminophen, or NSAID combinations; limit maximum dose; oxycodone is available generically as a single agent	Same as above
Hydromorphone (Dilaudid)	4 mg (q 3–4 h dosing)	Half-life may be shorter than morphine; toxicity similar to morphine	Similar to morphine
Sustained-release morphine (MS Contin, Oramorph, Kadian)	MS Contin, 30–60 mg (q 12 h dosing) Oramorph, 30–60 mg (q 12 h dosing) Kadian, 30–60 mg (q 24 h dosing)	Morphine sulfate in a wax matrix tablet or sprinkles; MS Contin and Oramorph should not be broken or crushed; Kadian capsules can be opened and sprinkled on food, but should not be crushed	Titrate dose slowly because of drug accumulation; rarely requires more frequent dosing than recommended on package insert; immediate-release opioid analgesic often necessary for breakthrough pain
Sustained-release oxycodone (Oxycontin)	15–30 mg (q 12 h dosing)	Similar to sustained-release morphine	Similar to sustained-release morphine
Transderm Fentanyl (Duragesic)	25- μ g patch (q 72 h dosing)	Reservoir for drug is in the skin, not in the patch; equivalent dose compared to other opioids is not very predictable (see package insert); effective activity may exceed 72 h in older patients	Drug reservoir is in skin, not patch; titrate slowly using immediate-release analgesics for breakthrough pain; peak effect of first dose may take 18–24 h; not recommended for opioid-naive patients
Fentanyl lozenge on an applicator stick (Actiq)	Rub on buccal mucosa until analgesia occurs, then discard	Short half-life; useful for acute and breakthrough pain when oral route is not possible	Absorbed via buccal mucosa, not effective orally

Limited number of examples are provided. For comprehensive lists of other available opioids clinicians should consult other sources.

even when morphine was administered by the epidural route.⁶² Advanced age is associated with a prolonged half-life and prolonged pharmacokinetics of opioid drugs. Thus, elderly people may achieve pain relief from smaller doses of opiate drugs than younger people.

Opioid drugs have the potential to cause cognitive disturbances, nausea, respiratory depression, constipation, and habituation in older people. Drowsiness, performance-based measures of cognitive impairment, and respiratory depression associated with opioids should be anticipated when opioids are initiated and doses are escalated rapidly. Central nervous system effects are dose dependent and can be used to judge rate of dose escalations. If patients have unrelieved pain with little drowsiness or cognitive impairment, doses may be escalated. Tolerance usually develops in a few days to central nervous system side effects, at which time patients usually return to a fully alert status and baseline cognitive function. Until tolerance develops, patients should be instructed not to drive and to take precautions against falls or other accidents. Once tolerance to these effects has developed, however, patients can return to normal activities, including driving and other demanding tasks, despite high doses of opioid drugs. In fact, cancer patients are often observed to improve physical and cognitive function once pain is adequately relieved on opioid analgesics.⁷

Constipation is a side effect of opioid drugs to which patients do not develop tolerance. The management of constipation must be preemptive and preventative and include increasing fluid intake, maintaining mobility, and regular use of cathartic medications. All patients require stool softeners and osmotic laxatives, such as milk of magnesia, lactulose, or sorbitol. For many patients, opioid-induced constipation also requires potent stimulant laxatives, such as senna or bisacodyl. It should be remembered that stimulants should not be used until impactions have been removed and obstruction has been ruled out. Finally, some patients require regular enemas to ensure bowel evacuation during opioid administration for severe pain.

Nausea also occasionally complicates opioid therapy. Nausea from opioid medications may result from several mechanisms and typically wanes as tolerance develops over several days to a week. Traditionally, antiemetics such as prochlorperazine, chlorpromazine, and antihistamines have been the mainstay of treatment for nausea in younger patients. Recently, low-dose haloperidol and metoclopramide have been used, anecdotally noting a lower side effect profile compared to other neuroleptic drugs. It should be remembered that all these agents have high side effect profiles in elderly patients, including movement disorders, delirium, and anticholinergic effects. Thus, clinicians should choose antiemetic medications with the lowest side effects and continue to monitor patients frequently.⁷

It is important for clinicians who prescribe opioid analgesics to understand issues of tolerance, dependency, and addiction. Tolerance is a pharmacologic phenomenon that occurs with many drugs. Tolerance is defined by diminished effect of a drug associated with constant exposure to the drug over time. For opioid drugs, tolerance is difficult to predict. In general, tolerance to drowsiness and respiratory depression occurs much faster than tolerance to analgesic properties of the drug. Previous reports that described tolerance among cancer patients resulting in the need for massive doses of morphine to achieve adequate analgesia were probably misinterpreted because those patients also had rapidly advancing cancer.⁶³ More recent studies of opioid-managed arthritis pain have noted that tolerance was not often significant.⁶⁴ Many patients have been noted to remain on stable doses of opioids for many years without demonstrating significant tolerance to the analgesic effects. Tolerance develops quickly to central nervous system side effects and to nausea and never develops to constipation.

Dependency is also a pharmacologic phenomenon associated with many drugs, including corticosteroids and beta-blockers. Dependency is present when patients experience uncomfortable side effects when the drug is withheld abruptly. Drug dependence requires constant exposure to the drug for at least several days. The minimum dose and duration of drug exposure and development of withdrawal symptoms is not precisely known, but it appears to vary with individual opioid compounds. Symptoms associated with abrupt opioid withdrawal may include anorexia, restlessness, nausea, diaphoresis, tachycardia, mild hypertension, and mild fever. Worsening symptoms may include skin mottling, gooseflesh, and frank autonomic crisis. Fortunately, these symptoms can be completely prevented by tapering opioids over a few days. Opioid doses can be reduced by 50% every few days and safely discontinued within a week. In severe cases, clonidine given short term in titrated doses will usually control serious autonomic signs. It is important to remember that physiologic effects of opioid withdrawal are usually not life threatening compared to those common with alcohol, benzodiazepine, or barbiturate withdrawal.⁶⁵

Addiction is a psychiatric and behavioral problem and is defined in such terms. Addictive behavior is defined by compulsive drug use despite negative physical and social consequences (harm to self and others) and the craving for effects other than pain relief. Addicted patients often have erratic behavior that can be observed in a clinical setting in the form of selling, buying, and procuring drugs on the street and using medication by bizarre means such as crushing or dissolving tablets for self-i.v. administration. It is now clear that drug use alone is not the major factor in the development of addiction. Other medical, social, and economic factors play immense roles in addic-

tive behavior.⁶⁵ It is also important to not construe certain behaviors as necessarily addictive behaviors. Hoarding of medications, persistent or worsening pain complaints, frequent office visits, requests for dose escalations, and other behaviors associated with inadequately treated and unrelieved pain has coined the term pseudo-addiction. Laws, regulations, and unintentional behavior by prescribing clinicians may require patients to hoard medication and seek other physicians for additional help. In fact, true addiction is rare among patients taking opioid analgesic medications for medical reasons. This observation is not meant to imply that opioid drugs can be used indiscriminately, only that exaggerated fear of addiction and side effects do not justify failure to treat pain in elderly patients, especially those near the end of life.⁶³

Fear of addiction has been identified as a major barrier to pain management in elderly people.⁶⁴ Unfortunately, fears by clinicians and patients have been overly influenced by social pressures to reduce illegal drug use among younger people and those who take narcotics for emotional rather than medical reasons. Regulation of controlled substances by state and federal authorities, as well as scrutiny of physician practices by state license boards, have intimidated many clinicians, who as a result may not prescribe potent analgesic medications, even for those with severe pain near the end of life. This hesitancy to treat symptom distress may actually contribute to patients who seek suicide rather than endure inadequately managed pain. More recently, many organizations, such as the American Medical Association, the American College of Physicians, and the American Geriatrics Society, have released position statements supporting comfort and the control of pain in patients near the end of life.^{3,66,67} As emphasized by these organizations, clinicians have an obligation to provide comfort, pain relief, and dignity for patients.

Other Nonopioid Medications for Pain

A variety of other medications not formally classified as analgesics have been found to be helpful in certain specific pain problems. The term adjuvant analgesic drugs, although frequently used, is a misnomer in that some of these nonopioid drugs may be the primary pain-relieving pharmacologic intervention in certain cases. Table 28.9 provides some examples of nonopioid drugs that may help certain kinds of pain. The largest body of evidence available relates to the use of these drugs for neuropathic pain, such as diabetic neuropathies, postherpetic neuralgia, and trigeminal neuralgia. Tricyclic antidepressants, anticonvulsants, and local anesthetics are the nonopioid analgesics most frequently used for neuropathic conditions. In general, these drugs have had limited success in pain syndromes that are not associated with neuropathic mechanisms.^{68,69} Most reports have found that these

agents are only partially successful. Typically, about 50% to 70% of patients subjects have a measurable response, and of those most experience only partial relief.⁶⁸⁻⁷⁰ Thus, these drugs are often not panaceas and are rarely totally successful as single agents. One exception may be trigeminal neuralgia, where carbamazepine is probably the drug of choice.⁷ Usually these agents work better in combination with other traditional drug and nondrug strategies in an effort to improve pain and keep other drug doses to a minimum. Failure of response to one particular class of drugs does not necessarily predict failure of another class of agents. In general, nonopioid medications for neuropathic pain should be chosen according to lowest side effects. Treatment should usually start with lower doses than recommended for younger patients, and doses should be escalated slowly based on known pharmacokinetics of individual drugs and appropriate knowledge of disease-specific treatment strategies. Unfortunately, most of the nonopioid medications for pain management have high side effect profiles in elderly people. Thus, these medications often must be monitored carefully.

Antidepressants have been the most widely studied class of nonopioid medications for pain. The mechanism of action for these drugs is not entirely known but probably has to do with interruption of norepinephrine and serotonin-mediated mechanisms in the brain.⁶⁸ For neuropathic pain, the major effect of these drugs is not their mood-altering capacity, although this may also be helpful in those with concurrent major depression. More is known about tricyclic antidepressants than the other subclasses. A randomized placebo-controlled trial of amitriptyline, desipramine, and fluoxetine indicated that desipramine may be as effective as amitriptyline, but fluoxetine is no better than placebo for the treatment of diabetic neuropathy.⁶² Thus, desipramine may be a better choice because it has a lower side effect profile in elderly people than amitriptyline. Other studies of the serotonin reuptake inhibitors, which may have lower side effect profiles for elderly people, have had mixed reviews, and most have not been shown effective for pain management, with the exception of chronic headache and diabetic neuropathy (paroxetine).⁶⁸

It has been known for many years that some medications with antiepileptic activity may relieve the pain of trigeminal neuralgia (tic douloureux).⁷¹ Studies have shown that compounds such as diphenylhydantoin, tegretol, and valproic acid may also help diabetic neuralgia and other neuropathic pains in some patients. In general, the usefulness of these drugs has been limited by their high side effect profiles in elderly people and the fact that most patients respond only partially, making the overall risk/benefit ratio large in this population. Indeed, these drugs are not simple analgesics and should not be used for the relief of trivial aches and pains.⁷ Of recent interest has been the effectiveness of gabapentin for treatment

TABLE 28.9. Selected nonopioid medications for pain.

Drug	Description	Comments
Antidepressants: Amytriptyline, desipramine, nortriptyline, others	Older people are more sensitive to side effects, especially anticholinergic effects; desipramine or nortriptyline are better choices than amytriptyline	Complete relief unusual; used best as adjunct to other strategies; start low and increase slowly every 3–5 days
Anticonvulsants Clonazepam, carbamazepine	Carbamazepine may cause leukopenia, thrombocytopenia, and rarely aplastic anemia; clonazepam side effects may be similar to other benzodiazepines in the elderly	Start low and increase slowly; check blood counts on carbamazepine
Gabapentin (also an anticonvulsant) Neurontin	Less serious side effects than other anticonvulsants	Start with 100 mg and titrate up slowly; tid dosing; monitor for idiosyncratic side effects such as ankle swelling, ataxia, etc.; effective dose reported 100–800 mg q 8 h
Antiarrhythmics Mexiletine (Mexitil)	Common side effects include tremor, dizziness, paresthesias; rarely may cause blood dyscrasias and hepatic damage	Avoid use in patients with preexisting heart disease; start low and titrate slowly; monitor EKGs; q 6–8 h dosing
Local anesthetics Lidocaine (intravenous) Lidocaine transdermal patch (Lidoderm) Capsaicin	IV lidocaine associated with delirium. Transdermal patch has minimal systemic absorption Capsaicin depletes nerve endings of substance P	i.v. lidocaine may predict response to anticonvulsants and antiarrhythmics May apply up to three patches alternating 12-h interval to improve pain, reduce denervation hypersensitivity, and decrease systemic absorption May take 2 weeks to peak effect
Tramadol (Ultram)	Partial opioid and serotonin agonist; more of a norepinephrine antagonist; may cause drowsiness, nausea, vomiting, and constipation	Has ceiling effect; dose >300 mg/24 h usually not tolerated because of nausea; q 4–6 h dosing
Muscle relaxants (baclo Fen chlorzoxazone [Paraflex], cyclobenzaprine [Flexaril])	Sedation; anticholinergic effects; abrupt withdrawal of baclofen may cause CNS irritability	Mechanism of action not precisely known; monitor for sedation and anticholinergic effects; taper baclofen on discontinuation Poorly tolerated in older adults
Substance P inhibitors (capsaicin) available OTC; for topical use only	Burning pain during depletion of substance P may be intolerable by as many as 30% of patients; may take 14 days for maximum response; avoid eye contamination	Start with small doses; can be partially removed with vegetable oil
NMDA inhibitors	<i>N</i> -Methyl- <i>D</i> -aspartate antagonists (NMDA)	Ketamine only available i.v.
Ketamine Dextromethorphan	Ketamine: potent anesthetic Dextromethorphan: common cough suppressant	Both may cause delirium
Drugs for osteoporosis Calcitonin Bisphosphonates	Pain relief mechanisms unknown	Not effective on pain other than osteoporosis
Corticosteroids Prednisone Dexamethasone	Decrease inflammation in many tissues	Classic corticosteroid side effects limit overall usefulness in chronic pain

Limited number of examples are provided. For comprehensive lists of other available medications for pain, clinicians should consult other sources.

TABLE 28.10. Anesthetic or neurosurgical pain management techniques.

Procedure	Possible indications	Comments
Continuous infusion opioids (morphine, hydromorphone, fentanyl)	Perioperative pain; severe cancer pain when oral route has failed	Subcutaneous infusions are usually well tolerated by patients in nursing homes or home care; i.v. infusions may require more skilled monitoring
Epidural analgesia (intermittent local anesthetics or opioids, or continuous opioids)	Perioperative pain; severe cancer pain when oral route has failed	Can be supplied by external or internally implanted pumps; does not avoid constipation and occasional delirium; serious complications are rare but can be devastating
Nerve blocks	Mononeuropathies, postherpetic neuralgia, intercostal nerve pain (postthoracotomy or postherpetic neuralgia)	Usually temporary relief limited to a few days or weeks
Intrathecal analgesia	Perioperative pain	Can cause respiratory depression
Stellate ganglia blockade	Sympathetically mediated pain of the upper extremity	Not to be confused with complex regional pain syndromes
Lumbar sympathetic blockade	Sympathetically mediated pain of the lower extremity, peripheral vascular disease	
Celiac plexus blockade	Severe pain from carcinoma of pancreas	Requires substantial skill
Neuroablation (permanent nerve destruction)	Severe recalcitrant mononeuropathic pain	May recur after several years
Cordotomy	Severe recalcitrant cancer pain	May not relieve all pain
Neurostimulation (dorsal column or thalamic)	Severe recalcitrant pain, usually following thalamic stroke or spinal cord injury	Requires substantial skill

of diabetic neuralgia and postherpetic neuralgia.^{72,73} Clinical observations suggest that this agent has a significant analgesic effect on neuropathic pain with a much lower side effect profile compared to other antiepileptic drugs and also most antidepressants.

Several local anesthetics have also been shown to relieve neuropathic pain when administered systemically, in addition to their known local anesthetic effects. Intravenous lidocaine has been found to sometimes predict the response to other anticonvulsant and systemically administered local anesthetics.⁷¹ Mexilitine (Mexitil), similar to lidocaine but active orally, has also shown some activity against neuropathic pain of diabetic neuralgia. Although this drug also has a high risk to benefit ratio, some studies have reported response rates at lower doses than are often recommended for cardiac arrhythmias.⁷⁴ Lidocaine transdermal patches have been effective for treatment of neuropathic pain.

Finally, chronic pain associated with osteoporosis has been shown to improve with calcitonin.⁷⁵ Most investigators of the effects of calcitonin on osteoporosis have reported anecdotally that pain improves significantly. These studies have not been designed as pain studies, but results thus far are encouraging.

Anesthetic and Neurosurgical Approaches to Pain Management

A wide variety of anesthetic and neurosurgical approaches to pain are available, and some require highly specialized skills.⁷⁶ Table 28.10 lists some common anesthesia and neurosurgical interventions for severe pain. Although it is beyond the scope of this chapter to review details of all these techniques, a few deserve mention.

Trigger-point injections have been used effectively for the treatment of myofascial pain syndromes. Trigger points may initiate a reflex mechanism that produces referred pain, tenderness, and muscle spasm. With local injection of the trigger point followed by stretching and reconditioning of the muscles, the myofascial pain syndrome may subside. More recently, similar results have been obtained using ice massage or vapocoolant spray applied topically, followed by specific muscle stretching and physical therapy techniques.⁷⁷ Trigger-point injection with dilute local anesthetics may be highly effective when combined with specific physical therapy for many myofascial pain syndromes.

Continuous drug infusions are effective for steady-state analgesic drug levels. Continuous infusions can be maintained by implantable pumps or external devices to deliver intravenous, subcutaneous, intrathecal, or epidural medications. Continuous infusions of opioid drugs have found widespread use in severe chronic cancer pain, especially among those nearing the end of life. Other uses have included continuous infusion of muscle relaxants for patients with muscle spasm from spinal injury, multiple sclerosis, or end-stage Parkinson's disease. Whether these invasive high-tech strategies are appropriate for patients with all kinds of chronic pain remains controversial. These techniques are expensive, but they are often reimbursed by third-party payors, including Medicare, raising ethical issues about the application of high-tech strategies for patients who might be equally well managed using oral medications that are not reimbursable.^{78,79} In general, invasive methods carry risk and should be used only when oral medications become ineffective or the oral route of administration is no longer viable.

Nondrug Strategies for Pain Management

Nondrug strategies, used alone or in combination with appropriate analgesic medications, should be an integral part of the care plan for most elderly patients with significant pain problems. Nondrug strategies for pain management encompass a broad range of treatments and physical modalities, many of which carry low risks for adverse effects (Table 28.11). Used in combination with appropriate drug regimens, these interventions often enhance therapeutic effects while allowing medication doses to be kept low to prevent adverse drug effects.⁷

Among the nondrug interventions, the importance of patient education cannot be overstated. Studies have shown that patient education programs alone significantly improve overall pain management.^{80,81} Such programs often include content about the nature of pain, how to use pain diaries and pain assessment instruments, how to use medications appropriately, and how to use

TABLE 28.11. Selected nondrug strategies for pain management.

Intervention	Comments	Limitations
Education	Content should include basic knowledge about pain (diagnosis, treatment, complications, and prognosis), other available treatment options, and information about over-the-counter medications and self-help strategies	May require substantial time
Exercise	Can be tailored for individual patient needs and lifestyle; moderate-intensity exercise should be maintained for 30 min or more 3–4 times a week and continued indefinitely	Maintenance is critical and difficult to continue indefinitely
Cognitive-behavioral therapy	Should be conducted by a trained therapist	Requires substantial cognitive function
Physical modalities (heat, cold, and massage)	A variety of techniques are available for application	Heat and cold should be used with caution in those with cognitive impairment to avoid thermal injuries
Physical or occupational therapy	Should be conducted by a trained therapist	Not appropriate for maintenance therapy; can be expensive if not reimbursed
Chiropractic	Has been shown to be as effective as Mackenzie exercises for acute back pain	Potential spinal cord or nerve root impingement should be ruled out before any spinal manipulation
Acupuncture	Should be provided only by a qualified acupuncturist	Effects may be short lived and require repetitive treatments
Transcutaneous electrical nerve stimulation (TENS)	Should initially be applied and adjusted by an experienced professional	Effects are often short lived; clear placebo effects have been observed
Relaxation and distraction techniques	Therapeutic modalities require individual acceptance and may require substantial training	Patients with cognitive impairment may not be good candidates

self-help nondrug strategies. Whether conducted in groups or individually, education should be tailored for individual patient needs and level of understanding. Written materials and methods of reinforcement are important to the overall success of the program.

Physical exercise is important for most patients with pain. A program of exercise can be tailored to most patients' needs and is extremely important for rehabilitation and the maintenance of strength and endurance. Clinical trials of older patients with chronic musculoskeletal pain have shown that moderate levels of exercise (aerobic and resistance training) on a regular basis are effective in improving pain and functional status.⁸²⁻⁸⁴ Initial training for chronic pain patients usually requires 8 to 12 weeks with supervision by a professional who can focus on the needs of older people with musculoskeletal disorders. There is no evidence that one form of exercise is better than another, so programs can be tailored for the individual's needs, lifestyle, and preference. The intensity of exercise, along with frequency and duration, must be adjusted to avoid exacerbation of the underlying condition, while gradually increasing and later maintaining overall conditioning. It is important to remember that feeling better often gives rise to a false impression that the discipline of regular exercise is not necessary. Continued encouragement and reinforcement is often required. Unless complications arise, the program of exercise should be maintained indefinitely to prevent deconditioning and deterioration.

Psychologic strategies have also been shown to be helpful for some with significant pain. Cognitive therapies are strategies aimed at altering belief systems and attitudes about pain and suffering. Cognitive therapies include various forms of distraction, relaxation, biofeedback, and hypnosis. Behavioral therapies are strategies aimed at enhancing healthy behaviors and discouraging abnormal behavior that is unpredictable and self-defeating. Cognitive therapy can be combined with behavioral approaches, and together they are known as cognitive-behavioral therapy. Cognitive-behavioral therapy in its purest form includes a structured approach to teaching coping skills that might be used alone or in combination with analgesic medications and other nondrug strategies for pain control. Effective programs can be conducted by trained professionals with individual patients or in groups, and there is some evidence that the effect is enhanced with caregiver involvement. Although it may not be appropriate for those with significant cognitive impairment, there is evidence from randomized trials to support the use of cognitive-behavioral therapy for many patients with significant chronic pain.^{85,86}

Finally, a variety of alternative therapies are also used by many patients. Many patients seek alternative medicine approaches with and without the knowledge or recommendation of their physician or other primary care

provider. Alternative medicine approaches to chronic pain may include homeopathy, spiritual healing, or the growing market of vitamin, herbal, and natural remedies. Although there is little scientific evidence to support these strategies for pain control, it is important that health care providers not abandon or react to patients using these modalities, but rather educate both themselves and their patients about their benefits and risks.⁸⁷

Palliative Care in Early, Moderate, and Advanced Dementia

Anna Monias and Diane E. Meier

Irreversible dementia is one of the most feared diagnoses in medicine. Patients with the disease face progressive deterioration of cognitive abilities, eventually resulting in loss of independence and inability to care for oneself. Prevalence of dementia increases with each decade of life over age 65.¹ Nineteen percent of the population suffers from dementia by age 80, 49% by age 90, and 60% among centenarians.^{2,3} Alzheimer's disease (AD) is the most common cause of dementia, accounting for 50% of all cases. Over 4 million Americans are affected; this number is expected to increase to a minimum of 14 million by the middle of this century.^{4,5} Worldwide, 22 million people are affected.⁶ The second most common cause of dementia in the United States is vascular dementia, which accounts for another 20% to 40% of dementia cases.⁷ Lewy body disease, Pick's disease, and Creutzfeldt–Jakob disease occur less often. Clinically, it is difficult to distinguish between different types of dementia, and many patients present with a “mixed” picture. In one study, the prevalence of “dementia of unknown etiology” increased with age and represented nearly 50% of dementia in those over age 90.⁸

Dementia is a chronic, terminal disease. All treatments are palliative, as there is no cure. The disease begins insidiously with mild decreases in memory, judgment, and spatial relationships. Care for the dementia patient should endeavor to preserve dignity and aggressively manage symptoms to sustain the best quality of life possible in patients with early, moderate, and end-stage dementia.

Each stage presents unique sources of suffering. In early dementia, patients may experience difficulties with word finding, driving, and learning new skills. Even in the early stages, patients require supervision. These patients may suffer depression, fear, and anxiety over their diagnosis and loss of independence. Over a period of time, on average 7 to 10 years, the disease progresses and patients suffer increased cognitive decline. Patients with moderate dementia lose the ability to perform previously

routine tasks, such as balancing a checkbook or finding their way home from a neighborhood store. Family members or paid help begin to play a larger role in the patient's care. Often, behavioral disturbances including agitation, wandering, and paranoia develop, affecting both the patient and the caregiver. In advanced dementia, patients depend entirely on their caregivers for the activities of daily living, such as dressing, bathing, and toileting. They suffer from incontinence, gait instability, and decreased ability to chew and swallow. Eventually, they may be unable to remember their caregivers' names and cannot recognize members of their own family. Patients cannot verbally express emotions or describe pain and discomfort. Often, they are bedbound. By the end stages of dementia, most patients require nursing home care.

Caring for patients with dementing illness is physically, financially, and emotionally exhausting. Fifty percent of caregivers have financial difficulties and 66% have their own health problems.⁹ Caregivers for dementia patients face different, and in some ways greater, stresses than caregivers in other terminal illnesses. The duration of family caregiving required often exceeds 10 years. In many cases, the disease affects the patient's personality. Paranoia and behavioral disturbances are common. In late stages, patients often can neither recognize nor appreciate their caregivers. In addition, the financial burden of this disease is staggering. In 1991, the direct costs of Alzheimer's disease were \$20.6 billion, with indirect costs estimated at \$67.3 billion.^{9,10} The estimated 10-year direct cost for a man with Alzheimer's disease is \$67,000. For women, who often have less support available in the home, the estimated 10-year direct cost is \$100,900.² Indirect costs of Alzheimer's disease include unpaid hours that caregivers spend with patients, as well as lost wages secondary to hours missed from paid employment. Due to hospital and nursing home costs, Medicaid and Medicare expenditures on dementia patients are significantly more than age-matched patients without dementia.^{11–14} When family labor is considered,

the costs for caregiving at home in cases of advanced dementia exceed the costs of nursing home care.¹⁵ The chronic stress associated with caring for a spouse with Alzheimer's disease has also been associated with decreased immunity and associated comorbidities, including depression.¹⁶ Physicians can minimize caregiver burnout by letting caregivers know that they are available to talk with them during stressful times, simplifying medications and treatments, encouraging caregivers to take some time each day for their own needs, and providing information about support groups and community services, including hospice.

This chapter seeks to describe the medical and social issues that may become problems for dementia patients and their caregivers during the course of dementia and suggests appropriate interventions that will alleviate suffering. The needs of patients and caregivers change dramatically in each stage of the disease; therefore, this chapter is divided into three sections: early dementia, moderate dementia, and advanced dementia. Every dementia patient goes through all three stages; however, the disease affects each patient differently.

Physicians need to tailor care to the individual patient and caregiver. The patient with dementia may have or develop other chronic medical problems, including coronary artery disease, vascular ulcers, osteoarthritis, diabetes, renal insufficiency, and malignancy. A life-threatening illness, such as acute myocardial infarction, pneumonia, or urinary tract infection, could strike during any stage of dementia. Concurrent illnesses put additional stress on caregivers; the burdens of dressing changes, administering medications, and giving injections fall to them. The stage of dementia will affect the patient's ability to understand and comply with therapy. Physicians should continue to prescribe treatments that enhance comfort for demented patients with concurrent illness who do not undergo surgery, chemotherapy, and other invasive testing.

Early Dementia

D.G. is a 75-year-old retired businessman who was diagnosed with Alzheimer's dementia 3 months ago. He lives with his 70-year-old wife in a three-bedroom house. Before his diagnosis, Mr. G. had been repeating the same questions over and over, which was a source of irritation and concern to his wife of 47 years. Mr. G. was started on vitamin E and donepezil for Alzheimer's dementia, and both he and Mrs. G believe that his condition has been stable over the last few months. Mr. G. tells his physician that his grandmother was senile for a few years before her death. He fears losing control of his life and becoming a burden on his wife and two adult children.

After a medical evaluation to exclude reversible causes of dementia, physicians should implement evidence-

based pharmacologic therapies to decrease the rate of cognitive decline. Treatment with cholinesterase inhibitors can modestly improve cognitive function and possibly improve activities of daily living in patients with mild to moderate Alzheimer's dementia.^{6,17,18} These drugs may slow progression of the disease and help patients retain independence for a longer period of time. Although the first drug in this class, tacrine, was associated with liver toxicity, donepezil and rivastigmine are safe and well tolerated. There is less evidence to support using Hydergine, statins, nonsteroidal anti-inflammatory drugs, vitamin E, and dehydroepiandrosterone (DHEA) to delay cognitive decline.¹⁹⁻²¹ Because the prevalence of AD is so high, much of the research on therapies has focused on AD rather than other types of dementia. Aggressive control of vascular risk factors may stabilize the rate of decline for patients with vascular dementia. Occupational therapy may also help patients with early and moderate dementia. Patients seem to derive both cognitive and behavioral benefits, at least in the short term, from reality orientation.²²

In the early stages of dementia, it is important to inform both patients and caregivers of the diagnosis.²³ Educating patients and families about the course of the disease will help them make plans for medical care, financial affairs, and the way that they want to spend their remaining functional time. At this stage of the disease, patients can still make decisions for themselves. Physicians should ask them about their preferences for medical treatments in later stages of disease. Specifically, patients should be asked under what circumstances they would no longer wish life-prolonging technologies, such as a feeding tube. Many patients respond to this question by stating that if they are no longer able to recognize loved ones, then medical care should focus on comfort and quality of life, and they should be allowed to die peacefully. This is a more important and useful question than queries about desires for or against specific medical technologies, any one of which might be appropriate or inappropriate depending upon the details of the clinical context. Patients should also be asked to designate one or more primary decision makers in preparation for the time when they are no longer able to make medical decisions for themselves.

Early conversations about advance directives prepare family members for the burden of decision making in late dementia and may reduce later stress associated with surrogate decision making.²⁴ Goals of care should also be discussed early in the course of the disease. Patients and family members should be reassured that goals might change as the disease progresses. For example, early in the course of dementia, goals may be preserving autonomy, financial planning, continuing to participate in social activities and travel, ensuring safety, prolonging life, and forming a care plan for more advanced stages of disease.

Health care providers should advise patients and their families to speak with a financial advisor or attorney regarding their financial affair.²⁵ Physicians should remember that goals of care are likely to differ in relationship to individual belief systems and values.

Psychiatric disturbances are among the most frustrating problems of dementia. Early in the course of dementia, patients are aware of progressive memory loss and fear loss of identity. This fear can cause considerable anxiety and depression. Forty percent of patients with dementia experience anxiety.²⁶ Depressive symptoms are reported in 50% of patients with Alzheimer's dementia and may be more prevalent in vascular and Parkinson's dementia.²⁶ Depression in progressive dementia may be caused by anatomic damage to the brain.²⁷ Patients with AD are often diagnosed with depression as much as 2 years before the diagnosis of AD is made.²⁸ Antidepressants sometimes help these symptoms; however, therapies for classical depression may not be as efficacious in depression associated with dementia. Patient support groups may help in the early stages of disease. Euphoria is uncommon in AD but may be associated with frontal lobe dementias.²⁸ Depression is sometimes confused with personality changes in patients with AD. Frequently, Alzheimer's patients exhibit indifference, limited emotional engagement, and decreased motivation.²⁸ Therapy with cholinesterase inhibitors may improve psychiatric symptoms.

The period after diagnosis is also a time of great adjustment and grief for family caregivers. Before diagnosis, the patient may have been physically healthier and stronger than the caregiver. For many married couples, a diagnosis of dementia means that the healthier spouse will need to take on chores previously done by the patient, such as driving, financial planning and bill paying, housework, cooking, gardening, or shopping. Adult children may also have to play a caregiving role for the first time. Some family caregivers may find support groups helpful at this time.

Moderate Dementia

Despite treatment with donepezil, D.G., now 79, has faced progression of his dementia. He still lives with his wife, now 74. The couple moved to a smaller apartment a year ago after Mrs. G. was hospitalized for 1 week with a myocardial infarction. Mr. G.'s son, B.G., stayed with him during that hospitalization. Although he called frequently and visited one to two times per month, B.G. had not previously realized how forgetful his father had become. Night after night, he would wake up and begin looking for his wife. He tried to leave the house each night to look for Mrs. G. Although Mr. G. had stopped driving shortly after his diagnosis, on one occasion he tried to drive his son's car using a house key that he found on the kitchen table. When they went to the hospital, D.G. would

repeatedly ask where they were going and why. Although he still "read" the newspaper, he could no longer understand the articles. Mrs. G. had been doing all the shopping for several months because Mr. G. could no longer count change correctly. During meals, D.G. would eat minimally but put food in his pockets and take it to his bedroom. B.G. realized taking care of his father and a three-bedroom house was too much work for his mother. He helped his parents move to an apartment closer to his own home. Mrs. G. now has help with cleaning, cooking, and caring for her husband.

The middle stage of dementia is extremely challenging to health care providers and caregivers. Goals of care during this stage may focus on keeping the home environment safe and providing regular respite for caregivers. Patients suffer from increased paranoia and fear. This phase is marked by the need for greater supervision of patients due to safety concerns, decreased ability to perform the activities of daily living, and increased behavioral disturbances. These changes in patients are sources of immense caregiver stress; they may lead to nursing home placement. Patients with moderate dementia but without other medical comorbidities are difficult to place in nursing homes because reimbursement for this type of care is low. Families who choose to take care of dementia patients at home may access services such as adult day care and respite care, but availability is scarce and out-of-pocket costs are high. Palliative measures include modifying the diet and environment to meet nutritional and safety needs and improve behavior without compromising patient dignity. These changes require training family members and nursing home staff in behavioral management and feeding techniques as described in the following paragraphs.

Eating behaviors change in patients with moderate dementia. Decreased acuity of smell and taste and decreased sensitivity to thirst receptors predispose dementia patients to weight loss and dehydration. At this stage of disease, patients may also have difficulty using utensils. Caregivers can compensate by offering frequent, nutritious snacks. Patients may find finger foods more acceptable than more formal meals. Creating a pleasant dining setting and giving specially designed utensils, such as deep dishes and large spoons, may make feeding easier. Adding extra sweeteners or spices may also improve caloric intake. Health care providers should evaluate correctable causes of anorexia, such as medications, depression, odynophagia, constipation, and urinary retention, and physicians should try to eliminate medications that may cause anorexia. Common classes of medication that cause anorexia include diuretics, beta-blockers, digoxin, and statins.

Although neuropsychiatric disorders are intermittent and may occur at any stage of disease, they are associated with more rapid cognitive and functional decline.²⁸ Symptoms become more frequent as disease progresses.²⁸ In

addition to anxiety and depression, patients with dementia suffer from paranoia, delusions, hallucinations, sleep disorders, agitation, and combativeness.²⁹ More than 50% of patients with Alzheimer's disease demonstrate aggressive behavior; nearly 20% physically assault their caregivers.³⁰ These symptoms affect quality of life for both patient and caregiver. Noncognitive features of dementia may have a greater impact on caregiver burden than decrease in cognitive function or decrease in activities of daily living.³¹ In fact, neuropsychiatric disturbances, particularly aggressive behavior and paranoia, increase the likelihood of nursing home placement more than decline in cognitive function.^{28,32}

Many pharmacologic and nonpharmacologic interventions have been studied to decrease behavioral disturbances. However, physicians should eliminate comorbid illnesses and pain as causes of behavioral disturbance before trials of neuroleptics or behavioral therapies. Treatment of medical illness leads to sustained improvement of cognition and behavior in a significant percentage of these patients.²⁶ When patients lose the ability to express themselves, they can only communicate through their actions. As with an infant, the caregiver needs to determine whether there is a reversible cause of agitation such as pain, hunger, thirst, or wet clothing. Identifying causes of discomfort may be difficult. Although patients with mild to moderate dementia can often complete a pain intensity scale, they may not verbally complain of pain in the same way as cognitively intact patients.^{33,34} Behavioral symptoms such as restlessness, insomnia, pugnacity, tense body posture, grimacing, vocalization, withdrawal, and fear may all be symptoms of pain; therefore, before trying to stop these behaviors, physicians should look for their cause.

If there is no obvious physiologic reason for discomfort, modifying care practices may reduce behavioral disturbances. For many dementia patients, bathing and grooming are frightening assaults. Changing the routine by giving sponge baths and adjusting water temperature can make the experience less threatening. Also, research has suggested that encouraging patients to participate in grooming and bathing themselves decreases agitation.³⁵ Sleep disturbances affect up to 70% of patients with dementia. Daytime exercises, a consistent bedtime routine, and minimizing daytime napping can help improve sleep patterns.³⁶ A calm environment featuring favorite music from the patient's early adulthood and frequent social activities may also diminish disruptive behavior. Recordings of family members recounting favorite memories may also provide comfort to dementia patients.³⁷ When nonpharmacologic measures do not help, low doses of neuroleptics can alleviate nocturnal confusion, hallucinations, and delusions. At low doses, second-generation neuroleptics (risperidal, quetiapine, olanzapine) cause less extrapyramidal toxicity than

haloperidol.³² Successful management of behavioral disturbances can prevent hospital admissions and nursing home placement.

Caregivers often begin to suffer from fatigue, emotional stress, and financial stress during this stage of Alzheimer's disease. Those who work return home and begin a second shift. Job performance may falter, secondary to lack of sleep and missed days resulting from caregiving demands. Often caregivers have to leave their jobs to care for loved ones. Hiring health aides and making safety modifications to the home is expensive. Day programs are also expensive. Unless the patient is on Medicaid, these services are not covered by health insurance. Caregivers may also feel unappreciated because patients may not be able to express appreciation or gratitude. During this stage, caregivers may begin to mourn the passing of the strong, independent people they once knew as they watch the patients gradually become shadows of their former selves. Health care providers should ask caregivers about fatigue, social isolation, depression, and physical symptoms. Caregivers should be given a list of local resources for adult day care, respite care, homemaker services, and support groups. Caregivers should be reminded to take breaks from patient care and encourage other family members or close friends to help care for the patient on a regular basis.

Advanced Dementia

D.G., now 85, was placed into a nursing home 1 year ago after Mrs. G. died. At first, he wandered frequently during the day and night. Four months ago, he fell while in the bathroom and suffered from a fracture to his left hip, requiring arthroplasty. Currently, he walks only with assistance. Although he has a walker, he does not remember to use it. He was unable to complete a physical therapy program after his surgery because he could not follow instructions. In the last few weeks, he has had decreased oral intake. Sometimes he seems to "pocket" food in his mouth without swallowing it. He often clamps his mouth shut or pushes the spoon away during feeding. He is incontinent of both urine and stool. His children visit frequently, but he does not seem to recognize them.

Patients with advanced dementia are at the end stage of a terminal disease. They are dying just as surely as patients with end-stage cancer, connective tissue disease, or heart failure are dying. Multiple studies have demonstrated a median 6-month mortality in persons with advanced dementia, with or without tube feeding, although the range of survival time is wide.³⁸ Advanced dementia patients may experience moments of lucidity; however, they do not consistently recognize caregivers or their own images in the mirror. Patients lose ambulation skills. They also experience weight loss as a result of for-

getting how to chew and swallow. Family and physicians should pay close attention to managing symptoms of disease to keep patients as comfortable as possible. Although palliation of suffering and maximizing quality of life are the most appropriate treatment goals for patients with advanced dementia, many patients in the last days of life receive unwanted and largely ineffective nonpalliative interventions, such as artificial nutrition and hydration, cardiopulmonary resuscitation, and systemic antibiotics.³⁹

At this stage, caregivers need to make difficult decisions about whether to proceed with potentially life-prolonging medical procedures, such as artificial nutrition and hydration, intravenous antibiotics, surgery, intubation, and cardiopulmonary resuscitation. If these decisions were made previously with advance directives, caregivers will have the heart-wrenching task of implementing them. These decisions should be based on two factors: (1) previously discussed wishes; and (2) the best interests of the patient, with particular regard to the benefits and burdens of the proposed medical intervention. In addition to the psychological burden of making decisions for patients, caregivers continue to suffer from the escalating physical demands of caring for loved ones. Patients with advanced dementia are often placed in a nursing home due to increasing care demands. Regardless of whether the patient resides at home or in an institution, palliative measures include paying close attention to possible sources of pain and offering continued support to caregivers and family members with regular and repeated review of goals and expectations. At this stage, the goals of care should focus on reducing caregiver stress and relieving the patient's physical and emotional symptoms.

Advanced dementia patients suffer from chronic pain and discomfort from comorbid chronic diseases, such as osteoarthritis, congestive heart failure, chronic obstructive pulmonary disease, and decubitus ulcers, as well as pain secondary to acute illnesses, such as fractures or infection. Yet, this pain is often untreated secondary to the patient's inability to complain. Cognitively intact patients receive more analgesics than patients with advanced dementia after hip fracture.⁴⁰ Therefore, physicians should treat advanced dementia patients with pain medication preventively and empirically before procedures known to cause pain, such as dressing changes or postsurgical procedures. Physicians also need to remember that patients with advanced dementia may have increased pain from routine phlebotomy, blood pressure monitoring, fingersticks, and bladder cannulation because they do not understand what is being done to them.⁴¹ Patients may view these minor procedures as assaults. Physicians can use topical anesthetic preparations to make needle sticks or catheter placement more comfortable.

Artificial Nutrition and Hydration

The development of dysphagia is a universal neurologic complication of advanced Alzheimer's disease and related dementias that puts patients at risk for aspiration pneumonia.⁴² Initially, patients are given a pureed diet with thickened liquids to counteract swallowing dysfunction. Slow feeding of patients with small spoonfuls of a soft, pureed diet may also help prevent aspiration.⁴³ If these methods fail to deliver sufficient calories to maintain body mass, caregivers must make decisions about artificial nutrition. This is an emotional issue for many family members, as many may see withholding artificial nutrition as tantamount to starvation. Although tube feeding may provide psychological comfort to caregivers, there is no evidence that it either prolongs or improves life in the long term for patients with advanced dementia.^{38,44–46} Studies of mentally intact terminally ill patients with anorexia have shown that symptoms of thirst can be alleviated with small sips of water and oral hygiene.⁴⁷ Often tube feeding is initiated to increase protein stores to promote wound healing in dementia patients with decubitus ulcers, but studies have not shown that enteral feeding improves wound healing or albumin levels.^{44,48} In fact, in one small study, 50% of nursing home patients had a decrease in albumin 13 to 18 months after beginning gastrostomy feeding.⁴⁸ One of the major reasons for starting artificial nutrition is to prevent aspiration pneumonia; however, there is no evidence that tube feeding reduces this risk and some evidence that it may actually increase risk of aspiration.^{44,49}

The decision to proceed with tube feeding should be made only after the risk of operative complications and long-term adverse effects, such as need for restraints, diarrhea, and infection, are considered.⁵⁰ Patients who can no longer eat can be fed through parenteral or enteral nutrition. Parenteral nutrition is generally not offered to patients with an intact gastrointestinal tract because placement of long-term intravenous access predisposes patients to infection; furthermore, intestinal integrity may deteriorate without intraluminal fuels, predisposing patients to systemic infection from gut flora.⁴⁹

Enteral feeding can be nasogastric, through gastrostomy tube, or through jejunostomy tube. Nasogastric feeding is recommended for temporary feeding, usually for a period of less than 30 days. This procedure may be appropriate if dysphagia occurs abruptly after a short illness and the patient is expected to recover. The most dangerous complications of nasogastric tube placement is inadvertent pulmonary intubation, chemical pneumonitis, and pneumothorax. Even when small-bore tubes are used, nasogastric feeding is uncomfortable. Patients often need to be restrained to prevent them from dislodging nasogastric tubes. Permanent placement of

gastrostomy or jejunostomy tubes also has complications. The initial procedure causes pain, requires the patient to receive local anesthesia, or in some cases general anesthesia, and sedation. Patients often require restraints for the first 24 to 48h after placement. The most common postoperative complication is local wound infection, but rarely perforation of a viscous, necrotizing fasciitis, and colcutaneous fistula can occur.⁴⁹ Once the tube is placed, common problems include aspiration, blockage of the tube, and diarrhea. Risk factors for aspiration include supine positioning during feeding, inability to clear oropharyngeal secretions, and bolus feeding. Diarrhea is multifactorial, and causes include formula composition, rate of infusion, hypoalbuminemia, and altered bacterial flora. *Clostridium difficile* infection rate is higher in patients receiving tube feeding than in similarly matched patients who are not tube fed.⁵¹ The decision to proceed with artificial nutrition and hydration should be made only after considering the risks of operative complications and long-term adverse effects, such as infection, diarrhea, and aspiration.⁵⁰

It is important to point out to family members that loss of appetite is a universal concomitant of the dying process, regardless of cause. Families should be encouraged to express their love and care through alternative means of nurturing when patients can no longer eat and drink. Mouth care with artificial saliva spray, moistened swabs, toothbrushing, ice chips, offers of small spoonfuls of ice cream, and hand and foot massage are all comforting and appropriate caregiving measures to suggest to family members.

Infection

Infection is the usual cause of death in patients with dementia.⁵² Immobility, incontinence, and aspiration put dementia patients at higher risk of developing pneumonia, infected decubitus ulcers, and urinary tract infections than healthy elderly people. Furthermore, infection in advanced dementia patients may be detected later than in cognitively intact patients, secondary to atypical presentation and inability of the patient to express themselves. Patients may present with increased agitation or decreased appetite. Immunologic function may also be impaired in dementia patients. One study showed increased energy in dementia patients when compared with other nursing home residents.⁴

Although infection in patients with advanced dementia is inevitable, risk factors can be reduced with careful attention to skin care and ambulation training. Incontinent patients should have diapers changed frequently; they should also be put on a toileting schedule. Turning on the sink while the patient is on the toilet sometimes stimulates micturition. Bedbound patients should be turned often and kept clean and dry to prevent decubiti.

When patients develop an infection, comfort measures should be implemented; these include antipyretics, pain medication, and oxygen. Atropine or glycopyrrolate can also be used to decrease tracheal secretions in an end-stage dementia patient. Physicians should avoid excess intravenous hydration, a cause of pulmonary and peripheral edema. Before starting antibiotics, risks and benefits should be weighed. Although there is no evidence that antibiotics improve survival in advanced dementia patients, they can provide comfort in some cases.⁵³ For example, antibiotics may alleviate dysuria, fever, sweats, shortness of breath, and cough. Antibiotic treatment can improve comfort by decreasing pain in patients with cellulitis and decreasing diarrhea in patients with *Clostridium difficile*. Drawbacks of antibiotic therapy include the risk of allergic reactions, development of infection with resistant organisms, the possible need to transfer the patient to the hospital for intravenous therapy, the need for repeat intravenous catheter placements, and frequent blood draws to monitor drug levels. Antibiotics can precipitate renal failure, diarrhea, rashes, bone marrow failure, seizures, nausea, and vomiting. These patients do not understand what is happening to them and may need to be restrained to tolerate placement and maintenance of intravenous lines, intramuscular injections, and other interventions and procedures.

The Hospice Benefit and Advanced Dementia

The Medicare Hospice Benefit requires that a physician certify an approximate prognosis of 6 months or less if the disease follows its usual course. Although multiple studies have shown a 6-month median survival in persons hospitalized with acute illness and advanced dementia, variability is high and prognostication unreliable.^{38,54,55} As a result, hospice is rarely accessed for patients dying of advanced dementia.⁵⁶ Volicer and others have proposed that patients with end-stage dementia qualify for extra services through an extension of the Medicare hospice benefit. In addition to providing personal care attendants to assist family caregivers, the Medicare hospice benefit also provides critically needed grief and bereavement services for caregivers. Most family members and physician members of the Gerontological Society of America believe that care focusing on comfort and pain control is most appropriate for end-stage dementia patients.⁵⁷ Enhanced hospice care with more support for personal care services is appropriate for these patients because dementia patients and their often exhausted caregivers require more help at home in the last year of life than cancer patients.⁵⁸ In fact, end-stage dementia patients may be more appropriate for inpatient hospice within a nursing home or other institutional setting than other terminal patients. Research demonstrates that patients cared for in dementia support care units with a hospice approach experienced less discomfort and utilized fewer

health care resources than similar patients treated in a traditional (usual care) long-term care unit.⁵⁹

Conclusion

Caring for patients with progressive, irreversible dementia is challenging for physicians and caregiver. By focusing on quality of life as the primary goal of medical care in the later stages of dementia, health care providers may help patients and family members prepare for the degenerative course of the disease and plan for the future. Physicians should focus on preservation of independence and relief of physical and emotional suffering for both patients and their caregivers.

The Value of Achieving a Peaceful Death

Daniel Callahan

The ancient Greeks got the point long ago. At the core of human life is necessity. As the classical scholar William Arrowsmith nicely put it in explaining their perspective, “Call it destiny, call it fate, call it the gods, it hardly matters. Necessity is, first of all, death; but it is also old age, sleep, the reversal of fortune and the dance of life; it is thereby the fact of suffering as well as pleasure, for if we must dance and sleep, we also suffer, age and die.”¹

This is a hard wisdom for twenty-first-century ears. What else is modern medicine useful for if not to overcome and pacify that necessity? What is contemporary life all about if not to overcome fate, to put choice in our hands where destiny once prevailed? Why should we accept aging and death as fixed parts of life if perhaps we can do something about them? Why not fight back?

The Greeks were right the first time. Aging and death have not been conquered, and their necessity is still a fundamental part of the human condition. More than that, it is still an indispensable way of defining that condition.

Yet it is also true that aging and death are not what they used to be. What is? Lives are longer, death less omnipresent among the young, and old age perhaps a more hopeful time of life than it was for the Greeks. It is precisely the tension between the ancient but still real necessity of aging and death and the new possibilities for altering their circumstances that create the peculiar and troubling problem for geriatrics. In particular, what is an appropriate stance toward death, and how is a sensible, prudent balance to be struck between the need to recognize the necessity of death and, at the same time, to keep open the possibility of continued life?

That question should push itself on us when we try to think about the desire for, the need for, and the hope for a peaceful death. Every society has wanted such a death and, save possibly for the ideal of a heroic death in warfare, so too have most people. In his great work, *The Hour of Our Death*, the late French historian Philippe Ariès wrote movingly of what he called the “tame death” of earlier times, perhaps part myth but surprisingly well

grounded in the human record.² It was a death that was tolerable and homely, expected with certainty, a common presence, and accepted without crippling fear.

There was, Ariès wrote, a “familiar simplicity” about death, in part because death came more quickly. It came across the life cycle, it was out in the open, and it was set within the context of religious and cultural rituals that tried, publicly and privately, to make sense of and give a meaning to death. For our part, he argued, we now have a “wild” death, drawn out by the chronic and degenerative diseases of aging societies, overshadowed and often dominated by technologies we barely control, and too often taking place within impersonal institutions, hospitals, or nursing homes, hidden from the public eye.

The struggle to move beyond a wild death has not been easy. It has seen the promotion of advance directives, the hospice movement, efforts to change the thinking and practice of clinicians, and, of late, a movement to introduce euthanasia and physician-assisted suicide. These are important developments (and dealt with elsewhere in *Geriatric Medicine*), but they need to be complemented by a clear idea of just what a decent death, an acceptable death—what might best be simply called a “peaceful death”—should encompass. It goes beyond having a choice about one’s death, raising questions about the place of death in human life and the response of medicine and geriatrics to it.

Let it be understood at the outset that a peaceful death can only be an ideal toward which patients and their physicians can strive. There is no way that such a death can be ensured, no human stance toward death or medical tactic in coping with the dying of a person that can ensure a perfect absence of pain, suffering, anguish, and loss. Although there are occasions when death seems a merciful release for a patient, death is the end of a life and thus the end of hope and possibility. It is therefore always a kind of evil, the most profound symbol of human limits and finitude. There may be a “death with dignity,” when everything comes together for a patient at the end,

but there is also a profound sense in which death itself is the ultimate indignity of human life.³ The idea of a peaceful death should always be in tension with that disturbing but abiding perception—as true for us as for the ancient Greeks.

I want to offer a preliminary notion of what might constitute a “peaceful death,” move from there to some of the obstacles standing in its way, and then return to and fill out the concept still further.

A peaceful death might, as a first rough sketch, be defined as a death that is accepted and not unduly feared, a death which is not marked by excessive pain and suffering, and a death that takes place, so far as possible, in the presence of other people who are there to offer comfort, support, and love. If death itself is unacceptable, as it must be for most of us, there can still be an acceptance of its inevitability and its inescapable necessity. A peaceful death requires coming to terms with that necessity, on the part of the patient, the family, friends, and the medical staff. If there is to be peace, that acceptance will be at its heart.

For the physician or others responsible for the last days of a patient, the acceptance must be both stark and profound, coming down to an unavoidable truth: every patient will eventually die and the end of aging is death. This understanding means that the necessity of eventual death and a reconciliation to its inevitability must be an integral part of the care of all patients, but the elderly patient in particular, for whom death will be a more familiar figure than for the young. Biologically, death is no mishap but part of the human condition. A peaceful death should be as high on the agenda of the caretaker as the health and well-being of a patient. Just as the pursuit of good health is an enduring goal of medicine, so also should be the pursuit of a peaceful death when health is no longer possible. A peaceful death is not something to be sought at the last minute when all else has failed, but is to be thought about early and approached with care, out of a recognition that it lurks out of sight in all of us, just awaiting its final, dominant moment—if we are fortunate enough to bring it about, doctors and patients together.

Obstacles to a Peaceful Death

Many obstacles can stand in the way of a peaceful death, but three seem most important: chance and luck, the response of the physician to the threat of death, and the prior life and values that a patient brings to his or her dying.

Chance and Luck

It may seem trivial, self-evident, and unnecessary to mention the place of chance and luck in the making of a

peaceful death. Yet it is there and must be taken account of. Some people will be fortunate in their dying, the victim of a condition that brings them a relatively benign death. Others will not be so blessed. We do not know, and can rarely know, which it is to be. Simply not knowing one's fate is, for many, part of the problem of dying: the fear of the unknown is as powerful a fear as any, sometimes all the worse because of the impossibility of preparing for it.

None of us can choose the disease from which we will die, and all of us might be likened to anxious spectators at a kind of poisonous feast, wondering which malady we will contract from those spread out on the medical table. Cancer? Stroke? Kidney failure? Perhaps it is just as well that we do not know in advance, although the uncertainty will itself be a source of anxiety. For those with a family history of a specific disease, there is often a special fear, not simply that they will themselves get the disease also, but that they will have to endure the suffering that they observed in others close to them. They may have an all-too-vivid image, an anxious foreshadowing of their final days from the memory of the last days of another. Their hope is that they will have the good luck to be spared the same fate. They may or they may not. And even if they contract the same disease, they may or may not have a peaceful death.

The physician is as helpless in the face of such fears as the patient. The physician can no more than the patient choose the fatal, final illness. There is no direct remedy that can be offered the patient at this point, with fears that are real but vagrant, with the utter certainty that death will come but matched by an utter uncertainty about how it will come. But when such fears surface, that is an occasion to begin the work of care and comfort, beginning with the recognition that the fear of dying, or of death itself (and they may, and probably will, run together in the patient's mind), can be as excruciating as anything that the dying itself might bring, if not worse. Fear should always be taken with utter seriousness. It can be lethal to the human spirit, as much so as any organic disease.

In the face of chance, luck, and uncertainty about death, the physician can only respond through talk and empathy, with the recognition that his or her ultimate fate is as open to the gratuitous play of chance as that of the patient. We are all in this together. Precisely because there is no medical remedy for this throw of the dice, the physician will be forced back on his or her own humanity—unable to give any more than his or her shared insight into the fragility of life, the defenselessness of all of us. Yet if that much can be done, then a decent foundation will have been laid for an ongoing conversation and relationship that can bear richer fruits as chance sooner or later reveals its hand. With luck, a peaceful death may be more readily attained—and with bad luck, more difficult.

The Response of the Physician

Why is it so hard to let a patient die, to give up in the face of the inevitability of death? And why is it that, once the physician has accepted the coming of death, there is too often a powerful temptation to turn away from this patient to those patients who are still amenable to improvement or cure? These are questions that have nagged at the conscience of medicine for some decades now, uncomfortably persistent, fretfully aware that it is by no means easy for a doctor in our day to accept death the way doctor a century ago could. That latter physician had a distinct advantage: he or she could do little or nothing about death. There was no choice but to accept it. This is no longer so. The means of struggling against death are considerable and compelling. Even so, of course, every patient will just as certainly die now as was the case then. It is the newfound power to keep death at bay longer which itself poses the greatest puzzle. When should that power be used, and when should it be relinquished?

Whether a person will have a peaceful death or not can hardly depend exclusively upon the behavior of the physician; chance and the patient's own response will be hardly less crucial. But if the physician is not able to relinquish the patient to death, then the patient's struggle is likely to be that much harder. The patient may well think that, in addition to the bad luck of the fatal illness itself, there is a double jeopardy in drawing a doctor who will not let go, even when that is the obvious thing to do.

There are three obstacles that physician attitudes can place in the way of a peaceful death: a tacit belief that individual deaths are accidental, a confusion between the value of life and the value of medical technology, and a failure to distinguish between killing and allowing to die.

Death as an Accident

Modern medicine is profoundly ambivalent about death. The clinician well understands that death is, as the saying goes, a part of life. Yet matters are otherwise with scientific research medicine, where death seems to remain the permanent enemy and the eradication of all fatal diseases the ultimate goal. Clinical medicine works, when it must, to accommodate itself to death, while scientific medicine always works to overcome death. Given these two stances, not easily reconciled, it is hardly a surprise that, even for the clinician, death can appear to be a kind of accident, a contingent event that, with enough skill, can be averted.⁴

Consider the paradox here. Death is understood well enough to be a biologic necessity, a part of all organic nature. But every known cause of death can be taken to be contingent, a matter of chance. By "contingent" and "chance," I mean that it need not exist, that in principle and in medical theory there is no reason why any partic-

ular fatal disease cannot be overcome. Put another way, although death in general is supposed to be accepted, none of the causes of death need be; each can be eliminated.

This paradox often surfaces at the bedside: this particular disease, with this particular patient, need not necessarily be the cause of death—so think many clinicians who want to struggle against an impending death. It is not that they disbelieve in the reality of an inevitable death for all, but that does not mean they must believe in this death at this time for this patient; that need not be. Yet there is a trap there, luring its victim into thinking that death is not a necessity, into evading its reality, its ineluctable force. There can be a kind of self-deceit when that happens, and an inadvertent deceit of patients and families as well, holding out meaningless hope and remote possibilities. A peaceful death, which requires an acceptance of death, is not possible if death is treated as an avoidable accident.

Valuable Life, Seductive Technology

Human life is of intrinsic value, a belief that is part of the traditional ethic of medicine and of every civilized society. Death is not a denial of the value of life or of its sanctity, to use the more religious term. Yet it is easy with a medicine dominated by science and technology to see in them a way of affirming the value of life—and thus turning to them to sustain life whatever this might mean to the patient as a person. It almost seems that technology has captured the value of life, giving the impression that life can only be respected by bringing the full force of technology to bear in the fight against death, as if it is our only way of acting upon our commitment to life.

Yet an ever-present hazard here is what might be termed "technologic brinkmanship," by which is meant an attempt to use technology up to the final moment out of some last, desperate hope that the hand of death can be stayed. It is an effort to go to the very edge of technologic possibility, but often naively assuming that technology can be mastered with the precision necessary to avoid overtreatment and the medical oppression of a patient. The brinkmanship itself is the danger—one more way of refusing to accept death, one more way of pretending that death need not take place.

While there has been much comment over the years about the "technologic imperative" in medicine, its full force has still to be grasped. Technology is seductive because it is, in truth, a potent way of extending and often improving life, sometimes all there is. It is no less seductive in its innovativeness, its promise to relieve burdensome uncertainty, and its attractiveness to patients and their families, who can be drawn to it no less than physicians.⁵ The most troublesome technologies are not those that are useless, but those that may bring some marginal

benefit, one last chance in the face of hopeless odds. Those are the technologies that both physicians and patients find seductive, and no less so sometimes than those elderly patients who had earlier insisted they did not want to battle death.

Yet medical technology that is deployed too compulsively, too optimistically, too unthinkingly can be a terrible impediment to a peaceful death. There is clearly a profound dilemma here between a desire to reject and struggle against death and an acceptance of death. There is no easy resolution of this dilemma, nor should there be, but it is a great help simply to approach technology with a sharp eye out for its capacity to interfere with a peaceful death. To get that far is already to make the dilemma more tractable.

Killing and Allowing to Die

Physicians are trained to be worried about making mistakes, about acting wrongly or incompetently. They are no less trained to preserve life, and in particular not to act in a way that would knowingly risk the life of a patient, or put that patient at greater risk than that already occasioned by illness. Yet it is unfortunately all too easy, with this kind of training in the background, reinforced by peer pressure and a fear of litigation, to feel excessively responsible for a patient's fate and welfare.

Nowhere is this possibility of excess more pronounced than in the anxiety that the cessation of treatment of a dying person is tantamount to killing that person. If something more could be done to extend life that remains undone, then many physicians feel that they and not the underlying disease are the real cause of death, and some philosophers would agree with them.⁶ The source of this anxiety is understandable: a patient's life can often be extended for a short time, even a long time in some cases, by modern medical therapy, and it is easy to believe that a failure to pursue that possibility itself becomes the cause of death.

Yet the logic of this anxiety is mistaken. If treatment is terminated or abated out of a genuine conviction based on clinical evidence that no further benefit to a patient is possible, then it is nature and not the physician that bears the ultimate responsibility for death. Death is not a medical invention, to be turned on or off at will. At some point, nothing the physician can do will stop death from occurring. For the physician to judge that death is inevitable, that the patient has moved beyond the possibility of meaningful therapy and real benefit to the patient, is to do no more than recognize the transcendent sovereignty of death. It is irrelevant, morally and clinically, that a few more days or sometimes even weeks could be added to a life if, as a result of the underlying lethal pathology, the end is inevitable and reasonably foreseeable.

The physician did not create the fatal pathology, and a failure to stand against it any longer is not to kill a patient, but to let our human nature take its necessary course. A physician should not, in short, confuse his or her role with that of nature. The power of the physician to manipulate nature a bit, to hold off death for a time, does not mean that nature has been transcended. Most particularly, it does not mean that life and death have passed out of the hands of nature into those of the physician. Not at all. A physician can stay the hand of nature for a time without thereby having taken over nature. To be sure, a physician can be said to "kill" a patient if he or she acts directly to knowingly and with intent to shorten life, but it makes no sense to equate killing a patient with giving way to the power of nature as a force that can no longer be combated. A peaceful death can be impeded, even made impossible, by a wrong belief that death has become the ultimate responsibility of the physician—a matter only of choice and decision. Not only does that tempt technologic brinkmanship, it no less sets the stage for self-blame when death does occur, as it eventually must. A peaceful death can only be possible if it is understood that the power of death in the end triumphs over human science and artifice, and that only stepping aside to allow it to happen can be faithful to the force of nature and the respect owed to patients.

The Art of Dying

Although we hear less of it these days, most cultures have given a place of importance to the way people prepare themselves for death. *Ars moriendi*, the art of dying, was a long-standing part of life in the Middle Ages, but finds its counterpart in many parts of the world to this day. It has long been understood that the human response to mortality, pain, and suffering is not biologically fixed, and that the way people respond to them will be as much a function of their character and personality, and the culture of which they are a part, as it will be a characteristic of the disease that afflicts them. Michel de Montaigne wrote in the eighteenth century words that remain true to this day: "Fortune appears sometimes purposely to wait for the last year of our lives in order to show us she can overthrow in one moment what she has taken long years to build. . . . In this last scene between ourselves and death, there is no more pretense. We must use plain words, and display such goodness or purity as we have at the bottom of the pot."⁷ The living of a life that is a preparation for a good death was understood then, and might well be understood now, as a wise counsel. How a patient dies will, in any case, reflect at least in part how that patient has lived a life and what kind of character is brought to the dying.

There is, of course, a problem here for the physician, who has had no hand in fashioning the earlier life of the

patient and whose role in shaping or altering the personality of a patient is of necessity limited. Does this mean that the physician is thereby rendered helpless, unable to do more than stand by and watch as the patient works out his or her response to death? Not necessarily. Particularly with the elderly patient, who is often open to talking about death, it is possible to bring the problem of dying to the surface and to broach lines of exchange between doctor and patient that can touch on *ars moriendi*.

Here the imagination and empathy of the physician will be crucial. In that elderly dying patient before one's eyes, one can and should see one's own fate some day, however much one would like to avoid thinking about it. The self-protection of a therapeutic distance, the objective, scientific detachment so often held up as a medical ideal, should now give way to a supreme effort to understand what it must be like to know that death is on its way. This means grasping the fear, the uncertainty, the self-doubt and self-interrogation, that goes with such knowledge. It means understanding the terror of losing control of one's body, one's fate, one's life. At stake is the dissolution of the self, and with that everything that has made life worth living.⁸

Few patients are likely to be open, much less garrulous, about matters so deep and so personal, and few people will have had the opportunity to learn how to talk about them. It may be necessary to coax these thoughts out of a patient, to put into words for the patient ideas and feelings that are only half-formed or confusingly jumbled together. Simply helping someone articulate thoughts, giving words to a sense of loss, to fear and terror, is itself a great contribution to a peaceful death. How a patient dies, how a patient reacts to pain and suffering, is far more likely to be determined by what is happening to the patient's thinking and feeling than to what is happening to his or her body. What counts is not just what happens to people when they die—not just “how we die”—but what they make of that event.

There are some characteristic issues that are likely to arise with elderly dying people, stances toward illness and death that they bring with them and to which the physician should be prepared to respond.

Losing Control

A peculiar and disturbing feature of modern societies, particularly the United States, is that many people believe that their self-respect and integrity depend upon having a life under their control. But dying is the ultimate loss of control, and the physician should do whatever is possible to reassure the patient that the loss is inevitable, our common fate, and no negative mark against a person. Helping a patient cope with the sense of self-loss is critical to a peaceful death. Sometimes all that can be

done is the expression of understanding and fellow-feeling, but that may be of great value.

Obsession with Pain and Suffering

People differ enormously in their capacity to bear pain and suffering, which in many cases will not bear a clear or direct relationship to their physical condition. They no less differ in their capacity to accept and understand their situation, which can make a great difference in their reaction to suffering. An obsession to overcome the suffering can itself exacerbate the strain. Nothing short of the most sensitive pain management and an awareness that suffering is not directly correlated with pain will do in these circumstances.⁹ The goal, not easy to achieve, is that of reducing the obsessions and helping the patient to acquiesce to the suffering when it cannot be fully relieved. An imperfectly peaceful death is better than one that is not at all peaceful.

A Flexible Self

As the ultimate threat to the self, death and the process of dying invite a premature mourning for the self that will be lost and for the self that is no longer what it once was. Lurking in the wings here sometimes is a belief on the part of the elderly dying that there once existed in the past a kind of optimal or ideal self, which they now see falling away from them. It can be “destructive” to see all change and decline as loss. A better attitude, which the physician can help foster, is that all stages of life have their own demands and challenges, that aging and death are not some kind of fall from grace but instead a new demand on the self that can rise to the occasion. There is no ideal self or ideal stage of life. There is just life, and if the physician can help the patient see that, then a great contribution will have been made to the last days of a person.

Accepting Dependency

If self-control and self-determination are high on the list of Western cultural values, a desire not to be dependent or a burden on others is not far behind. Yet there is no inherent evil in being dependent upon others, or even in being an involuntary burden on them. The long decline that is now so often a part of the death of the elderly will no less often impose a period of dependency. Some will be lucky and not require the help of others. Many, however, will not be so fortunate. There are many kinds of reassurance the physician can offer in those circumstances: that the burden on others is often not as great or as damaging to others as they may think (if that can truthfully be said); that life with other human beings is a life of mutual interdependence; and that dependence does not necessarily rob a person of the respect of others or

self-respect. It will be the response of the patient to dependency that will often matter far more than the actual fact of dependency. Physicians should help their patients to see this.

Death and Dignity

It is surely the case that others can treat us with indignity as if we count for little and are fit only for disposal. But real dignity is best understood as an interior virtue, the stance we take up within ourselves to confront what life—and death—throw in our path.¹⁰ People cannot be deprived of that interior dignity, but whether they have it will have much more to do with the way they have lived and shaped their lives than with the way they have been treated by others. A physician can do many things to reduce the external indignities that medical treatments and medical institutions can unwittingly and haphazardly impose on patients, and it is important that they do so. They cannot as easily help the patient find the necessary inner dignity to cope with dying and the prospect of death. But even here there is a place for the sensitive, thoughtful physician who can help the patient to distinguish between external and internal dignity, cultivating the latter and not confusing the former with self-worth.

Pursuing a Peaceful Death

The idea of a peaceful death can now be filled out in greater detail. I have tried to suggest that it is not something any physician can guarantee to a patient. Chance and luck, not to mention the character of the patient, can always intervene and subvert the best intentions. But it also seems true that there is room to work with a patient—and for a patient to work with himself or herself—to enhance the possibility of a peaceful death. A peaceful death is rarely precluded altogether just as it is rarely guaranteed. There is thus considerable room for enhancing its possibility.

A first approach to the notion of a peaceful death encompasses an acceptance of death, the absence of excessive pain and suffering, and the presence of other people. That notion needs to be filled out and enriched. It is a starting point only. A full picture would include a sense of the meaning of death for a patient (a critical part of the acceptance of death); respectful and sensitive treatment by family and health care workers; a belief on the part of the dying that their deaths matter to others, a belief that their deaths signify a loss to the human community; a state of conscious awareness as close to the actual time of death as possible; a relatively quick death; and a sense of reassurance on the part of the dying person that he or she has not been an undue burden on others. (And sometimes they may be, so the truth may need to be hedged.)

By expanding the list of ingredients of a peaceful death, do I not thereby make it all the harder of achievement? Possibly so, but I would underline my earlier point that a peaceful death is an ideal, a goal toward which care should strive but may only rarely achieve with any degree of perfection. The expanded list touches, moreover, on most of those aspects of dying beyond pain and suffering that are most fearful for patients—an attenuated, drawn-out dying, loss of control, being a burden to others, despair and a feeling of meaninglessness, and the indifference of others to one's death. No physician can make others care that a person is dying, and no one may care. No physician can do much to relieve the burdens that a long illness and a slow dying may impose upon family members and friends. The point is to try to do what one can and to be aware that a peaceful death is multidimensional, with some of the dimensions more open to intervention and change than others. The point is to work as fully as possible with each of the dimensions, hoping at least for a partial success and maybe more than that.

The Presumption to Treat

A critical aspect of the goal of a peaceful death is that of the traditional presumption to treat a critically ill patient. When should that presumption be suspended, to be replaced by a presumption not to treat? By "treat," I mean the application of life-extending, life-preserving therapies, not the provision of comfort and palliation. The latter are always required, but not the former.¹¹ The presumption to treat should be suspended: (1) when there is a likely, although not necessarily certain, downward course of an illness, making death a strong probability (multiorgan failure in an elderly patient is an obvious example); (2) when the available treatments for a potentially fatal condition entail a significant likelihood of extended pain or suffering without compensatory benefits; (3) when successful treatment is more likely to bring extended unconsciousness or advanced dementia than cure or significant amelioration; and (4) when, whatever the medical condition, the available treatments increase the probability of a bad death, even if they also promise to extend life.

Obviously there can be no tidy algorithm for making these judgments. They all turn on probabilities that are often difficult to calculate, depend to a considerable degree upon clinical experience, and run the risk of error. Yet the fitting goal of a peaceful death justifies the risk. One way to think about the decision here is that of the need for and value of creating a strong struggle between two goals. One of them is the traditional medical goal of saving and extending life, certainly a dominant, usually overriding goal in modern medical culture. The other goal, no less traditional but easily pushed aside, is that of a peaceful death.

These two goals should, fittingly, be in tension with each other with critically ill, potentially dying patients. To allow a patient to die who could have genuinely benefited from treatment is a serious medical failure. But it is no less a medical failure when a person dies an avoidable bad death, the victim of insensitivity, medical timidity, technologic brinkmanship, or, that last refuge of evasion, fear of legal liability (almost always a non-issue, despite pervasive anxiety on the subject in treatment termination decisions with dying patients).¹² If there is to be fear, then there should be a fear of not preserving life pitted against the fear of increasing the possibility of a poor death. If there is to be optimism, then there should be the optimism that a peaceful death might be achieved pitted against the optimism that another round of disease-modifying treatment might benefit a patient.

Stages of Treatment Termination

A subtle error that can sometimes insinuate itself into medical decisions is to draw too sharp a line between getting sick and dying. Obviously not all sickness leads to death, and that is why it is struggled against. Yet there is another point, no less obvious but harder to face: every death will occur because of some fatal pathologic process, some final illness. In that sense, just as death will always sooner or later finally win, so will illness, each occasion of which can be avoided except the last one. Not only does this perception strengthen the case for the pursuit of a peaceful death, which will ordinarily in the elderly come with some illness, but it also brings to the foreground the value of taking a stance toward potentially fatal illness no less than a stance toward death. Here it is possible to work with patients to think about different stances toward illness and termination of treatment decisions. I will express these different stances in the language of stages that can be articulated and considered, and which range over a continuum:

Stage One: A patient can decide to refuse altogether to respond to health threats, even those potentially fatal, backing up this refusal by making no effort whatever to seek therapeutic medical treatment, accepting palliative care only.

Stage Two: A patient may be open to diagnosis or identification of a potentially lethal condition but refuse to undertake any curative efforts at all, embracing only palliation.

Stage Three: A patient can refuse to accept any medical treatment, for curative or ameliorative purposes, that does not promise a high probability of success and a minimum of unpleasant side effects in extending life.

Stage Four: A patient may be willing to accept any medical treatment that offers some probability, even if low, of success in preserving life.

Stage Five: A patient may be eager to pursue any medical treatment, established or experimental, that offers even a remote possibility of saving life.

One reason why it is worth considering these stages and trying to determine where a patient might psychologically be in relationship to them bears on an often-neglected aspect of advance directives. If the focus of an advance directive (or even informal discussions with patients) is on final decisions, when death is staring the patient in the face, then it becomes all too easy to avoid considering the full course of illness that leads to the threat or likelihood of death. Quite apart from what a patient says he or she wants done when death is imminent, what is the patient's attitude toward life-threatening illness in general? Here elderly patients may differ significantly from younger patients, depending in great part whether they have come to terms with the inevitability of death and are prepared to accept the illness and decline most likely to precede it.

Two patients can have exactly the same desires about what is to be done when they are indubitably dying—but one of them may be eager to avoid therapy when a critical illness occurs while the other may want maximum technologic brinkmanship in the face of illness. It is important, if possible, to unearth these different attitudes toward illness and not to let them get slighted in discussions of what is to be done at the last minute, when death is clearly on the way. It is, in short, just as important to determine how patients think about illness (and they may need help here if they have never given the subject much thought at all) as how they think about death and dying. They are inextricably tied together.

The Culture of Dying

All of us live our lives embedded in a culture that supplies us with our language, most of our values, and the social and political institutions within which we live out our lives. Our culture is enormously ambivalent about death, and the medicine that is part of that culture (and a shaper of it) is no less ambivalent. The clinical face of medicine lives day to day with death and works to remove its sting, acquiescing in its force when necessary. The scientific face of medicine, by contrast, continues to carry out unrelenting warfare against all the known causes of death, none of which it finds acceptable. These two faces are in endless conflict with each other, even if the conflict is rarely acknowledged in an open way. Scientific medicine tutors the physician to see death as a correctable accident, while clinical medicine counsels its inevitability and necessity.

The kind of a culture likely to enhance the possibility of a peaceful death requires a number of elements. It must be a culture that accepts the place of death in life and helps people find some meaning in death. It must be

a culture that does not allow itself to become bemused with medical possibility and medical progress, as if a cure for death (or lethal cancer or heart disease) will be found just over the next hill. It must be a culture that no longer hides death, as if it is some kind of human scandal in a modern age. It must be a culture that supports physicians in their desire to foster peaceful death, not scaring them with lawsuits or treating them as failures when their patients die. It must be a culture that nurtures in its people the need to think about the kind of people they want to be and the kind of character they want to have when death comes near to them. It must be, in the end, a culture that understands death as part of the human condition, where patients and doctors work together, each doing what they can and must to make death as tolerable as possible. That goal should be understood as an achievement, not necessarily easy but possible and desirable.

Of course American culture, and increasingly other cultures as well, do not well fit those specifications. Human beings do not want to die. They did not in the past and they do not now. Yet medical progress, ambivalence about accepting the inevitability of death even when it is inevitable, and the love of last-chance technology interventions throw great obstacles in the way of a peaceful death.

Can those obstacles be overcome? Perhaps not directly, and often not within a contemporary medical context at all. People come to their final days with the experience and reflection of a lifetime behind them, and by definition that is the situation of the elderly. But it is imperative that there be such reflection, and that is a task beyond the reach of medicine, even though it can help. Only if death is a more general topic for public educa-

tion, for religious ministries, and for ordinary day-to-day discourse can progress be made. Only then will people come to their death ready and prepared. That is the larger cultural task. Getting there will be slow work, hard work, an uphill struggle as often as not. The good of a peaceful death makes it a necessary struggle, and even now movement can be seen. That is a start.

Cancer in the Elderly: An Overview

Harvey Jay Cohen

Cancer is an important problem in the geriatric population because it occurs with increasing incidence throughout the middle and older years. In aggregate, it is the second leading cause of mortality in people age 55 and older. Moreover, 60% of all cancers occur in persons over 65.^{1,2} It also produces a reservoir of older people living with the disease and its resultant morbidity. Of course, cancer is not one disease but many. Therefore, this section of the volume is organized to address some general issues, such as the biology of disease and approaches to prevention and screening (Chapters 31 and 32), and then to address those cancers responsible for the major portion of this mortality and morbidity (Chapters 33–38). In addition, cancers of the skin are addressed in Chapter 58.

In this overview, I want to add a general perspective on the approach to the older cancer patient. We still have much to learn about this interaction, as it has only recently become a subject of scientific investigation. An appropriate framework for the discussion is to consider the Biopsychosocial Model as applied to the elderly cancer patient, as we have previously described in the “Comprehensive Geriatric Model.”³ The concept is that in the setting of decreased hemostatic reserve of the elderly patient, the potential interactions of an emerging or established cancer will be impacted upon by changes in each part of the patient’s hierarchy, that is, biologic, psychologic, and social, at the clinical interface. All must be considered if effective care for the older cancer patient is to be accomplished. Ways in which the model of comprehensive geriatric assessment can be applied to the older cancer patient are now being proposed.^{4,5}

At the biologic level, as described in Chapter 31, issues relating to the reasons why cancer incidence increases with age are important to understand with regard to developing potential preventative approaches. This is a rapidly evolving area with new considerations arising regularly. Studies of cancer course in older people have shown variation, with some more and others less aggres-

sive, a situation paralleled in animal models. Finally, the knowledge of physiologic changes with age, well detailed throughout this volume, is applicable to the treatment of the cancer patient at many levels; for example, cardiopulmonary changes for surgery and cardiopulmonary toxic drugs, skin changes for wound healing, central nervous system (CNS) changes for patient communications and CNS toxic drugs, special senses for dealing with nutrition and radiation therapy, hematopoietic changes for chemotherapy and radiation therapy, immune system changes for infection, and hepatic and kidney changes for chemotherapeutic agent metabolism.⁶ Recent work on the syndrome of frailty is of great relevance to the management of the older cancer patient. The vulnerability created by the combination of physiologic decline, comorbidities, and systems dysregulation must be addressed if appropriate management strategies are to be utilized.^{7,8} Assessment of functional status and quality of life is an issue common to geriatricians and oncologists and may be useful in treatment planning, as well as determination of prognosis and response.^{9,10}

Psychosocial issues can be as critical to the management of the older cancer patient as any of the biologic features. Thus, resistance to participation in screening programs and to responding to early warning signs and symptoms of cancer must be recognized and handled. Older people’s fears about the dying process, misconceptions about the disease and about health care facilities, and concern of being a burden to family and friends can present problems. Communication issues, such as those presented by cognitive impairment, concerns about how much to tell, informed consent, and the involvement of caregivers are particularly prevalent in dealing with the older cancer patient. Assessing overall quality of life may be difficult. Although there are decrements in social support systems that can have adverse affects, older people, even with cancer, generally rate their quality of life better than do caregivers and health professionals, who thus do not always make good proxies. Moreover,

specific side effects, such as nausea, vomiting, and pain, may be less in older cancer patients, and they and their caregivers seem to adapt and cope better with the disease than do younger patients.¹¹ Nevertheless, the caregiver for the older cancer patient faces a number of challenges that must be addressed.¹²

With respect to cancer management, because of the heterogeneity of the older population, care must be individualized and is complex.^{13,14} Unfortunately, we do not have good biomarkers of treatment vulnerability, so we must use the aggregate of physiologic factors (noted above) and presence of comorbidities and functional disability to aid in decision making.^{15,16} Thus, in decisions about cancer surgery, the physiologically intact elderly person without comorbidities appears to tolerate even extensive surgery well. Radiation therapy can be delivered effectively, but special attention must be paid to nutrition and hydration. Age-related chemotherapy responses and toxicities have only been critically examined over the past 15 years. Supportive and palliative care are discussed in Chapters 24 through 30 and are of particular relevance to the older cancer patient. Disease-specific therapy is addressed in the individual chapters, but patterns have arisen.

In treatment trials (information from which may not be applicable to all older cancer patients because they generally select the most physiologically fit),¹⁷ single-agent and low-intensity therapy has generally been tolerated well and with equivalent outcomes in the elderly. Even here, particular attention must be paid to physiologic changes, which can impact upon toxicities (e.g., renal function for methotrexate use). As therapy complexity and intensity is increased, there is a progressive relative increase in toxicity in the elderly, in some cases with continued equivalent responses to the younger patient, but ultimately, in diseases such as acute leukemia and Hodgkin's disease, poorer outcomes as well. Newer approaches to these problems are being evaluated, including tailoring regimens with better effect, toxicity ratios, seeking new agents with better therapeutic profiles, and enhancing supportive care so that higher-intensity therapy can be delivered (e.g., bone marrow transplantation). These concerns should all be active areas for clinical research in the near future.

The overlapping concerns of oncology and geriatrics have led to a call for closer collaboration between the disciplines in patient care, research, and education.^{18,19} We appear to be seeing the emergence of a combined discipline of gero-oncology.

The Science of Neoplasia and Its Relationship to Aging

Robert E. Martell and Harvey Jay Cohen

Demographics of Cancer in the Elderly

Cancer poses a significant health issue for the elderly. The incidence and mortality from cancer are progressively greater in older age groups. Sixty percent of all cancers exist in the 12% of the population over age 65. Even within the 65 to 84 age group, the incidence of cancer has increased steadily over the past 20 years. Furthermore, we are presently in the midst of a dramatic increase in the size of the older cohorts in our society due to increased longevity and the aging “baby boom” generation in the United States. Cancer is the second leading cause of death and is one of the most feared diseases in this age group. Indeed, the risk of dying from cancer increases exponentially with age.

The expanding incidence of cancer in the elderly is not uniform for all cancers. The incidence of lung, colon, breast, prostate, and B-cell hematologic malignancies, such as chronic lymphocytic leukemia and multiple myeloma, all increase with age. However, the incidence of many childhood cancers, as well as Hodgkin’s disease, testicular cancer, and cervical cancer, do not show such a persistent increase with age and may even decrease in incidence in the elderly.

Biology of Cancer and Its Relationship to Aging

Given the striking increase in the incidence of cancer with age, it is prudent to consider relationships between aging biology and cancer biology.¹⁻³ Much of our understanding of cancer biology comes from pragmatic studies of physical and molecular forces that govern cell transformation and malignant progression without necessarily linking these findings to the reality of the age-related demographics of cancer. However, demographics reflect biology. In fact, much of cancer biology can be directly

linked to characteristics of cellular aging. This chapter provides a systematic review of the major areas of study in cancer biology and, importantly, provides a scientific basis for a link with aging biology where relevant.

Factors That Impart Cancer-Causing Cellular Changes

Environmental and cellular factors have been identified as etiologic factors for cancer development. Many factors result in disruption of genetic integrity. The consequence of this disruption is altered expression of gene products critical for cell growth, which can lead to neoplasia. A distorted local cellular environment can also facilitate tumorigenesis (Fig. 31.1).

Disruption of Genetic Integrity

Disruption of genetic integrity is the cornerstone of cancer development.⁴ Multiple sequential genetic changes are likely to be required for development of a tumor. Because acquisition of these changes is in part a time-dependent process, the elderly have had more time to acquire detrimental changes. Examples of disrupted genetic integrity include point mutations, frame shifts, chromosomal translocations, or deletions. Additionally, the body’s ability to maintain genetic integrity is impaired at older ages. DNA repair is reduced in the elderly, whereas telomere shortening, formation of DNA adducts, DNA hypomethylation, and chromosomal breakage and translocation are more common in this age group. The most clearly studied example of the sequential accumulation of genetic change associated with development of cancer is the progression of colon cancer. A series of genetic changes have been defined that occur during the transformation of normal tissue to advanced colorectal carcinoma. In a variety of ways, this genetic change

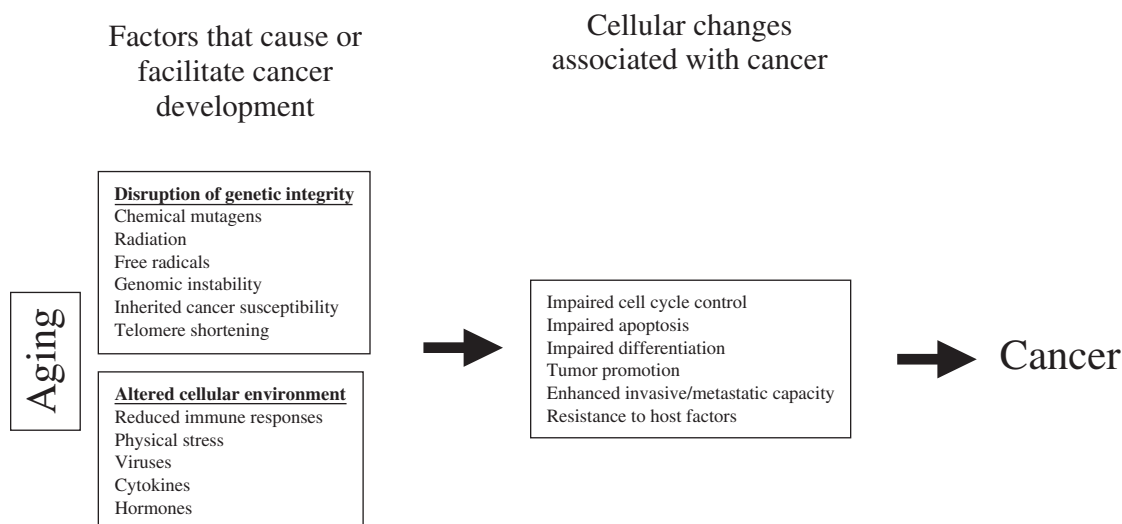

FIGURE 31.1. The etiology of cancer.

creates selective growth advantages for the affected cells. These advantages are often accomplished by a change that results in altered function of a protein end product, such as a factor that drives cell proliferation or impairs a cell's ability to undergo apoptosis.

Many genotoxic agents have been studied, and these can account for a subset of cancers, yet a large percentage of tumors harbor genetic alterations for which no clear link to a genotoxic agent can be made. Specific genotoxic modalities include chemical mutagens, radiation, and free radicals. In many cancers, the situation is compounded by disrupted DNA repair mechanisms, which accelerate accumulation of tumor-facilitating mutations. DNA mutations can also be acquired by inheritance of a mutant allele, the phenotype for which may be revealed at a later point by a subsequent mutation in the other allele.

Chemical Mutagens

The role of chemical mutagens in cancer⁵⁻⁷ had been characterized initially by observing cancer rates in certain occupations and has been subsequently confirmed by experimental cell and animal studies. Agents that can cause genetic damage tend to have high chemical reactivity and form covalent adducts with DNA. Selectivity of the agents for tissue or cell type, nucleotide type, and DNA synthesis exists. The genetic damage involves base mispairings or small deletions, which result in missense or nonsense mutations. Other types of damage cause chromosomal breaks or large deletions. Examples of genotoxic substances include *N*-nitrosal compounds, aliphatic epoxides, aflatoxins, mustards, polycyclic aromatic hydrocarbons, combustion products of fossil fuel or vegetable matter, aryl aromatic amines, aminoazodyes, and hetero-

cyclic aromatic amines. Genetic polymorphisms of enzymatic pathways for carcinogen metabolism and activation are thought to play a significant role in cancer susceptibility.

Nongenotoxic carcinogens cause cancer in laboratory animals, but neither they nor their metabolites cause DNA damage. The mechanisms of carcinogenesis of these compounds are speculative but may involve regenerative hyperplasia in response to tissue damage, hormonal effects, induction of oxygen radicals, depurination, or deamination of 5-methylcytosine.

Radiation

Ionizing radiation and ultraviolet radiation have the capacity to invoke genetic damage. Many examples exist of association of cancer with ionizing radiation exposure. Potential sources of this type of radiation include natural radiation (cosmic rays or radioactivity from the earth), medical radiology, and nuclear power. Ionizing radiation releases large amounts of energy as it strikes a cell, sufficient to break chemical bonds in DNA. Solar ultraviolet (UV) radiation is highly associated with skin cancer, including malignant melanoma. UV radiation induces pyrimidine dimers, which are a unique form of DNA damage compared to other carcinogens. Efficient DNA repair is a critical factor in avoiding untoward effects from this damage. Additionally, UV radiation appears to impair local immune responses, which may result in greater permissiveness for tumor development.

Free Radicals

Reactive oxygen species and reactive nitrogen species are formed in conjunction with certain types of cell stress,

including cell damage. Free radicals form initial chemical products with DNA itself or with other products to produce DNA-damaging agents, for example, oxidative activation of a procarcinogen. Free radicals are formed as a consequence of a variety of processes, such as radiation damage, exposure to cigarette smoke, exposure to asbestos, and even exposure to certain chemotherapy agents. They appear to play a role in the aging process *per se* as well.

Genomic Instability

Genomic instability implies increased propensity for developing DNA sequence changes (deletions, insertions, and point mutations) or chromosomal aberrations (gaps, breaks, translocations, and other chromosomal rearrangements).⁸ At the level of the DNA sequence, important factors include the fidelity of DNA replication, detection of DNA damage, DNA damage repair, and mechanisms to discard cells that are badly damaged (e.g., cell cycle checkpoints and apoptosis). Genetic instability can be inherited or acquired. Cancer is highly associated with the impaired DNA repair seen with certain inherited genetic polymorphisms.

Acquired deficits in DNA repair appear to be the hallmark of progression of some types of cancer, including colon cancer. The gene for the p53 transcription factor is one of the most frequently mutated genes in cancers. The loss of functional p53 impairs the ability of the cell to recognize and repair DNA damage, thus enhancing the rate of selection of growth-facilitating mutations.

Inherited Cancer Susceptibility

In addition to the inherited cancer predispositions described involving DNA repair processes, several other familial cancer syndromes exist.^{9,10} The breast and breast-ovarian cancer syndromes, involving inheritance of a mutant allele of the BRCA1 or BRCA2 tumor suppressor gene, are important examples. Other examples of inherited cancer susceptibility syndromes include adenomatous polyposis coli, retinoblastoma, Wilms' tumor, Li-Fraumeni syndrome, MEN 1 and 2, neurofibromatosis, and Beckwith-Wiedemann syndrome; these generally occur in younger individuals.

Telomere Shortening

The study of telomeres has revealed exciting links between aging biology and cancer.¹¹⁻¹⁸ Telomeres are specialized regions of reiterative DNA sequence found at chromosomal ends that play a role in chromosomal integrity. Due to the inability of DNA synthesis machinery to replicate DNA completely to the end, telomeres shorten incrementally during each cell division, presumably reducing the protective effect of telomeres. Indeed,

it has been shown that older individuals have shorter telomeres than younger individuals. Thus, the deterioration of these chromosomal ends in the elderly may make this group more susceptible to genetic damage.

It has been proposed that cells in the body have evolved a form of defense mechanism against this potential for genetic instability produced by telomere shortening. When grown in tissue culture, normal somatic human cells are able to replicate only a finite number of times before undergoing a cell cycle arrest. It appears that shortening of telomeres to a critical point induces some sort of signal, such as a DNA damage signal, causing cellular growth arrest. This growth arrest, or "replicative senescence," can be thought of as a tumor suppressive mechanism, whereby cells that have been driven to proliferate excessively will stop growing. Interestingly, normal germline cells express an RNA protein enzyme called telomerase, which adds telomeric repeats back on to chromosomal ends, giving these cells the capacity to be replicated beyond a point that might normally be associated with replicative senescence. Unfortunately, cancer cells have evolved to express this same enzyme, giving them the ability to proliferate beyond a point at which they would normally senesce.

Links between telomere shortening and replicative senescence have been described in detail. One model describes replicative senescence as mortality phase 1, or M1. Early events in tumorigenesis, such as disruption of genes such as p53 or Rb, allow cells to have extended proliferative capacity. However, the population eventually again arrests in an M2 state, also called "crisis." In this state, chromosomal stability is substantially reduced, enhancing recombination events and genetic mutations. Ultimately, it is the acquisition of telomerase expression that allows cells to continue to proliferate and progress to an advanced malignant phase.

Alteration of Local Cellular Environment

In addition to agents that directly involve the genetic integrity of cells, there are several nongenotoxic modalities that affect cancer development and progression. These agents ultimately affect cell-signaling pathways. These agents range from physical stress to hormonal receptor agonists to viruses that actually enter and function within the cell.

Reduced Immune Response

Deficits in immunologic function have been observed in the aging population,¹⁹⁻²¹ including deterioration of the ability of lymphocytes to proliferate in response to stimuli and a shift in T-cell and natural killer cell populations. Interestingly, the expression of cell-surface antigens by cells often mediates tumor cell growth. Human

leukocyte antigen (HLA) molecules play a critical role in presentation of tumor antigens to cytotoxic T lymphocytes. The ability of the immune system to recognize these abnormal cells and deal with them appropriately is important in maintaining a low incidence of cancer and fighting existing tumors. The loss or downregulation of HLA class I molecules correlates with an invasive tumor phenotype. There is evidence that certain HLA determinants correlate with increased incidence of cancer. It is possible that these disease-associated alleles present antigens to T lymphocytes in a fundamentally different manner, resulting in an altered immune response. Finally, there are several clinical and experimental examples of an association between reduced systemic immune response and cancer. The variety of immune function changes that occur with age are covered in great depth in Chapter 53, Immunology of Aging.

Physical Stress

Tissue irritation and chronic inflammation are factors that can facilitate tumor promotion. For example, although the mechanism of asbestos carcinogenesis is not completely understood, it appears that cellular reactions to these nondegradable fibers activate tumor-promoting cell-signaling pathways. Additionally, inflammatory cell responses may produce carcinogenic by-products, such as oxygen radicals.^{22–24}

Viruses

Viruses represent important agents in development of certain tumors and are thought to be responsible for one in seven cancers worldwide.²⁵ Studies of cancer-related viral mechanisms have provided vast insight to the mechanistic etiology of cancer. Tumor viruses function in a variety of ways to provide oncogenic stimuli for the cells they infect and for the surrounding tissue.

Retroviruses, including HTLV-I, HTLV-II, and HIV, all exhibit oncogenicity. Reverse-transcribed DNA from retroviruses is actually incorporated into the cellular genome. The oncogenic influence from these agents results from the virus providing cellular growth-related genes (virally transduced oncogenes) or by driving transcription of an existing cellular gene (proto-oncogene). Although the basic principle of these oncogenes is utilization of cellular or cell-derived genes to induce cell growth, they tend to have high mutation rates when present within the viral genome. This high mutation rate may contribute to evolution of further selective growth advantage.

DNA viruses, such as hepatitis B and C viruses, human papilloma virus (HPV), human herpesvirus 8 (HHV-8), and Epstein–Barr virus (EBV), are tumorigenic. These viruses may or may not become integrated into the host's genome. They can induce immunomediated injury and subsequent cellular proliferation that serves as an onco-

genic force. Evidence suggests that these viruses can provide growth stimulatory signals, not only by activating genes adjacent to the viruses site of incorporation, but also by producing products that activate distant cellular genes.

Cytokines

Cytokines are soluble mediators of cell–cell communication and include interferons, interleukins, and colony-stimulating factors (CSF). Following interaction with their receptors, these factors initiate signaling cascades that activate or suppress transcription of various genes important for cell growth and survival.

Hormones

Hormone receptor/effector pathways appear to be important for growth of a variety of cancers.^{26,27} Tumor cells may produce excess growth factors, such as platelet-derived growth factor (PDGF), transforming growth factor (TGF), fibroblast growth factor (FGF), hepatocyte growth factor-scatter factor (HGF-SF), or epidermal growth factor (EGF). Steroid hormone receptors are overexpressed in several cancers, such as breast, prostate, and endometrial cancer. Long-term estrogen replacement therapy is associated to some degree with increased incidence of breast cancer and, if unopposed by progesterone, with endometrial cancer. Steroid hormones act by binding their receptors and activating gene transcription in the nucleus. This process results in the expression of genes important in cell proliferation.

General Associations of Advanced Age with Cancer

As already described here, advanced age is highly associated with the development of cancer as well as the mortality from cancer. Because cancer is a multistep process, it has been proposed that time is required for accumulation of the requisite cellular and genetic changes to induce cancer, resulting in a frequent appearance later in life. Interestingly, the only known life span-prolonging intervention in animal models, dietary restriction, also reduces the incidence of cancer. Age is associated with a variety of cellular changes that could predispose to carcinogenesis, such as increased susceptibility to genetic change, telomere shortening, and impaired immune function.²⁸ These relationships are discussed in this chapter.

Cancer Cell Biology

The preceding section describes factors that have the ability to induce cancer-related change in cells. This section describes the nature of those changes. One of the

FIGURE 31.2. Steps in carcinogenesis.

things that makes cancer so difficult to understand and treat is that there is no single unifying mechanism or genetic endpoint that explains malignancy. Many different types of cellular abnormalities can induce one type of cancer. Each individual tumor is relatively unique in its composite of genetic and cellular abnormalities. Indeed, a common characteristic of cancer is genetic instability, which creates an environment in which genetic change and evolution of a cell population occur in a somewhat random manner. These genetic and cellular changes exert their influences on cell functioning in several general and sometimes overlapping ways.³

At a very basic level, cancer-facilitating events impair a cell's ability to sense or respond to signals from the environment or signals from within itself. For example, a quiescent cell given altered environmental cues will proliferate and may induce vascular proliferation to support its proliferation. A damaged cell that should normally undergo apoptosis and die will continue to live. A cell that should remain compartmentalized will invade surrounding tissue. A cell that should develop a mature phenotype will remain poorly differentiated. The term checkpoint refers to specific phases in the cell cycle at which the cell in some way assesses the appropriateness of further progression in the cell cycle. If inappropriate signals or disruption of some aspect of cellular integrity is detected, the cell exits the cell cycle or undergoes apoptosis. Cancer cells often lose the ability to sense or heed checkpoint controls.

The events required for carcinogenesis can be thought of as a stepwise progression in which a normal cell undergoes transformation to a malignancy (Fig. 31.2). The first step, *initiation*, involves a genetic event, usually altering the activity of a growth-related signaling pathway. (Specific pathways are discussed in detail later in the chapter.) The second step is *promotion*, which is a nongenotoxic influence that provides a selective growth advantage to the initiated cell. Mechanistically, tumor promoters exert effects such as altering activity of cell-surface receptors,

cytosolic enzymes, and nuclear transcription factors. As a result, tumor promoters may stimulate cell proliferation or inhibit apoptotic cell death. The next step is *pre-malignant progression*, which involves acquisition of further genetic or chromosomal alterations. This progression is facilitated by genomic instability and is somewhat dependent on selection of cell clones that have acquired further selective growth advantage. Mutation of the p53 tumor suppressor gene is an example that may fall into this phase of carcinogenesis. The final step, *malignant conversion*, involves cell changes that facilitate migration and invasion.

Several general classes of cancer-related genes have been described. An “oncogene” refers to a gene whose activation is associated with development of cancer. An apposition is a “tumor suppressor gene,” whose inactivation is associated with development of cancer. The following subsections describe different types of cellular changes associated with cancer.

Impairment of Cell Cycle Control

Cell cycle control has been one of the central icons in the study of cancer.^{29–35} Changes in the cell cycle are also associated with cellular senescence, one of the important processes involved in the biology of aging. Because the mechanisms involved in cell cycle control are integral to both cancer cell growth and cellular senescence, detailed discussion of this topic is essential in this chapter.

The term cell cycle refers to a cyclic series of events through which a cell goes to replicate itself (Fig. 31.3). To proceed through the cell cycle, a normal diploid cell, existing in the “G₁” phase of the cycle, enters the “S” phase following the appropriate signals. In S phase, the cell replicates its entire genome and then enters the second gap phase, G₂. Next, the cell enters the mitosis or “M” phase, where it physically divides into two equal daughter cells. Each daughter cell is then considered to be back in the G₁ phase of the cell cycle. Cells can maintain a resting, or quiescent, state by exiting the cell cycle into a “G₀” state. There are also several checkpoints

FIGURE 31.3. The cell cycle.

within the cell cycle where abnormal cells or cells lacking appropriate signals are prevented from proceeding further. The two primary checkpoints exist just before S phase and before M phase.

A key factor of most cancers is the presence of a force that promotes passage of cells abnormally through the cell cycle and usually influences entry into S phase. Importantly, this force does not necessarily require more rapid cell proliferation, just the inability to control it. Furthermore, this process can involve either lack of inhibitory signals (tumor suppressors) or the presence of cell cycle stimulatory signals (oncogenes).

Production of many of the enzymes and factors required for DNA synthesis and DNA replication is regulated by the E2F and Rb families of nuclear proteins. In fact, Rb, or retinoblastoma protein, derives its name because it is mutated in retinoblastomas, causing E2F to be deregulated in its action to initiate DNA synthesis. Several tumor-causing viruses, including human papilloma virus and SV40 virus, produce factors that bind to Rb, releasing E2F which then drives the cell cycle. Activity of the Rb family of proteins is in turn regulated by cyclins D and E and the cyclin-dependent kinases (cdk) cdk4 and cdk6. There are several examples of cancers where a primary upregulation of these cyclins and/or kinases appears to be etiologic in the cancer, for example, in chronic lymphocytic leukemia or breast cancer.

Several signaling pathways regulate *cyclin/cdk* activity (Fig. 31.4). Ras and Ras-related pathways are very important in cellular growth signaling. Growth factors such as epidermal growth factor (EGF) utilize Ras pathways, involving activation of mitogen-activated protein kinases (MAPK) and ultimately the nuclear transcription factors,

c-fos, *c-jun*, and *c-myc*. Subsequent steps lead to mediation of the cdk/Rb/E2F pathway. Ras also activates other pathways that are involved in cell growth control. Another pathway, the Jak/STAT pathway, is initiated by binding of a cytokine such as interferon to its receptor, ultimately resulting in cell cycle advancement. A third pathway that is associated with tumor cell growth and differentiation is the inositol phosphate/protein kinase C (IP/PKC) pathway. Protein kinase C (PKC) is important for tumor promotion in some cells, and it can directly regulate the MAPK pathway. Another important pathway is associated with the adenomatous polyposis coli (APC) gene, which is mutated in familial adenomatous polyposis. This pathway, when APC is mutated, stimulates the cell cycle.

The following components of signaling pathways provide numerous examples of cancer-associated alterations.

Growth Factors

A variety of growth factors, including platelet-derived growth factor (PDGF), TGF- α , colony-stimulating factor 1 (CSF-1), fibroblast growth factor (FGF), and other polypeptide growth factors, are overexpressed in certain tumors.^{36,37}

Growth Factor Receptors

Growth factor receptors can be activated by genetic mutations or overexpressed in certain human cancers.³⁸ Examples include TRK (nerve growth factor receptor), MET (hepatocyte growth factor/scatter factor receptor), ERB-B (epidermal growth factor receptor), ERBB-2/neu (orphan receptor), FMS (colony-stimulating factor-1),

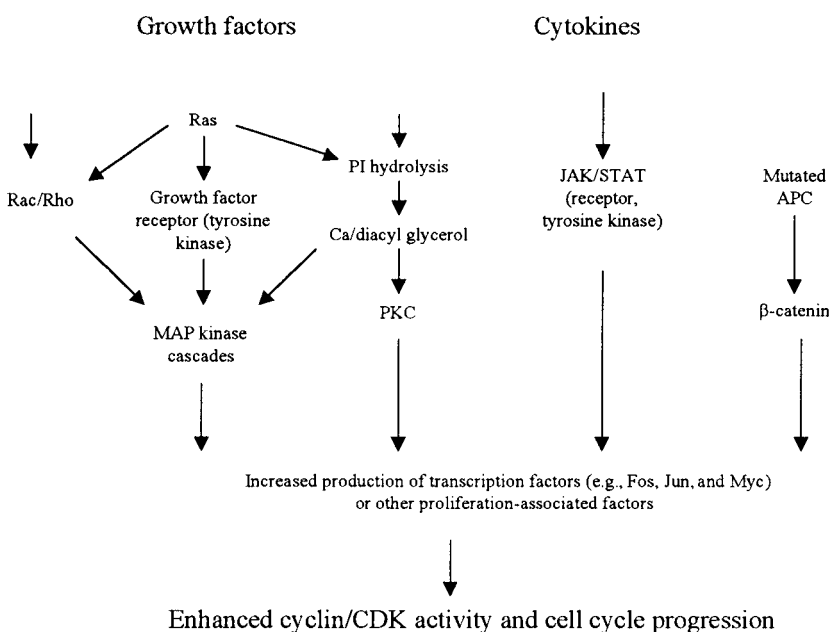

FIGURE 31.4. Signaling pathways that affect the cell cycle in cancer.

RET (orphan receptor), ROS (orphan receptor), and SEA (orphan receptor). The ERBB family, for example, is overexpressed in some breast, ovarian, and squamous carcinomas as well as in glioblastomas.

G Proteins

G proteins, or GTP-binding proteins, translate signals from cell-surface receptors to intracellular signaling cascades.³⁹ Activating mutations of the Ras family of G proteins are the most common dominant mutations in human cancer. The gene for neurofibromatosis produces a Ras-regulating protein.

Nuclear Oncogenes

Several transcription factors, including myc, fos, and jun, directly regulate gene expression that leads to cell proliferation, division, and differentiation.⁴⁰⁻⁴⁷

In addition to being unregulated by cyclins, cyclin-dependent kinases (cdk) are also inhibited by cdk inhibitors (cdki). There are two families of cdki: the first includes p21 and p27, and the second family, or INK4 family, includes p16, p15, p18, and p19. P15 and p16 are frequently mutated in human cancers. Additionally, p53, the most frequently mutated gene in cancer, conveys part of its activity through a cdki (p21).

Nutrient deprivations is yet another potential point of control over unregulated proliferation. If a cell population grows so rapidly that it outstrips its nutrient supply, the cells will enter a quiescent or G₀ state. Indeed, without additional vascularization, a tumor can grow no more than a few millimeters. Many tumors have adapted to this problem by secreting vascular growth factors that stimulate new vascular growth; this provides for the needed nutritional supply to support tumor growth.

Impairment of Apoptosis

An important cellular event that is often in apposition to cellular proliferation is apoptosis, or programmed cell death.⁴⁸⁻⁵⁰ At a cellular level, this process involves an orderly, energy-requiring dismantling and processing of a cell, as opposed to necrosis, which is disorganized and probably more toxic to the organism. Apoptosis occurs naturally in a developing organism, with the coordinated loss of specific cell populations. It can also be induced by stress or cell damage. Cells arrested at cell cycle checkpoints (see Fig. 31.3), for example, with a certain level of DNA damage, will exit the cell cycle and undergo apoptosis. The number of cells in a tissue or tumor can be considered to represent a balance between proliferation and apoptosis.

The induction of apoptosis and inhibition of the cell cycle are closely linked. A central mediator of these processes is the p53 transcription factor, which is a recipi-

ent of cellular signals indicating damage or stress. Probably the most publicized and most frequently observed alteration in cancer is mutation of p53. In addition to inhibiting the cell cycle as already discussed, p53 appears to regulate a cascade of events resulting in apoptosis. Therefore, disruption of p53 in cancer results not only in disruption of the cell's ability to halt growth but also in impairment of its ability to carry out apoptosis.

The association of aging with apoptosis as it relates to cancer is more complex. Aging results in a generalized enhancement in apoptosis in a variety of organ systems. This increased tendency toward apoptosis is insufficient to result in reduced tumor development in the elderly. A malignant tumor clone has developed multiple mutations, some of which impair the cell's ability to recognize these apoptotic forces. Furthermore, the generalized increased apoptosis seen with aging may result in impaired organ function that actually facilitates tumor growth. For example, greater apoptosis of specific T-cell subsets may reduce the body's ability to mount an adequate immunologic response to a tumor.

Impairment of Differentiation

A phenotype associated with many cancers is impaired cellular differentiation or maturation. Conceptually, all cells within the body derive from some form of stem or germ cell. This stem cell lacks phenotypic characteristics of mature tissues but has the capacity to produce daughter cells that undergo such maturation. Differentiation involves acquiring functional capabilities and expression of unique structural and functional components as well as loss of proliferative capacity in many cases. This process is thought of as an irreversible commitment. A common theme among cancers is the loss of this phenotypic differentiation, yet the molecular etiology for this change is understood in many fewer cases.

Tumor Promotion

The phorbol esters were the first class of compounds characterized as tumor promoters.^{51,52} These compounds bind and activate protein kinase C (PKC). PKC regulation of the Ras/MAPK pathway may be its mechanism of tumor promotion. Dietary fat intake has been associated with increased cancer incidence, which may be the result of the direct tumor-promoting effects of certain lipids.

Enhanced Invasive/Metastatic Capacity

A critical issue in terms of a tumor's lethality is its ability to invade surrounding tissue and metastasize.⁵³⁻⁵⁶ Cancer cells accomplish metastasis using several mechanisms. Rapid cellular growth results in mechanical pressure that

may damage surrounding tissue or physically facilitate local invasion. Cancer cells acquire enhanced mobility, loss of cell-to-cell cohesive forces, and increased ability to degrade basement membranes and connective tissue extracellular matrix. Expression of enzymes such as metalloproteinases, collagenase, and heparinase correlates well with metastatic potential.

Resistance to Host Factors

Tumor cells exhibit immunogenic antigens. Although a tumor cell that is recognized by the immune system can be destroyed, certain tumor cells are actually stimulated to grow by cytokines involved in an immune response. Alternatively, certain tumor cells have developed reduced capacity to resist other factors that might result in the cell's demise.⁵⁷⁻⁵⁹

Tumor Biology

The biologic characteristics of individual tumors vary greatly depending on the tissue of origin, genetic makeup, and environmental stimuli. For example, leukemia, carcinomas, and sarcomas tend to have general growth and treatment-response factors that differ. Even tumors from the same organ can be vastly different; for example, basal cell carcinoma versus malignant melanoma, or chronic lymphocytic leukemia versus acute lymphocytic leukemia. These differences are largely a result of differing complements of genes being expressed. The tumor environment may also play a role in the tumor phenotype. The hormonal milieu or the presence of inflammatory cytokines may slow or hasten tumor growth. Tumors in the elderly may be less aggressive.

Biology of Cancer Therapy

Pharmacology of Therapeutics in the Elderly

A number of physiologic and pathophysiologic changes occur as people age that significantly affect the pharmacokinetics (the way in which drugs are absorbed, distributed, metabolized, and excreted) and pharmacodynamics (the body's response to the drug).^{60,61} Pharmacokinetic changes include changes in body composition that result in decreased water content and increased lipid content. These changes affect the volume of distribution of drugs, depending on their polarity. A steady cross-sectional decline in renal function occurs as people age. This renal function decline can go unnoticed because of reduced muscle mass and deceptively low serum creatinine levels in the elderly. In addition, hepatic metabolism is reduced in the elderly because of an overall decline in hepatic blood flow. The expression of p-glycoprotein by resistant

tumor cells represents a pharmacokinetic change at the cellular level.

Impaired responsiveness of the cardiovascular system in the elderly results from a series of pharmacodynamic changes, including reduced β -receptor sensitivity and increased vascular rigidity. These changes place the elderly at increased risk from events or treatments that produce hemodynamic compromise, including sepsis and cardiovascular-acting agents.

Chemoprevention

A number of agents are being studied that may reduce cancer-causing cellular events.⁶²⁻⁶⁴ A reduction in development of contralateral breast cancer has been shown for patients taking the antiestrogen tamoxifen as an adjuvant therapy for breast cancer. This drug purportedly reduces the tumor-promoting effect of hormonal stimulation. Nonsteroidal anti-inflammatory agents have been proposed as a cancer-preventing intervention, particularly for colon carcinoma. Finally, a variety of antioxidants are being studied for their ability to reduce the incidence of cancer.

Cell Cycle-Directed Agents

The primary mechanism of action of most anticancer drugs currently in use is the disruption of the cell cycle.⁶⁵ Antimetabolites such as methotrexate interfere with DNA synthesis by inhibiting dihydrofolate reductase. Incorporation of modified pyrimidines, such as cytosine arabinoside during DNA synthesis, causes chain termination. Fluorinated pyrimidines, such as 5-fluorouracil, inhibit DNA and RNA synthesis. Platinum agents, such as cisplatin, and alkylating agents, such as nitrogen mustards and nitrosoureas, cross-link DNA and disrupt DNA repair. Topoisomerase inhibitors, like topotecan and etoposide, interfere with transcription, DNA synthesis, and mitosis. Microtubule-disrupting agents, such as vincristine and paclitaxel, impair cell division. Anthracyclines such as doxorubicin disrupt DNA synthesis, but also induce free radical formation and damage cell membranes. Regardless of the mechanism, the end result of a variety of chemotherapy agents is to inhibit cell proliferation of rapidly cycling cells, thus removing these cells from the cell cycle or delaying the cell cycle.

Apoptosis-Directed Agents

The initial effect of the chemotherapy agents previously described is inhibition of cell proliferation. As a result of these insults, a cell may undergo apoptosis. The action of many chemotherapeutic agents is also associated with apoptosis. In addition to cytotoxic chemotherapy, apoptosis can be induced by growth factor or hormone with-

drawal and irradiation. As described, p53 is an important mediator of apoptosis. p53-deficient cells are resistant to the apoptosis-inducing effect of chemotherapy or radiation.

Receptor–Effector Antagonism

Because growth of many tumors depends on disrupted receptor activation, therapies have been developed to antagonize these receptors.⁶⁶ Hormonal agents, such as antiandrogens, antiestrogens, gonadotropin-releasing hormone analogues, and aromatase inhibitors, represent important classes of anticancer drugs currently widely in use for treatment of hormone-dependent tumors, such as breast, prostate, and endometrial cancer. Because G-protein farnesylation appears to be important in Ras signaling, an experimental approach currently being developed is the characterization of farnesylation inhibitors.

Angiogenesis-Directed Agents

Angiogenesis appears to be important for tumors that exceed several millimeters in size and has therefore become a target of intense investigation. Endogenous peptide angiogenesis inhibitors have been identified, and one experimental approach has been to produce and administer these or similar peptides. Other agents such as thalidomide have been shown to inhibit angiogenesis and are currently being evaluated for their ability to stem tumor growth.

Differentiation-Directed Therapy

Cancer therapies can be directed at mediating cellular differentiation. An important example of this is the treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid. Because the disease arises from inappropriate expression of the retinoic acid receptor, treatment of the leukemic blasts with retinoic acid results in rapid induction of differentiation of the cells. Retinoic acid has subsequently become an important agent for treatment of this disease.

Immunomediated Therapy

Enhancing immune function has been associated with antitumor responses in animal models and in humans. For example, interleukin-2 has antitumor efficacy in malignant melanoma and renal cell carcinoma. Interferon alpha also has efficacy in melanoma and renal cell carcinoma as well as in chronic myelogenous leukemia. It is believed that these agents stimulate the immune system's antitumor activity.⁶⁷

Inhibitors of Basement Membrane-Degrading Enzymes

Still in the phase of discovery and development are agents that inhibit basement membrane-degrading enzymes such as matrix metalloproteinase.^{53–56}

Resistance to Therapy

Genetic instability acquired by cancer cells during tumor progression increases the rate of tumor cell adaptation to specific stresses such as cancer therapy.^{57–59} A related mechanism a cell may use is the development of the multidrug resistance (MDR) phenotype, which can be induced in acute leukemia in older patients. Upon exposure to chemotherapeutic agents, cancer cells increase expression of proteins that excrete the agent from the cell, maintaining low intracellular concentrations of drug. The best studied example of this involves cell-surface expression of p-glycoprotein (Pgp).

Conclusions

The biologic basis for cancer is clearly multidimensional and complex. This chapter systematically discusses the key elements of the development, progression, and treatment of cancer with a specific focus on the role of aging in these processes. Unfortunately, there is no unifying explanation that describes the essence of cancer. There are, however, many biologic and epidemiologic links to aging. Biologic changes that occur during aging probably increase the likelihood of developing cancer. Age-associated changes also impact significantly on cancer therapeutics. All these areas need more research, but understanding them can help the clinician at the forefront of cancer prevention, diagnosis, and treatment in an aging population.

Screening for Cancer

Eugene Z. Oddone, Mitchell T. Heflin, and John R. Feussner

When to Seek Early Diagnosis

Screening for cancer is an attractive and important component of comprehensive primary care. Clinicians understand and support this part of early disease detection because it may allow definitive and potentially curative therapy at a time when the patient's quality of life can be preserved, perhaps even prolonging their life. Patients also generally understand the concept of screening and, when questioned directly, place a high value on averting late-stage or metastatic cancer. Health care systems support the concept by using screening rates for certain cancers as markers of quality of care. Despite the generally accepted concept of screening for cancer, there are often wide gaps in the performance of screening for individual patients within practices and across health care systems. In some instances, conflicting or vague guidelines for particular screening tests lead to confusion for both clinicians and patients about what the suggested strategy should be. In other cases, the evidence for screening with a specific test is strong and mechanisms for payment exist, yet compliance with repeated screening is only average. The decision to screen for cancer in the elderly is even more difficult than for a younger population because the elderly were not included in many screening studies. Additionally, older patients face a high competing risk of dying from other causes, which reduces the potential effectiveness of any screening strategy.

As attractive as early detection of cancer may seem, certain principles should be considered to assure the appropriateness of any decision to seek early diagnosis. A paradigm upon which to evaluate the evidence for or against screening includes the importance or seriousness of the target disease; the presence of a detectable preclinical phase; the accuracy and acceptability of diagnostic tests used to detect cancer; the risk associated with the initial and any subsequent diagnostic tests necessary to confirm the diagnosis; and the efficacy, risk, cost, and

availability of treatment for the cancer once it is uncovered. The absence of clear information about any one of these important considerations will diminish the potential value of a screening strategy.

The disease being considered as a potential target for early diagnosis should be an important problem. It should either occur frequently, be more readily treated when detected early, or be readily treated even though the prevalence may be low. Sackett and colleagues have succinctly summarized this point: the disease should be so common or so awful as to justify the effort and expense of early detection.¹ Cancer qualifies as an example of an important target disease that is both common and awful in the elderly.

For any screening strategy to be effective, knowledge about the natural history of the target disease should be apparent. Clinicians should know that early detection of disease is likely to be useful because the disease has a detectable preclinical phase. There must be evidence that detection of the disease at the presymptomatic stage matters. Finding and treating the disease at this point must result in either improved quality of life, reduced disability, or reduced mortality for screening to make a difference.

For a screening program to be feasible, diagnostic tests must be available that are accurate and acceptable to patients. The screening test should minimize false positives (healthy patients inaccurately identified by positive test results) and false negatives (patients with the disease of interest who have negative test results). The accuracy of most diagnostic tests is expressed in terms of the test sensitivity (patients with disease who are correctly identified by a positive test) and test specificity (patients without disease who are correctly identified by a negative test). Alternatively, these characteristics can be combined into likelihood ratios, which describe the odds that patients with positive or negative test results either do or do not have the target disease. The screening test should also be acceptable to patients in terms of risk, discomfort,

TABLE 32.1. Considerations in deciding to seek an early diagnosis.

1. Is the target disease an important clinical problem?
 - a. Does the burden of disability warrant early action?
2. Is the natural history of the target disease understood?
 - a. Is there a latent or early symptomatic period?
3. Is the screening diagnostic strategy effective?
 - a. Is the accuracy of testing established?
 - b. Is the test acceptable to patients, with little discomfort and low risks?
 - c. If the screening test is positive, will patients accept subsequent diagnostic evaluation?
4. Is there a known treatment for the target disease at the detectable stage?
 - a. Is the treatment effective and available?
 - b. Is the cost of testing balanced by the benefit of treatment?

and cost. Patients must also understand that screening may involve a sequence of tests depending on results because additional definitive diagnostic tests are often required before definitive therapy.

Target diseases that meet the four criteria listed in Table 32.1 are often the focus of clinical studies that seek to establish the effectiveness of a particular screening strategy. In these studies, and unique to all clinical studies that seek to measure early diagnosis, the interpretation of the effectiveness of a specific strategy is susceptible to two specific biases. First, lead-time bias occurs when early detection establishes a diagnosis of cancer sooner than usual but without actually influencing the natural history, or survival time, of a given cancer. The duration of survival measured from the time of diagnosis to death will appear longer for the patient who underwent screening than for the patient whose cancer was detected when symptoms first appeared. Therefore, the screened patient did not actually live longer than the unscreened patient but appeared to live longer because the diagnosis of cancer was made earlier. Second, length-time bias describes a phenomenon whereby slower-growing cancers are more likely to be discovered by routine periodic screening than are faster-growing cancers. Faster-growing cancers, being more aggressive, grow and spread in the interval between screening events; this results in a longer average survival in the screened population because of the disproportionate detection of slower-growing cancers in the cohort.

Issues Specific to the Older Patient

The decision to offer cancer screening to the older patient is complex.² There are competing forces that simultaneously favor and dissuade clinicians from adopting screening for any individual. In addition to the traditional

inquiries about the strength of evidence supporting a given screening test, clinicians must consider other questions specific to the elderly (Table 32.2).

1. *What is the impact of the disease in older patients?* Sixty percent of persons affected by cancer are over age 65. Age-specific incidence rates for various cancers are severalfold higher in older patients when compared to their younger counterparts. Additionally, mortality rates rise dramatically as patients age into their eighth and ninth decades of life (Fig. 32.1). The burden of cancer is clearly significant in the elderly.

2. *Is cancer biology different in older patients?* In many cases, the detectable preclinical phase of a cancer changes with aging. For example, breast cancer in older women appears to evolve more slowly than in younger patients, whereas cervical cancer may become invasive in a shorter period. The specific biology of a cancer fundamentally determines its candidacy for screening.

3. *Do screening tests perform differently in older patients?* Often, screening tests perform differently in older patients due to factors such as comorbid illness or age-associated changes in anatomy or cellular biology. Mammography, for instance, performs better in older patients, whereas the Pap smear is less reliable.

4. *Will this patient or group of patients survive long enough to derive a benefit from screening?* Many groups making recommendations for screening in the elderly state that screening should be continued if the patient has “good health” or “a reasonable life expectancy.” Because of a lack of clinical trial data in older patients, the answer often must be derived from the expected time to benefit projected from younger patients as well as the patient’s estimated life expectancy. Estimated life expectancy is difficult to predict for individual patients. Current estimates from census life tables set the average life expectancy of a 75-year-old woman at 12.2 years and a 75-year-old man at 10 years. These numbers may be decreased, however, by the presence of comorbid illness. In fact, several studies have demonstrated that chronically ill patients diagnosed with early-stage cancer tend to die of a comorbid illness and not from cancer.^{3,4}

TABLE 32.2. Questions specific to screening for cancer in the elderly.

What is the specific impact of the disease in older patients?
 Is the biology of the cancer different in older patients?
 Are the characteristics of the screening tests different in older patients?
 Will this patient or group of patients survive long enough to benefit from screening?
 What barriers exist to screening for this cancer in the patients?
 How do patient preference and values impact the decision to offer screening in older patients?

FIGURE 32.1. Age-specific incidence and mortality from cancer, 1993–1997. (Adapted from NCI SEER program data, online at www.seer.cancer.gov/publications.)

5. *What barriers exist to screening for cancer in the elderly?* Social factors such as race, access to health care, and socioeconomic status impact the receipt of screening. Likewise, provider knowledge and communication skills strongly influence patient understanding and compliance with recommended screening strategies.

6. *How do patient preference and quality of life impact screening decisions?* Consideration must be given not only to changes in survival associated with screening, but also to the stress associated with early diagnosis, the threat of disability with longer life, and the potential harm associated with treatment.

These questions must be answered separately for each cancer considered for screening and for each patient. This review attempts to identify the evidence available for screening for several cancers in the elderly and to provide clinicians with guides for decision making in each case.

Breast Cancer

Breast cancer is the leading cause of cancer and the second leading cause of cancer-related deaths among women in the United States. In 2002, although the number of new cases of breast cancer in the United States was expected to remain stable at approximately 203,500, the number of total deaths was expected to drop to fewer than 39,600 from more than 46,000 in 1994. Older women

continue to experience the majority of morbidity and mortality from breast cancer. The annual incidence among women over age 65 is nearly six times that of women under age 65 (441/100,000 versus 76/100,000). Additionally, 67% of breast cancer deaths occur among women over age 60, and 24% occurred in those over age 80.^{5,6}

In addition to advancing age, other well-established risk factors include personal or family history of breast cancer, a history of benign breast disease with atypical hyperplasia, and a longer duration of estrogen exposure, either endogenous or exogenous. The specific impact of these risk factors in older compared to younger women is not clear. Recent analyses of large populations of older women enrolled in studies of osteoporotic fractures have revealed marked decreases in breast cancer risk among those with the lowest bone mineral densities. Researchers speculate that bone mineral density may be a marker of lifetime estrogen exposure and, thereby, an indirect indicator of breast cancer risk.^{7,8}

In addition to its high prevalence and mortality, breast cancer qualifies for screening due to its more favorable prognosis with early detection. For localized disease, 5-year survival rates in patients over 50 are 97.6%. With spread to regional lymph nodes at diagnosis, the 5-year survival in this group drops to 77.5% and with distant metastases to 20.1%.⁵ These rates do not appear to change with advancing age, particularly for early-stage disease. Additionally, strong evidence exists that tumors diagnosed in the elderly appear to be more slow growing

and therefore more amenable to screen detection and eradication with treatment.⁹

Screening strategies for the early detection of breast cancer include breast self-examination (BSE), clinical breast examination (CBE), and mammography. Breast self-examination has been studied in large, prospective, international trials. Although these trials have demonstrated a higher detection rate of smaller, more localized tumors, none of the studies has documented a mortality benefit for BSE.^{10,11} Other studies indicate that BSE has a low sensitivity, between 20% and 30%, which may be even lower among older women.¹² Based on this evidence, BSE appears to have limited utility in screening for breast cancer.

Independent test characteristics for CBE are difficult to assess secondary to a lack of direct evidence. Clinical results from breast physical examination are likely to be variable and directly related to the skills of the health care professional performing the breast examination. Overall, the sensitivity of CBE has been estimated to be about 50%.¹² As with other screening modalities, specificity is difficult to determine because women with normal examinations do not receive the reference standard test, breast biopsy. Studies that use manufactured models to simulate breast examination show an average sensitivity of 65% for registered nurses and 87% for physicians.¹³ CBE may augment screening with mammography but cannot stand alone as a screening maneuver.

The mammogram, on the other hand, remains the cornerstone of breast cancer screening. It detects smaller deeper breast masses and thereby allows the discovery of cancer earlier than physical exam alone. Overall, the sensitivity of mammography alone has been estimated to be approximately 75% to 90%, varying with age, breast density, and screening interval.¹⁴ When combined with CBE, estimates have ranged from 75% to 88%; specificity ranges from 83% to 98.5%.¹⁵ A significant body of evidence exists demonstrating that mammography has excellent test characteristics in elderly patients.¹⁶ Researchers attribute the improved performance of mammography to a decrease in overall breast density and increased content of radiolucent fat with aging.

Several experimental trials have demonstrated that screening for breast cancer with mammography reduces disease-specific mortality. The standard trial establishing the efficacy of the combination of mammography and CBE was the Health Insurance Plan of Greater New York study that documented a 23% reduction in mortality at 18 years of follow-up.¹⁷ This trial, however, excluded older women. Only the Swedish Two County trial and the Malmö trial included patients who were over age 65 years at the time of randomization. The Two County Trial reported a relative risk reduction of death from breast

cancer between 25% and 44% for patients aged 50 to 74 years.¹⁵ A subsequent subgroup analysis of patients aged 70 to 74 among *all* the Swedish trials, however, revealed an insignificant risk reduction of 0.94 (95% CI, 0.63–1.53) at 12 years of follow-up.¹⁸ This analysis cast some doubt on the resilience of the mortality benefit from breast cancer screening in the elderly population. In addition, a recent meta-analysis by the Cochrane Collaboration has highlighted methodologic flaws in several trials of screening mammography and, in so doing, has called into question the survival benefits described above.¹⁹ However, this analysis is highly controversial, and its implications for decisions to offer breast cancer screening to older patients remain unclear. Additional evidence for benefit, however, may be found in observational studies, including a large case-control study from the Netherlands comparing patients responding to invitation to screen with those not responding. Among those aged 65 to 74, relative risk of death from breast cancer was 0.34 at 13 years follow-up and 0.45 at 18 years for biennial screening. Although this study demonstrated a strong effect, its validity is weakened by the bias inherent in its design.²⁰ More recently, in a retrospective analysis of information from the SEER program, McCarthy et al. found that older women with primary breast cancer who had not had screening mammograms within the previous 2 years were significantly more likely to have advanced-stage disease at diagnosis [stage II or greater, adjusted odds ratio (OR) 3.12 (2.74–3.58)] and were more likely to die of breast cancer [adjusted HR 2.28 (1.79–2.91)].²¹ The clinician deciding whether or not to offer breast cancer screening to a woman over age 75 faces a clinical dilemma. On the one hand, the disease is highly prevalent and most deadly among this population. On the other hand, little direct evidence exists of the benefits of screening in this group. Further complicating the matter is the higher rate of comorbid illness and lower life expectancy among elderly women. Researchers have attempted to model such decisions. Mandelblatt and colleagues used a Markov decision model to evaluate screening elderly women with common comorbidities for breast cancer. They included four groups in the model: white and black women with average health, women with mild hypertension, and women with congestive heart failure. Assuming that women aged 65 to 85 would be screened with CBE and mammography, the model produced favorable but modest improvements in survival for all groups. The benefit was more pronounced for black women and women of average health.²² Another model using a clinical database from the Netherlands compared the benefit of screening in terms of quality-adjusted life-years (QALYs) gained with the “excess burden” incurred by increased lead time in diagnosis without impact on sur-

vival. The authors concluded that the benefit from screening might extend to patients up to ages 75 to 80.^{23,24}

In regard to the optimal frequency of screening with mammography, analyses indicate that no significant decrease in survival occurs with increasing the interval from 1 to 2 years.^{16,23} Biennial screening is deemed appropriate for older women as the preclinical detectable phase in this group appears to exceed 2 years.

Utilization of breast cancer screening declines steadily as patients age. Several population studies in the mid-1990s of women over age 75 reported screening rates of 30% to 40%, values well short of national standards and goals.^{25,26} In the latest statistics from the Centers for Disease Control, however, the overall rate of recent receipt of breast cancer screening in Americans over age 65 had reached 64% in 1998, up from 48% in the same population in 1991. Participation appears to be mediated by a number of patient- and physician-related factors. Family history of breast cancer and a personal history of benign breast disease both *increase* the likelihood of screening.²⁷ Age, comorbid illness, and functional decline *decrease* the likelihood of receiving screening.²⁵ In addition, a number of socioeconomic factors, including low income, knowledge deficits, low perceived benefit or susceptibility, lack of private insurance, and lack of access to a regular source of health care, negatively impact breast cancer screening.²⁸ For the provider, knowledge of current evidence and effective direct communication of recommendations have a strong positive impact on rates of receipt of screening among older women.

Most groups recommend screening with CBE and mammography or mammography alone every 1 to 2 years beginning at age 40 or 50. The American Cancer Society also recommends monthly BSE over age 40. They do not set a specific upper age limit but state that "as long as the woman is in good health" to continue to offer screening services.²⁹ The United States Preventive Services Task Force (USPSTF) recognizes the highest level of evidence exists to support screening for breast cancer between ages 50 and 69, and that convincing data is lacking outside this age range. They do acknowledge that women over age 70 with "reasonable life expectancy" might continue to warrant an offer of screening based on the high impact of the disease in the older population.³⁰

The authors agree with the consensus of offering biennial screening mammography to women over 50 (Table 32.3). Additionally, if a woman has a life expectancy of greater than 5 to 7 years, regardless of age, she should continue to receive offers to screen. Routine exploration of potential barriers to screening should accompany each refused offer or missed appointment; these might include addressing misperceptions, economic concerns, transportation issues, or simply fear and uncertainty.

Cervical Cancer

Although cervical cancer has a lower overall prevalence than breast cancer, it remains an important, preventable cause of morbidity and mortality for women. In 2002, the estimated number of new cases of invasive cervical cancer in the United States was expected to be 13,000 with 4100 deaths.⁵ Additionally, approximately 55,000 cases of carcinoma in situ (CIS) are diagnosed annually. As with most other malignancies, the incidence of invasive cancer increases with age, with 25% of all cases occurring in people over age 65. Importantly, 40% to 50% of deaths related to cervical cancer occurs in this same age group.³¹

Risk factors for cervical cancer are well recognized; these include early sexual intercourse, multiple sexual partners, and a history of human papilloma virus infection. For elderly patients, an additional consideration is the added risk associated with a lack of previous screening. In one case-control study, investigators found that 55% of women over the age of 65 diagnosed with cervical cancer reported never having a Pap smear versus 15% for cancer-free controls.³²

The natural history of squamous cell cancer of the cervix involves the progression of cervical dysplasia or CIS to invasive cancer. The detectable preclinical phase associated with this change is estimated to last from 1 to 20 years, although most agree that the average duration is approximately 10 years. This period may shorten with aging, with estimates as brief as 4 years in those over 50 and 1 year in those over 65.³³ When discovered before invasion, however, local treatment with conization or cryotherapy confers a definite survival advantage. For localized cancer, 5-year survival is 90%, as opposed to 40% for more advanced disease. Successful early intervention also avoids the extensive surgery and radiation employed to treat invasive disease.

The Papanicolaou test, or Pap smear, has been the standard method of screening for cervical cancer for more than three decades. Cervical cancer is not diagnosed with the Pap smear but rather is suggested by certain cellular abnormalities. Follow-up testing with colposcopy and biopsy is required to establish the presence of cancer. Sensitivity and specificity of the Pap smear have been difficult to gauge for reasons of variability in methods of specimen collection and pathologic analysis. A recent systematic review by Nanda and colleagues showed that Pap smear sensitivities ranged from 30% to 87% and specificities ranged from 86% to 100%.³⁴ The review also found that liquid-based monolayer preparations consistently outperformed traditional slide-based methods.³⁴ Further complicating matters, test characteristics change with aging. In older women, the target region for cell

TABLE 32.3. Recommendations for cancer screening in the elderly.

Cancer	Test(s)	ACS ^a	USPSTF ^b	CTFPHC ^c	Authors	Medicare reimbursement
Breast	Mammography ± CBE	Annual beginning at age 40, “as long as in good health”	Annual or biennial between 50 and 69; consider continuing if “reasonable life expectancy”	Annual or biennial between 50 and 69	Start biennial screening at age 50; continue to offer between 70 and 80 if life expectancy greater than 5–7 years, explain risks, explore barriers	Yes (1991); annually (2000)
Cervix	Pap test	Annual × 3, then “less frequently,” no upper age limit	Biennial or triennial, may stop at 65 if has had regular, normal smears	Annual × 2, then triennial to age 69 Consider more frequently in higher-risk subjects	Biennial or triennial screening, stop at 65 if has had regular, normal smears; history of prior Pap smears and risk factors; initial speculum exam before excluding from screening for hysterectomy	Yes (1991); Pap smear and pelvic exam biennially (2001)
Colorectal	FOBT Flex sig Colonoscopy ACBE	Annual FOBT; or flex sig every 5 years; or both; or colonoscopy every 10 years; or ACBE every 5–10 years	Annual FOBT, flex sig every 3–5 years, or combination. Colonoscopy or ACBE also appropriate, but interval undetermined.	Annual or biennial FOBT, periodic flex sig, or combination. Insufficient evidence for colonoscopy or ACBE.	Annual FOBT ± flex sig every 5 years; assess risks/benefits in choosing invasive vs. noninvasive methods; consider one-time colonoscopy or combination of ACBE and flex sig	FOBT annually; flexible sigmoidoscopy q 48 mo (1997); Colonoscopy q 10 yr (2001)
Prostate	DRE PSA	Both annually starting at age 50	Not recommended	Not recommended	Discuss benefits and harms, assist in individual decisions	DRE (as part of office exam) and PSA annually (2000)
Lung	CXR Sputum cytology Spiral CT Fluoroscopy bronchometry	Not recommended	Not recommended	Not recommended	Not recommended	No
Ovary	Pelvic exam CA 125 TVS	Not recommended	Not recommended	Not recommended	Not recommended	No
Skin	Skin inspection	Annual	Not recommended	Not recommended	Annual only for high-risk patients	No
Oral	Mouth inspection and palpation	Annual	Not recommended	Not recommended	Annual only for high-risk patients	No

ACS, American Cancer Society; USPSTF, U.S. Preventive Services Task Force; CTFPHC, Canadian Task Force on Preventive Care; CBE, clinical breast examination; FOBT, fecal occult blood test; flex sig, flexible sigmoidoscopy; ACBE, air contrast barium enema; DRE, digital rectal exam; PSA, prostate-specific antigen; CXR, chest x-ray.

collection, the squamocolumnar junction, recedes into the cervical canal, making sampling more difficult and less reliable. A study of 50 asymptomatic older women with negative Pap smears found that 11 had positive findings on subsequent colposcopy.³⁵ Additionally, aging predisposes the cervix to inflammation and injury, conditions that can result in higher false-positive rates. No prospective, controlled trials have been performed to demonstrate the effectiveness of the Pap smear on improving survival in any age population. A large body of epidemiologic evidence, however, reveals that women dying of cervical cancer are eight to nine times less likely to have received a Pap smear in the past than those without the diagnosis. Few patients over 65 were included in these analyses.³⁶

Human papilloma virus (HPV) testing may become an important adjunct of Pap smears in the future. Up to 99% of patients in whom cervical neoplasia is identified are infected with HPV. Subtypes 16 and 18 predict the most aggressive lesions. Widespread use of HPV testing will depend on the development of an affordable, easily performed test that identifies both the presence of infection and the subtype. At this time, such assays are still under development.²⁹

Many recommendations from professional organizations disagree with regard to suggested intervals between screening Pap smears. A comprehensive review revealed little decrement in the diagnostic rate of invasive cervical cancer with triennial versus annual screening (93.5% reduction in rate of invasive cancer versus 90.8%).³⁶ Cost-effectiveness analysis predictably reveals that among women over age 65 triennial screening reduces mortality by 74% at a cost of \$2254 per year of life saved. Continuing to screen women over age 65 who have had regular screening in the past (with normal cytologies) is not cost-effective, with little additional survival benefit.³⁷

In addition to avoiding repeated screening in women over age 65, screening is also unnecessary in women who have never had sexual intercourse and those who have undergone total hysterectomy for benign lesions. The clinician must recognize, however, those patients who have undergone *partial* hysterectomies in which the cervical stump has not been removed continue to be at risk for cervical cancer. Providers should consider performing an initial speculum exam on newly encountered patients to clarify their anatomy.

The greatest challenge in the prevention of cervical cancer is compliance. In most cases, this involves overcoming socioeconomic and educational barriers. Several epidemiologic studies have established that rates of receipt of Pap smear are adversely impacted by lower income, lower level of education, and urban location. It is unclear if Medicare funding for the procedure has improved rates over the last decade. Additionally, once the procedure is performed, adequate follow-up is

impeded by several factors, including older age.³⁸ Studies demonstrate that most of these barriers may be overcome by provider and patient education and improved social support.²⁸

Groups issuing recommendations for cervical cancer screening generally agree on the performance of Pap smears at least every 3 years in women who have a uterine cervix and who have had sexual intercourse in the past. The American Cancer Society sets no specific upper age limit, whereas the Canadian Task Force recommends stopping at age 69. The USPSTF recommends suspending screening at age 65 if the woman has had repeatedly normal smears (see Table 32.3).

The authors concur with the recommendations of the USPSTF with the following amendments:

1. Take a careful history of prior Pap smears and potential risk factors in all women, regardless of age.
2. In women with a history of hysterectomy, perform initial speculum examination to clarify anatomy before excluding from screening.
3. If a woman is sexually active and has a life expectancy of greater than 5 to 7 years, consider offering continued screening beyond age 65.

Ovarian Cancer

Compared to other cancers covered in this chapter, the overall prevalence of ovarian cancer is low. An estimated 23,300 new cases of ovarian cancer and 13,900 deaths were expected in 2000.⁵ The lifetime probability of developing ovarian cancer is about 1 in 60, and 46% of cases and 67% of deaths occur in women over age 65.⁶ Ovarian cancer continues to be the most frequent cause of death from any gynecologic malignancy, excluding breast cancer, in the United States. The high case fatality to incidence ratio reflects the fact that less than 25% of patients who present with ovarian cancer have disease localized to the ovary.⁵ Only lung and stomach cancer have lower proportions of patients who present with localized disease. Because a majority of women who present with ovarian cancer have either regional or distant metastases at the time of diagnosis, the 5-year survival rate is low, approximately 50% for all stages.⁶ Five-year survival rates are particularly low for women who are over age 65 at initial diagnosis, that is, 31%, compared to 64% for women who are younger than age 65.⁶ Despite new surgical and chemotherapeutic regimens, there has been almost no change in the age-adjusted death rate from ovarian cancer in the past 30 years. However, 5-year survival is excellent for women who present with localized disease, approximately 95%, and does not vary according to age at diagnosis.⁶ This finding has perpetuated a search for new and more effective screening methods.

The major difficulty with ovarian cancer is that symptoms do not usually develop until patients experience complications of advanced disease, a stage for which therapy is only palliative. It is unlikely that any strategy that relies on symptom recognition or clinical examination will ever improve detection rates or change the 5-year survival rates in this disease. Thus, screening strategies that utilize more detailed radiologic or chemical assessment need to be developed. Due to the low incidence of disease, however, these screening strategies must be highly sensitive and specific before any strategy is considered for mass screening.

Three major screening tests are available for detecting early ovarian cancer: pelvic examination, ultrasound imaging, and monoclonal antibodies such as CA 125. There is no evidence that any frequency of pelvic examination leads to increased case-finding for early ovarian cancer. In the few studies that have evaluated the independent contribution of pelvic examination, the prevalence of ovarian cancer was too low to provide stable estimates of either sensitivity or specificity.³⁹

Both abdominal and transvaginal ultrasonography have been studied extensively as screening tests. Both modes of ultrasonography are able to detect ovarian abnormalities in asymptomatic women with normal pelvic examinations. There is also more information from larger screening studies to calculate better estimates of the sensitivity and specificity of each of these tests. Carlson and colleagues reported an overall sensitivity for both ultrasound studies of 85% (95% CI, 80%–90%), based on a weighted average of all published studies.³⁹ The summary specificity for ultrasonography from the same studies was reported to be 93.8% (95% CI, 93.3%–94.3%). There does not appear to be a meaningful difference in either the sensitivities or specificities of these tests that would lead clinicians to prefer one above the other.

The development of monoclonal antibodies reactive to ovarian cancer-specific antibodies, particularly CA 125, was thought to be very promising with respect to ovarian cancer screening. CA 125 is elevated in 80% of women with epithelial ovarian cancer, but it is also elevated in some women with benign gynecologic conditions such as endometriosis, uterine fibroids, pelvic inflammatory disease, and ovarian cysts,⁴⁰ which lowers the sensitivity of the test compared to imaging studies such as ultrasonography. Carlson and colleagues³⁹ reported a summary sensitivity for CA 125 based on a reference value of 35 U/mL of only 78% (95% CI, 73%–83%) and a summary specificity of 98.9% (95% CI, 98.6%–99.2%). No information is available for any of these tests concerning the potential differential performance in young versus older women.

A recent randomized controlled trial evaluated the feasibility and potential effectiveness of a two-step

screening strategy using first, CA 125 and second, pelvic ultrasound for women with CA 125 values of greater than or equal to 30 U/mL compared to no screening in approximately 22,000 women in the United Kingdom.⁴¹ In this 3-year trial, women over age 45 were highly compliant with the screening strategy, with 86% completing at least one screen. Of the 29 women in the screening group who went on to surgical evaluation, 6 had a cancer (positive predictive value = 21%). In women who developed cancer, survival was longer in the screening group compared to the no screening group, but the overall mortality from index cancers did not differ between the two groups. The study, however, was not powered to detect a difference in overall mortality. This trial tells us that a screening strategy is feasible in a highly motivated group of women, but a much larger trial must be done before we can understand if this method of early detection reduces mortality from ovarian cancer.

The best evidence concerning the impact of screening tests is still derived from a decision model designed to evaluate both CA 125 antigen level and ultrasonography. Shapira et al. performed a decision analysis in which they modeled a screening strategy including transvaginal ultrasound and utilization of CA 125.⁴² The combined sensitivity and specificity of this strategy were 81% and 99.95%, respectively. Even with this near perfect specificity, eight false-positive results are obtained for every early-stage cancer detected. Overall, the screening strategy resulted in a less than 1-day increase in the average life expectancy.

Ovarian cancer fulfills several of the important criteria for screening. It is an important disease that leads to premature mortality. The early-stage forms of the cancer can be treated effectively, and good screening tests exist. The main problem with advocating a mass screening strategy is that the disease has a relatively low overall prevalence. In diseases of low prevalence, high test specificity is crucial to minimize the ratio of false to true positives. A decision analysis model documented that the threshold value for test specificity below which a no-screening strategy would be preferred over screening was very high, 98.53%,⁴² which implies that screening for ovarian cancer will never be feasible unless the specificity of the test is nearly perfect. A randomized controlled trial that enrolled 22,000 women has not added sufficient evidence to adopt this screening strategy.⁴¹ Because of this lack of evidence, both the U.S. Preventive Services Task Force and the American College of Physicians state that routine screening for ovarian cancer is not recommended.^{30,39} The American Cancer Society does not make a recommendation for routine screening for ovarian cancer for any aged population (see Table 32.3).²⁹

Although ovarian cancer is more prevalent and more deadly than cervical cancer, there are no currently available screening tests or combination of tests that provide

sufficiently high sensitivities and specificities to warrant mass screening. Until new screening tests are developed or until a more definitive trial evaluating the combination of CA 125 and ultrasonography is performed, it is not prudent to routinely screen women for ovarian cancer at any age.

Prostate Cancer

Prostate cancer is the most common cancer in men and the second leading cause of cancer mortality. Based on projections, 189,000 men are expected to be diagnosed with prostate cancer and 30,200 men are expected to die of the disease in 2002.⁵ In the late 1990s, prostate cancer death rates began to decrease. Prostate cancer incidence rates are also dropping after a significant increase coincident with the rapid assimilation of prostate-specific antigen (PSA) testing that occurred in the early 1990s. As with many cancers that we have discussed, prostate cancer is a disease of older people. The incidence and mortality for men over age 65 is 1025 per 100,000 and 226 per 100,000 men, respectively. The incidence and mortality for men under age 65 is 50 per 100,000 and 2.6 per 100,000, respectively.⁶ More than 80% of cases occur in men over age 65, and fully half of the deaths from prostate cancer occur in men over age 74. For men, the lifetime risk of being diagnosed with prostate cancer is 16%, and the lifetime risk of dying from the disease is 3.4%.⁶

Despite an incomplete understanding of the cause of prostate cancer, two factors identify patients as being at higher risk for developing and dying of the disease. First, advanced age is the dominant risk factor. Second, African-American men experience the highest rate of developing and dying of prostate cancer of any racial group; their risk is approximately twice that of white men and four times that of Asian men.⁶ Having a family history of prostate cancer in a first-degree relative also confers an elevated risk.

Although the natural history of prostate cancer is not well understood, it is clear that patients diagnosed with localized disease have better survival rates. The 5-year survival rate for men diagnosed with local disease is 80%, compared to 8% for those with evidence of distant metastases at diagnosis.⁶ Whether this favorable survival rate is due to effective treatment given for limited-stage disease or because of lead-time or length-time biases remains unclear. An additional confounder in the survival data is the fact that some men, particularly older men, may have less aggressive forms of prostate cancer and therefore may be much less likely to die of the disease. Autopsy studies have consistently shown that the majority of men over age 60 have evidence of prostate cancer at death, yet only a small percentage has clinically evident disease.⁴³

The two principal screening tests used to detect early prostate cancer are the digital rectal examination (DRE) and the serum PSA. It is widely recognized that the DRE has limited usefulness in any early detection strategy. In the best of hands, the sensitivity of DRE for prostate cancer is only 33% with positive likelihood ratios of only 1.5 to 2.0 for organ-confined tumors.⁴⁴ Because of this poor sensitivity, a normal test does not significantly lower the odds of having prostate cancer. Serum PSA is an alternative method of screening that has become widely utilized. PSA is highly specific for the prostate, but elevated blood levels are not specific for prostate cancer. This fact significantly deteriorates its sensitivity. The normal range is taken to be 0 to 4 ng/mL, but several common prostatic disorders (e.g., prostatitis, benign hyperplasia) may raise PSA levels beyond this range. Likelihood ratios for different PSA cutpoints are shown in Table 32.4. Men whose PSA levels are elevated above 4.0 ng/mL have an approximate threefold increased odds of having organ-confined prostate cancer.

There is evidence that DRE and PSA may detect different prostate cancers, posterior lobe versus periurethral cancers, respectively. Therefore, clinicians that advocate screening most often use both tests.⁴⁴ Because this strategy increases the number of men identified with abnormal findings, combined testing may increase subsequent testing, treatment, and the associated morbidity. Approximately one in four asymptomatic men have an elevated PSA or abnormal DRE.⁴⁴ Furthermore, there is no evidence that any screening or treatment strategy improves survival. Current trials and observational studies are underway.⁴⁵

Until these studies are completed and improved information is available concerning the role of screening and treatment in this disease, no currently available test or combination of tests is sufficiently accurate for detecting localized prostate cancer. As with other cancers for which the evidence is either inconclusive or not available, there are discordant recommendations from the various professional societies. The American Cancer Society recom-

TABLE 32.4. Likelihood ratios for PSA at different cutpoints.

PSA level	Likelihood ratio ^a	
	Intracapsular Tumor	Extracapsular Tumor
<4.0 ng/ml	0.7 to 0.98	0.09 to 0.5
4.1–10 ng/ml	1.4 to 3.0	3.2 to 5.1
>10 ng/ml	0.4 to 3.0	23.7 to 49.6

PSA, prostate-specific antigen.

mends DRE plus PSA annually in men older than 50 years.⁶ Their recommendation is similar to the American Urological Association. The U.S. Preventive Services Task Force does not recommend routine screening for prostate cancer with any available tests (see Table 32.3). An expert panel for the American College of Physicians has recently reviewed the evidence for prostate cancer screening and treatment.⁴⁶ They recommend that physicians should be prepared to discuss the benefits and harms of screening, diagnosis, and treatment and then assist men in making individual decisions. We concur with the recommendations of the American College of Physicians.

Colorectal Cancer

Colorectal cancer is the third leading cause of cancer and cancer-related death among both men and women in the United States. Recent projects estimated that 107,300 new cases would be diagnosed in 2002 and that more than 48,100 people would die of the disease.⁵ Data from the surveillance, epidemiology, and end results (SEER) program, however, show that between 1985 and 1997 the overall incidence of colorectal cancer dropped by 9% to 43.9 cases per 100,000. Mortality has declined as well over the same period to 16.4 deaths per 100,000. Despite these trends, colorectal cancer continues to be a disease of late life. Age-adjusted incidence rates rise from 17.1 cases per 100,000 in patients under 65 to 287.8 cases per 100,000 in those over 65. This increase continues without plateau to 450 cases per 100,000 in patients over 85. Mortality, likewise, increases with age, from 5.7 deaths per 100,000 in those under 65 to 120 deaths per 100,000 in those over 65.⁶

Traditional factors that increase risk for colorectal cancer include inherited disorders such as familial polyposis, family history of colorectal cancer in a first-degree relative, and inflammatory bowel disease. For patients with colorectal cancer diagnosed over age 65, however, family history appears to play a less significant role.⁴⁷

The natural history of colorectal cancer is well understood. The majority of cancers evolve from premalignant adenomas. The estimated time for progression from an adenomatous polyp to cancer is 5 to 10 years. Removal of these slowly growing lesions prevents the development of cancer. Predictably, the 5-year survival associated with an early lesion is very favorable compared with more advanced disease. For localized disease, 5-year survival is 90%, compared to 64% for regional spread and 8% for disease with distant metastases. Because of its prolonged detectable preclinical phase and responsiveness to therapy in early stages, colorectal cancer is an excellent candidate for screening.

For patients of average risk, digital rectal examination (DRE), fecal occult blood testing (FOBT), flexible sig-

moidoscopy, air contrast barium enema, and colonoscopy are commonly considered screening tests. Among these, DRE has the least supporting evidence. In retrospective analyses, less than 10% of colorectal cancers are within a finger's reach of the anus. In addition, a case-control study in patients with rectal carcinoma revealed no survival benefit with recent DRE.⁴⁸ It is still unclear if hemoccult of stool obtained via DRE is an adequate substitute for FOBT.

In contrast, FOBT boasts the strongest level of supporting evidence of any of the tests. The most commonly used is the Hemoccult test, but several other options now exist, including immunologic assays. Test utility relies on the fact that early cancers and some polyps bleed occultly, allowing early detection. In large trials with high rates of compliance, sensitivity is estimated to be 50% to 90%.⁴⁹ Specificity varies less, with estimates of 90% to 98%. The test characteristics appear dependent on a number of factors, including rehydration status of the sample and frequency of testing.⁵⁰ A recently proposed strategy initially screens patients with the traditional Hemoccult followed by confirmation of positive tests with an immunologic assay. Theoretically, this method would maintain sensitivity while maximizing specificity.⁴⁹ Standard follow-up for a positive screen with FOBT (one or more positive samples) is colonoscopy. The combination of flexible sigmoidoscopy and air contrast barium enema has been used frequently as an alternative in patients unable to tolerate colonoscopy.⁵¹

Five major prospective trials of FOBT have been conducted comparing screened versus unscreened populations. The trials unanimously demonstrate a mortality reduction in patients using FOBT (12%–43%).⁴⁹ This benefit appears to extend to the elderly, with similar reductions in mortality in subgroup analyses.⁵⁰ Inconsistencies in methods among the trials deserve note, however. The Minnesota trial examined rehydrated samples, resulting in a much higher positive rate compared with other studies (9% versus 1%–2%). This trial also reported a higher overall mortality reduction (33% versus 12%–18%). Critics speculate that the additional mortality reduction resulted from the “excess” number of colonoscopies performed due to “false” positives. Of note, the positivity rate among patients over 80 years old in this study was 16%. Nonetheless, in the remaining studies, a smaller but significant mortality benefit was found. Review of the optimal frequency of screening with FOBT using the trial data just cited reveals a significant survival advantage with annual versus biennial screening.⁵¹

Flexible sigmoidoscopy has become the other mainstay of colorectal cancer screening. Use of a 60-cm flexible scope allows direct visualization of the rectosigmoid and descending colon. Indications for follow-up colonoscopy include adenomatous polyps smaller than 1 cm, any polyp

larger than 1 cm, or cancerous-appearing lesions. Its sensitivity, as estimated for only the portion of bowel within the reach of the scope, is 96.7% for cancers and large polyps and 73.3% for small polyps. Specificity is estimated to be 94% for cancers and 92% for small polyps.⁵¹ The major complication is perforation, which occurs approximately once in every 10,000 procedures.

Two recent studies have also helped clarify the relationship between distal findings and proximal disease. Researchers performed colonoscopies in asymptomatic individuals and found that the presence of larger adenomas (>1 cm), adenomas with high-grade dysplasia, or invasive cancer in the distal colon predated the presence of proximal colon lesions.^{52,53} However, in half of those found to have advanced proximal neoplasia, no distal findings were present. Additionally, both studies found that increasing age predicted more advanced neoplasia in the lesions discovered through colonoscopy.

The best evidence supporting a mortality benefit from screening flexible sigmoidoscopy is a case-control study of 261 HMO members who died of cancer arising in the distal colon or rectum (case group) and 868 matched controls. Investigators observed that control patients were three times more likely than cases to have undergone screening with flexible sigmoidoscopy in the 10 years preceding the diagnosis of cancer. A subgroup analysis revealed that the survival benefit was limited to cancers within the reach of the sigmoidoscope. Further analysis found that the protective effect of this procedure extended up to 10 years.⁵⁴ Screening flexible sigmoidoscopy is currently under investigation in the PLCO trial, a 16-year randomized controlled trial of screening procedures for prostate, lung, colorectal, and ovarian cancer.

Most recommendations currently support a combination of annual FOBT and flexible sigmoidoscopy every 3 to 5 years. There is scant specific evidence for this schedule of screening, but many support the rationale that the combination provides improved surveillance of the entire colon.⁵¹

Considering the anatomic limitations of flexible sigmoidoscopy and the imperfect performance characteristics of FOBT, colonoscopy presents an attractive alternative for screening. Endoscopic visualization of the entire colon requires conscious sedation and has a somewhat higher complication rate (perforation in 1 of 1000 procedures), but it delivers a high sensitivity for small polyps (78.5%) and high specificity (98%) for all lesions.⁵¹ The performance of colonoscopy in selected patients over 80 years of age resulted in a complication rate comparable to the younger population.⁵⁵ Direct evidence for its use as a screening tool is still lacking, but observational data from the National Polyp Study and a large VA case-control study indicate a significant mortality benefit. Major questions remain, however, regarding the cost-

effectiveness and feasibility of widespread screening with colonoscopy. Newer radiologic studies may afford the same views using computed tomography (CT) scanning. These virtual colonoscopies are currently under study as diagnostic tools but may offer older patients a safer means of screening for colorectal cancer.⁵⁶

An alternative means of "total colonic" screening is air contrast barium enema. Although it has a lower complication rate than colonoscopy and comparable performance characteristics in large polyps (>1 cm) and cancers, its utility is limited by its insensitivity for small polyps (about 50% for polyps <1 cm) and lack of evidence for impact on mortality. Most experts feel that it is most appropriately employed in combination with flexible sigmoidoscopy for follow-up of positive FOBT in patients who cannot tolerate colonoscopy. This combination has achieved a sensitivity of 98%.⁵¹

Despite the available evidence that colorectal cancer is amenable to screening, compliance remains poor. Compliance with FOBT ranges from 30% to 90%. For flexible sigmoidoscopy, rates are estimated to be 30% to 50%. Predictors of participation include family history of colorectal cancer, female gender, and higher level of education and, specifically, knowledge of risks of colorectal cancer.⁵⁷ For flexible sigmoidoscopy, although patients admit to experiencing pain and embarrassment, most state that they would undergo the procedure again, considering its potential benefit.⁵⁸

Due to the different procedures available, recommendations for screening for colorectal cancer are varied. The American Cancer Society issued an updated set of recommendations in 2001. For adults over 50 years of age at average risk of colorectal cancer, one of the following maneuvers is recommended: (1) FOBT yearly, (2) flexible sigmoidoscopy every 5 years beginning at age 50, (3) a combination of annual FOBT and flexible sigmoidoscopy every 5 years (preferred to either test alone), (4) double-contrast barium enema every 5 years, or (5) colonoscopy every 10 years.⁵⁹ These guidelines set no upper age at which to suspend screening, suggesting instead that screening be continued as long as the elderly patient is in good health. Recent recommendations from the USPSTF and the Canadian Task Force strongly recommend screening for colorectal cancer in all average risk adults over age 50. Both organizations recognize that the strongest evidence exists supporting the use of annual or biennial FOBT and periodic flexible sigmoidoscopy. The USPSTF further indicates support for use of colonoscopy based on its superior diagnostic performance in examining the entire colon. (Table 32.3) A recent study also demonstrated the relative cost-effectiveness of all of these methods of colorectal cancer screening (less than \$30,000 per life year gained).^{91,92}

The authors recognize that screening for colorectal cancer has the potential to prevent an enormous amount

of morbidity and mortality. Considering the evidence available at this time, options 1, 2, or 3 listed above are valid screening regimens. If the patient has a life expectancy of 5 to 7 years, a discussion of the potential risks and benefits of the various options should ensue. If the patient accepts screening, then the provider should guide him or her in selecting a specific screening regimen, taking into account preferences for the use of initially invasive versus noninvasive techniques. With the high rate of proximal neoplasia in older patients, studies of the efficacy, safety, and cost-effectiveness of screening colonoscopy should be monitored carefully by those providing primary care for the elderly, because this strategy may become preferred in subsequent years.

Lung Cancer

Lung cancer is the leading cause of cancer-related death for both men and women in the United States. Each year, more people die of lung cancer than breast, prostate, and colon cancer combined. Lung cancer, traditionally a disease of men, is increasingly prevalent in women, and deaths from lung cancer now exceed those from breast cancer among women.⁶ In 2000, there were approximately 164,000 new cases of lung cancer, resulting in 157,000 deaths.^{5,6} The incidence rates for lung cancer increase with age, beginning at 40 years and peaking at about age 70 to 75 years. The incidence rates of lung cancer for men aged 65 and older is 481 per 100,000 compared with a rate of 24 per 100,000 in men under age 64.⁶ The incidence rate in women over age 65 is 253 per 100,000, a rate rapidly approaching the rate in men.⁶

Cigarette smoking is the major risk factor for developing lung cancer, and this risk dramatically increases with duration of tobacco use and the quantity of cigarettes smoked. Incidence rates for lung cancer are about 10 times higher in smokers versus nonsmokers.⁶⁰ Asbestos, radon gas, and several environmental agents (including chromate, nickel, polyhydrocarbons, and alkylating compounds) have also been demonstrated to increase lung cancer risk.^{61,62} Advanced-stage lung cancer is particularly lethal, with 5-year survival remaining under 2%.⁶ When lung cancer is localized at diagnosis, 5-year survival rate is 48%, a difference that affords a window of opportunity for screening. Surgical resection of localized cancer offers the only real potential for long-term cure.

Asymptomatic lung cancer can be detected by plain chest radiography or sputum cytology. Practically speaking, however, the discovery of "silent" lung cancer usually occurs during the investigation of a patient's nonspecific complaints (for example, cough, fatigue, weight loss). With both tests, there are problems of performance and interpretation that diminish their overall accuracy and

usefulness. Screening chest radiographs are hampered by operational problems (radiographic technique, exposure) and by problems in the interpretation of the radiograph itself. In fact, significant disagreement between radiologists often occurs.⁶³ Similarly, screening with sputum cytology has the difficulties associated with obtaining adequate sputum samples and the problems of pathologic interpretation of the sputum cells. Finally, both chest radiography and sputum cytology require the "reference standard" of tissue biopsy to confirm the screening test result. With these inherent problems, determining the sensitivity of these tests is very difficult. Additionally, because patients with negative tests rarely receive further evaluation, specificity is difficult to estimate.

The high incidence rate and poor prognosis of lung cancer prompted three randomized trials of mass screening to detect and treat early-stage disease in the United States. In the Memorial Sloan-Kettering trial,⁶⁴ 10,040 male smokers over age 45 were randomized to receive either annual chest radiography plus sputum cytology every 4 months or annual chest radiographs alone. The trial at Johns Hopkins⁶⁵ was designed identically with more than 10,000 participants. Both trials followed study participants for 6 years. There were no differences in the lung cancer survival rates between the screened and control populations.

The Mayo Clinic trial⁶⁶ had a different design but similar results. The 10,900 study participants, relatively few of which were over 65, were assessed initially with chest radiography and sputum cytology to detect prevalent cases of lung cancers. All subjects who did not have lung cancer were then randomized. A screened group received chest radiography and sputum cytology every 4 months for 6 years. The control group was advised at baseline to obtain annual chest radiography and sputum cytology, but this advice was not repeated. About 50% of the control group obtained chest radiographs during the follow-up period. More cancers were discovered in the screened group, slightly more lung cancer deaths in the screened group, and no significant differences in mortality rates between the screened group (13.2 deaths per 1000 person-years) and the control group (13.0 deaths per 1000 person-years).

Despite the disheartening results from these trials, new advances in diagnostic testing are being evaluated. Currently, the "new" technology for early detection of lung cancer is low-dose spiral computed tomography (CT). Two recent studies suggested that spiral CT is more sensitive for the detection of noncalcified pulmonary nodules and early lung cancers.^{67,68} Still, the test is not very specific, with a high false-positive rate. In the Early Lung Cancer Action Project, the positive predictive value of spiral CT was only 12% for detection of lung cancer.⁶⁷ These new studies have rekindled old controversies about the effectiveness of mass screening for lung cancer.

The full extent of the reemerging controversy for or against early detection of lung cancer was summarized in two recent papers.^{69,70} Relying on essentially the same scientific evidence, Petty asserted that it is now time to embark on mass screening,⁶⁹ while Frame cautioned that the technology is not yet of proven value.⁷⁰ Fortunately, the National Cancer Institute (NCI) has supported the design of a multicenter, randomized, controlled trial of 7,000 persons at high risk for developing lung cancer.⁷¹ The NCI is considering also an even larger trial with nearly 90,000 participants to evaluate whether these “new” technologies will reduce mortality from lung cancer.

Despite these recent studies, virtually all organizations (American Cancer Society, National Cancer Institute, U.S. Preventive Services Task Force, American College of Physicians, and the Canadian Task Force) concur that mass screening for lung cancer is not efficacious. However, elderly subjects were not adequately represented in the cancer screening trials even though they represent one of the highest risk groups. Whether selective screening for lung cancer in elderly smokers is useful remains to be established. Some studies suggest that lung cancer detected in older aged groups is more likely to occur at the local stage, and thus the possibility of surgical cure may be greater.⁷² Additional research is needed to assess the efficacy of selective screening in this targeted high-risk group. At present, no advisory society or task force recommends screening for lung cancer in any group with any test at any frequency (see Table 32.3).

Oral Cancer

There were an estimated 28,900 new cases and 7400 deaths from oral cancer in the United States in 2002.⁵ Two-thirds of the cases and 65% of the deaths occurred in men. The overall 5-year survival is poor and has not changed in the last 30 years. Five-year survival ranges from 21% for patients with distant spread at diagnosis to 81% for patients with localized disease.⁶ As with all cancers we have reported in this chapter, oral cancer incidence increases with advancing age. The age effect in incidence and mortality, however, is not as steep as it is for other cancers; both rates plateau by age 65. Persons over age 65 account for approximately 50% of all cases and a majority of all deaths attributable to oral cancer.⁷³ In addition to advancing age as a risk factor for developing oral cancer, men experience approximately twofold increased incidence compared to women. This gender difference is most likely attributable to the increased prevalence of smoking in men, although this is diminishing as smoking becomes equally prevalent in men and women. Other risk factors include excessive alcohol intake, use of smokeless tobacco, and family history of oral cancer.

Approximately 96% of all oral cancers are squamous cell carcinomas, implying that the majority of these cancers begin on the mucosal surfaces.⁷⁴ However, the natural history of oral cancer is not as well described as it is for other cancers. Leukoplakia and erythroplakia are two precancerous lesions that may progress to squamous cell carcinoma, although not all oral cancer arises from one of these lesions. The prevalence of leukoplakia ranges from 0.2% to 11%, depending on the patient population, while erythroplakia is rare with an incidence of less than 0.1%.⁷⁵ Good evidence concerning the rates of transformation to oral cancer for either of these lesions is lacking.

Arguments for screening for oral cancer involve detecting and treating leukoplakia, erythroplakia, or early-stage squamous carcinoma before more extensive local spreading. Early detection does improve survival, a fact that provides the main argument for proponents of mass screening. A 2-cm tongue squamous cell carcinoma has a 90% cure rate with radiation therapy or local resection, with minimal treatment-associated morbidity. A lesion about twice that size may require total glossectomy and radiation with a cure rate of only 20%.⁷⁶

Inspection and palpation of the oral cavity are the principal screening tests available for oral cancer. The reason that palpation is suggested in addition to inspection is that the majority of oral cancers arise on the lateral aspects of the tongue and on the floor of the mouth, making detection difficult with routine inspection. The recommended examination technique involves exploration of the oral cavity with a gloved hand using a gauze pad to retract the tongue and expose the ventral and posterolateral surfaces in addition to the floor of the mouth.⁷⁵ The sensitivity and specificity of this screening exam depend on the skill of the examiner and the criteria used to define a positive test. Maximum sensitivities have ranged from 71% to 81%, with specificity of 99% when screening is performed by dental practitioners.⁷⁷

Several researchers have attempted to improve the performance of the clinical examination by visual enhancement of cancerous or precancerous lesions with vital staining agents such as toluidine blue. The use of this agent may improve the sensitivity of the oral examination (as high as 100% in one study) but at the expense of lower specificity.⁷⁵ No organization currently recommends use of toluidine blue or other agents until further research is conducted.

Because of an incomplete understanding of the natural history of the precancerous lesion, the utility of population screening for oral cancer is in question. If all patients with leukoplakia were classified as positive screenees, significant overdiagnosis and potentially overtreatment would occur. Most researchers require stronger levels of evidence before adopting screening for oral cancer. Unfortunately, as Rodrigues and colleagues have pointed out, a study designed to detect a 20% difference in

mortality from oral cancer between a screened and unscreened group would require 1.4 million subjects.⁷⁵ It is unlikely that this large study will ever be done.

Until more definitive studies documenting the efficacy of the screening oral examination are published, there is insufficient evidence to warrant routine screening for all elderly patients, despite the increased risk in this population. Dentists should continue to examine elderly patients for evidence of oral cancer, although they will see only a minority of at-risk individuals. We believe that it is prudent for physicians to screen higher-risk elderly patients with a history of tobacco exposure or excessive amounts of alcohol. This recommendation mirrors the recommendation of the USPSTF. Despite the paucity of clinical evidence on the efficacy of oral examination, the American Cancer Society recommends a complete gloved oral examination as part of the routine cancer checkup (see Table 32.3).

Skin Cancer

Nonmelanoma skin cancer (NMSC), consisting of both basal and squamous cell cancers, is the most common cancer in the United States, with an estimated annual incidence of 800,000.⁷⁸ These cancers are readily diagnosed, highly treatable, and rarely metastasize. Basal cell carcinomas account for 80% of all NMSC.⁷⁹ They arise most commonly on the head and neck, although they can be found in sun-protected areas. Squamous cell carcinoma has a much higher proclivity for sun-exposed areas. Seventy-five percent of lesions are found on the face, 15% on the upper extremity, and 10% elsewhere.⁸⁰ Unlike basal cell carcinoma, squamous cell carcinoma has a higher tendency for metastasis (3%–11%). In a population-based study of NMSC, deaths from squamous cell carcinoma outnumbered deaths from basal cell carcinoma by 3:1.⁸¹ The incidence of both NMSC increases markedly with age because they are thought to be associated with cumulative lifetime sun exposure.

Malignant melanoma is less common than NMSC, but it carries a much graver prognosis and, accordingly, accounts for 75% of all skin cancer deaths. In 2002, approximately 53,600 new cases of melanoma were diagnosed and 7400 people died of their disease.⁵ The lifetime cumulative risk of developing melanoma is 1 in 90, making it the eighth most common cancer in the United States. More importantly, unlike many cancers, the incidence of melanoma has doubled in the past decade, and the incidence is not leveling off. Like many cancers, melanoma has a greater impact in older patients: 36% of cases and 54% of deaths from the disease occur in patients over age 65.⁶

Risk factors that increase the likelihood of developing both NMSC and melanoma have been established. For

NMSC, older age, fair complexion, prior NMSC, poor ability to tan, and cumulative lifetime sun exposure are identified risk factors.⁸² Similar risk factors increase the likelihood of developing melanoma. Recent research has extended risk factor assessment to develop personal risk factor scales that could be used in population-based screening. The MacKie risk factor flowchart has undergone the greatest degree of clinical evaluation.^{83,84} This flowchart asks patients to answer four questions: (1) Does your skin have freckles or tendency to freckling? (2) Does your skin have moles? (3) Does your skin have any large moles with irregular borders? and (4) How many times in your life have you had a bad sunburn (0, 1 or 2, 3+)? Primary care patients have been shown to provide reliable answers when compared with dermatologists' examination. In primary care practices, approximately 4% of patients fall in a very high risk category.⁸⁴ However, it has not been established that widespread use of this or any risk stratification flowchart reduces morbidity or mortality from any skin cancer.

There is evidence that treatment of early-stage NMSC and melanoma confers improved outcomes for patients identified early. Early treatment of NMSC reduces disfigurement and may improve quality of life. In malignant melanoma, survival is closely linked to the thickness of the tumor, termed Breslow thickness. Approximately 40% of patients present with thin tumors (<1.5 mm); their 5-year survival is 93%. For the 30% who present with midthickness tumors (1.5–3.49 mm), 5-year survival drops to 67%. Last, for the 30% of patients who present with tumor thickness greater than 3.5 mm, 5-year survival is only 37%.⁸⁵ Unfortunately, no study has been published that establishes the efficacy of screening for skin cancer.

The primary screening test available for detecting early-stage skin cancer is physical examination of the skin by a clinician. However, no data from experimental studies support the efficacy of any frequency of screening by any clinician in any risk group. The primary problem is that the disease is rare and the sensitivity and specificity of the skin examination are poor. Estimates of sensitivity (30%–98%) and specificity (45%–95%) of screening by dermatologists vary widely across different studies.^{86,87} Primary care clinicians who do not routinely evaluate skin lesions are no better than dermatologists: sensitivity, 57% and specificity, 88%.⁸⁸

Despite the lack of evidence establishing efficacy for skin examination as a screening test for any skin cancer, the American Cancer Society recommends monthly skin self-examination for all adults and annual skin examination by clinicians for all people over 40 years old.⁸⁹ The USPSTF concludes that there is poor evidence to support screening for skin cancer with any currently available modality (see Table 32.3). The National Institutes of Health Consensus Development Panel recommends skin self-examination and skin as part of the periodic health

examination.⁹⁰ Lastly the American College of Preventive Medicine issued a recent statement on skin cancer prevention and early screening. They state that high-risk individuals (based on family history, history of previous skin cancers, fair skin, or multiple nevi) should be screened periodically but that low-risk individuals cannot be recommended for screening.⁷⁹ They also state that physicians performing screening should receive adequate training to ensure high-quality examinations. The authors believe that the American College of Preventive Medicine's recommendation seems prudent for high-risk elderly. Until total skin examination is proven to be efficacious, the additional time and expense are not warranted. The frequency of any screening strategy has not been determined.

Summary

Screening for cancer has been an important component of comprehensive primary care for decades. Because most research projects designed to determine the efficacy of individual screening strategies require such large sample sizes and long follow-up periods, there is relatively little high-grade evidence to support specific screening strategies. Additionally, relatively few of the available studies enrolled a sufficient number of older patients to allow accurate generalization of efficacy to this population. Nevertheless, patients, providers, and health care systems are interested in screening. Additionally, there is epidemiologic evidence to support the importance of cancer as a leading killer in the elderly. In this chapter, we have summarized the evidence for or against screening for eight of the most common and deadly cancers. We find sufficient evidence to recommend screening for breast, cervical, and colorectal cancer. A decision to screen for prostate cancer requires individual discussions and cannot be justified in a blanket statement. We do not recommend screening for lung, ovarian, skin, or oral cancer at present. Providers should be encouraged to keep abreast of ongoing studies that will further direct the debate on screening for cancer in the elderly.

Breast Cancer

Ann Partridge and Eric Winer

Breast cancer is the most common malignancy in women in the United States, with more than 180,000 reported cases yearly.¹ Despite recent advances,^{2,3} more than 41,000 women per year die of breast cancer in the United States alone.¹ Other than female gender, age is the most important risk factor for the development of breast cancer. In the United States, women aged 65 years or older represent about 13% of the female population but account for nearly 50% of the newly diagnosed breast cancers.^{4,5} More than 60% of breast cancer deaths occur among women over age 65.^{5,6}

Despite the high prevalence of breast cancer among older women and the significant associated morbidity and mortality, researchers have only recently focused on treatment questions in this patient group. Most clinical trials and almost all randomized trials have included few women over age 65.⁷⁻⁹ Extrapolation of results of many clinical trials to the geriatric population must be done with caution because of potential differences in tumor biology, host physiology, and problems common among older patients, including comorbidity, impaired functional status, and lack of social support.

This chapter examines the epidemiology, natural history, treatment, and care patterns of breast cancer in the elderly. Screening issues, discussed in Chapter 16, are not covered here.

Epidemiology

Incidence and Mortality

In 2000, an estimated 182,800 women were diagnosed with breast cancer in the United States.¹ This figure represents approximately 30% of cancer diagnoses in women, with breast cancer ranking as the most frequently diagnosed cancer and the second leading cause of cancer death among women in the United States. The average American woman has a 12% lifetime risk of a personal

breast cancer diagnosis.¹⁰ The longer a woman lives without cancer, the lower her future risk of breast cancer. For example, a 50-year-old woman who has not had breast cancer has an 11% chance of having breast cancer in her lifetime; a 70-year-old woman has a 7% chance of developing breast cancer during the remainder of her life.¹⁰ However, these risks can increase dramatically depending on an individual's personal and family history. Although breast cancer can affect younger women, it is most commonly seen in women in their middle to later years. In women under age 30, breast cancer is extremely uncommon. The annual incidence rises precipitously with each decade until age 50, then more gradually as a woman enters her sixth, seventh, and eighth decades. Data from the surveillance, epidemiology, and end results (SEER) Program at the National Cancer Institute, a population-based data system consisting of nine separate state and local cancer registries that cover about 10% of the U.S. population, clearly demonstrate the relationship between age and incidence of breast cancer¹¹ (Table 33.1).

Despite the estimate that a U.S. woman has a 1 in 8 chance of developing breast cancer in her lifetime, a woman only has a 3.4% risk of dying of breast cancer.^{10,12} The majority of women diagnosed with breast cancer will not die of the disease. Approximately 80% of women with breast cancer can expect to survive at least 5 years following diagnosis. The survival rate has been increasing in recent years,^{2,3} largely because of improvements in screening for early disease and the use of hormonal and cytotoxic treatments for early and advanced disease (Fig. 33.1). There is no question that the use of adjuvant systemic therapy has made a real, although modest, impact on mortality as demonstrated by multiple randomized controlled trials. Despite an increasing incidence of breast cancer from the 1970s to 1997, the annual breast cancer mortality per 100,000 from 1987 to 1997 decreased by 19% among U.S. women aged 20 to 49, 18% for women aged 50 to 69, and 9% for women aged 70 to 79.² In 1997, the annual breast cancer mortality rate per

TABLE 33.1. Age and incidence of breast cancer.

Age group	Cases/100,000 person-years
25-29	7.4
30-34	26.7
35-39	66.2
40-44	129.4
45-49	159.4
50-54	220.0
55-59	261.6
60-64	330.7
65-69	390.7
70-74	421.8
75-79	461.4
80-84	451.3
≥85	411.9

Source: Data are from the Surveillance, Epidemiology, and End Results (SEER) Program (1984-1988).¹¹

100,000 U.S. women aged 70 to 79 was 112.5, compared to 10.8 and 65.0 among women aged 20 to 49 and 50 to 69, respectively.²

Conventionally, breast cancer in the elderly is thought to be a more indolent disease. However, several studies indicate that survival in older women (65 years of age and older) diagnosed with breast cancer is lower than in younger women.^{2,3,13-26} The reasons for decreased survival may be related to differences in tumor characteristics and patient factors. There are also differences in health care services received by older women compared to younger women, including differential screening and treatment for breast cancer. Several recent studies have revealed that the negative effect of age has diminished significantly after adjustment for other prognostic factors, such as extent of disease and treatment.²⁷⁻³¹

FIGURE 33.1. Recent decrease in U.K. and U.S. breast cancer mortality at ages 50-69 years. (From Peto et al., with permission.²)

Risk Factors

Identification of risk factors is important in explaining the variation in breast cancer incidence across different populations. Risk factors can also identify women who may benefit from increased surveillance or preventive treatments. Table 33.2 outlines the major established risk factors for breast cancer, which include family history of breast cancer, early age at menarche, late age at birth of first child, nulliparity, late age at menopause, benign breast disease with proliferative changes, radiation exposure, and hormone replacement therapy.^{10,12,32} Given the heightened risk of breast cancer with age, *all* older women should be considered at increased risk.

The relationship between exogenous hormone therapy and breast cancer risk may be of particular concern to older women and their physicians. Recent meta-analyses reveal small but statistically significant increases in risk (relative risks ranging from 1.02 to 1.35) of breast cancer among women exposed to hormone replacement therapy.³³⁻³⁵ Risk appears to increase with current use and longer duration of use; it also appears to be reduced after cessation of hormone replacement therapy. These findings are consistent with the evidence that post-menopausal women with higher concentration of endogenous estrogen levels have a greater risk of developing breast cancer than women with lower estrogen levels.³⁶⁻³⁸ Recent studies have also found statistically significant increases in risk in women taking both estrogen and progestin compared to those taking estrogen alone for hormone replacement therapy.^{39,40} The decision to use hormone replacement therapy is complex and should entail careful consideration of the risks, including baseline breast cancer risk in an individual and potential benefits.

There are several other less well established risk factors for breast cancer that have also been studied

TABLE 33.2. Established risk factors for breast cancer.

Risk factor	Relative risk
Age (≥50 vs. <50 years old)	6.5
Family history of breast cancer	
First-degree relative	1.4-13.6
Second-degree relative	1.5-1.8
Age at menarche (<12 vs. ≥14 years old)	1.2-1.5
Age at menopause (≥55 vs. <55 years old)	1.5-2.0
Age at first live birth (>30 vs. <20 years old)	1.3-2.2
Benign breast disease	
Breast biopsy (any histologic finding)	1.5-1.8
Atypical hyperplasia	4.0-4.4
Hormone replacement therapy	1.0-1.5
Radiation	1.7-3.0

extensively, including obesity, height, alcohol consumption, and oral contraceptive use.¹² Of these, moderate alcohol consumption has most consistently been associated with increased breast cancer risk.^{41–43} The influence of diet on breast cancer risk has attracted great interest. The large variation in international breast cancer incidence rates suggests a possible relationship between breast cancer and diet.

Many studies have examined the effects of specific dietary components on breast cancer risk. Despite the lack of evidence that specific components such as fiber or individual vitamins and minerals confer any significant protective effect, a diet high in fruits and vegetables may decrease breast cancer risk.^{44,45} Although national per capita fat consumption correlates with incidence and mortality from breast cancer, investigators have been unable to detect any relation between risk of breast cancer and total fat intake or consumption of specific types of fats.^{46–48}

Studies of the relationship between energy balance and breast cancer have been more revealing. Although being overweight during early adult life has been associated with a lower incidence of premenopausal breast cancer, weight gain after age 18 is associated with a significantly increased risk of postmenopausal breast cancer.^{49–51} The increased risk associated with weight gain and obesity in later adult life has been hypothesized to be due to the increased estrogen levels in these women secondary to increased production in adipose tissue.⁴⁹ Furthermore, these findings would appear to be consistent with the possible influence of physical activity on breast cancer risk. Limited evidence suggests that physical activity is protective against breast cancer.^{52–54} This benefit may occur because exercise influences body fat stores, the principal source of estrogen in postmenopausal women. However, to date, the association of physical activity and decreased breast cancer risk is more pronounced among premenopausal women.⁵²

With the exception of inherited susceptibility genes (see following), all the identified risk factors are associated with only weak to moderate increases in risk. Women without any identifiable risk factors still have a considerable lifetime risk of breast cancer (approximately 7% through age 80).³² All women may improve their overall health, perhaps decreasing breast cancer risk, by maintaining a healthy weight, avoiding cigarettes, limiting alcohol consumption, getting regular exercise, and avoiding nondiagnostic ionizing radiation. Nevertheless, no lifestyle modifications have been proven to prevent or definitively lower the risk of breast cancer.

Genetics and Risk

For years, investigators have attempted to understand the clustering of breast cancer that occurs in certain families.

Familial breast cancer has been characterized by an earlier average age of onset, an increased risk of bilateral disease, and an increased risk of ovarian cancer.⁵⁵ Mutations in two genes, BRCA1 and BRCA2, have subsequently been found to confer an inherited predisposition to breast and ovarian cancer. An estimated 5% of breast cancer cases are thought to be due to such mutations, and the lifetime risk of cancer in mutation carriers is high. In women with BRCA1 mutations, cumulative risk of breast cancer is estimated to be 3.2% by age 30, 19.1% by age 40, 50.8% by age 50, 54.2% by age 60, and 85% by age 70.^{56,57} Furthermore, BRCA1+ women who have had breast cancer have a 64% estimated cumulative risk of a contralateral breast cancer by age 70.⁵⁷ This risk is substantially increased from the estimated 1.0% annual risk of contralateral breast cancer for women with a history of sporadic breast cancer. In women with BRCA2 mutations, the risk of breast cancer appears to be similar to the risk among women with BRCA1 mutations.⁵⁷ More recent population-based studies^{58,59} have demonstrated lower, although still substantial, breast cancer risk ranging from 55% to 85% for BRCA1 carriers and 37% to 85% for BRCA2 carriers.⁶⁰

To date, no significant differences have been observed in terms of response to treatment between sporadic and inherited forms of breast cancer.^{61–64} However, two recent studies have suggested that the presence of a BRCA1/2 mutation in women with breast cancer with a strong family history or of Ashkenazi Jewish ethnicity may portend a worse prognosis.^{65,66} Further studies are necessary to confirm and extend these findings. As mutations of BRCA1 and BRCA2 have been identified, testing for these genetic mutations has become more common. This practice has led to recommendations for screening and prevention strategies for women with one of these mutations or with a high likelihood of having one.⁵⁷ These strategies, including more frequent and earlier screening, chemoprevention, or surgical prevention (prophylactic mastectomy), may make a substantial impact on the incidence and mortality of breast cancer in these populations. Ultimately, deciphering the functions of BRCA1 and BRCA2, which are assumed to have tumor suppressor functions, will lead to a better understanding of carcinogenesis and may lead to new strategies for therapy and prevention. Although known mutations of BRCA1 and BRCA2 are thought to account for only approximately 5% of all breast cancers, and an even smaller percentage among older women, this is still an important issue to consider in an older woman with breast cancer and a strong family history.

BRCA1 and BRCA2 are the first of what may be a series of breast cancer susceptibility genes. Other known although less common genetic syndromes that confer increased breast cancer risk include Li–Fraumeni syndrome, Cowden’s disease, Peutz–Jeghers syndrome,

Muir-Torre syndrome, and ataxia telangiectasia.^{60,67} These syndromes are associated with several other abnormalities and, in general, breast cancer appears earlier in life.

Biology and Natural History of Breast Cancer in the Elderly

Normal breast tissue changes with age. The dense fibrous and glandular breast tissue of early adulthood is replaced by increasing amounts of fat as a woman ages.⁶⁸ After menopause, there is further involution of the glandular structures. The fatty replacement simplifies mammographic screening in older women as there is better contrast between the density of a malignancy and the density of fatty tissue. With aging, there is also a decreased tendency to develop benign breast lesions.⁶⁸ The breast nodularity or fibrocystic change, occurring in response to cyclic hormonal changes in premenopausal women, rarely occurs in postmenopausal women unless they are receiving hormone replacement therapy. Gross cysts, which occur most commonly in women during the 15 years before menopause, are rare in the elderly. Fibroadenomas, most common between the ages of 20 and 35, are also rare in postmenopausal women. For these reasons, most newly developing breast masses in postmenopausal women are carcinomas.

Numerous studies have examined the relationship between age and extent of disease at time of breast cancer diagnosis. Stage at diagnosis is determined by two sets of factors: (1) tumor/host biology; and (2) patient/physician behavior surrounding the diagnostic process. Several studies have noted that older women have a higher likelihood of presenting with advanced disease.^{14,20,31,69,70} The largest database is from the SEER program, which includes more than 125,000 women with breast cancer¹⁴ (Table 33.3). These data indicate that a greater proportion of elderly women present with distant

TABLE 33.3. Stage distribution by age of breast cancer patients in the Surveillance, Epidemiology, and End Results (SEER) Program, 1973–1984.

Age group	Number	Localized disease, %	Regional disease, %	Distant disease, %	Stage unknown, %
<35	3,684	48.6	42.1	4.5	4.7
35–44	12,214	49.8	41.9	4.5	3.8

TABLE 33.4. Established prognostic factors for breast cancer and risk of recurrence.

Prognostic factor	Effect on risk of recurrence
Axillary lymph node involvement present	Increased
Size of the primary tumor (large)	Increased
Tumor histologic and/or nuclear grade (higher)	Increased
Lymphatic and vascular channel invasion present	Increased
Estrogen and/or progesterone receptor positive	Decreased
Her-2/neu overexpressed	Increased
Measures of tumor proliferation (higher)	Increased

disease, although a smaller proportion present with regional disease. The proportion of patients who present with localized disease does not vary with age and remains about half in all age groups.

Although there is little evidence that biologic differences in tumor or host account for stage differences in older and younger patients at presentation, there is evidence that patient/physician behavior surrounding the diagnostic process is different for older women. Older women are less likely to practice breast self-examination, obtain regular breast examinations from their physicians, or undergo screening mammography.⁷¹ Samet et al.⁷² conducted a population-based study of 194 women with breast cancer, 65 years or older at diagnosis, to examine factors associated with stage at presentation. Factors associated with an advanced stage at presentation included longer delay between initial symptom and seeking medical care, older age, absence of breast self-examination, and poor performance on a short test of knowledge about cancer. Of the women who were symptomatic at time of diagnosis, 29% had delay of at least 3 months between symptom onset and seeking medical care. Delay in seeking care was associated with a lack of social support, a relatively common problem among the elderly.

Established prognostic factors for localized breast cancer include number of involved axillary lymph nodes, size of the primary tumor, tumor histologic and nuclear grade, lymphatic and vascular channel invasion, estrogen and progesterone receptor status, Her-2/neu overexpression, and measures of tumor proliferation such as mitotic index, Ki-67, and percent of cells in S phase of the cell cycle⁷³ (Table 33.4). In general, poor prognostic factors are less common in breast cancers of older women. Information from several large databases indicates that older women with localized disease have a higher proportion of estrogen and progesterone receptor-positive tumors^{74–76} and a lower incidence of Her-2/neu overexpression.⁷⁷ The tumors of elderly women are more likely to be lower grade and have lower breast cancer cell proliferation rates.^{78–81} Several groups have reported an increased proportion of mucinous and papillary carci-

nomas, histologic subtypes with a favorable prognosis, among older women.^{14,68,82} These subtypes still account for less than 10% of breast cancers in older women, and the most common subtype in both older and younger women is infiltrating ductal carcinoma.

Age-related changes in the host may also have an effect on prognosis. In experimental animal models, some tumors behave less aggressively while others behave more aggressively in an older host.⁸³ Tumors that behave less aggressively tend to be those that are less immunogenic. Several investigators have proposed that immune senescence may be the cause of this altered tumor behavior with age. Cell-mediated and humoral immune responses to foreign antigens decrease with age. In experimental systems of less immunogenic tumors, manipulations that cause immunodeficiency actually inhibit tumor growth.⁸³ An intact immune system might actually be enhancing tumor growth, possibly through production of growth factors or tumor induction of suppressor T cells that block antitumor immunity. In contrast, highly immunogenic tumors in these same experimental models behave more aggressively in hosts with immune deficiencies and in older hosts. Most human tumors are thought to be relatively nonimmunogenic.

Although there is a subset of older women with early-stage disease who have exceptionally good survival,⁸⁰ older women have been found in general to have overall lower survival rates compared to younger women with breast cancer.^{2,3,13-26} Adami et al.¹⁶ examined the survival of 57,068 Swedish women diagnosed with breast cancer between 1960 and 1978. This database included about 98% of all cases diagnosed in Sweden during this period. The investigators found that relative survival declined markedly after age 49, and women over age 75 had the worst relative survival, although the results were not controlled for stage. Host and Lund examined the survival of 31,594 Norwegian women diagnosed with breast cancer between 1955 and 1980.¹⁷ This database includes almost all cases diagnosed in Norway during this period. After controlling for stage, the worst relative survival was found in patients over the age of 74 and in patients under the age of 35. In their analysis of the SEER data, Yancik et al. found that stage-specific relative survival is worse only for women aged 85 years or older diagnosed with metastatic disease.¹⁴

In summary, examination of prognostic factors and tumor pathology indicates that older women, as a group, have slower-growing, more indolent, and more hormonally responsive tumors and should have a better prognosis. However, despite these findings, older women appear to have lower relative survival compared with younger women. Older women have a higher likelihood of presenting with metastatic disease, and differences in survival exist even after controlling for stage. Differences in the screening and treatment of older women may account

for some of this discrepancy, and patterns of care are examined later in this chapter.

Prevention of Breast Cancer

Significant research over the past three decades has focused on the screening, early detection, and treatment of breast cancer. More recently, efforts have focused on primary prevention, particularly in women who are deemed to be at increased risk for the disease. Surgical prevention with bilateral mastectomy was the traditional approach, but there were no conclusive studies supporting the benefits of prophylactic mastectomy. More recently, Hartmann et al. have demonstrated, using a retrospective study design, that prophylactic mastectomies reduce the risk of breast cancer by approximately 90%.⁸⁴ A decision model suggests that prophylactic mastectomies could extend survival in young women with BRCA1 and BRCA2 mutations, but in older women prophylactic surgery will have little, if any, impact on survival.⁸⁵ Given the morbidity associated with prophylactic surgery, this is generally not an approach that should be considered in an older patient population.

In the National Surgical Adjuvant Breast and Bowel Project (NSABP) P1 trial,⁸⁶ tamoxifen significantly decreased the risk of both invasive and noninvasive breast cancer by approximately 50% compared to placebo at 55-month median follow-up. Eligibility for the trial was based on a breast cancer risk score calculated by the Gail Model,³² and, given the increased risk of breast cancer with age, all women over the age of 60 were eligible to participate. The reduction in risk was seen in all groups regardless of age at enrollment; 30% of the participants were over 60 years of age and 6% were over 70. Unfortunately, tamoxifen therapy was associated with significantly increased risks of thromboembolic disease and endometrial cancer.⁸⁶ These risks are substantially higher in women over 50 than in women under the age of 50 and alter the therapeutic index of tamoxifen as a preventive agent in older women.⁸⁷ In moderate-risk white women, the risks associated with tamoxifen are greater than the benefits after age 60, and in moderate-risk black women, the risks exceed the benefits by age 50. In general, the risk/benefit analysis of tamoxifen for the prevention of breast cancer weighs strongly against recommending that older women take tamoxifen for primary prevention unless they are at extraordinary risk of breast cancer in the next 5 years.⁸⁷ Because the majority of breast cancer occurs in women over age 60, alternative chemoprevention strategies are desirable.

Other potential hormone-based strategies under consideration include newer selective estrogen receptor modulators (SERMs) and, for postmenopausal women, estrogen deprivation with agents that inhibit aromatase,

the critical enzyme in conversion of androgen precursors to estrogen in adipose and breast tissue.⁸⁸⁻⁹⁰ Currently underway is the NSABP-P2 trial, the STAR trial, which compares the efficacy and adverse effects of tamoxifen with raloxifene, another SERM not associated with an increased risk of endometrial cancer but with similar risk of thromboembolic disease.^{91,92} Other studies are underway assessing the risks and benefits of aromatase inhibitors in the prevention of breast cancer in high-risk postmenopausal women.⁹³

Treatment

Disease status, comorbidity, life expectancy, patient preferences, and goals of therapy should guide treatment of an older patient with breast cancer. These decisions should be made with an understanding of the treatment regimens that have been shown to improve survival or quality of life. Numerous advances have been made over the past 30 years in the treatment of breast cancer. Both local and systemic therapy have changed substantially during this time, guided by the results of large randomized clinical trials, often performed through large cooperative groups. Because most randomized clinical trials in breast cancer have not included patients over the age of 70, cautious extrapolation of the results to older women is often necessary.

A woman's likelihood of dying of breast cancer versus other causes can be assessed with competing risks analysis.⁹⁴ When devising rational treatment plans for an older woman with breast cancer, one must consider not only her risk of disease recurrence as influenced by disease stage, tumor grade, and hormone receptor status, but also her life expectancy as determined by age and comorbidity. Life expectancy for women in Western societies is approximately 15.5 years at age 70 and 9.2 years at age 80⁹⁵ (Table 33.5). As one might expect, comorbidity is a significant risk factor for shortened life expectancy in women with breast cancer.⁹⁶⁻¹⁰⁰ Satiriano and colleagues

revealed that among breast cancer patients identified through the Metropolitan Detroit Cancer Surveillance System, 3-year mortality was four times higher in women with three or more comorbid conditions when compared to women with no comorbid illness.¹⁰⁰ In women aged 55 to 84 years, those who died within 2 years after assessment of comorbidity were more likely to have reported one or more comorbid conditions than were survivors (62% versus 38%).⁹⁸ Furthermore, the greater the number of comorbid illnesses, the higher the risk of death from all causes, including breast cancer, independent of age and stage of disease.^{98,101} Because the number of comorbid conditions tends to increase with age, older women with breast cancer are at increased risk of dying of nonbreast cancer-related causes. Fish et al.⁹⁴ analyzed 678 patients diagnosed between 1971 and 1990. Among women who died, 20% of women over age 65 died of causes other than breast cancer compared to 3% of women under age 65.

In the following sections, we review current breast cancer treatment recommendations, focusing on the data available regarding older patients and relevance of existing studies to breast cancer in the elderly.

Ductal Carcinoma In Situ (Intraductal Carcinoma)

Ductal carcinoma in situ (DCIS) in a noninvasive form of breast cancer in which tumor cells are confined to the ductolobular system and surrounded by an intact basement membrane. If left untreated, DCIS has a substantial risk of evolving into invasive ductal carcinoma of the breast. Currently in the United States at least 12% to 15% of newly diagnosed breast cancer cases annually are DCIS.¹⁰² There was a marked increase in DCIS incidence beginning in the early 1980s, correlating with the widespread use of mammography for screening.^{103,104} Average annual increases in rates between 1973 and 1983 and between 1983 and 1992 changed from 5.2% to 18.1% among women aged 50 years or older, compared to 0.3% to 12.0% among women aged 30 to 39 years and 0.4% to 17.4% among women aged 40 to 49 years.¹⁰³ Because DCIS cannot cause serious morbidity in and of itself, the major issue in the management of DCIS is the risk of progression to invasive breast cancer. Although many women with DCIS will ultimately develop invasive disease, not all untreated DCIS will go on to become invasive breast cancer in a woman's lifetime.¹⁰⁵ This issue is particularly important when considering the treatment of DCIS in an older woman with a potentially limited life expectancy.

In the past, mastectomy was the standard treatment for DCIS. In light of the success of breast-conserving surgery

TABLE 33.5. Average remaining life expectancy at age 55 years and beyond.

Age (year)	Life expectancy, males and females (years)	Life expectancy, females (years)
55-60	25.1	27.2
60-65	21.1	23.1
65-70	17.5	19.2
70-75	14.2	15.5
75-80	11.2	12.2
80-85	8.5	9.2
≥85	6.2	6.6

with radiation for invasive disease, there has been great interest in breast-conserving therapy with or without breast irradiation for the treatment of DCIS. NSABP protocol B-17 demonstrated that overall local recurrence rate for patients treated with excision alone was 27% at 8 years compared to 12% for those patients treated with excision plus radiotherapy.¹⁰⁶ Despite the improvement in local recurrence, there was no evidence that survival was compromised in the group that did not receive radiation. The use of tamoxifen as adjuvant therapy for DCIS has also been evaluated. In NSABP protocol B-24,¹⁰⁷ treatment with tamoxifen after breast-conserving therapy yielded a further reduction in breast cancer events (8.2% versus 13.4%; $p = 0.0009$) including recurrence of noninvasive disease and development of invasive disease. Once again, despite the decreased risk of breast recurrence, there was no impact of tamoxifen on survival. Several recent studies have revealed that older women with DCIS have a significantly decreased risk of recurrence than younger women after local therapy,^{108,109} perhaps due to increased surgical margins obtained among older women.¹⁰⁹ Although radiation and tamoxifen are both considerations for the treatment of an older woman with DCIS, the option of wide excision alone remains a reasonable choice, particularly for patients with low- to intermediate-grade DCIS with clear margins.¹¹⁰ Although tamoxifen is a consideration, the absence of a survival benefit and the increased risk of complications (thromboembolic disease and endometrial cancer) with tamoxifen mandate careful consideration of the risk and benefits of tamoxifen in an older woman with DCIS.

Invasive Breast Cancer: Early-Stage Disease

Local Therapy

Local treatment refers to treatment directed at the breast and regional lymph nodes. Local treatment alone can be curative in the majority of patients with stage I breast cancer and a substantial proportion of women with stage II and III disease. Table 33.6 presents breast cancer staging by the American Joint Committee on Cancer.

The two principal options for local treatment of early-stage breast cancer are mastectomy and breast-conserving surgery combined with breast irradiation. With either option, assessment of lymph node involvement is usually performed, either by full axillary node dissection or a sentinel lymph node biopsy. Several large randomized studies have compared mastectomy to breast-conserving surgery followed by radiation therapy.^{111–114} These studies have revealed no difference in distant disease-free survival or overall survival between women who had a mastectomy compared to those who received breast-

TABLE 33.6. Breast cancer staging.

Stage	Definition
Stage I	Primary tumor ≤ 2 cm without axillary lymph node involvement
Stage II	Primary tumor > 2 cm and ≤ 5 cm with or without axillary lymph node involvement Primary tumor ≤ 2 cm with axillary lymph node involvement Primary tumor > 5 cm without axillary lymph node involvement
Stage III	Any primary tumor size with fixed axillary lymph nodes Primary tumor directly extending to chest wall or skin with or without axillary lymph node involvement Any primary tumor size with internal mammary lymph node involvement
Stage IV	Presence of distant metastases including supraclavicular lymph node involvement

conserving therapy. Based on these studies, the 1990 National Institutes of Health Consensus Development Conference on the Treatment of Early-Stage Breast Cancer concluded that, when possible, breast-conserving surgery combined with axillary lymph node dissection and postoperative radiation therapy is the preferred treatment for patients with early-stage breast cancer because it provides equivalent survival rates while preserving the breast.¹¹⁵ No change was made in this recommendation at the 2000 Consensus Conference.¹¹⁶ Although the four trials referenced above enrolled a total of 3947 patients, few of these women were over age 65 and none were over age 70. There are no compelling reasons, however, to believe that the relative efficacy of these two treatment strategies would be different in older compared to younger women.

In a retrospective study comparing women age 65 years and older to younger women, Merchant et al.¹¹⁷ found that breast-conserving surgery plus radiation results in local failure rates at 10 years of 4% versus 13%, disease-free survival of 72% for both groups, and overall survival of 82% and 84%, respectively, despite significantly less aggressive adjuvant therapy among the older women in this study. In general, elderly patients tolerate breast surgery well and even with general anesthesia have little documented postoperative morbidity and mortality.^{118–120} Furthermore, both breast-conserving surgery and mastectomy can be performed under local anesthesia with mortality rates approaching zero. Comorbid illness rather than age appears to be the main factor influencing surgical morbidity.^{14,20,101}

Studies of quality of life and functional outcomes following breast cancer surgery have revealed that perceptions of body image are better among women who have undergone breast-conserving surgery rather than

mastectomy. There does not appear to be excess concern about recurrence in women who opt for conservative surgery in lieu of a mastectomy.^{121–124} Although these findings are largely from younger women, there is no reason to believe that this would be significantly different in older women. Investigators have shown that older women prefer and are more likely to choose breast conservation over mastectomy.^{125,126} Sandison et al.¹²⁵ found that 34 of 38 women aged 70 or older who chose their own treatment had breast conservation and only 4 opted for mastectomy. Importantly, only 2 women in this study were unhappy with their choice of treatment at 12-month follow-up. Evaluating quality of life in a group of older women undergoing breast cancer surgery, Vinokur et al.¹²⁷ found that more extensive surgery was associated with greater physical impairments following surgery.

Radiation Therapy Following Breast-Conserving Surgery

Breast irradiation following breast-conserving surgery significantly decreases the risk of recurrence in the breast. In the NSABP B-6 trial, breast irradiation following breast-conserving surgery in women age 70 or younger decreased the local recurrence rate from 39% to approximately 10%.¹¹⁴ The Milan group confirmed the risk reduction with breast irradiation, revealing that 0.3% of women in their study developed local recurrence after radiation compared to 8.8% of women who did not receive adjuvant radiation therapy with median follow-up of 39 months.¹²⁸ Despite the significant improvement in local recurrence rates, the omission of radiation therapy following conservative surgery does not appear to compromise survival. Among older women, there have been conflicting reports regarding the benefits of adjuvant breast irradiation. There is some evidence that the risk of recurrence in the breast decreases with age, with recurrence rates reported as less than 4% in older women after breast-conserving surgery without radiation.^{128,129} Other studies have shown a risk of recurrence of more than 20% in elderly patients who do not receive adjuvant radiation after lumpectomy or partial mastectomy.^{130–132} The Cancer and Leukemia Group B has completed accrual to a trial designed to test the value of radiation in older women, but there are no results available at this time. Although radiation therapy may provide only modest benefit in older women, breast irradiation should not be omitted based on advanced age alone in the absence of additional findings from clinical trials. Importantly, breast irradiation appears to be well tolerated in older women.¹³³ On the other hand, it is reasonable to consider omitting breast radiation in an individual of any age who has multiple comorbid conditions and is unlikely to survive more than a few years.

Axillary Lymph Node Assessment

Axillary nodal status is the single best predictor of overall survival in women with breast cancer. The presence or absence of lymph node involvement has been an important determinant for the use of systemic adjuvant treatment. An axillary dissection also reduces the risk of axillary recurrence as a result of removing lymph nodes that contain cancer.¹³⁴ Unfortunately, axillary lymph node dissection increases the risk of postoperative complications, including lymphedema, and increases the morbidity, hospital stay, recovery time, and cost of surgery.^{135–137} Research to date has been conflicting regarding the impact of age at diagnosis on late complications after full axillary nodal dissection. Two studies^{138,139} have reported older age at diagnosis to be a significant factor while a more recent study¹⁴⁰ found younger age to be a risk factor for lymphedema, and yet another study¹³⁵ revealed that age was unrelated to lymphedema incidence.

Using the newer sentinel node technique, a surgeon can identify patients with negative lymph nodes without performing a full axillary lymph node dissection. Sentinel lymph node biopsy entails injecting blue dye or radiolabeled colloid in the area of the breast lesion and following it out to the first lymph node that drains the cancerous area, the “sentinel” node. This lymph node, or a small group of nodes, is then assessed for tumor involvement. The status of the sentinel node can be used to predict the status of the remaining nodes in the axilla. However, the procedure can be technically challenging, and the success rate varies according to the surgeon and the characteristics of the patient.¹⁴¹ When performed by experienced surgeons, the sentinel lymph node technique is minimally invasive and highly accurate. It can be performed successfully in more than 90% of eligible breast cancer patients, and the tumor status of the sentinel node accurately predicts the status of all axillary nodes in more than 95% of cases.^{137,141–144} It should be noted that sentinel node biopsy is appropriate only for patients with a clinically negative axilla. Sentinel lymph node evaluation has been shown recently to provide accurate staging in elderly patients as well as younger women.¹⁴⁵

The question of whether any form of axillary surgery (sentinel biopsy or a full dissection) is necessary has arisen based in part on studies assessing the utility and efficacy of node dissection in older women.^{146–148} For an increasing number of patients, systemic treatment decisions will not be affected by nodal status. In older women with breast cancer, decisions about the use of tamoxifen or chemotherapy can often be made based on the size and characteristics of the primary tumor. Although some women desire axillary dissection to obtain prognostic information, others will be content without this information if they can be spared surgery to the axilla and the potential associated morbidity. In women who have had

conservative surgery and have a clinically negative axilla, axillary irradiation can be administered at the same time as breast irradiation to prevent axillary recurrence.^{134,146-149} The evaluation and management of the axilla has become increasingly complex in recent years. The options are varied, and physicians should carefully consider the treatment goals and a patient's preferences in the decision-making process.

Alternative Management Strategies for Local Disease

For most older women, treatments offered should be similar to those considered for younger women. However, alternative, less aggressive approaches to local therapy have been sought for older women, particularly for those in whom life expectancy is very limited or who are unable or unwilling to undergo standard therapy. Surgery or tamoxifen alone have been compared to each other and to combination therapy as the primary treatment for localized breast cancer in older women. Tamoxifen alone has been studied extensively as the initial treatment.¹⁵⁰⁻¹⁶²

In general, tamoxifen instead of surgery for localized breast cancer results in an initial response rate up to 70%. The median time to response is approximately 3 months (range, 5-124 weeks), and responses can be durable in a large number of patients.^{101,156,157} Relapse rates with tamoxifen alone are high, however, and additional local therapy is necessary in more than 50% of patients. In a recent series, Ciatto and colleagues¹⁶² reported on 120 women over age 69 treated initially with tamoxifen alone. After at least 6 months treatment, they report complete responses in 12 patients, partial response in 46 patients, and minor response or stable disease in 53 patients. Progressive disease was observed in 9 patients. Response duration was limited, and progression was observed increasingly over time. After 12 months, more than 50% of subjects were still showing response to treatment, which decreased to approximately 30% at 60 months follow-up. In a subset of 27 subjects, treatment response was strongly associated with tumor estrogen receptor content, progression being 100%, 43%, or 6% in subjects with 0%, 30% to 60%, or more than 60% immunostained cells, respectively.

When tamoxifen has been compared to surgery with or without tamoxifen,^{153-155,160,161} survival rates are not significantly different among patients who did not undergo surgery (ranging from 66% to 88% after 2 to 6 years for both groups). However, local recurrence rates are more common among patients treated with tamoxifen only, up to 56% in one series compared to 44% with surgery alone after 6 years follow-up.¹⁶⁰ In the short term, tamoxifen

appears to provide an acceptable alternative to surgical therapy in the older patient with early-stage hormone receptor-positive breast cancer. With longer follow-up, however, tamoxifen only delays surgical therapy for the majority. Primary management of early-stage disease with tamoxifen alone should probably be reserved for patients who have a very limited life expectancy or for patients who refuse surgical intervention. However, limited surgery without axillary dissection plus adjuvant tamoxifen may achieve a local regional control rate in older women comparable to that obtained with more aggressive strategies.¹²⁶

Alternative regimens of radiation therapy including weekly schedules have been considered for older patients who may be unable or unwilling to undergo daily radiation treatments or primary surgery. In two small retrospective analyses,^{163,164} weekly high dose per fraction breast irradiation was well tolerated in older women and resulted in encouraging local control rates. Treating 70 older women (median age, 81 years) with all stages of disease with daily tamoxifen and weekly radiation, Maher et al.¹⁶⁴ reported an overall survival rate of 87%, disease-specific survival rate of 88%, and disease-free survival of 72% at a median follow-up of 36 months. The local control rate was 86% at 36 months. Based on such encouraging preliminary data, alternative radiation schedules should be explored further in clinical trials.

Adjuvant Systemic Therapy

Despite advances in local therapy, a substantial proportion of women with early-stage disease will not be cured with local treatment alone. Ten-year disease-free survival rates for patients treated with radical mastectomy alone are shown in Table 33.7. Despite optimal local therapy, many women develop distant disease over time, presumably because micrometastases have already spread to other parts of the body from the original breast tumor. Adjuvant systemic therapy attempts to eradicate this sub-clinical disease and improve disease-free and overall survival. The principal options for adjuvant therapy are hormonal treatment (tamoxifen) and cytotoxic chemotherapy.

Well over 100 randomized clinical trials examining adjuvant therapy for early-stage breast cancer have been

conducted worldwide. Large meta-analyses of adjuvant trials were updated in 1995.^{165,166} The most recent publication of the Early Breast Cancer Trialists' Collaborative Group included 124 randomized trials beginning before 1990 from which primary data could be obtained, including data on more than 67,000 women. In general, tamoxifen treatment substantially reduced proportional mortality at 10 years by up to 26% among all women with estrogen receptor-positive (ER-positive) and ER-unknown tumors. Importantly, tamoxifen had essentially no impact on disease-free and overall survival in women

whose tumors were estrogen receptor-negative. Adjuvant chemotherapy also substantially reduced risk of recurrence and mortality in all age groups. Among women under 50, chemotherapy results in a proportional reduction in mortality of 15% to 27%, whereas among women age 50 or older, the proportional reduction was of the order of 8% to 14%. Thus, overall, adjuvant chemotherapy and hormonal treatments result in significant improvements in disease-free and overall survival (Fig. 33.2). Unfortunately, despite adjuvant therapy, a significant number of women will relapse and ultimately die of breast cancer. Thus, decisions about adjuvant therapy should be based on the risk of recurrence, and proportional risk reduction with specific therapies balanced with toxicities of therapy, life expectancy, and patient preferences.

Tamoxifen

Tamoxifen is an oral synthetic antiestrogen. It is believed to exert its antiestrogenic activity primarily by competitively blocking the binding of estradiol to the estrogen receptor.¹⁶⁷ When estrogen combines with the estrogen receptor in the cell nucleus, stimulation of cell growth occurs, as well as production of growth factors that function by autocrine and paracrine mechanisms. Breast cancer cells treated with tamoxifen accumulate in the G₀/G₁ stages of the cell cycle.¹⁶⁷ Tamoxifen is generally considered to be cytostatic rather than cytotoxic, although the significance of this distinction is often overemphasized. Tamoxifen also has nonestrogen receptor-mediated antitumor effects.^{168,169} In the treatment of metastatic disease, tamoxifen has demonstrated substantial activity, particularly in patients with hormone receptor-positive tumors.

Most randomized trials of adjuvant tamoxifen have included some older women. Of the 37,000 women participating in the Oxford overview analysis of tamoxifen,¹⁶⁵ approximately 34% were age 60 or older and approximately 7% were over age 70. The proportional reductions in risk of recurrence and death with tamoxifen were similar across all age groups (Table 33.8), with

TABLE 33.8. Adjuvant tamoxifen in postmenopausal women (after exclusion of women with ER-poor disease): data from the 1998 overview analysis.

Age group (years)	Number of patients		Proportional reduction in recurrence (SD)	Proportional reduction in mortality (SD)
	5 years tamoxifen	Controls		
50–59	1285	1251	37% (6)	11% (8)
60–69	1606	1568	54% (5)	33% (6)

benefits increasing with increasing duration of tamoxifen therapy up to 5 years. Based on the overview and randomized trials that have compared 5 years of tamoxifen treatment with a shorter duration,^{165,170,171} 5 years of treatment has become the standard of care for patients with ER-positive breast cancer. There is also the suggestion that longer duration of therapy is of no additional benefit,¹⁷²⁻¹⁷⁴ although two worldwide trials addressing this issue are ongoing.

The absolute benefits from tamoxifen are dependent on a patient's risk of recurrence and the proportional reduction in recurrence achievable with tamoxifen (up to 50% with 5 years of therapy). Two randomized trials have examined adjuvant tamoxifen therapy specifically in women 65 years of age or older who had one or more positive axillary nodes.^{175,176} Both trials demonstrated significant improvements in disease-free survival in patients who received tamoxifen, despite competing causes of mortality in this older population. Among women with negative axillary lymph nodes, the benefits of tamoxifen have also been demonstrated,¹⁷⁷ although the absolute risk reduction is generally smaller because the risk of recurrence is lower in such women.

Tamoxifen may have beneficial effects apart from reducing the risk of breast cancer recurrence. Five years of tamoxifen has been shown to reduce the occurrence of contralateral breast cancers by up to 50%, consistent with its preventative effects in women at high risk for breast cancer.^{86,165} The beneficial effects of tamoxifen on breast cancer prevention and risk reduction are thought to be secondary to the antiestrogenic effects of tamoxifen. Other antiestrogenic effects of tamoxifen include vasomotor symptoms and vaginitis.

Because it is a mixed estrogen antagonist and agonist, tamoxifen also has some estrogenic effects. The estrogenic activity is manifested as lowering of serum lipid levels, decreased rate of bone mineral loss, and stimulation of endometrial proliferation. It is not clear whether the effects on the bones and blood lipids can lead to clinically relevant improvements in fracture rates or cardiovascular mortality. It is clear that tamoxifen use leads to a significant although small increased risk of endo-

metrial cancer, deep venous thrombosis, and pulmonary embolism. There is also some excess incidence of cataract development among tamoxifen users.^{86,87} Thus, the benefits of tamoxifen must be balanced against the risks for a given individual. Although tamoxifen is generally well tolerated, common side effects include menopausal symptoms, such as hot flashes, and gynecologic symptoms, including vaginal discharge.¹⁷⁸ Importantly, many other symptoms commonly reported by women on tamoxifen, including psychologic symptoms, weight gain, and changes in overall quality of life, have been found to be not significantly different from placebo in large double-blinded studies.^{86,178}

Chemotherapy

The role of adjuvant chemotherapy in older women is controversial. Although earlier trials showed minimal benefit in older women, recent larger trials and the Oxford overview analyses have revealed that adjuvant chemotherapy results in modest benefits in postmenopausal women (Table 33.9). In the most recently published overview analysis,¹⁶⁶ there were too few women in the 70 and older age group to draw conclusions about chemotherapy in this population, and few randomized trials have included many women over 70 years of age. Among women aged 50 to 69 years, chemotherapy for women with estrogen receptor-negative tumors resulted in a reduction in the risk of recurrence of 30% ($\pm 5\%$) compared to a reduction of 40% ($\pm 7\%$) in women less than 50 years of age. For women with estrogen receptor-positive tumors who will also benefit from tamoxifen, chemotherapy resulted in a decrease in the risk of recurrence of 18% ($\pm 4\%$) among women aged 50 to 69 years compared to 33% ($\pm 8\%$) proportional risk reduction in women less than 50 years of age.^{166,179}

An important question for older women with ER-positive tumors is whether adjuvant chemotherapy adds anything to the benefits of tamoxifen. The overview analysis, as well as individual studies, have demonstrated that combination therapy with tamoxifen and chemotherapy is better than the use of either treatment alone in

TABLE 33.9. Adjuvant polychemotherapy for breast cancer: data from the 1998 overview analysis.

CA: cytoxan and adriamycin	3 months
CA-T: cytoxan and adriamycin, followed by taxol	6 months
CAF: cytoxan, adriamycin, 5-fluorouracil	4–6 months
CEF: cytoxan, epirubicin, 5-fluorouracil	4–6 months

women with estrogen receptor-positive tumors.^{166,180,181} In the overview, combination therapy resulted in an overall reduction in the risk of both recurrence and death of 19% ($\pm 3\%$) and 11% ($\pm 4\%$), respectively, among women aged 50 to 69 compared to tamoxifen alone. Because the benefits of chemotherapy appear to decrease with age,¹⁶⁶ however, the absolute incremental benefit of chemotherapy added to tamoxifen in older women with hormone receptor-positive tumors may be relatively small. In women with ER-positive disease of all ages, combination chemotherapy and tamoxifen resulted in a reduction in risk of recurrence and death of 52% ($\pm 8\%$) and 47% ($\pm 9\%$) respectively, compared to chemotherapy alone.^{165,166,182} The overview analysis also suggested that anthracycline-containing chemotherapy regimens are superior to non-anthracycline-containing regimens.¹⁶⁶ However, concern about the inherent risk of cardiotoxicity with anthracycline-based chemotherapy mandates careful consideration of its use in older women in the adjuvant setting. Table 33.10 lists the standard adjuvant chemotherapy regimens for breast cancer.

The benefits of chemotherapy must also be weighed against the risks. The acute toxicities of standard chemotherapy regimens have been well studied, although largely in younger patient populations.¹⁸³ These toxicities are generally short term in nature. Some degree of nausea with or without vomiting is common but usually controllable with modern antiemetics. Mild mucositis is occasionally seen, although it is almost never severe. Myelosuppression is nearly universal; however, a systemic infection occurs in less than 5% of patients. Total alopecia will occur in almost all patients who receive an anthracycline-based regimen (including doxorubicin or epirubicin), compared to approximately 50% of patients who receive CMF (cyclophosphamide, methotrexate, and 5-fluorouracil). Weight gain is also not uncommon among women who receive adjuvant chemotherapy. Addition of paclitaxel to adjuvant chemotherapy results in an incidence of severe neuropathy of less than 5%. An increased risk of thromboembolic disease has been observed in patients receiving chemotherapy, particularly when it is given concurrently with tamoxifen. Long-term risks include a risk of less than 1% of cardiotoxicity resulting in congestive heart failure with anthracycline-

based therapy, as well as a very small risk of treatment-related leukemia. It is unclear whether these risks are increased further among older women, although the risk of cardiotoxicity is increased in patients with cardiac disease, which is more common in older women.

The addition of the new biologic therapy, trastuzumab (Herceptin), to adjuvant regimens is currently being studied. Trastuzumab is a humanized monoclonal antibody to the Her-2/neu receptor, which is overexpressed in about one-third of breast cancers.¹⁸⁴ The use of trastuzumab alone and in combination with chemotherapy has resulted in significant disease responses and improvements in overall survival among women with Her-2/neu-overexpressing metastatic disease.¹⁸⁵ There is no reason to believe that trastuzumab would not benefit women of all age groups with Her-2/neu-positive tumors, and the treatment is generally well tolerated, although there may be an increased risk of cardiac problems in elderly.¹⁸⁶ However, older women have Her-2/neu-positive tumors much less frequently than younger women.⁷⁷

It is widely assumed that older patients are less tolerant of chemotherapy than younger patients. Although a few small studies have reported significantly increased toxicity in the elderly, larger recent studies provide evidence to the contrary. Crivellari et al.¹⁸⁷ studied the burdens and benefits of adjuvant CMF and tamoxifen in elderly women. In this group, the 76 women aged 65 years or older had higher grades of toxicity, including hematologic and mucosal toxicity, than younger women. The subjective burdens of treatment, however, were similar for older and younger patients based on quality of life measures. Begg and Carbone¹⁸⁸ examined 19 Eastern Cooperative Oncology Group studies that included a total of 780 patients aged 70 years or older. These patients were compared with patients under age 70. Older patients had increased hematologic toxicity; otherwise, the incidence of severe toxicities was similar between groups. Giovanazzi-Bannon and colleagues¹⁸⁹ examined data from the Illinois Cancer Center database on the 672 patients treated in phase II trials, including 271 patients aged 65 or older. Except for experiencing slightly more hematologic toxicity, there were no differences in incidence of other toxicities, dose reductions, or length of treatment delays between the two groups.

In a more recent study, Dees and colleagues¹⁹⁰ treated 44 women ages 35 to 79 with early-stage breast cancer with four cycles of adjuvant AC (adriamycin and cyclophosphamide) chemotherapy. In this cohort, although myelosuppression was increased in older women, neither neutropenic complications, nor alteration in cardiac function, nor change in quality of life scores were significantly age-related. Pharmacokinetic analyses did not demonstrate age-related differences in the clearance of doxorubicin or cyclophosphamide. Although patients in these studies may represent a highly selected group, it

is reassuring that the older patients appear to tolerate chemotherapy nearly as well as the younger patients.

Summary

Decisions regarding adjuvant therapy should take into account a woman's risk of disease recurrence, her life expectancy, the benefits and risks of each treatment, and her preferences. Adjuvant tamoxifen clearly reduces the risk of recurrence and death in older women, although the benefits are limited to women with hormone receptor-positive tumors. Five years of tamoxifen has a favorable side effect profile and should be considered for all older women with hormone receptor-positive tumors. Adjuvant chemotherapy appears to reduce the risk of recurrence and death in women under the age of 70. To date, there is not enough information about women age 70 and older to make definitive conclusions regarding the benefits of chemotherapy in this population. Chemotherapy should be considered in this age group if the tumor is hormone receptor negative or in the setting of a high risk of disease recurrence. In 1998, a panel of experts at the St. Gallen Breast Cancer Conference made recommendations for adjuvant therapy for women older than 70 years¹⁹¹ (Table 33.11).

In addition to disease characteristics as outlined in the aforementioned recommendations, concern regarding toxicity of therapy, comorbidities, and life expectancy will weigh heavily on a decision to treat an elderly woman with adjuvant chemotherapy. Extermann and colleagues used a Markov model to determine the threshold risk of relapse for which women up to age 85 with or without comorbidity would derive benefit from adjuvant therapy.¹⁹² For healthy women at age 65, the threshold risk of relapse was 11% for a 1% benefit in 10-year survival from tamoxifen. This threshold increased to 20% for women age 65 with significant comorbidity. For healthy women age 85, the threshold risk of relapse was 28% for a 1% benefit in 5-year survival, increasing to 35% for

sicker women in the same age group. Of note, no 10-year survival benefit was seen in the older age group. For chemotherapy, the threshold risk for a 1% benefit rose from 19% in a healthy 65-year-old to 62% in a sick 85-year-old. This model was sensitive to quality of life as well, a major consideration because of the relatively small impact of adjuvant therapy on survival in older women.

Future studies of adjuvant therapy should be designed to include more elderly women. These studies should measure quality of life as well as traditional endpoints. With its toxicities and modest benefits even in younger women, it is unlikely that adjuvant cytotoxic chemotherapy will ever be used extensively in women over age 70. Studies examining the benefits of new hormonal agents and other less toxic drugs, including trastuzumab, hold promise for the future adjuvant treatment in women of all age groups, including those age 70 or older.

Metastatic Breast Cancer

Metastatic breast cancer is incurable with currently available therapies. Median survival ranges from 2 to 3 years; however, there is substantial variability in survival, with as many as 10% of patients living more than 10 years. Factors associated with longer survival include disease involving soft tissue and bone only (rather than visceral organs), hormone receptor positivity in the tumor, a long disease-free interval from diagnosis to recurrence, and limited number of metastatic sites. Response to therapy is also quite variable. Patients with the better prognostic factors for survival as just described are more likely to respond well to hormonal therapy. The heterogeneity among breast cancer patients with metastatic disease must be considered carefully in the care of these patients.

The primary goals of treatment of metastatic breast cancer are palliation of symptoms, prolongation of survival, and improvement in quality of life. Only a few randomized studies have incorporated quality of life endpoints. Comparing a variety of treatments, each of these trials has shown that quality of life was better with the treatment that had the higher objective response rate, even if that treatment was more toxic.¹⁹³⁻¹⁹⁵ Treatment of metastatic breast cancer may prolong survival, but proving that a survival benefit exists is difficult because trials have not randomized patients to a supportive-care-only arm. In a meta-analysis of 50 randomized chemotherapy trials comparing a more effective treatment to a lesser one, the more effective chemotherapy prolonged median survival by as much as 6 months.¹⁹⁴ This small improvement in average survival should not be used as routine justification to treat asymptomatic or minimally symptomatic patients with toxic therapy, particularly because there is no evidence that early initiation of therapy extends life.

TABLE 33.11. Consensus panel recommendations for adjuvant treatment of elderly breast cancer patients.

Risk category	Treatment
Minimal/low: (ER or PR positive, ≤1 cm, grade 1)	None or tamoxifen
Intermediate: (>1-2 cm, hormone receptor positive, grade 1-2)	Tamoxifen ± chemotherapy
High: (>2 cm, hormone receptor negative, grade 2-3, node positivity)	Tamoxifen (± chemotherapy) If hormone receptor negative, chemotherapy

Source: Adapted with permission from Goldhirsch et al.¹⁹¹

Management of metastatic disease involves the judicious use of local and systemic therapies that best palliate the patient's symptoms with the least toxicity. In certain clinical situations, local therapy may be preferable to systemic therapy, such as in the situation of an isolated local recurrence. Such a recurrence can often be managed with local excision, radiotherapy, or both. A small percentage of patients with local regional recurrence will do well without evidence of progressive disease for an extended period of time. Other situations when local therapy is preferable include impending fracture from a bone metastasis, spinal cord compression, and brain metastases. In each of these cases, radiation therapy can result in significant palliation. Surgery may also play an important role in these situations.

Systemic treatment for metastatic breast cancer includes hormonal therapy and chemotherapy. Hormonal therapy should be considered first as it is usually much better tolerated than cytotoxic chemotherapy and can result in long remissions. Patient characteristics that predict for response to hormonal therapy include estrogen or progesterone receptor positivity, a long disease-free interval (from time of diagnosis to recurrence), the absence of visceral disease, postmenopausal status, and prior response to hormonal therapy. The majority of elderly patients have hormone receptor-positive tumors, and hormonal therapy is usually the initial treatment of choice. Overall objective response rates to hormonal therapy are in the range of 20% to 40%, depending on the patient population, with higher response rates seen in patients with multiple characteristics as just listed. In most randomized trials comparing two different hormonal treatments, response rates and duration of response have been similar. Tamoxifen, which is one of the least toxic hormonal agents, has traditionally been the first agent administered, followed by an aromatase inhibitor (e.g., anastrozole, letrozole, or exemestane). Recent data also suggest that aromatase inhibitors are at least as active as tamoxifen in the first-line setting in postmenopausal women with metastatic breast cancer.^{196,197} Table 33.12 lists the principally used hormonal therapies and their main toxicities. Patients who respond to one hormonal treatment should usually be treated with another hormonal agent at the time of disease progression, unless they have extensive visceral disease or rapid disease progression, in which case chemotherapy should be considered. Studying initial therapy for metastatic disease in elderly women, the Eastern Cooperative Oncology Group randomized 181 women over the age of 65 to receive either tamoxifen or cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) with crossover to the other treatment at the time of progression.¹⁹⁸ Response rates were not significantly different between the two groups: initial response rates were 45% with tamoxifen and 38% with CMF, and response rates after

TABLE 33.12. Hormonal agents currently considered in postmenopausal women with breast cancer.

Class	Agents	Principal toxicities
Estrogen antagonists	Tamoxifen Toremifene	Hot flashes, vaginitis Rarely, endometrial cancer, venous thrombosis
Aromatase inhibitors	Anastrozole Letrozole Exemestane	Hot flashes, gastrointestinal distress
Progestins	Megestrol acetate	Weight gain, fluid retention Rarely, venous thrombosis
Androgens	Fluoxymesterone	Masculinizing effects

crossover were 29% with tamoxifen and 31% with CMF. Survival was slightly higher in the group treated initially with tamoxifen. Combined endocrine treatment (combinations of tamoxifen, aminoglutethamide, hydrocortisone, and fluoxymesterone) has been studied in older patients and thus far shown no significant benefit.¹⁹⁹ Newer specific aromatase inhibitors may show more promise, and combinations with them are currently being evaluated in clinical trials.

Older women should be offered chemotherapy when they are judged to be poor candidates for endocrine therapy (i.e., hormone receptor-negative tumors) or when their disease becomes refractory to hormonal treatment. Unfortunately, most trials evaluating chemotherapy in metastatic breast cancer have included few women over age 65. With combination regimens, approximately 40% to 50% of patients will have an objective response, and a small percentage will have a complete response (complete disappearance of disease). Patients with a good performance status, limited number of metastatic sites, and long disease-free interval (from diagnosis to recurrence) are most likely to respond to chemotherapy. Age and menopausal status have not been shown to predict for response. Response rates and toxicity profiles of standard regimens for metastatic breast cancer have not been found to be significantly different in older patients.¹⁰¹ In a case comparison study of patients with metastatic breast cancer treated in five clinical trials,²⁰⁰ 70 women aged 70 or older were compared to 60 patients aged 50 to 69 and 40 patients less than 50 years old. Evaluation of response rates, time to progression, survival, and toxicity revealed no significant differences between the three groups. Response rates were 40%, 30%, and 29%, respectively ($p = 0.53$) among the three groups. Estimates of time to progression and survival were 9.1 and 17.9 months, 6.2 and 12.8 months, and 7.2 and 14.2 months, respectively. Importantly, there were no significant differences in toxic effects, dose delivery, and dose delays among the three groups. Based on information from studies such as this, women age 70 or greater should

not be excluded from chemotherapy clinical trials for advanced breast cancer based on age alone.

Combination chemotherapy has been compared to single-agent chemotherapy in women with advanced breast cancer.^{201,202} Although response rates and duration of response tend to be increased, there is no significant difference in survival when combination chemotherapy is compared to single-agent sequential chemotherapy. Furthermore, treatment-related toxicity tends to be higher and quality of life worse with multiagent regimens. For these reasons, single-agent chemotherapy is used increasingly in the treatment of advanced breast cancer. In a patient who responds to therapy, physicians are often faced with the decision of how long to continue treatment. Therapy should be administered for at least 3 to 6 months. Continuing beyond that time will extend the time to disease progression but will not change overall survival.^{193,203} The decision to continue treatment must be individualized based on the toxicity profile of the treatment regimen, disease-related symptoms, and patient preferences.

Concern regarding toxicity will weigh heavily on a decision to treat an elderly woman with cytotoxic chemotherapy. Although organ function and metabolism of drugs may be compromised in older patients, comparative studies show that chemotherapy-related toxicity is similar in older and younger patients.^{200,204,205} Hematologic reserve is decreased in older individuals; therefore, hematologic toxicity from chemotherapy may be more severe in elderly patients. Cardiotoxicity, gastrointestinal effects, and neurotoxicity may also be more common in older patients. For chemotherapeutic agents that are primarily renally excreted, such as methotrexate and cyclophosphamide, dose adjustment based on creatinine clearance is recommended in older patients.^{204,205} Agents such as vinorelbine and 5-fluorouracil derivatives such as capecitabine, which have favorable side effect profiles, are particularly suitable for treatment of elderly patients.^{206,207} Although elderly women do not have a high proportion of Her-2/neu-positive tumors, the efficacy and favorable toxicity profile of trastuzumab make this a reasonable treatment option for older women with Her-2/neu-positive tumors. Future randomized trials evaluating these drugs in elderly women with metastatic breast cancer are warranted.

After failure of first-line chemotherapy, response rates to other regimens are lower in women of all ages. Second-line and subsequent chemotherapy regimens can be considered, but the potential toxicities of treatment must be weighed against potential benefits. Palliation of symptoms, pain management, other supportive care, and consideration of visiting nurse services and hospice care are of utmost importance. Bisphosphonate therapy (e.g., pamidronate) has resulted in significant reductions in skeletal complications, that is, pathologic fractures,

surgery for fracture or impending fracture, radiation, spinal cord compression, and hypercalcemia in women with metastatic breast cancer.^{208,209} Intravenous (i.v.) pamidronate every 3 to 4 weeks is currently recommended in patients with metastatic breast cancer who have imaging evidence of lytic destruction of bone and who are concurrently receiving systemic therapy with hormonal therapy or chemotherapy.²¹⁰

Quality of Life in Older Women with Breast Cancer

A number of studies suggest that older women adjust to breast cancer better than younger women.^{211–214} In a study of 304 women immediately after completion of therapy for early-stage breast cancer, Wenzel et al.²¹⁴ compared quality of life (QOL) among women age 50 or younger to women over age 50. QOL was evaluated using standardized measures, including the Functional Assessment of Cancer Therapy—Breast instrument, the Center for Epidemiologic Studies Depression Scale, and the Impact of Event Scale. In this study, QOL was significantly worse for younger women globally ($p = 0.021$) and with regard to domains of emotional well-being ($p = 0.0002$) and breast carcinoma-specific concerns ($p = 0.022$). Furthermore, symptoms of depression ($p = 0.041$) and disease-specific intrusive thoughts ($p = 0.013$) were significantly worse for younger women. Of note, no significant sexual dysfunction or body image differences were noted between older and younger women. Although elderly women who survive breast cancer seem to cope better than their younger counterparts, their distress must not be overlooked. Older women are more likely to have decreased social support, limitations in physical and cognitive functioning, and significant comorbidity. Furthermore, rates of depression are high in elderly populations, particularly when faced with a serious illness. Interventions, such as use of social support, spirituality, and exercise, have demonstrated therapeutic benefits for older women with cancer and should be considered.²¹⁵

Patterns of Care

Numerous studies have documented that there are significant treatment differences in older patients compared to younger patients.^{14,18–20,70,117,216–225} Elderly women with early-stage breast cancer are less likely to undergo breast-conserving surgery than younger women, despite the increase in breast conservation over recent years among all age groups.^{222,223,225} Older women are also more likely to have radiotherapy or lymph node dissection omitted after breast-conserving surgery.^{18–20,117,219,220,222,225} Concerning systemic therapy, older women are more

likely to be treated solely with adjuvant tamoxifen and are much less likely to undergo chemotherapy than younger women.^{18–20,117,219,222,225}

Less aggressive care of elderly breast cancer patients may be associated with a poorer outcome. Studying 390 women ages 45 to 90, Lash et al.²²⁶ found that patients who received a less than definitive prognostic evaluation had an adjusted relative hazard of recurrence of 1.7 [95% confidence interval (CI), 1.0–2.7] and an adjusted relative hazard for breast carcinoma mortality of 2.2 (95% CI, 1.2–3.9). Patients who received less than definitive therapy had an adjusted relative hazard of recurrence of 1.6 (95% CI, 1.0–2.5) and an adjusted relative hazard of breast carcinoma mortality of 1.7 (95% CI, 1.0–2.8). Women aged 75 to 90 were least likely to receive definitive care and had relative hazards associated with less than definitive care as great or greater than the relative hazards observed in the whole cohort. This finding has implications for older women with localized breast cancer who are not receiving standard evaluations and therapy, as they may be at excess risk for disease recurrence and mortality. Other authors have not found differences in survival between older women who receive standard treatment and those who receive less aggressive care, after controlling for age, stage, and other clinical factors.^{18–20,76,117} Because elderly patients have more comorbidity, as well as functional limitations, less aggressive care may represent appropriate clinical judgment. Several studies indicate, however, that comorbidity or functional impairment cannot always explain less aggressive care. Furthermore, there is significant geographic variation in the care received by older breast cancer patients that cannot be explained by differences in functional status or comorbidity.^{220,221,223,225} For example, Mandelblatt and colleagues found that, between 1995 and 1997, women with localized breast cancer from five regions in the United States were 3.3 times more likely to have a mastectomy if they lived in Texas than if they lived in Massachusetts.²²⁵

Other studies have shown that elderly patients with metastatic disease also appear to receive less aggressive care.^{227,228} In a population-based study of the treatment of metastatic breast cancer, Fetting et al.²²⁸ evaluated 132 cases of women who died of metastatic breast cancer in Washington County, Maryland, from 1984 to 1991. Sixty percent of women aged 75 years and older were referred to a medical oncologist, in contrast to 68% of women aged 65 to 74 years and 89% of women under age 65. Seventy-four percent of patients less than 65 years old received chemotherapy, compared to 42% of patients aged 65 to 74 years and 12% of women aged 75 years or older, despite the fact there is not evidence that metastatic breast cancer responds differently to chemotherapy by age. Adjusting for other medical conditions and whether or not the patient saw a medical

oncologist, there was still a significant effect of age on whether patients received chemotherapy. Of note, the different patterns of chemotherapy utilization were not associated with survival differences. Radiation therapy was also utilized significantly less frequently in older patients; however, there was no age effect on the utilization of hormonal therapy in this study. Less frequent utilization of palliative chemotherapy and radiation in older patients may be caused by a combination of patient and physician factors and may result in less effective palliation for older patients.

The specific reasons underlying these variations in care have not been studied extensively. Physician attitudes about appropriateness of therapy, patient comorbidity, and patient preferences, including body image and side effect concerns, have been found to influence the selection of treatment for elderly women with breast cancer.^{216,219,222,225} In a recent study of 718 women with early-stage breast cancer aged 67 years and older, Mandelblatt et al.²²⁵ found that women who were concerned with body image were 1.8 times more likely to receive breast-conserving surgery and radiotherapy compared to women without this concern. After controlling for other factors, women who preferred no therapy beyond primary surgery were 3.9 times more likely to undergo mastectomy than other women. In this study, women 80 years and older were 3.4 times less likely to undergo radiation therapy after breast-conserving surgery when compared to women ages 67 to 79 years, independent of comorbid illnesses, performance status, or women's treatment preferences. Furthermore, older women were 70% less likely to receive chemotherapy than women aged 67 to 79. However, women 80 years and older tended to receive tamoxifen more often than the younger women in this study. The finding that patient preferences were independent predictors of therapy among these women has implications for shared decision making and communication between elderly patients and their physicians.

Silliman et al.²¹⁹ surveyed physicians who did not recommend adjuvant therapy as part of a study in which women aged 75 years or older were significantly less likely to receive adjuvant therapy (including radiotherapy following breast-conserving surgery, chemotherapy, and hormonal therapy). Physicians' attitudes about appropriateness of therapy appeared to be the major determinant of what treatment was received. In the majority of cases, physicians believed that the treatment was not indicated on the basis of patient stage or treatment efficacy. Patient factors, such as age, comorbidity, functional status, ability to tolerate treatment, and patient preferences, were cited infrequently.

Goodwin and Samet²²⁹ studied a population-based cohort of women 65 years or older with early-stage breast cancer in New Mexico. In this study, specific characteris-

tics other than age that were associated with nonstandard treatment included impairments in activities of daily living, low physical activity, impaired mental status, poor access to transportation, and low social support. There was only a small, statistically nonsignificant relationship between comorbidity, based on patient self-report, and not receiving definitive treatment. It is likely that patient factors and preferences, as well as physician attitudes and beliefs, play an important role in explaining age-related variations in breast cancer care.

Elderly breast cancer patients (and elderly cancer patients in general) are substantially underrepresented in treatment protocols.^{7-9,230} Some of the same physician and patient factors that contribute to less aggressive treatment of elderly patients probably contribute to this underrepresentation in clinical trials. Studies are necessary to better understand physician attitudes, patient preferences, and other barriers to standard care and protocol therapy for older women. Kemeny and colleagues studied barriers to participation in clinical trials among breast cancer patients.²³¹ After controlling for other conditions including comorbidity, older age was associated with whether a patient was offered participation in a clinical trial even when a patient met eligibility criteria. Reasons that physicians did not offer patients trial participation were similar for older and younger patients except for two factors: (1) the presence of comorbid conditions that was not excluded by the protocol but that the physician believed would have affected the patient's response was a factor in 17% of older patients and none of the younger patients; and (2) the opinion that the regimen was too toxic was a factor in 27% of the older patients and none of the younger patients. Patient difficulty in understanding, costs, transportation, and short life expectancy did not appear to influence physicians' decisions. Importantly, there was no evidence that age was associated with whether or not a patient accepted clinical trial participation when offered.

Conclusion

The incidence of breast cancer increases dramatically with age. Given the demographic changes occurring in the United States, the number of elderly women developing breast cancer will continue to rise. Older women as a group have more favorable prognostic factors but have lower relative survival compared with younger women. Older women have a higher likelihood of receiving nonstandard and less aggressive treatment compared to younger women, even after controlling for comorbidity. Treatment recommendations are based primarily on randomized trials of younger women. Extrapolation of these results is complicated by differences in tumor biology, host physiology, and problems common in the

elderly, including comorbidity, impaired functional status, and lack of social support. Local treatment of early-stage breast cancer should be similar to that in younger women and consist of either mastectomy or breast-conserving surgery followed by breast irradiation. Most older women with hormone receptor-conserving surgery followed by breast irradiation. Most older women with hormone receptor-positive tumors should receive adjuvant tamoxifen. Some elderly patients may also benefit from adjuvant chemotherapy. Ongoing and future study results should be instructive in determining the relative efficacy of breast irradiation in older women, as well as the benefits and toxicities of different adjuvant chemotherapeutic regimens. In elderly women with advanced breast cancer, hormonal therapy will usually be the initial treatment of choice. Chemotherapy should be considered when a patient has symptomatic hormone receptor-negative disease, extensive visceral involvement, and rapid disease progression, with particular attention to the potential risks of therapy. Most importantly, patient preferences, comorbidities, disease status, and available evidence for improvement in survival and quality of life should guide treatment of older women with breast cancer of all stages.

Colon Cancer and Other Gastrointestinal Malignancies

Peter C. Enzinger and Robert J. Mayer

In the year 2001, it was anticipated that 235,700 new cases of digestive tract cancer would be diagnosed in the United States,¹ accounting for just under one-fifth (19%) of all new cancers. The majority of these new gastrointestinal malignancies were colorectal cancers (57%), followed by pancreas (12%), stomach (9%), liver (7%), and esophagus (6%) cancers.¹ Digestive tract cancers tend to be highly aggressive tumors. Nearly one-quarter (24%) of all cancer deaths in the United States are caused by these malignancies.¹ Fortunately, diagnosis and treatment of these cancers is improving, and small but statistically significant improvements in survival have been documented for most digestive tract cancers during the past three decades.¹

Age is clearly a risk factor for gastrointestinal malignancies. The majority (>65%) of these cancers occur in patients older than age 65 years (Fig. 34.1).^{2,3} The incidence increases by 14- to 42 fold between the fourth and eighth decades of life. Survival is also reduced with increasing age. In a European study, 5 year survival rates for 170,000 elderly patients (65–99 years old) with colorectal, stomach, and pancreas cancer were obtained (Fig. 34.2).⁴ Survival in these malignancies was 25% to 33% less in persons older than 80 years of age when compared to those younger than 70 years. Coexisting illnesses almost certainly contributed to this poorer outcome.

Although advanced age in itself is not a substantial risk factor for treatment-related morbidity and mortality, it is generally associated with a progressive decline in functional reserve of multiple organ systems and may reduce the tolerance of normal tissues to treatment complications.⁵ Elderly patients often suffer from partial loss of organ function secondary to atherosclerosis, emphysema, diabetes, and other comorbidities. Further loss of tissue function from treatment-related stresses may lead to organ failure. Patients with multiple medical problems have a higher surgical complication rate and require more time to recover from their operations. Older patients, with decreased bone marrow and epithelial stem

cell reserves, have an increased likelihood of developing myelosuppression and mucositis following radiation therapy.⁶

It appears that older patients generally tolerate chemotherapy as well as their younger counterparts.^{7,8} With increasing age, however, the metabolism of cytotoxic drugs and the ability of normal cells to recover from damage caused by these drugs are diminished. Glomerular filtration rate is known to decline with increasing age, tending to reduce the excretion of certain chemotherapy agents. Hepatic function may also be impaired in older patients through decreased hepatic blood flow and a decline in the intracellular activity of P-450 cytochrome enzymes. Also, the elderly are more likely to require additional medications that can compromise hepatic functions. Many antitumor drugs are susceptible to these changes in hepatic metabolism. Older patients generally have decreased total body water and albumin levels, leading to increased free drug concentrations. Hematopoietic stem cell reserves are often compromised and lead to increased neutropenia, anemia, and fatigue. Anemia, in turn, may increase the free drug concentration of certain antitumor agents that are heavily bound to red blood cells. Decreased mucosal stem cell reserves in the elderly may lead to increased mucositis and diarrhea.⁹

Colorectal Cancer

Colorectal cancer is the third leading cause of cancer death in the world, after lung and gastric cancer.¹⁰ Its highest incidence is in developed countries. In the United States, 98,200 cases of colon cancer and 37,200 cases of rectal cancer were diagnosed in 2001, leading to 48,100 and 8600 deaths, respectively.¹ Colorectal cancer has become the second leading cause of cancer-related death in the United States. At the time of diagnosis, approximately 40% of patients with colorectal cancer have

FIGURE 34.1. Age-specific incidence of gastrointestinal malignancies (per 100,000) in the United States. (From Ries et al.,³ with permission.)

localized disease, 40% have lymph node involvement, and 20% have distant metastases.³ The majority of colorectal cancers arise in the distal colon; however, a slight increase in the incidence of proximal colorectal cancer has been documented in the last decades.¹¹

The probability of developing colorectal cancer increases from 0.05% in the first four decades of life to 3% to 4% in the sixth and seventh decades.¹ In women over 80 years of age, mortality from colorectal cancer significantly exceeds that of breast cancer and is nearly equal to that of lung cancer.¹ The mortality data vary

slightly in different countries. For instance, in the Netherlands, colorectal carcinoma has become the most common cancer in women and the second most common cancer (after prostate) in men aged 85 to 94 years.¹²

Older patients tend to have a higher frequency of right-sided colon cancers than do younger patients.^{13,14} They generally present at diagnosis with the same percentages of localized and advanced disease as their younger counterparts.² Some studies, however, suggest that patients older than 80 years have earlier-stage disease than younger patients¹¹ and tend to have higher rates

FIGURE 34.2. Age-specific 5-year survival (%) for 170,000 elderly patients with gastrointestinal malignancies from the EUROCORE II Project. (From Vercelli et al.,⁴ with permission.)

of obstruction and perforation.¹³ This, in turn, results in a higher likelihood of acute presentations, leading to a higher perioperative mortality rate in this older age group.^{15,16} This trend is also suggested in a French series of 1734 patients (including 163 patients older than 80 years), in which 5-year survival was 35% for patients older than 80 years versus 46% for younger patients ($p < 0.05$).¹⁷ However, this difference in survival no longer was significant if noncancer deaths were excluded from this series.

Comorbid conditions can have a significant impact on the outcome of older patients with colorectal cancer. In a population-based analysis, the National Institute on Aging stratified patients, listed in the surveillance, epidemiology, and end results (SEER) tumor registry, into three cohorts: 55 to 64 years, 65 to 74 years, and 75 years and over.¹⁸ The number of comorbid conditions, such as hypertension, heart disease, and chronic obstructive pulmonary disease, was found to increase with age and was significant in predicting early mortality ($p = 0.0007$) in older patients.

Risk Factors

Approximately 75% of patients with colorectal cancer lack clearly defined risk factors for their disease.¹⁹ Of the remaining patients, 15% to 20% have a history of inflammatory bowel disease or first-degree relatives with either colorectal cancer²⁰ or adenomatous polyps.²¹ Patients with hereditary autosomal dominant colorectal cancer syndromes are rare. The two most common syndromes, hereditary nonpolyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP), account for only 5% and 1% of all colorectal cancers, respectively.²²⁻²⁴ These hereditary syndromes are even less important in the elderly, because 90% of persons with FAP and 68% to 75% of individuals with HNPCC are diagnosed before the age of 65 years.^{23,24}

Other factors that have been suggested to increase the risk of colorectal cancer include physical inactivity,

obesity, consumption of red meat or alcohol, tobacco use, and diets low in fruits and vegetables.²⁵ Contrary to prior beliefs, the consumption of coffee and tea or a diet low in fiber do not appear to increase risk.^{26,27}

Prevention and Surveillance

Colon cancers are thought to develop from normal colonic epithelial cells through a series of pathologic changes that involve mutation or deletion of critical genes.²⁸ As these sequential genetic events occur, the epithelium first hyperproliferates and forms aberrant crypt foci.²⁹ Adenomatous polyps eventually develop in these areas of hyperproliferation. These premalignant lesions may become progressively larger and atypical until cancer evolves, usually within a period of 5 to 10 years.³⁰ Approximately one in three persons have an adenomatous polyp in their colon by the age of 50. By age 70, the incidence increases to approximately 50%.³¹

Chemoprevention

Various dietary factors, supplements, and drugs have been proposed as chemopreventative agents for colorectal neoplasia (Table 34.1). Of these, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are the most widely studied and appear to show the most conclusive benefit. These drugs are thought to induce apoptosis in abnormal colonic epithelial cells by cyclooxygenase-dependent and cyclooxygenase-independent mechanisms. The process by which cyclooxygenases increase apoptosis is unclear. Cyclooxygenase-independent pathways may inhibit the activation of nuclear factor- κ B (NF- κ B) or may interfere with the binding of peroxisome proliferator-activated receptor- δ (PPAR δ) to DNA.^{32,33} Cyclooxygenases may also act as angiogenesis inhibitors.³⁴

Cyclooxygenase-2 is elevated in 90% of sporadic colon cancers and in 40% of colonic adenomas, but is found at

TABLE 34.1. Chemoprevention trials of colorectal cancer.

normal levels in the unaltered colonic epithelium.³⁵ Inhibition of this enzyme can significantly reduce the number of colonic polyps in animal models³⁶ as well as in patients with hereditary polyposis syndromes.^{37,38}

In the general population, multiple prospective cohort studies (but not randomized controlled trials or RCTs) have demonstrated that aspirin use reduces the risk of colon cancer. In the Cancer Prevention Study II, death rates from colon cancer decreased with increasing aspirin use.³⁹ Persons who used aspirin 16 or more times per month had the lowest risk of colorectal cancer death. In the Health Professionals Follow-Up Study, 25% of persons used aspirin more than twice per week.⁴⁰ In this group, the relative risk of colorectal cancer was only 0.68 compared to nonaspirin users. If regular aspirin use persisted for at least 6 years, this relative risk fell even further to 0.35. Moreover, in the group of patients who underwent regular screening sigmoidoscopies, regular aspirin use also reduced the development of distal colorectal adenomas (relative risk, 0.72). In the Nurses' Health Study, regular aspirin use two or more times per week for 20 years lowered the relative risk of colorectal cancer to 0.56. However, little or no reduction in risk was noted during the first 9 years of follow-up.⁴¹

Other anti-inflammatory drugs (NSAIDs) are also likely to reduce the risk of colorectal cancer in the general population; prospective studies examining this issue have not been completed. Recently, however, a large retrospective analysis of Medicaid patients who filled prescriptions for nonaspirin NSAIDs suggested that individuals who used these drugs for at least 2 of the past 5 years had a relative risk of colorectal cancer of 0.49.⁴² In this study, the protective effect appeared to be most pronounced for right-sided colon lesions.

Fruits and vegetables, rich in folate and other micronutrients, are thought to lower the incidence of colorectal adenomas and cancer.^{43,44} In fact, high intake of dietary folate has been shown to reduce the number of malignant and premalignant lesions in cohort and case-control studies.^{45,46} In the Nurses' Health Study, long-term use (>15 years) of folate-containing multivitamins reduced the relative risk of colorectal cancer to 0.25.⁴⁷ Shorter periods (5–14 years) of folate supplementation had less impact (relative risk, 0.80–0.83). No benefit was noted when the duration of folate use was less than 5 years. These data suggest that folate may play a role in the early pathogenesis of colorectal cancer, although randomized trials are still needed.

There is also evidence that diets rich in red meat and animal fat are associated with a higher incidence of colorectal adenomas and cancer.⁴³ A fatty diet increases the production of bile acids, which in turn may cause hyperproliferation of the colonic epithelium.⁴⁸ Calcium, on the other hand, can bind bile acids and may therefore reduce the risk of colorectal cancer.⁴⁹ In a recent randomized

double-blind placebo-controlled trial, patients with a history of colorectal adenoma received 3 g of calcium carbonate supplementation per day or a placebo. After only 1 year, the group allocated to calcium had a significant reduction in the number of recurrent colorectal adenomas compared to those patients who received placebo [relative risk (RR), 0.73].⁵⁰ The percentage of patients who were found to have no further adenomas at the time of follow-up colonoscopy increased from 62% to 69% following calcium supplementation.

Estrogens may also reduce the risk of colorectal cancer, but the exact mechanism of this effect is unclear. It has been hypothesized that this hormone acts by decreasing bile acid secretion or by a direct effect on the colonic epithelium.⁵¹ Estrogens have been shown to reduce the risk of colorectal adenomas and carcinomas in multiple observational (non-RCT) studies.⁵² The average risk reduction in these reports is approximately 20%. Similar benefits have been demonstrated in prospective cohort trials. Thus, women who used estrogen replacement therapy in the Cancer Prevention Study II had a significantly decreased risk of fatal colon cancer (RR, 0.71).⁵³ In the subgroup of active estrogen users, this reduction in risk was even more pronounced (RR, 0.55). Similar reductions in the incidence of colorectal cancer with estrogen use were also reported in the Nurses' Health Study.⁵⁴

Vitamin supplementation with beta-carotene and vitamins A, C, D, or E does not appear to reduce the risk of colon cancer. Multiple prospective cohort studies and one randomized study have found no benefit for supplementation with these vitamins in the prevention of colorectal neoplasia.^{47,55–57} Likewise, dietary fiber has not been found to be protective for primary or secondary prevention in various prospective cohort studies²⁷ and in several randomized trials.^{58,59}

Screening

The rationale for surveillance screening of the colon and rectum is straightforward. Sporadic colorectal cancers typically evolve from adenomatous polyps over a 5- to 10-year period.³⁰ If these polyps can be identified and removed before they transform into a malignancy, the risk of colorectal cancer can be reduced by 50% to 90%.^{60,61} Furthermore, if a colorectal cancer is discovered at an early stage, prognosis is dramatically improved. For a detailed discussion of screening for colorectal cancer, the reader is directed to Chapter 32, Screening for Cancer.

Diagnosis and Workup

Elderly patients tend to have similar symptoms at the time of presentation as those of younger patients.⁶² Symp-

TABLE 34.2. American Joint Committee on Cancer (AJCC) and modified Dukes' classification of colorectal cancer.

AJCC (TNM)	Modified Dukes'	Pathologic description	Approximate 5-year survival
I (T1N0 M0)	A	Cancer limited to mucosa and submucosa	>90%
I (T2 N0 M0)	B1	Cancer extends into muscularis	85%
II (T3-4 N0 M0)	B2	Cancer extends into or through serosa	70%–85%
III (Any T N1-2 M0)	C	Cancer involves regional lymph nodes	30%–60%
IV (Any T Any N M1)	D	Distant metastases (i.e., liver, lung, etc.)	5%

TNM: T, depth of tumor invasion; N, lymph node involvement; M, metastatic disease.

toms of occult bleeding, including fatigue, shortness of breath, and even angina, are most common. Blood studies in such patients may reveal a microcytic hypochromic anemia, indicative of iron deficiency. Changes in bowel habits or stool diameter are most characteristic of rectal lesions. Rectal lesions and distal colonic lesions most often present with frank bleeding. Tumors of the ascending colon may produce "mahogany stools," in which blood is admixed with feces. These right-sided lesions can grow quite large and are sometimes palpable on physical examination. Peritonitis or obstruction is indicative of locally advanced disease.

Such symptoms are frequently attributed to hemorrhoidal bleeding, diverticulitis, inflammatory bowel disease, or irritable bowel syndrome. Elderly patients with bleeding or changes in bowel habits should always be evaluated with colonoscopy. If a cancer or advanced polyp is found, a routine workup should be initiated; this includes a CT scan of the abdomen and pelvis, chest radiograph, and routine blood work. A carcinoembryonic antigen (CEA) level should also be measured before resection. Although this test is not diagnostic and cannot predict the resectability of colorectal cancer, elevated levels are associated with a poorer prognosis and may be an indication for postoperative therapy.^{63–66} Patients considered unresectable for reasons of metastatic disease should undergo a confirmatory biopsy.

Patients with rectal cancers, in addition to undergoing a standard diagnostic evaluation, should also be assessed with endorectal ultrasound or magnetic resonance imaging. These studies can differentiate between relatively superficial tumors, which can often be treated with local excision, and more advanced disease, which may require radical surgery, excision of the anal sphincter, and a permanent colostomy (i.e., abdominoperineal resection).

Staging

Survival for patients with colorectal cancer is dependent on the stage of disease. The true stage of a colorectal cancer can only be determined by careful pathologic examination of the resected specimen. For many years,

the Dukes' staging system has been used to predict outcome and to determine treatment for individual patients (Table 34.2). Over the years, various modifications to this staging system have been made to improve its prognostic value. Currently, the TNM staging system, proposed by the American Joint Committee on Cancer, is employed. Prognosis worsens with depth of tumor invasion (T) and lymph node involvement (N); patients with metastatic disease (M) have the shortest survival.

Treatment

Surgery: Colon Cancer

Cancers of the colon are typically resected with a hemicolectomy. In this procedure, the cancer is removed with adjacent healthy bowel and mesentery, including blood vessels and lymphatics. The operative mortality is low and appears to decrease slightly (from 5.5% to 3.5%) when the resection is performed at a hospital at which such procedures are performed more often.⁶⁷ Such a high procedure volume is also associated with a modest increase in long-term survival, particularly for patients with stage II and III disease ($p < 0.001$). In patients between 70 and 79 years of age, the operative mortality rate may be as low as 2%;⁶⁸ this may rise to 7% to 9% in patients of 80 years or older.^{68,69} Patients undergoing palliative resections, due to advanced disease, have higher mortality rates. In patients 70 to 79 years of age, the mortality may be as high as 21% and in octogenarians it may reach 38%. Age-related mortality is also evident in a series of 5586 patients from the Johns Hopkins Hospital in which the perioperative mortality rate was 9.3% in patients 85 years and older but only 3.3% in patients aged 66 to 69 years.⁷⁰

Surgery: Rectal Cancer

The standard surgical procedure for cancer of the rectum is a radical resection with anastomosis. Most commonly, a low anterior resection is performed. Increasingly, colorectal surgeons are being trained to perform a total mesorectal excision. This procedure maximizes the

volume of perirectal tissue removed and theoretically removes perirectal tumor deposits that would otherwise have remained in place.

Traditionally, rectal cancers close to the anal sphincter have required an abdominoperineal resection. In this procedure, the anal sphincter is resected along with the rectum and a permanent colostomy is created. Morbidity is significant and includes urinary and male sexual dysfunction. For locally advanced disease, this procedure remains the standard of care. However, for minimally invasive, early-stage distal rectal cancers (T1–T2, stage I), transanal sphincter-sparing surgery and abdominoperineal resection appear to have similar local recurrence (5%–15%) and long-term survival (80%–90%) rates.^{71–74} Patients with invasion of the muscularis propria or lymphovascular invasion benefit from postoperative chemoradiation.^{74,75}

Postoperative Chemotherapy: Colon Cancer

Randomized studies have repeatedly demonstrated the value of 6 to 12 months of 5-fluorouracil-based (5-FU-based) chemotherapy given prophylactically after the resection of lymph node-positive (stage III/Dukes' C) colon cancer.^{66,76} Postoperative chemotherapy can reduce the recurrence rate of colon cancer by 40% and mortality by 33%.⁶⁶ In absolute terms, chemotherapy can improve 5-year survival for lymph node-positive patients from 45% to more than 60%.

Such a clear benefit for postoperative chemotherapy has not been conclusively demonstrated in patients with fully resected, muscle-invasive, lymph node-negative (stage II/Dukes' B2) colon cancer.⁷⁷ In part, this is because the 5-year survival for this group is so favorable (75%–80%) that it is difficult to demonstrate a statistically significant improvement when chemotherapy is utilized without studying very large numbers of patients. Certain adverse prognostic factors, however, such as clinical obstruction,⁷⁷ perforation,⁷⁷ elevated preoperative plasma CEA levels,⁶⁶ poorly differentiated histology,⁶⁶ invasion of or adhesion to adjacent organs,⁶⁶

TABLE 34.3. Poor prognostic predictors following total surgical resection of a colorectal cancer.

Tumor spread to regional lymph nodes
Tumor penetration through the bowel wall

lymphatic invasion,⁷⁸ and vascular invasion⁷⁹ (Table 34.3) increase the risk of recurrence substantially in this group. Therefore, many experts recommend postoperative chemotherapy to patients with these adverse prognostic factors.

Current postoperative chemotherapy for high-risk resected colon cancer is based on the combination of 5-FU and leucovorin. Fluorouracil is an antimetabolite that binds to the enzyme thymidylate synthase, thereby depleting thymidine pools and inhibiting DNA synthesis.^{80,81} Leucovorin (also known as folinic acid) stabilizes the complex formed between 5-FU and thymidylate synthase, prolonging inhibition of this enzyme by more than 20 fold.⁸²

Older patients receive adjuvant chemotherapy less often than their younger counterparts (Table 34.4).^{13,83} Although chemotherapy has become the standard of care for high-risk resected colon cancer in the general population, some controversy remains regarding the relative benefit of this treatment in patients older than 70 years of age. Recently, an intention-to-treat meta-analysis was completed, pooling 3351 patients from seven randomized trials.⁸⁴ In these trials, patients with Dukes' B2 or C (stage II or III) colon cancer had been randomized to receive surgery alone or surgery followed by 5-FU-based chemotherapy. Patients were stratified by decade of life (<50, 50–60, 60–70, >70), with 15% of patients older than 70 years of age. Treatment effect (i.e., overall survival and disease-free survival) and toxicity were essentially the same for all age groups. It therefore appears that postoperative chemotherapy in high-risk colon cancer is as beneficial and tolerable in patients over age 70 years as it is for younger patients.

Adjuvant Chemotherapy and Radiation Therapy: Rectal Cancer

Chemoradiation after surgery reduces the local recurrence rate and increases disease-free survival in patients with deeply invasive (T3–T4) or lymph node-positive rectal cancer. In one study, 5-year disease-free survival

increased from 46% to 70% in those patients who received chemoradiation after their surgery.⁸⁵ Similarly, regional recurrences were reduced from 24% to 11% with this approach. Radiation therapy is typically given over 5 to 6 weeks. Fluorouracil-based chemotherapy may be administered during this time either as a bolus⁸⁶ or as a continuous infusion.⁸⁷ Additionally, at least 4 months of 5-FU based chemotherapy is generally given.

Chemoradiation for rectal cancer may also be administered before surgery.^{88,89} Preoperative chemoradiation is most often recommended if there is evidence by endoscopic ultrasound or magnetic resonance imaging of lymph node involvement or deep invasion through the rectal wall. If this approach is undertaken, patients should still receive postoperative chemotherapy following surgical resection. If imaging studies reveal superficial disease with no lymph node enlargement, surgery would seem to be the preferred initial treatment because patients with early-stage cancer do not require further therapy.

There are few data to suggest that elderly patients respond any differently to chemoradiotherapy than younger patients. Older patients, however, do appear to be at increased risk for radiation-related small bowel damage.⁹⁰ Therefore, particularly in this group, an effort should be made to limit the amount of small bowel in the radiation field.

Follow-Up

Prospective data have failed to show any survival benefit for the use of surveillance CT scans, chest radiographs, liver function tests, and fecal occult blood tests following the resection of a colorectal cancer.⁹¹⁻⁹³ However, a careful history and thorough physical examination every 3 to 6 months is recommended for the first 3 years following resection and annually thereafter.⁹⁴

The use of serial determinations of the plasma carcinoembryonic antigen (CEA) level as an early indication of clinically occult recurrent disease, although not universally accepted, has been recommended at 3-monthly intervals for the first 3 postoperative years.⁹⁴ Such a recommendation is based on evidence showing an elevated CEA level to be the initial indication of disease in 60% to 64% of cases and to be the most cost-effective approach to detect potentially resectable disease.^{91,92,95}

Patients should undergo a colonoscopy within 1 year of the time of their diagnosis, with a goal of detecting other polyps or cancer within the large bowel. The purpose of this procedure is not to screen for recurrent cancer at the suture line, because such anastomotic recurrences are exceedingly rare. Colonoscopy should be repeated yearly so long as further polyps are discovered. If no polyps are detected, the interval between future examinations may be extended to every 3 to 5 years.⁹⁴

Advanced Colorectal Cancer

Surgery: Advanced Colorectal Cancer

Patients with anatomically isolated tumor recurrences may be candidates for an attempt at surgical resection, particularly if several years have elapsed since the time of the initial diagnosis. Five-year survival has been reported in 25% to 39% of selected patients who underwent the resection of liver or lung metastases.^{96,97} In a series from the Memorial Sloan-Kettering Cancer Center, 128 patients 70 years of age or older underwent liver resection for metastatic colorectal cancer between 1985 and 1994.⁹⁸ Although these patients experienced a 4% perioperative mortality rate and a 42% complication rate, their median survival was 40 months and 5-year survival rate was 35%. These older patients had a similar outcome to 449 patients less than 70 years old who underwent comparable liver resections during the same time period. Similarly, studies have shown that appropriately selected octogenarians can tolerate lung resections with acceptable morbidity and mortality.⁹⁹

Patients who did not initially receive postoperative 5-FU-based chemotherapy for their resected colon cancer should be considered for chemotherapy after complete resection of their recurrence. In patients who have received prior chemotherapy, the benefits of further treatment after resection are uncertain.⁹⁷

The merits of hepatic arterial infusion chemotherapy (delivered by an implanted abdominal pump) after resection of hepatic metastases from colorectal cancer have been the source of debate. Such treatment clearly reduces the likelihood of recurrence in the liver but does not protect against extrahepatic recurrences and does not appear to prolong survival.^{100,101}

Chemotherapy: Advanced Colorectal Cancer

For many years, the standard treatment for advanced colorectal carcinoma has been the combination of 5-FU and leucovorin, given either for 5 consecutive days monthly or for 1 day per week. Small randomized studies have shown such chemotherapy to prolong survival when compared to best supportive care alone (11 versus 5 months; $p = 0.006$) and to improve quality of life.¹⁰²

SEER data from 1992 demonstrated that the usage of chemotherapy in patients with advanced colorectal cancer falls with increasing age (see Table 34.4).⁸³ Furthermore, elderly patients are underrepresented in clinical trials. Although 72% of all advanced colorectal cancer patients are 65 years or older (1992-1994 SEER data), less than 50% of patients in clinical trials sponsored by the National Cancer Institute (United States) were in this elderly age group.^{103,104}

The reasons for this disparity in treatment remain unclear. In a review of major trials of advanced colorectal cancer, researchers from the Royal Marsden Hospital in London found no difference in the probability of disease regression (24% versus 29%), toxicity, failure-free survival, or 1-year overall survival (44% versus 48%) between patients older and younger than 70 years of age.¹⁰⁵ The median overall survival was shorter for the older patients (9.6 versus 11.5 months; $p = 0.04$), likely due to competing comorbidities.

Irinotecan (CPT-11, Camptosar) is a new antitumor agent that has been recently approved for the treatment of colorectal cancer. It acts primarily by inhibition of the topoisomerase I enzyme. Once bound to the topoisomerase I–DNA complex, irinotecan blocks reannealing of the parent DNA, thereby halting nucleic acid synthesis in the cell, leading to cell death. Severe diarrhea, neutropenia, and nausea may occur with this drug in approximately 25% to 33% of patients. The administration of irinotecan leads to disease regression in 13% to 23% of patients whose disease is refractory to 5-FU.¹⁰⁶ Compared to best supportive care alone in similar patients resistant to 5-FU, irinotecan therapy has been demonstrated to improve both survival duration and quality of life.¹⁰⁷ In patients who have received no prior chemotherapy, the probability of response to irinotecan is higher (29%) and is similar to that of 5-FU and leucovorin.¹⁰⁸

Weekly irinotecan can safely be added to weekly 5-FU and low-dose leucovorin. Recently, this triple combination was compared to 5-FU and leucovorin alone in a randomized trial.¹⁰⁸ The response rate of the irinotecan/5-FU/leucovorin combination was superior to 5-FU and leucovorin (50% versus 28%; $p < 0.0001$) as was the median progression-free survival (7.0 months versus 4.3 months; $p = 0.004$). Overall toxicity and quality of life were similar with both regimens. Although these promising results have led some oncologists to consider this combination as initial therapy for patients with advanced colorectal cancer, only 40% of patients enrolled in the trial were 65 years of age or older, and the tolerance of treatment may well be poorer in the elderly. Conceivably, the same therapeutic effect may be achieved with less toxicity by giving 5-FU/leucovorin and irinotecan sequentially rather than concomitantly.

Fluorouracil may also be given as a continuous infusion. This form of administration offers a moderate improvement in response rate (22% versus 14%; $p = 0.0002$) and a small improvement in survival (13 versus 12 months; $p = 0.04$) compared to bolus 5-FU in patients with advanced colorectal cancer.¹⁰⁹ Infusional 5-FU causes less diarrhea, mucositis, and hematologic toxicity and may shrink colorectal cancers that no longer respond to bolus 5-FU therapy. The major side effect is palmar-plantar dysesthesia (burning, redness, and peeling of the

hands and feet), which is severe in approximately one-third of patients. These advantages must be balanced by the inconvenience of continuous therapy and the complications that may arise from portacath placement.

To circumvent the complications and inconvenience of infusional 5-FU, orally administered forms of 5-FU have been developed. Of these, only capecitabine (Xeloda) is currently approved for use in the United States. In randomized studies, capecitabine and 5-FU/leucovorin appear to lead to equivalent outcomes.¹¹⁰

A number of antitumor agents are under active development for this disease. Among these, oxaliplatin¹¹¹ and IMC-C225¹¹² appear most promising. Both have demonstrated activity in 5-FU-refractory advanced colorectal cancer.

Pancreatic Cancer

In the United States, the number of expected new cases (29,200) and the number of expected deaths (28,900) for pancreas cancer in the year 2001 are almost identical.¹ In part, this dire prognosis is due to the advanced stage of disease at presentation. At the time of diagnosis, less than 10% of patients have localized disease.³ The other patients have nodal (30%) or metastatic (60%) spread. Overall, the probability for 5-year survival for this cancer is less than 5%. For patients undergoing a potentially curative resection, this estimate rises to approximately 17%. The median survival for this group of resected patients is 12 to 18 months versus 3 to 6 months for patients with metastatic disease. The median age at presentation is 60 years, and thus a significant proportion of patients is elderly. Both genders are equally affected, and African-Americans have a slightly higher rate of disease.

Smoking appears to be the greatest risk factor for pancreas cancer. In one prospective study of 167,767 patients, the proportion of pancreatic cancers attributable to cigarette smoking was 25%.¹¹³ Risk was reduced by 48% and then approached that of nonsmokers after 2 and 10 years of smoking cessation, respectively. Other risk factors are disputed. Pancreatitis and diabetes, among others, have been linked to this malignancy in some^{114,115} but not all^{116,117} studies.

Prevention and Surveillance

Smoking cessation is the most important preventative step for this disease. As indicated above, risk is reduced by nearly half within 2 years of quitting and drops to normal after less than 10 years of smoking cessation.¹¹³ With the possible exception of those few individuals who have a strong family history of this cancer, serial imaging studies as a means of screening are not indicated.¹¹⁸

Diagnosis and Workup

Many patients seek medical attention because of jaundice, which may be unaccompanied by any pain. Several weeks or months of epigastric or back pain, as well as weight loss, are also common. Patients may recently have been diagnosed with glucose intolerance or malabsorption syndrome. The initial diagnostic evaluation usually includes a CT scan with contrast and endoscopic retrograde cholangiopancreatography (ERCP). Often, the latter procedure not only establishes the diagnosis of cancer but also can serve to relieve the jaundice (through endoscopic stent placement) with which the patient originally presented. Additionally, the blood tumor marker CA 19-9 should be obtained; although this marker is not diagnostic for pancreatic cancer, it has been shown to independently predict resectability.¹¹⁹ Patients may be resectable if there is no evidence of distant disease or encasement or occlusion of the celiac axis or superior mesenteric artery. Those patients who appear resectable require further evaluation with magnetic resonance angiography (MRA) or laparoscopy but do not require a preoperative biopsy. Patients with metastatic lesions or unresectable tumors should undergo pathologic confirmation of their disease.

Such a pathologic diagnosis is often not established in older patients having a clinical suspicion of pancreatic cancer. In one series, tissue confirmation was established in 88% of persons in their sixties but only in 41% of persons in their nineties.¹²⁰ Patients with a clinical diagnosis of what appeared to be a locally confined pancreatic neoplasm had a 5-year survival of 27% compared to 4% for those with biopsy-proven cancer. Thus, a disproportionate number of elderly patients may be misdiagnosed with this malignancy and may be incorrectly given a poor prognosis in an attempt to spare them the discomfort of an accurate pathologic diagnosis. In experienced hands, the major complication rate for CT- or ultrasound-guided biopsy of pancreatic lesions is approximately 1%.¹²¹

Treatment

Patients with pancreas cancer can be divided into three groups. The first group, with resectable disease, usually receives postoperative chemoradiation. In the second group, who have a cancer that is unresectable but has not spread to other organs, slightly different regimens of chemoradiation are offered. The third group, having metastatic disease, may be treated with chemotherapy or may receive palliative care alone.

Surgery: Resectable Pancreas Cancer

Pancreaticoduodenectomy (the Whipple procedure) is the only potentially curative therapy for pancreas cancer.

The resection includes the distal duodenum, the proximal jejunum, the neck, head, and uncinate process of the pancreas, the gallbladder, and the distal biliary tree. Historically, this procedure is associated with a high morbidity and mortality. In the last decade, however, mortality rates at hospitals at which the procedure is frequently performed have dropped to less than 3%.^{122,123}

There is ample evidence that pancreaticoduodenectomy can be safely performed in geriatric patients. For instance, in 206 patients over 70 years of age treated at the Mayo Clinic from 1982 through 1987, operative mortality was 9% with a surgical morbidity of 28%.¹²⁴ Overall survival was 19 months and 5-year survival was 4%. Similarly, the operative mortality in 138 patients older than 70 years of age who underwent pancreatic resection at Memorial Sloan-Kettering Cancer Center was 6% and the major complication rate was 45%. These results were virtually identical to those of younger patients. However, 5-year survival was slightly lower in the group of older patients (21% versus 29%; $p = 0.03$).⁹⁸

An even older cohort was reported from the Johns Hopkins Hospital.¹²⁵ At that institution, 46 patients older than 80 years of age who underwent pancreaticoduodenectomy had an operative mortality of 4.3%, compared to 1.6% for patients under 80 years ($p = \text{NS}$). The complication rate was 57% and 41%, respectively ($p = 0.05$). Other studies from Germany,¹²⁶ Sweden,¹²⁷ and Italy¹²⁸ provide further evidence that pancreatic surgery can be safely performed in the elderly with results akin to those of younger patients.

Postoperative Chemoradiation: Resectable Pancreas Cancer

Following the complete resection of pancreas cancer, the use of adjuvant postoperative chemoradiation should be considered. Trials have shown that such combined modality therapy can double the 2-year actuarial survival (43% versus 18%) and median survival (21 months versus 11 months) compared to surgery alone.^{129,130} In one study, 19% of patients randomized to receive chemoradiation were alive 5 to 11 years following their surgery, whereas only 5% of patients randomized to surgery alone lived to the 5-year point.¹³⁰

The results of these relatively small studies have recently come under question. Two large European trials have shown no statistical benefit for postoperative chemoradiation in pancreatic cancer.^{131,132} It is too early to determine if these new studies will impact present practice patterns in the United States.

Some investigators have advocated preoperative chemoradiation¹³³ or intraoperative radiation therapy¹³⁴ for patients with localized pancreas cancer. There are theoretical advantages for these approaches, but the available data have emerged from small patient cohorts at

single institutions in a setting where selection bias is likely. For these reasons, the use of preoperative or intraoperative therapy should be reserved for clinical trials only.

Advanced Pancreas Cancer

Patients who are found to be unresectable at the time of attempted pancreaticoduodenectomy may be candidates for surgical palliation for jaundice and pain. Typically, these patients undergo a retrocolic gastrojejunostomy, a hepatojejunostomy, and a chemical splanchnicectomy. In one series of 118 patients from the Johns Hopkins Hospital, the perioperative mortality for these procedures was 2.5%; only 3% subsequently developed gastric obstruction and only 1.6% developed jaundice.¹²² In a randomized trial, chemical splanchnicectomy with 50% alcohol significantly reduced or prevented pain when compared to placebo injection with saline.¹³⁵

Chemoradiation: Locally Unresectable Pancreas Cancer

It is unclear if chemoradiation is superior to chemotherapy alone or to supportive care in patients with locally unresectable pancreas cancer because no randomized trials have been performed in this clinical setting. However, promising results at single institutions^{136,137} led investigators of the Gastrointestinal Tumor Study Group to randomize patients with unresectable pancreas cancer to chemotherapy plus radiation or to radiation therapy alone.¹³⁸ The median survival was 10 months for patients who received 5-FU in addition to radiation therapy versus 5.5 months for those who received radiation therapy alone ($p < 0.01$). Similarly, the 1-year survival was superior for the chemoradiation group (40% versus 10%). Therefore, chemoradiation is now commonly employed for this group of patients.

Chemotherapy: Metastatic Pancreas Cancer

Metastatic pancreas cancer has been treated with 5-FU since the early 1960s; disease regression rates have ranged from 7% to 19%, and the median survival has varied from 4.5 to 6.0 months. The addition of other anti-tumor agents to 5-FU, while sometimes increasing the response rate, has had no impact on survival.^{139,140} In small, randomized trials, the use of these 5-FU-based regimens has, however, shown a significant survival advantage when compared to supportive care alone (30–33 weeks versus 7–15 weeks).^{141,142}

More recently, gemcitabine, a nucleoside analogue, has been found to have antitumor activity in pancreas cancer.^{143,144} Partial responses have been reported in 6% to 11% of patients, with an associated median survival of

5.6 to 6.3 months. Gemcitabine has been compared to weekly bolus 5-FU as initial therapy in patients with advanced pancreas cancer.¹⁴⁵ Although the improvements in response (5.4% versus 0%) and median survival (5.7 versus 4.4 months) for gemcitabine were modest, improvements in symptom control led to acceptance of the drug as standard therapy for this disease. Of note, patients up to 79 years of age were included in this trial, with a median age of 62 years. Efforts to combine gemcitabine with other agents are underway.

Palliation: Metastatic Pancreas Cancer

Neurolytic block of the celiac plexus and/or splanchnic nerves is an important adjunctive therapy to oral analgesia in pancreas cancer. In this procedure, ethyl alcohol is injected into the nerve via a small-gauge needle, guided by CT scan or other imaging technique. In experienced hands, this technique relieves pain in approximately 75% of patients.¹⁴⁶ Up to 50% of patients may have minimal or no pain 15 days following their procedure, without opioid therapy.¹⁴⁷ Effective pain relief is often attained for several months.

Gastric Cancer

Worldwide, gastric cancer is the second leading cause of cancer death (after lung cancer) in both men and women.¹⁰ In East Asia, it is the most common cancer in men and the leading cause of cancer death in women. In the United States, the predicted number of new cases for 2001 was 21,700 with 12,800 deaths expected.¹ Symptoms occur relatively late in the development of the disease. Thus, more than 40% of patients present with metastatic cancer and only one-fifth of patients have localized disease.³ The distribution of gastric cancers has changed over the past three decades, primarily due to an increase in the number of adenocarcinomas of the cardia and an even greater decline in cancers of the fundus, body, and antrum.¹⁴⁸

Over the past decades, beginning in the early 1930s, the incidence of gastric cancer has shown a remarkable decline in the United States,¹⁴⁹ probably due to improvements in refrigeration and sanitation. Consumption of preserved, smoked, or cured foods has decreased and inversely intake of fresh fruits and vegetables has increased.¹⁵⁰ Infection with *Helicobacter pylori*, which increases the risk of gastric cancer by approximately twofold, has also declined.^{151–153}

In general, it is thought that achlorhydria leading to dysplasia of the gastric mucosa, resulting from such etiologic causes as atrophic gastritis (occasionally accompanied by pernicious anemia), chronic active gastritis from *H. pylori* infection, and prior antrectomy for peptic ulcer

disease, may lead to an increased risk of gastric cancer.^{154–157} Less firm associations with this malignancy include cigarette smoking, blood group A, prior radiation exposure, family history, and Epstein–Barr virus infection.¹⁴⁹

Prevention and Surveillance

Continued improvements in refrigeration and sanitation throughout the world will likely result in a further decrease in the prevalence of this disease. Although the eradication of *H. pylori* infection may further reduce the risks of this malignancy, such an appealing concept has not yet been validated in a clinical trial.^{151,158} Endoscopic screening for gastric cancer may be justifiable in endemic areas, such as East Asia, but is not warranted in the United States.

Diagnosis and Workup

Generally, patients with epigastric pain and weight loss are first found to have a gastric cancer by the identification of an abnormality on upper GI series. Upper endoscopy usually reveals a malignant ulcer or suspicious rugal thickening. Biopsy, in most cases, demonstrates an adenocarcinoma. CT scan of the abdomen and pelvis and chest radiographs are utilized to determine the extent of disease. In contrast to colorectal cancer, which generally spreads initially to the liver, gastric cancer frequently metastasizes to the ovary (“Krukenberg tumor”), pelvic peritoneal cul-de-sac (“Blumer’s shelf”), or periumbilical area (“Sister Mary Joseph node”). Operative candidates at many centers now undergo staging laparoscopy to “rule out” such intraperitoneal spread before attempting a surgical resection.

Treatment

Surgery: Resectable Gastric Cancer

Gastrectomy is the only curative treatment for gastric cancer. In patients who undergo the resection of all macroscopic and microscopic tumor (R0 resection), the long-term survival is approximately 35%.^{159,160} Multivariate analysis reveals that the ratio of involved to removed lymph nodes, followed by depth of tumor invasion and postsurgical complications, are the most important prognostic factors for patients who have undergone a complete resection.

The extent of the surgical resection required to obtain an optimal clinical outcome has been the source of controversy. At a minimum, a so-called D-1 resection should be performed.¹⁶¹ In this procedure, patients undergo an omentectomy and gastrectomy with complete removal of the perigastric lymph nodes. Such an operation generally

results in the recovery of 17 lymph nodes on average.¹⁶² In addition, many surgeons, particularly from Japan, advocate a D-2 resection, which adds the removal of the omental bursa portion of the transverse mesocolon, the removal of the left gastric, celiac, and splenic lymph nodes, and occasionally the spleen to the D-1 procedure. In the D-2 operation, approximately 30 lymph nodes are recovered in the resected specimen.¹⁶² Proponents of the D-2 procedure have claimed a greater rate of surgical cure for this more radical approach while detractors have focused on a higher likelihood for perioperative morbidity and mortality. Consequently, two large prospective randomized trials have compared the D-1 and D-2 surgical procedures.^{162,163} Neither demonstrated a survival benefit for the D2 operation, but both documented a significantly higher rate of complications (43% versus 25%; $p < 0.001$) and postoperative deaths (10% versus 4%; $p < 0.004$) for this more radical procedure.

Gastric surgery may be performed safely in patients older than 70 years of age. A prospective review of 310 elderly patients with gastric cancer found that surgery in this group was reasonably tolerated and led to a survival duration comparable to the results obtained in younger patients.¹⁶⁴

Postoperative Chemotherapy: Gastric Cancer

Since the late 1960s, numerous randomized trials have attempted to demonstrate that postoperative chemotherapy reduces the rate of recurrence and prolongs survival after the resection of a gastric cancer. Most of these trials showed no significant survival benefit as summarized in a 1993 meta-analysis.¹⁶⁵ That review revealed a slight but nonsignificant improvement in survival for patients treated with postoperative chemotherapy (odds ratio, 0.88; 95% CI, 0.72–1.08). However, a more recent analysis, using stricter inclusion criteria and incorporating more current trials, showed a statistically significant 4% reduction in recurrence for postoperative chemotherapy in patients who had undergone R0 resections (odds ratio, 0.80; 95% CI, 0.66–0.97).¹⁶⁶ The greatest benefit was obtained in patients with tumor spread to regional lymph nodes.

Postoperative Chemoradiations: Gastric Cancer

Postoperative radiation therapy alone does not appear to offer a survival benefit in resectable gastric cancer.¹⁶⁷ Fluorouracil-based chemotherapy, however, has been shown to be a potent radiation sensitizer in this disease.¹⁶⁸ To explore the value of such radiosensitization, the impact of postoperative radiation therapy and 5-FU-based chemotherapy was recently compared to no postoperative therapy in a randomized trial involving more than 550 patients who had undergone a complete resection of a locally advanced adenocarcinoma of the stomach or the

gastroesophageal junction.^{169,170} The patient cohort randomly allocated to receive chemoradiation experienced a significant improvement in 3-year disease-free survival (49% versus 32%; $p = 0.001$) and 3-year overall survival (52% versus 41%; $p = 0.03$). The success of this combined modality treatment program required sophisticated radiation therapy planning.¹⁷¹ At present, all patients with fully resected muscle-invasive or lymph node-positive gastric cancer should now be considered for postoperative chemoradiation.

Advanced Gastric Cancer

Surgery: Advanced Gastric Cancer

Radical surgery is not indicated for gastric cancer patients in whom tumor has spread within the peritoneum, to other organs, the omentum, or distant lymph nodes. However, a less extreme resection or a bypass procedure may be appropriate to provide more effective palliation.¹⁷²⁻¹⁷⁵

Chemotherapy: Advanced Gastric Cancer

The benefit of chemotherapy in the presence of unresectable or widely metastatic gastric cancer has been the topic of debate and the focus of several randomized trials. These studies, in which patients have been randomly allocated to received chemotherapy or supportive care alone, have consistently revealed a prolongation of survival^{176,177} and an improvement in quality of life¹⁷⁸ in association with treatment.

The choice of chemotherapy regimens in this setting is difficult. Single-agent therapy generally has less toxicity than combination chemotherapy and may be better suited for older individuals. Chemotherapeutic compounds that have significant activity (15%–20% response rate) in gastric cancer include 5-FU, cisplatin, the anthracyclines (doxorubicin and epirubicin), irinotecan, and the taxanes (paclitaxel and docetaxel). Of these, 5-FU, irinotecan, and the taxanes are least toxic. The most widely studied is 5-FU, which forms the backbone of most combination regimens in this disease.

The use of chemotherapy combinations in gastric cancer has been characterized by response rates as high as 50% in uncontrolled studies that have not been confirmed in randomized trials.^{139,179-181} A number of randomized trials have been completed during the past decade, comparing various antitumor combinations that have been developed for the treatment of advanced gastric cancer. The most promising among these is the combination of epirubicin, cisplatin, and continuous infusion 5-FU (ECF), which has had a response rate of 41% to 45% and a median survival of 8.9 to 9.4 months.^{182,183} The treatment program is somewhat inconvenient be-

cause of the cumbersome administration of 5-FU as a prolonged continuous infusion and uncertainty about the contribution of epirubicin. As a result, some oncologists continue to consider a 5-FU and cisplatin combination as the standard of care.¹⁸⁴

Esophageal Cancer

Cancers arising from the esophagus, including the gastroesophageal junction, are typically either squamous cell carcinomas or adenocarcinomas and are the sixth leading cause of cancer death worldwide.¹⁰ Eighty percent of these deaths occur in developing countries, particularly South Africa and China, where squamous cell carcinomas predominate. In contrast, esophageal cancer is less common in the United States, although it has increased significantly during the past three decades. In 2001, 13,200 new cases and 12,500 deaths from this disease were anticipated.¹ Esophageal cancer is now the seventh leading cause of cancer death in American men. The rise in the incidence of esophageal cancer in the United States is primarily due to a significant increase in adenocarcinomas of the distal esophagus and, to a lesser extent, of the gastroesophageal junction. Between 1974 and 1994, adenocarcinomas of the esophagus increased dramatically in white males whereas squamous cell carcinomas of the esophagus declined slightly.¹⁴⁸ This trend is particularly evident in older men; the appearance of esophageal adenocarcinomas has doubled in white men younger than 55 years but has quadrupled in white men ages 65 to 74 years.

Smoking is thought to increase the risk of all esophageal cancers.^{148,185,186} Significant alcohol intake, especially when combined with smoking, greatly enhances the risk of squamous cell carcinoma but has no impact on the development of adenocarcinoma.¹⁸⁵ The greatest risk for esophageal adenocarcinoma appears to be gastroesophageal reflux disease and the development of Barrett's esophagus. In Barrett's esophagus, the normal stratified squamous epithelium of the esophagus is replaced by columnar epithelium, presumably in response to chronic gastroesophageal reflux. Recurrent symptoms of reflux result in an eightfold increase in the risk of esophageal adenocarcinoma.¹⁸⁷ Patients with Barrett's esophagus are at even higher risk, with an annual rate of cancer development of approximately 0.8%.¹⁸⁸ Drugs that relax the gastroesophageal sphincter and increase reflux, such as anticholinergics and aminophyllines, may contribute to the development of as many as 10% of these cancers.^{189,190} Obesity, which increases intra-abdominal pressure and gastroesophageal reflux, is also thought to add to the rising incidence of these tumors.^{190,191}

The epidemiologic pattern of esophageal carcinoma does not appear different in elderly patients. In one

series, 74% of patients 70 years or more of age were found to have adenocarcinoma and 26% had squamous carcinoma.¹⁹² In another study, the incidence of Barrett's associated adenocarcinoma was lower in the patients 70 years or older compared to younger age groups (15.6% versus 24%; $p = 0.046$).¹⁹³ The location of tumors in the esophagus does not, however, differ between older and younger patients. A similar distribution in early- and late-stage cancers has also been reported.

The overall prognosis for this cancer is poor. More than half of all patients already have metastatic disease at the time of their diagnosis.¹⁹⁴ Five-year survival even with the earliest stages of cancer is only in the range of 60%.¹⁹⁵ With lymph node involvement, 5-year survival drops below 25%. Patients with metastatic disease have a median survival of less than 1 year.

Prevention and Surveillance

Smoking cessation and moderation of alcohol intake are important steps in reducing the appearance of squamous cell carcinoma of the esophagus. The risk for this cancer decreases substantially after a decade of smoking cessation.¹⁸⁶ In contrast, the risk for adenocarcinoma of the esophagus does not change appreciably even 30 years after exposure to cigarettes ceases.¹⁸⁵

Patients with Barrett's esophagus who are otherwise in good health may be candidates for regular endoscopic surveillance. Endoscopic ablation therapy combined with proton pump inhibition may revert Barrett's esophagus to a normal squamous mucosa in some patients.¹⁹⁶ Small uncontrolled experiences have led to claims that endoscopic surveillance is cost-effective,¹⁹⁷ leads to the diagnosis of earlier-stage tumors,¹⁹⁸ and may improve survival.¹⁹⁹ Such observations remain anecdotal in the absence of randomized data. Some experts have recommended that endoscopy be performed every 2 years in patients with Barrett's esophagus in the absence of epithelial dysplasia and more frequently if mild dysplasia is discovered.^{196,200} The identification of severe dysplasia (i.e., carcinoma in situ) has been considered an indication for an esophagectomy, because many of these patients have been found to have invasive cancer in their resection specimens.²⁰¹ Patients not considered surgical candidates may undergo mucosal ablation with photodynamic therapy or other techniques.^{202,203}

Diagnosis and Workup

Patients with esophageal cancer usually experience dysphagia and often complain of odynophagia at the time of diagnosis. Weight loss is also common and is an independent poor prognostic indicator if greater than 10%. Barium swallow is often the first diagnostic study

obtained and typically shows a stricture or erosion of the esophagus. Upper endoscopy reveals a friable, ulcerated mass; squamous cell carcinoma and adenocarcinoma appear visually similar and can only be distinguished histologically. A CT scan of the chest, abdomen, and pelvis should be performed as a means of detecting metastatic disease.

Patients with disease restricted to the esophagus may be further evaluated with endoscopic ultrasonography. This procedure is particularly effective in determining the depth of invasion of the tumor. Positron emission tomography is increasingly utilized to identify radiographically undetectable metastatic disease.²⁰⁴ Scanning of the head or skeleton is not routine and should be reserved for symptomatic patients only.

Treatment

Surgery: Resectable Esophageal Cancer

Localized esophageal cancer may be resected either by a transthoracic or a transhiatal approach. Neither retrospective²⁰⁵ nor prospective²⁰⁶ trials have shown any difference in mortality or morbidity between these types of surgery. Patients who underwent surgery alone in recent, large randomized trials have had an operative mortality of 4% to 6% and perioperative morbidity of 26%.^{207,208} In these trials, patients had a median survival of 16 to 19 months and 5-year survival probabilities of 20% to 26%. Age does not appear to be a limiting factor in surgery of the esophagus. Although elderly patients tend to have a higher incidence of respiratory and cardiovascular complications than younger patients, this does not appear to have a significant effect on operative mortality or survival.^{193,209-213}

Chemoradiation: Localized Esophageal Cancer

Although radiation therapy alone cannot cure esophageal cancer,²¹⁴ the combination of radiation therapy with concurrent chemotherapy has led to long-term survival in about 25% of patients, similar to the results associated with surgery.²¹⁵⁻²¹⁷ Such chemoradiation therapy appears equally effective in patients 70 years of age and older as in younger individuals.^{215,216}

Adjuvant Therapy: Localized Esophageal Cancer

Preoperative radiation therapy does not appear to enhance the outcome associated with surgery.²¹⁸ However, the data assessing the value of preoperative chemotherapy are conflicting: a mature, randomized trial involving 440 American patients showed no benefit,²⁰⁸ while the preliminary results from a seemingly similar study in 802 British patients suggested that the same treatment prolonged survival.²¹⁹

With these uncertain results, attention has focused on the combination of chemotherapy and radiation therapy before surgery.²²⁰⁻²²⁶ Of five randomized trials that have attempted to demonstrate a benefit for preoperative radiation therapy and concurrent chemotherapy in esophageal cancer, only one study from a single institution has shown a statistical improvement in survival.²²⁷ More recently, a larger multi-institutional trial²⁰⁷ demonstrated no difference in median overall survival. The other studies have had too few patients to give statistically meaningful results.²²⁸⁻²³⁰

Advanced Esophageal Cancer

Chemotherapy

Several forms of chemotherapy are effective in esophageal cancer.^{194,231-236} Response durations are typically brief, lasting no longer than a few months, and survival is short, rarely exceeding more than 1 year. Although combination chemotherapy regimens tend to result in higher response rates, the therapeutic value of such intensive treatment must be balanced with a greater likelihood of toxicity. Cisplatin has become the cornerstone of combination chemotherapy in esophageal cancer, generally being combined with 5-FU, or more recently with paclitaxel,^{237,238} irinotecan,²³⁹ vinorelbine,²⁴⁰ or gemcitabine.²⁴¹ The combination of weekly cisplatin and irinotecan appears particularly active, with objective disease regression occurring in more than half of patients.²³⁹

Hepatocellular Carcinoma

Hepatocellular carcinoma (or primary liver cancer) is the fourth most common cause of cancer death in the world, leading to almost half a million deaths annually.¹⁰ More than half of these deaths are in China and Taiwan, where the condition represents the leading cause of cancer death in men.²⁴² In contrast, the annual incidence in the United States has been relatively low, with 16,200 cases expected in 2001.¹

The incidence of hepatocellular carcinoma has nearly doubled in the United States in the past two decades, primarily due to a significant increase in hepatitis B and C infections, which, along with alcoholic cirrhosis, are the primary causes of this cancer in the developed world.²⁴³ Eighty-five percent of patients infected with hepatitis C and 5% of patients infected with hepatitis B will develop persistent, chronic disease.^{244,245} Cirrhosis develops in approximately 20% of chronic disease patients, and, in turn, hepatocellular carcinoma is diagnosed in 2% to 7% of patients with cirrhosis.²⁴³

Because the latency period for the development of hepatocellular carcinoma in patients infected with hepa-

titis B or C is one to three decades, it is thought that the rising incidence of this malignancy is a result of transfusion of unscreened blood and blood products, intravenous drug abuse, needle sharing, and unsafe sexual practices during the 1960s and 1970s.²⁴³

Other risk factors for this disease in the United States include alcoholic cirrhosis, inherited hemochromatosis, and the use of hormone supplements such as oral contraceptives and exogenous androgens. In the developing world, aflatoxin B₁ exposure (from the mold *Aspergillus flavus* on grain) and schistosomiasis are important additional etiologic factors.

Prevention and Surveillance

Important steps in reducing the incidence of this cancer in the United States include vaccination of all children and sexually active adults for hepatitis B and the recently implemented screening techniques of the blood supply for hepatitis B and C.

Approximately 75% of patients with hepatocellular carcinoma demonstrate an elevation in their serum alpha-fetoprotein level. Consequently, it has been proposed that patients at increased risk for the development of this tumor such as those with hepatitis B or C infections, alcoholic cirrhosis, or hemochromatosis undergo periodic alpha-fetoprotein testing as a form of surveillance screening.²⁴⁶ This strategy has thus far been shown to be effective in Alaskan Native Americans with serologic evidence to hepatitis B exposure, in whom hepatocellular carcinomas were detected more frequently at a resectable stage than had occurred previously when such testing had not been performed.²⁴⁷

Prospective and retrospective studies of patients with hepatitis C, treated with short periods of interferon (3-6 months), have demonstrated a 50% to 34% reduction in the incidence of hepatocellular carcinoma.^{248,249} Interferon therapy is less successful in the treatment of hepatitis B, and its efficacy in reducing the incidence of hepatocellular carcinoma has not been studied. The potential benefits of interferon therapy in this setting must be balanced by the numerous and often severe side effects (e.g., flu-like symptoms, fatigue, weight loss, depression, anemia, thrombocytopenia, cardiac toxicity) associated with this treatment, especially in older individuals.

Diagnosis and Workup

Patients most often seek medical attention for the development of an often painful abdominal mass in the right upper quadrant or epigastrium that is frequently accompanied by weight loss. In patients with cirrhosis, the development of hepatocellular carcinoma may be

heralded by ascites, portal hypertension, and relatively abrupt clinical deterioration. Abnormal levels of serum transaminases and alkaline phosphatase on standard liver function testing are observed in most cases, but normal liver tests do not exclude the diagnosis. Alpha-fetoprotein is commonly elevated and is considered diagnostic when above 500 ng/mL.²⁵⁰

Ultrasonography and CT scan of the liver can determine the anatomic distribution of hepatocellular carcinoma and can also provide orientation for percutaneous needle biopsy. Patients with relatively small tumors and no evidence of distant disease or malignant ascites may be evaluated for resection. Magnetic resonance imaging, angiography, and laparoscopy can determine the resectability of the cancer. Contraindications to surgery include portal or hepatic vein invasion or portal vein thrombosis.²⁵¹ Relative contraindications include severe cirrhosis, active hepatitis, large or multifocal tumors, and comorbidities.

Treatment

Treatment options for hepatocellular carcinoma restricted to the liver include operative resection, orthotopic liver transplantation, nonsurgical tumor ablation, or transarterial hepatic chemoembolization. Patients treated with a partial hepatectomy at specialized medical centers have a 5-year survival rate of approximately 35% to 50% and an operative mortality rate less than 5%.²⁵⁰ However, intrahepatic recurrences occur in up to 75% of patients²⁵²; spread to distant sites is also common. There is no evidence that postoperative treatment with chemotherapy is useful following the resection of a hepatocellular carcinoma.²⁵³ Orthotopic liver transplantation is not tolerable in the geriatric population.

Localized tumor ablation with ethanol, cryotherapy, or radiofrequency has been increasingly utilized to eradicate small tumors and may be particularly appropriate for older patients, who are frequently considered poor candidates for surgery. Percutaneous ethanol injection (PEI) is the most commonly employed of these ablative techniques. Absolute or 95% ethanol is injected directly into the tumor either percutaneously or with direct visualization through a small incision. The probability of 5-year survival (32%–52%) and the rate of intrahepatic recurrence (60%–74%) are similar to those reported with surgical resection.^{254–257} Surgical resection and PEI have not been compared in a randomized trial.

Transarterial chemoembolization (TACE) represents the most commonly used management strategy for patients with unresectable hepatocellular carcinoma.²⁵⁰ The rationale for this treatment approach focuses on the observation that hepatocellular tumors derive nearly their entire blood supply from the hepatic artery while normal liver tissue is also oxygenated through the portal

vein. In patients undergoing TACE, selective branches of the hepatic artery are occluded (often with gel foam), leading to tumor necrosis without destruction of adjacent normal tissues. Additional intrahepatic chemotherapy may also be given. Although this procedure often results in dramatic tumor shrinkage and transient symptomatic palliation, randomized trials have failed to show a survival advantage when compared to observation alone.^{258,259}

Surgery and chemoembolization in the geriatric population have been found to be tolerable in most^{260–262} but not all^{261,263} experiences. In patients with advanced hepatocellular carcinoma, the use of chemotherapy has been disappointing²⁵¹; randomized trials have not demonstrated a survival advantage for treated patients.^{250,264}

Gallbladder Cancer

Cancers of the gallbladder occur infrequently in the United States.¹ The incidence increases with age and reaches its peak in the seventh decade of life. Women and Native Americans, who are more prone to gallstones, have a higher risk of gallbladder cancer.²⁶⁵ Other risk factors include choledochal cysts, exposure to various carcinogens, gallbladder polyps, and calcification of the gallbladder (“porcelain gallbladder”).²⁶⁶ The 5-year probability for survival is favorable (>85%) only for those gallbladder cancers that do not invade beyond the muscular layer of the gallbladder.²⁶⁶ Once the tumor invades the adjacent connective tissue, the probability of 5-year survival drops sharply (to <25%), falling to less than 10% in the presence of lymph node involvement or extension into the liver.

Prevention and Surveillance

Patients with sufficient symptoms attributable to gallstones to require medical attention have a fourfold increased risk of developing gallbladder cancer.²⁶⁷ For these individuals, a cholecystectomy may represent cancer prophylaxis. However, there are no data to justify the morbidity and expense of such a surgical procedure as cancer prophylaxis in patients with asymptomatic gallstones.²⁶⁵

Diagnosis and Workup

Gallbladder tumors most frequently are detected because of symptoms indistinguishable from those of cholelithiasis and cholecystitis. Symptoms of bile duct obstruction, including jaundice, pruritis, clay-colored stools, and dark urine occur relatively late with this cancer and are associated with advanced disease. Evaluation of these tumors often includes ultrasound exami-

nation, CT scan, cholangiography, and magnetic resonance imaging. Extensive regional lymphadenopathy, hepatic artery or portal vein encasement, and liver or peritoneal metastases are contraindications to surgery.²⁶⁸

Treatment

Surgery is the only potentially curative treatment for this disease. Superficial tumors, which are usually incidental findings following routine cholecystectomy, are often cured with this surgical procedure. More deeply invasive tumors are sometimes approached with an extended or radical cholecystectomy, in which adjacent liver tissue and regional lymph nodes are removed,^{269,270} occasionally followed by local radiation therapy.^{271,272} Randomized data to support this aggressive approach are lacking.

Advanced Disease

Patients with unresectable gallbladder cancer and jaundice should be considered for either an endoscopic or percutaneous biliary stent. Patients with pain may benefit from a percutaneous celiac ganglion nerve block to reduce the need for narcotics.

Chemoradiation is often recommended for locally advanced, unresectable biliary tract cancer,²⁷³⁻²⁷⁵ and chemotherapy may be considered for patients with metastatic disease.^{276,277} It is uncertain whether such treatments prolong survival.

Conclusion

Gastrointestinal malignancies are diseases of the elderly. As the population continues to age and the proportion of elderly grows, these cancers will become more prevalent and a further public health problem. Changes in diet, smoking, and alcohol use, however, can reduce their incidence. Dysphagia, dyspepsia, weight loss, abdominal pain, and gastrointestinal bleeding should prompt a careful and thorough evaluation. Such symptoms should not be attributed simply to depression, hemorrhoids, or irritable bowel syndrome. Most elderly patients should be regularly screened for colorectal neoplasms. Such screening has been shown to reduce the risk of cancer and to uncover cancers at an earlier stage.

Although the majority of patients with gastrointestinal cancers are 65 years or older, treatments have been designed and tested mostly in younger patients. Nonetheless, treatment of the elderly is generally well tolerated. Surgical morbidity and mortality rates of older patients are now equivalent to those of younger patients a decade ago. Many procedures once thought too dangerous for young patients can now be performed safely in otherwise

healthy octogenarians. Likewise, radiation therapy is well tolerated in older individuals, perhaps with slight increases in bone marrow suppression and small bowel toxicity. Most chemotherapeutic agents do not cause increased toxicity in elderly patients. At present, too few elderly patients are enrolled in clinical trials. Prospective studies involving older patients should evaluate the efficacy, toxicity, and quality of life in this important and rapidly expanding age group.

Surgery remains the only effective curative modality for most gastrointestinal malignancies. Patients should be evaluated thoroughly before this option is dismissed. Based on randomized studies that have shown improved survival, postoperative chemotherapy or radiotherapy or both are currently given after the complete resection of locally advanced colorectal cancer, locally advanced stomach cancer, and resectable pancreas cancer. Patients with rectal and esophageal cancers may be considered for preoperative chemoradiation therapy. In the setting of disseminated disease, chemotherapy has demonstrated both palliative and survival advantages for many gastrointestinal malignancies. Particularly for the more aggressive cancers, however, the survival benefits are marginal, and the value of such treatment in elderly or infirm patients must be balanced with potential toxicities that may diminish their quality of life.
