Preface

Through its past five editions, *Pediatric Nephrology* has become the standard medical reference for health care professionals treating children with kidney disease. This new edition, published only five years since the previous version, reflects the tremendous increase of critical information required to clinically translate molecular and cellular pathophysiology into the prevention, diagnosis, and therapy of childhood renal disorders. This text is particularly targeted to pediatricians, pediatric nephrologists, pediatric urologists, and physicians in training. It is also targeted to the increased number of health care professionals involved in the multidisciplinary team caring for children with kidney disease and their families: geneticists, genetic counselors, nurses, dialysis personnel, nutritionists, social workers, and mental health professionals. Finally, this reference is designed to serve the needs of primary care physicians (internists and family practitioners), as well as internist nephrologists who are increasingly involved in the initial evaluation and/or longitudinal care of children with renal disease under managed health care delivery systems evolving throughout the world.

The new, sixth edition of *Pediatric Nephrology* is organized into twelve main sections. The text begins with an overview of the basic developmental anatomy, biology and physiology of the kidney which provides the critical information necessary to understand the developmental nature of pediatric renal diseases. This is followed by a comprehensive presentation of the evaluation, diagnosis and therapy of specific childhood kidney diseases, including the extensive use of clinical algorithms. Of particular note is a special section on how rapidly-evolving research advances in molecular genetics, cell biology, and evidence-based medicine are being translated into new clinical approaches and therapies for many childhood renal diseases. The final sections focus on comprehensive, state-of-the art reviews of acute and chronic renal failure in childhood. To keep pace with the dramatic changes in pediatric renal medicine since the previous edition, the content of the sixth edition has been extensively revised. More than 40% of the sixth edition has been completely re-written by new authors, all recognized as global authorities in their respective areas. The remainder of the text has been completely revised and updated, often with new junior authors joining senior authors from the previous edition. In addition to the "Around the World Section", which focuses on unique aspects of pediatric nephrology practice and the epidemiology of pediatric renal disease in different regions of the world, all of the chapters have been rewritten to reflect a global, worldwide perspective. **This has led to the official endorsement of the sixth edition of *Pediatric Nephrology* by the International Pediatric Nephrology Association (IPNA) as the standard global reference text in the field of childhood kidney disease. We are proud that the IPNA logo adorns the cover of *Pediatric Nephrology* in recognition of this endorsement.** The Editors look forward to a dynamic interaction with IPNA to take advantage of future opportunities that such a collaboration may provide in the areas of education and outreach activities.

Other significant changes are also present in this new, sixth edition of *Pediatric Nephrology*. The textbook has a new publisher, Springer, which has led to a new "look" of the cover and printing, as well as the welcome expansion to two volumes. In addition, in accord with all previous editions of the text, a new Editor, Professor Norishige Yoshikawa of Wakayama University, Japan, has joined the Editorial Team. This regular change in editors continues to provide a dynamic mixture of continuity, new ideas, new perspectives and globalism. The current editors are internationally recognized leaders in complementary areas of pediatric nephrology, and reflect the global nature of the text and the subspecialty it serves. The Senior Editor, Professor Ellis D. Avner, serves as Associate Dean for Research and Professor of Pediatrics and Physiology of the Medical College of Wisconsin and Director of the Children's Research Institute, and has a focused interest in developmental renal biology, congenital/genetic diseases of the kidney, and research methods in nephrology. Professor William E. Harmon, serves as Director of Pediatric Nephrology and Professor of Pediatrics at the Children's Hospital Boston and Harvard Medical School, and is a leading expert in the field of childhood chronic renal disease and its treatment. Professor Patrick Niaudet, Director of the Pediatric Nephrology Unit at the University of Paris

© Springer-Verlag Berlin Heidelberg 2009

and the Hôpital Necker Enfants Malades, is an internationally-recognized educator and clinician-scientist in childhood nephropathy with a particular focus on childhood nephrosis. Professor Norishige Yoshikawa serves as Chairman and Professor of Pediatrics at Wakayama University, and has a focused interest in all aspects of childhood glomerulopathies, particularly IgA nephropathy.

In closing, the Editors wish to thank a number of individuals whose efforts were critical in the success of this project. The book would never have reached this sixth edition without the dedication of our professional colleagues at Springer, Ms. Marion Krämer, Ms. Gabriele Schröder, and particularly Mr. Andrew Spencer, our Managing Development Editor, who served as our "guide for the perplexed" in all aspects of project management. We thank our families, and particularly our wives Jane, Diane, Claire, and Hiro for their support and understanding. In particular, the Senior Editor wishes to recognize his lifetime partner in all endeavors, Jane A. Avner, PhD for her extraordinary editorial assistance. And finally, we thank our mentors, our students, and most importantly, our patients and their families. Without them, our work would lack purpose.

Development

1 Embryology

Adrian S. Woolf · Jolanta E. Pitera

Introduction

In the last few decades, considerable advances have been made in understanding kidney development (1, 2). In previous years, this process was described in purely anatomic terms, but we can now interpret the anatomy in terms of dynamic morphogenesis, or acquisition of form, driven by the expression of specific genes. Although our long-term aim is to understand human kidney development, most functional studies have been performed in mice and therefore these animal experiments are described in some detail. As is obvious to any Pediatric Nephrologist, developmental disorders account for a wide spectrum of kidney diseases that cause considerable morbidity and mortality in the first years of life (3–5). Renal malformations such as agenesis (absence of the kidney) and dysplasia (failure of normal renal differentiation) represent major defects of development, whereas hypoplasia (too few nephron units) is another, more subtle, developmental defect. Furthermore, enhanced proliferation, a characteristic of undifferentiated cells, occurs in Wilms tumor and cystic kidney diseases. Although these diseases are described in detail elsewhere in this book, they are alluded to here as illustrative examples of "nephrogenesis gone wrong": in some of these disorders, defined aberrations of cell biology and genetics shed light on normal human kidney development.

Anatomy of Kidney Development

Overview

Potter has provided the most complete anatomic description of human kidney development (6). The reader is also referred to recent reviews (1, 2). Three sets of "kidneys" form in mammalian embryos: the pronephros, mesonephros, and metanephros. The metanephros is the direct precursor of the adult kidney, whereas the others essentially involute before birth. The anatomic events of human and mouse nephrogenesis are similar, but the timetable of development differs. Human gestation is 40 weeks but mouse gestation is about 20 days. The human metanephros appears 5 weeks after fertilization and on late embryonic day 10 in mice. The first metanephric vascularized glomeruli form by about 7 weeks in humans and day 14–15 in mice. The final layer of nephrons forms by 36 weeks' gestation in humans, whereas nephrogenesis continues for one postnatal week in mice. In addition, there are some anatomic differences. The human mesonephros contains glomeruli with capillary loops, but mouse mesonephric tubules have rudimentary glomerular tufts. Healthy adult humans have approximately 1–2 $\times$ 10^6 glomeruli in each kidney (7) and murine species (8) have proportionately fewer glomeruli per kidney. Finally, whereas the human renal pelvis has multiple papillae, the murine kidney has one. A cartoon of the early stages of human metanephric development is depicted in *Fig. 1-1*, and a histologic analysis is shown in *Fig. 1-2*. *Fig. 1-3* indicates the major cell lineages derived from the metanephros, and *Fig. 1-4* addresses the formation of blood vessels in the metanephros.

Pronephros and Mesonephros

The mesoderm forms during gastrulation, and embryonic kidneys subsequently develop from nephrogenic cords, masses of intermediate mesoderm located behind the embryonic coelom between the dorsal somites and the lateral plate mesoderm. At the height of their development, the pronephros and the mesonephros extend in series from the cervical to lumbar levels. They develop in a segmental manner as tubules that are induced to differentiate from mesoderm by the adjacent pronephric and mesonephric (or Wolffian) duct. In humans, the pronephros develops from the third embryonic week and contains rudimentary tubules opening into the pronephric duct. The human mesonephros begins to develop in the fourth week of gestation and contains well-developed nephrons comprising vascularized glomeruli connected to proximal and distal type tubules draining into the mesonephric duct, itself a continuation of the pronephric duct. The mesonephric duct extends to fuse with the cloaca, the urinary bladder precursor, at the end of the fourth week. The pronephros and mesonephros can be regarded as a

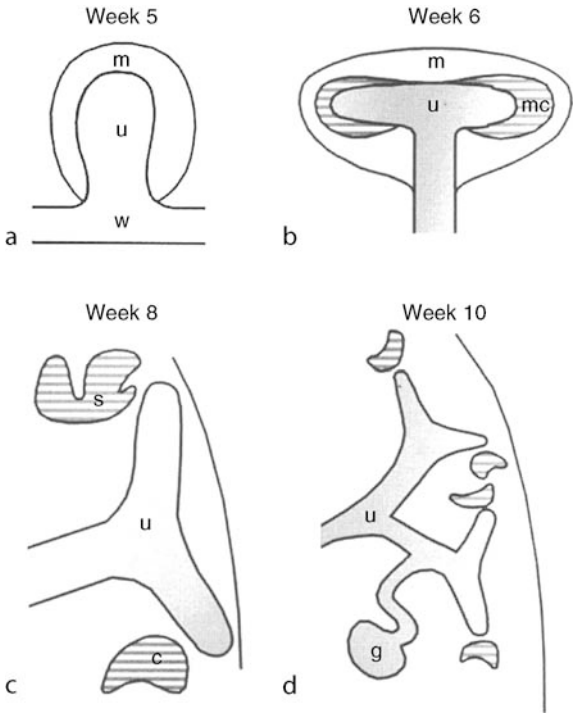
Figure 1-1

Early development of the metanephros. Cross-sectional diagrams of the human metanephros at approximately 5 weeks' (a), 6 weeks' (b), 8 weeks' (c), and 10 weeks' gestation (d). Note that the most primitive structures are located in the periphery of the maturing organ. *u*, Ureteric bud; *m*, mesenchyme; *mc*, mesenchymal condensate; *c* and *s*, comma and S-shaped bodies; *g*, glomerulus; *w*, Wolffian duct.



single unit, and as the wave of differentiation spreads caudally, the cranial end of this organ complex begins to regress. By one-third of the way through human gestation, most cells in these organs have involuted. In the male, mesonephric tubules in the area of the gonad form the efferent ductules, and the mesonephric duct gives rise to the epididymis and ductus deferens. In the female, some mesonephric tubules persist as the epoophoron and para-oophoron.

Metanephros

The metanephros is the last embryonic kidney to develop and is identified in humans and consists of two components (1, 6). These are the ureteric bud epithelium, which branches from the caudal part of the mesonephric duct around 4 weeks of gestation, and the metanephric mesenchyme, which condenses from the intermediate mesoderm around the enlarging tip, or ampulla, of the bud. The metanephric kidney can be identified as an entity around week 5–6 of gestation. The ureteric bud and its branches form epithelia of the collecting ducts, renal pelvis, ureter and bladder trigone, whereas the metanephric mesenchyme differentiates into nephron tubules (glomerular, proximal tubule, and loop of Henle epithelia) and the interstitial fibroblasts. These lineages may be more plastic than previously considered, as discussed later in this chapter. In humans, the renal pelvis and major calyces are apparent by the tenth to 12th week of gestation. The pelvis forms from remodeling of the first

Figure 1-2

WT1 immunostaining in human fetal kidneys. (a) Normal human fetal kidney shows a gradient of WT1 immunoreactivity (*black*) from nephrogenic cortex (*on right*) to maturing nephrons (*on left*). Cells in condensates and vesicles (*arrowheads*) are weakly positive for WT1. Expression increases in the mesenchymal to epithelial transition with high WT1 levels in the proximal limb of S-shaped bodies (*open arrowheads*) and the podocytes of fetal glomeruli (*g*). A ureteric bud branch tip (*u*) is negative. (b) Intense WT1 expression is maintained in the podocytes of maturing glomeruli. Bars are 10 μm. Figure 1-3

Main cell lineages arising in the metanephros. (Modified from Hardman P, Kolatsi M, Winyard PJD et al. Branching out with the ureteric bud. *Exper Nephrol* 1994;2:211–219; with permission from S. Karger, AG Basel.)

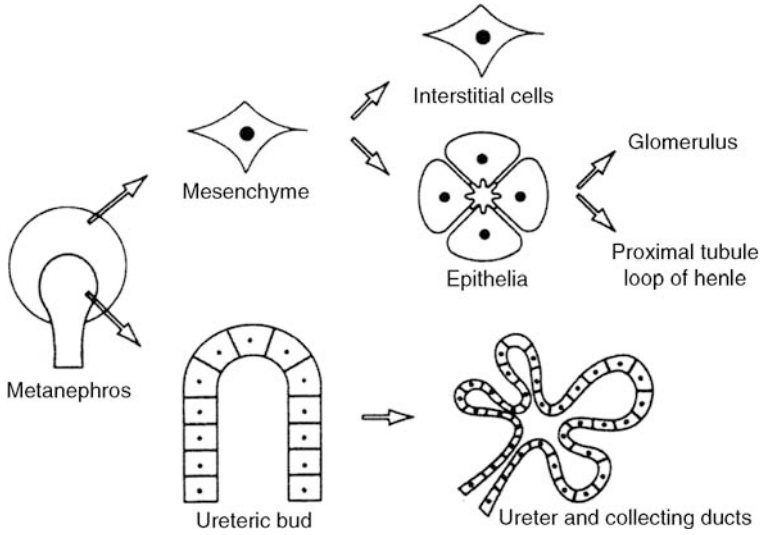

Figure 1-4

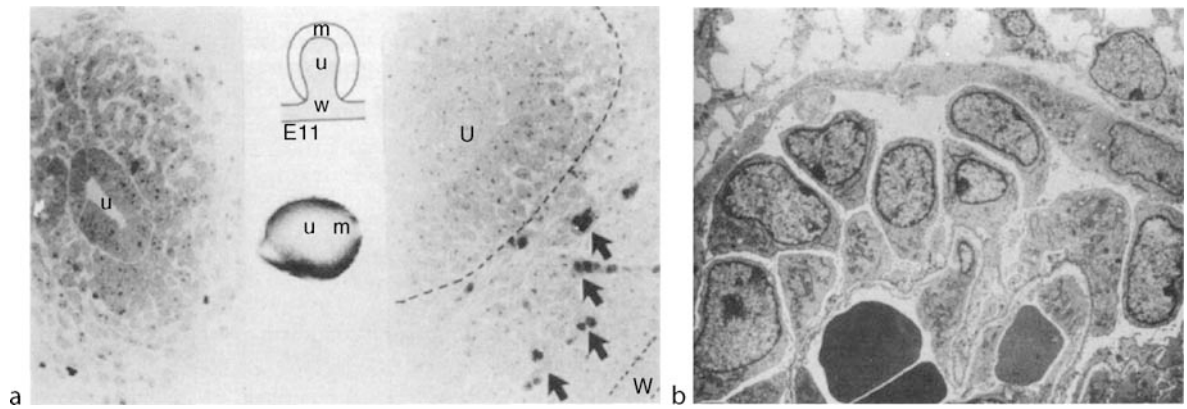
Capillary formation in the mouse metanephros. (a) The mouse metanephros at the ureteric bud stage contains no formed capillaries. Center panel shows diagram of the ureteric bud stage above a photograph of the intact organ. Flanking panels are histology sections of the organ in different planes: the right panel shows an area of loose connective tissue and capillaries between the metanephros itself and the Wolffian duct. (b) Electron microscope image of a glomerulus that has formed in the metanephros. *u*, Ureteric bud; *m*, mesenchyme; *w*, Wolffian duct.



six generations of ureteric bud branches, and the minor calyces arise from the next generation of branches. Each minor calyx is associated with 20 ampullae, which will form the papillary collecting ducts: these indent the calyx to form the familiar cup shape seen in intravenous urograms.

Up to 14 weeks' gestation, the formation of each new collecting duct is associated with the induction of a nephron from adjacent metanephric mesenchyme. The differentiation of each nephron starts with mesenchymal cell aggregation around ureteric bud branch tips. Each condensate subsequently forms a lumen (the vesicle stage) and elongates to form a tubule (the comma-shaped body), which then shows regional specialization into primitive glomerular and proximal tubular epithelia (the S-shaped body). The proximal end of each S-shape

becomes the glomerular epithelium while the distal end of each tubule fuses with the adjacent branch of the ureteric bud. With each division of the ureteric bud, a new layer of nephrons is induced from stem cells in the periphery of the organ. Between 14 and 20 weeks, each ampulla induces 3–6 nephrons without dividing. During this process, the connecting tubule of the older, innermost nephron shifts the position of its point of attachment away from the ampulla to the connecting tubule of the next-formed nephron so they are joined together in arcades of 4–7 nephrons. Up to 34–36 weeks' gestation, the ureteric bud branch tips advance further outward and another 4–7 nephrons form and attach separately just behind the ampullary tips. Thereafter, no new nephrons form although each tubule continues to mature even into the postnatal period. These changes include the elongation of the loops of Henle toward the medulla as well as convolution of the proximal tubule.

The adult kidney is highly vascular and receives approximately 20% of the cardiac output. However, at the inception of the metanephros, no mature vessels are present in the renal mesenchyme. The first patent capillaries are evident around the stalk of the ureteric bud, when it has branched once or twice and capillaries later appear in the glomerular crevices of the S-shaped bodies (9). The primitive multilayered visceral glomerular epithelium subsequently forms a monolayer of podocytes, which abut glomerular capillary loops. At 9–10 weeks' human gestation, the most mature nephrons, located toward the center of the metanephros, are the first to acquire capillary loops and a patent Bowman's space. The forming glomerular basement membrane is thought to be synthesized by both the endothelium and epithelium (10). The fusion of the two embryonic membranes and its subsequent biochemical maturation correlates with the progressive restriction of filtration of macromolecules. At its inception, the human metanephros receives its blood supply from the lateral sacral branches of the aorta. As development proceeds, the organ is located at progressively higher levels and is supplied by higher branches of the aorta. By 8 weeks' gestation, the metanephros is located in the lumbar position, and ultimately the definitive renal arteries arise from the aorta at the level of the second lumbar vertebra.

The Ureter and Urinary Bladder

The lower urinary tract forms in synchrony with the metanephric kidney (11). The urogenital sinus is the urinary bladder rudiment, and it separates from the rectum by 4 weeks of human gestation. At this time, its epithelium fuses with that of the mesonephric duct and the ureteric bud arises as a diverticulum from the posteromedial aspect of the mesonephric duct near where it enters the forming bladder. Between 4 and 5 weeks the human ureter is patent and it has been assumed, because the cloaca is imperforate at that time, that mesonephric urine maintains ureteral patency by increasing intraluminal pressure. The mesonephric duct above the ureteric bud becomes the vas deferens males but involutes in the female. At 5 weeks of gestation, the mesonephric duct below the ureteric bud, the "common excretory duct," involutes, allowing the lower end of the ureteric bud stalk to fuse with the nascent bladder; thereafter, ureteric orifices migrate cranially and laterally. Over the next few weeks, the ureter apparently becomes occluded and then recanalizes, the later event perhaps coinciding with urine production from the first metanephric glomeruli. The embryonic "ascent" of the metanephros from the level of the sacral segments to the lumbar vertebrae is partly associated with ureteric elongation. The urinary bladder becomes a recognizable entity by about 6 weeks of gestation, and the urogenital membrane ruptures around week 7, providing a connection between the bladder and outside of the body. The allantois, another potential outflow tract on the anterior of the developing bladder, forms at 3 weeks days of gestation and involutes by 12 weeks. Towards the end of the first trimester, the ureteric urothelium assumes a pseudo-multilayered arrangement and its walls become muscularized; by this time, the bladder wall has differentiated into circular and longitudinal smooth muscle fibers which continue to mature in the second trimester (11).

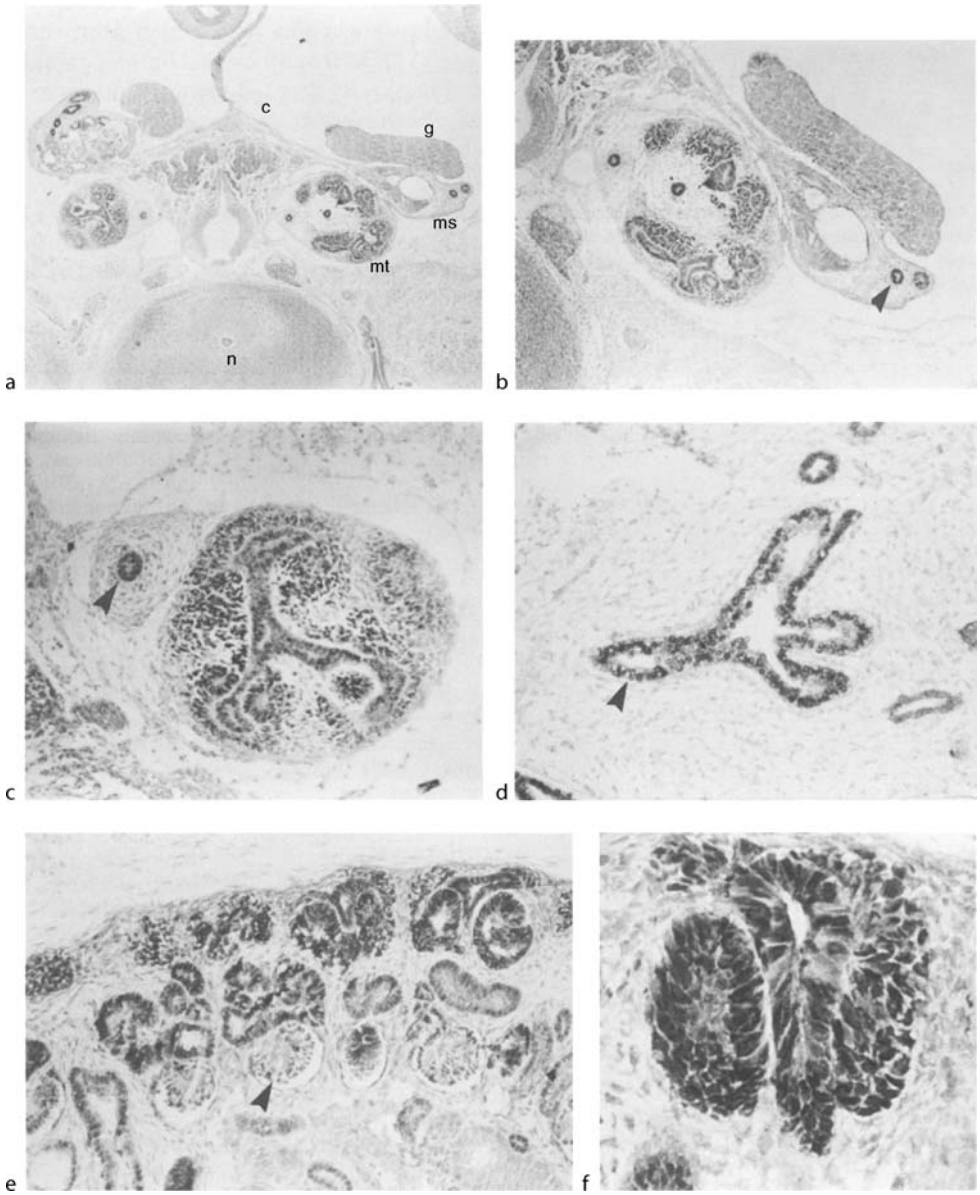
Methods Used to Study the Biology of Nephrogenesis

Descriptive Studies of Gene Expression

Patterns of cell division, death, differentiation, and morphogenesis can be correlated with changes in spatial and temporal patterns of gene expression in terms of messenger ribonucleic acid (mRNA) and protein using by in situ hybridization and immunohistochemistry (*Figs. 1-2* and 5). More recently, microarray "chip" technology has been used to study the spectrum genes expressed during human kidney development (12, 13). These observations provide data for the generation of hypotheses regarding the molecular control of nephrogenesis. These hypotheses can be tested by studying the effects of diverse interventions during normal development. These functional

Figure 1-5

Early human metanephros and the mesonephros. Sections are stained with antibody to PAX2 transcription factor: positive nuclei appear black, whereas others are counterstained with methyl green and appear gray. (a) Transverse section of a 5- to 6-week gestation human embryo showing, on each side of the embryo, a mesonephros (*ms*), metanephros (*mt*), and gonadal ridge (*g*) (×5). Also shown is the central notochord (*n*) in a mass of cartilage that will form the vertebral body, and the coelom (*c*). (b) Enlarged view of (a). Note the mesonephric duct (*arrowhead*) stains for PAX2, as does the flanking paramesonephric duct (x20). (c) High power of metanephros containing the first branches of the ureteric duct with adjacent mesenchymal condensates. The mesonephric duct (*arrowhead*) is nearby (×20). (d) Medulla of an 11-week human kidney shows a major branch of the fetal ureter (*arrowhead*) branching to form collecting ducts: most nuclei in these structures stain for PAX2 (×20). (e) Cortex of an 11-week human fetal kidney shows presence of a nephrogenic outer cortex with increasingly mature nephrons and glomeruli (*arrowhead*) toward the center of the organ. Note that PAX2 is downregulated in more mature elements (×20). (f) High power of (e) Intense staining for PAX2 in the branch tip of a ureteric bud and the flanking renal mesenchymal condensates (×63). (Pictures courtesy of Dr PJD Winyard, Institute of Child Health, London, UK.)



experiments can be performed in the intact animal, in vivo, or "in the test tube," in vitro.

Functional Studies In Vitro

Experiments performed by Grobstein several decades ago are classic examples of in vitro studies (14). Grobstein found that the mouse metanephros would form a small kidney in organ culture over days. *Figure 1-6* shows how the explanted renal tract of a midgestation mouse embryo grows in organ culture over several days. Of note, other branching organs, such as the lung and the salivary gland, can also be grown in the same manner (*Fig. 1-7*). If either the renal mesenchyme or the ureteric bud was cultured in isolation, however, Grobstein noted that they failed to differentiate. This clearly demonstrates that embryonic tissue interactions are critical for kidney development, and we now know that growth factors are important signaling molecules involved in these inductive processes. Growth may be modulated in organ culture with antisense oligonucleotides that impair the transcription of metanephric mRNAs or with antibodies that block the bioactivity of secreted or cell surface proteins (15–17).

Figure 1-6

Whole-mounts mouse embryonic tissues immunostained (black) for the PAX2 transcription factor. (a) Series of lateral views of embryos at embryonic day 9 (E9) to embryonic day 11 (E11); the former time-point approximately anatomically-equivalent to a 3.5 week human gestation, and the latter time point equivalent to 5 week human gestation. Note the pronephric/mesonephric duct (*arrowheads*) expresses PAX2. By E10, the upper part of the mesonephric duct connects to mesonephic tubules (labeled *meso*), while the most caudal part branches to form the ureteric bud which invades a section of PAX2 expressing intermediate mesoderm, to form the metanephros (boxed area, labeled *meta*). (b) These frames depicted the growth and differentiation of a complete E10.5 renal tract (paired mesonephric ducts, mesonephroi and metanephroi). Note that, over 72 h, the mesonephros involutes while the metanephros grows in size and complexity.

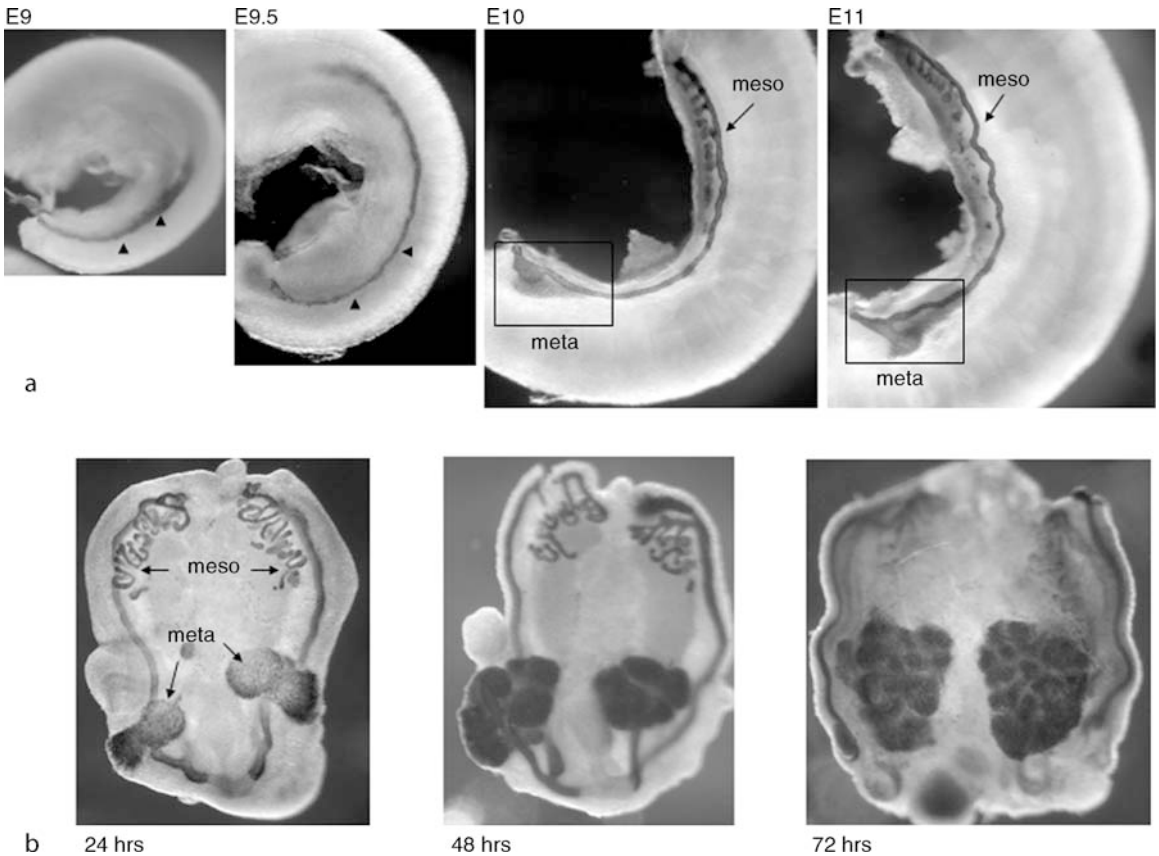


Figure 1-7

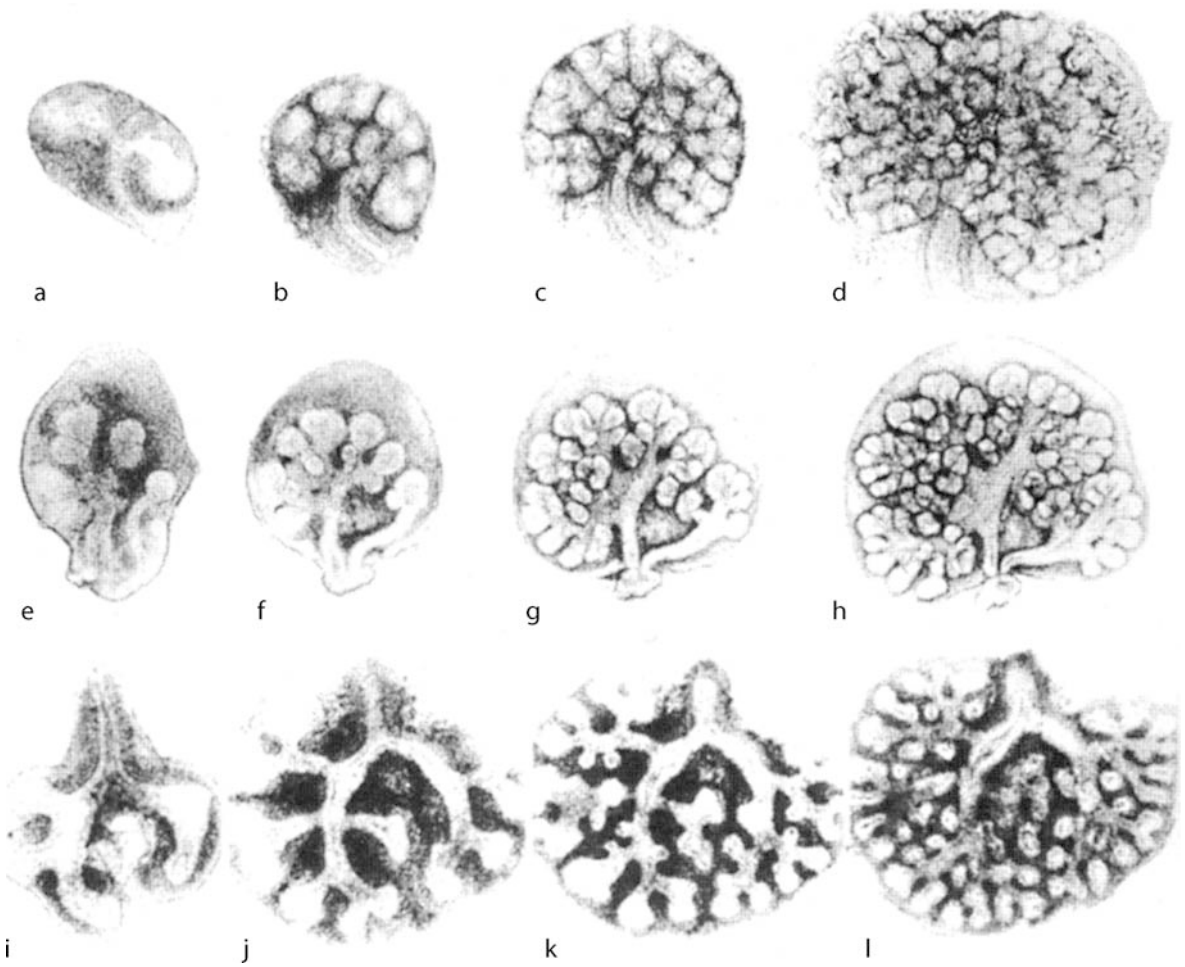
Growth of mouse embryonic tissues in organ culture. Note branching morphogenesis occurs over 1 week in organ culture. (a–d) show the metanephros; (e–h) show the salivary gland; and (i–l) show the lung. (Modified from Hardman P, Kolatsi M, Winyard PJD et al. Branching out with the ureteric bud. *Exp Nephrol* 1994;2:211–219; with permission from S. Karger, AG Basel.)



Other technological advances have made it feasible to transfer new genes into the metanephros in vitro (18, 19). Qiao and Herzlinger used retroviral transduction to introduce a reporter gene into renal mesenchymal cells; they subsequently demonstrated that these precursors not only formed nephron tubules, as expected, but also differentiated into a minor proportion of cells within collecting duct epithelia (19). Finally, the generation of metanephric cell lines has made it feasible to study the expression of multiple genes in homogeneous populations of precursors (13, 16) as well as the potential normal and abnormal differentiation of these cells in response to defined stimuli (13, 20).

Functional Studies In Vivo

In vivo experiments on developing kidneys have used physical, teratogenic (e.g., chemical), and genetic strategies. For example, surgical interruption of the avian mesonephric duct prevents the conversion of intermediate mesoderm into mesonephric tubules and also prevents the formation of the metanephros (21). Complete obstruction of the sheep fetal ureter in midgestation generates hydronephrotic kidneys, with generation of cysts and disruption of nephrogenesis resembling human renal dysplasia (22). With regard to teratogenic studies, an example is the generation of urinary tract malformations after

exposure to high doses of vitamin A (23) or elevated levels of glucose (24). Welham et al (8, 25) reported that the imposition of mild (9%) dietary protein restriction during rat pregnancy reduced numbers of glomeruli per kidney measured postnatally when nephrogenesis has finished. This was associated with enhanced apoptotic deletion of renal mesenchymal precursors, and an altered spectrum of gene expression, at the start of metanephrogenesis. In humans, the equivalent developmental timeframe would be 5–7 weeks gestation, and this might represent a critical window when kidney morphogenesis might be affected by dietary influences.

The most powerful in vivo experiments, however, alter the expression of metanephric molecules by genetic engineering using transgenic animal technology. First, levels of a specific protein can be increased by inserting a coding deoxyribonucleic acid (DNA) sequence, linked to a strong promoter, into the genome of early embryos. This is usually done by microinjection into the male pronucleus of fertilized ova. The phenotype of such mice illustrates the effects of an excess of a molecule (26). Even more informative is the technique of homozygous recombination in which the function of a gene can be ablated. Here, mouse embryonic stem cells are genetically engineered in vitro and then incorporated into early embryos that develop into chimeric mice. If the altered cells contribute to the germ-line, animals with homozygous and heterozygous gene deletions can be generated by further breeding (27). The phenotypes of these null mutant or "knock-out" mice, which include the complete absence of metanephric development, have so far suggested that several tens of genes are essential for normal nephrogenesis in vivo: *Table 1-1* lists some of these. Many of these animal models also have defects in nonrenal systems because the same genes are expressed in and critical for the normal development of organs other than the kidney.

Hundreds of molecules are known to be expressed during nephrogenesis (28), and tens of these have been considered to be functionally important based on organ culture studies. However, mice with null mutations of the same genes sometimes have normal kidney development in vivo. Hence, we can speculate that numerous metanephric molecules are of little functional significance or are redundant in the intact embryo. It also follows that organ culture must constitute a relatively stressful milieu in which it is comparatively easy to disrupt development by altering levels of a single molecule. Of note, the genetic background, or strain, of mice with defined mutations can affect the kidney phenotype, suggesting the presence of modifying genes. When two structurally similar molecules are expressed at identical locations in

Table 1-1

Examples of Mutant Mice with Renal Malformations

Transcription factor genes
FOXD1 (small, fused and undifferentiated kidneys)
BRN1 (poorly differentiated loops of Henle)
EYA1 (absent kidneys)
FOXC1(duplex kidneys)
FOXC2 (hypoplastic kidneys)
HOXD11 paralogue compound mutants (small or absent kidneys)
LIM1 (absent kidneys)
LMX1B (poorly formed glomeruli)
PAX2 (small or absent kidneys)
SALL11 (failure of ureteric bud outgrowth)
SIX1 (small or absent kidneys)
SIX2 (accelerated tubulogenesis and small kidneys)
TBX18 (hydronephrosis)
TSHZ3 (hydronephrosis)
WT1 (absent kidneys)
Growth factors and receptor genes
AT1 (poor papillary growth)
AT2 (diverse kidney and lower urinary tract malformations)
BMP4 (kidney and ureter malformations)
BMP7 (undifferentiated kidneys)
FGF7 (small kidneys with fewer glomeruli)
GDF11 (small or absent kidneys)
GDNF or its receptor *RET* (small or absent kidneys)
NOTCH2 (malformed proximal nephron)
PDGFB (absent mesangial cells)
ROBO2 (duplex kidneys)
SHH (hydronephrosis)
WNT4 (undifferentiated kidneys)
Adhesion molecules and receptor genes
ITGA3 (decreased collecting duct branching)
ITGA8 (impaired ureteric bud branching and nephron formation)
FRAS1 (absent kidneys)
FREM2 (absent kidneys)
GPC3 (dysplastic kidneys)
LAMB2 (nephrotic syndrome)
Other genes
BCL2 (small kidneys)
RAR compount mutants (small or absent kidneys)
UPK3A (hydonephrosis and vesicoureteric reflux)

the metanephros, both loci may have to be ablated to generate a renal malformation in vivo (29, 30).

Cell Biology of Nephrogenesis

Cell Proliferation and Cell Death

Proliferation is prominent in the tips of the ureteric bud branches and in the adjacent mesenchymal cells in the nephrogenic cortex of the metanephros (31). Renal mesenchymal stem cells may reside within this area, and such cells are believed to divide to generate a copy of themselves and also another cell. These cells subsequently differentiate into nephron epithelia or interstitial cells. Other evidence, discussed later in this chapter, suggests that cells in the renal mesenchymal compartment can also differentiate into glomerular capillaries and juxtaglomerular cells. Stem cells have previously been considered to be absent from the mature kidney; although if they did exist, they might provide a source of cells for the regeneration of nephron epithelia after nephrotoxicity. Recently, preliminary evidence was provided that a rare subpopopulation of medullary kidney stromal cells may in fact constitute such a population in the adult kidney (32).

Not all cells born in the developing kidney are destined to survive the fetal period. In 1926, Kampmeier reported that the first layers of metanephric nephrons "disappeared" before birth (33), a process likely to be associated with the remodeling of the first divisions of the ureteric bud during formation of the pelvis. In fact, a degree of cell death normally occurs in the mesenchyme adjacent to primitive nephrons, where it may regulate the number of cells in each tubule, the number of nephrons formed, or perhaps the density of adjacent stromal/interstitial cells (8). These cells die by apoptosis, a process accompanied by nuclear condensation and fragmentation. These deaths are sometimes called programmed because they are part of the normal program of development and each cell "commits suicide" by an active program of biochemical events, including digestion of genomic DNA into fragments of about 200 nucleotides by calcium-dependent endonucleases. Apoptosis also occurs in the developing medulla (*Fig. 1-8*) and it has been suggested that this process is implicated in the morphogenesis of the thin ascending limb of the loop of Henle (34) and also in deleting excess β intercalated cells in the collecting duct (35). Furthermore, apoptosis appears to be a normal event in morphogenesis of capillaries in developing glomeruli, critical for lumen formation (36).

Therefore normal nephrogenesis involves a fine balance between cell proliferation and death. Excessive proliferation is associated with the generation of neoplasms (e.g. Wilms tumor) and cysts (e.g., polycystic kidney diseases) (37). Conversely, excessive apoptosis would cause a reduction of kidney growth resulting in an organ with fewer nephrons than normal (e.g., a hypoplastic kidney) or even involution of a metanephric kidney (e.g., some dysplastic kidneys) (38, 39).

Differentiation

As individual renal precursor cells become specialized, they undergo differentiation. For example, some renal mesenchymal cells differentiate into primitive nephron epithelia, while others differentiate into stromal cells, or interstitial fibroblasts (40). Precursor cells later become "terminally differentiated" to enable them to perform specific functions of the adult organ. For example, cells within a nephron precursor form the glomerular parietal and visceral epithelia as well as the cells that comprise the proximal tubule and loop of Henle. The term *lineage* describes the series of phenotypes as a precursor differentiates into a mature cell.

Morphogenesis

Morphogenesis describes the developmental process by which groups of cells acquire complex three-dimensional shapes. Examples include the formation of nephron tubules from renal mesenchymal cells and the serial branching of the ureteric bud to form the collecting duct system. The process of morphogenesis also occurs during angiogenesis and vasculogenesis, modes of renal capillary formation discussed later in this chapter (9). Angiogenesis also involves the fundamental cellular process of directional movement, or migration.

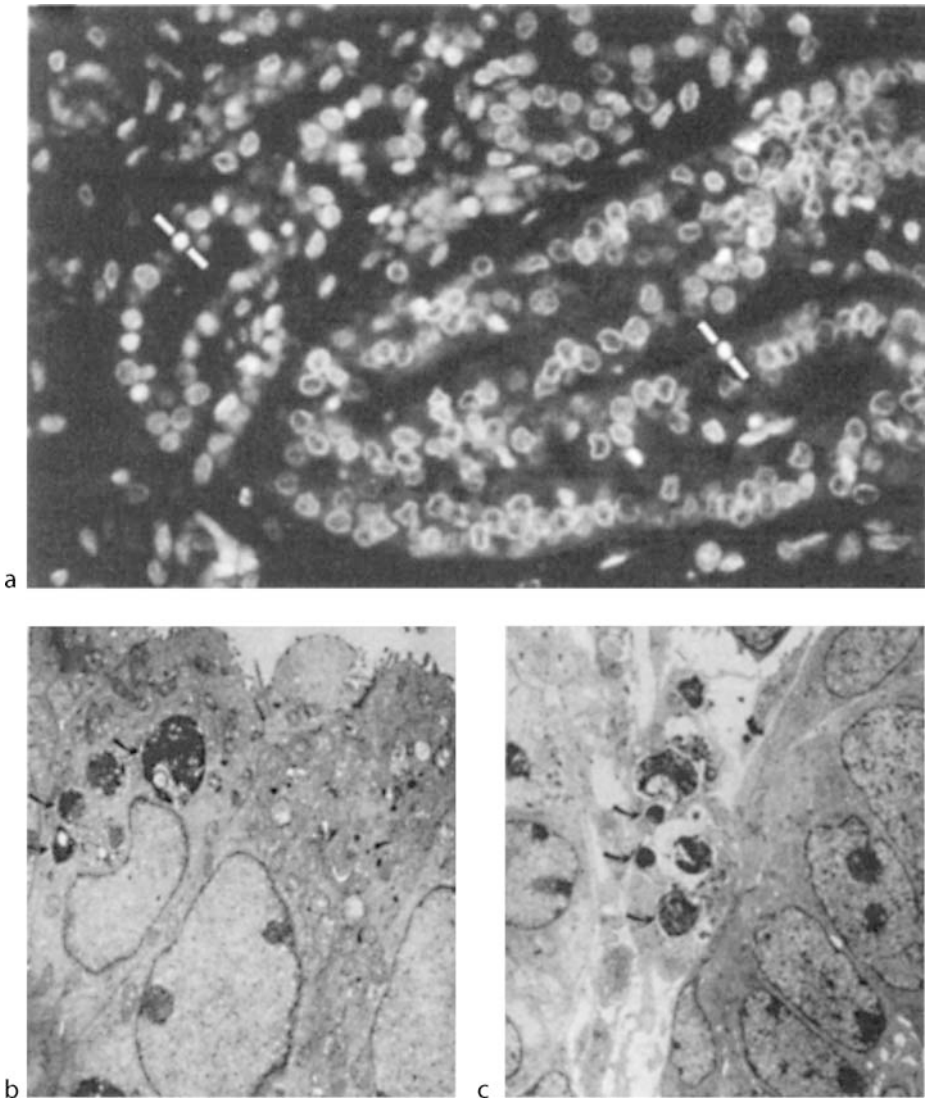
Molecular Control of Nephrogenesis

Overview

Three main classes of molecules are expressed during nephrogenesis: transcription factors, growth/survival factors, and adhesion molecules. Several have been implicated in kidney development, as assessed by studies of mutant mice (see *Table 1-1* for a selective list) and humans with kidney malformations (1–5, 28, 41, 42).

Figure 1-8

Cell death in normal nephrogenesis. (a) Apoptotic cell death is detected in the outer medulla of the human metanephros, as assessed by bright, condensed, propidium-iodide stained nuclei (between the *white bars*) in primitive loops of Henle and other tubules, probably collecting ducts (×63). (Courtesy of Dr PJD Winyard, Institute of Child Health, London, UK.) (b, c) Electron microscope images of the medulla of a mouse metanephros to show apoptotic nuclei (*curved arrows)* being engulfed by epithelial cells (b) and cells within the interstitium (c).



Note that italics are used when referring to genomic sequences, whereas regular typescript is used for gene products e.g., *PAX2* gene and PAX2 protein (*Figs. 1-5, 6, 9–11*). The following criteria should be satisfied for a molecule to be definitively involved in normal nephrogenesis: it must be expressed by the metanephros in an appropriate spatial or temporal manner; functional experiments should demonstrate that its absence perturbs kidney development in organ culture and in vivo; and the molecule should have an appropriate bioactivity on isolated populations of precursor cells. At present, few molecules have been shown to fulfill all three criteria. Expression patterns of several key molecules active in the metanephros are shown in *Figs. 1-9–12*.

Figure 1-9

Gene expression in initiating mouse metanephros; ureteric bud stage. Sections of mouse metanephric kidneys at embryonic day 10.5, the anatomical equivalent to human 4.5 week gestation metanephros. Gene expression (appearing in *black*) has been assessed by either in situ hybridization to detect RNA (HOXD11, GDNF and RET) or immunohistochemistry (SIX1, SIX2, PAX2 and SALL1) to localize protein. The tissue has been lightly counterstained with hematoxylin (appears *grey*). Note expression of the transcription factors HOXD11, SIX1, SIX2 and SALL1 in the metaneprhic mesenchyme (*m*) only. The PAX2 transcription factor is expressed in both the metanephric mesenchyme and the urteric bud (*u*) which is growing into the mesenchyme. The growth factor GDNF is expressed in the mesenchyme and signals via the RET receptor tyrosine kinase in the bud.

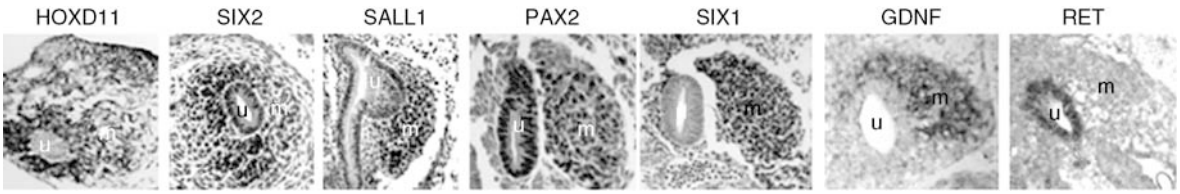


Figure 1-10

Gene expression in initiating mouse metanephros: initiation of branching stage. Sections of mouse metanephric kidneys at embryonic day 11, the anatomical equivalent to human 5 week gestation metanephros. Gene expression (appearing in *black*) has been assessed by either in situ hybridization to detect RNA (EYA1, HOXD11, PAX2, GDF11, GDNF and RET) or immunohistochemistry (SALL1, SIX1, SIX2, ITGA8, LIM1 and BRN1) to localize protein. The tissue has been lightly counterstained with hematoxylin (appears *grey*). The ureteric bud has branched one-two times and that the metanephric mesenchyme is condensing around the branch tips. Note the expression in the mesenchyme-only of the transcription factors EYA1, HOXD11, SALL1, SIX1 and SIX2. The transcription factor PAX2 the growth factor GDF11 are expressed in both the urteric bud branches and the mesenchyme. The growth factor GDNF is expressed in mesenchyme around the RET-expressing tips of the arboring bud branches. The integrin ITGA8 is expressed in the condensed mesenchyme. The transcription factors LIM1 and BRN1are beginning to be expressed in mesenchymal condensates which are nascent nephrons.

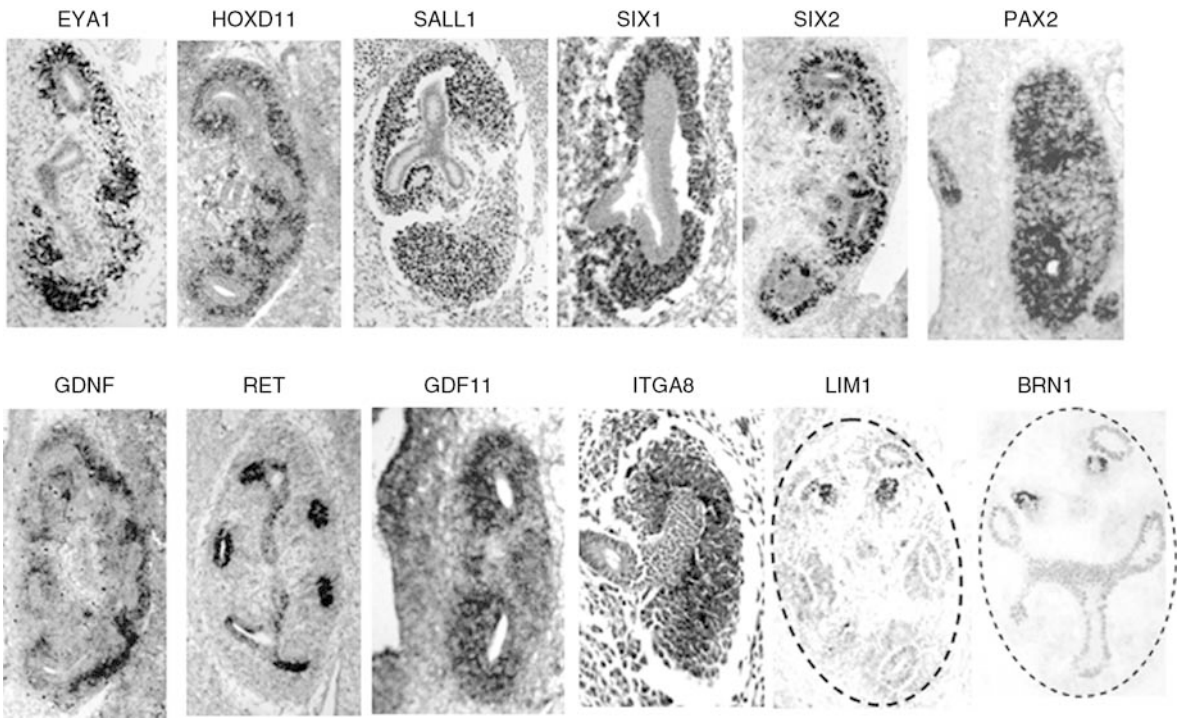

Figure 1-11

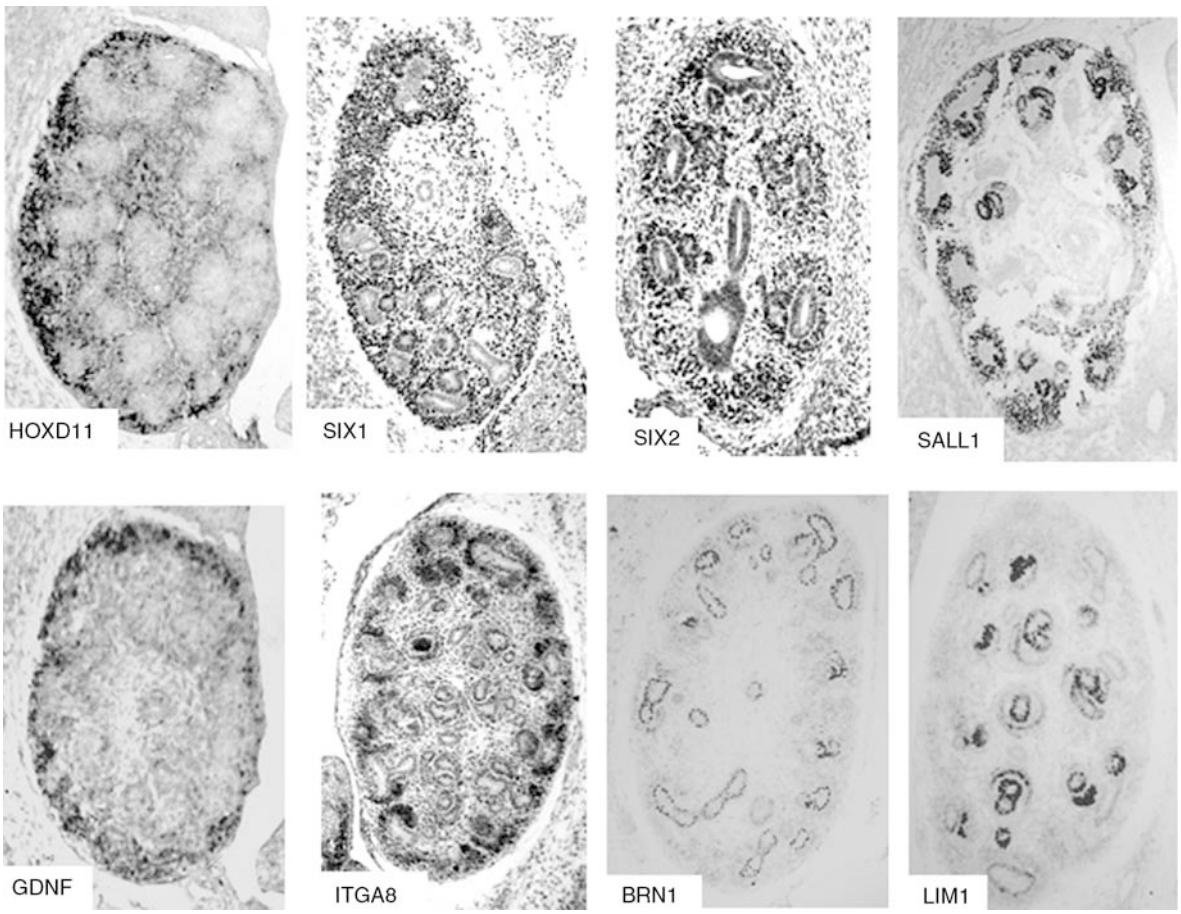
Gene expression in initiating mouse metanephros: nephron precursor stage overview. Sections of mouse metanephric kidneys at embryonic day 12, the anatomical equivalent to human 6 week gestation metanephros. Gene expression (appearing in *black*) has been assessed by either in situ hybridization to detect RNA (HOXD11 and GDNF) or immunohistochemistry (SIX1, SIX2, SALL1, ITGA8, BRN1 and LIM1) to localize protein. The tissue has been lightly counterstained with hematoxylin (appears *grey*). By this stage, the bud has undergone multiple rounds of branching and the first nephron precursors have differentiated into vesicles and S-shaped bodies; a rim of mesenchyme remains in the periphery and will continue to generate new nephrons. HOXD11, SIX1, SIX2, SALL1, GDNF and ITGA8 continue to be expressed in the mesenchyme while BRN1 and LIM1 are prominently expressed in various parts of the emerging nephron (see also *Fig. 1-12*).

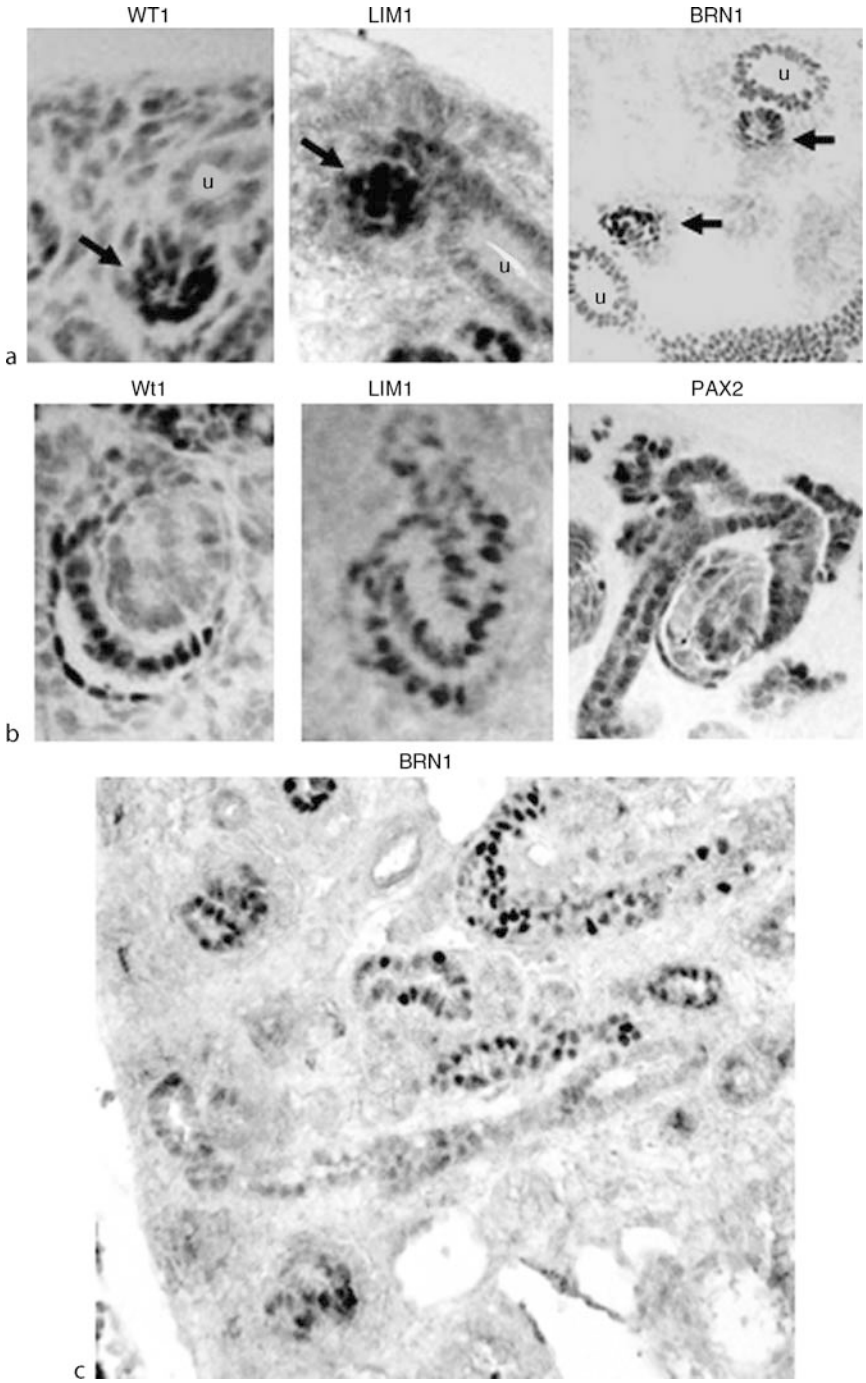


Transcription Factors

Transcription factor proteins bind to DNA and regulate expression of other genes. Because they can enhance or switch-off the transcription of mRNAs, transcription factors have been likened to conductors of an orchestra during normal development. These molecules can be classified into families that share similar DNA-binding protein motifs and domains. One such motif is called the zinc-finger, which describes a projection of the molecule that intercalates with DNA. Examples of transcription factors expressed during nephrogenesis include members of the homeobox (HOX) family (30), that contain DNA-binding homeodomains, as well as the paired-box (PAX) family, which contain DNA-binding paired-domains (27). At present, little is known about the specific targets of many of the transcription factors expressed in the developing kidney. However, it has been reported that levels of integrin α8 (ITGA8), which links metanephric cell membranes with the extracellular environment, are increased by HOXD11 (43), and that this homeobox gene, acting on concert with PAX2 and another molecule called eyes

Figure 1-12

Gene expression in initiating mouse metanephros: nephron precursor stage high power views. (a) in the nephrogenic zone, the transcription factors WT1, LIM1 and BRN1 are upregulated in condensates and vesicles (*arrows*), as the mesenchyme undergoes transition to nephron epithelium. BRN1 is also weakly expressed in cells near ureteric bud branch tips (*u*). (b) In more mature nephronic structures, the S-shaped bodies, WT1 is expressed in nascent glomerular epithelia, Lim1 is expressed in the emerging glomerulus and proximal tubule, while PAX2 is dowregulated but it remains expressed in adjacent ureteric bud branches. (c) BRN1 is also expressed in forming loops of Henle.



absent 1 (EYA1), stimulates the expression of the metanephric growth factor called glial cell line-derived neurotrophic factor (GDNF) (44).

Growth Factors

The metanephros is rich in growth factors that modulate cell survival, proliferation, differentiation and morphogenesis. Factors that have a positive effect on growth include angiopoietin 1 (ANGPT1), bone morphogenetic protein 7 (BMP7), epidermal growth factor (EGF) and its embryonic homologue transforming growth factor α (TGFα), fibroblast growth factors (FGFs), GDNF, growth differentiation factor 11 (GDF11), hepatocyte growth factor (HGF), insulin-like growth factor I and II (IGFI and II), leukemia inhibitory factor (LIF), platelet derived growth factor A and B chains (PDGFA and B), and vascular endothelial growth factor (VEGF). Less studied are those which have negative effects on growth and differentiation include TGFβ and tumor necrosis factor α (TNFα); the importance of these factors may be more apparent in malformed kidneys, where their expression is up-regulated and they may perturb normal growth (45, 46). Some factors, such as BMP4, have positive or negative effects on growth and differentiation depending on the specific stage of renal tract morphogenesis being studied. In some cases, a single factor can have multiple effects by virtue of binding to more than one different receptor; for example, angiotensin II generally acts to promote growth through its type I (AT1) receptor but also stimulates apoptosis through the AT2 receptor (47).

When acting on neighboring cell, growth factors are *paracrine* factors, but when acting on the producing cell, they are *autocrine* factors. Growth factors bind to cell-surface receptors, many of which are receptor tyrosine kinases that, after ligand binding, dimerize and become phosphorylated, thereafter transducing signals into the cell. Factors acting via receptor tyrosine kinases include ANGPTS, EGF, FGFs, HGF, IGFs, TGFα, and VEGF. Others, including BMPs, GDF11 and TGFβ, bind receptors with threonine and serine kinase activity. GDNF is a distant relative of TGFβ but signals through a receptor tyrosine kinase after binding to an accessory receptor. Yet other metanephric growth factors, including angiotensin, LIF and TNFα, signal through different classes of receptor.

Adhesion Molecules

The third major class of molecule comprises the adhesion molecules. Some mediate the attachment of cells to one another while a second group mediates attachment of cells to the surrounding extracellular matrix (ECM). Examples of the former include neural cell adhesion molecule (NCAM), whose adhesive properties are independent of calcium, and E-cadherin, whose adhesive properties depend on calcium. Molecules in the second group include collagens, fibronectin, laminins, nidogen, and tenascin. Many bind to cell surfaces via integrin receptors to provide a physical framework for epithelial tubules and endothelia. Some of these interactions also modulate growth and differentiation in an analogous fashion to the binding of growth factors to their receptors. Proteoglycans, including syndecan and heparan sulfate, constitute another type of adhesion molecule. They also bind growth factors such as FGFs and VEGF, hence sequestering and storing these molecules as well as modulating their binding to receptor tyrosine kinases. Recently, the Fraser syndrome (FRAS1/FREM) gene family has been identified; these encode several proteins form a complex in the basement membrane near the basal surfaces of developing renal epithelia and the complex most likely interacts with both growth factors, modifying their activities, and with other ECM proteins and with integrins: these, and similar, molecules are discussed in detail later in this chapter.

Conversion of Metanephric Mesenchyme into Nephron Epithelia

Uninduced Metanephric Mesenchyme Is Preprogrammed to Form Nephrons

Isolated metanephric mesenchyme can be induced to form nephrons in vitro by recombination with the ureteric bud or by apposition to embryonic spinal cord. However, mesenchyme from other embryonic organs cannot be stimulated to produce nephrons by either the ureteric bud or heterologous inducers (14). Hence, by the time the metanephros can first be detected, the renal mesenchyme has already been programmed to form nephrons, but it requires additional, inductive signals from the ureteric bud to permit its differentiation. There has been some progress regarding the molecules responsible for this programming of the renal mesenchyme. The transcription factor LIM1 (LIM homeobox 1) is expressed in the intermediate mesoderm before it forms the renal mesenchyme, and the metanephros fails to form in mice, which lack LIM1 (48). However, the embryonic expression of this gene is widespread, and diverse nonrenal organs are malformed in null mutants. Another transcription-associated

molecule, EYA1 (Figs. 1-9 and 1-10), was found to be dispensable for formation of the mesonephric duct but it specifies the part of the intermediate mesoderm which will form the metanephric mesenchyme (49). *EYA1* heterozygous mutations in humans can cause a spectrum of renal malformations, including agenesis in the context of the branchio-oto-renal syndrome (50). Of note, another transcription factor called SIX1 is expressed in an overlapping pattern to EYA1 (Figs. 9-11) and both may act in a similar pathway to stimulate expression of other nephrogenic genes (51). Indeed, *SIX1* mutations can also cause branchio-oto-renal syndrome in humans (50).

Uninduced Metanephric Mesenchyme Is Preprogrammed to Die

When cultured in isolation, murine renal mesenchyme fails to survive. In contrast, the recombination with either ureteric bud epithelium or embryonic spinal cord rescues mesenchymal cells from death and induces them to form nephrons. Koseki et al. demonstrated that death of the isolated renal mesenchyme was mediated by apoptosis and that it was an active process, as assessed by a requirement for mRNA and protein synthesis (52). They also reported that isolated renal mesenchyme could be rescued from death by the addition of EGF, the adult homolog of TGFα, or by phorbol ester, a chemical that enhances the activity of protein kinase C. Perantoni et al. reported that FGF2 could also facilitate survival of isolated renal mesenchyme (53), an important observation when taken with the fact that the ureteric bud secretes this factor (54). Barasch et al (55) have reported that metalloproteinase-2 stimulates mesenchymal growth by preventing this cell population from dying. Recent experiments show that HOX11 transcription factors enhance the expression of SIX2 in renal mesenchyme (Figs. 1-9–11) to perpetuate the uninduced, precursor population (30, 56). Furthermore, *SIX2* mutations have been found in humans affected by a spectrum of kidney malformations (57).

The *Wilms tumor 1* (*WT1*) gene produces multiple transcripts, some of which act as transcription factors, while others are likely to affect splicing of mRNA before export from the nucleus (58). WT1 is expressed at low levels in metanephric mesenchyme, and levels are upregulated during differentiation into nephron precursors (31) (Fig. 1-2). In vivo, absence of WT1 protein causes fulminant death of the intermediate mesoderm, which would normally form the metanephric mesenchyme, producing renal agenesis (59). To date, *WT1* human mutations have yet to be associated with renal agenesis, although the importance of this molecule in nephrogenesis is emphasized by the occurrence of mutations in some cases of Wilms tumor, thought to arise from kidney precursor cells (60). It has been reported that WT1 regulates the expression of members of the EGF family which are expressed in the metanephros and which enhance ureteric bud growth (61). A similar final phenotype can be generated in mice that are homozygous null mutants for either *PAX2* or *GDNF* or *RET*, a gene coding for a GDNF receptor on the ureteric bud. In these cases, the primary defect is a failure of outgrowth of the ureteric bud from the mesonephric duct: the defect in the renal mesenchyme is secondary to the loss of its normal inducer tissue in vivo. Nishinakamura et al. (62) have recently reported that mesenchymal expression of the SALL1 (sal-like 1/homologue of Drosophila spalt) transcription factor (Figs. 1-9 and 1-10) is necessary for early inductive events in the murine kidney; the human homologue is mutated in the Townes-Brockes syndrome, a disorder associated with renal tract malformations (63).

Condensation of Renal Mesenchyme

The first morphologic step in nephron formation is the aggregation of renal mesenchymal cells to form a condensate. At the same time, these nephrogenic precursor cells undergo a burst of proliferation and upregulate the expression of the transcription factors WT1 (31) and PAX2 (Figs. 1-5, 6, 9–11) (31). PAX2 prevents kidney cells from undergoing apoptosis (64) and inhibition of PAX2 by antisense oligonucleotides prevents condensation in metanephric organ culture (65). Mice lacking one copy of the *PAX2* gene are born with small kidneys (27, 66) and humans with heterozygous, inactivating mutations of *PAX2* have renal hypoplasia as part of the renal-coloboma syndrome (67). Other genes that are switched on or upregulated as renal mesenchymal cells aggregate include MET (68, 69), ITGA8 (70) (Figs. 1-10 and 1-11), and BCL2 (31). HGF is expressed by renal mesenchyme and it induces the expression of epithelial markers in the same population of cells. Mice deficient in ITGA8 have small, severely malformed kidneys, with defective nephron formation and impaired ureteric bud branching. A ligand for this integrin is expressed on the surface of ureteric bud branches, and therefore this heterodimer most likely coordinates morphogenetic interactions between the mesenchymal condensate and the ureteric bud epithelium (71). BCL2 is located in the nuclear and mitochondrial membranes and prevents apoptosis, perhaps by interfering

with lipid peroxidation. Homozygous null mutant mice have fulminant renal apoptosis during development and are born with renal hypoplasia (38, 72). Thus, this combination of molecules together enhances the survival, growth and differentiation of mesenchymal cells as they begin their journey to becoming nephron epithelia.

Morphogenesis into Nephron Tubules

Next, the mesenchymal condensate forms a lumen and differentiates into an increasingly mature nephron via the vesicle, comma, and S-shaped stages. This process is associated with the replacement of the intermediate filament vimentin by cytokeratin in all segments apart from glomerular podocytes. In addition, there are profound changes of expression of adhesion molecules. Neural cell adhesion molecule (NCAM) becomes downregulated (73) while E-cadherin appears at sites of cell-cell contact (adherens junctions) in the primitive nephron (17). Numerous studies have implicated the latter molecule as playing a part in the genesis of epithelia (74, 75). At the same time, the expression of the extracellular matrix molecules collagen I and fibronectin are downregulated, and primitive tubular epithelia begin to synthesize a basement membrane containing collagen IV, laminin, heparan sulfate, and nidogen (17, 76). Evidence from organ culture experiments supports the concept that the interaction of laminin-1, a cruciform trimeric molecule, with a cell-surface receptor, ITGA6, is essential for lumen formation of the primitive nephron (17, 77).

Other types of molecules have been implicated in the growth of primitive nephrons. WNT (wingless-type MMTV integration site family) glycoproteins are secreted signaling factors. WNT4, a member of this family, is upregulated by PAX2 in renal mesenchymal cells as they differentiate into nephrons and may have an autocrine role in this process (78). Mice with *WNT4* homozygous null mutations have metanephroi in which the renal mesenchyme has become induced but it fails to differentiate passed the condensate stage (79). Furthermore, *WNT4* mutations have been reported in humans who have a syndrome of renal agenesis, Mullerian duct derivative anomalies and virilization (80, 81). BMPs are members of the TGFβ superfamily and transduce growth signals through type I and II receptor serine/ threonine kinases. BMP7 is expressed by the branches of the ureteric bud and is also upregulated in primitive nephrons (82, 83). Nephrogenesis is impaired in *BMP7* null-mutant mice with formation of only a few nephrons and ureteric bud branches. LIF, a member of the interleukin-6 family, is secreted by the ureteric bud and can transform renal mesenchyme into epithelia, including proximal tubules and glomeruli, acting together with FGF2 and TGF family members (84, 85). Other growth factors, such as the IGFs, may play permissive roles in growth at this stage of nephrogenesis (86).

While several recent studies have implicated molecules in construction of glomeruli (see next section), presently little is known about genes which control the differentiation of primitive nephrons into the specialized non-glomerular cells in the mature mammalian nephron i.e. proximal tubule, loop of Henle and distal convoluted tubule. However, this type of detailed analysis has been performed for cells in the Malpighian excretory tubule of embryonic *Drosophila* fruit flies (87). The zebrafish embryonic (pronephric) tubule contain proximal tubule-like segments, and these are abolished upon downregulation of retinoic acid (vitamin A-mediated) signaling (88). The significance of this striking observation with regard to mammalian tubule segmentation is unknown although vitamin A supplements enhance nephrogenesis in metanephric organ culture (89) and very high doses of vitamin A derivatives can impair kidney differentiation in utero (23), suggesting the need for an optimal level of retinoic acid signaling in mammals as well as fish. Indeed, the retinoic acid-upregulated growth factor called midkine is expressed in nephron precurors where it enhances nephrogenesis (90).

The LIM1 transcription factor (*Figs. 1-10–12*) is strongly-expressed in the renal vesicle and subsequently in the proximal section of the S-shaped body in cells destined to form proximal tubule and glomerular epithelia (48). The NOTCH signaling system was first implicated in controlling cell fate in embryonic flies; NOTCH 1 and 2 are expressed in the renal vesicle and Notch 2 is essential for differentiation of proximal tubules and podocytes (91). Whether LIM1 controls expression of NOTCH has not been established. Mutations of genes coding for components of the renin-angiotensin system have been reported in individuals with renal tubular dysgenesis, an autosomal recessive disorder in which kidneys form but lack properly-differentiated proximal tubules (92). The mechanism of this effect is uncertain and may be explained either by direct, differentiating-enhancing effects of angiotensin II on proximal tubules or by an indirect effect of underperfusion of the fetal kidney associated with systemic hypotension. The observation is also interesting in view of the fact that the incidence of kidney malformations may be increased in fetuses of mothers taking angiotensin enzyme converting inhibitors (93). Finally, BRN1 (also known as POU domain, class 3, transcription factor 3), another transcription factor, is expressed in the distal

portion of the nephron vesicle and S-shaped body and eventually in the thick ascending limb of the loop of Henle (*Figs. 1-10–12*); it controls the elongation of the loop of Henle and expression of segment specific molecules such as uromodulin (Tamm-Horsfall protein), the Na^+:K^+:$2Cl^-$ cotransporter (NKCC2) and barttin (BSND) (94).

Formation of the Glomerulus

WT1 transcription factor is essential for the maintenance of the mature podocyte, where it downregulates the transcription of PAX2 (95) (*Fig. 1-12*) and, in mice, transgenic overexpression of PAX2 causes congenital nephrotic syndrome (26). In humans, heterozygous mutations of *WT1* can cause the Denys Drash syndrome in which congenital nephrotic syndrome and propensity to Wilms tumor are key features; affected glomeruli have PAX2 overexpression in podocytes (96). Frasier syndrome, in which glomerular degeneration occurs later in childhood, also features *WT1* mutations and is associated with progressive glomerulopathy, male pseudohermaphroditism, and gonadal dysgenesis with increased risk of gonadoblastoma and malignant germ cell tumors (97). LMX1B (LIM homeobox transcription factor 1) is another transcription factor expressed in podocytes and human heterozygous mutations lead to glomerular proteinuria in the context of the nail patella syndrome (98). In glomeruli of null mutant *LMX1B* mice, the normal switch (99) from immature/embryonic α1 and α2 forms of collagen IV to the mature forms α3 and α4 (mutated in autosomal forms of Alport syndrome) fails to occur; moreover, the transcription factor binds upregulates expression of human COL4A4 (100). Nephrin is a transmembrane protein of the immunoglobulin family of cell adhesion molecules and is a key component of the glomerular slit diaphragm; human mutations of *NPHS1* which codes for this protein lead to congenital and also to later onset steroid-resistant nephritic syndrome (101, 102). Podocin is another important podocyte protein: it appears to link the slit diaphragm with the cytoskeleton and mutations of *NPHS2* which codes podocin are associated with autosomal recessive steroid-resistant nephrotic syndrome (103). Among the molecules which show deregulated expression in mice with *NPHS2* mutation include LMB1B, discussed above, and TGFβ1 encoding a growth factor implicated in scarring (104).

As the glomerular epithelium matures, the basement membrane becomes rich in laminin b2. Mice without the functional gene encoding this protein develop albuminuria and enhanced glomerular basement membrane permeability to ferreting soon after birth, before structural changes such as foot process effacement and loss of slit diaphragms (105). Humans with Pierson syndrome have early onset nephrotic syndrome together with microcoria (nonreactive narrowing of the pupils due to aplasia of the dilatator pupillae muscle) have heterozygous mutations of *LAMB2* (106). Laminin a5 is another protein expressed in the glomerular basement membrane and both nascent podocytes and glomerular endothelia express and insert this protein into the glomerular basement membrane (107). *LAMA5* null mutations in mice are associated with a failed switch from laminin a1 which normally occurs during the invasion by capillaries of the fetal glomerulus (see below); mutant gomeruli lack endothelia and mesangial cells (108). Podocytes express α3β1 integrin dimers and they appear critical for the normal construction and maintenance of intact glomeruli as assessed by lesions in mice with ablations of either the *ITGA3* or the *ITGB1* gene (109, 110).

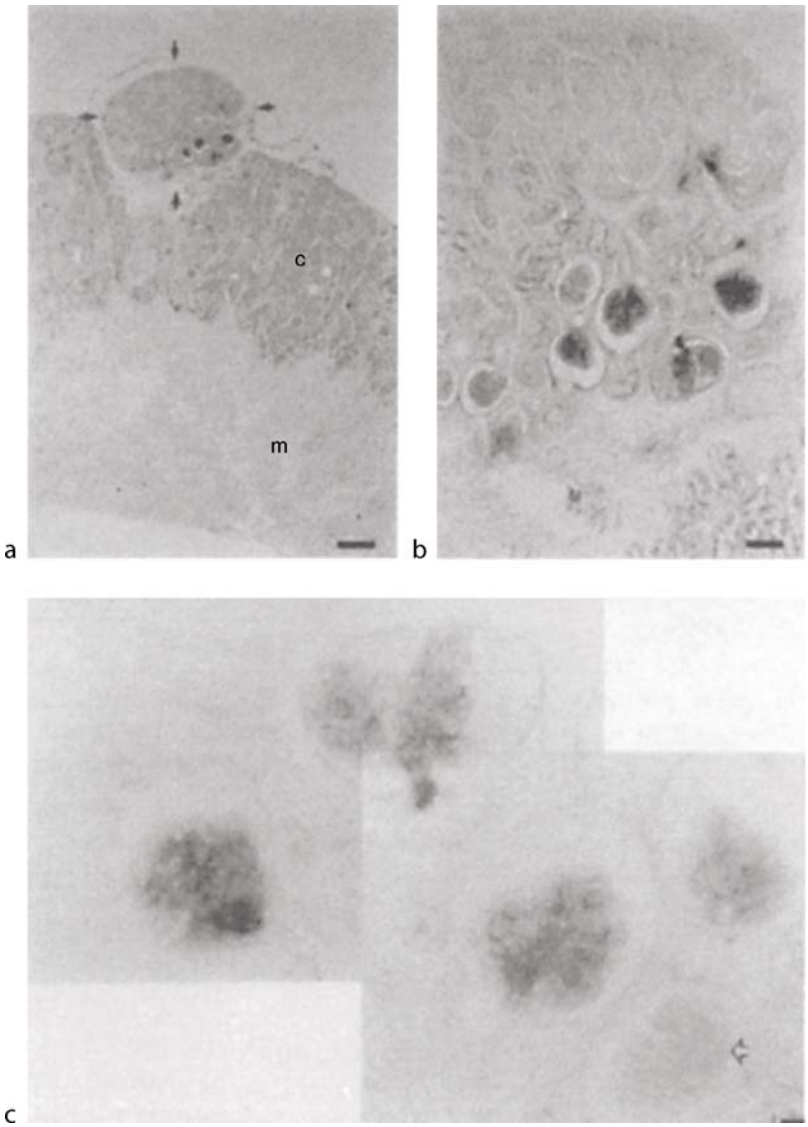
Embryonic blood vessels arise by vasculogenesis or angiogenesis. In vasculogenesis, mesenchyme differentiates in situ to form capillaries. In contrast, angiogenesis involves ingrowth from existing capillaries. The first embryonic vessels of the yolk sac, endocardium, and dorsal aorta arise by vasculogenesis, but thereafter, descriptive studies alone cannot ascertain the origin of embryonic vessels. When avascular murine renal mesenchyme is induced to differentiate in organ culture, the glomeruli that develop lack capillaries as assessed by light and electron microscopy (111), a result used to argue against the possibility of glomerular vasculogenesis. When mouse metanephroi were transplanted onto avian chorioallantoic membranes, forming glomeruli acquired capillary loops but these were of host origin as assessed by a quail-specific nuclear marker and antisera to chick collagen IV, a component of endothelial basement membrane (10, 112). These results were used to argue that glomerular vessels form by angiogenesis in vivo. However, neither organ culture nor chorioallantoic membrane are likely to provide a normal environment for growth of glomerular capillaries.

More recent studies have found that morphologically undifferentiated renal mesenchyme contains subsets of cells which express markers characteristic of endothelial cells, including receptors for the vascular growth factors, VEGF and ANGPT1 (113, 114). When transgenic mice were used, in which an endothelial-specific β-galactosidase reporter gene product could be detected histochemically, endothelial precursors were visualized in intermediate mesoderm condensing around the caudal end of the mesonephric duct, with a similar pattern noted in renal mesenchyme at the ureteric bud stage (113, 115).

Loughna et al. (113) determined whether these precursors could differentiate into endothelia using a model in which metanephroi form filtering glomeruli after transplantation into the neonatal nephrogenic cortex. When transgenic avascular metanephroi were transplanted into wild type hosts, differentiated donor tissue contained transgene-expressing glomerular arterioles and capillary loops (Fig. 1-13). Using other transplantation strategies (e.g. to the anterior eye chamber), others have provided similar evidence that renal capillaries can arise directly from early metanephroi (115, 116). Furthermore, in organ culture, metanephric capillary survival and growth

Figure 1-13

Transplantation of *TIE1/LACZ* metanephroi into wild-type neonates. (a) After 1 week, the E11 transplant differentiated (*arrows*) in the host cortex (*c*). Transgene expression (*black*) was confined to the transplant. No staining was detected in host cortex or medulla (*m*). (b) Donor glomeruli expressed the transgene intensely. (c) Positive capillary loops in glomeruli are visible. Podocytes (*open arrow)* do not express the transgene. Bars: 120 μm in (a) 30 μm in (b) 10 μm in (c). (Loughna S, Hardman P, Landels E et al. A molecular and genetic analysis of renal glomerular capillary development. *Angiogenesis* 1997;1:84–101, with permission from Kluwer Academic Publishers, Dordrecht, The Netherlands.)



are enhanced by addition of VEGF or ANGPT1, or by growth in a hypoxic atmosphere (117–119). Indeed, the contention that the developing kidney is "hypoxic" in vivo is supported by the observation that it expresses high levels of hypoxia-inducible factor proteins, which are normally down-regulated postnatally in healthy kidneys (120). One can speculate that capillary formation within the metanephros is at least in part driven by hypoxia, and that that low oxygen tension increases expression of diverse vascular growth factors and their receptors. Indeed, nascent podocytes express high levels of VEGF, and when this gene is experimentally-downregulated capillaries are severely disrupted in forming glomeruli (121).

Other molecules are implicated in vascular growth within the metanephros. These include the Eph/ephrin family of membrane receptors which appear to be critical in cell-cell recognition (122). Renin is widely expressed in perivascular cells in the arterial system of the metanephros but becomes restricted to juxtaglomerular cells during maturation. Recent evidence suggests that the metanephric mesenchyme contains renin-expressing cells precursor cells which can contribute to the vasculature and perhaps also to tubule epithelia (123, 124). In addition, other molecules required to generate bioactive angiotensin are expressed in the metanephros, as are its AT1 and AT2 receptors. In rats there is evidence that angiotensin II may enhance glomerular endothelial growth in vivo (125, 126). Furthermore, the ANGPTs and TGFB1 also play roles in glomerular capillary morphogenesis, perhaps by controlling endothelial survival (36, 127, 128).

It has been speculated that mesangial cells arise from the same lineage as glomerular capillaries because neither cell forms when the metanephros is cultured under standard organ culture conditions (111). It was assumed that mesangial cells were derived from cells outside the embryonic kidney. However, mesangial cells develop when metanephroi are transplanted and grown in oculo (116), and thus mesangial precursor cells may be present in renal mesenchyme. Whatever their origin, PDGFB is crucial for the differentiation of mesangial cells in vivo. Mice with null mutations of either the gene coding for this growth factor, or its receptor, lack mesangial cells and develop bizarre, malformed glomeruli (129, 130). PDGFB is expressed by primitive nephron epithelia, and mesangial precursors express the receptor, suggesting a paracrine mode of action. As mesangial cells mature, both that ligand and receptor are coexpressed, suggesting an autocrine activity. Other growth factor signaling systems may play roles in development of this lineage: for example, HGF and MET are coexpressed by immature mesangial cells (131).

Branching Morphogenesis of the Ureteric Bud

Growth Factor Control of Ureteric Bud Growth

When the mouse ureteric bud is grown in organ culture with its adjacent renal mesenchyme, it undergoes branching morphogenesis; however, it fails to differentiate when cultured in isolation. It is established that the epithelia of the ureteric bud express various receptors, mostly tyrosine kinases, that transduce differentiation signals by binding to mesenchyme-derived growth factors. The most important signaling system involves RET, a receptor tyrosine kinase expressed in mesonephric duct, ureteric bud, and its branching tips (132–137) (*Figs. 1-9–11*). GDNF causes tyrosine phosphorylation of RET after binding to a membrane-linked accessory receptor called GDNFRα. The ligand is expressed by condensing renal mesenchyme, while GDNFRα is expressed in the same cells as RET. Lower levels of the accessory receptor are found in renal mesenchyme, where it may concentrate the ligand and also prevent its diffusion with initiation of ectopic ureteric bud branches. Mice with homozygous null mutations of *RET* or *GDNF* do not develop kidneys because of deficient outgrowth of the ureteric bud. Experiments using culture of whole metanephric rudiments with blocking antibodies to GDNF demonstrate that this signaling system is critical for stimulation branching after initial outgrowth of the ureteric bud. Equally impressive, the addition of recombinant GDNF to cultured metanephroi induces ectopic ureters. When the ureteric bud is cultured as a monolayer, it dies by apoptosis over a few days but GDNF can partially reverse this process (137). The factor also stimulates survival and morphogenesis of RET-transfected collecting duct cells in vitro (138). Recently heterozygous mutations of *RET* have been identified in humans with bilateral renal agenesis (139) and a rare *RET* polymorphism has been reported in individuals with primary, non-syndromic vesicoureteric reflux (140).

The site of GDNF-induced initiation of the ureteric bud from the mesonephric duct has to be tightly-regulated because too caudal or too cranial buds will not optimally meet the nearby renal mesenchyme, thus risking failure of kidney formation. Furthermore, multiple buds, which might generate duplex ureters and kidneys, are to be avoided. For these reasons, there exists a complex molecular machinery to regulate bud initiation, and to regulate its branching into the collecting duct system. For example, Sprouty-1 prevents aberrant bud initiation as does the ROBO2/SLIT2 signaling system; when either

system is downregulated, bud initiation and branching are abnormal and multiple ureters arise from each mesonephric duct (141–144). Of note, *ROBO2* mis-sense gene variants have been noted in rare families with multiple cases affected by vescio-ureteric reflux and/or duplex kidneys (144). The growth factor BMP4 is expressed in a broad band around the mesonephric duct, but not where the ureteric bud normally emerges: it appears to prevent ectopic branching, although its effects are complex, and it also enhances the elongation of the ureter and is implicated in muscularization of the ureter (145). Recently, BMP4 mutations have been reported in humans with renal tract malformations (57). The actions of BMP4 itself are fine-tuned by the action of another secreted factor, gremlin-1, a BMP4 antagonist (146). Apart from GDNF, other growth factors enhance the growth and branching of this lineage, either directly, such as EGF family members, FGF7 and HGF, or by indirectly upregulating GDNF signaling, such as GDF11 and WNT11 (61, 147–150).

Transcription Factors and Ureteric Bud Growth

As yet, little is known about how the expression of transcription factors within the ureteric bud affects growth of this lineage. One exception is PAX2 which is expressed in the mesonephric duct and in the ureteric bud branch tips and thereafter in maturing collecting ducts (31) (*Fig. 1-6*). The expression of PAX2 in the ureteric bud lineage correlates with growth, and both are downregulated as the ducts mature. In these cells, however, PAX2 appears to act as a survival factor rather than a molecule which directly enhances proliferation. Mice with heterozygous null mutation of *PAX2* show enhanced apoptosis in fetal collecting ducts (64). Moreover, collecting duct cyst apoptosis is increased, and cyst growth slowed, in congenital polycystic kidney (*cpk Cystin* mutant) mice which also have one inactivated allele of *PAX2* (151). In mice genetically engineered to lack both *PAX2* alleles, the ureteric bud fails to branch from the mesonephric duct, producing renal agenesis (27). In this context, ureteric bud initiation appears to fail because of GDNF/RET signaling is disrupted. Indeed, in normal development PAX2 normally upregulates expression of RET within the bud itself (152) and renal mesenchyme also expresses PAX2 where it binds to the *GDNF* promoter and upregulates the transcription of this growth factor (153). In fact, within the mesenchyme, PAX2 co-operates with other transcription factors, such as the HOXD family and EYA1, to enhance expression of GDNF (44) (*Figs. 1-9–11*). β-catenin is a transcription factor-associated molecule expressed in the ureteric bud lineage and is required for branching morphogenesis; in this context it is required to upregulate LIM1, PAX2, RET and WNT11 (154).

Cell Adhesion Molecules and Ureteric Bud Growth

The stalk of the ureteric bud is surrounded by a basement membrane composed of laminins and collagen IV, as well as nidogen/entactin and tenascin. As assessed by electron microscopy, the basement membrane is attenuated around the tips of the ureteric bud (19), and branching epithelia may be exposed to a renal mesenchymal matrix rich in collagen I and fibronectin. There is evidence that matrix molecules affect branching morphogenesis in vitro. In monolayer culture of ureteric buds epithelia, proliferation is enhanced by a fibronectin versus laminin substrate (137), consistent with the observation that cells at the branching tips have a high proliferation rate (31). Collagen I appears permissive for branching of collecting duct cells, whereas some components of the basement membrane are inhibitory (155). HGF-induced branching into collagen I is accompanied by an increase in matrix degrading molecules (e.g., collagenases, such as matrix metalloproteinases, and plasminogen activating proteases, such as urokinase) (156). *LAMA5* mutants sometimes have absent kidneys (108) and mice genetically engineered to lack ITGA3, which forms functional dimers with ITGB1 subunits, have a reduced number of medullary collecting ducts (110). Renal mesenchymal expressed adhesion related molecules may have important indirect effects on growth of the ureteric bud; an example is provided by ITGA8 (*Figs. 1-10* and *11*) which is expressed in a heterodimer with ITGB1 in condensing renal mesenchyme where it, by an unknown mechanism, upregulated GDNF expression and hence bud growth (157).

In humans, a protein called anosmin-1 coats the surface of the ureteric bud and its branches where it is thought to mediate activities of growth factors; mutations of the gene, *KAL1*, which codes for anosmin-1 lead to renal agenesis in the context of X-linked Kallmann syndrome (158, 159). This provides a paradigm for several other basement-membrane associated molecules in the ureteric bud and collecting duct lineage. For example, FRAS1 (Fraser syndrome 1) and FREM2 (FRAS1-related extracellular matrix) are large, multidomain proteins inserted into the basal plasma membrane and which protrude into the extracellular space; the proteins form a complex where they may mediate the expression and

actions of nephrogenic growth factors at the same time interacting with structural molecules such as integrins. Null mutation of either gene in mice and humans are usually associated with renal agenesis in the context of Fraser syndrome, which also features embryonic skin blistering (160–163). Similarly, glypican-3 is a ureteric bud-associated cell surface heparan sulfate proteoglycan which regulates the tempo of arborization in part by regulating activities of BMPs and endostatin (164, 165); in humans, *GPC3* mutations are associated with cystic kidney maldevelopment in the context of the Simpson-Golabi-Behmel syndrome, an X-linked condition characterized by prenatal and postnatal overgrowth with visceral and skeletal abnormalities (166).

Further Maturation of the Collecting Ducts

As the bud branches, the stems mature into the collecting ducts, which contain three types of cell: the potassium-handling principal cells and the proton-handling α and β intercalated cells (167). Corticosteroids enhance collecting duct differentiation, and there is also some plasticity regarding the lineage of these cells based on in vitro studies (168, 169). During this period of maturation, the Na^+-K^+-ATPase becomes relocated from the apical to basal plasma membrane, and this process is perturbed in some polycystic kidney diseases (170). Galectin-3 is a cell adhesion molecule which is prominently expressed by maturing collecting stalks. Here it may regulate epithelial growth by interaction with laminin and other extracellular matrix molecules (171, 172). Furthermore, the protein is also located in primary cilia (173), flow sensors which protrude into the lumen of the tubule (174). Downregulation of galectin-3 enhances cyst formation in a mouse model of recessive congenital polycystic kidney disease (173). The protein is also involved in the genesis of apical epithelial characteristics of collecting duct cells (175) and, on the basal side of collecting duct cells it acts in concert with another extracellular molecule called hensin to enhance epithelial differentiation (176). *Polycystic kidney disease 1* (*PKD1*) the gene most commonly mutated in human autosomal dominant polycystic kidney disease is prominently expressed by fetal collecting ducts (177).

Fetal collecting ducts also express various transcription factors which play roles in maturations. As examples, p53 is associated with collecting duct dilatation (178) and experimental downregulation of hepatocyte nuclear factor 1β (HNF1B) causes polycystic kidneys associated with deregulation of the normal longitudinal arrangement of mitotic spindles found in extending tubules (179, 180). It is notable that *PKD1* is under transcriptional control of p53 (181), and that HNF1B normally up-regulates the transcription of several "anti-cyst genes," including the one mutated in human autosomal recessive polycystic kidney disease (179). In humans, inherited or de novo heterozygous mutations of *HNF1B* cause the renal cysts and diabetes syndrome; here, affected individuals have a predisposition to diabetes mellitus and can also have a spectrum of structural kidney defects from cystic dysplasia to a polycystic phenotype (182–184). The gene may also control tubular physiological functions because mutations are associated with increased plasma levels of uric acid and also with hypomagnesemia (183, 184).

Metanephric Stromal Cells

Little is known about the mechanisms that control the differentiation of renal mesenchyme into stromal cells (40), or interstitial fibroblasts, but there is evidence that stromal cells are essential for epithelial development. For example, the G_{D3} ganglioside is expressed by stromal cells surrounding the stalk of the ureteric bud, and antibodies to this molecule prevent bud morphogenesis (185). Metanephric stromal cells also express the BF2 winged-helix transcription factor, also known as FOXD1 (186). Mice that were homozygous null mutants for this gene have impaired branching of the collecting ducts and also perturbed conversion of renal mesenchyme to nephrons (187). Other evidence emphasizes that metanephric stromal and epithelial cells are involved in complex reciprocal signaling loops, with expression of retinoic acid receptors in the stroma playing important roles (188). A similar example is provided by stromal cells which express the KIT receptor tyrosine kinase for stem cell factor; some of these cells express angiogenic markers and these cells may enhance development of adjacent epithelia (186). Interestingly, other data show that, at the inception of the metanephros, a subset of cells at the periphery of the organ express VEGF receptors and these cells appear to send an unknown signal with upregulates PAX2 and thereafter GDNF expression (189). Some metanephric stromal cells have neuronal characteristics, staining positively with neurofilament markers; the role of these cells is unknown, but their survival can be modulated by neurotrophin 3 (190). Clifford Grobstein found that when an embryonic spinal cord was placed on the opposite side of a filter to metanephric mesenchyme, nephrons were induced to differentiate (14). Further investigations showed that neurons had penetrated the mesenchyme through

the microscopic pores of the filter, and if the neurons in the spinal cord were destroyed, induction did not occur (191). As assessed by antibodies against neurofilaments and neural cell surface gangliosides, neuronal cell bodies can be observed around the ureteric bud in vivo and their terminals surround mesenchymal condensates (192).

Lower Urinary Tract Development

At the same time that the metanpehric kidney, the lower urinary tract develops in harmony, with the ureters and bladder maturing into structures ready to receive urine and to respectively propel it into the bladder which in turn stores urine, intermittently expelling it via the urethra.

The separation of the urogenital sinus from the cloaca is in part mediated by EPH/EPHRIN reciprocal signaling and by sonic hedgehog (SHH), a secreted morphogen (193, 194). A series of cell rearrangements join the embryonic ureter (i.e. the ureteric bud stalk) to the bladder to generate the uretero-vesical junction which prevents reflux of urine upon bladder contraction (195, 196). After the basic anatomy of the lower tract has been established in this manner, the nascent urothelium in the bladder and ureters secretes SHH which acts via the PTCH1 receptor expressed in surrounding mesenchymal cells first to enhance their proliferation and then, via upregulation of BMP4, to induce differentiation of these cells into visceral smooth muscle (11, 197–200). In mice, the T-box 18 (TBX18) and Teashirt-3 (TSHZ3) transcription factors are expressed in ureteric mesenchymal cells and are required for ureteric mulscularization antenatally (201, 202). At later stages of ureteric smooth muscle maturation, angiotensin II appears to become important and, acting through its AT1 receptor, it enhances peristalsis and also may have a direct effect on morphogenesis (203). Mutation of *SHH* or *TBX18* or *TSHZ3* or genetic or pharmacological downregulation of angiotensin signaling all lead to hydronephrosis in the absence of anatomical obstruction (200–204), emphasizing the importance ureteric peristalsis in moving urine from the kidney pelvis into the urinary bladder. At the same time that ureteric smooth muscle is differentiating, the adjacent epithelium differentiates into a water-tight pseudo-stratified urothelium. BMP4 is apparently needed to prompt the ureteric bud epithelium to form urothelium and indeed overexposure of the intrarenal ureteric bud branches induces them to acquire urothelial characteristics (205). FGF7 stimulates fetal urothelial proliferation (206) and terminal differentiation is associated with upregulation of five types of uroplakin proteins which aggregate in plaques at the urothelial apical surface. Not only to they confer water-tight properties to the lower urinary tract but they are somehow also essential in morphogenesis because mice which lack UPK3A and humans with heterozygous mutations of *UPK3A* have malformed ureters, sometimes with vesicoureteric reflux (207–209).

2 Glomerular Circulation and Function

Tracy E. Hunley · Valentina Kon · Iekuni Ichikawa

The essential function of the kidney is to preserve constancy of body fluid and electrolytes by removing water and potentially harmful metabolic end-products, e.g., uric acids, sulfates, phosphates, while preserving blood pressure, and essential solutes, e.g., sodium, chloride, bicarbonate, sugars, amino acids. The process begins in the renal glomerulus, where plasma is ultrafiltered under pressure through a semipermeable glomerular capillary wall. The ultrafiltration separates plasma water and crystalloids from blood cells and protein macromolecules, which remain in the glomerular circulation. The magnitude of this filtration process is enormous and requires a high rate of renal blood flow (RBF). Indeed, the entire plasma volume is cycled through the glomerular system 20 times per hour. The RBF and glomerular filtration rate (GFR) are interrelated such that maintenance of an adequate RBF is crucially important for optimal GFR while the glomerulus is an active participant in determining the RBF.

Renal Blood Flow

Blood flow to the kidneys comprises 20–30% of cardiac output (CO) and is determined by two factors: renal perfusion pressure (RPP), which is approximately equal to the systemic arterial blood pressure (BP), and renal vascular resistance (RVR), which is determined primarily by the afferent and efferent arterioles. The relationship can be expressed as RBF = BP/RVR. Although renal blood flow is the parameter usually discussed, it is the renal plasma flow (RPF) that is clinically relevant. Thus, at a given level of RBF, RPF may vary with the relative volume of packed red cells. For example, RPF increases with anemia. Lambs bled to decrease their hematocrit from 33 to 14% double their RPF (1). Because RBF is partly determined by the need for oxygen delivery, RPF may be high with severe chronic anemia such as occurs with sickle cell disease. In such circumstances both the RPF and the GFR are elevated because of decreased volume of red blood cells.

Like most organs, the kidneys possess intrinsic autoregulatory mechanisms that adjust local renal vascular resistance when renal perfusion pressure changes. This autoregulation maintains RBF relatively constant in the face of changing BP and RPP under physiologic conditions (2). Many hormonal systems regulate RVR and hence RBF. The nature and magnitude of their effects are often age-specific because anatomic factors (innervation), presence and distribution of receptor subtypes (angiotensin II receptors), and postreceptor signaling events change with development (3–6). In addition, autoregulatory efficiency is impaired in several conditions including extracellular fluid (ECF) depletion, diuretic exposure, congestive heart failure, and renal parenchymal damage (7–10). Each of these conditions makes the organism more susceptible to acute renal failure in the face of relatively minor changes in BP that cause substantial changes in RBF (see below).

Development of Renal Blood Flow

Prenatal Renal Blood Flow

Fetal renal blood flow is low, but increases with gestational age. Doppler ultrasound at 25 weeks of gestation shows the RBF to be 20 ml/min while at 40 weeks the RBF is 60 ml/min (11). Within the kidney, the relative perfusion varies with cortical depth with deeper nephrons of the cortex receiving more blood flow than nephrons in the superficial layers (12). This distribution of blood flow parallels morphologic maturation because deeper nephrons are the first to form and mature; superficial nephrons are not completed until near term (13).

Although the kidneys in the human embryo produce urine by 12 weeks' gestation, the role of kidneys in fetal homeostasis is minor compared to the placenta. The percentage of cardiac output perfusing the kidneys is low during intrauterine life. For example, during late gestation, the kidneys of fetal lambs receive only about 2.5% of the cardiac output while the placenta receives 40%. The kidneys of 10- to 20-week human fetus receive only 3–7% of cardiac output (14). Thus, the clinical relevance of intrauterine RBF and also glomerular filtration is less for the clearance of fetal plasma than for the formation of urine and hence amniotic fluid.

Fetal hemodynamics and urine formation are affected by maternal factors such as the maternal volume status,

© Springer-Verlag Berlin Heidelberg 2009

drugs, and vasoactive substances that cross the placenta. For example, acute oral hydration, which is sufficient to decrease plasma osmolality of healthy pregnant women, increases fetal urine production in near-term fetuses (15). Furosemide given to pregnant women induces diuresis in the fetus; likewise, maternally administered nonsteroidal antiinflammatory drugs lessen urine production and may lead to low glomerular filtration even after the baby is born (16, 17). Angiotensin II (Ang II) has distinct effects on the maternal, uteroplacental and fetal hemodynamics. Maternal circulation appears to be particularly sensitive to the vasoconstrictive effects of Ang II, which would tend to preserve uteroplacental and fetal circulations (18, 19). However, this fetoprotective effect disappears with long-term exposure to elevated levels of Ang II. Thus, although the first 4 h of Ang II infusion into pregnant ewes did not compromise uteroplacental/fetal perfusion, more than 20 h of heightened Ang II caused a dramatic decrease in the placental perfusion and compromised fetal gas exchange (20). These observations illustrate the important effect of Ang II on the uteroplacental circulation and by extension on fetal well-being. Ang II actions to maintain BP in utero and at the same time maintain RVR at a high level can be counteracted by inhibitors of its actions. Angiotensin converting enzyme inhibitors (ACEI's), e.g., captopril, lead to a decrease in fetal BP, RVR, and GFR in ewes, resulting in oligoanuria (21), and has been observed to cause anuria in the human fetus and newborn (22, 23). These hemodynamic changes may result from decreased Ang II synthesis and/or accumulation of bradykinin. Angiotensin II receptor antagonism did not affect blood pressure or RVR in fetal piglets or puppies (24, 25) while bradykinin receptor antagonism attenuated renal vasodilation following Ang II receptor antagonism of neonatal rats (26). These findings indicate a role for vasodilatory role of kinins offsetting Ang II-modulated vasoconstriction in the maturing kidney and complement the observations that the developing kidney expresses high levels of immunoreactive bradykinin and receptors. It is interesting that the kinin components localize to the deeper parts of the kidney, which would favor preferential perfusion of the deeper and not the superficial nephrons that characterizes the fetal kidney (27). Nonetheless, prenatal exposure to angiotensin II type 1 receptor blockers (ARBs) is now well documented to cause anuria/renal failure resulting from structural and functional renal impairment. At least in part, this reflects bradykinin generation from increased Ang II interaction with the angiotensin II type 2 receptor (AT2) (28, 29).

Another vasodilator that likely plays an important role in fetal renal hemodynamics is nitric oxide (NO) (30). Basal production of NO in third-trimester fetal sheep maintains baseline RBF; its inhibition increased RVR by 50% and blocked the increase in GFR and the natriuresis that accompany volume loading. The NO effects may be direct or through modulation of AII actions. Overall, the low renal blood flow in utero reflects incomplete renal mass that increases exponentially during fetal life, structural immaturity of resistance vessels (narrower vascular lumina) as well as unique modulation by vasoactive compounds such as Ang II, prostaglandins, kinins and nitric oxide.

Postnatal Renal Blood Flow

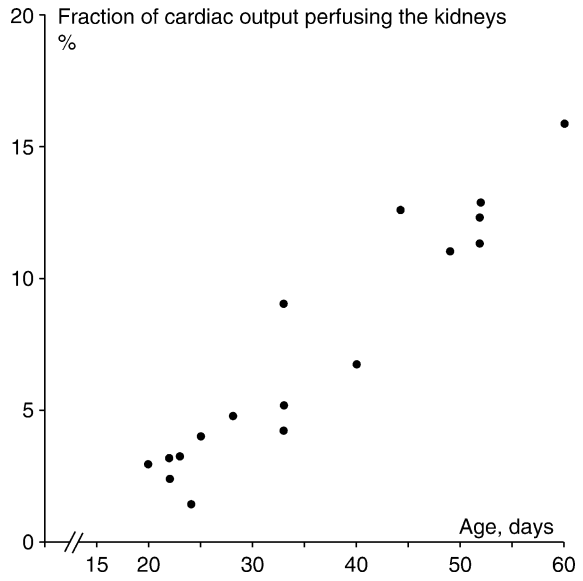
Renal blood flow, measured as a clearance of PAH (CPAH) and corrected for body size, is low in human neonates and correlates with gestational age. For example, CPAH is 10 ml/min/m^2 in babies born at 28 weeks, and 35 ml/min/m^2 in those born at 35 weeks of gestation (31). After birth, RBF increases steadily, doubling by 2 weeks and reaching mature levels by 2 years of age (32). The postnatal change in RBF primarily reflects the considerable increase in the relative RBF to the outer cortex (33–35).

Renal blood flow is governed by two factors: cardiac output (CO) and the ratio of renal to systemic vascular resistance. After birth, both an increase in CO and a decrease in RVR favor an increase in RBF. Furthermore, RVR decreases much more than systemic vascular resistance (12), allowing for a progressive increase in the renal fraction of CO. For example, RBF increases 18-fold in newborn pigs during the first 5 weeks of life, while CO (corrected for body surface area) increases only 7.2 times during the same period (*Fig. 2-1*). Not only is renal vascular resistance a function of the arteriolar resistance offered by the sum of the glomerular vessels, but also by the number of existing vascular channels. New nephron formation increases the number of channels, and hence decreases renal vascular resistance. New nephron formation contributes to the postnatal decrease in renal vascular resistance and increase in RBF only in premature babies born before 36 weeks of gestation (13).

Other factors that control the postnatal decrease in renal vascular resistance are largely those affecting the resistance of glomerular arterioles. In rats, both afferent and efferent arteriolar resistances decrease by a factor of 3 between 40 days of life and maturity (36). This decrease in renal vascular resistance may be linked to a decrease in vasoconstrictors and/or activation of potent vasodilators. Catecholamines, but especially the renin angiotensin

Figure 2-1

Renal blood flow as a percentage of cardiac output, plotted versus age, in growing rats between 17 and 60 days of age (reprinted with permission from (33)).



system, are high in the early postnatal period of premature and term infants (37–41). The role of the renin angiotensin system has been studied most extensively. Angiotensinogen undergoes a dramatic postnatal increase in liver expression before decreasing and settling to the adult level (42); renin production in neonates is robust and expands beyond the juxtaglomerular apparatus to include more proximal segments of the renal arterial tree (43); abundance of renal ACE increases postnatally such that within 2 weeks of birth it surpasses adult levels, as does the level of circulating ACE (44). Both the angiotensin II type 1 receptor (AT1) and AT2 receptor subtypes are expressed in the neonatal kidney (3, 39–46). The AT2 receptor is believed to play an important role in apoptotic processes during organogenesis including that of the kidney and urinary tract and wanes after birth (45, 47). Expression of AT1 receptor peaks postnatally at twice the adult level (46). Overall, the substrate, receptors as well as the enzymes required for production and actions of Ang II are exuberantly expressed in the neonatal kidney and contribute to the vasoconstriction of the neonatal kidney. In addition Ang II has been shown to have important role in the development and function of the renal outflow tract by inducing the development of the renal pelvis by stimulating the proliferation and differentiation of smooth muscle cells around the ureters and by promoting ureteral peristalsis (48). Absence of these Ang II-mediated effects results in renal hydronephrosis.

Locally counteracting these vasoconstrictive effects is the postnatal increase in the activity of prostaglandins, nitric oxide and kinins, that serves to temper renal vasoconstriction and contribute to the maturational increase in RBF. Indomethacin (which inhibits prostaglandin) lowers RBF in newborn rabbits (49) and decreases renal function in infants indicating an important role for vasodilator prostaglandins (49–52). Endothelium-derived nitric oxide release by the renal artery, as well as constitutive nitric oxide synthase activity in the renal microvasculature increases with fetal and postnatal maturation of guinea pigs (53). This increase in nitric oxide production is paralleled by increased sensitivity of vascular smooth muscle to nitric oxide after birth, which contributes to nitric oxide's modulation of postnatal renal blood flow. As in utero, an important contribution of the vasodilators to the maturational increase in RBF is undeniable; however, as in the fetus, it may be linked back to the renin–angiotensin system through the AT2 receptor, which is known to be a potent stimulator of prostaglandin, nitric oxide and kinins (54).

Measurement of Renal Blood Flow

Concept of clearance. Substances reaching the kidney through the circulation may undergo glomerular filtration, tubular reabsorption, or tubular secretion. Most solutes are freely permeable across the glomerular capillary and undergo filtration, followed by tubular reabsorption or secretion along the various nephron segments. Renal clearance of a substance X (C_x) is the volume of plasma from which X is removed or cleared by the kidney within a period of time. Glomerular filtration and tubular secretion facilitate clearance of a solute, while tubular reabsorption impedes it. It is calculated as follows:

$$C_x = (U_x \times V)/P_x$$

where U_x and P_x are the concentrations of X in urine and plasma, respectively, and V is the urine flow. The units of clearance are volume per unit time, usually milliliter per minute. For example, if P_x = 40 mg/ml, U_x = 80 mg/ml, and V = 100 ml/min, then C_x = 200 ml/min. Clearance is a more appropriate concept in describing the renal handling of a certain substance than urinary excretion rate (i.e., $U_x \times V$) because clearance takes into account the plasma level of X.

If a plasma substance is totally excreted on a single passage through the kidneys, it can be used as a marker

of RPF. However, in reality, only about 92% of the total RPF passes through the functioning excretory tissue, a fraction termed effective renal plasma flow (ERPF). Effective renal plasma flow is commonly measured as a clearance of para-amino hippurate (PAH), a weak acid that is almost completely extracted by the renal tubule cells and eliminated in the urine (55). Measurement of ERPF as CPAH requires a constant infusion of PAH and multiple plasma and urine specimens. A simplified modification using a single injection technique, although less accurate, can be used. The use of CPAH as an estimate of RBF has a major limitation in young infants because the renal tubular extraction of PAH is incomplete; it is 65% in infants younger than 3 months of age and reaches adult levels only by 5 months of age (56). Thus, CPAH underestimates RBF in infants younger than 5 months of age.

Indirect Assessment of Renal Blood Flow

Radionuclide markers and radiographic techniques can be used to assess RBF. Radiopharmaceuticals used in imaging of the kidneys can provide estimates of RBF or GFR. They have gained wide use in clinical studies of both children and adults because they do not require biochemical assays. The markers are usually labeled with radioactive iodine or technetium. Because of concern over accumulation of radioactive iodine in the thyroid, noniodine radioactive tags are usually preferred in children. The major usefulness of nuclear methods is the ability to obtain "split" renal function (i.e., separate measurements for each kidney). This information is invaluable when renal function is asymmetric, such as in unilateral renal hypoplasia, scarring, obstruction, or renal vascular lesions.

Radioactive hippuran is another agent used for assessing renal function. It is excreted by glomerular filtration (20%) and tubular secretion (80%), both governed by RPF. After intravenous injection, timed images are obtained and a computer-generated time activity curve is obtained for the region of interest drawn around each kidney. Split renal function is also calculated from the renogram by computer analysis. Other markers include iothalamate (57), orthoiodophippurate (handled by the kidney in a manner similar to PAH and hence a marker of RBF), pentaacetic acid (DTPA), and dimercaptosuccinic acid (DMSA) (58, 59).

Doppler ultrasonography is a radiologic method that assesses blood velocity in the renal vessels. Although limited in its sensitivity and by the position of the vessels, this method can provide screening information regarding the patency and flow through the renal vessels and detect significant arterial stenosis (60). The resistive index (RI), often mistakenly thought of as a measurement of RBF, is a crude index of the resistance of the kidneys to blood flow. It takes into account systolic and diastolic blood flow in the renal vessels as measured by Doppler and may be helpful in the follow-up of some forms of acute renal failure.

Glomerular Filtration

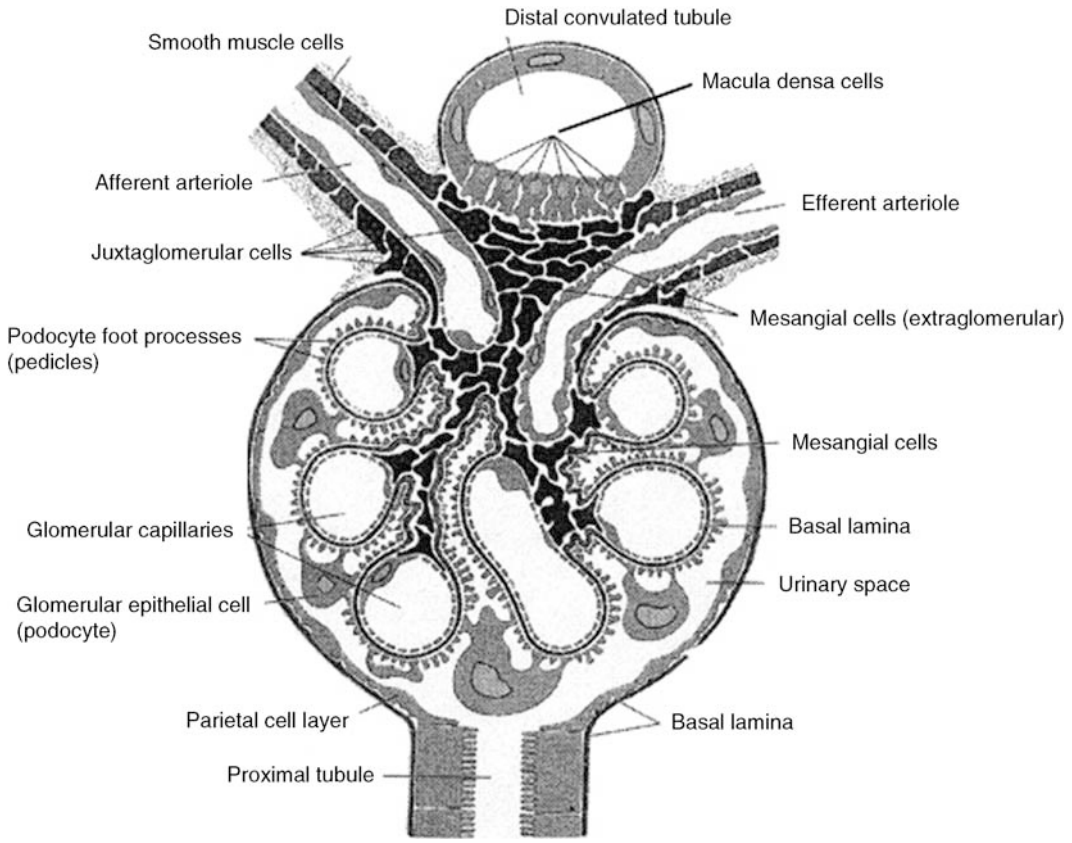
Whole kidney GFR represents filtration occurring in both kidneys and is the product of single-nephron glomerular filtration rate (SNGFR) and the number of filtering nephrons. Formation of new nephrons, nephronogenesis, occurs mainly during intrauterine life and proceeds at different rates in different species. In humans, it is complete by 36 weeks gestation (13). Nephronogenesis continues postnatally in rats until 1 week (33), in dogs until 3 weeks (61), and in guinea pigs until 6 weeks of age (62). However, regardless of the species, once nephronogenesis is complete, it is not reactivated even in the face of reduction in the functional renal mass, i.e., disease or surgical resection. Any increase in GFR after nephronogenesis, therefore, reflects increased filtration in individual residual nephrons. The degree of this compensatory increase correlates with the magnitude of the initial loss of renal mass and is more pronounced in the young (63–72). Apart from lack of new nephron formation after nephron loss, compensatory renal growth reflecting increased tubule length and interstitial expansion can start in utero. For example, in the model of unilateral obstruction in fetal lambs at 60 days, contralateral kidney weight increased by 50%, together with an increase in indices of cell proliferation (hyperplasia), however, there is no increase in glomerular number (66, 67). The increase in single nephron function that follows a loss of other nephrons early in life is greater in glomeruli in the outer cortex; however, when loss occurs later in life, the increase is more evenly distributed among all nephrons (73).

Theoretical Considerations of Glomerular Filtration

As a filtering structure, the glomerulus is essentially a tuft of capillaries, and filtration is transudation of fluid across the capillary wall into Bowman's space (*Fig. 2-2*). Two characteristics distinguish glomerular ultrafiltration

Figure 2-2

Schematic representation of a glomerulus. Blood enters the glomerular capillaries through the afferent arteriole, courses through the capillary tuft, and exits through the efferent arteriole. Filtration takes place across the capillary wall into Bowman's space. Mesangial cells are strategically located to control the filtration surface area. The juxtaglomerular apparatus, one of the sites of tubuloglomerular feedback regulation, is depicted. Terminals from the renal nerve are also shown (reprinted with permission from the artist, Dr. W. Kriz).



from transcapillary exchange in other organs: (1) The glomerular capillary wall exhibits an extraordinarily high net permeability to water and small solutes, with up to 33% of intraglomerular plasma being filtered; and (2) the glomerulus almost completely excludes plasma proteins the size of albumin and larger from its filtrate. The filtration rate is determined by the same Starling forces governing movement of fluid across other capillary walls, that is, imbalance between transcapillary hydraulic and oncotic pressure differences. These can be summarized as follows:

1. Mean glomerular transcapillary hydraulic pressure difference, $\Delta P = (P_{GC} - P_{BS})$
2. Systemic plasma colloid osmotic pressure, π_A
3. Glomerular plasma flow rate, Q_A
4. Glomerular capillary ultrafiltration coefficient, K_f

When the individual pressures are expressed as average values over the entire length of the capillary, SNGFR is given by the equation:

$$\begin{aligned} \text{SNGFR} &= k \times S \times (\Delta P - \Delta\pi) \\ &= k \times S \times P_{UF} \\ &= K_f \times (\Delta P - \Delta\pi) \\ &= K_f \times P_{UF} \end{aligned}$$

where P_{BS} is the hydraulic pressure in Bowman's space; $\Delta P - \Delta\pi$ are the mean glomerular transcapillary hydraulic and colloid osmotic pressure difference, respectively; S is the total surface area available for filtration; K_f the glomerular ultrafiltration coefficient, is the product of k and S. In this equation, average values are used for $\Delta P - \Delta\pi$ because ΔP decreases and $\Delta\pi$ increases

as the plasma flows from the beginning to the end of the capillary within a given glomerulus.

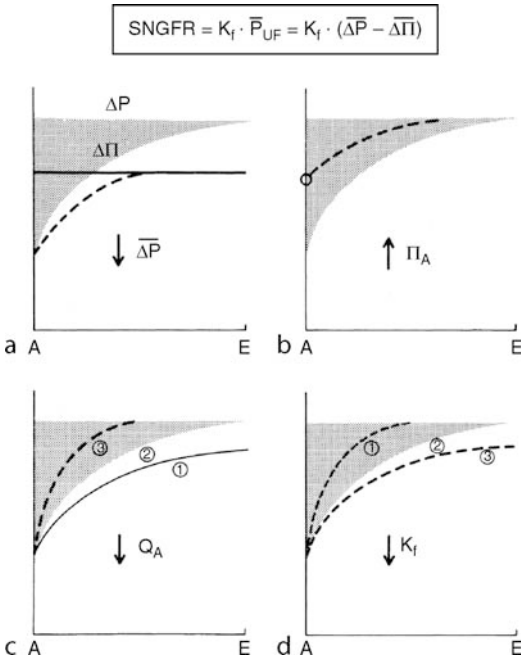
Effect of Perturbation in the Determinants of SNGFR

Mean Glomerular Transcapillary Hydraulic Pressure Difference, ΔP

Changes in ΔP seldom play a significant role in altering SNGFR because the autoregulatory mechanism in the afferent arteriole sustains glomerular capillary pressure despite large changes in systemic BP (*Fig. 2-3*). For example P_{GC} remained unchanged in Munich-Wistar rats despite a drop in renal perfusion pressure from 115 to 80 mm Hg induced by aortic constriction (8). Similarly, GFR in patients with mild to moderate hypertension is usually normal (72). As BP rises, spontaneously hypertensive rats maintain normal P_{GC} by increased afferent arteriolar resistance (73). However, when BP changes outside the autoregulatory range, both P_{GC} and GFR change accordingly. In circulatory collapse, GFR is severely reduced. Significant reductions in P_{GC} and SNGFR are noted in rats when BP falls below 80 mm Hg (8). As ΔP becomes equal to systemic plasma oncotic pressure πA, filtration diminishes to zero. Conversely, when an increase in BP is extreme, P_{GC} and filtration increase despite a marked concurrent increase in preglomerular vascular resistance. During a decrease (or increase, respectively) in renal perfusion pressure, autoregulation of P_{GC} is largely determined by the ability of the afferent arteriole to constrict/dilate and of the efferent arteriole to respond conversely. Importantly, the autoregulatory range is not fixed. For example, renal autoregulation is impaired by volume contraction. In volume-depleted animals, lowering BP leads to a reduction in P_{GC} and GFR at a relatively high renal perfusion pressure, whereas little or no change occurs in euvolemic animals (8). This effect and low circulating volume play significant roles in the reduction in GFR that accompanies hypovolemic shock. Renal autoregulation is also readjusted in severe chronic hypertension in which acute hypotensive treatment may lead to a decrease in GFR and a rise in serum creatinine. Such phenomenon in the setting of chronic hypertension might reflect a structural (i.e., not readily reversible) rather than functional narrowing of arteriolar lumen, as a consequence of long-standing elevation in renal perfusion pressure. Although this change may be beneficial in maintaining P_{GC} and GFR in the steady state, it leads to a loss of responsiveness of the renal vasculature to an acute reduction in RPP.

Figure 2-3

Schematic portrayals of the process of glomerular ultrafiltration. In each panel, the *vertical axis* represents pressure and the horizontal axis represents distance along the glomerular capillary from afferent arteriole (A) to efferent arteriole (E). The *shaded areas* represent normal mean net ultrafiltration pressure (P_{UF}), determined by the hydraulic pressure (ΔP) exceeding oncotic pressure ($\Delta\pi$). P_{UF} decreases along the length of the capillary with the increase in oncotic pressure in the capillary as colloid-free plasma is filtered. In (a), the reduced mean transcapillary hydraulic pressure difference (ΔP) is shown as a lower *horizontal line*, resulting in less ultrafiltration; (b) increased systematic colloid osmotic pressure (π_A) is represented by the *raised interrupted line*, resulting in less ultrafiltration; C, reduced glomerular plasma flow rate (Q_A); D, reduced ultrafiltration coefficient (K_f). The altered ΔP profile as a consequence of each of the above changes is given by an *interrupted curve* in each panel. Curve 1 in C and curve 3 in D represent conditions of filtration pressure disequilibrium, whereas curve 3 in C and curve 1 in D represent equilibrium. The Starling equation is also given and describes the determinants for SNGFR.



Changes in ΔP can also occur because of changes in P_{BS}. These occur with acute urinary tract obstruction and some forms of acute renal failure. Early in acute ureteral

obstruction, whether partial or complete, SNGFR is well maintained despite marked elevation in P_{BS} due to compensatory increases in both P_{GC} and Q_A. Twenty-four hours after complete ligation of a ureter, P_{BS} returns to near normal, yet GFR remains low as a result of a low Q_A secondary to vasoconstriction.

Systemic Plasma Colloid Osmotic Pressure, π_A

Derived primarily from serum proteins, π_A is a function of the number of molecules of protein present per unit volume of solution. At the same concentration, a small protein (e.g., albumin) will contribute more to oncotic pressure than a large protein (e.g., globulin). An isolated change in systemic plasma protein concentration (C_A), and hence in π_A, would theoretically be expected to change SNGFR in an opposite direction (*Fig. 2-3*). However, this does not occur. Acute reductions in C_A from 5.5 g/dl to 3.5 g/dl, induced by infusion of colloid-free solutions into rats, did not increase SNGFR because the fall in π_A and hence the rise in P_{UF} elicited a decrease in K_f through an unknown mechanism; the opposing influences of an increase in P_{UF} and a decrease in K_f maintained SNGFR nearly constant (34). In an experimental rat model of nephrotic syndrome, K_f was markedly low, accounting for the markedly low SNFGR (74). This reduction of K_f observed in the nephrotic syndrome may account for the low or normal GFR rather than higher values that would be predicted when C_A is low and circulation volume is not appreciably affected (75).

Hypoproteinemia in association with severe malnutrition is often accompanied by a decrease in GFR (76, 77). This decrease in GFR may be overlooked because serum creatinine (S_{Cr}) may not be elevated, consequent to a low muscle mass and creatinine production. GFR is reduced in protein malnutrition even when C_A is normal. The reduction in SNGFR is a result of reduced filtering surface area because glomerular size is smaller in protein-malnourished animals.

Glomerular Plasma Flow Rate, Q_A

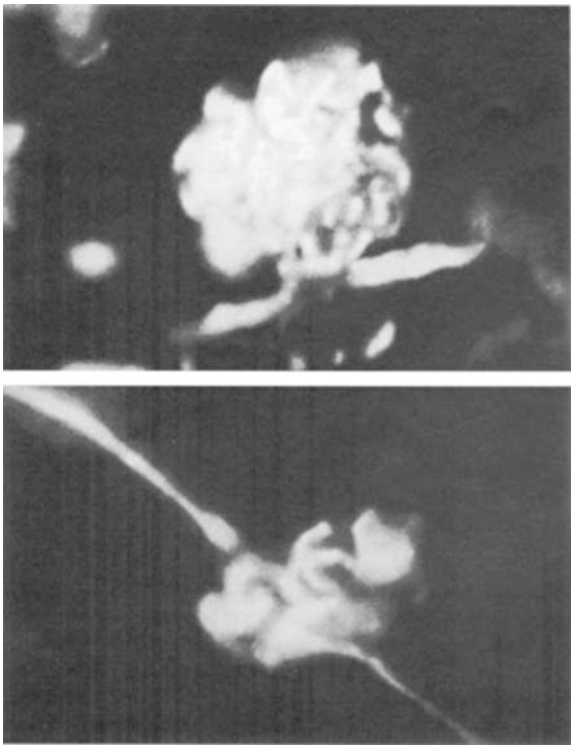
The impact of a change in Q_A on SNGFR will depend on whether the other determinants of SNGFR have been concurrently modified (*Fig. 2-3*). For example, infusion of isooncotic plasma selectively increases Q_A, while constriction of the aorta or the renal artery decreases both Q_A and ΔP (8). Under certain circumstances, filtration does not occur along the entire length of the glomerular capillary, but ceases at some point before its end. This is because plasma oncotic pressure increases progressively from the beginning to the end of the glomerular capillary. This progressive rise in oncotic pressure is accelerated when K_f is high or Q_A is low. Thus, a decrease in Q_A results in cessation of glomerular filtration at an earlier portion of the glomerular capillary tuft and hence a reduction in GFR. Experimental administration of renal vasodilators, such as PGE_1, acetylcholine, bradykinin, or histamine, causes substantial increase in renal blood and plasma flow in humans or in animals, but GFR is unaffected. SNGFR remains constant because of the opposing influences of an increase in Q_A and a decrease in K_f that occurs in response (78). The unexpected decrease in K_f could represent a direct action of these substances on the glomerular capillary, distinct from their known dilatory effects. Conversely, vasoconstrictors, such as AII and norepinephrine, are capable of producing substantial reductions in RPF, but little resultant change in GFR. Again, this is a result of a significant compensatory increase in P_{GC} as a consequence of the pressor-induced increase in efferent arteriolar resistance (79).

Glomerular Capillary Ultrafiltration Coefficient, K_f

Glomerular capillary ultrafiltration coefficient is the product of the glomerular capillary permeability to water (k) and the surface area available for filtration (s). Because changes in K_f inevitably lead to directionally similar changes in $\Delta\pi$ (*Fig. 2-3*), changes in K_f, unless extreme, are not expected to cause major changes in SNGFR. Nevertheless, a profound fall in K_f can affect GFR as demonstrated in rats with various experimental conditions. Many of these are disease models, such as minimal change nephrotic syndrome, acute renal failure, acute and chronic ECF depletion, and congestive heart failure, in which a reduction in K_f is the main factor in decreasing SNGFR (10, 80, 81). A variety of hormones and vasoactive substances, including antidiuretic hormone (ADH), adenosine, AII, endothelin, catecholamines, prostaglandins, acetylcholine, histamine, and vascular endothelial growth factor (VEGF) modulate SNGFR by influencing K_f (10, 78, 82, 83). The mesangial cells are thought to be the main locus of their actions because they appear to have a capillary surface area-regulating function. They possess intracellular contractile myofilaments, bear receptors to vasoactive agents and contract in response to these agents (*Fig. 2-4*) (84). It is speculated that hormones and

Figure 2-4

Structural expression of a reduction in the glomerular capillary ultrafiltration coefficient, K_f. The *top panel* represents the cast of a normal glomerulus; the *bottom panel* represents a glomerulus after a stimulus (renal nerve stimulation known to induce contraction of mesangial cells and a decrease in K_f) is applied. Mesangial cell contraction leads to obliteration of some of the glomerular capillaries, i.e., anatomical reduction in the surface area available for filtration, reflected as a decrease in the functional parameter K_f (from Ichikawa I, Kon V, Fed Proc 1983; 42:3078. With permission).



vasoactive substances regulate glomerular capillary filtering surface area, S, and hence GFR, by affecting mesangial contractility.

Defense of Glomerular Filtration Rate

Nonmammalian vertebrates have effective homeostatic mechanisms to alter GFR, drastically which is critically important to maintain hydration in these species (85). They can afford to alter GFR because toxic nitrogenous wastes are excreted through nonrenal organs such as gills, skin, and cloacae. In contrast, mammals, with their highly and variable fluid intake, have developed a greater capability to conserve and eliminate water from the body, largely through an expanded and highly regulated reabsorptive capacity of the renal tubules. However, because glomeruli are the only route for elimination of metabolic wastes and toxins, the GFR in mammals is remarkably constant, and high relative to other species. Mammals have developed specific mechanisms that maintain GFR stable over a wide range of blood pressure and extracellular fluid (ECF) volume, which ensures an effective removal of large amounts of nitrogenous waste that are constantly produced. The mechanisms that maintain GFR stable depend on adjustments at the glomerular loci, namely the afferent and efferent arterioles, and likely also in the glomerular capillary bed itself (*Fig. 2-5*). Two mechanisms, namely the myogenic reflex and tubuloglomerular feedback, are important for the autoregulation of GFR during changes in blood pressure. In the young, autoregulation of RBF is maintained through the same mechanisms but over a lower range of RPP that reflects the lower prevailing BP in the young (2, 24).

Myogenic Reflex

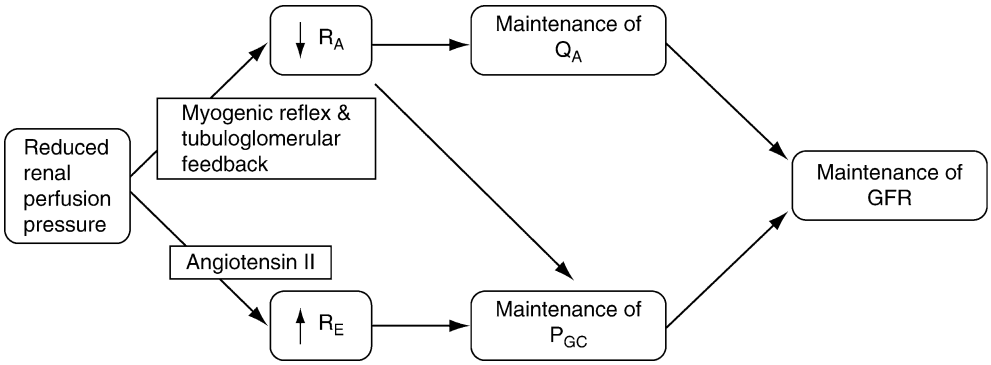
The myogenic reflex describes the theory that an increase in transmural pressure increases vascular tone. In the renal circulation this is particularly important in the afferent arteriole, which dilates in response to a decrease in RPP. This dilation also serves to preserve P_{GC}. At the same time, P_{GC} (and GFR) is also maintained in the adult animal through stimulation of renin release and the selective vasoconstrictor effect of AII on the efferent renal arteriole (10). This reflex is independent of renal nerves or macula densa mechanisms and reflects the inherent characteristics of the vessel (24, 86–88). This response has been demonstrated in isolated perfused renal vessels in which a change in vasomotor tone occurs in response to changes in the perfusion pressure in mature animals. However, a definitive role of the myogenic reflex during gestation and early life has not been defined.

Tubuloglomerular Feedback (TGF)

Constancy of GFR is also determined by the tubuloglomerular feedback system, which describes the coupling of the distal nephron flow and SNGFR. Anatomically, in each nephron, the distal tubule returns to the parent glomerulus and contributes to the formation of the macula densa, which consists of specialized cells of the ascending loop of Henle located between the afferent and efferent arterioles and the glomerulus. In this system, the stimulus to adjust SNGFR is related to the rate of distal

Figure 2-5

Mechanisms contributing to the autoregulatory maintenance of renal blood flow and glomerular filtration rates in the face of a reduction in renal perfusion pressure. R_A, afferent (and R_E, efferent) arteriolar resistance; Q_A, glomerular plasma flow rate P_{GC}, glomerular capillary hydraulic pressure; GFR, glomerular filtration rate. In the young animal, high baseline level of AII, inability to maximally activate the renin–angiotensin system on stimulation under certain circumstances, and low responsiveness of the vasculature to the constrictor action of AII may limit ability to autoregulate GFR (reprinted with permission from (10)).



tubular flow and also to the composition of the tubular fluid, particularly the chloride concentration and the tubule fluid osmolality (80, 81, 89–91). The signal is perceived in the macula densa and transmitted to the vascular structures of the nephron, particularly the afferent arteriole, but also to the efferent arteriole and the glomerular capillaries, which in concert adjust the rate of filtration. This feedback system is well suited to adjust the rate of filtration and maintain constancy of salt and water delivery to the distal nephron where tubular reabsorption is precisely regulated. Thus, an inverse relationship between filtration and tubular flow is established such that a decrease in tubular flow increases the rate of SNGFR and vice versa.

TGF is triggered by activation of the apical Na,K,2Cl cotransporter (NKCC2) in the macula densa cells by luminal NaCl (92). There are two NKCC2 isoforms. Targeted disruption of the A isoform of NKCC2 results in diminished blunting of GFR in response to increasing perfusion rate or NaCl concentrations (93). Mice with targeted disruption of the B isoform of NKCC2 have reduced TGF sensitivity at low flow rates (94). These findings indicate that the two isoforms are necessary for normal TGF response across the physiologic ranges of tubular flow and NaCl concentration. Increases in luminal NaCl have been shown to induce dramatic swelling in the macula dense cells that is accompanied by swelling and contraction of the afferent arteriole, particularly the intraglomerular segment (95, 96). This is accompanied by release of ATP into the juxtaglomerular interstitium, where enzymatic degradation to adenosine occurs. The smooth muscle cells within the afferent arterioles express receptors for ATP and adenosine and perfusion of isolated afferent arterioles with adenosine results in vasoconstriction (97). Purinergic receptor knockout mice have markedly impaired TGF as do mice lacking the A1 adenosine receptors. (98, 99) Likewise, interruption of ecto-5′-nucleotidase/CD 73 (ecto-5′-NT), which catalyzes the extracellular dephosphorylation of AMP to adenosine in the juxtaglomerular interstitium, dramatically impairs TGF (100). TGF is also impaired in mice lacking capacity for juxtaglomerular dephosphorylation of ATP/ADP to AMP (101). Regulation of the ATP to adenosine conversion, is modulatable. Thus, high ambient sodium chloride concentration increases ecto-5′-NT enzymatic activity while activity is decreased in the presence of a nitric oxide donor compound (102). Notably, provision of exogenous ecto-5′-NT improved impairment of renal autoregulation in experimental anti Thy-1 nephritis (103).

The constituents of the juxtaglomerular apparatus (macula densa tubular epithelium, mesangial cells, afferent arteriolar myocytes, and endothelium) are tightly linked by gap junctions enabling rapid intercellular communication. (104–106) The TGF-mediated increase in cytosolic calcium within the JGA mesangial cells is propagated through the gap junctions to the proximal afferent arteriole and as far as the podocytes (107). Gap junction proteins, connexin 37 and connexin 40, appear crucial in this signal transmission (108). Ang II is an important cofactor in the adenosine mediated vasoconstriction of the afferent arteriole. A1 adenosine receptor knockout mice have decreased afferent arteriolar vasoconstriction in response to Ang II (109). Conversely, TGF is impaired in experimental animals with genetic disruption of ACE or AT1A, a circumstance where the AngII signal is interrupted (110–112).

The interaction between adenosine and Ang II is complex. Repeated exposure to Ang II causes progressive reduction in vasoconstriction of isolated perfused afferent arterioles. However, adenosine pretreatment prevents diminution of this vasoconstrictive response by increasing the calcium sensitivity of the smooth muscle contractile apparatus (myosin light chain kinase) that involves post receptor interaction, particularly through G proteins (92, 113).

Recent observations suggest that connecting tubules also regulate glomerular arteriolar tone, through a connecting tubule glomerular feedback (CTGF) (114). In superficial cortical nephrons, the connecting tubule (CNT) is observed to return to the glomerulus in close proximity to the afferent arteriole. Rabbit CNT perfused with increasing sodium chloride concentrations demonstrate afferent arteriolar dilatation. The vasodilatation is blocked when CNT is infused with amiloride (but not hydrochlorothiazide), indicating that ENaC mediates this novel crosstalk between tubule segment and the glomerulus. In contrast to TGF, which functions to preserve whole organism sodium, CTGF favors sodium excretion. Identification of CTGF adds another level of understanding to aldosterone's role in sodium and potassium homeostasis, given its similar dependence on ENaC (115).

The existence of a tubuloglomerular feedback mechanism has been established in the superficial nephrons of young (30-day-old) rats (116). Its sensitivity (i.e., the change of SNGFR induced by a given change in tubule flow rate) is maximal around the values of SNGFR and tubule flow rate prevailing under normal undisturbed conditions. As SNGFR and tubule flow rates increase with growth, adjustments in the TGF mechanism take place to maintain this relationship, and the relative sensitivity of the system remains unaltered.

As noted earlier, afferent arteriolar dilation and RBF adjust to decreasing renal perfusion pressure in both adults and immature animals. However, one study found that although decreasing the renal perfusion pressure by ~ 30% from baseline was accompanied by a minimal fall in the GFR in adult rats, in young rats, GFR plummeted by more than 80% (117). Micropuncture experiments revealed that the profound hypofiltration in the young rats reflected decreased glomerular capillary pressure. Because glomerular capillary pressure, in large part, reflects efferent arteriolar vasoconstriction maintained by AII, the autoregulatory decompensation observed in the young animals likely reflects incompetence in the AII-mediated vasoconstriction of the efferent vessels. In this connection a similar degree of water deprivation causes a greater increase in the plasma renin activity in adult animals than in immature animals and a higher dose of AII is required in immature than in adult animals to effect a similar increase in glomerular capillary pressure (117). Taken together, it appears that the young have limited ability to activate AII and that the immature efferent arteriole has a limited responsiveness to AII. Thus, even in the face of afferent vasodilation following decreasing renal perfusion pressure, young animals develop hypofiltration. These observations provide a mechanism for dissociation between renal blood flow and the GFR in that dilation in the afferent arteriole without sufficient vasoconstriction in the efferent arteriole is insufficient to maintain a transcapillary pressure that promotes glomerular hypofiltration in the young (*Fig. 2-5*).

As noted above, of the two currently recognized receptors for AII, AT1 and AT2, the AT1 is most abundantly expressed and transduces the bulk of the recognized actions of AII including efferent arteriolar constriction (3, 118). Glomerular AII hyporesponsiveness in the neonatal kidney does not appear to reflect inadequate AT1 receptor density, as kidney AT1 expression peaks postnatally at twice the adult level (46). Further, as noted above, AII availability is also maximized reflecting an abundance of renal angiotensinogen, renin, angiotensin converting enzyme (ACE) (42–44). The observed hyporesponsiveness of the neonatal kidney, therefore, appears to reflect inadequate postnatal maturation of postreceptor processes. It is possible, however, that the blunted vasoconstriction of the neonatal efferent arteriole in response to AII reflects the vasodilatory contribution of the AT2 receptor, which is abundant during development but wanes with maturation. This may occur though a direct effect of the AT2 receptor or though AT2-mediated stimulation of NO and bradykinin (54).

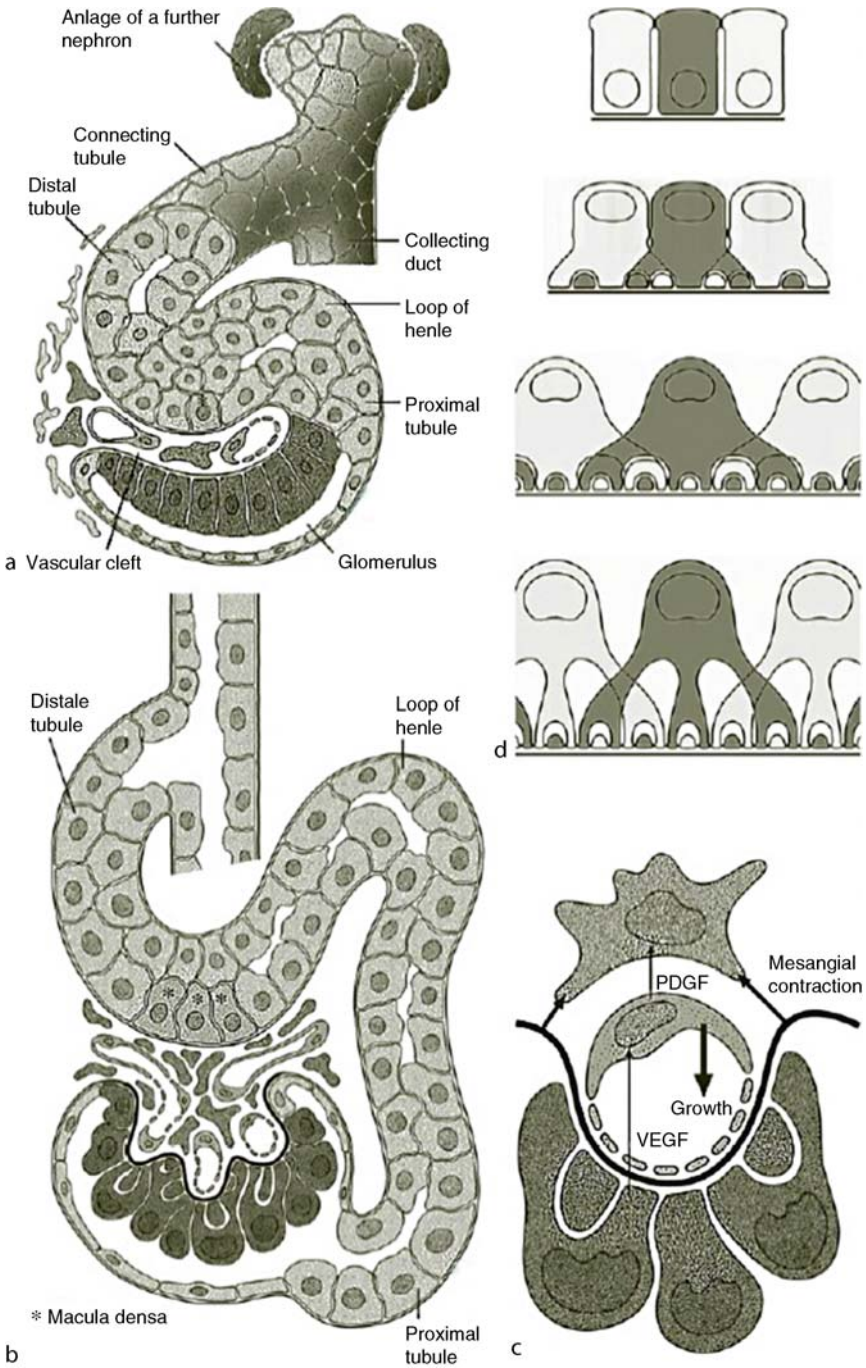
Development of Glomerular Filtration Rate

Ontogenic Development of Glomerular Capillaries

Glomerulogenesis in humans begins at 5 weeks gestation with reciprocal induction of the ureteral bud and nearby metanephric blastema (condensing mesenchyme) (119). At the point of contact between these primordial structures, epithelial cells are progressively generated as the renal tubule precursor, and eventually as the glomerular epithelial cell layers whose earliest precursor is the comma shaped body (120). A further indention of the comma shaped body creates a distal vascular cleft, defining the glomerular precursor as an S shaped body (*Fig. 2-6*). The proportion of developing nephrons in the S shaped body stage peaks in the second trimester

Figure 2-6

Stages in the development of a glomerulus and the filtration barrier. (a) The S-shaped body stage after formation of a distal vascular cleft. The cleft separates the presumptive podocytes (distally) from the tubule cell precursors of macula densa cells (proximally). In the cleft are infiltrating endothelial and mesangial cells. (b) The capillary loop stage with early formation of a glomerular tuft. (c) The podocyte – endothelial cell – mesangial cell paracrine axis. (d) Consecutive stages of podocyte development, finishing as complex cells with interdigitating foot processes connected by a slit membrane. (Reprinted with permission from (120)).



of human gestation (121). On the distal surface of this distal vascular cleft, podocytes develop under the influence of WT1 (122).

Under the influence of podocyte-derived vascular endothelial growth factor A (VEGF-A), endothelial cells migrate into the distal cleft of the S shaped body, interposing between podocytes and macula densa cells (120, 123). The developing glomeruli are not invaded by intact capillary loops. Instead, the migrating and proliferating endothelial cells form capillary cords that undergo central apoptosis to form a lumen, a process regulated by TGF beta (124). A critical role of podocyte VEGF-A generation to glomerular ontogeny has been highlighted by studies of podocyte haploinsufficiency of the VEGF gene (125). Thus, a single VEGF-A allele results in abnormally swollen glomerular endothelial cells and proteinuria. Glomeruli in which podocytes have but a single hypofunctional VEGF A allele show complete disappearance of endothelial cells a few days after glomerular maturation, with the affected animals dying at 3 weeks of age. Absence of a functional podocyte VEGF-A allele results in small glomeruli with no endothelial cells and no filtration barrier. Taken together, these observations underscore the importance of VEGF in development as well as maintenance of the normal endothelial cell integrity.

Endothelial cells, recruited and maintained by podocyte-derived VEGF A, in turn release PDFG (126). PDGF, in turn, induces migration of mesangial cells from nearby mesenchyme into the vascular distal cleft where they proliferate alongside the developing endothelial cell capillary (127). Infiltration by the mesangial cells has the effect to split the capillary in loops that results in a glomerular capillary tuft with multiple parallel branches. PDGFR-beta receptor gene null mice have glomeruli with a single balloon-like capillary loop that is devoid of mesangial cells (128). Similarly, impairment of mesangial cell anchoring to the basement membrane surrounding the endothelial capillary, as seen in mice with mutation in laminin alpha 5, leads to reduced capillary loop formation (129, 130).

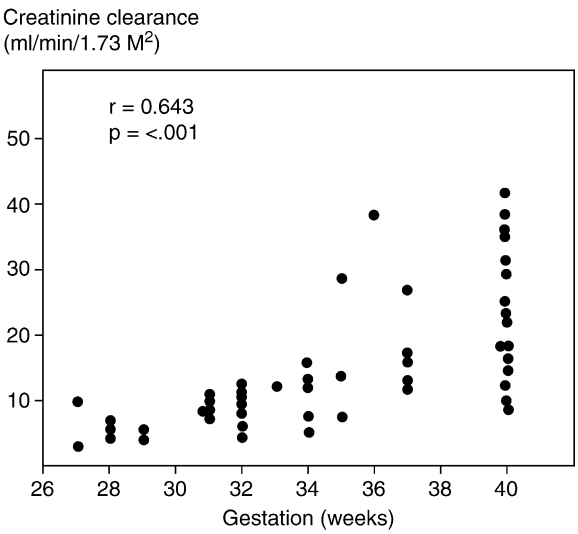
A variety of factors appear important for podocyte survival and differentiation in the S shaped body and later stages. WT-1 is essential (122, 131–133). Thus, WT-1 expression peaks in podocyte precursors where it regulates expression of podocyte membrane protein podocalyxin as well as VEGF-A, which are central to normal glomerular development. Interruption in the signaling of bone morphogenic proteins (BMP)-2, -4, and -7 results in abnormal localization of podocytes, such that parietal epithelial cells have podocyte markers, express VEGF, and have even been observed to give rise to ectopic glomerular capillaries (134). Mesangial cell density in these mutants is also dramatically decreased, resulting in collapsed glomerular tufts. That dosage of BMP in normal glomerular development is tightly controlled is evidenced by observations that transgenic mice selectively overexpressing BMP4 in podocytes have decreased podocyte VEGF together with inadequate numbers of endothelial cells and mesangial cells. Notably, nephrin, thought to be the sine qua non protein of the mature podocyte and essential to formation of the slit diaphragm between podocyte foot processes, does not appear to be essential to podocyte development or viability (135).

Prenatal GFR

Glomerular filtration rate in the fetus correlates with gestational age and body weight and parallels the increase in renal mass (136, 137). However, even corrected for body weight, prenatal GFR at every stage of development is much lower than in adults. For example, creatinine clearance measured within 24–40 h of birth in 30-week and younger premature infants is less than 10 ml/min/1.73 m^2 body surface area; at 34 weeks it is <15 ml/min/1.73 m^2; while at 40 weeks, ranges between 10–40 ml/min/1.73 m^2 (*Fig. 2-7*) (137, 138). Direct measurement of intrauterine glomerular function is obviously limited and creatinine is not an ideal indicator of fetal renal function because it freely crosses the placenta such that the fetal level actually reflects maternal levels. Endogenous low molecular weight proteins such as Cystatin C and b2-microglobulin have been

Figure 2-7

Creatinine clearance measured within 24–40 h of birth in premature and full term infants (reprinted with permission from (138)).



shown to be useful in assessing renal function of adults, children, and infants and have been used to assess prenatal renal function, see below (139, 140). Cordocenteses measurements of Cystatin C and β2-microglobulin have generated reference values in fetuses with normal amniotic fluid volume, normal chromosomes and absence of sonographic evidence of renal/extrarenal abnormalities as well as fetuses with abnormalities in these parameters and/or postnatal evidence of renal dysfunction (139).

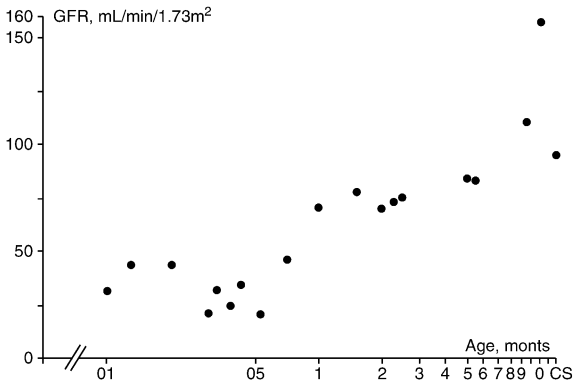
Postnatal GFR

At birth, the placental function of regulating fetal homeostasis becomes shifted to the kidneys. Compared to the adult, the GFR of a term newborn baby is less than 10% of the adult level whether expressed per gram of kidney weight, body weight or surface area and correlates closely with the gestational age (*Figs. 2-7*, *2-8*, *2-9*) (137, 138, 141–145). However, during the first 2 weeks of life, the GFR doubles and continues to increase, reaching adult levels by 2 years of age (146). This increase lags in premature babies (142, 144–146). As with RBF, development of GFR proceeds centrifugally within the kidney and the maturational increase in whole kidney GFR reflects primarily an increase in the single nephron GFR within superficial nephrons and less in the juxtamedullary nephrons (33, 147, 148).

All four determinants of SNGFR, ΔP, π_A, Q_A, and K_f contribute to the maturational increase in GFR to varying degrees. In early stages, the systemic blood pressure in humans averages 40 to 70 mmHg, which is below the autoregulatory range (148, 149) and likely contributes to a low P_{GC} and ΔP that has been shown in immature animals (36). Indeed, the blood pressure in babies born at 28–43 weeks of gestation predicted their creatinine clearance (33, 38). Plasma protein concentration, therefore the resultant π_A, is lower in newborns than in older children (5–6 vs. 6–8 g/dl) and is a factor that would increase ultrafiltration. However, the maturational increase in π_A that would hinder ultrafiltration is offset by a more profound increase in P_{GC} having the net effect on P_{UF} to promote ultrafiltration. Experimental studies during later postnatal maturation indicate that π_A and P_{GC} are at adult levels and remain constant (36). The further increase in SNGFR is attributable to an increasing plasma flow rate, Q_A that reflects an increasing caliber of afferent and efferent arterioles and decreasing resistances in these arterioles. Experimental and human observations support the parallel increase in plasma flow and GFR. Thus, increasing circulating blood volume by delayed clamping of the umbilical cord or intravenous fluid infusion increases inulin clearance (150, 151). Finally, rising hydraulic conductivity as well as surface area of the glomerular capillaries likely contribute to maturational increase in the capillary ultrafiltration coefficient, K_f. Glomerular size, glomerular capillary basement membrane surface area, and capillary permeability to macromolecules all increase from neonatal period to adulthood (152, 153). However, neither human nor animal data can provide the precise contribution of such changes to the increasing GFR.

Figure 2-8

GFR during the first year of life (reprinted with permission from (143)).

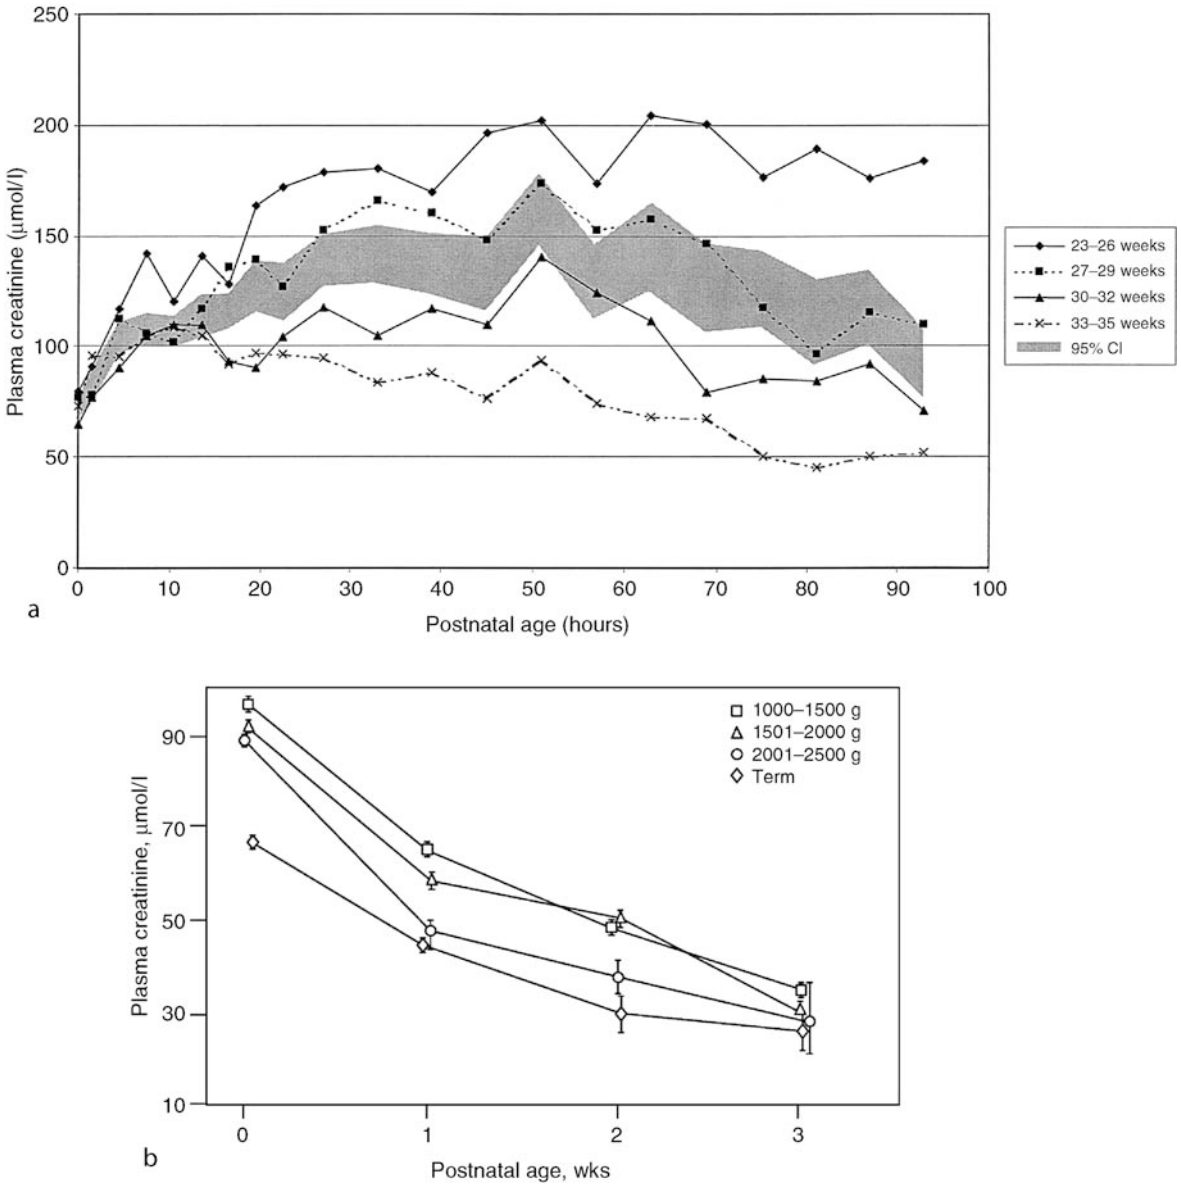


Impaired Fetal Glomerular Development and Adult Disease

As noted above, total GFR is the product of single nephron GFR and the number of filtering nephrons. Thus, failure to attain sufficient nephrons during glomerulogenesis may negatively impact the whole kidney GFR at birth. The number of glomeruli in healthy humans has been estimated at ~1 million in each kidney (154, 155). Recent observations, however, indicate considerable interindividual variability in the final number of nephrons, which is impacted by an assortment of prenatal factors. For example, low birth weight, especially fetal growth retardation, protein malnutrition, vitamin A deficiency, drugs such as aminoglycosides, cyclosporine A and glucocorticoids as well as metabolic disorders such as maternal hyperglycemia have all been shown to cause a significant nephron deficit in the fetus (155–162). In addition, recent evidence suggests that a reduced number of nephron units leads to adverse cardiovascular and renal consequences in adulthood. Thus, individuals who have even a modest decrease in the number of nephrons are at an increased risk of developing hypertension, cardiovascular disease and progressive chronic renal dysfunction (154, 163).

Figure 2-9

The shaded area represents 95% CIs for the mean plasma creatinine of all infants (reprinted with permission from (144)). (b) Plasma creatinine values during the first 3 weeks of life in preterm infants. The plasma creatinine inversely correlates with body weight and gestational age in the first weeks of life (reprinted with permission from (145)).



Low Birth Weight

Assessments of nephron number in autopsies of intrauterine growth retarded infants have observed significant decrease in the nephron complement compared to normal weight control infants (156). A study on autopsy kidneys from all ages revealed a direct correlation of nephron number with birth weight (164). Indeed, among patients younger than 18 years (who have minimal aging-related nephron loss), regression analysis estimated a gain of 518,000 nephrons for every kilogram increase in body weight. The ramifications of decreased nephron mass become detectable even by the time a child reaches school age. Thus, youngsters who were growth retarded as newborns

were found to have higher blood pressures, though not overt hypertension (165, 166). Adults with hypertension have been found to have fewer nephrons compared to nonhypertensive controls (167–169). Hypertensive patients also have larger glomeruli, more than twice the size of nonhypertensive controls, a finding that is indicative of glomerular environment at heightened risk for sclerosis (170). A large cohort of former premature infants in the Netherlands assessed at age 19 years showed a correlation between lower birthweight and lower GFR in adulthood, though all were still in the normal range. Attesting to the presence of incipient renal disease in these individuals was the finding of a more than twofold increase in microalbuminuria in those who were formerly small for gestational age. (171). Among a very large cohort in Norway, those with birth weight less than 2 standard deviations below the mean had an odds ratio of 2.4 (95%CI 1.46–3.94) for GFR $<$ 92 ml/min/1.73 m^2 in men aged 20–30. In women of similar birth weight, the odds ratio of GFR $<$ 86 ml/min/1.73 m^2 was 2.0 (95% CI 1.21–3.29) (172). The more robust association of deleterious renal consequences of low birth weight in men in this Norwegian study is reiterated by the recent observation of increased chronic kidney disease in American men (but not women) with birthweight $<$ 2,500 g. (173). It is worth noting that serum creatinine may be insufficiently sensitive to detect small differences in GFR attributable to decreased nephron mass early in life. In this regard, a study of children at age 8–13 years found no correlation between GFR (estimated by serum creatinine) and birth weight whereas the more accessible assessment of systolic blood pressure documented an inverse relationship with birth weight. Interestingly, GFR measurement, estimated by serum Cystatin C, was significantly lower in the lower quartiles of birthweight even by the age 8–13 years, with an estimated GFR of 73–92 ml/min/1.73 m^2 for those born weighing less than 2,500 g compared to GFR 89–109 for those born weighing greater than 3,000 g (174). (See discussion of clinical assessment of GFR below).

Extreme Prematurity

Nephronogenesis continues through postconceptional age of 36 weeks. Previously, it was believed that nephronogenesis continued unimpeded in infants born before this gestation. However, recent findings reveal a significantly reduced glomerular count among premature infants who lived past the end of nephronogenesis (175) Thus, the radial glomerular count (RGC) of whole kidneys in infants born at 27 weeks of gestation obtained at autopsy examination at age 63 weeks post conception was 8 compared to RGC of 6 in infants at 25 week of gestation dying within a week. These findings confirm that there is postnatal nephronogenesis in preterm infants. However, RGC of 8 already represents impairment of nephronogenesis when compared to term infants in whom RGC was 10.4, suggesting that the extrauterine environment for ill premature infants is hostile to nephron development. Among infants with even transient elevations in serum creatinine, the RGC was further reduced, to 6.5, indicating the marked deleterious consequences of renal impairment during nephronogenesis (175).

Maternal Factors

A variety of maternal factors can negatively impact nephronogenesis in the infant. These include maternal malnutrition, placental insufficiency, Vitamin A deficiency, corticosteroid exposure, and maternal hyperglycemia. Maternal malnutrition and placental insufficiency are two major factors that contribute to programming a subsequent increase in risk of adult cardiorenal diseases (176). Notably, improvement in a deficient intrauterine environment even late in nephronogenesis can benefit the ultimate nephron number. Thus, placental restriction in rat pups (through uterine vessel ligation) that is followed by postnatal fostering by inadequately lactating mothers caused a nephron deficit and hypertension at 20 weeks of age (177). By contrast, similarly placentally-restricted rat pups nursed by mothers with intact lactation from postnatal day 1 to weaning showed improved nephron number (~25% higher) and no adult hypertension. These improvements likely reflected restored nephronogenesis during the last stages, which in the rat, continues for the first week of postnatal life. (177).

The effect of protein malnutrition on nephron number appears to be mediated, at least in part, by an increase in apoptosis of mesenchymal cells of the very early metanephros and through reduced expression of periureteric genes, prox-1 and cofilin-1. (178, 179). Retinoic acid, derived from dietary vitamin A, regulates the c-Ret receptor for GDNF, a crucial mediator for ureteric bud branching. (155, 157, 168). Moreover, recent evidence suggests that retinoic acid supplementation may improve nephron endowment in rats exposed to low protein diet in utero (180). Dexamethasone exposure of cultured metanephroi down regulated GDNF and upregulated BMP-4 culminating in impaired renal branching morphogenesis. (181). Even near physiologic levels of natural corticosterone administered to pregnant rats during gestation has

resulted in nephron deficit, pointing to potential deleterious developmental effects of maternal stress during gestation (182). Lastly, experimental induction of diabetes in pregnant mice resulted in smaller, less numerous glomeruli in the offspring. Further studies reveal that hyperglycemia in these mice results in apoptosis of developing glomerular podocytes and tubular cells in association with dramatic upregulation of NF-κB as well as the renal renin angiotensin system (which also exhibits ectopic expression) (183).

Clinical Assessment of Glomerular Filtration Rate

Inulin Clearance

Assessment of glomerular filtration rate is the single most important measurement of renal function. Substances reaching the kidney may undergo one of several processes including glomerular filtration, tubule reabsorption, tubule secretion, and intrarenal metabolism. These considerations necessitated the search for an "ideal GFR marker." Among various substances considered, inulin emerged and has remained the standard against which all other techniques of measuring GFR are compared to validate their accuracy (184, 185). Inulin is a polymer of fructose, containing, on average, 32 fructose residues and has a molecular weight of about 5,700 Da. Natural inulin is derived from plant tubers such as dahlias, chicory, and Jerusalem artichokes. Although the molecular configuration of inulin varies depending on the source, the Stokes-Einstein radius that affects filtration is constant at about 5.0 nm. Inulin fulfills the following criteria:

1. It is freely and completely filterable at the glomerulus.
2. It is neither secreted nor reabsorbed by tubules.
3. It is neither metabolized nor synthesized by the kidney.
4. It is not bound to plasma proteins, or if it is, the free unbound as well as the bound components can be measured separately.
5. It is physiologically inert.

Because of these characteristics of inulin, the rate of inulin filtered into Bowman's space equals the urinary excretion of inulin. Moreover, inulin concentration in Bowman's space equals that of plasma. Thus, the flow rate of the fluid filtered into Bowman's space: GFR = C_{inulin} = U_{inulin} × V/P_{inulin}. For example, if P_{inulin} = 0.5 mg/ml, U_{inulin} = 50 mg/ml, and V = 1.1 ml/min, then GFR = C_{inulin} = 110 ml/min. Although this is a straightforward relationship, there are several points worth emphasizing. It is plasma, not urine that is being cleared of inulin. In the above example, all inulin is removed from 110 ml of plasma each minute. The inulin clearance is independent of the rate of urinary flow rate. Thus, the concentration of inulin in the urine increases as the volume decreases and vice versa at a given GFR. The inulin clearance is also independent of the concentration of inulin in the plasma; thus, as plasma inulin concentration increases, its appearance in the urine increases as more is filtered. Although inulin clearance remains the most accurate method of assessing GFR, it is cumbersome in routine clinical settings. The drawbacks include difficulty in obtaining inulin, the preparation of inulin and requirement for continuous intravenous infusion to maintain constancy in its plasma concentration. Moreover, measurements of inulin levels are not routinely available in hospital clinical laboratories. These drawbacks have led to the development of other methods to estimate GFR.

Modifications of the Standard Clearance Method

Because of the difficulty in maintaining intravenous access and obtaining urine samples in newborn infants and young children, various modifications of the standard clearance tests have been used to yield indirect assessments of GFR. One earlier modification used an intravenous infusion of a GFR marker, without urine collection (186). Because at steady state the amount of marker infused per unit time (I) equals the amount excreted in the urine, as well as the amount filtered,

$$U_x \times V = I$$

$$= GFR \times P_x,$$

hence

$$GFR = I/Px$$

Thus, only blood sampling is required, together with accurate knowledge of infusion parameters (infusion rate and marker concentration), and certainty that a steady state has been attained. One such marker used for clearance determination is either unlabeled or ^{125}I-iothalamate infused subcutaneously via a portable minipump (187). After steady state (8–24 h), the marker clearance can be calculated. Significant tubular secretion of iothalamate, however, has curtailed its use as a marker of GFR (188).

Clearance of a marker has also been measured by a single injection of that marker, followed by analysis

of its disappearance rate, as assessed from repeated plasma samples. This method bypasses the necessity of both continuous intravenous infusion and urine collection. Radiolabeled markers such as ^{51}Cr-EDTA (147), ^{125}I-iothalamate (57), and ^{99m}-Tc-DTPA have all been used for GFR measurement after single injection. Beyond radioactivity, use of these agents has been limited by availability, tubular excretion and overestimation of GFR, and variability among commercial sources, respectively (188). Renewed interest in ioxehol as a GFR marker has been stimulated by need for precise but manageable GFR measurement for a multicenter study of chronic kidney disease (CKD) in pediatric patients (189). Iohexol is a nonionic, low osmolarity contrast agent (Omnipaque™) with a molecular weight of 821 Da, long-used as a marker for GFR in Scandinavia (190–192). It fulfills several criteria of an ideal GFR marker, in that it is cleared only by glomerular filtration without being absorbed, secreted, or metabolized by the kidney (189–193). Additionally, iohexol has negligible extrarenal clearance (even with reduced renal function), is <2% protein bound, and is readily measurable by high performance liquid chromatography (HPLC)/ mass spectrometry. Importantly, iohexol clearance after single injection shows excellent agreement with traditional inulin clearance (193). Schwartz and coworkers have demonstrated in children with Chronic Kidney Disease that as few as two venous blood samplings 120 min and 300 min after iohexol injection are sufficient for GFR determination (189). Moreover, accurate GFR has been obtained after iohexol injection with HPLC/mass spectrometry measurement of finger prick blood spots collected on filter paper, raising the possibility of reduced clinic time for patients (194). Formal clearance studies remain costly and are still reserved for selected cases when accurate estimation of renal function is necessary.

Creatinine as a Marker of GFR

In clinical practice, GFR is most often estimated from measurements of serum creatinine concentrations or the clearance of endogenously produced creatinine. These require only collections of blood and/or urine samples. Most commonly, renal function is estimated simply by obtaining a serum creatinine measurement as the initial screening assessment, and in monitoring the increase as an estimate of the rate of deterioration of renal function. In the steady state, U_{creat} V (creatinine excretion rate) equals creatinine production rate which is constant. GFR is inversely proportional to plasma creatinine concentration because GFR = (U_{creat} V)/P_{creat}. Thus, an increase in plasma creatinine from 1 to 2 mg/dl or from 4 to 8 mg/dl represents a functional loss of 50% of GFR between measurements, although the absolute decline in function is less in the latter as is the fractional residual function. The utility of serum creatinine measurement stems from the relatively constant production of daily creatinine, and is independent of diet, protein catabolism, and physical activity. Creatinine production is a function of muscle mass. Approximately 1 g creatinine is derived from 20 kg muscle mass in 1 day (i.e., 50 mg/kg muscle) (195). Thus, if GFR completely ceases, e.g., acute renal failure, the plasma creatinine concentration is expected to increase by approximately 1.5 mg/dl/24 h. In individuals of average proportions, creatinine production is 15–20 mg/kg per day in boys and 10–15 mg/kg per day in girls and infants. This is the amount that is expected to be found in a complete 24-h urine collection, although more recent data indicate somewhat higher levels of urinary creatinine excretion. Thus, females < 10 years excreted 15.8 mg/kg/day urinary creatinine (SD 3.1), whereas boys of the same age excreted 17.7 mg/kg/day (SD 4.1). Females aged 10–14 and 14–21 years had urinary creatinine excretion of 17.8 (SD 2.9) and 17.1 (SD 4.7) mg/kg/day, respectively. Males aged 10–14 and 14–21,with the impact of increasing muscle mass, had urinary creatinine excretion of 18.4 (SD 3.4) and 22.3 (SD 5.4) mg/kg/day, respectively (196). Notably, even with precise clinic urine collection techniques, daily creatinine excretion variability may be as high as 20% (197). Nevertheless, the above ranges are helpful in detecting incomplete 24 h urine collections. It is also notable that dietary supplementation with creatine (a myocyte component taken by athletes for improved muscle function) can lead to elevated serum creatinine. Such creatine supplementation can lead to the erroneous diagnosis of decreased kidney function based on serum creatinine level (198).

Creatinine clearance (C_{Cr}) is a well accepted estimate of GFR (as measured by C_{In}) in patients who are older than 1 month of age (199) who have normal or have only moderately decreased renal function. However, in some settings, C_{Cr} is an unreliable estimate of GFR. C_{Cr} overestimates GFR with severely decreased renal function; when GFR falls below 20 ml/min per 1.73 m^2, C_{Cr} overestimates Cin by approximately 20%. C_{Cr} has been shown to overestimate C_{In} in adults with nephrotic syndrome (200) and in kidney transplant donors and recipients (201, 202). Both C_{Cr} and C_{In} underestimate GFR in some forms of acute renal failure in which the functional integrity of the renal tubule is disrupted. Under these conditions, filtered creatinine and inulin can be reabsorbed by passive back diffusion. In acute tubular

necrosis following cardiac surgery, 50% of filtered inulin undergoes tubular backleak (203). Thus, measurements of GFR in the setting of acute renal failure with tubule injury are invalid for assessing glomerular filtration rate. Nevertheless, in practice, changes in S_{Cr} have sufficient accuracy to follow the course of patients with acute renal failure.

Values for S_{Cr} in human newborns approximate the maternal S_{Cr} level, reflecting fetal–maternal equilibration of creatinine during the second half of gestation and dependence on placental/maternal clearance (204). Over the first few weeks of life, S_{Cr} decreases, and represents GFR maturation, which eliminates both the maternal creatinine and the newborn's endogenous creatinine production (*Fig. 2-9*). However, in preterm infants, a significant increase in S_{Cr} has been noted in the first few days of life, most pronounced in the most premature (144, 205) (*Fig. 2-9a*). The rise in creatinine in these infants has been attributed to delayed establishment of glomerular filtration, possible tubular resorption, or passive back diffusion of creatinine by the immature renal tubule. In this regard, although mature rabbits have creatinine clearance that exceeds inulin clearance ($C_{Cr}/C_{In} = 1.21$), reflective of tubular secretion of creatinine, newborn rabbits have creatinine clearance that falls short of inulin clearance (C_{Cr}/C_{In} 0.84), pointing to creatinine back diffusion(206). Low-birth weight infants have daily urinary creatinine excretion rates during the first 2 weeks of life that correlate with birth weight, gestational age, and body length (207). Serum creatinine concentration in normal infants and children increases with age and is slightly higher at any age in males than in females (*Fig. 2-10*) (208).

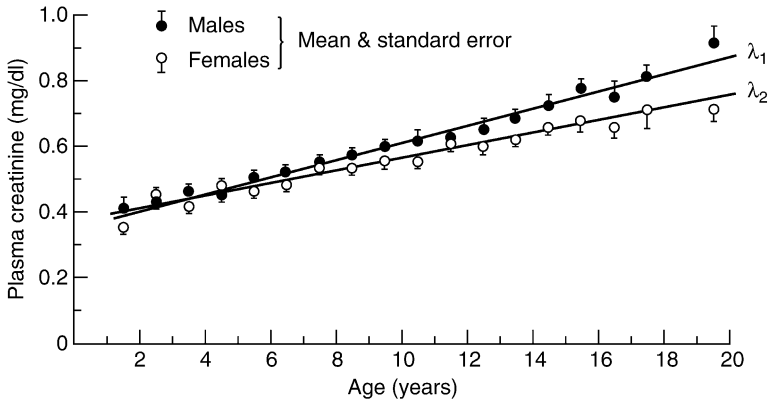
Estimation of GFR by C_{Cr} entails obtaining an accurately timed urine collection over a long period and is thus impossible in children who are not toilet trained (without the use of an indwelling urinary catheter) and remains a challenging exercise for most children. To ease GFR determination, investigators have attempted to derive formulas to estimate creatinine clearance from serum creatinine level, in conjunction with anthropometric measurements such as height, weight, or BSA. The following formula, derived by Schwartz and others, yields values of GFR that correlate with those obtained from C_{Cr} and C_{in} (209):

$$GFR = \delta L/S_{Cr}$$

where GFR is expressed in ml/min per 1.73 m^2; L represents body length in centimeters; S_{Cr} is serum creatinine in milligrams per deciliter; and δ, a constant of proportionality is age and sex dependent. Since the emergence of the Schwartz formula, the prevailing method of creatinine measurement has changed from the Jaffe reaction to newer enzymatic methods, which produce lower serum creatinine levels (210, 211). For this reason, altered δ values have been proposed. Thus, rather than $\delta = 0.55$ for most children and adolescent females, $\delta = 0.47$ has been suggested (188, 212). This need for systematic alteration in δ in light of changes in creatinine measurement is in accordance with significant overestimation of GFR by the Schwartz formula noted in recent studies (189, 213). Equations have been developed from the Modification of Diet in Renal Disease (MDRD) study which more accurately estimate GFR in adults (214). The equations take into account the individual's serum creatinine, blood urea

Figure 2-10

Mean plasma creatinine concentration (mg/dL) plotted against age for both sexes. The regression equations are for males: y = 0.35 + 0.025 × age, and for females: y = 0.37 + 0.018 × age (reprinted with permission from (208)).



nitrogen, serum albumin, age, gender, race and body size. In children, however, the MDRD equation significantly overestimates GFR. (213). Cockcroft-Gault, an equation developed in adults to estimate GFR, has been considered unsuitable for children, though some recent studies indicate its closer approximation in children to C_{In} than the Schwartz formula. (213, 215). Although these formulae are useful in day-to-day management, a more precise measurement of GFR should be obtained whenever a high accuracy is required.

Cystatin C as a Marker of GFR

While inulin clearance remains the gold standard and serum creatinine concentration and creatinine clearance are currently most widely used to estimate GFR, Cystatin C is another endogenous marker which may improve upon limitations of the creatinine-based estimates of GFR. (216, 217) Cystatin C may be particularly useful in detecting changes in GFR between 60 and 90 ml/min/1.73 m^2, the "creatinine-blind range" of GFR, where significant decline in GFR may occur without change in serum creatinine (218, 219). Cystatin C is a 13 kDa protease inhibitor that is constitutively synthesized by all nucleated cells and is freely filtered through the glomerulus and completely reabsorbed and catabolized by tubular cells, so that none returns to the blood flow (217, 218, 220). There are two commercially available methods for measuring Cystatin C in serum: immuno-nephelopmetric and immuno-turbidimetric assays, though availability is still restricted to reference laboratories and associated with high turn around time in clinical practice (218). Nephelometric Cystatin C has shown greater correlation with measured GFR and there remains disagreement about the interchangeability of Cystatin C levels from various methodologies (216, 221, 222).

A Cystatin C reference range has been established for adults (223–225). A pediatric reference range for Cystatin C together with levels of serum creatinine was published based on measurements in 291 children aged 1 day to 17 years, including preterm infants (*Fig. 2-11*) (225). These data reiterate the high creatinine values at birth and during the first week of life (see above) and the fall that occurs over the first month. Creatinine levels then remain constant until 2 years of age when they rise to adolescent values. By contrast, Cystatin C values more closely parallel functional clearance studies. Preterm babies have the highest levels of Cystatin C followed by infants < 1 year reflecting kidney immaturity. By 1 year of age Cystatin C levels approximate those in adults. Recent studies also find that Cystatin C may be a more accurate serum marker than creatinine in individuals with impaired renal function (226, 227). Notably, fetal serum Cystatin C levels do not show any relationship to maternal serum Cystatin C (228). For this reason, fetal serum concentrations of Cystatin C appear to be useful predictors of postnatal renal function (139).

Clinical factors which may confound Cystatin C interpretation have been described. Hyperthyroidism elevates and hypothyroidism decreases Cystatin C levels (218). Glucocorticoids increase and cyclosporine A can lower Cystatin C levels which may complicate GFR estimation after transplantation and obscure early cyclosporine nephrotoxic effects (229). High blood ketone levels have been associated with reduced Cystatin C levels. Gender and race have some impact on Cystatin C levels; women have levels that are 9% lower while blacks have levels that are 6% higher for a given GFR (230). Thus, for a GFR of 60 ml/min/1.73, the Cystatin C level of a white woman and black man would differ by 13%, less than the 50% difference in serum creatinine predicted on the basis of the same variables by the MDRD equation (231).

Given that its production is not limited to muscle cells, Cystatin C may be preferred for determination of renal function in groups at the extremes of muscle mass. In a study of healthy adults with differing physical activity, serum and urinary creatinine correlated directly with fat-free body mass while Cystatin C did not (232). Thus, serum creatinine levels were 0.95 ± 0.17, 0.96 ± 0.13, and 1.04 ± 0.12 mg/dl for those with sedentary, mild, or moderate/intense physical activity. In the same groups, serum Cystatin C levels were identical (0.82 ± 0.14, 0.80 ± 0.14, and 0.79 ± 0.14 mg/L), evidencing normal renal function in all groups, without the confounding impact of muscle mass on serum creatinine level (232). By contrast, patients with spina bifida have reduced muscle mass, and GFR estimated by Cystatin C shows superior correlation with ^{99}Tc-DTPA-measured GFR; the Schwartz formula does not correlate well and markedly overestimates GFR (233, 234).

As with creatinine, equations have been derived utilizing serum Cystatin C levels in an attempt to improve accuracy of GFR estimation (*Table 2-1*). Because of the inverse relationship of serum Cystatin C and GFR, the basis of most of these equations is GFR = 1/Cystatin C or GFR = $[\text{Cystatin C}]^{-1}$ with different factors and coefficients derived by linear regression from relatively small, often single center populations. Differences may also be attributable to the different Cystatin C assays and GFR methodologies (235–243). Recently, equations have emerged which incorporate both serum Cystatin C and

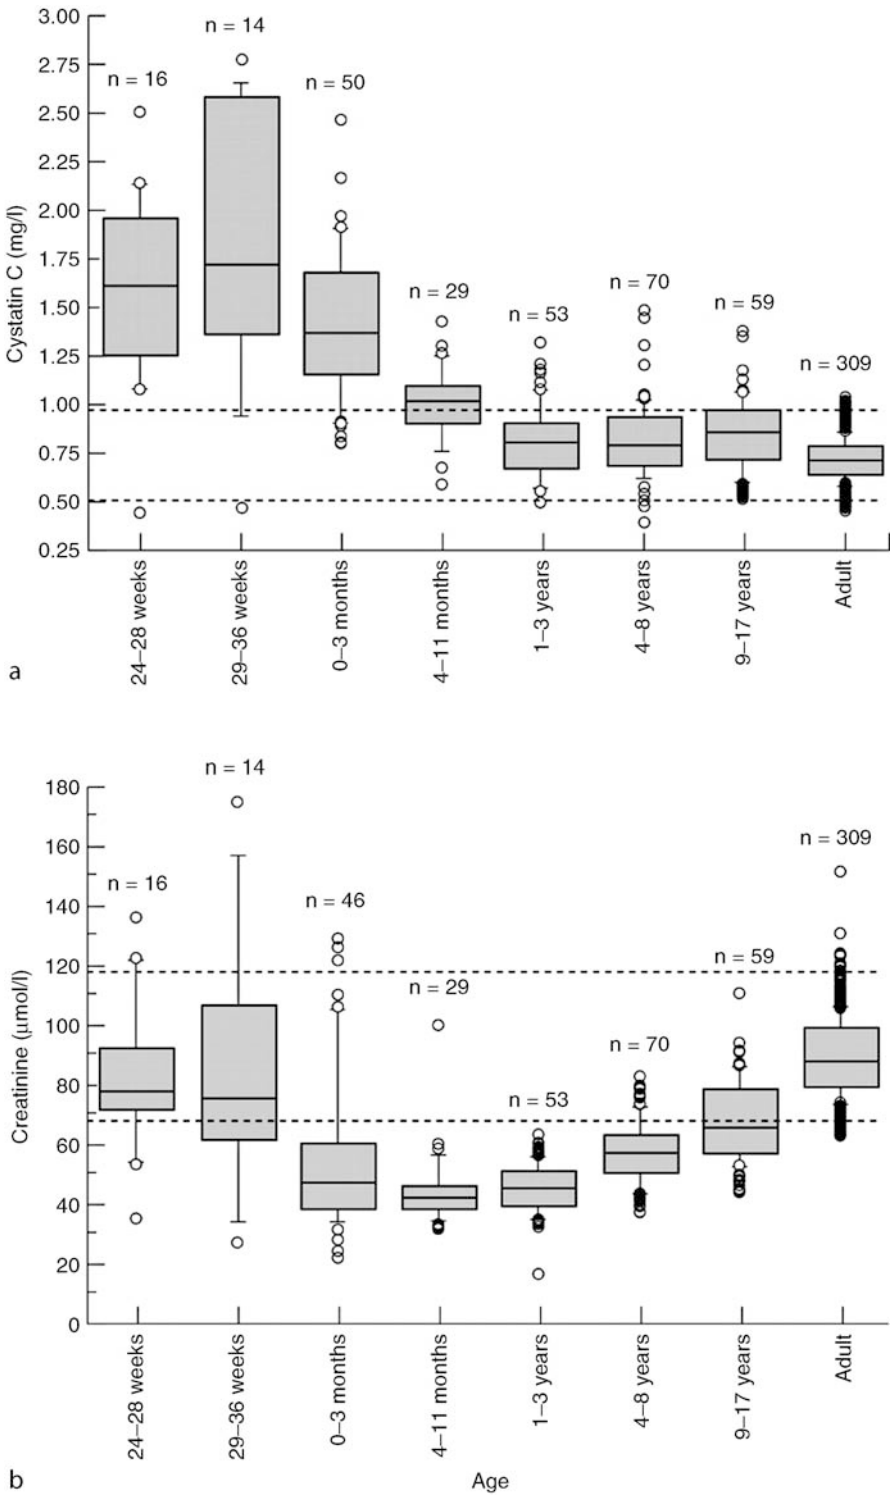
creatinine which more closely correspond with measured GFR than either creatinine or Cystatin C alone. Whereas pediatric equations are derived from relatively small sample sizes, a GFR-estimating equation for use in adults has recently been published which may prove more robust by including both Cystatin C and creatinine as well as being derived from a large, multicenter cohort of CKD patients (230).

Other Endogenous Markers of GFR

Variability of current endogenous markers of GFR with certain pathophysiologic conditions, e.g., Cystatin C derangement with corticosteroid therapy, has prompted an ongoing search for additional markers of GFR. β trace protein (β-TP) is one such marker (244). β trace protein (also known as lipocalin prostaglandin D2 synthase) is a 24 kDa protein freely filtered at the glomerulus which originates in the central nervous system, synthesized by glial cells. It is a major component of cerebrospinal fluid where its conversion of prostaglandin H2 to D2 contributes to nociception, temperature and sleep regulation. A recent pediatric reference range for β trace protein (age 2–20) shows stable serum levels from at 0.43–1.04 mg/L without gender effects. In patients with reduced renal function, β-TP increases. In pediatric patients with reduced renal function, β-TP showed higher percentage

Figure 2-11

Range for cystatin C and creatinine measured in 291 children aged 1 day to 17 years (225).



increase at GFR < 30 ml/min/1.73 m^2, than did Cystatin C. In children with neuromuscular disorders, however, significant deviation above and below the β-TP reference range was seen, likely reflecting neuromuscular pathology rather than renal dysfunction (244). Similarly, although Cystatin C is a useful marker of GFR in spina bifida patients, β-TP does not correlate with ^{99m}Tc-DTPA clearance, likely due to the obscuring impact of meningomyelocoele on β-TP production (234). Lastly, β-TP also appears to be significantly impacted by corticosteroids so that it does not improve in this regard over Cystatin C (245).

Glomerular Sieving of Macromolecules

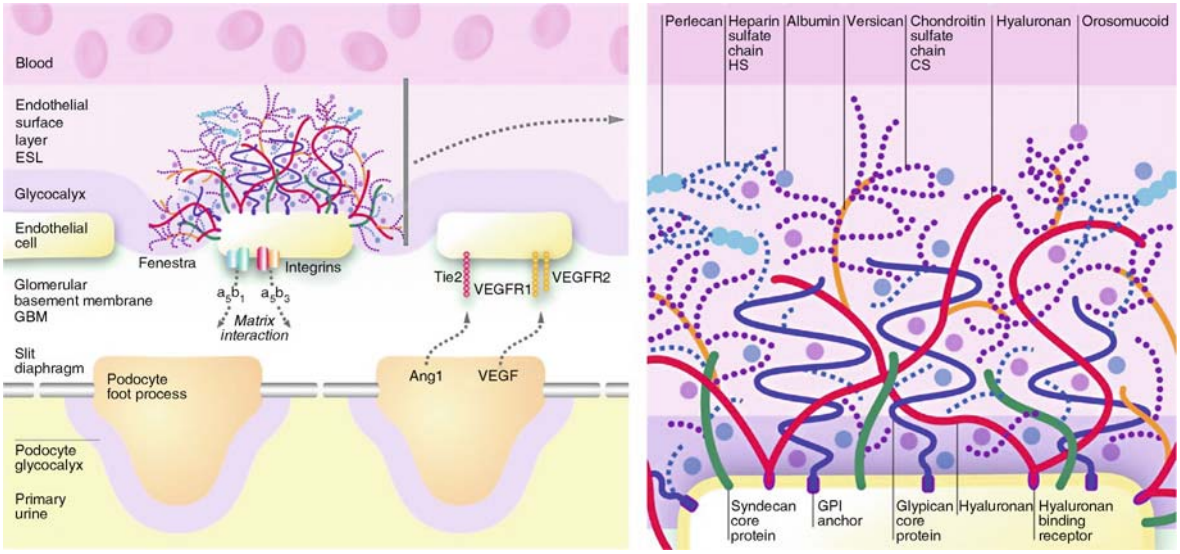
The enormity in the quantity of filtration generated by the glomerulus underscores specific features of the glomerular capillary bed that allows high permeability to water and small molecules while at the same time providing efficient selectivity that bars cells, proteins larger than albumin, and charged molecules (246). This barrier function of the glomerular capillaries is influenced by the size, shape, and charge of the macromolecules. Micropuncture studies and urinary clearance analyses that compare concentration of a given macromolecule in Bowman's space/urine to plasma have been used to obtain the glomerular sieving coefficient for a variety of macromolecules. Sieving coefficients are inversely correlated with the effective radius of the macromolecules. Thus, clearance of the larger proteins, such as albumin and globulin, is markedly less than that of smaller proteins such as monomeric immunoglobulin light chains (247, 248). Molecules without charge, including dextran and polyvinylpyrolidone, that are neither reabsorbed nor secreted (unlike proteins), have been used extensively to study glomerular capillary size selectivity both in experimental settings and in human diseases (247–253). Greater restriction of anionic than of neutral or cationic molecules suggests an electrostatic barrier that is charge selective. The observation that for a given chromatographic radius and charge density, the protein sieving coefficient is smaller than that of neutral dextrans suggests that the glomerular capillary barrier is also shape-selective. Thus, proteins are believed to behave as rigid spheres, whereas dextrans are more compliant so as to have smaller effective radii (248). It appears that each of the three major components of the glomerular capillary wall (endothelial cells, basement membrane and epithelial cells with their podocytes and slit diaphragms) provide impedance to macromolecular filtration. That endothelial cells and/or epithelial cells are important in this barrier function is illustrated by the observation that permeability of the isolated glomerular basement membrane is much higher than in the intact glomeruli (254). Indeed, native anionic ferritin particles accumulate in the endothelial fenestrae and in the lamina rara externa of the basement membrane.

Role of Endothelial Cells

Until recently, glomerular endothelial cells, with 60–80 nm fenestrations comprising 20% of their surface area, have not been thought to contribute significantly to the filtration barrier, aside from cellular exclusion from the urinary space (255). However, new observations clearly show that the glomerular endothelium contributes significantly to both size selectivity and charge selectivity of the filtration barrier. Only 5–10% of vascular albumin passes through the glomerular basement membrane (256, 257). Newer techniques allow visualization of a continuous glycocalyx which lines the endothelium and fenestrations, extending 10–20 nm into the vessel lumen. Additionally, a delicate endothelial surface layer (ESL), has been observed to extend~200 nm above the glomerular endothelium (*Fig. 2-12*) (258). Whereas the glycocalyx is composed of membrane-bound proteoglycans, the most abundant of which is heparan sulfate proteoglycan, the ESL additionally contains secreted proteoglycans and adsorbed plasma proteins (259). One group found proteinuria in mice transgenic for human heparanase, potentially related to degradation of glycocalyx (260). In vitro enzymatic degradation of the glycocalyx, without disruption of underlying endothelial cells (achieved by using neuraminidase, heparinase III, and human heparanase), resulted in several fold increase in albumin flux across a cultured endothelial cell monolayer (261). Infusion of glycocalyx-degrading enzymes into mice (hyaluronidase, heparinase III, and chondroitinase) increased by 2.5-fold the penetration of circulating lipids to within 50 nm of the endothelium. Isolated perfused kidneys from chondroitinase-treated mice showed fivefold increase in the fractional clearance of albumin (262). Moreover, clearance of Ficoll 35.5 A (similar to albumin in size but neutral rather than anionic) did not increase, suggesting that the endothelial glycocalyx contributes substantially to the charge selectivity of the glomerular filtration barrier. Similar results were obtained in experimental mice, in which 40 weeks of diabetes caused a threefold increase in glomerular albumin clearance but no change in clearance of neutral Ficoll 35.5 A. This increase in albumin clearance was associated with

Figure 2-12

Molecular model of the glomerular filtration barrier. The three layers of the barrier are the fenestrated endothelial cells lining the inside of the glomerular capillary, the glomerular basement membrane and the podocyte foot processes with their intervening slit diaphragm. Components of the endothelial surface layer are shown in detail in the right panel (reprinted with permission from (259)).



down regulation of ESL components versican and the chondroitan sulfate proteoglycan decorin (263).

Role of Glomerular Basement Membrane

The glomerular basement membrane, five times as thick as basement membranes of other vascular beds, is recognized as providing an important barrier to macromolecular passage (259). The glomerular basement membrane is composed of a fibrous network of type IV collagen, laminin, and proteoglycans (including perlecan and agrin, containing high levels of negatively charged heparin sulfate moieties) that provide size and charge-selective restriction to glomerular filtration. (264–266). Type IV collagen is a trimer formed from three of six chains (alpha 1 to alpha 6) encoded on three chromosomes. The trimer α1:α1:α2 constitutes Type IV collagen in embryonic GBM, whereas α3:α4:α5 is expressed postnatally (267, 268). Mutations of the alpha 5 chain, encoded on the X chromosome, leads to defects in the adult collagen IV and to thinning and distortion of the glomerular basement membrane that characterizes X-linked Alport's hereditary nephritis. Heterozygous mutations of the alpha 3 and alpha 4 chains underlie thin basement membrane nephropathy, whereas homozygous mutations lead to autosomal Alport's hereditary nephritis (268). Laminin plays an increasingly recognized role in basement membrane structure and sieving impedance. Mice deficient in laminin-2 chain develop nephrotic syndrome (269, 270). In humans, truncating mutations in the gene for laminin β2 (LAMB2) produce Pierson syndrome consisting of congenital nephrosis with eye abnormalities and mental retardation (271, 272). Nonsyndromic congenital nephrosis is described with missense mutations of LAMB2 (273, 274). Prevailing opinion for some time has been that negatively-charged heparan sulfate in the GBM constitutes the main charge selective filter of the glomerulus, although recent evidence is challenging this notion (275). In vivo removal of GBM sulfated glycosaminoglycans in rats by heparinase III does not result in proteinuria; neuraminidase treatment causes proteinuria while leaving heparan sulfate intact in the GBM (276). Similarly, mice transgenic for human heparanase show fivefold reduction in glycosaminoglycan anionic sites in GBM, but lack proteinuria (277). A function proposed for heparin, is that by attracting and holding water molecules, it enables the GBM to function as a gel (278), a description which may be eroding the older concept of GBM as a sieve (279).

Role of Podocytes

The epithelial cell layer of the glomerular capillary network furnishes the restrictive size selection of macromolecular filtration, preventing passage of proteins the size of albumin or larger. Glomerular epithelial cells (podocytes) consist of a large cell body, major processes, and long, interdigitating foot processes separated by a filtration slit diaphragm that is ~30–50 nm wide and possesses numerous pore-like structures measuring 40 × 140 A. Recent studies have clarified the molecular structure and functional implications of the slit diaphragms. The gene mutated in congenital nephrotic syndrome of the Finnish type, NPHS1, was found to encode a slit diaphragm protein, nephrin. Nephrin is a transmembrane glycoprotein similar to immunoglobulin-like cell adhesion molecules, which participates in an interdigitating homophillic interaction from opposing podocytes, forming a zipper-like sheet between them (280–284). A variety of other proteins are now known to contribute to the slit diaphragm linking podocyte foot processes, including NEPH-1 and NEPH-2, FAT1, P-Cadherin, and podocin (285). Besides comprising the physical barrier which impedes the flow of albumin into the urinary space, each of these slit diaphragm components is linked through their intracellular domains to other proteins connecting them to the actin cytoskeleton of the podocytes (*Fig. 2-13*). Intracellularly, nephrin interacts with CD2-associated protein (CD2AP) and other proteins such as Nck that connect with actin (286). Mice deficient in CD2AP have massive proteinuria and early death (287). Likewise, selective deletion of Nck from podocytes of transgenic mice results in defects in the formation of foot processes and in congenital nephrotic syndrome (288). Nephrin phosphorylation sites Y1204 and Y1228 appear to be the sites of Nck binding. Induction of puromycin nephrosis in rats decreased phosphorylation of nephrin's Nck binding sites as well as loss of filamentous actin and increase in globular actin. Loss of phosphorylation, thus, appears to sever the linkage of nephrin to actin leading to dramatic perturbations in podocyte structure and function. Preliminary data also indicate that phosphorylated nephrin is decreased in human minimal change nephrotic syndrome as well (289) These studies underscore the appreciation for the pivotal role of the podocyte and slit diaphragm in glomerular filtration barrier function.

VEGF appears to be critical for normal function and maintenance of the glomerular filtration barrier, beyond its role in glomerulogenesis. Thus, VEGF functions in an autocrine manner on podocytes and reduces podocyte apoptosis, doing so in concert with nephrin (290, 291). Autocrine VEGF upregulates podocin in podocytes and increases its interaction with CD2AP (292). Downregulation of a podocyte VEGF receptor, VEGFR2 (by infusion of semaphorin 3a) disrupts podocytes leading to acute nephrotic-range proteinuria, foot process effacement, and down regulation of slit diaphragm proteins nephrin and podocin, as well as CD2AP. Endothelial cells were also impaired with swelling and loss of fenestrations as well as detachment from the GBM (293). The importance of intact VEGF signaling to maintenance of glomerular endothelium is further underscored by the observation of renal thrombotic microangiopathy in patients after treatment for neoplasia with monoclonal antibodies to VEGF (294). Similarly, a soluble placental-derived inhibitor of VEGF (sflt1) is elevated in the maternal circulation in preeclampsia, the renal lesion of which is characterized by microangiopathy (295, 296).

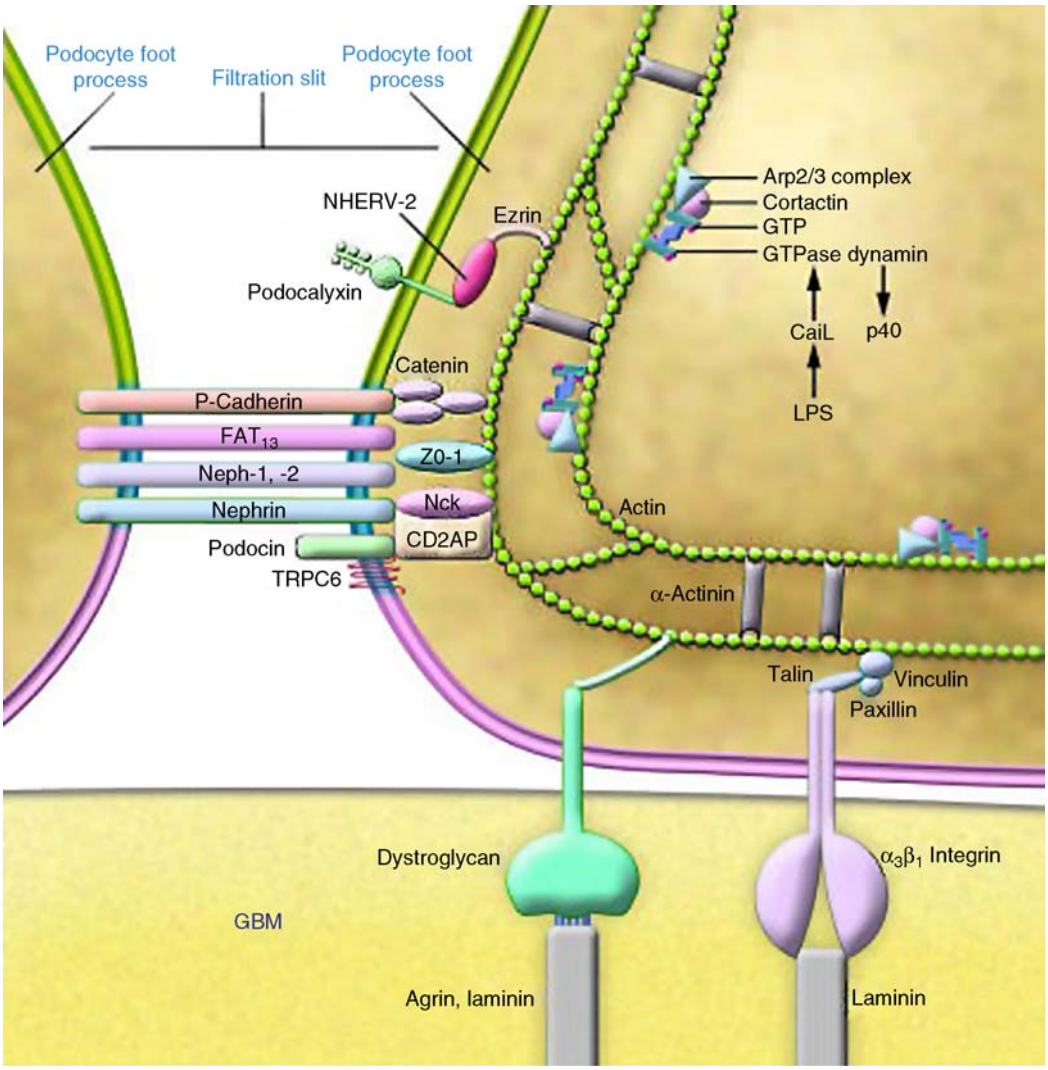
A newly appreciated component of the filtration barrier is the space bounded below by the GBM and foot processes and above by the underside of the podocyte cell bodies, the subpodocyte space (SPS) (297). The subpodocyte space (including the overlying and defining podocyte cell bodies) covers 60% of the total filtration barrier but is not readily imaged by either scanning electron microscopy or transmission electron microscopy which has limited its examination (298). In SPS-covered areas, glomerular filtrate cannot enter directly into the urinary space without traversing the long and tortuous subpodocyte space, exited by a very limited number of pores. In fact, the area available for efflux from the SPS appears to be several hundredfold lower than the area for influx, increasing glomerular flow resistance by 1.3–26 times that posed by areas of uncovered glomerular filtration barrier (299). Stated another way, glomerular filtration through SPS-covered areas may be only 4–75% (mean 29%) that of uncovered areas. Beyond this, evidence supports retention of 10 kDa dextran–rhodamine in this space (but not 450 Da lucifer yellow or 3 kDa dextran), suggesting the SPS makes a size selective contribution to the glomerular filtration barrier as well (300).That the contractile apparatus of podocytes (defining the dimensions of the SPS and exit pores) is readily functional, raises the possibility for particular relevance of the SPS in certain pathophysiologic settings.

Role of the Renin Angiotensin System

In addition to the structural characteristics of the capillary wall components that determine its permeability, individual determinants of SNGFR also impact filtration of macromolecules. Glomerular capillary flow rate, but particularly the glomerular capillary pressure, is thought to modulate membrane characteristics such that an in-

Figure 2-13

Schematic drawing of the basolateral portion of podocytes. The filtration slit is composed of nephrin and other structural molecules between podocytes. Many of these filtration slit components are themselves linked to the intracellular actin cytoskeleton of the podocyte. Podocytes are also linked to the glomerular basement membrane through their actin cytoskeleton (reprinted with permission from (280)).



crease in glomerular pressure augments proteinuria. Infusion of Ang II, or endogenous stimulation of Ang II activity, increases the fractional excretion of protein, whereas decreasing the glomerular capillary pressure has the opposite effect (301–303). These studies underscore that glomerular hemodynamic changes can allow macromolecules to escape into the urinary space. It is of interest that acute exercise-induced proteinuria, in which the sieving defect is believed to be linked to increased intraglomerular pressure, is lessened by pretreatment with ACEI (304). Conversely, antagonism of Ang II actions by ACEI or ARB acutely lessens proteinuria and is well documented to decrease protein excretion in many different chronic settings (305–307). The mechanism for this antiproteinuric effect is in part related to decreased efferent arteriolar resistance and therefore glomerular capillary pressure, attributable to both reduction of Ang II effect and augmentation of bradykinin effect (308).

Independent of hemodynamic changes, RAS-inhibition enhances glomerular barrier size selectivity, underscoring the deleterious impact of Ang II. Thus, infusion of neutral dextrans into patients with chronic proteinuric

nephropathies produces a pattern of dextran clearance that is significantly lessened by treatment with enalapril, ramipril, or valsartan, particularly at high molecular radius (251, 309, 310). Mechanisms of Ang II-induced barrier dysfunction appear to include direct podocyte effects. Thus, Ang II (through AT1) increases albumin flux across podocyte monolayers in vitro that is associated with F-actin disorganization and zonula occludens-1 fragmentation (311). Injured podocytes in vitro have diminished ability to stimulate glomerular endothelial cell growth, which is restored by AT1 antagonism, in part by restoring VEGF signaling (312). Ang II also appears to decrease podocyte expression of slit diaphragm components nephrin and podocin through AT1, whereas AT2 appears to have a salutary effect on slit diaphragm components (313). Interestingly, in nonglomerular vascular tissues, evidence supports a direct role for VEGF stimulation through the AT2 receptor. These latter studies raise AT2 as a potential therapeutic target for stimulation in order to enhance glomerular filtration barrier function, even beyond AT1 receptor blockade (314, 315).

3 Renal Tubular Development

Michel Baum

Organization of the Nephron

The kidney is faced with the enormous task of maintaining a constant composition and volume of the extracellular fluid. The adult ingests nutrients and water and generates waste products that must be eliminated to maintain this balance. In other words, the amount of electrolytes that are ingested and absorbed must be eliminated and the waste products from metabolism must also be excreted. This challenge is all the more complex as our dietary intake is quite variable from day to day. Despite this variable intake, there is virtually no change in the volume or composition of the extracellular fluid volume from day to day.

There are two possible ways that our kidney could balance ingestion and excretion. The kidney could be a secretory organ, from where all the excess solutes and water would be excreted by tubular secretion. This would be very inefficient and require an enormous amount of energy. In addition, in times of a disturbance in the extracellular fluid volume such as a high salt intake or volume loss from diarrhea, for example, the regulatory systems necessary to maintain a constant extracellular fluid volume and composition while excreting waste products would be very complex. On the other hand, the kidney could filter an enormous quantity of extracellular fluid, which would be very efficient in removing waste products, and reclaim the desired salt, organic solutes and water. The mammalian kidney actually uses both mechanisms to perform its job, which is necessary for our survival on land. The adult kidney filters ~150 l of isotonic fluid a day and reclaims most of it, leaving the waste products to be excreted. In addition, there are secretory processes for solutes such as organic anions and cations in the proximal tubule and secretory mechanisms to excrete the excess acid generated from metabolism in the distal nephrons, which aid in maintaining homeostasis.

To accomplish the remarkable task of reclamation of the necessary solutes and water in the filtered load, the mammalian kidney has evolved into a highly specialized organ with one million units called nephrons. Each nephron is a tube consisting of epithelial cells and is divided into 12 specialized segments as shown in *Fig. 3-1*. The epithelial cells allow the vectorial transport of solutes. The proximal tubule is responsible for the bulk reclamation of solutes and for the secretion of organic cations and anions. Approximately two-thirds of the glomerular filtrate is reabsorbed by the proximal tubule in an isotonic fashion. Virtually all of the organic solutes, as well as the majority of bicarbonates, phosphates, and chlorides, are reabsorbed in this segment. The proximal tubule is divided into S_1, S_2, and S_3 segments, on the basis of the rates of transport of some solutes, and morphological changes that occur down the proximal tubule. The nephron makes a hairpin turn, which aids in the generation of concentrated urine. The length of the thin descending and ascending limb is variable among species, with desert rodents having very long thin limbs as they need to conserve water and excrete very concentrated urine. The length of the thin ascending and descending limbs increases as one goes from the superficial cortex down to the medulla. The thin descending limb expresses aquaporin 1 on the apical and basolateral membranes and is very permeable to water (255), but is impermeable to solutes. This results in a concentrated fluid in the medulla with a very high sodium chloride content, providing a passive driving force for sodium chloride diffusion in the thin ascending limb. The thin ascending limb is impermeable to water but has a high permeability to NaCl (145). The chloride channel (CLC-K1) in the thin ascending limb is developmentally regulated (160). There is no expression in the fetus and until the end of the first week of life, in rats. There is a correlation between CLC-K1 and urinary osmolality, suggesting the important role of this channel in generating a hypertonic medulla (160). Diffusion of NaCl causes a high interstitial osmolality. This loop structure, along with the thick ascending limb, generates the countercurrent multiplication system that results in a medullary osmolality far greater than that of blood (162, 258). The importance of the passive properties of the thin limbs in this counter current system is exemplified in mice which are deficient in the water channel designated aquaporin 1, and do not express aquaporin 1 in the thin descending limb (182). The urine osmolality of aquaporin 1 deficient mice is greater than plasma, but far less than control mice expressing

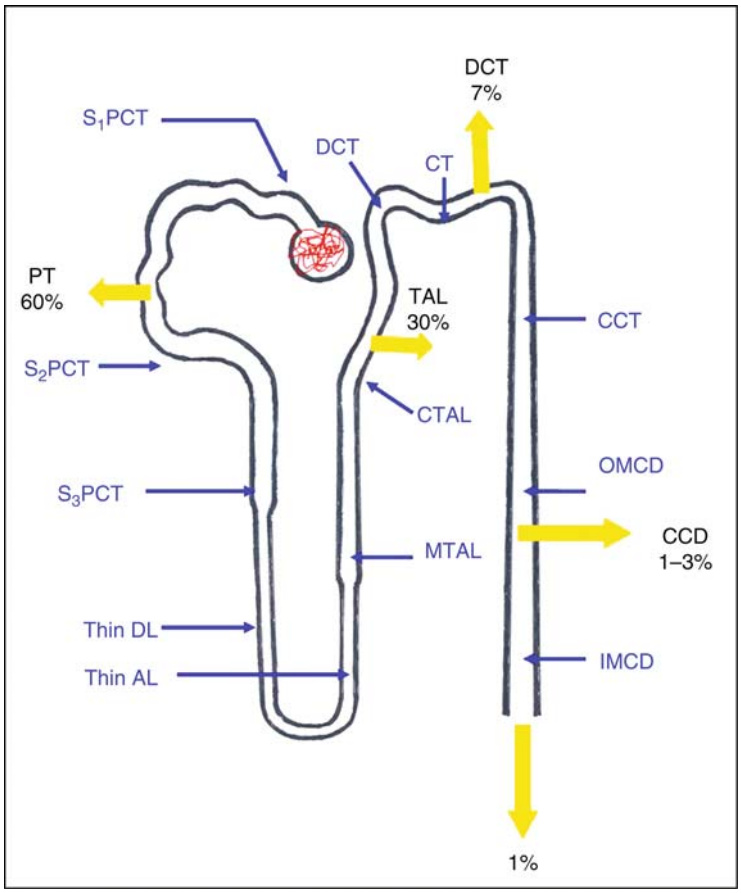
Figure 3-1

This cartoon depicts the nephron with its 12 segments. Shown in blue are the nephron segments. S_1, S_2, S_3 PCT depict the three segments of the proximal tubule. The loop of Henle consists of the thin descending limb (thin DL) and thin ascending limb (thin AL), the medullary (MTAL) and cortical thick ascending limb (CTAL). The distal convoluted tubule is comprised of the (DCT), connecting tubule (CT) and the initial cortial collecting tubule. The collecting duct is made up of the cortical collecting tubule (CCT), outer medullary (OMCD) and inner medullary collecting duct (IMCD). Shown in yellow is the percentage of sodium reabsorbed by the proximal tubule (PT), thick ascending limb (TAL), distal convoluted tubule (DCT) and cortical collecting duct (CCD). One percent of the filtered sodium is excreted.



aquaporin 1 (182). Unlike control mice, aquaporin 1 knock-out mice cannot increase their urine osmolality in response to water deprivation.

The thick ascending limb is the segment responsible for ~30% of sodium chloride transport and has a vital role in generating a concentrated medulla. Apical sodium chloride absorption is mediated by the bumetanide sensitive cotransporter. One of the unique features of this segment is that it is impermeable to water and thus the fluid leaving this segment is hypotonic to blood. In addition, this segment has a very high paracellular permeability to cations and is responsible for much of calcium and magnesium transport. The distal convoluted tubule is responsible for ~5–10% of NaCl transport. NaCl transport in this segment is mediated by the thiazide sensitive cotransporter. Active transcellular calcium and magnesium transport also occurs in this segment.

The rest of the distal tubule is separated into the connecting tubule and the cortical, outer and inner medullary collecting tubule. These segments are responsible for potassium secretion, final urinary acidification and water absorption, the latter mediated by the action of vasopressin. While the fraction of salt transport and renal acidification is only a fraction of that in other

nephron segments, the collecting tubule is responsible for the final modulation of the tubular fluid. Thus, the final composition of urine and significant regulation of transport occur in this segment.

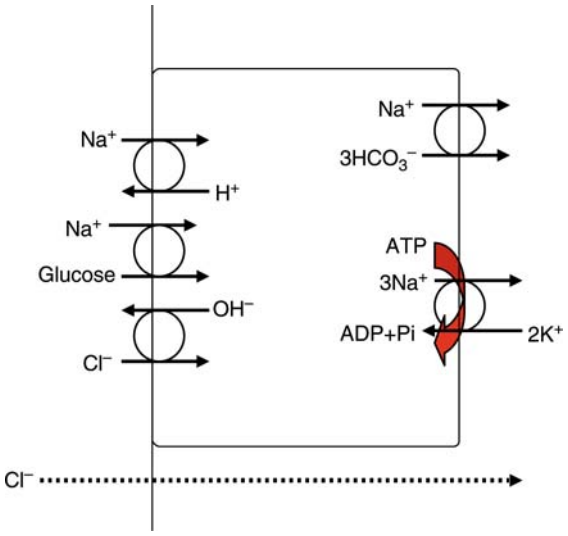
Principals of Membrane Transport

The cells along the nephron are quite different in the various nephron segments, as will be discussed in the subsequent sections. The cells in each nephron segment are poised for vectorial transport. The apical and basolateral membranes are, by and large, a lipid bilayer which would be impermeable to water and solutes if there were not specific proteins to facilitate transport across the apical and basolateral membranes. In addition, many transporters are regulated to adjust their rate of transport to meet the physiologic changes in volume status or concentration of solutes in the extracellular milieux.

The reabsorption of solutes along the nephron is characterized by active and passive transport processes. A typical cell is shown in *Fig. 3-2.* It should be appreciated that if all active transport was inhibited along the nephron, we would excrete urine with the composition and volume of the glomerular ultrafiltrate. Passive transepithelial transport is, by and large, the result of gradients generated by active transport. Most active transport is the result of the basolateral Na^+-K^+-ATPase. This transporter pumps three sodiums out of the cell in exchange for two potassium ions. The pump utilizes ATP and it is an example of primary active transport. This pump is vital to the generation of the low intracellular sodium and high intracellular potassium concentration as well as the negative intracellular potential difference across the apical and basolateral membranes. Both the low intracellular sodium and this potential difference can provide a driving force for secondary active transport. For example, in *Fig. 3-2*, the reabsorption of glucose via a sodium-dependent transporter utilizes both the sodium gradient and the relative negative cell potential to bring glucose to the cell. The Na^+/H^+ exchanger on this cell is electroneutral and utilizes the sodium gradient to secrete protons and reabsorb sodium. Both the sodium glucose and the Na^+/H^+ exchanger are secondary active transport processes dependent on the basolateral Na^+-K^+-ATPase. The secretion of protons will cause the luminal pH to drop, providing a favorable driving force for the Cl^-/OH^- exchanger, an example of tertiary active transport. Thus, in secondary and tertiary active transport, the transporters do not utilize ATP directly; however, inhibition of the ATP-dependent Na^+-K^+-ATPase would bring these transport processes to a halt.

Figure 3-2

A proximal tubule cell which shows the Na^+-K^+ ATPase on the basolateral membrane, an example of primary active transport. Na^+-K^+ ATPase decreases the intracellular sodium to about 10 mEq/l and increases the intracellular potassium to approximately 140 mEq/l. The pump is electrogenic with a cell negative potential of about 60 mV. The sodium gradient provides the driving force for the apical Na^+/H^+ exchanger and both the sodium gradient and the potential difference provide the driving force for the apical sodium glucose transporter. The secretion of protons via the Na^+/H^+ exchanger results in the driving force for the Cl^-/OH^- exchanger which is an example of tertiary active transport. Chloride is shown transversing the paracellular pathway. Bicarbonate is exiting the basolateral membrane via a sodium bicarbonate cotransporter.



In addition to active transport, a substantive amount of passive transport occurs between the cells across the tight junction. Active transport along the nephron will generate ion and solute gradients between the lumen and peritubular fluid. Depending on the permeability properties of the tight junction, passive absorption or secretion can occur. In the cell depicted in *Fig. 3-2*, there is passive chloride transport across the paracellular pathway. It has become apparent that the characteristics of the tight junction vary along the nephron. The tight junction creates the primary permeability barrier to the diffusion of solutes across the paracellular pathway. Occludin and claudin proteins are localized to junctional fibrils and are transmembrane components of tight junctions (4, 199, 200). These tight junction fibrils or strands are a major factor determining the permeability properties of the

paracellular pathway (4, 75, 75, 76, 76). The claudin family of tight junction proteins now numbers 24. Occludin has a ubiquitous distribution and is not responsible for the differential permeability properties in the various nephron segments. The claudin isoforms present at the tight junction of various epithelia determine the resistance and the permeability properties of the epithelia (4, 75, 75, 76, 76). The distribution of claudin isoforms varies along the nephron and is responsible for the unique permeability properties of each nephron segment.

The final form of passive transport is called solvent drag. Solvent drag has been postulated to be responsible for a small fraction of transport in the proximal tubule. The reabsorption of solutes could result in water movement that could entrain or carry solutes with it. For this to occur, the solute should have a low reflection coefficient or high sieving coefficient (sieving coefficient = 1/refection coefficient). In other words when a solute is entrained in fluid and hits a membrane or tight junction, it could pass through it and be transported or bounce off and not be transported. Direct measurements of solute drag in the proximal tubule of neonates and adults have shown that it contributes to a negligible fraction of transport (79, 146, 230, 233).

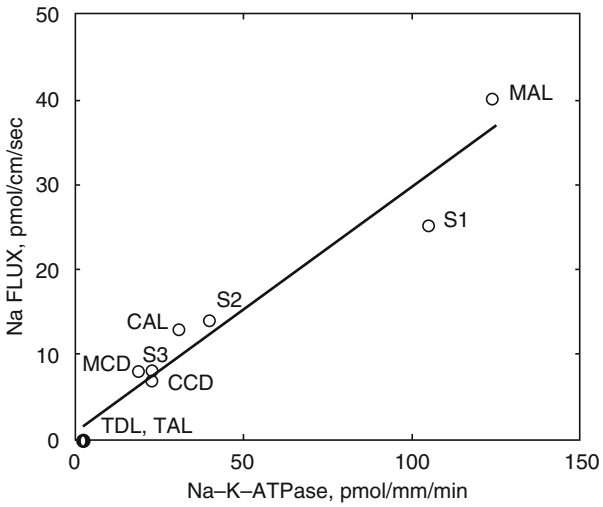
Maturation of Na^+-K^+-ATPase along the Nephron

The Na^+-K^+-ATPase is located on the basolateral membrane of most tubules in the kidney. It is a heterodimer composed of an α and β subunit. There are four different α subunits and 3 β subunits on mammalian cells which have different functional properties (47) There is also evidence for a small γ subunit that is not required for Na^+-K^+-ATPase activity (47, 244). The γ subunit binds to the α subunit, stabilizes the enzyme, and plays a regulatory role in enzyme activity (47, 244). The adult kidney expresses the α1 and ß1 isoforms of the Na^+-K^+-ATPase (100, 214). The α subunit is the catalytic subunit and has the cation, ATP and ouabain binding sites (47). The β subunit is the regulatory subunit and is essential for the function of the enzyme (47, 189). Several hormones that regulate sodium transport along the nephron act, at least in part, by regulating Na^+-K^+-ATPase activity (42, 47, 99, 109, 154, 188, 208, 264–268, 311).

The Na^+-K^+-ATPase is responsible for lowering the intracellular sodium concentration and establishing the negative cell potential difference. Thus, the Na^+-K^+-ATPase provides the driving force for sodium transport across the nephron. As shown in *Fig. 3-3*, there is a direct relationship between sodium transport and Na^+-K^+-ATPase activity factored per millimeter of tubule along the nephron (111). Neonates have a lower renal Na^+-K^+-ATPase activity than adults (10, 11, 109, 271, 274, 325). As will be discussed, there is a developmental increase in sodium transport in each nephron segment, which is paralleled by an increase in Na^+-K^+-ATPase activity as shown in *Fig. 3-4*.

Figure 3-3

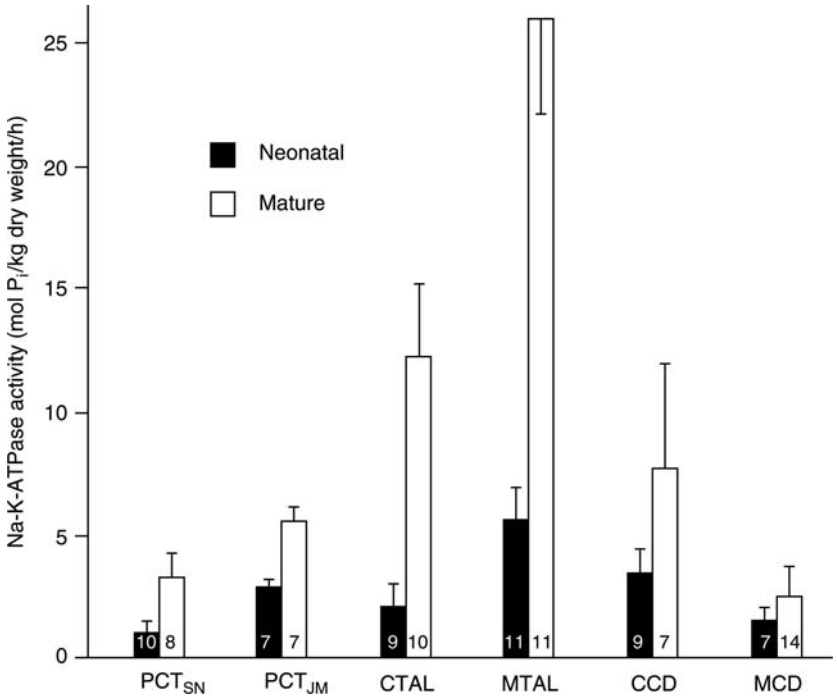
Sodium transport is plotted against Na^+-K^+ ATPase activity. As is shown, the rate of sodium transport in various nephron segments parallels Na^+-K^+ ATPase activity (111).



The parallel maturational increase in sodium transport with Na^+-K^+-ATPase activity (274) along with the striking relationship between sodium transport and Na^+-K^+-ATPase activity (111), suggests that the maturational increase in apical sodium transport may contribute to the postnatal increase in Na^+-K^+-ATPase activity. In cell culture studies an increase in intracellular sodium caused a stimulation in Na^+-K^+-ATPase activity (126, 166) as well as an increase in the α subunit mRNA and membrane pump density (80). In addition to in vitro studies, there is evidence that a chronic increase in Na^+/H^+ exchanger activity induced by metabolic acidosis, increased Na^+-K^+-ATPase activity, an effect that was blocked by coadministration of the Na^+/H^+ exchange inhibitor, amiloride (108). Finally, there is a postnatal increase in both serum thyroid hormone and glucocorticoid levels with age (28, 131, 132, 323). Both glucocorticoids and thyroid hormone have been shown to increase Na^+-K^+-ATPase activity (11, 68, 70, 71, 112, 208).

Figure 3-4

Na^+-K^+ ATPase activity is shown in nephron segments of neonates and adults. As is demonstrated, there is a maturational increase in Na^+-K^+ ATPase activity in every nephron segment (271).



Proximal Tubule Transport

Proximal tubule transport is characterized by a phenomenon called threshold, which is depicted in *Fig. 3-5.* It is the threshold that keeps our serum bicarbonate at 25 mEq/l. If we were to ingest bicarbonate and try to raise the serum bicarbonate level, we would have a bicarbonaturia and our serum levels would return to 25 mEq/l as long as we were euvolemic. Our serum glucose is set by other factors well below the threshold level. As shown in *Fig. 3-5*, if we increased the serum glucose level, we would reabsorb more glucose until the load of glucose delivered to the proximal tubule exceeded its ability to reabsorb glucose and we would have glucosuria.

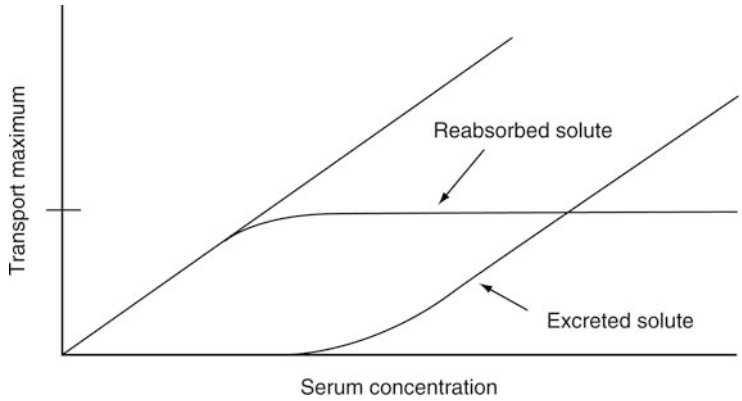
In the adult kidney there is a parallel change in proximal tubule transport with alterations in glomerular filtration rate. This phenomenon has been designated glomerular tubular balance. If this did not occur, an increase in glomerular filtration rate would swamp the distal nephron with solutes and water and there would be a huge natruresis and diuresis. A similar phenomenon must occur during postnatal development. There must be a parallel increase in proximal tubule transport with the maturational increase in glomerular filtration rate. If this did not occur the neonate would die of dehydration when the glomerular filtration rate increased after birth.

In the neonate there is a concomitant increase in tubular transport to accommodate or balance the increase in glomerular filtration rate (140, 163, 305). However, glomerular tubular balance is not present in the fetus (198). Renal development is characterized by centrifugal maturation. The surface nephrons are relatively immature compared to the juxtamedullary nephrons. These immature nephrons with short proximal tubules have glomerular tubular imbalance (198). This is clinically relevant as neonates born before 34 weeks of gestation can have glucosuria and very premature neonates can have significant salt wasting (12).

The proximal tubule reabsorbs 60% of the glomerular filtrate in an isoosmotic fashion. Due to the fact that the proximal tubule has a relatively high permeability to many ions, even solutes which are not actively transported by this segment get absorbed by the paracellular pathway. The luminal fluid concentration of magnesium, which is not actively transported, would rise over two-fold by the end of the proximal tubule as over half of the fluid is reabsorbed. This does not happen because magnesium is passively reabsorbed across the paracellular pathway as

Figure 3-5

This figure depicts the concept of renal threshold. As the delivered load increases to the tubule either by an increase in the serum concentration or an increase in glomerular filtration rate, the amount of solute absorbed increases. At some point, the renal tubular absorption reaches a maximum, called the threshold for that solute, and any further increase in the filtered load is excreted.



the magnesium concentration rises above that in the peritubular capillaries.

Glucose Transport

Glucose is reabsorbed solely by the proximal tubule. Physiologic studies have demonstrated that the S_1 proximal tubule reabsorbs glucose through a high capacity–low-affinity transporter, while in the late proximal tubule (S_3) glucose transport is via a low capacity–high affinity transporter (22). Similar axial heterogeneity of glucose transport kinetics was validated using cortical brush border membrane vesicles to measure apical membrane transport and outer medullary brush border membrane vesicles which contain vesicles from the S_3 segment (316). The high capacity–low affinity sodium dependent glucose transporter on the apical membrane is designated as SGLT-2 (332). This removes the bulk of the glucose from the glomerular ultrafiltrate. The low capacity–high affinity transporter is designated SGLT-1 (130, 143). The glucose that is transported by the tubule exits across the basolateral membrane by facilitative diffusion. As shown in *Fig. 3-6*, SGLT-2 transports one sodium with one glucose molecule while SGLT-1 transports two sodium with each glucose molecule. A defect in SGLT-1 causes glucose-galactose malabsorption as this transporter is also present in the intestine (95, 96, 193, 195). Some patients with familial glucosuria, a benign condition, have a mutation in SGLT2 (63, 184). This axial arrangement of glucose transporters results in reabsorption of virtually all the filtered glucose.

Sodium-dependent glucose reabsorption results in a positive charge entering the proximal tubule cell. This charge leaves a lumen negative transepithelial potential difference. This negative potential provides a driving force for the absorption of an anion or the back diffusion of a cation (sodium) across the paracellular pathway. Thus glucose transport can result in a net absorption of sodium chloride with sodium moving into the cell with glucose and chloride across the paracellular pathway. Whether sodium is recycled or chloride is reabsorbed is dependent on the relative sodium/chloride permeability of the paracellular pathway.

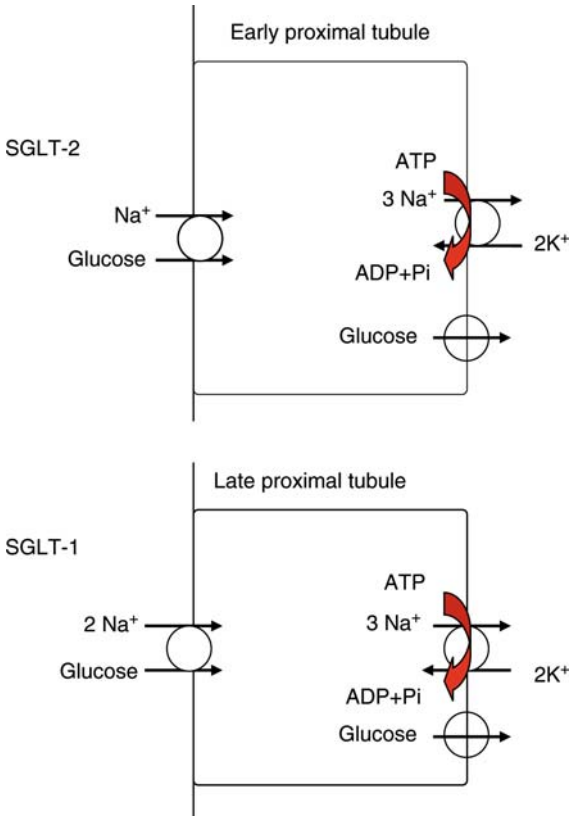
Numerous studies using various techniques and animal species have shown that the fetus and neonate transport glucose at a slower rate than the adult (13, 36, 106, 198, 273). These studies are of clinical relevance as premature neonates can have glucosuria (12, 127, 317). Despite the fact that the glomerular filtration rate is about 100th of that of the adult and the filtered load delivered to the neonatal nephron is also about 100th of that of the adult, the filtered load exceeds the reabsorptive capacity for glucose transport in the premature neonate. Thus there is a time during development when glomerular tubular balance is not present.

Amino Acid Transport

All amino acid transport occurs in the proximal tubule. Unlike most cells, which have amino acid transporters to provide substrates for protein synthesis, the proximal tubule mediates the vectorial transport of amino acids

Figure 3-6

Diagram of glucose transport in the proximal tubule. The early proximal tubule has SGLT-2 on the apical membrane which is a high capacity, low affinity transporter, while in the late proximal tubule the low capacity high affinity transporter, SGLT1 is on the apical membrane. Glucose exits the cell across the basolateral membrane by passive diffusion.



from the filtrate to the blood. The basic principal for transport is similar to glucose transport. The uptake of amino acids is sodium-dependent and electrogenic, with the basolateral exit mediated by facilitated passive diffusion. While there are 20 amino acids that are utilized in the synthesis of proteins, there are not 20 different amino acid transporters on the apical and basolateral membranes. Since some amino acids are similar in structure or charge, there is promiscuity among the classes of transporters. We will briefly discuss the three major classes of amino acid transporters.

The neutral amino acids include leucine, valine, isoleucine, methionine, phenylalanine, tyrosine, cysteine, glutamine, alanine, glycine, serine, histidine, tryptophan and proline. Transport of these amino acids is electrogenic with one sodium being transported with the amino acid across the apical membrane. B^0 AT1 (SLC6A19) has recently been cloned (158, 283). This transporter is expressed on the proximal tubule (250), and transports all neutral amino acids, though there is greater affinity for valine, leucine, isoleucine, and methionine (49). Mutation of SLC6A19 causes Hartnup disease which is an autosomal recessive disorder of variable expression, characterized by a pellagra-like rash, cerebellar ataxia, psychological and neurological disturbances (60, 158, 283). There are other neutral amino acid transporters but their transport properties have been less well characterized (60, 243) (250).

The acidic amino acids are aspartate and glutamate. They are transported across the apical membrane of the proximal tubule in an electrogenic fashion where two sodium ions are transported for each of these negatively charged amino acids (150, 257). Brush border membrane vesical studies have shown that there are at least two apical transporters for glutamate, one with a high substrate affinity and one with a low affinity (330). The high affinity transporter has been cloned and designated EAAC1 (149). EAAC1 is expressed on the apical membrane of the proximal tubule (288). Eaac-1 knockout mice have a dicarboxylic aciduria proving the importance of this transporter in acidic amino acid transport (218). The basolateral transport of glutamate is via a sodium dependent cotransporter, indicating that the intracellular glutamate levels must be very high in the proximal tubule to provide an adequate driving force for sodium exit across the basolateral membrane (256). In addition there is a sodium independent aspartate/glutamate transporter which is localized to the basolateral membrane designated AGT1 (186).

The basic amino acids lysine and arginine utilize the same amino acid transporter as cystine. There are a number of basic amino acid transporters (280). rBAT is a cystine/dibasic amino acid transporter expressed along the proximal tubule but predominantly in the S_3 segment (43, 103). rBAT protein is undetectable in the fetal kidney and is expressed at very low levels even after weaning (110). Mutations in SLC3A1, the gene encoding rBat, results in type I cystinuria (65, 66, 222, 223). B^{0+} AT is a recently cloned cystine transporter/dibasic amino acid transporter (102, 105). Unlike rBAT, B^{0+} AT is predominantly expressed in the early proximal convoluted tubule but it overlaps with the expression of rBAT (103, 201). While both rBAT and B^{0+} AT can function as cystine/dibasic amino acid transporters, they likely function in vivo as a heterodimer (219) (103).

Neonates have a generalized aminoaciduria which is more pronounced in premature neonates (59, 89, 279). While there have been numerous studies examining amino acid transport using a number of species, most

have utilized kidney slices or slurries of renal tubules. These studies are complicated by the fact that one is looking simultaneously at cellular uptake, often from a collapsed tubule, metabolism of the amino acid and basolateral exit. Examinations of glycine transport in tubule suspensions and kidney slices of neonates and adults have provided disparate results. Glycine uptake has been shown to be the same in neonates and adults in some studies (241, 252) and lower in neonates than adults in others (19, 191). The few studies looking at brush border membrane during development, a more direct way of studying uptake transport across the apical membrane, have shown lower rates of transport in the neonate, compared to the adult (73, 192).

Organic Acid Transport

In addition to filtration and reclamation, the kidney has the ability to secrete some substances through organic anion transporters. There are five organic anion transporters on the basolateral membrane (OATS) of the proximal tubule (20, 167, 282, 339, 344). Different OATS have different substrate specificities. Organic acids transported by OATS include prostaglandins, uric acid, nonsteroidal anti-inflammatory drugs, β lactam antibiotics, antiviral medications, para-amino hippurate, probenecid, uric acid, bumetanide, salicylates, methotrexate and many others (167, 282, 339). Many of these substances are protein bound in the blood which limits their excretion by glomerular filtration. The basolateral uptake of OATS is an example of tertiary active transport (167, 282). OATS take up organic anions into the cell predominantly in exchange for α-ketoglutarate. The α-ketoglutarate that is exchanged for the organic acid enters the cell via an α-ketoglutarate transporter. The energy for this whole process is the basolateral Na^+-K^+-ATPase. The organic acid transported inside the cell must exit across the apical membrane to enter the primordial urine. The mechanism for this is less well understood but includes members of the multidrug resistance protein family (167, 282, 339), which has been localized to the apical membrane of the proximal tubule (318).

Para-amino hippurate is almost totally removed from the blood with one pass through the kidney and is used as a measure of renal blood flow. Para-amino hippurate has been used to assess the maturation of renal blood flow in humans and to determine the maturational changes in organic anion transport. Studies in humans have shown that there is a maturational increase in para-amino hippurate secretion with adult values being attained at about 2 years of age (64, 253). Para-amino hippurate secretion is less in premature than term neonates (101).

There are a number of factors that could contribute to the maturational increase in organic anion secretion. Since organic anion secretion requires an organic anion transporter (OAT), a sodium dependent organic acid cotransporter and the Na^+-K^+-ATPase to mediate intracellular transport of the organic acid and an apical secretory mechanism to secrete the organic acid, a developmental paucity in any of these transporters, compared to the adult, could be the rate limiting step. OAT1 and OAT2 have been shown to be present in the late gestation fetus and mRNA and protein expression increase during postnatal development (207, 217).

One of the unique features of organic anion transport is that it can be induced prematurely during renal development by itself or another organic anion (134–136, 276). This is not true of adult animals where organic anions do not cause a stimulation in transport (134). In vitro microperfusion studies demonstrated that there was an intrinsic increase in the rate of transport with postnatal age in rabbits and that pretreatment with penicillin increased the rate of para-amino hippurate secretion in vitro (276). The mechanism of this induction of organic anion transport by organic acids is unclear.

Phosphate Transport

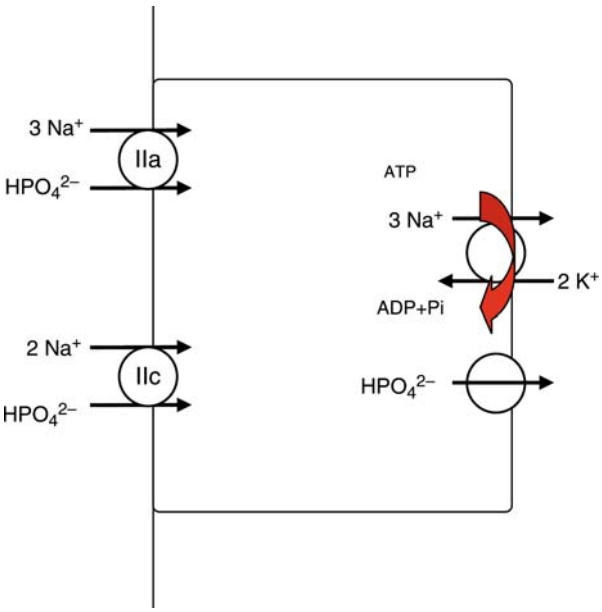
The adult ingests approximately 1–1.5 g of phosphorus a day and 80% of that is absorbed. The adult must be in neutral phosphorus balance: the amount of phosphorus absorbed from day to day has to equal that excreted. The phosphorus in our body is predominantly in the form of phosphate. At a pH of 7.4 there is a 4:1 ratio of HPO_4^{-2}/$H_2PO_4^{-1}$. The kidney maintains phosphate balance by its ability to regulate phosphate transport, which occurs predominantly in the proximal tubule. The main factors that regulate renal phosphate transport are dietary intake itself, and a number of hormones including parathyroid hormone, FGF-23, and growth hormone. Phosphate is essential for bone growth and 85% of our phosphate is in the bones. In addition, phosphate is involved in a myriad of enzymatic reactions and is present in nucleotides, phospholipids, and proteins. Unlike the adult, the neonate must be in positive phosphate balance for growth. The serum phosphate level is higher in the neonate than in the adult. This section will review phosphate transport and then discuss developmental changes which occur in transport and its regulation, which allow the neonate to be in positive phosphate balance.

The transporters involved in the regulation of phosphate transport are shown in *Fig. 3-7*. The first phosphate transporter cloned, designated NaPi-1, did not have the characteristics previously identified in physiologic studies and its function is still not clear (333) (44). There are two sodium-dependent phosphate transporters on the apical membrane of the proximal tubule, one designated NaPi-IIa (183), and the other NaPi-IIc (281). NaPi-IIa is an electrogenic transporter that transports three sodium ions with one phosphate HPO_4^{-2}, while NaPi-IIc transports two sodium ions with every phosphate and is electroneutral (107, 281). NaPi-IIa is regulated by PTH and dietary phosphate intake (155, 172, 173, 310). Phosphate exits the proximal tubule by a transporter which has not yet been identified and characterized. NaPi-IIb is the phosphate transporter on the intestinal apical membrane responsible for absorption of dietary phosphate (133).

The serum phosphate levels are higher in neonates than adults (77, 137). Since the glomerular filtration rate in the neonate is only a fraction of that of the adult, it is possible that this is the factor that is responsible for the relative hyperphosphatemia in neonates. However, early studies in human neonates found that the fraction of phosphate reabsorbed compared to the glomerular filtration rate was higher in neonates and infants than that in adults (77, 83, 137, 242). In the first 24 h of life, human neonates reabsorb over 95% of the filtered phosphate (137). This level drops to 90% later in the first week of life (77, 137). This fractional reabsorption of phosphate meets or exceeds the reabsorptive capacity of adults and older children eating a normal phosphate diet (242).

Figure 3-7

A proximal tubule cell reabsorbing phosphate is shown. The top apical phosphate transporter NaPi-IIa is the predominant phosphate transporter in adult rodents. NaPi-IIc is the predominant phosphate transporter on the apical membrane of neonatal rodents. NaPi-IIa is electrogenic while NaPi-IIc is electroneutral.



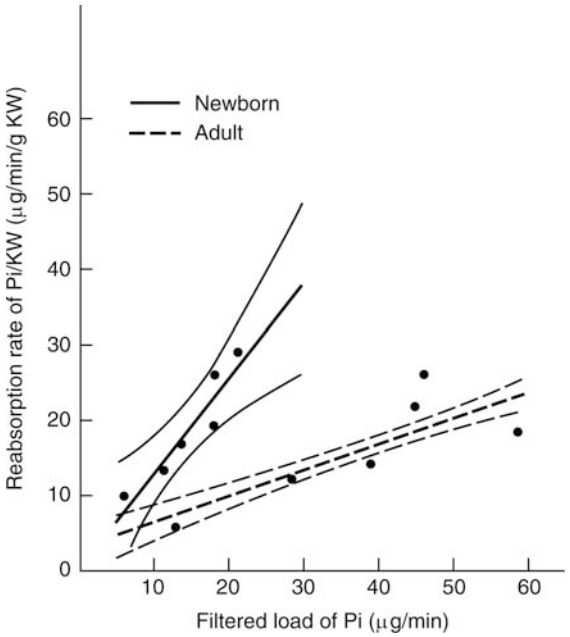
Animal studies demonstrated that young rats had a greater rate of phosphate reabsorption than adult rats (69). This was seen in rats that received parathyroidectomy, indicating that an altered response to parathyroid hormone was not the factor that caused the disparity in renal phosphate uptake (69). Finally, both young and adult rats responded to a low phosphate diet with an increase in the fractional reabsorption of phosphate; the magnitude of phosphate absorption was again higher in young animals (69).

While the above studies are consistent with an enhanced tubular reabsorptive capacity in neonates, this could be due to a higher reabsorptive capacity of the neonatal tubule, a diminished response to a phosphaturic factor or the result of an increased response to a substance which increases phosphate transport. To determine if there was an inherent increase in tubular phosphate transport, Johnson and Spitzer examined phosphate absorption in neonatal and adult kidneys perfused in vitro (147). As shown in *Fig. 3-8*, neonatal kidneys had a higher phosphate reabsorptive rate at any filtered load of phosphate which can only be due to an increased inherent rate of phosphate transport. In addition, they found that while addition of parathyroid hormone to the perfusate caused a phosphaturia in adult kidneys, there was no increase in phosphate excretion in neonatal kidneys. These studies directly demonstrate that neonates also have an attenuated effect of the parathyroid hormone, the primary factor regulating phosphate transport. A blunted effect of parathyroid hormone on phosphate reabsorption has also been demonstrated in young rats compared to adult rats in vivo (125, 328).

Micropuncture studies of neonatal and adult guinea pigs and rats have also demonstrated that there is a higher intrinsic rate of phosphate transport in young animals (153) (336). Studies using brush border membrane vesicles have demonstrated that the maximal rate (Vmax) of phosphate transport was several-fold higher in neonates than in adults, while there was no difference in the Km, the phosphate concentration at half maximal velocity (209). A low phosphate diet increased the Vmax of the

Figure 3-8

The rate of phosphate absorption by isolated perfused kidney preparation. As the filtered load increases, there is an increase in the reabsorptive rate in both the neonate and the adult kidney. At all filtered loads the rate of phosphate reabsorption per gram of kidney weight was higher in the neonate. From (147), with permission.



sodium phosphate transporter in adult guinea pigs, while a high phosphate diet had the opposite effect. There was no significant difference in Vmax in brush border membranes from neonates gavaged with different phosphate containing diets (209). As shown in *Fig. 3-9*, the 3-week-old rat has a maximal rate of phosphate absorption that was higher than that of adult rats (205). At all ages, there was an augmentation in the maximal capacity of phosphate reabsorption with a low phosphate diet (205). A greater effect of phosphate deprivation on brush border membrane vesicle phosphate uptake and NaP-IIa protein abundance was demonstrated in 4-week-old rats compared to older adult rats (336). Finally, the driving force for phosphate entry across the apical membrane may be greater in neonates. The intracellular phosphate concentration was almost 40% lower in kidneys measured using NMR (21).

Maturational studies examining the changes in NaPi-IIa expression have revealed that NaPi-IIa mRNA and protein are not detected in developing nephrons until there is a distinct brush border membrane (314). NaPi-IIa protein abundance was greater in brush border membranes from 13-day-old rats compared to 22-day-old rats (314). Others however have found that brush border membrane vesicle from suckling and adult rats had a slower rate of phosphate uptake than weanling rats (21 days old) (312). There was no change in NaPi-IIa mRNA abundance, but NaPi-IIa protein abundance from brush border membrane vesicles confirmed the transport findings that 21-day-old rats had the highest NaPi-IIa protein expression (312). Studies comparing 28-day-old rats to adult rats have also demonstrated greater brush border membrane NaPi-IIa protein abundance in young rats than in adults (336).

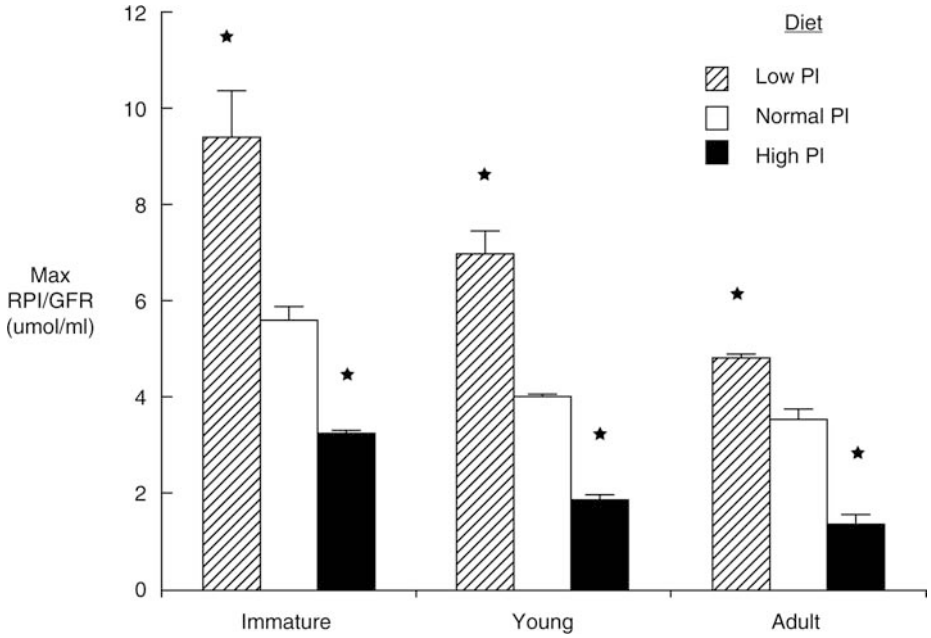
The high rates of phosphate transport in weanling rodents suggested that there may be a developmentally regulated transporter with greater expression at that of development (304). Indeed, NaPi-IIc was recently cloned and is a brush border phosphate transporter with its highest expression at the time of weanling in the rat (281). NaPi-IIc, like NaPi-IIa, is regulated by dietary phosphate uptake (281). The relative importance time of NaPi-IIa and NaPi-IIc may be quite different in humans. Patients with hereditary hypophosphatemic rickets with hypercalciuria, a rare autosomal recessive characterized by hypophosphatemia secondary to renal phosphate wasting and high vitamin D levels, have a mutation in the gene encoding NaPi-IIc, suggesting that NaPi-IIc may be the predominant renal phosphate transporter in humans and that NaPi-IIa cannot compensate for the loss of NaPi-IIc (40).

Growth hormone increases phosphate transport via stimulation of IGF-1 in the proximal tubule (228). Brush border membrane vesicle phosphate transport increased in dogs that were administered growth hormone compared to vehicle treated controls (122). While growth hormone is not a significant regulator of phosphate transport in the adult, this may not be the case in the growing animal. Administration of a growth hormone-releasing factor antagonist, which suppresses growth hormone secretion, has no effect on phosphate transport in adult rats, but significantly reduces phosphate absorption in young growing rats (124, 206, 338).

There are a number of hormones that have been shown to regulate phosphate transport including insulin (84), fibroblast growth factor-23 (34, 57, 291), frizzled-related protein 4 (41) and klotho (164, 227). These hormones may have differential effects on phosphate transport in the neonate and adult, but this is yet to be determined.

Figure 3-9

Age dependent maximal phosphate reabsorption is seen in 3–4 week old rats (immature), 6–7 week old rats (young), 12–13 week old rats (adult). All rats were parathyroidectomized. A low dietary phosphate intake stimulated phosphate absorption in all age groups. The maximal capacity for phosphate absorption was in the immature groups which need phosphate for growth. From (205), with permission.



Proximal Tubule Acidification

The proximal tubule reabsorbs 80% of the filtered bicarbonate. Luminal proton secretion is via the Na^+/H^+ exchanger and the H^+-ATPase. In the adult, one-third of proton secretion is via the luminal H^+-ATPase, and two-thirds is mediated by the luminal Na^+/H^+ exchanger that is designated NHE3 (24, 225). The secreted proton titrates the filtered HCO_3^- to generate H_2CO_3 which is converted to CO_2 and H_2O by luminal carbonic anhydrase (Carbonic anhydrase IV). CO_2 diffuses into the cell and combines with H_2O, which is facilitated by intracellular carbonic anhydrase (Carbonic anhydrase II) to regenerate H_2CO_3. H_2CO_3 dissociates into a proton that can be secreted across the apical membrane, and bicarbonate that exits the basolateral membrane via the basolateral $Na(HCO_3)_3$ symporter. The sodium which enters the cell via the Na^+/H^+ exchanger exits the basolateral membrane by the Na^+-K^+-ATPase, which provides the driving force for luminal proton secretion by the Na^+/H^+ exchanger. There are maturational changes in most of these processes that will be described below.

Neonates have a lower serum bicarbonate concentration than adults, which is the result of a lower threshold for bicarbonate (92). Premature neonates can have physiologic bicarbonate concentrations as low as 15 mEq/l (277). The lower bicarbonate threshold is mediated in large part by the lower rate of proximal tubule acidification. The fine tuning of renal acidification is mediated in the distal nephron which, by and large, is responsible for the secretion of acid from metabolism and new bone formation. Studies have shown that there is a maturational increase in bicarbonate absorption during postnatal development (30, 273), which accounts for the mutational increase in the bicarbonate threshold.

The greatest developmental changes in proximal tubule acidification occur on the apical membrane. There is a four-fold increase in Na^+/H^+ exchanger activity during postnatal maturation and an even greater increase in apical H^+-ATPase activity (23, 24, 284). Low levels of Na^+/H^+ exchanger activity have been measured in the fetus as well (37). Despite the fact that there was Na^+/H^+ exchanger activity on the apical membrane of the

neonatal rat at 1–2 weeks of age, as shown in *Fig. 3-10*, there was virtually no NHE3 on the brush border membrane (38, 284), the Na^+/H^+ exchanger on the apical membrane of the adult proximal tubule (45, 340).

NHE3 knock-out mice have been shown to have substantive proximal tubule apical membrane Na^+/H^+ exchanger activity (74). The apical Na^+/H^+ exchanger likely responsible for this non NHE3 Na^+/H^+ exchanger activity is NHE8, a recently discovered NHE isoform (116, 117). NHE8 has sodium dependent proton extrusion capabilities, which made it a potential candidate for the developmental isoform (345). As shown in *Fig. 3-10*, apical NHE8 was predominantly present in neonatal proximal tubules at a time when NHE3 was almost undetectable (38). Thus there is a developmental Na^+/H^+ exchanger isoform.

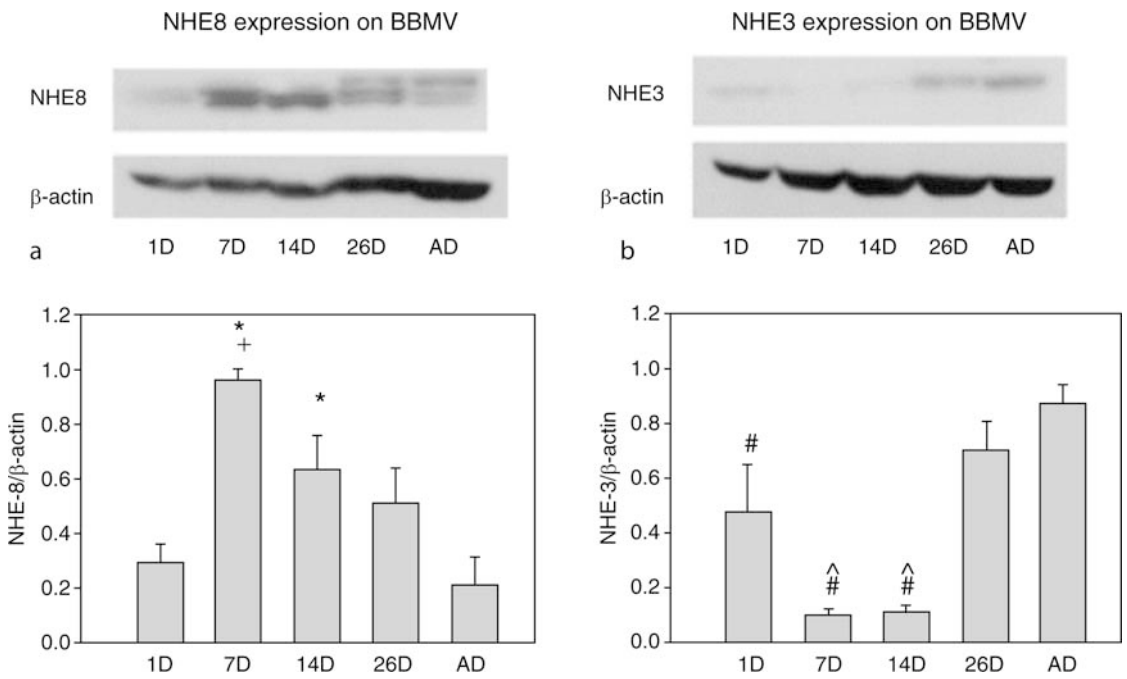
The $Na(HCO_3)_3$ symporter mediates bicarbonate exit in both the neonatal and adult proximal tubule. While there is a maturational increase in basolateral membrane $Na(HCO_3)_3$ symporter activity, it is relatively small compared to the magnitude of the change in Na^+/H^+ exchanger activity on the apical membrane (31). In addition to bicarbonate exit, the basolateral membrane Na $(HCO_3)_3$ symporter plays an important role in pH regulation of the proximal tubule cell (31).

Carbonic anhydrase which increases the rate of the interconversion of CO_2 and H_2O to Carbonic anhydrase II is located intracellularly in proximal and distal tubule acidifying cells and comprises ~95% of cell carbonic anhydrase activity. Carbonic anhydrase IV is on the apical and basolateral membrane of renal acidifying cells and comprises ~5% of carbonic anhydrase activity (275). Both carbonic anhydrase II and IV increase during maturation of proximal and distal acidification, but neither is likely a limiting factor causing the maturational increase in renal acidification in the proximal or distal tubule (335) (152, 278).

Since the developmental increase in renal acidification is due primarily to apical proton secretion, many studies have examined the cause for the increase in Na^+/H^+

Figure 3-10

Immunoblots of rat brush border membrane vesicles depict the changes in NHE8 (a) and NHE3 (b) protein abundance. As is seen, there is higher expression of NHE8 in the neonate than in the adult brush border membrane. The expression of NHE3 is highest in the adult. The higher NHE3 protein abundance at 1 day of age is likely the result of the surge of glucocorticoids at the time of birth. From (38), with permission.



exchanger activity. There is a substantive increase in both thyroid hormone and glucocorticoids during postnatal development and both hormones increase in parallel with the increase in proximal tubule Na^+/H^+ exchanger activity (28, 131, 132, 323). Administration of either glucocorticoids or thyroid hormone prior to the maturational increase in either hormone results in a precocious increase in exchanger Na^+/H^+ activity and NHE3 protein abundance (28–30). Both thyroid hormone and glucocorticoids increase NHE3 activity by increasing transcription (25, 67). Glucocorticoids have also recently been shown to increase the insertion of NHE3 into the apical membrane of proximal tubular cells by a posttranscriptional mechanism (48).

Interestingly, neither prevention of the maturational increase in glucocorticoids or thyroid hormone alone can totally prevent the postnatal increase in Na^+/H^+ exchanger activity and NHE3 mRNA and protein abundance (27, 28, 30, 287). Thus, there appears to be some redundancy in the postnatal maturational triggers for NHE3. As demonstrated in *Fig. 3-11*, prevention of the maturational increase in both hormones results in the total prevention of the postnatal increase in NHE3 mRNA, protein abundance and Na^+/H^+ exchanger activity (119).

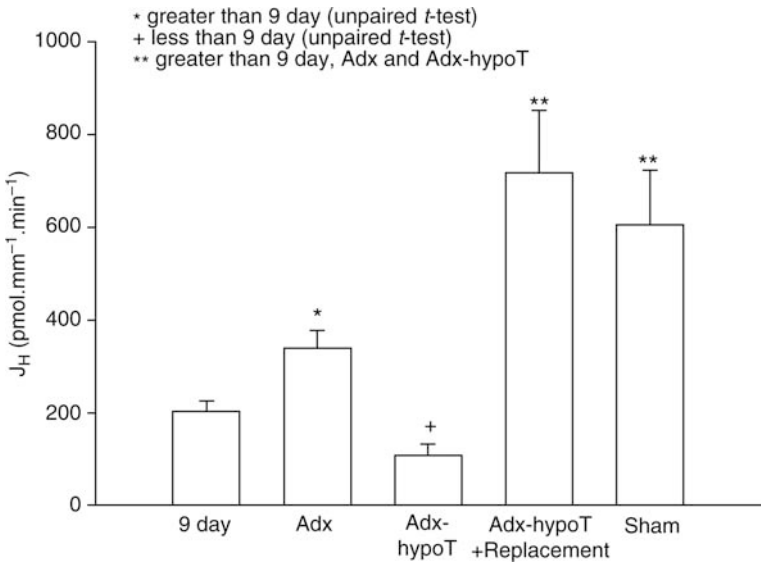
Proximal Tubule NaCl Transport

The glomerulus receives an ultrafiltrate of plasma and as shown in *Fig. 3-12*, immediately changes the luminal composition of the tubular fluid. The early proximal tubule reabsorbs glucose, amino acids and bicarbonate in preference to chloride (176, 239). The reabsorption of sodium with glucose and amino acids results in a lumen negative potential difference. This leaves the luminal fluid in the late proximal tubule with a higher chloride and lower bicarbonate concentration than that of the peritubular fluid.

The axial changes in luminal fluid create the potential for passive chloride diffusion across the paracellular pathway. The lumen to peritubular chloride gradient provides a driving force for the passive diffusion of chloride across the paracellular pathway. In the early proximal tubule, the transcellular reabsorption of sodium with glucose and

Figure 3-11

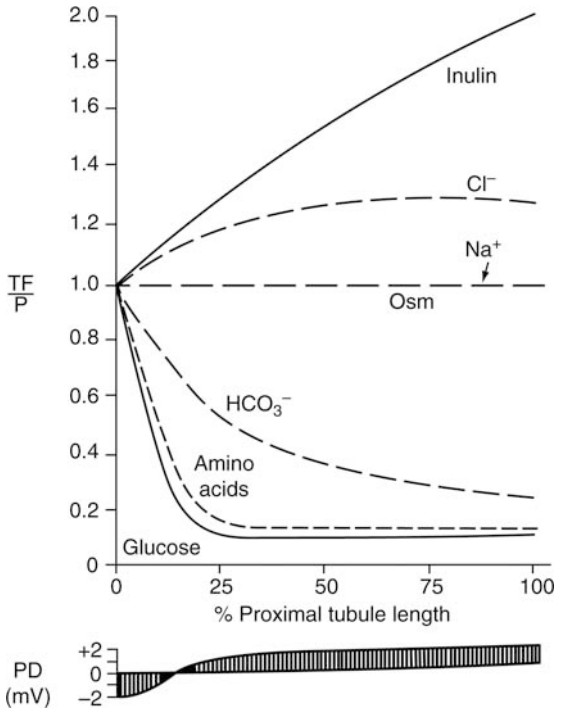
Apical Na^+/H^+ exchanger activity in perfused tubules in 9 day old, and adults that were adrenalectomized as neonates, adults that were adrenalectomized and hypothyroid since the neonatal period, adults that were adrenalectomized and hypothyroid (adx-HypoT) since the neonatal period but given thyroid and glucocorticoid replacement before study and sham controls. The 9 day old rats had a lower rate of Na^+/H^+ exchanger activity than the sham adult. Neonatal adrenalectomy did not totally prevent the maturational increase in Na^+/H^+ exchanger activity, but the maturational increase in Na^+/H^+ exchanger activity was abrogated in the adrenalectomized hypothyroid group. From (119), with permission.



amino acids results in a lumen negative potential difference as depicted in *Fig. 3-12*. This lumen negative potential provides a driving force for either chloride absorption or sodium secretion across the paracellular pathway. Whether chloride is absorbed or sodium is secreted is dependent on the relative permeabilities of chloride to sodium in the proximal tubule. The relative chloride to sodium permeability is higher in the adult than the neonate, so passive chloride transport secondary to the lumen negative potential difference in the early proximal tubule does not occur to a significant degree in the neonate (33, 230). As shown in *Fig. 3-12*, the luminal chloride gradient in the late proximal tubule results in a driving force for chloride diffusion across the paracellular pathway (33, 230). The diffusion of chloride across the paracellular pathway results in a lumen positive potential difference, and a driving force for the paracellular transport of sodium.

Figure 3-12

The axial changes in proximal tubular transport are depicted in this figure. The early proximal tubule preferentially reabsorbs glucose, amino acids and bicarbonate, leaving the luminal chloride solution higher than the blood in the peritubular capillaries. The early proximal tubule has a lumen negative transepithelial potential difference due to sodium dependent glucose and amino acid reabsorption. The higher luminal chloride concentration in the late proximal tubule provides a driving force for passive chloride absorption across the paracellular pathway, causing a lumen positive potential difference. From (239), with permission.



In the adult proximal tubule, approximately half of the sodium chloride is active and transcellular and half is passive and paracellular (3, 26, 287). Active chloride transport is mediated by parallel action of the Na^+/H^+ and Cl^-/base exchangers on the apical membrane (17, 286, 287, 290). It is still somewhat unclear what the nature of the base is as there is evidence for chloride exchange for hydroxyl, formate, and oxalate ions (14–16, 18, 165, 287). The rate of active transcellular chloride transport is lower in the neonate than in the adult. This is due to the lower rate of the apical Cl^-/base exchanger (285, 287), and the Na^+/H^+ exchanger discussed above (23, 24, 284). The driving force for active transcellular NaCl transport is the basolateral Na^+/K^+-ATPase that has lower activity in the proximal tubule (139, 271, 274). There are a number of factors that regulate proximal tubule NaCl transport, including renal nerves, dopamine, and angiotensin II, which are shown in *Table 3-1*. The serum levels of most hormones that regulate sodium absorption are equal or higher in the neonate than in the adult, but in general there is a blunted response to the action of most regulator hormones.

There are also changes in the properties of the paracellular pathway during postnatal development (1, 33, 230, 289). Most importantly, the permeability of the proximal tubule to chloride ions is less in the neonate than in the adult (33, 230, 289). The low permeability to chloride ions results in almost no passive paracellular chloride transport in the neonate (33, 230). As discussed, the permeability properties of an epithelium are determined by the expression of a family of proteins called claudins. The claudin proteins in the tight junction change during postnatal development. Claudins 6, 9, and 13 are present in the neonatal proximal tubule but not in the adult (1). The claudin isoform responsible for the low paracellular chloride permeability in the neonate as well as the factors that cause the claudin isoform changes during development are yet to be determined.

Of the potential factors that cause the maturational changes in paracellular chloride transport, only the thyroid hormone has been examined (32). Administration of thyroid hormone prior to the normal maturational increase results in an increase in chloride permeability. On the other hand, maintaining a hypothyroid state into adulthood prevents the maturational increase in chloride

Table 3-1

Comparison of the serum levels of hormones and their effect on sodium transport in neonates compared to adults

Hormone	Effect on urinary sodium excretion in adult	Neonatal serum level compared to adult	Effect of hormone on sodium in neonatal sodium excretion compared to adult	References
Renin		↑	Level responds appropriately in neonate	(88, 104, 114, 309)
Aldosterone	Increases distal sodium absorption	↑	↓	(8, 39, 104, 293, 307, 309, 319)
Atrial natriuretic peptide	Increases sodium excretion	↑	Probably (93) ↓	(58, 245, 251, 329)
Dopamine	Decreases proximal tubule sodium absorption	↑	↓	(9, 109, 151, 174)
PGE-2	Causes natriuresis and diuresis	Blunted synthesis in the medullary and cortical collecting tubule (269)	↓	(185, 215)

permeability. It is yet to be determined if thyroid hormone is the factor that causes the proximal tubule claudin isoform changes during postnatal development.

Proximal Tubule Water Transport

The proximal tubule reabsorbs most of the glomerular filtrate without a significant change in the luminal osmolality. For this to occur, the proximal tubule must be very permeable to water. Water movement is predominantly through the cell and not across the paracellular pathway (224, 231). The constitutively water permeable proximal tubule and thin descending limb have water channels on the apical and basolateral membranes (255). The isoform of this water channel was previously designated CHIP-28 but has been renamed aquaporin 1 (210–212, 226). Direct evidence of transcellular water transport comes from aquaporin 1 knock-out mice which have a marked decrease in proximal tubule sodium absorption (272). There is a paucity of water channels in the fetal kidney and an increase in expression of aquaporin 1 does not occur until birth (50, 303).

Direct measurements of water permeability have demonstrated that the neonatal rabbit proximal tubule has a higher water permeability that that of the adult (229). To determine the mechanism for the higher water permeability in neonatal rabbit tubules, studies were performed examining the water permeability of apical and basolateral membrane vesicles (202, 235, 234). Despite the higher transepithelial water permeability, the water permeability of the apical and basolateral membrane were lower in the neonate than the adult and there was less aquaporin 1 expression on both the apical and basolateral membranes of the proximal tubule of the neonate (234, 235). The apparent paradox between the higher water permeability in the neonatal proximal tubule and the lower water permeability of the apical and basolateral membranes was resolved with measurements of the contribution of the intracellular compartment to water movement in the neonatal and adult proximal tubule. The intracellular compartment was found to cause a large resistance to water flow and the neonatal proximal tubule intracellular compartment was less of a constraint to transcellular water movement than that of the adult (231).

The postnatal increase in glucocorticoids is a likely factor in mediating the above maturational changes in water permeability and aquaporin 1 expression. Administration of glucocorticoids to neonatal rabbits resulted in an increase in brush border membrane water permeability and aquaporin 1 expression (203). However, the developmental increase in thyroid hormone was shown not to be a factor mediating these postnatal maturational changes in water transport (204).

Thick Ascending Limb

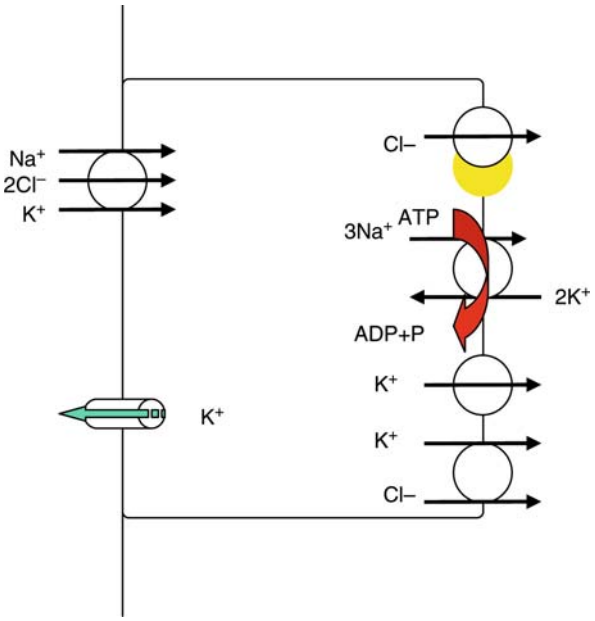
The thick ascending limb is responsible for the reabsorption of 30% of filtered NaCl. The thick ascending limb is

impermeable to water. The reabsorption of NaCl without water by the cortical and medullary TAL along with the distal convoluted tubule generates a luminal fluid with an osmolality of 50 mOsm/kg water. In the absence of ADH action on the collecting tubule, this dilute urine will be excreted. The medullary interstitial hypertonicity is largely generated by active NaCl reabsorption without water by that segment.

The reabsorption of NaCl is due to secondary active transport with the basolateral Na^+-K^+-ATPase generating a low intracellular sodium to provide a driving force for luminal sodium entry. A cartoon of a thick ascending limb cell is shown in *Fig. 3-13.* Sodium enters the cell via the furosemide or bumetanide sensitive $Na^+/K^+/2Cl^-$ cotransporter (128, 129). The $Na^+/K^+/2Cl^-$ cotransporter is electroneutral, yet there is a lumen positive transepithelial potential difference in the thick ascending limb (118). The positive luminal potential is generated by apical potassium recycling via the potassium channel ROMK1 (196, 341). With recycling of potassium back into the lumen, there is the net reabsorption of one sodium and two chloride ions which exit the cell across the basolateral membrane. Sodium exits the cell via the Na^+-K^+-ATPase. Chloride predominantly exits the cell via a chloride channel designated ClC-Kb (2, 156, 161). A subunit of this chloride channel designated barttin is important in the function of ClC-Kb (97). The lumen positive potential difference, generated by potassium secretion into the lumen, generates a driving force for the passive reabsorption of cations including Mg^{++} and Ca^{++}. The thick ascending limb has a very high permeability to magnesium and calcium ions, which results in a substantial fraction of filtered calcium and magnesium being reabsorbed passively across the paracellular pathway in this segment (56, 61, 62, 144, 248). The unique permeability properties of the thick ascending limb are due to the expression of claudin 16 which is mutated in familial hypomagnesemia with hypercalciuria and nephrocalcinosis where there is renal magnesium and calcium wasting (301).

Figure 3-13

The figure depicts a thick ascending limb cell. On the apical membrane is the $Na^+/K^+/2Cl^-$ cotransporter that is sensitive to loop diuretics and the potassium channel designated ROMK that is depicted as the green arrow. The basolateral membrane has a Na^+-K^+ ATPase, a KCl cotransporter, a chloride channel designated ClC-Kb, with its accessory channel designated barttin in yellow and a potassium channel. A loss of function mutation in the $Na^+/K^+/2Cl^-$ cotransporter, ROMK, ClC-Kb, or barttin results in Bartter's syndrome.



Mutations of the $Na^+/K^+/2Cl^-$ cotransporter (297), ROMK (179, 298), ClC-Kb (296) and barttin (46, 97) all cause Bartter's syndrome. Barttin is also expressed in the ear where it is a subunit of ClC-Ka and ClC-Kb. Mutations in barttin cause sensory neural hearing loss (46, 97).

Micropuncture studies of fluid from the early distal tubule showed that the osmolality of the fluid was significantly lower in the adult than in the neonatal rat (347). This is consistent with lower rates of sodium transport in the thick ascending limb but this study did not examine the latter parts of the diluting segment. Human neonates are able to dilute their urine to the same level as an adult (50 mOsm/kg water). This is vital as neonates ingest a hypotonic fluid, mother's milk. Sodium transport in the thick ascending limb has been directly examined in vitro and shown to be five-fold lower in the neonate than in the adult (138).

The $Na^+/K^+/2Cl^-$ cotransporter can first be detected in the mid-late gestation rat's thick ascending limb and macula densa (170). In the rat, there is a postnatal maturational increase in $Na^+/K^+/2Cl^-$ cotransporter, ROMK, Na^+-K^+-ATPase mRNA and protein abundance, but no change in ClC-K mRNA abundance (308). Administration of dexamethasone before the normal maturational increase at the time of weaning resulted in a premature increase in urinary concentrating ability and increase in $Na^+/K^+/2Cl^-$ cotransporter, Na^+-K^+-ATPase mRNA and protein abundance, but no change in ROMK protein abundance (308). There is also a postnatal maturational increase in thick ascending limb Na^+-K^+-ATPase activity

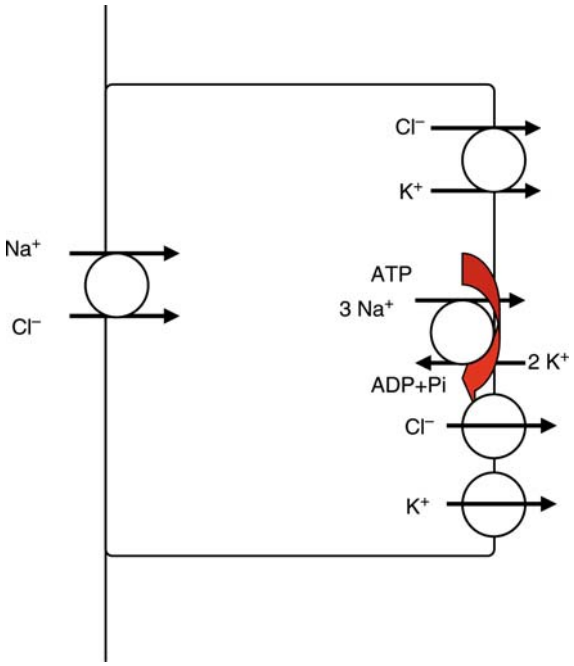
(238, 271) (87). The maturational increase in thick ascending limb Na^+-K^+-ATPase activity could be accelerated precociously by glucocorticoids and prevented by neonatal adrenalectomy (87, 237).

Distal Convoluted Tubule

The distal convoluted tubule reabsorbs approximately 7% of the filtered sodium. This segment is water impermeable and further reabsorption of salt without water occurs in this segment resulting in the nadir of luminal fluid osmolality. The transporters responsible for NaCl transport in the distal convoluted tubule are shown in *Fig. 3-14.* Sodium entry is via the thiazide sensitive cotransporter (94, 213, 292, 322). Mutations in the thiazide sensitive cotransporter cause Gitelman's syndrome (299, 300, 302). There is also evidence for parallel Na^+/H^+ and Cl^-/base exchange mediating sodium entry in the rat (324). The isoform of this Na^+/H^+ exchanger is NHE2 (72). Chloride exits the cell via a basolateral chloride channel ClC-K (178) and a KCl cotransporter KCNQ1 (175, 321). There is also a basolateral potassium channel (346). There is active transcelluar calcium and magnesium transport in the distal convoluted tubule but there is no information about the developmental expression and regulation of these transporters (81, 197).

Figure 3-14

Distal convoluted cell showing the transporters involved in active sodium reabsorption. The apical NaCl transporter is the thiazide sensitive cotransporter. Inactivating mutations in the thiazide sensitive cotransporter lead to Gitelman's syndrome.



The distal convoluted tubule is very difficult to study in vitro and in vivo. No studies have been performed to date, examining the relative abundance of the thiazide sensitive cotransporter in the neonate and adult. A study has been preformed that suggests that there is increased sodium absorption in 24- compared to 40-day-old rats (6, 115). Before detailing this study, it is important to know that studies have shown that the neonate is less able to excrete a salt load compared to the adult (5, 82, 115). For example, administration of isotonic saline equal to 10% of the dogs weight to an adult dog resulted in excretion of 50% of the salt load over 8 h but only 10% of the salt load was excreted in the 1–2 week old dog (115). This limited ability to excrete a sodium load was not due to the lower glomerular filtration rate in the neonate (115). Because sodium transport is less in the proximal tubule, thick ascending limb and collecting tubule, the nephron segment where there was avid neonatal sodium reabsorption was unclear. It must be stated that it was never considered that the volume of distribution of the saline infusion was greater in the neonate than the adult to account for these findings.

A micropuncture study suggested that the sodium retention in the neonate was the result of avid sodium reabsorption in the distal convoluted tubule (6). The tubular fluid to plasma Na/inulin (a volume marker) was greater in the early distal tubule in the 24-day-old neonate compared to the 40-day-old neonate due to decreased proximal and loop sodium absorption in the younger rat. This difference disappeared by the late distal tubule indicating that the 24-day-old rat had a higher rate of sodium absorption in that distal convoluted tubule. Volume expansion resulted in a higher distal delivery of sodium from the early proximal tubule of the 24-day-old rat, and there was less sodium remaining by the end of the distal nephron consistent with the distal convoluted tubule being the segment responsible for neonates' failure to excrete a sodium load compared to adults.

Urinary Concentration and Dilution

The urine exiting the distal convoluted tubule and entering the collecting duct has an osmolality of ~50 mOsm/kg water. Whether the urine will be of this osmolality or

maximally concentrated will depend on the presence or absence of vasopressin (ADH). Neonates can dilute their urine to nearly the adult level of nearly 50 mosm/kg water (7, 187, 249). Thus the neonates which imbibe mother's milk can excrete free water (169, 187, 249). However, unlike the normal adult where it is almost impossible to drink enough water to cause hyponatremia (30 l/day), neonates have a rather limited ability to generate and excrete free water and improperly mixed and dilute formula can result in hyponatremia (187).

The maximum urine osmolality of the human neonate is ~400–600 mOsm/kg water (123, 220, 334). The adult urine osmolality can be achieved at 1.5–2 years of age (334). There are many potential developmental factors that could limit the ability of the neonate to generate a maximally concentrated urine. The factors involved in urine concentration include:

1. The ability to sense an increase in serum osmolality or decrease in extracellular volume and secrete vasopressin.
2. There must be vasopressin receptors on the basolateral membrane of the collecting duct.
3. The collecting duct must be able to generate cAMP.
4. The loop of Henle must have generated a concentrated interstitium.
5. The architecture of the medulla must not limit the concentrating ability.
6. The collecting tubule must have aquaporins on the apical and basolateral membrane.
7. There must not be extracellular or intracellular mechanisms upregulated in the neonate, which limit urinary concentrating abilities.

During prenatal and postnatal maturation, there are anatomical changes which occur that likely affect urinary concentrating ability. There is an increase in the medullary capillary density, a decrease in medullary intersitial connective tissue, an increased presence and length of the thin limbs and the tubules become more tightly packed with cells in the loop decreasing in height with maturation (55, 315). The length of the papilla increased linearly from day 10 to day 40 in the rat (238). All these developmental anatomical changes are necessary for the counter current multiplication system to be maximally efficient. Accompanied by these anatomical changes are concomitant increases in the medullary sodium and urea concentration (238, 306). Administration of a high protein diet or urea to human neonates results in an increased ability to concentrate urine, implying that the ability of urea to accumulate in the medulla can be limited by dietary intake (90, 91). Adrenalectomy in neonatal rats prevented the maturational increase in urine osmolality while administration of glucocorticoids prior to the maturational increase caused a premature increase in urinary concentrating ability (238).

Principal cells in the collecting tubule and the cells in the medullary collecting duct express aquaporin 2 on the apical membrane and aquaporins 3 and 4 on the basolateral membrane (35, 52, 159, 313, 326). Aquaporin three null mice have diabetes insipidus whereas aquaporin 4 null mice only have a small concentrating defect after water deprivation indicating that basolateral water movement is primarily via aquaporin 3 (180, 181). Vasopressin causes the intracellular vesicles containing aquaporin 2 to fuse with the apical membrane resulting in the insertion of aquaporin 2 into the apical membrane (326). There is a developmental increase in aquaporin 2 expression (35, 52, 254, 342, 343). The maturational increase in aquaporin 2 is accelerated by administration of synthetic glucocorticoids prior to the normal postnatal increase in plasma glucocorticoids (343). Neither aquaporin 3 nor aquaporin 4 are factors impairing urinary concentration in the neonate (35, 157).

The fetus and neonate respond to increases in serum osmolality, stress and hypovolemia with appropriate increases in plasma vasopressin levels. The fetal sheep has an increase in plasma vasopressin with an infusion of hypertonic saline and increase in plasma osmolality (168, 294, 331). Plasma vasopressin also increases in fetal sheep in response to volume depletion induced by hemorrhage or diuretics (85, 168, 247) Despite the fact that the fetal lamb can increase serum vasopressin levels, infusion of vasopressin resulted in a blunted increase in urine osmolality compared to adult sheep (246). It is hard to assess these issues in humans. However, comparison between a relatively stressful vaginal delivery compared to a cesarian section has consistently demonstrated higher vasopressin levels in neonates born vaginally (86, 121, 221, 240). However, there was no correlation with vasopressin levels and the degree of perinatal asphyxia in one study (221), while there was a correlation in another (86). In total, it appears that the fetus and neonate can respond to appropriate stimuli with vasopressin secretion.

There is a developmental increase in vasopressin receptors in the kidney, however vasopressin receptor abundance does not appear to be a limiting factor in urinary concentration in the neonate (216, 236). Exogenous administration of vasopressin has been show to increase the urine osmolality in fetal sheep showing that vasopressin action on the collecting tubule is a prenatal event (246). Vasopressin acts in the collecting tubule by increasing cAMP. There is some discrepancy about the

extent of cAMP production during postnatal maturation in comparison to adults. The sum of the data indicate that while vasopressin stimulates cAMP production in the neonate, the amount of cAMP generated is attenuated compared to the adult (113, 148, 236, 270).

The response of the collecting tubule to vasopressin has been examined in vitro (54, 141, 232, 295). The neonatal water permeability did not increase in response to vasopressin comparably to that seen in the adult (54, 141, 232, 295). Studies have shown that the phosphodiesterase activity is greater in the neonatal collecting tubule (232). The water permeability of the neonatal collecting tubule was identical to the adult in the presence of a phosphodiesterase inhibitor demonstrating that the predominant factor limiting the action of vasopressin in the collecting tubule was the enhanced degradation of cAMP generated by vasopressin in the neonatal collecting tubule (232). Vasopressin increases prostaglandin production in the collecting tubule which attenuates the vasopressin mediated increase in cAMP production (51, 53). Vasopressin mediated cAMP production, while less in the neonatal collecting tubule, increases to adult levels in the presence of indomethacin, a prostaglandin synthesis inhibitor (53). Thus, prostaglandin production by the collecting tubule may attenuate the effect of vasopressin in the neonatal tubule to a greater extent than in the adult tubule (53).

Distal Tubule Acidification

The distal nephron makes the final adjustment in distal acidification. The distal nephron, under normal circumstances, secretes the protons equal to that generated from metabolism and in children the protons liberated from the formation of bone. The cortical collecting tubule has two types of cells that are involved in renal acidification. The α-intercalated cell is responsible for proton secretion and is shown in *Fig. 3-15*. There is also a β-intercalated cell, which can secrete bicarbonate when the animal is alkalotic or eats a diet with alkali content (190). This is unusual for humans but not for some mammals which can ingest an alkali diet (194). The β-intercalated cell has the reverse polarity of the α-intercalated cell but the Cl^-/HCO_3^- exchanger on the apical membrane of the β-intercalated cell is different from that on the apical membrane of the α-intercalated cell.

The neonatal cortical collecting tubule has fewer and less differentiated intercalated cells than that of the adult segment (98, 260). The rates of both bicarbonate secretion and luminal acidification are less in the neonate than in the adult (194, 260, 263). The intercalated cells in the inner medullary collecting duct were much more differentiated in appearance and secreted protons at a rate comparable to the adult (194, 263). The collecting tubule also has a luminal H^+-K^+ ATPase which causes proton secretion and potassium absorption from the luminal fluid. It is activated under states of metabolic acidosis and hypokalemia (120). The H^+-K^+ ATPase can function at comparable rates in the neonatal cortical collecting tubule to that of the adult (78).

Cortical Collecting Tubule Sodium Transport

While relatively little sodium is reabsorbed by the cortical collecting tubule compared to the proximal nephron segments, it is the final nephron segment responsible for regulating sodium absorption and thus is vitally important for the regulation of sodium homeostasis. Sodium absorption occurs in the principal cell of the collecting tubule which is shown in *Fig. 3-15*. Sodium transport is through the epithelial sodium channel designated ENaC which has three subunits. The driving force for sodium entry across ENaC is the low intracellular sodium concentration and the potential difference across the luminal membrane generated by the basolateral Na^+-K^+ ATPase. The Na^+-K^+ ATPase undergoes a maturational increase in this segment but is not the limiting factor for the maturational increase in sodium absorption (271). The abundance of ENaC on the apical membrane is by and large determined by aldosterone in the adult, but aldosterone has a blunted effect in the neonate, despite the fact that there are higher serum levels in the neonate and ample aldosterone receptors (8, 39, 104, 293, 307, 309, 319).

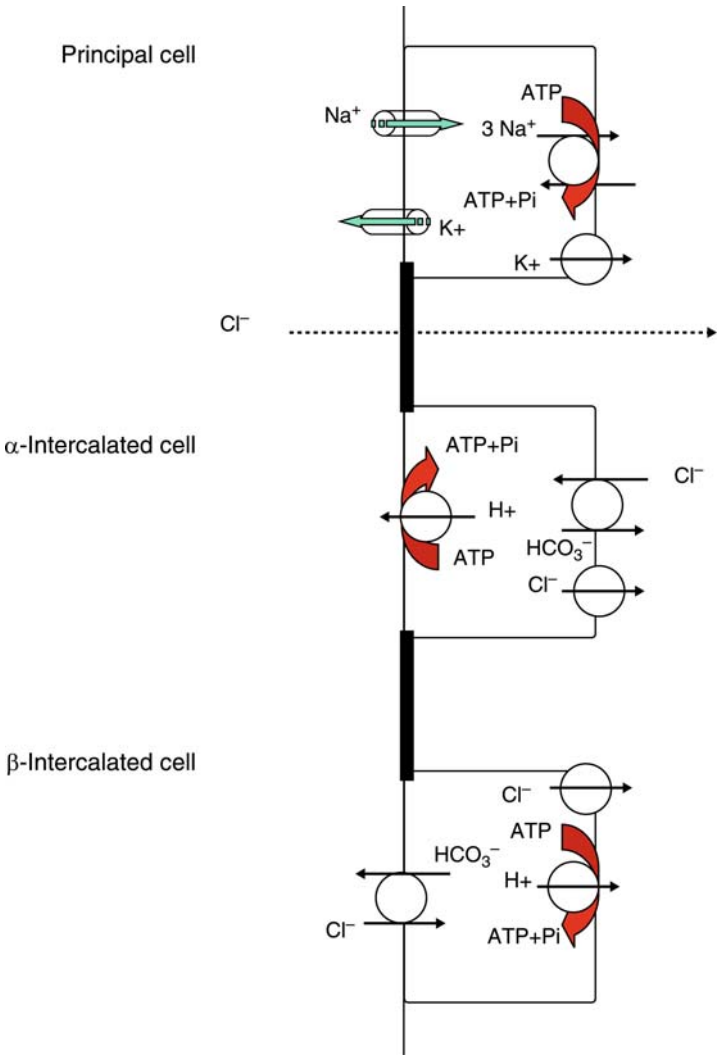
Sodium transport in the cortical collecting tubule increases with postnatal development (259, 319). This increase in sodium transport is paralleled by an increase in the apical expression of ENaC, as ENaC expression is the limiting factor in sodium absorption in this segment (261). ENaC is composed of α-, ß-, and γ-subunits and there is a developmental increase in mRNA and protein abundance of each during postnatal maturation (142, 261, 320, 327, 348).

Potassium Transport

Neonates have higher serum potassium levels than adults. Potassium is the predominant intracellular cation and neonates must be in positive potassium balance for

Figure 3-15

Three cells of the cortical collecting tubule are demonstrated. The principal cell is shown above with sodium entering the cell down its electrochemical gradient via a channel designated ENaC. This generates a lumen negative transepithelial potential difference. Potassium is secreted into the lumen down its electrochemical gradient via ROMK. Chloride is moving through the paracellular pathway down the electrical gradient generated by the lumen negative potential difference. The cell below is an alpha intercalated cell which secretes protons into the cell lumen via a H^+-ATPase. The bicarbonate generated in this process is secreted across the basolateral membrane via a Cl^-/HCO_3^- exchanger. The third cell is a beta intercalated cell which secretes bicarbonate ions in the face of metabolic alkalosis. This cell is the reverse of an alpha intercalated cell but the Cl^-/HCO_3^- exchanger is a different isoform.



growth, unlike adults, which excrete the quantity of potassium absorbed from their diet in their urine (120). Adult animals are more readily able to excrete an exogenous potassium load than is a neonate (177). Approximately half of the filtered potassium is reabsorbed in the proximal tubule of the adult and neonate by passive diffusion across the paracellular pathway (171). The loop of Henle reabsorbs 80% of the delivered potassium in the adult and only 45% in the neonate (171). Thus, the adult delivers approximately 10% of the filtered

potassium to the distal nephron while the neonate delivers 25%. The distal convoluted tubule, connecting tubule and cortical collecting duct are the sites of potassium secretion and final modulation of urine potassium excretion.

Potassium secretion in a principal cell is depicted in *Fig. 3-15*. Sodium enters the principal cell through the apical sodium channel down the favorable electrochemical gradient generated by the Na^+-K^+ ATPase on the basolateral membrane. This results in a lumen negative potential difference and a favorable electrochemical gradient for potassium secretion. While there is a maturational increase in the sodium channel and the Na^+-K^+ ATPase, these are not the limiting factors for potassium secretion. There are two potassium channels in the collecting tubule, one channel designated ROMK is on the apical membrane of principal cells and a flow-dependent channel that is activated by stretch designated maxi-K channel (120). There is a maturational increase in potassium secretion in cortical collecting tubules perfused in vitro (259). The secretion of potassium by principal cells is paralleled by the maturational increase in potassium channels (ROMK) on the apical membrane of the principal cell (262, 348). There is also a developmental increase in the maxi-K channel (337). As noted above and in *Table 3-1*, potassium secretion is regulated by aldosterone and there is resistance to the action of aldosterone despite higher serum levels in the neonate (8, 39, 104, 293, 307, 309, 319).

4 Perinatal Urology

Richard S. Lee, MD · David A. Diamond, MD

The increased use of maternal-fetal ultrasound has led to the development of the field of perinatal urology. Antenatal hydronephrosis (ANH) is identified in approximately 1–3% of all pregnancies and is one of the most common birth defects detected (1–4). Other urologic abnormalities have been diagnosed prenatally as well, including renal cystic disease, renal agenesis, stones and tumors. For the pediatric urologist, these prenatal findings have created numerous clinical dilemmas that challenge our understanding of normal and abnormal renal embryology and physiology. In this chapter, we discuss the diagnosis of prenatal urologic abnormalities and the postnatal implications, the rationale behind prenatal intervention, and our clinical experience in managing children with prenatal urologic abnormalities.

Diagnosis

In a large prospective Swedish, study, the incidence of prenatally detected renal anomalies was 0.28% in which two-thirds (0.18%) were hydronephrosis (5). A British study, in which 99% of the pregnant population in Stoke-on-Trent were scanned at 28 weeks' gestation, demonstrated hydronephrosis prenatally in 1.40% of cases, which was confirmed postnatally in 0.65% (3). These authors defined prenatal hydronephrosis as an anteroposterior (A–P) diameter of the renal pelvis greater than 5 mm but noted the lack of consensus on the definition of antenatal hydronephrosis (6–8). Many variations in the definition and management of ANH exist in the literature and clinical practice, including method and frequency of in utero testing, radiographic documentation, classification, or postnatal management (9–15).

When an abnormality of the urinary tract is determined by maternal-fetal ultrasound, several questions should be raised by the ultrasonographer and consulting urologist. Combinations of specific findings direct the differential diagnosis and permit more accurate prognosis and tailoring of postnatal evaluation. The principal findings and their implications are listed in *Table 4-1*.

Diagnostic Accuracy

As both ultrasound and MRI technology improve, more accurate radiographic information is obtainable (16). However, predicting accurate postnatal diagnosis and outcome, regardless of the prenatal information, still remains challenging. The importance of accurate diagnosis is particularly critical in cases where fetal intervention is considered, such as posterior urethral valves (PUV). In other cases, the ability to identify some degree of ANH is adequate to permit a postnatal evaluation if deemed clinically appropriate.

A recent systematic review of the ANH literature attempted to determine the risk of a pathological diagnosis for patients with varying severity of ANH (15). In this review of 1,308 patients with any ANH and postnatal radiographic follow-up, 36% had a postnatal pathological diagnosis. The degree of ANH was defined by the anterior posterior diameter (APD) identified in a particular trimester (*Table 4-2*) (15). The overall risk for any pathology increased with the degree of hydronephrosis; except for vesicoureteral reflux which remained consistent regardless of the degree of ANH (*Table 4-3*) (15).

Although the risk of pathology with degrees of ANH appears to be increased, accurately determining the diagnosis remains difficult (15). An early report by Hobbins et al. suggested that the correct prenatal identification of the site of obstruction could be confirmed postnatally in 88% of cases (17). Subsequent studies reported fairly high false-positive rates ranging from 9 to 22% (6). The majority of false positives in these studies were nonobstructive causes of hydronephrosis, such as high-grade reflux, large, nonobstructed, extrarenal pelves, or transient hydronephrosis. Similarly, the diagnosis of vesicoureteral reflux is extremely challenging to make in-utero, as evidenced by the fact that the risk for vesicoureteral reflux is the same regardless of the degree of ANH (15).

As another example, the accurate diagnosis of posterior urethral valves (PUV), in which intervention might be considered, has proven difficult. In one series, the false-positive rate was as high as 58%, but the criteria for

Table 4–1

Major diagnostic findings in prenatal imaging

	Finding	Comment
Kidney	Hydronephrosis	Assess degree
	Unilateral & bilateral	May be different degrees
	Parenchymal echogenicity	Should be less than spleen or liver; if increased and organ enlarged, suggests autosomal recessive polycystic kidney disease
	Duplication	Often with dilation of upper pole; may be lower pole dilation
	Cysts	Small cysts associated with dysplasia; simple cyst of upper pole suggests duplication with ureterocele or ectopic ureter; genetic cystic disease
	Urinoma	Perinephric or subcapsular
Ureter	Dilation/tortuosity	Obstruction or reflux
Bladder	Distended	Variation with time
	Wall thickness	In relation to filling status
	Intravesical cystic structure	Ureterocele
	"Keyhole" pattern	Dilated posterior urethra; PUV
	Not visible	Exstrophy
Amniotic fluid	Absence; oligohydramnios	Impaired urine output
	Polyhydramnios	May be seen with mild-moderate hydronephrosis
Gender	Penis/scrotum/ testes	Sex-associated conditions (e.g., PUV)
Spine	Meningocele	Neural tube defect

PUV, posterior urethral valves

Table 4–2

Classification of antenatal hydronephrosis (ANH) by anterior posterior diameter (APD)

ANH Classification	APD	
	2nd Trimester (mm)	3rd Trimester (mm)
1. Mild	≤7	≤9
2. Mild/Moderate	<10	<15
3. Moderate	7–10	9–15
4. Moderate/Severe	≥7	≥9
5. Severe	≥10	≥15

diagnosing valves were quite liberal and perhaps inappropriate (18). In another population-based series, the sensitivity in detecting valves was as low as 23% (6). Increased renal echogenicity and decreased amniotic fluid have been suggested to be indicative of obstructive conditions (19). Although the hallmark signs of an in-utero diagnosis of posterior urethral valves have been described (oligohydramnios, dilated posterior urethra, thickened bladder, and hydroureteronephrosis), there are very few studies that have prospectively examined the clinical urologic implications of these findings alone or in combination (15).

Ureteropelvic Junction Obstruction

The basic features of ureteropelvic junction obstruction (UPJO) in the fetus include dilation of the renal pelvis and collecting system with no evidence of ureteral dilation (*Fig. 4-1*). The best way to detect ureteral dilaion is at the level of the bladder, preferably in transverse view. The threshold for recommending postnatal follow-up is largely arbitrary and currently there are no long-term prospective studies to best determine the degree of postnatal evaluation. Lee et al. demonstrated that increasing severity of ANH increased the chance of identifying postnatal UPJO (15). Others have recommended that unilateral APD over 7 or 8 mm in the third trimester

Table 4-3

Risk of pathology by degree of antenatal hydronephrosis

Postnatal Pathology [% (95% CI)/[a]]	Degree of Antenatal Hydronephrosis					
	Mild (*N* = 587)	Mild-Moderate (*N* = 213)	Moderate (*N* = 235)	Moderate-Severe (*N* = 179)	Severe (*N* = 94)	Trend P-value[b]
Any Pathology	11.9 (4.5, 28.0)	39.0 (32.6, 45.7)	45.1 (25.3, 66.6)	72.1 (47.6, 88.0)	88.3 (53.7, 98.0)	<0.001
UPJ	4.9 (2.0, 11.9)	13.6 (9.6, 18.9)	17.0 (7.6, 33.9)	36.9 (17.9, 61.0)	54.3 (21.7, 83.6)	<0.001
VUR	4.4 (1.5, 12.1)	10.8 (7.3, 15.7)	14.0 (7.1, 25.9)	12.3 (8.4, 17.7)	8.5 (4.7, 15.0)	0.10
PUV	0.2 (0.0, 1.4)	0.9 (0.2, 3.7)	0.9 (0.2, 2.9)	6.7 (2.5, 16.6)	5.3 (1.2, 21.0)	<0.001
Ureteral Obstruction	1.2 (0.2, 8.0)	11.7 (8.1, 16.8)	9.8 (6.3, 14.9)	10.6 (7.4, 15.0)	5.3 (1.4, 18.2)	0.025
Other[c]	1.2 (0.3, 4.0)	1.9 (0.7, 4.9)	3.4 (0.5, 19.4)	5.6 (3.0, 10.2)	14.9 (3.6, 44.9)	0.002

[a]Pointwise 95% confidence intervals were estimated by logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure to adjust for clustering by study for all degrees of antenatal hydronephrosis except mild-moderate. Because only one study had subjects with mild-moderate antenatal hydronephrosis, the pointwise 95% confidence intervals had to be estimated using logistic regression with unadjusted standard errors

[b]Testing for trend in risks with increasing degree of antenatal hydronephrosis using logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure

[c]Includes prune belly syndrome, VATER syndrome, solitary kidney, renal mass, and unclassified

(5–6 mm with bilateral dilation) warrants postnatal follow-up (20). Some have recommended that all children with any ANH should be investigated postnatally (21). Nevertheless, in the case of significant unilateral hydronephrosis, there is little rationale for in utero intervention. In a few cases with massive dilation, therapeutic aspiration has been recommended for dystocia. In the case of bilateral UPJO, the efficacy of in utero intervention is difficult to assess.

Attempts to correlate prenatal ultrasound appearance with postnatal outcomes have been complicated by the long-standing controversy regarding postnatal evaluation and management of UPJO. Grignon et al. developed a system of grading hydronephrosis secondary to UPJO based on the APD and degree of calyceal dilatation (22, 23). Mandell et al. attempted to correlate the degree of APD relative to gestational age with subsequent need for postnatal surgical intervention (24). They found the "at risk" diameter to be greater than or equal to 5 mm at 15–20 weeks' gestation, greater than or equal to 8 mm at 20–30 weeks' gestation, and greater than 1 cm at over 30 weeks' gestation. An alternative system proposed by Kleiner et al. defined hydronephrosis as the ratio of APD to A-P diameter of the kidney as being greater than 0.5 cm (25); caliectasis was later added as an additional indicator of significant hydronephrosis. Mild degrees of renal pelvic dilatation may resolve in utero. Mandell et al. noted this occurred in 23% of cases, with 66% remaining stable and 9% worsening over the course of the pregnancy (24). Similarly, Lee et al. noted that 88.1% of mild ANH were found to have no postnatal pathology (15). Severe forms of UPJO may be associated with urinary ascites or perinephric urinomas, which often precede nonfunction of the kidney (26).

Cystic Kidneys

The distinction between severe unilateral hydronephrosis and a multicystic dysplastic kidney may occasionally be unclear. The findings of multiple noncommunicating cysts, minimal or absent renal parenchyma, and the absence of a central large cyst are diagnostic of a multicystic dysplastic kidney (MCDK) (*Fig. 4-2*). Bilaterally enlarged echogenic kidneys, particularly if associated with hepatobiliary dilatation or oligohydramnios, suggests autosomal recessive polycystic kidney disease (*Fig. 4-3*). A more challenging finding is normal-sized, diffusely echogenic kidneys that are not associated with other urologic

Figure 4–1

Unilateral renal pelvis dilation with no ureteral dilation in 37-week old fetus.

lesions. Estroff et al. described 19 cases (14 bilateral), including 10 with normal function who survived and 4 with autosomal recessive polycystic kidneys who died (14).

Ureterovesical Junction Obstruction

Less common than UPJO, ureterovesical obstruction (UVJ) is characterized by ureteral dilation along with varying degrees of renal pelvic and calyceal dilation (*Fig. 4-4*). More extreme cases may be confused with single system ectopic ureters, particularly in males. In general, the differentiation is made postnatally.

Duplication Anomalies

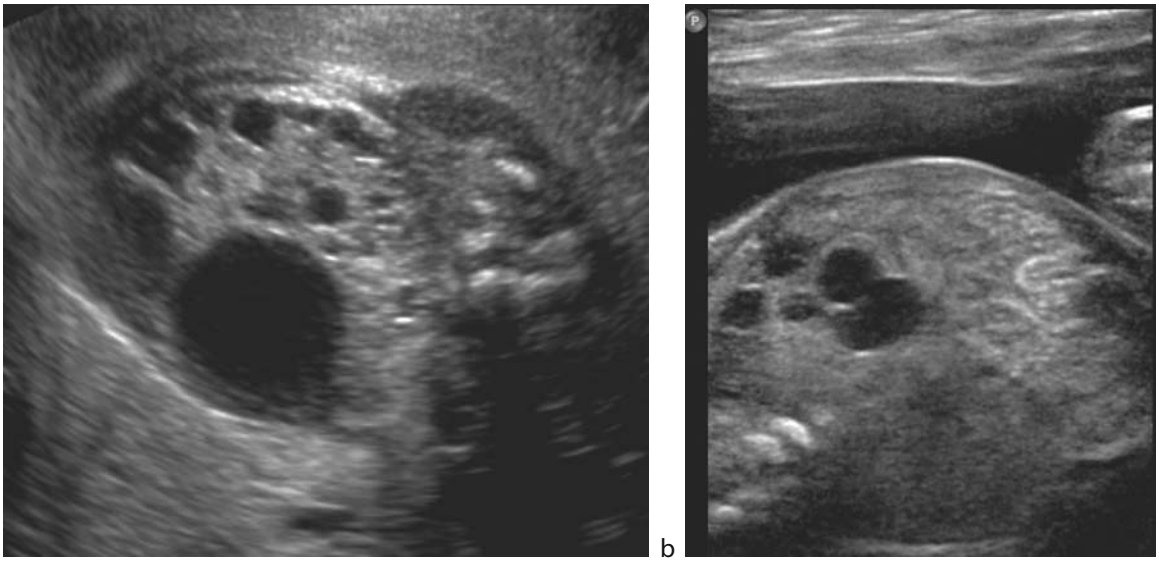
Among the most interesting prenatal urologic findings are duplication anomalies. These are often recognized on the basis of upper pole hydroureteronephrosis, associated with either an obstructing ureterocele within the bladder, or ectopic ureter inserting outside of the bladder (27) (*Fig. 4-5*). Lower pole hydronephrosis may be present as a result of vesicoureteral reflux or more rarely a lower pole UPJO. Occasionally, lower pole dilation is due to obstruction of both the upper and lower pole ureter by the large ureterocele. In some cases of a very large ureterocele, the ureterocele may be mistaken for the bladder.

Vesicoureteral Reflux

One cannot make a firm diagnosis of vesicoureteral reflux (VUR) based on prenatal ultrasound, although intermittent hydronephrosis or hydroureter is highly suggestive. Vesicoureteral reflux may be present in as many as 38% of children with prenatal hydronephrosis (28). Reflux occurred in 42% of children in whom postnatal imaging revealed persistent upper tract abnormalities and in 25%

Figure 4–2

Two different fetal images (a) at 19 weeks) and (b) at 26 weeks of a multicystic dysplastic kidney with multiple noncommunicating cysts.



of those with normal findings on postnatal ultrasound but having a history of prenatal dilation. Tibballs and Debrun reported that in patients with prenatal dilation and postnatally normal renal units by ultrasound, 25% had grade III-V reflux (29). The incidence of high-grade reflux was greater in males than in females as noted in previous studies. In two systemic reviews of the ANH literature a 10–15% incidence of VUR was identified regardless of the degree of ANH (15, 30) indicating that ANH is not indicative of VUR and may not be the appropriate trigger for postnatal evaluation. In a neonate with prenatally detected hydronephrosis, the importance of diagnosing vesicoureteral reflux remains controversial. While, several studies have demonstrated that a high incidence of reflux is associated with prenatally detected hydronephrosis, its clinical significance is unclear.

Posterior Urethral Valves

Perhaps the most important diagnosis to be made prenatally is that of PUV in the male fetus. PUV, at the very least, mandates prompt postnatal intervention and in some cases, prenatal intervention may be warranted. Fetal sonographic findings of PUV include bilateral hydroureteronephrosis, a thick-walled bladder with dilated posterior urethra, and, in more severe cases, dysplastic renal parenchymal changes with perinephric urinomas and urinary ascites (*Fig. 4-6*) (31). When characteristic sonographic findings are present, the differential diagnosis includes prune belly syndrome (with or without urethral atresia), massive vesicoureteral reflux, and certain cloacal anomalies (in genetic females) (32, 33). Prenatal diagnostic accuracy for PUV is far from perfect but is probably better than the 40% figure previously reported (18).

Rationale for Prenatal Intervention

The scientific rationale for prenatal treatment of hydronephrosis is to maximize normal development of renal and pulmonary function. These two aspects of fetal development are closely linked because urine comprises 90% of amniotic fluid volume, and oligohydramnios during the third trimester has been causally related to pulmonary hypoplasia.

Before embarking on prenatal surgical intervention for obstructive uropathy, it is critical to assess the risk-benefit ratio. The most widely accepted indicator of salvageable renal function is analysis of fetal urine. When the urinary sodium is less than 100 mg/dL and urine osmolarity less than 200 mOsm/dL, renal function appears to be salvageable with in utero intervention (*Table 4-4*) (34). The accuracy of these predictors has been challenged (35, 36). More recently, serial aspirations of fetal urine have been reported to yield more valuable results (37). Guez et al. reported ten fetuses who underwent multiple urine samplings and in whom severe obstruction reduced sodium and calcium reabsorption (38).

Figure 4–3

Bilateral markedly enlarged echogenic (“bright”) kidneys (a) with a small cystic lesion (b) in a fetus with oligohydramnios, consistent with autosomal recessive polycystic kidney disease.

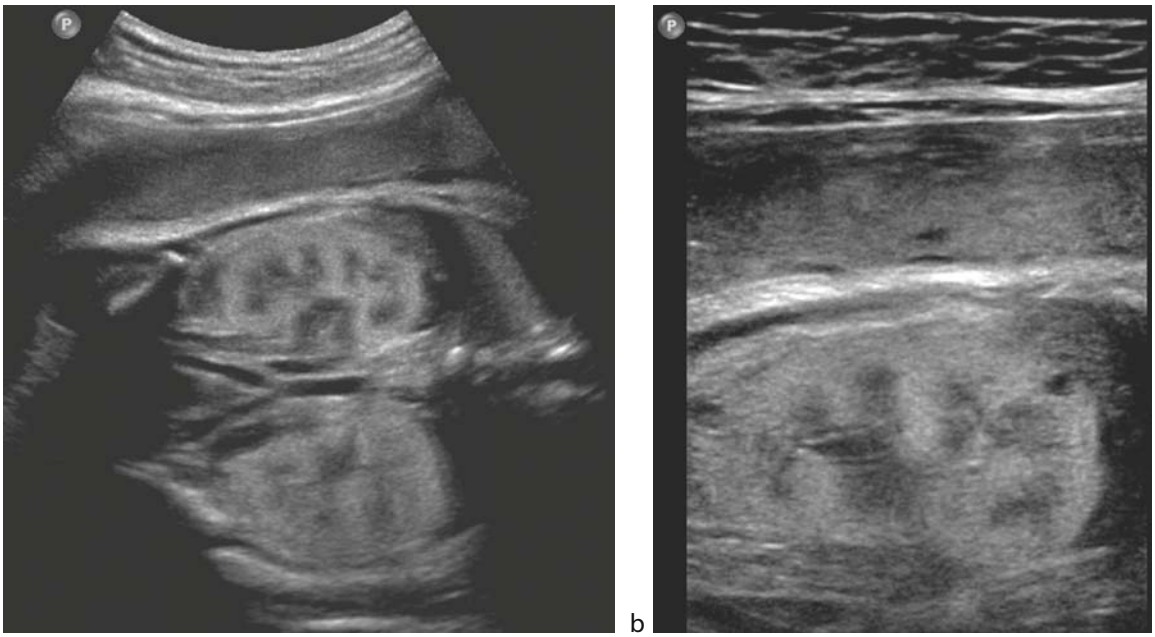


Figure 4–4

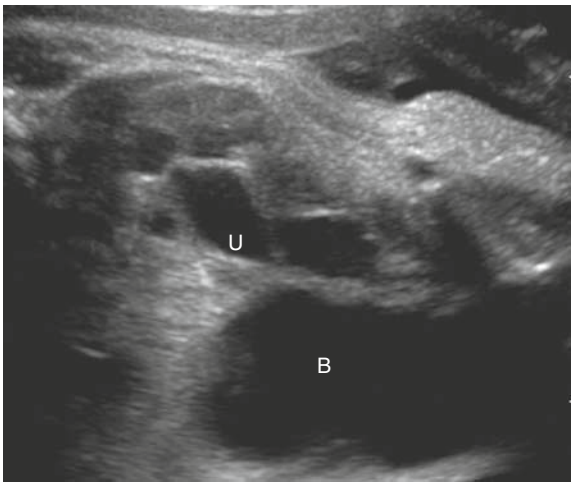
Unilateral hydroureteronephrosis at 35 weeks. Note the dilated ureter (U) and bladder (B). Postnatal imaging confirmed this to be a ureterovesical junction obstruction.



They concluded that fetal urinary chemistries were reasonably predictive of severe but not moderate postnatal renal impairment. Other investigators have suggested the use of fetal urinary beta-$\tilde{}_{22}$ microglobulin as an indicator of tubular damage. Using this parameter, poor renal-outcome has been predicted with a specificity of 83% and sensitivity of 80% (39).

The time of onset of oligohydiamnios has been shown to be an important determinant of outcome (40, 41). In fetuses in which adequate amniotic fluid was documented at up to 30 weeks’ gestation in association with a urologic abnormality, pulmonary outcomes were satisfactory, and postnatal clinical problems were related to renal disease. It seems inappropriate to recommend late urinary tract decompression from a pulmonary or renal basis. It is unclear whether early delivery, to permit earlier postnatal urinary decompression, is beneficial.

Clinical Experience with Intervention for Prenatal Hydronephrosis

The ability to diagnose severe prenatal hydronephrosis and advances in fetal intervention helped develop prenatal surgery for obstructive uropathy. In 1982, Harrison et al. described the initial report of fetal surgery in a 21-week-old fetus with bilateral hydroureteronephrosis secondary to PUV (42). After the 1986 report of the International Fetal Surgery Registry in which outcomes did not seem to justify risk, a de facto moratorium on in utero urinary tract shunting evolved (43). More recently, with improved technology and renewed interest in fetal shunting, most

Figure 4–5

cases have been referred to a small number of highly specialized centers actively engaged in prenatal surgery. The initial method of decompression with open surgery has largely been replaced by in utero shunt placement, although this has been complicated by technical problems of shunt dislodgement and, in the case of the double-J shunt, bowel herniation (44). Some investigators have explored the use of fetoscopic methods for direct intervention to provide prolonged bladder drainage, whereas others have attempted direct endoscopic valve ablation (45–49).

Harrison et al. have clearly outlined the indications and contraindications of intervention for prenatal obstructive uropathy (*Table 4-5*) (50). Additionally, serial bladder sampling over 3 days has been used to help determine if the fetus is a viable candidate. The serial nature of the procedure allows one to see the response of the fetal kidneys to bladder decompression (37). The principal reason for considering vesicoamniotic shunting is to prevent early neonatal pulmonary insufficiency and death. The risks that one accepts with intervention include induction of premature labor, perforation of fetal bowel and bladder, and fetal and/or mother hemorrhage and infection.

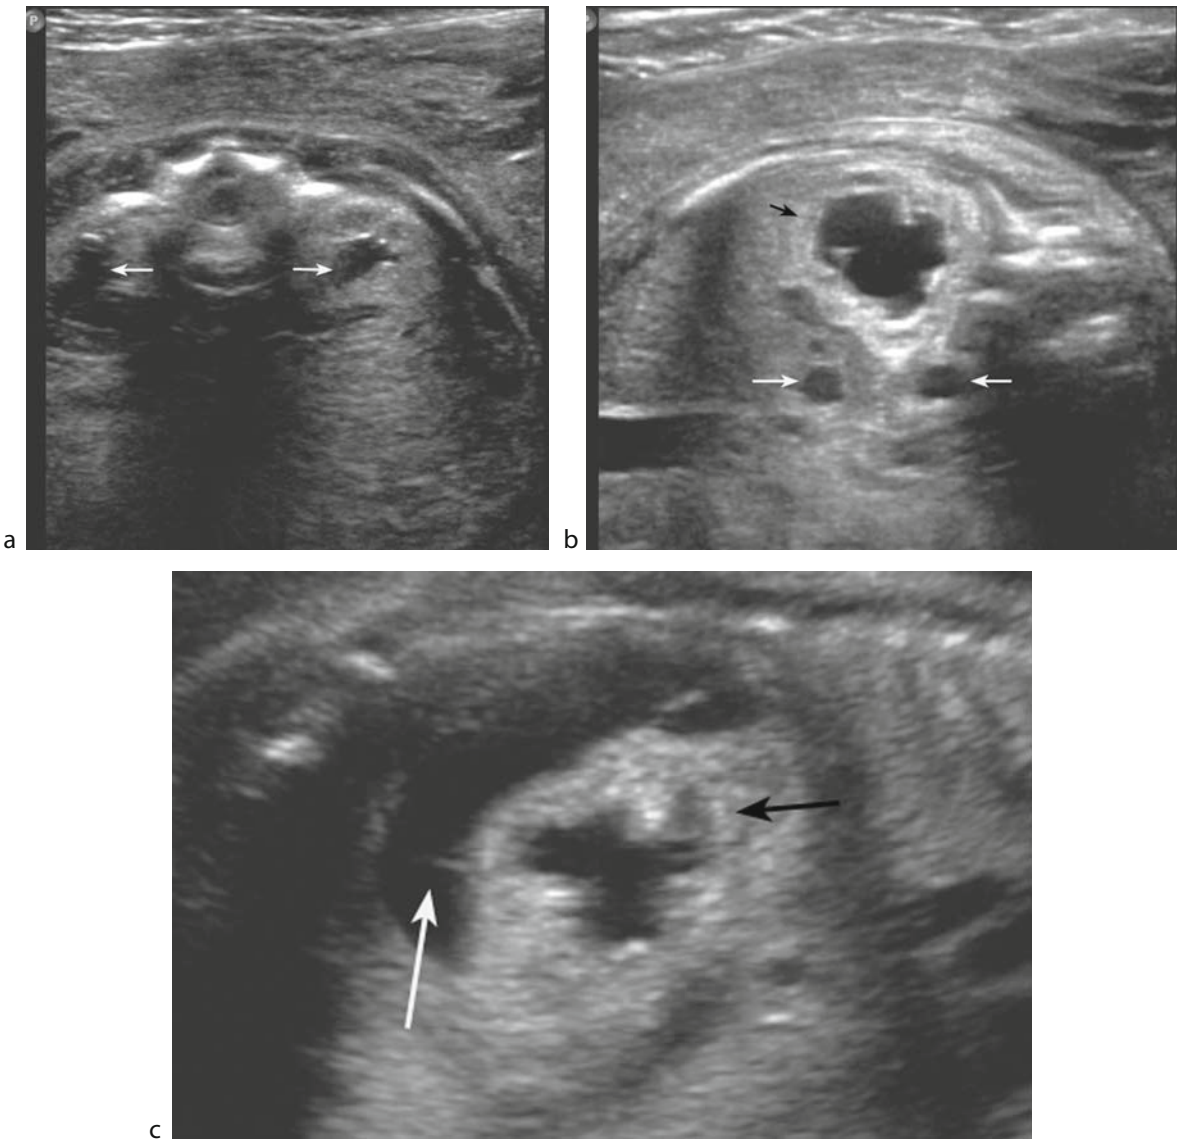
More recently, the ability to influence renal outcome in male patients with PUV but without oligohydramnios has been suggested as a possible indication for in utero intervention. The principal goal of intervention is not to prevent pulmonary hypoplasia and deaths but to prevent or delay end-stage renal failure. Although some reports have shown promise in the ability to distinguish those fetuses with likely early renal failure from those with later-onset failure, the specificity and accuracy of methods using a combination of ultrasound and urinary chemistries (sodium, beta$_2^{\sim}$ microglobulin, and calcium) has not been well defined (51–53). In summary, precise identification of those situations in which intervention may benefit the fetus with obstructive uropathy remains unclear.

Overall, the need to consider in utero intervention for obstruction is not common. In one study, only 9 of 177 fetuses with a diagnosis of hydronephrosis were considered to have PUV and only 3 warranted serious consideration for intervention (24).

To date, the reported long term outcomes of antenatal intervention for severe obstructive uropathy (e.g. PUV, prune belly syndrome, urethral atresia) are mixed (54–62). Variability in patient selection and assessment of outcome within these studies has limited the ability to determine if prenatal intervention has altered the postnatal course. A large systematic review of the prenatal intervention for obstructive uropathy showed a statistically significant perinatal survival advantage with shunting (60). Of the studies that have reported long term outcomes of in-utero vescioamniotic shunting, many of the children have renal insufficiency (57%), and growth impairment (86%) (54, 56, 57). Recently, Baird et al., reported on long-term follow-up (5.8 years) of patients who have survived in-utero shunting (54). They noted

Figure 4–6

Images of a fetus with posterior urethral valves. (a) depicts bilateral echogenic kidneys with hydroureteronephrosis (arrow). (b) demonstrates the associated thickened bladder wall (black arrow) and hydroureter (white arrow). (c) further imaging revealed a perinephric urinoma (white arrow) surrounding the hydronephrotic kidney (black arrow).



acceptable renal function in 44%, mild impairment in 22%, and renal failure in 33%. Prune belly patients had the best renal outcome (57%), followed by PUV (43%), then urethral atresia (25%). Overall, it appears that in-utero intervention for the appropriate patient may reduce the risk of neonatal mortality and may potentially improve renal function. To further improve outcomes, more sensitive and specific markers to better identify which fetus will benefit from in-utero shunting need to be defined.

Postnatal Management of Infants with Prenatally Diagnosed Urologic Renal Abnormality

A child with a prenatal diagnosis of a urologic renal abnormality such as ANH should be carefully evaluated and followed by a pediatric urologist from birth. The vast majority of these children appear entirely healthy and, in the absence of prenatal ultrasound findings, would not have

Table 4–5

Prenatal intervention for hydronephrosis

Indications (prerequisites)	Contraindications
Presumed obstructive hydronephrosis, persistent or progressive, bilateral or insolitary unit	Unilateral hydronephrosis with an adequately functioning contralateral kidney
Otherwise healthy fetus	Chromosomal abnormalities or presence of associated severe anomalies
Oligohydramnios	Bilateral hydronephrosis without oligohydramnios
No overt renal dysplasia	Severely dysplastic kidneys
Adequate renal functional potential based on urinary indices (see text)	Evidence or uretheral atresia
Informed consent	Presence of a normal twin

any indications for regular urologic follow-up. Parental anxiety is common and should be addressed directly with prenatal counseling and education.

Unilateral Hydronephrosis

The presence of unilateral dilation of the kidney warrants postnatal evaluation in a timely but non urgent fashion (3–8 weeks of life) with an ultrasound (51). The most common diagnoses associated with this finding are UPJO, VUR and UVJO/megaureter. Early ultrasound is unlikely to miss a significant abnormality. A normal postnatal ultrasound indicates that obstructive uropathy is not present; however, it does not determine whether or not the child has VUR (29).

The decision to perform a voiding cystourethrogram (VCUG) or initiate prophylactic antibiotics in the newborn period is unclear. Although some groups advocate postnatal VCUG in any child with a history of prenatal hydronephrosis, others have questioned the value of this approach (63). Infants with severe ANH should be placed on prophylactic antibiotics (amoxicillin, 10 mg/kg/day or 50 mg/day) and undergo a VCUG. Severe ANH may be associated with an increased risk of febrile urinary tract infection (64). As for mild ANH, a recent prospective study of 192 infants with ANH noted that the majority of patients with mild ANH had no significant events during infancy (65). In another study, female infants with a history of ANH and postnatal uropathy had a higher risk of febrile urinary tract infection (66). Regardless, no appropriate prospective studies with coordinated and comprehensive postnatal follow-up have examined this question in a rigorous fashion to provide consensus guidelines (15, 30).

At our institution, children with moderate or severe ANH are placed on prophylactic antibiotics at birth. They undergo renal bladder ultrasound and VCUG postnatally. Diuretic renography is reserved for those with persistent moderate or severe postnatal hydronephrosis not related to VUR. Infants with persistent mild on serial US or no postnatal hydronephrosis are observed and followed clinically. Infants with any degree of antenatal or postnatal

ureteral dilation undergo ultrasound, VCUG and possibly diuretic renography (after 3 months) if clinically indicated.

Perhaps the most challenging aspect of managing prenatal hydronephrosis is determining if and when postnatal surgical correction for obstruction is appropriate. Some have suggested that regardless of the degree of ANH, moderate or severe postnatal hydronephrosis with evidence of decreased renal function should be the indications for surgical intervention (67). Despite the improved anatomic detail afforded by real-time ultrasound and the increasing experience with functional nuclear medicine studies (mercaptotriglycylglycine) no radiographic or clinical gold standard for physiologically significant obstruction exists. Over time, some kidneys have been seen to improve, whereas others appear to lose function. The natural history of prenatal hydronephrosis is not clearly defined.

The debate over the appropriate management of infants with unilateral ANH continues and may ultimately be determined by a combination of epidemiologic, radiographic, and new innovative biomarker discoveries. More accurate and reproducible prenatal and postnatal radiographic documentation of the degree of hydronephrosis and function combined with appropriate natural history data are needed to better categorize the infants. Finally, new serum or urine biomarkers indicative of ongoing renal damage will be critical in helping to further define which infants are truly at risk.

Bilateral Hydronephrosis

Infants with bilateral hydroureteronephrosis may have PUV, bilateral VUR, bilateral UPJO or UVJO, or a combination of the above. For the child with bilateral hydroureteronephrosis suggestive of bladder outlet obstruction, an ultrasound and VCUG should be performed promptly. In boys, PUV is the most important diagnosis to be ruled out. In girls, an obstructing ectopic ureterocele would be the most likely cause for bladder outlet obstruction. In the event that an obstructive lesion is discovered, it should be corrected promptly. For children with suspected lower urinary tract obstruction (e.g. PUV), prompt bladder decompression and antibiotic prophylaxis (amoxicillin 10 mg/kg/day or 50 mg/day) should be initiated prior to radiographic intervention.

Renal Agenesis, Renal Ectopia and Unilateral Multicystic Dysplastic Kidney

Infants born with solitary kidneys (renal agenesis), renal ectopia or unilateral multicystic dysplasia should be evaluated postnatally by US and VCUG. Functional studies such as a dimercaptosuccinic acid study (DMSA) are occasionally needed to confirm the diagnosis. The need for further screening is controversial. It has been reported that among infants with a solitary kidney, 30% have VUR, 11% UPJO, and 7% UVJO (68, 69). Similarly, those with renal ectopia (simple or crossed fused ectopia) may also be at risk for VUR in the ectopic or contralateral kidney (30%) (70–72). However, there are others that report a very low incidence of associated urologic anomalies and do not recommend screening (73).

Multicystic dysplastic kidneys (MCDK) are primarily unilateral, isolated and associated with a good prognosis. If at birth the US findings are not absolutely diagnostic of a classic MCDK, a DMSA study can be used to confirm the diagnosis with the absence of uptake. Patients with MCDK are often thought to be similar to those born with a solitary kidney. Additionally, patients with MCDK have an increased frequency of VUR and UPJO in the contralateral normal kidney (74, 75).

Summary

With the increased use of maternal-fetal ultrasound, more genitourinary abnormalities are being detected prenatally. Although advances in imaging have increased the detection and characterization of these abnormalities, further work is needed to identify which abnormalities are clinically significant. Research directives should focus on identifying which infants require postnatal diagnostic imaging and intervention. Developments in the fields of imaging, proteomics, and genomics may provide the necessary information to not only detect the abnormality, but to also prognosticate which ones require further testing and medical intervention.

Acknowledgment

The authors acknowledge the assistance of Carol E. Barnewolt, M.D., for providing many of the fetal ultrasound images.

5 Renal Dysplasia/Hypoplasia

Paul Goodyer

Introduction

During normal kidney development, interactions between the branching ureteric bud (UB) and the metanephric mesenchyme (M) generate all the nephrons of each kidney by about the 8th month of gestation. Nephrons are attached like apples to branches of the arborized collecting system. At birth, this crop of nephrons constitutes the individual's nephron endowment for life and ranges widely among normal humans from 0.3 to 1.1 million nephrons per kidney (1).

Normal human renal development begins at about 4 weeks gestation when the ureteric bud grows out from the nephric duct and begins to arborize within the adjacent metanephric mesenchyme. Failure of this initial process leads to bilateral renal agenesis. The fetus is unable to generate amniotic fluid and develops characteristic features of facial compression and pulmonary hypoplasia (Potter syndrome). At the other end of the spectrum, children with subtle renal hypoplasia appear normal but may be at increased risk for hypertension and renal insufficiency following an acquired renal insult later in life (2, 3). Between these extremes are infants in whom kidney development is initiated, but not completed according to plan, leading to small, dysfunctional kidneys (*Fig. 5-1*).

Antenatal ultrasound screening suggests that about 1 in 400 neonates are born with at least one hypoplastic kidney (4). However, postnatal compensatory hypertrophy tends to mask subtle renal hypoplasia and ultrasound screening in school-age children identifies one or more hypoplastic kidneys in only 1 per thousand (5). When renal hypoplasia is bilateral, nephron number may be insufficient for normal extrauterine life, and as somatic growth outstrips nephron endowment, these children develop progressive renal insufficiency and require renal replacement therapy (6).

While pure renal hypoplasia may be caused by a simple paucity of nephrons (e.g., oligomeganephronia), it is more often associated with histopathologic evidence of aberrant developmental fates of the metanephric mesenchyme and profound disturbance of the normal patterning of renal tissue (renal dysplasia). Normal renal architecture is disrupted by isolated tubules surrounded by mesenchymal cuffs (*Fig. 5-2*), fibrotic interstitial zones and even islands of cartilage (*Fig. 5-3*) scattered amid fairly normal-appearing renal tubules.

In the 2007 NAPTRCS report, about 15% of the 11,874 children in the transplant and dialysis databases had a primary diagnosis of renal aplasia/dysplasia/hypoplasia (https://web.emmes.com/study/ped). An additional 20% have primary diagnoses associated with renal hypoplasia/dysplasia (urinary tract obstruction, vesico-ureteral reflux, prune belly syndrome). In the past, clinicians have been advised to perform renal ultrasonography to screen for renal malformation in infants with minor ear malformations (low-set ears, misshapen pinnae, preauricular tags or preauricular sinuses) but the cost-effectiveness of this approach is now questionable because the background prevalence of minor ear malformations is fairly high (7.5 per thousand) in the normal population (7, 8).

Current approaches to classification of human kidney hypoplasia/dysplasia must meld recent advances in the understanding of nephrogenesis with clinico-pathologic observations. In this chapter, we first consider isolated renal agenesis, renal dysplasia and pure hypoplasia as defects in primary initiation, nephron differentiation or ureteric bud branching, respectively. We then review the evidence that renal hypoplasia/dysplasia may be a feature of vesico-ureteral reflux and obstructive uropathy. Syndromes involving renal hypoplasia/dysplasia are many and will be tabulated elsewhere, but we will touch on a few examples of renal dysplasia which can be attributed to mutant genes. Finally, we will consider the genetic and environmental factors which are thought to account for subtle renal hypoplasia in a significant fraction of the normal population.

Renal Agenesis

Bilateral Renal Agenesis (BRA)

Bilateral failure of primary nephrogenesis during fetal life causes a characteristic pattern of facial compression and pulmonary hypoplasia (Potter syndrome) due to the absence of amniotic fluid. Most cases of the Potter syndrome are associated with obstruction of the urinary tract or severe bilateral renal hypoplasia, but primary

© Springer-Verlag Berlin Heidelberg 2009

bilateral renal agenesis (BRA) is estimated to occur in about 1 per 5,000 fetuses (9). If screening is performed in the second trimester by transvaginal ultrasound, the incidence appears to be even higher (1 per 705 fetuses) (10). Severe oligohydramnios, evident clinically or by ultrasonography in the second trimester (21–23 weeks), raises difficult issues for parents and the medical team about postnatal viability of the infant (11). High-resolution color Doppler ultrasonography is helpful to detect the fetal renal arteries, distinguishing severe renal hypoplasia from renal agenesis (12). Antenatal MRI has been used to detect the full range of renal malformations (13). BRA is often found in association with unilateral umbilical artery (14). Complete absence of renal parenchyma (renal agenesis) and amniotic fluid predicts that pulmonary hypoplasia will be extreme, often causing pneumothorax and/or inability to oxygenate without ventilatory support in the newborn period (*Fig. 5-4*).

In those who initially survive, the decision about whether or not to embark on chronic peritoneal dialysis is usually dominated by several key issues: A) whether lung development is sufficient to allow oxygenation without respiratory support beyond the first few perinatal days; B) whether there is any functional renal parenchyma (identifiable by MAG3 imaging and/or ultrasonography) allowing sufficient urine volume to permit minimal long-term oral nutrition (100 Kcal/kg/day); C) whether family/institutional resources can sustain dialytic therapy long enough to achieve growth to a body weight which allows renal transplantation. While once considerable hopeless, recent data suggest that aggressive renal replacement therapy is now at least an option. Klassen has reported a 70% survival rate among 23 infants with antenatal oligohydramnios and pulmonary hypoplasia, despite a requirement for ventilation in 16/23 for 1–60 days (15). Thus, there appears to be gradual improvement in lung function during the postnatal period. Among 193 NAPRTCS infants who began peritoneal dialysis within the first

month of life, 10% died during the initial dialytic period and another 15% died in a later phase – in some cases after renal transplantation (16). In the cohort from 1999–2005, 80% were transplanted within 3 years (16).

The causes of renal agenesis in humans are not well understood, but reports of absent renal arteries during the second trimester suggest arrest of kidney development at a very early stage. Study of homozygous "knockout" mice has identified a number of critical developmental genes causing experimental bilateral renal agenesis. For example, inactivation of GDNF (a growth factor expressed in the undifferentiated mesenchyme) or RET (the GDNF receptor which is expressed at the surface of ureteric bud cells) or its co-receptor, GFRα results in failure of primary ureteric bud outgrowth (17, 18). Knockout mice lacking key transcription factor genes such as PAX2 or WT1 are also anephric (19, 20). Presumably, homozygous mutations for any one of these genes could account for occasional "sporadic" cases of complete renal agensis in humans. Recently, Skinner et al. identified RET mutations in seven of nineteen stillborn fetuses with bilateral renal agenesis; no causative mutations of GDNF or GFRα were noted (21).

Unilateral Renal Agenesis (URA)

Estimates of the incidence of URA vary: 1 per 750 by transvaginal antenatal ultrasound screen (10); 1 per

1,000 in autopsy series (22); 1 per 1,300 by ultrasound screening of Taiwanese school children (5); 1 per 2,900 by ultrasound screening of North American infants (23). URA is more common in infants of diabetic mothers and among Afro-American mothers than in others (adjusted odds ratio of 4.98 and 2.19, respectively) (23). In a screening study of normal Japanese newborns, 52 of 4,000 newborns (1.3%) had evidence of unilateral hypoplastic/dysplastic kidneys; during follow-up of three of these cases, the abnormal renal tissue involuted in early postnatal life so that eventually no detectable kidney was evident (4). Thus, adults with "congenital" absence of one kidney may often be born with at least some partial, though abortive, renal tissue which regresses at an early stage.

URA is associated with developmental abnormalities of other tissues, particularly the inner ear, genital tract and axial skeleton. Among 40 girls with unilateral renal agenesis, 4/40 (10%) had an ipsilateral mild-moderate sensorineural hearing deficit and 14 (35%) had mullerian duct abnormalities (24). In a retrospective study of patients with mullerian duct abnormalities, 30% had unilateral renal agenesis (25); this association was particularly strong for girls with uterus didelphys (13/16 cases), uterine agenesis (2/5 cases) and unicornuate uterus (2/7 cases). URA was seen in all 11 cases of obstructed uterus didelphys, ipsilateral to the side of the obstructing transverse hemivaginal septum. The incidence of genital tract anomalies in boys with URA is reported to range from 12 to 77%; ipsilateral cystic dysplasia of seminal vesicles and bilateral absence of the vas deferens (with ipsilateral syndactyly) have all been described (26–28). In a prospective study, 202 patients with congenital vertebral abnormalities 54 (26.7%) had at least one genitourinary abnormality detected by intravenous pyelography or ultrasonography; the most frequent being unilateral renal agenesis (29). Although the pathogenetic mechanisms are not well understood, it is evident that defective developmental pathways or genes may disturb morphogenesis of mesenchyme in the ear, genital tract and skeleton, and it is not unreasonable to screen children with URA for these associated anomalies.

The mechanisms which might lead to complete absence of one kidney while sparing the other kidney are not obvious, but again there are lessons to be learned from knockout mice. While most mice lacking both copies of the Ret gene are anephric, a small percentage manage to achieve outgrowth of the ureteric bud and generate a small, though suboptimal, kidney on one side (17). Although counter-intuitive, this suggests that some cases of URA could in fact be caused by inherited mutant genes which affect the two kidneys unequally. In a study of 4,099 fetal/infant autopsies, dysplastic elements were found in 4% of kidneys overall, but, in patients with URA, dysplastic elements were found in 45% of contralateral kidneys. Occasional cases of autosomal dominant URA have been reported (30) and recently, Skinner and colleagues identified RET mutations in two of ten stillborn infants with URA (21). First degree relatives of patients with URA have considerably increased risk of either URA (5%) or BRA (0.8%) (9).

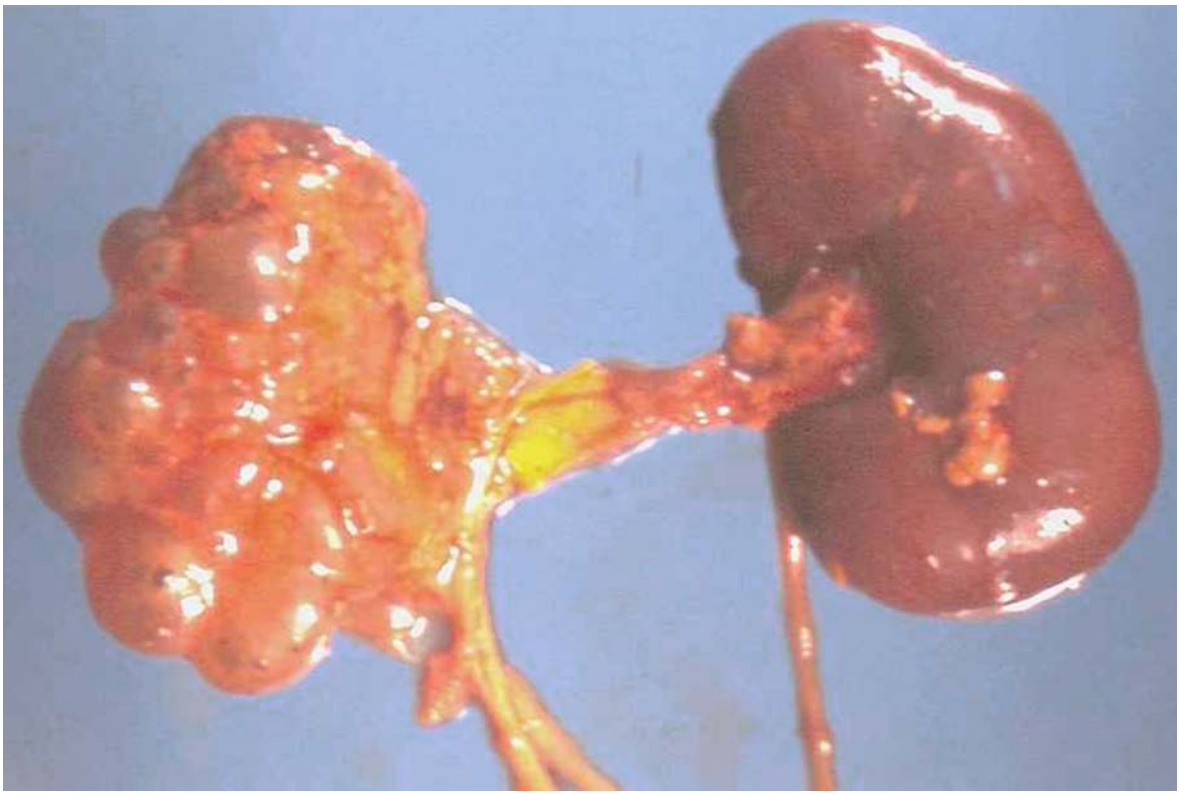
At birth, nephron number is suboptimal in children with URA and the contralateral kidney is stimulated to undergo compensatory hypertrophy. In most cases, plots of renal length or volume versus body length demonstrate gradual compensatory hypertrophy of the unaffected contralateral kidney over the first 3–4 months, crossing percentiles established for normal populations. Failure to undergo compensatory hypertrophy usually indicates contralateral renal dysplasia and may predict progressive renal insufficiency. Evidence of patchy dysplasia detectable by ultrasonography or renal scans is predictive of increased risk of hypertension in childhood. In a study of 29 cases of URA, the hypertrophied contralateral kidney had normal contour in 14 and "scarring" in 15 (31). Mild hypertension was detected by ambulatory blood pressure monitoring in 1/14 and 8/15 subjects, respectively (31). Finally, nuclear DMSA or MAG3 scanning may identify residual hypoplastic/dysplastic tissue instead of complete URA on the affected side. This is sometimes associated with hypertension which responds to excision of the dysplastic tissue.

Multicystic/Dysplastic Kidney (MCDK)

While URA implies a disruption of primary renal development, many infants are born with a unilateral multicystic/dysplastic kidney (MCDK) attached to an atretic ureter (*Fig. 5-5*). This suggests that initial ingrowth of the fetal ureteric bud may have been successful, but that renal development was disrupted at an later stage. MCDKs are recognized as clusters of multiloculated thin-walled cysts which do not appear to connect, distinguishing them from hydronephrotic kidneys. Nuclear scans often show little or no functional parenchyma and ureters are not usually patent, indicating little or no urine formation from an early stage in fetal life. The cystic mass usually lacks a reniform shape; the scanty tissue between cysts is hyperechoic and there is usually no detectable renal artery by Doppler ultrasonography. Microscopic analysis reveals disorganized renal architecture with islands of undifferentiated mesenchymal cells,

Figure 5-5

Non-functional multicystic/dysplastic right kidney and grossly normal-appearing left kidney from an infant who died in the perinatal period of non-renal causes. (See color plate 4)



occasional bizarre differentiation (e.g., cartilage) and few if any normal-appearing nephrons. Cysts are often rimmed by collars of fibromuscular cells. The incidence of unilateral MCDK is about 1 in 4,000 live births (32). Very rarely, bilateral MCDK has been reported and is fatal in the newborn period (33).

More recently, antenatal detection and long term follow-up studies of unresected MCKDs have suggested that the pathogenesis and prognosis for this entity is more complex than was initially appreciated. In about 15% of unilateral cases, postnatal nuclear scans show some minimal functional renal tissue amid the dysplastic areas, so complete absence of renal function is no longer the *sine qua non* (34). Numerous cases of localized (restricted to one pole) cystic dysplasia have been reported (35). More importantly, the contralateral kidney often (20–30% of cases) exhibits some form of limited dysplasia (36–38). About one quarter of contralateral kidneys exhibit vesico-ureteral reflux and this may be associated with recurrent urinary tract infections and progressive renal insufficiency (39). Careful evaluation of contralateral renal growth by serial postnatal ultrasonography, DMSA nuclear scans to detect foci of dysfunctional parenchyma and voiding cystourography to identify contralateral vesico-ureteral reflux may be considered to identify cases with significant contralateral dysplasia (40).

Because experimental obstruction may produce cystic dysplasia, it has been proposed that first trimester urinary tract obstruction might account for MCKD (32, 40). However, the putative obstruction would have to be intrarenal since MCKD ureters are atretic and lower tract obstruction could not explain cases of localized dysplasia. Furthermore, there are reports of autosomal dominant MCKD and chromosomal anomalies (41, 42) suggesting that failure of key genes can lead to MCDK by perturbing the normal pattern of nephrogenesis. A high incidence of subtle genital and other non-renal abnormalities suggest aberrations in shared developmental programs rather than urinary tract obstruction as the primary etiology (37, 38).

About 3% of children with unilateral MCKD develop hypertension (39); in some cases, hypertension resolves

when the dysplastic tissue is resected (43). Ectopic renin gene expression has been documented in macrophage-like interstitial cells (44). Although hypertension is not commonly identified in children with unilateral MCDK (<5%), its prevalence may be underestimated. Subtle abnormalities of blood pressure were found in 5 of 25 such children when studied by ambulatory blood pressure monitoring (45).

It has long been appreciated that MCKDs may undergo complete or partial involution, but the significance of this observation is not yet clear (46). Involution of MCKD tissue has been observed during fetal life and 20–25% of MCDKs involute completely in the first 1–2 years of postnatal life (47–49). When involution does not occur, the spectre of rare malignant transformation is raised. Multiple cases of Wilms tumor (about 3–10 fold increased incidence over the normal population) (50, 51) and renal cell carcinoma (52–55) arising from within the cystic tissue have been reported. On the other hand, because Wilms tumors grow rapidly, effective ultrasound screening would have to be done about every 3 months for 8 eight years (56); renal carcinomas may arise in adulthood. Several recent reports advise conservative management and routine early excision of MCDKs has become much less common than in the past (56, 57). However, the approach to MCKD tissue which does not involute is still made on an individual basis after discussion with the family.

Abnormalities of Kidney Position and Patterning

Variations in the gross architecture of the kidney are fairly common. Nearly 1% of patients undergoing ultrasonography are found to have duplex kidneys; of these 80% have ureteral duplication as well (58). However, there is no evidence that duplication of the collecting system by itself carries any associated morbidity. Very rarely, ectopic kidneys have been reported in the thorax, but these are usually functional and are identified when the unidentified chest mass is spotted incidentally (59).

Horseshoe kidneys represent the most common renal fusion abnormality and occur in every 400–800 individuals (60). They are unusually common (30%) in Turner syndrome (61). Horseshoe kidneys are usually found by ultrasonography but other imaging modalities are needed to identify the anomaly in about one third of cases. In one series, vesicoureteral reflux was noted in 32% and ureteropelvic junction obstruction obstruction in 23% (62). The risk of Wilms tumor is slightly increased in children with horseshoe kidney and there are over 40 reports of this association in the literature (63). However, regular screening for this complication is probably unwarranted. Although 0.5% of Wilms tumors arise within a horseshoe kidney, this is only about 3 times the expected incidence. The arterial supply to the horseshoe kidney is highly variable, presenting a special technical challenge for transplantation. Nevertheless, horseshoe kidneys can be transplanted into recipients en bloc or after division of the isthmus and success rate is equivalent to normal cadaveric transplantation with either approach (60).

Primary Renal Hypoplasia

Renal Coloboma Syndrome

Normal mature kidneys contain about 617,000 glomeruli with mean glomerular size of about 6 μ^3 (64). In the 1970's, pediatric nephrologists recognized a familial form of "oligomeganephronia" in which renal hypoplasia and progressive proteinuric renal failure in childhood were associated with unusually large but otherwise normal-appearing glomeruli (65). During the same period, an autosomal dominant syndrome of renal hypoplasia associated with colobomas of the optic nerve (Renal-Coloboma Syndrome) was also characterized (66). In 1995, Eccles showed that Renal-Coloboma syndrome (RCS) was caused by heterozygous mutations of the PAX2 gene and drew attention to the high frequency of vesico-ureteral reflux in affected families (67–69). When patients with oligomeganephronia were subsequently re-investigated, these patients also proved to have heterozygous PAX2 mutations, though the optic nerve abnormality is often barely detectable (70–72). About 20 different inactivating mutations of the PAX2 gene have been described and the most common (a single base-pair insertion in the second exon of PAX2) also causes RCS in the inbred *1Neu* mouse strain (73). Studies of fetal kidney development in *1Neu* mice have led to the hypothesis that a critical function of the PAX2 gene is to prevent apoptosis of cells in the branching ureteric bud during kidney development (74, 75). Absence of one PAX2 gene is sufficient to permit increased ureteric bud cell apoptosis, compromising nephron number by slowing the rate of branching nephrogenesis. Presumably, PAX2 function also influences structure of the uretero-vesical junction. In this form of primary renal hypoplasia, there is little evidence of dysplasia and glomerular hypertrophy is presumably the compensatory response to the deficit in nephron number.

Branchio-Oto-Renal Syndrome

Renal hypoplasia is seen in another autosomal dominant disorder, the branchio-oto-renal (BOR) syndrome (OMIM 113,650). The BOR syndrome combines variable degrees of renal hypoplasia with branchial arch defects (lateral cervical fistulas or cysts) and a hearing disorder associated with malformed auricle, atresia of the ear canal, anomalies of the middle ear and hypoplasia of the cochlea or semicircular canals) (76). The otic defects can usually be delineated by computerized axial tomography and/or nuclear magnetic resonance imaging to help with diagnosis (77). Most commonly, the BOR syndrome is caused by mutations of the EYA1 gene on chromosome 18q13.3 (78). About 80 different EYA1 mutations have been reported and each tends to be unique to a particular family (79). In a screen of 435 families with features of BOR syndrome, about 40% are associated with EYA1 mutations (79, 80). Renal hypoplasia may be very subtle or may cause end-stage renal failure between 12 and 36 years of age. EYA1 is the human homolog (chromosome 18q13.3) of a small family of transcription factors originally identified in Drosophila because of their importance to eye development, but in humans the eye is unaffected. Within the same family, heterozygous mutations of EYA1 may cause renal defects ranging from bilateral renal agenesis to mild unilateral hypoplasia (81). Although renal hypoplasia can be quite variable in BOR, children with branchial arch defects and normal kidneys (BO syndrome) are probably due to mutations of a different gene on chromosome 1q31 (82).

During normal renal development EYA1 is expressed in the metanephric mesenchyme and homozygous EYA1 knockout mice lack primary outgrowth of the ureteric bud with subsequent failure of nephron induction (83). The developmental pathway regulated by EYA1 also involves members of the SIX family of transcription factors (84); some families with BOR syndrome (<5%) are caused by mutations of the SIX1 or SIX5 genes (80, 85).

Renal Tubular Dysgenesis (RTD)

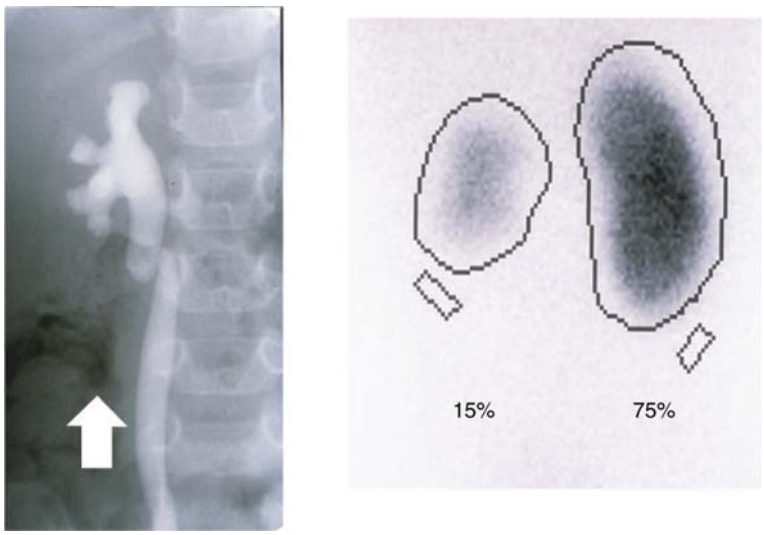
Renal hypoplasia can occasionally be restricted to specific segments of the nephron. Fetuses with autosomal recessive mutations of genes in the renin-angiotensin pathway are born with severe hypotension and Potter syndrome from failure to develop proximal tubules (86). Although glomeruli are relatively normal, the hypoplastic kidneys lack markers of differentiated proximal tubular cells; fetal oligo-anuria is accompanied by cranial hypoplasia (cranial suture diastasis) and survival past the neonatal period is unusual (87). However, it has been reported that infusions of fresh frozen plasma are effective in maintaining blood pressure and improving renal perfusion at birth (87). In one survivor treated with continuous infusion of FFP (1 ml/kg/hour) for 9 days and peritoneal dialysis from day 3, there was spontaneous recovery of urination at one month of age, allowing discontinuation of dialysis after two months (87). The syndrome is genetically heterogeneous and has been associated with autosomal recessive mutations of renin, angiotensin, angiotensin converting enzyme or type I angiotensin II receptor (86). Similar pathophysiology may be operative in children born to mothers taking high dose ACE inhibitors or AT II receprtor therapy for maternal hypertension.

Renal Dysplasia/Hypoplasia and Vesico-Ureteral Reflux

In 1973, Bailey first drew attention to children with urinary tract infection and vesico-ureteral reflux (VUR), who displayed "reflux nephropathy" (*Fig. 5-6*) involving distortion of renal calyces, patchy loss of renal parenchyma and, in some cases, progressive proteinuric renal disease leading to chronic renal failure (88, 89). Children with reflux nephropathy constitute 5% of pediatric renal transplant patients and 3.5% of pediatric dialysis patients in the NAPRTCS 2007 database. Since Bailey's original description, there has been an extensive and confusing literature concerning the pathogenesis of reflux nephropathy; the debate has focused on whether renal scars are acquired lesions due to VUR itself (and preventable by antireflux surgery) or from the aftermath of pyelonephritis (and preventable by prophylactic or early antibiotic therapy) or whether they are a congenital form of renal hypoplasia/dysplasia. It is generally agreed that VUR is associated with urinary tract infection, and that upper tract infection can occasionally lead to the appearance of new renal scars and that the severity of parenchymal loss correlates with the severity of VUR (90). However, reflux nephropathy is strongly familial (62, 91) and most renal "scars" are evident at the time of the first imaging studies (92, 93). Parenchymal defects are associated with VUR in utero (4) and most are recognizable prior to any proven urinary tract infection, particularly in male infants (94). Renal size estimated by magnetic resonance imaging is significantly reduced in children with unilateral or bilateral VUR compared to control children without VUR and correlates with severity of reflux (95). Interestingly, the presence of

Figure 5-6

Renal hypoplasia associated with ipsilateral vesico-ureteral reflux in a 2 year-old boy who presented with his first lower urinary tract infection. DMSA scintigraphy demonstrates normal reniform appearance of the hypoplastic parenchyma which contributes only about 10% of total renal function.



unilateral VUR predicts reduced renal size in both the refluxing and non-refluxing kidney (95).

A mechanistic link between abnormalities of the vesico-ureteral junction and dysplasia of the renal parenchyma is evident from the developmental biology of the urinary tract. During early fetal life, the two nephric (Wolffian) ducts migrate caudally toward the cloaca and, in response to a trophic signal (glial derived neurotrophic factor) from the adjacent mesenchyme, give rise to bilateral ureteric buds at sites corresponding to the future vesico-ureteral junctions. The ureteric buds arborize within the lateral metanephric mesenchyme, inducing nephrons at the tip of each branch. In 1975, Mackie and Stephens observed (by ureteroscopy) that many children born with duplex collecting systems and/or vesico-ureteral reflux also had malpositioned ureteric orifices (96). Recent animal studies have shown that the site of GDNF expression within metanephric mesenchyme and, thus, the site of ureteric bud outgrowth, is under complex regulation by various developmental genes including Pax2, Gdnf, Foxc2, Robo2 and Slt which are crucial for kidney development. In mutant mice, homozygous inactivation of the transcription factor gene Foxc2 causes anatomic abnormalities of the ureters associated with renal hypoplasia in about 60% of offspring (97). Foxc2 is normally expressed in the metanephric mesenchyme and is thought to be involved in guiding outgrowth of the ureteric bud (97). Interestingly the gross abnormalities were often unilateral (70–85% of offspring) and were highly dependent on the genetic background of the mice (97).

VUR and renal hypoplasia are seen in infants bearing heterozygous PAX2 mutations and renal-coloboma syndrome (98). However, this is rare and does not account for most cases of reflux nephropathy (98). More recently, Lu et al. identified a *de novo* translocation and two missense mutations affecting ROBO2 in several patients with renal anomalies and VUR (99). A subsequent study demonstrated ROBO2 missense mutations in about 5% of families with VUR and various congenital anomalies of the kidney and urinary tract (CAKUT) (100).

Renal Hypoplasia/Dysplasia and Fetal Urinary Tract Obstruction

Numerous observations indicate that antenatal obstruction of the urinary tract (UTO) may be associated with disturbances of normal nephrogenesis. Most commonly, renal hypoplasia/dysplasia is reported in males with posterior urethral valves but is also evident in other UTO settings such as prune-belly syndrome and urethral atresia (101–103). Dysplastic areas containing cysts, fibrotic interstitial zones and even islands of cartilage may be scattered amid fairly normal-appearing renal tubules. In fetal monkeys, obstruction produced by injection of agaral

beads into the collecting system at mid-gestation causes progressive diminution in renal size associated with evidence of apoptosis (particularly of collecting duct and glomerular cells), cysts with pericystic fibrotic collars and a defect in branching of the ureteric bud (104). Thus, although the molecular mechanisms are not yet well-understood, fetal UTO appears to modify survival of selected cell lineages and affect signals regulating developmental cell fates. Timing of the fetal obstruction may be important; very early (50 days gestation) obstruction of the urinary tract in lambs causes severe hypoplasia and interstitial fibrosis, whereas obstruction at 60 days results in a larger, cystic kidney with less fibrosis (105). In humans, striking obstruction has sometimes been reported in association with "normal" renal histology, prompting the speculation that UTO late in fetal life may have less effect on determinants of developmental cell fate (106).

As in other forms of renal hypoplasia/dysplasia, the risk of progressive renal insufficiency due to congenital UTO is highly influenced by the number of functioning nephrons at birth. The likelihood of developing end-stage renal disease ranges from 22% to 70% in various studies of boys with posterior-urethral valves and a key predictor of long-term outcome is serum creatinine level one year after relief of obstruction (103, 107). In 29 patients with the prune belly syndrome (deficient abdominal musculature, evidence of UTO, and cryptorchidism), about 1/3 die in the perinatal period from the Potter syndrome; among smaller portions of the renal parenchyma were dysplastic, but most develop end-stage renal disease (108).

Syndromic Renal Hypoplasia/Dysplasia

Renal dysplasia is associated with many different recognizable patterns of malformation, presumably involving genes or developmental pathways shared by multiple organs. Although a more complete list appears elsewhere, several syndromes of interest will be mentioned briefly. Mutations in the hepatocyte nuclear factor (HNF)-1beta gene (TCF2) are responsible for an autosomal dominant syndrome characterized by maturity-onset diabetes of the young, nondiabetic progressive nephropathy, genital malformations, and liver dysfunction (109). The HNF1beta gene is normally expressed in the Wolffian duct, metanephric tubules and Mullerian during fetal life; its absence results in a form of cystic renal dysplasia in which glomerular number is significantly reduced (110, 111). Interestingly, early onset progressive nephropathy may be seen without evidence of diabetes mellitus in some cases and renal dysplasia is quite variable, producing renal hypoplasia on one side with cystic dysplasia in the contralateral kidney (111).

Renal dysplasia is also part of the autosomal dominant HDR syndrome (hypoparathyroidism, deafness and renal anomalies) caused by mutations of another transcription factor gene, GATA3 (112) and is part of the Bardet Biedl syndrome caused by mutations at six different loci including the MKKS gene (113). Other monogenic syndromes with renal dysplasia include, Townes-Brock syndrome (SALL1 gene) (114) and nail-patella syndrome (LMX1B gene) (115).

Variable degrees of renal dysplasia have been described in numerous syndromes for which the etiology is unknown. The causes of the VATER syndrome (vertebral defects, anal atresia, tracheoesophageal fistula and renal dysplasia) are thought to be heterogeneous but presumably identify a common developmental pathway in these tissues (116). In the VACTERL syndrome (with additional limb and cardiac defects), 93% of patients have either vesicoureteral reflux in 39%, unilateral aplasia (23%) or unilateral multicystic dysplasia (7%) (117). Similarly renal dysplasia may be seen in association with developmental defects in the pancreas and liver (Ivemark syndrome) (118), jejunal atresia (119), encephalocoele (Meckel syndrome) (120) and with pancreatic fibrosis, liver dysgenesis and situs inversus (121). In Perlman syndrome, renal dysplasia and Wilm's tumor are associated with fetal gigantism and multiple congenital anomalies (122, 123).

Genetic and Environmental Causes of Subtle Renal Hypoplasia

Genetic influences on kidney size. Among "normal" humans, nephron number varies five-fold (1, 64, 124). While once dismissed as a benign reflection of human diversity, Brenner et al. proposed that individuals born at the low end of the nephron endowment spectrum may have increased risk of developing "essential" hypertension and renal insufficiency later in life (125, 126). They hypothesized that signals driving compensatory hypertrophy of overworked nephrons cause glomerulosclerosis and a cycle of subtle, slowly progressive renal dysfunction (127).

Recent evidence supports this theory; an autopsy study by Keller et al. showed that German adults with essential hypertension had 47% fewer nephrons per kidney than well-matched normotensive controls (128). As predicted, hypertensive subjects had hypertrophic glomeruli (glomerular volume = 233% of controls) and increased glomerulosclerosis (5.5% of glomeruli vs. 0%

in controls). Other evidence suggests that racial differences in congenital nephron number might also explain the relatively high incidence of end-stage renal disease in Aboriginal vs. Caucasian populations (129). At autopsy, Aboriginal subjects had 23% fewer glomeruli (683,174/kidney) than Caucasians (885,318/kidney) ($p < 0.04$).

Little is known about the factors which set nephron number, but the GDNF/RET signaling pathway appears to play a central role. GDNF released from metanephric mesenchyme elicits outgrowth of ureteric bud cells bearing its receptor (RET) (130); homozygous *Ret* knockout mice are anephric (17). Both GDNF and RET are expressed during kidney development (*Fig. 5-7*) under the control of the transcription factor, PAX2 (131). Recently, it was found that 15% of human neonates bearing genetic variants of the *PAX2* and *RET* genes are born with kidneys which are 25% smaller than those with the more common alleles (132). It is not yet known whether these genes or the modest reduction in kidney size affect risk for hypertension or susceptibility to renal injury later in life.

Environmental influences on kidney size. Fifty years ago, Wilson reported that severe vitamin A (retinol) deficiency causes renal agenesis (133, 134). More recent observations indicate that even modest maternal retinol deficiency (50% reduction in circulating levels of retinol) can cause significant renal hypoplasia in rodents; postnatal kidney weight is decreased by 24% and nephron number is reduced by 20% (135). Normally, the fetus acquires retinol from the maternal circulation and converts it to an active metabolite, all-trans retinoic acid (atRA), in the kidney and other peripheral tissues (136). In fetal rat kidneys cultured ex vivo, all-trans retinoic acid (0.1–1 μM), accelerates new nephron formation by 2–3 fold (137, 138). In many developing countries, Vitamin A deficiency is widespread but and in North America most pregnant women (99%) have retinol levels in the normal range. Interestingly, newborn kidney size (factored for body size) is 40% smaller in Bangalore, India (where 40% of women were found to have gestational vitamin A deficiency) compared to newborns from Montreal (139). It is not yet known whether this form of subtle renal hypoplasia is directly due to maternal vitamin A deficiency or some other factor.

As discussed above, neonates with mutations of genes in the renin-angiotensin system pathway develop Potter Syndrome and proximal tubular agenesis (86). Similarly, infants born to mothers who receive angiotensin converting enzyme inhibitors during pregnancy have high risk of oligohydramnios and renal insufficiency in the newborn period (140).

Figure 5-7

Initiation of kidney development in a fetal mouse bearing a HoxB7/GFP transgene to identify nephric duct and early ureteric bud. Gdnf production by the metanephric mesenchyme and expression of Ret receptors in the ureteric bud lineage are indicated.

6 Syndromes and Malformations of the Urinary Tract

Chanin Limwongse

Introduction

Birth defects involving the kidney and urinary system are often encountered and frequently occur in association with other structural abnormalities. A congenital urinary tract anomaly may provide the first clue to the recognition of multiorgan developmental abnormalities. Nevertheless many renal anomalies remain asymptomatic and undiagnosed. Therefore it is critical, not only for pediatric nephrologists but also for pediatricians in general, to be familiar with the common anomalies involving the kidney and urinary system and the more complex disorders with which they may be associated.

The kidney is a pivotal organ in dysmorphology. Although the number of single malformations involving the kidney is limited, combinations of these malformations in conjunction with anomalies involving other organ systems are found in more than 500 syndromes. In addition, many well-known sequences and associations involve the kidney and urinary tract. This chapter discusses common malformations, sequences and associations involving the kidney and urinary tract, and provides a summary of conditions that have these anomalies as one of their features. In addition, *Tables 6-1–6-3* summarize more detailed information about a large number of disorders, including their phenotypic features, reported urinary tract anomalies, pattern of inheritance, causative genes and related references. These tables can be used both to provide readily available information about potential urinary tract anomalies for patients with a diagnosed genetic syndrome and to suggest a differential diagnosis when anomalies are identified. Readers interested in additional details about a specific syndrome are referred to standard reference textbooks and databases about syndromes and malformations for further reading (e.g., (5–7)).

To understand the pathophysiologic basis of structural abnormalities, it is important to be familiar with the meaning of certain terms as they are used in describing malformations and syndromes.

Malformation refers to a single structural anomaly that arises from an error in organogenesis. Such an error may be due to the failure of cells or tissues to form, to die (programmed cell death), or to induce others. Examples include renal agenesis, horseshoe kidney, and bladder exstrophy.

Deformation refers to a single structural anomaly that arises from mechanical forces, such as intrauterine constraint. Examples include many cases of metatarsus adductus, torticollis, and congenital scoliosis. The underlying tissue may be normal or abnormal, and sometimes a malformation (e.g., renal agenesis) can predispose patients to a deformation (e.g., Potter's sequence from oligohydramnios).

Disruption refers to a single structural anomaly, that results from a destructive event after normal morphogenesis. Such events can be caused by lack of vascular supply, an infectious process, or mechanical factors. Examples include limb amputation from amniotic bands and abdominal wall defect from vascular insufficiency related to maternal cocaine use.

Sequence refers to a cascade of abnormalities that result from a single initiating anomaly. Sequences can be malformational, deformational, or disruptive, and they sometimes represent more than one of these categories. Obstruction of urine flow at the level of the ureter during early gestation, for example, can cause malformation of the kidneys, intestines, and abdominal wall – a malformation sequence. At the same time, decreased urine flow will produce oligohydramnios, fetal compression, and multiple deformities of the face, limbs, and chest wall – a deformation sequence.

Syndrome refers to a consistently observed pattern of anomalies found in an individual, whether malformation, deformation, or disruption. Anomalies comprising a syndrome are thought to have a single cause, although in many cases, their causes are still unknown. Examples include Turner syndrome and fetal alcohol syndrome.

Association refers to a constellation of anomalies that occur together more often than expected by chance alone but cannot be explained by a single cause or sequence of events, and so do not represent a syndrome or sequence. VATER association, which is discussed later in this chapter, is a common example.

Table 6-1

Syndromes and disorders that have urinary tract anomalies as a frequent feature

Syndromes	Urinary tract abnormalities											Other associated anomalies	Other associated anomalies	Gene(s)	Ref.
	Renal agenesis	Ectopia/ horseshoe	Cystic/dysplasia	Duplication	Hypoplasia	Hydronephrosis/ ureter	Diverticulae	Atresia/stenosis	Reflux	Nephritis/ sclerosis	Tumor/ nephromegaly				
Abruzzo-Erickson		H										Coloboma, cleft palate, hypospadias, deafness, short stature	XR	Unk	(48)
Acrocephalopolydactylous dysplasia (Elejalde syndrome)			+		+	+						Acrodactyly, hand hexadactyly, overgrowth, visceromegaly, globular body, redundant neck skin	AR	Unk	(49)
Acrorenal (Dieker)	1	E		+	+	+	Ua					Ectrodactyly, oligodactyly, hypoplastic carpal/tarsal bones	Sporadic	Unk	(50)
Acrorenal (Johnson-Munson)	1, 2					U, Ua						Aphalangy, hemivertebrae, genital/ intestinal/anal dysgenesis	AR	Unk	(50)
Acrorenal (Siegler)		E				+		U	+			Short stature, hypoplastic radii/ ulnae/humeri, oligodactyly	Uncertain	Unk	(50)
Acro-renal-mandibular	1		+									Ectrodactyly, hypoplastic mandible	AR	Unk	(51)
Acro-renal-ocular	1	E			+		B					Hypoplastic thumb, optic coloboma, cleft lip/palate	AD	SALL4	(52)
Adrenoleukodystrophy, neonatal												See Pseudo-Zellweger			
Aglossia-adactylia	1											Micrognathia, cranial nerve palsy	Sporadic	Unk	(53)
Agnathia-holoprosencephaly		H				+						Arrhinencephaly, situs inversus, midline defects	Sporadic	Unk	(54)
Alagille	1		+	+						+		Cholestasis, peripheral pulmonic stenosis, characteristic face	AD	JAG1	(55)
Alport										+		Nephritis, proteinuria, deafness	AD, AR, XL	COL4	(56)
Alsing										+		Nephritis, nephronophthisis, optic coloboma, hip dislocation	AR	Unk	(57)
Alstrom										+		Diabetes mellitus, retinopathy, short stature, deafness	AR	ALMS1	(58)

Amelogenesis imperfecta type IG										+		Enamel hypoplasia, nephrolithiasis, enuresis	AR	Unk	(59)
Amyloidosis type 5										+		Nephropathy, proteinuria, cranial nerve palsy, cutis laxa	AD	GELSOLIN	(60)
Angiotensin converting enzyme (ACE) inhibitor, maternal use										+		IUGR, oligohydramnios, patent ductus arteriosus, limb anomalies, renal artery stenosis, progressive renal failure	Sporadic	none	(61)
Aniridia-Wilms tumor (WAGR)											+	Aniridia, ambiguous genitalia, hypospadia, short stature	AD	WT1	(62)
Axial mesodermal dysplasia	1											Bladder exstrophy, vertebral anomalies, Goldenhar-like	Uncertain	Unk	(63)
Baldellou	1											Hypoparathyroidism, ocular coloboma, MR, seizures	Uncertain	Unk	(64)
Baller-Gerold	+	E	+		+							Craniosynostosis, radial aplasia, malformed ear, anal atresia	AR	RECQL4	(65)
Barakat										+		Mesangial sclerosis, MR, optic atrophy, nystagmus	AD	GATA3	(66)
Bardet-Biedl			+	+		+	+		+	+		Obesity,polysyndactyly, MR, retinopathy, hypogonadism	AR	BBS1-12	(67, 68)
Beckwith-Wiedemann		E	+	+		+					+	Overgrowth, macroglossia, omphalocele, embryonal tumors	Sporadic, AD	CDKN1C, NSD1, H19	(69–72)
Berardinelli						+					+	Insulin resistance, lipodystrophy, acanthosis nigricans, MR	AR	BSCL2	(73)
Brachymesomelia-renal			+									Micrognathia, corneal opacity, craniofacial dysmorphism	Uncertain	Unk	(74)
Branchio-oculo-facial	1											Philtrum hypertrophy, cleft lip/palate, branchial remnant	AD	TFAP2A	(75)
Branchio-oto-renal	1, 2	E	+	+	+	+			+			Branchial remnant, preauricular pit/tag, microtia, deafness	AD	EYA1, SIX5	(76)
Braun-Bayer				+				U		+		Deafness, bifid uvula, digital anomalies	Uncertain	Unk	(77)
Cat eye												See *Table 6-3*	Chromosomal		
Caudal duplication	1, 2	E		+		+			+			Duplication of colon, sacrum, genitalia, vertebral defects	Sporadic	AXIN1	(78)
Caudal regression	1, 2	E, H			+	+	Ua		+			Atresia of colon, anus, genitalia, vertebral defects, TE fistula	AD, AR	VANGL1	(79–80)

Table 6-1 (Continued)

Syndromes	Urinary tract abnormalities											Other associated anomalies	Other associated anomalies	Gene(s)	Ref.
	Renal agenesis	Ectopia/ horseshoe	Cystic/dysplasia	Duplication	Hypoplasia	Hydronephrosis/ ureter	Diverticulae	Atresia/stenosis	Reflux	Nephritis/ sclerosis	Tumor/ nephromegaly				
Cerebro-hepato-renal (Passarge)			+									See Zellweger syndrome	AR	PEX	(81)
Cerebro-oculo-hepato-renal			+									Cerebellar hypoplasia, hepatic fibrosis, Leber amaurosis	AR	Unk	(82)
Cerebro-osteo-nephro dysplasia			+							+		Rhizomelic limb shortening, cerebral atrophy, MR, seizures	AR	Unk	(83)
CHARGE	+	E	+		+	+	+	U	+			See text for details	Sporadic, AD	CHD7	(33–37)
Chondroectodermal dysplasia (Ellis van Creveld)	1		+			+				+		Acromelic dwarfism, polydactyly, nail dystrophy, tooth hypoplasia narrow thorax, CHD	AR	EVC, EVC2	(84–85)
Cocaine, maternal use	1, 2				+	+	Ua		+			Vascular disruption anomalies affecting multiple organs	Sporadic	none	(86)
Cornelia de Lange	1		+		+	+					+	SS,microcephaly, limb defect, hirsuitism, synophrys	Sporadic	NIPBL, SMC1L1	(87)
Crossed renal ectopia-pelvic lipomatosis		E				+		U				Clubbing of fingers, gynecomastia	Uncertain	Unk	(88)
Czeizel						+		U				Ectrodactyly, spina bifida, megacystis	AD	Unk	(89)
Diabetic mother, infant of	1, 2	E, H	+	+	+	+	Ua		+			Neural tube defect, cardiac/limb anomalies, sacral agenesis	Sporadic	none	(90–91)
DiGeorge/velocardiofacial	1, 3	E		+	+	+		+	+			See *Table 6-3*	Chromosomal		
Denys-Drash		E		+						+	+	Pseudohermaphroditism, Wilms tumor, proteinuria	Sporadic	WT1	(92)
Down												See *Table 6-3*	Chromosomal		
Ectrodactyly-ectodermal dysplasia-clefting (EEC)	1		+	+		+			+			Ectrodactyly, hypohidrosis, sparse hair, cleft lip/palate	AD	Unk	(93)

Elejalde												See acrocephalopolydactylous dysplasia			
Epstein										+		Thrombocytopenia, nerve deafness, cataract	AD	MYH9	(94)
Facio-cardio-renal		H				+		U				Cardiomyopathy, conduction defect, MR, typical face	AR	Unk	(95)
Fanconi anemia	1	E, H	+	+	+	+						Pancytopenia, limb defects, leukemia, lymphoma	AR	FANCA-N	(96–97)
Fetal alcohol	1	E, H	+	+	+	+						IUGR, DD, microcephaly, short palpebral fissure	Sporadic	none	(98)
Fibromatosis, infantile					+						+	Multiple myofibromatosis, myositis ossificans	AR	Unk	(99)
Fraser cryptophthalmos	1, 2		+					U				Fused eyelids, ear/genital anomalies, syndactyly	AR	FRAS1	(100)
Frasier					+					+		Male pseudohermaphrodite, amenorrhea, ovarian cysts	AD	WT1	(101)
Goeminne			+							+		Congenital torticollis, keloids, cryptorchidism	XR	Unk	(102)
Goldenhar (oculo-auriculo-vertebral)	1	E	+	+	+	+			+			Hemifacial microsomia, ear anomalies, vertebral defects	Sporadic, AD	Unk	(103)
Goldston			+									Dandy-Walker malformation, cerebellar malformation	Uncertain	NPHP3	(104)
Graham			+								+	Cystic hamartoma of lung and kidney	Sporadic	Unk	(105)
Hemifacial microsomia (oculo-auriculo-vertebral)												See Goldenhar syndrome			
Hemihyperplasia			+								+	Asymmetry, vascular malformation, embryonal tumors	Sporadic	LIT1, H19	(106)
Hepatic fibrosis			+									Congenital hepatic fibrosis	Sporadic	PKHD1	(107)
Holzgreve	2											Potter sequence, cardiac defect, polydactyly, cleft palate	Uncertain	Unk	(108)
Hypertelorism-microtia-clefting		E		+								Microcephaly, cleft lip/palate, MR	AR	Unk	(109)
Ivemark	1		+		+	+						Poly/asplenia, complex CHD, laterality defects	Sporadic, AR	Unk	(110)
Jeune			+									Narrow chest, short limbs, polydactyly, glomerulosclerosis	AR	EVC, EVC2	(84–85)

Table 6-1 (Continued)

Syndromes	Urinary tract abnormalities											Other associated anomalies	Other associated anomalies	Gene(s)	Ref.
	Renal agenesis	Ectopia/ horseshoe	Cystic/dysplasia	Duplication	Hypoplasia	Hydronephrosis/ ureter	Diverticulae	Atresia/stenosis	Reflux	Nephritis/ sclerosis	Tumor/ nephromegaly				
Joubert			+									Vermis aplasia, apnea, jerky eyes, retinopathy, ataxia	AR	JBTS1-7	(111)
Juberg-Hayward		H			+							Microcephaly, cleft lip/palate, abnormal thumbs/toes	AR	Unk	(112)
Kabuki		H		+		+		U	+			MR, characteristic Kabuki-like face, large ears, cleft palate	Uncertain	Unk	(113)
Kallmann	1				+							Anosmia, cleft lip/palate, hypogonadotrophic hypogonadism	AD, AR, XR	KAL1-4	(114)
Kaufman-McKusick		E	+	+		+		Ua				Hydrometrocolpos, polydactyly, anal/urogenital sinus defect	AR	GLI3	(115)
Kivlin		E		+								Short stature, Peters' anomaly, MR, genital/cardiac defects	AR	B3GALTL	(116)
Klippel-Feil	1	E		+								Short neck, cervical vertebral fusion, low posterior hairline	Sporadic, AD	Unk	(117)
Kousseff	1											Sacral meningocele, hydrocephalus, cardiac defects	AR	Unk	(118)
Leprechaunism (Donohue)			+								+	Insulin resistance, lipodystrophy, hirsutism	AR	INSR	(119)
Limb-body wall complex	1	E	+			U, Ua						Lateral body wall defect, limb reduction, CHD	Sporadic	Unk	(120)
Mammo-renal				+								Ipsilateral supernumerary breasts/ nipples	Sporadic	Unk	(121)
Marden-Walker			+		+							Microcephaly, blepharophimosis, micrognathia, contractures	AR	Unk	(122)
Meckel-Gruber			+		+	U, Ua						Encephalocele, cardiac defects, cleft lip/palate, polydactyly	AR	MKS1-4	(123)
Megacystis-microcolon						+		U				Large bladder, intestinal hypoperistalsis, oligohydramnios	AR	Unk	(124)

Melnick-Needles osteodysplasty						+		U				Bowing long bones, short upper limbs, micrognathia	XR	FLNA	(125)
Mendelhall											+	Insulin resistance, acanthosis nigricans	AR	INSR	(126)
Microgastria-upper limb anomaly	1	E			+							Hypoplastic spleen, limb reduction defects	Uncertain	Unk	(127)
Miranda	+		+									Brain malformation, liver dysplasia	Uncertain	Unk	(128)
Moerman	1		+	+	+	+						Short limbs, brain malformation, cleft palate	Uncertain	Unk	(129)
MURCS association	1	E	+					U				See text for details	Sporadic	Unk	
Nager acrofacial dysostosis	+			+		+			+			Facial bone hypoplasia, cleft eyelid, radial ray defect	AD	Unk	(130)
Nail-patella										+		Absent/hypoplastic nails and patellae	AD	LMX1B	(131)
Neu-Laxova	1											IUGR,lissencephaly, CHD, pterygia, ichthyosis	AR,sporadic	Unk	(132)
Neuro-facio-digito-renal	1											Prominent forehead with vertical groove, MR, ear anomaly	Uncertain	Unk	(133)
Neurofibromatosis type I	1							Ua			+	renal artery stenosis, hypernephroma, cafe-au-lait spots	AD	NeUnkro fibromin	(134)
Nezelof			+							+		Arthrogryposis, hepatic impairment, hypotonia, club feet	AR	Unk	(135)
Noonan			+	+		+						Webbed neck, short stature, MR, pulmonic stenosis	AD	NS1	(136)
Occipital horn						+	B	Ua				Cranial exostosis, hyperextensibility, cutis laxa	XR	cUnkATPase	(137)
Ochoa				+		+	B U, Ua +					Facial grimacing with lateral displacement of mouth	Uncertain	Unk	(138)
Oculo-auriculo-vertebral												See Goldenhar syndrome			
Oculo-hepato-encephalo-renal			+		+							Encephalocele, hepatic fibrosis, coloboma	AR	Unk	(82)
Oculo-renal-cerebellar										+		MR, spastic diplegia, choreoathetosis, retinopathy	AR	Unk	(139)
Oculorenal												See Pierson syndrome			
Oculorenal (Karcher)	1				+					+		Optic nerve coloboma	AD	Unk	(140)

Table 6-1 (Continued)

Syndromes	Urinary tract abnormalities											Other associated anomalies	Other associated anomalies	Gene(s)	Ref.
	Renal agenesis	Ectopia/ horseshoe	Cystic/dysplasia	Duplication	Hypoplasia	Hydronephrosis/ ureter	Diverticulae	Atresia/stenosis	Reflux	Nephritis/ sclerosis	Tumor/ nephromegaly				
OEIS (omphalocoele-exstrophy of bladder-imperforate anus-spinal dysraphism) complex			+			+		Ua	+			Malrotation of colon, sacral defect, tethered spinal cord, pelvic bone abnormalities	Sporadic	Unk	
Otorenal			+			+	+	U				Renal pelvis diverticulae, nerve deafness	AD	Unk	(141)
Pallister-Hall	1, 2	E, H	+			+						Hypothalamic hamartoblastoma, polydactyly	AD	GLI3	(142–143)
Pierson			+									Hypoplastic retina, cataract, anterior chamber anomalies	AR	LAMB2	(144)
Penoscrotal transposition		E	+		+	+	B	U				Abnormal placement of external genitalia	Sporadic	Unk	(145)
Perlman			+	+		+				+	+	Early overgrowth, typical face, nephroblastomatosis	AR	Unk	(146)
Polydactyly-obstructive uropathy						+	Ua		+			Post-axial polydactyly of hands and feet	Uncertain	Unk	(147)
Potter (oligohydramnios)	1, 2		+		+			Ua				See text for details	Sporadic	Unk	
Prune belly			+	+		+	Ua		+			See text for details	Sporadic	Unk	
Pseudo-Zellweger			+								+	Hypotonia, seizures, MR, typical face, FTT, hepatomegaly	AR	PTS1	(148–150)
Pyloric stenosis		H	+	+	+	+						Cystic kidney	Sporadic	Unk	(151)
Rass-Rothschild	+					+						Klippel-Feil anomaly, sacral agenesis, cryptorchidism	Uncertain	Unk	(152)
RAPADILINO						+						Radial/patella hypoplasia, diarrhea, short stature, long nose	AR	RECQL4	(153)
Renal/Mullerian hypoplasia		H			+				+			Absent uterus, broad forehead, DD, large fontanel	AR	Unk	(154)

Renal dysplasia or adysplasia	1	E	+		+	+	Ua		+			Abnormal uterus in some patients	AD	RET, UnkPK3A	(155)
Renal-hepatic-pancreatic dysplasia			+									Pancreatic cysts, extrahepatic biliary atresia, Caroli disease	AR	EVC, EVC2	(84–85)
Retinoic acid, maternal use					+	+		U				Ear anomalies, CHD, cleft palate, neural tube defect	Sporadic	none	(156–157)
Roberts	1	H	+			+						Limb reduction, oligo/syndactyly, CHD, dysmorphic face	AR	ESCO2	(158)
Robson										+		MR,macrocephaly, deafness, proteinuria, Alport-like	XR	COL4A	(159)
Rokitansky-Mayer-Kuster-Hauser	1	E	+	U	+							Absence of vagina, uterine anomalies, amenorrhea	Sporadic	Unk	(160)
Rubella, congenital	1		+	+								CHD, MR, deafness, cataract, growth retardation	Sporadic	none	(161)
Rubinstein-Taybi	1	E	+	+	+			Ua				SS, MR, broad thumbs and great toes, typical face	Sporadic	CREBBP	(162–163)
Russell-Silver						+		Ua				SS, triangular face, asymmetry, clinodactyly, hypoglycemia	Sporadic,AD	Unk	(164)
Santos	1											Hirschsprung disease, hearing loss, postaxial polydactyly	AR	Unk	(165)
Say			+									SS,microcephaly, micrognathia, large ear, cleft palate	AD	Unk	(166)
Schimke										+		SS,spondyloepiphyseal dysplasia, immunodeficiency	AR	SMARCAL1	(167)
Schinzel-Giedion		E		U		+		U				CHD, distinctive face, figure 8 head shape, eyelid groove	AR	Unk	(168)
Senior-Loken			+							+		Nephronophthisis, tapeto retinal degeneration	AR	NPHP1,4,5	(169)
Setleis						+		U				Cutis aplasia with temporal scarring, abnormal eyelashes	AD,AR	Unk	(170)
Short rib, Beemer Langer			+		+	+		U				Hydrops, cleft lip, bowed long bones, atretic ear canal	AR	Unk	(171)
Short rib-polydactyly, type 1–3	1		+					Ua				Urethral fistula, CHD, cloacal/ urogenital sinus anomalies	AR	Unk	(171–172)
Silverman (dyssegmental dwarfism)						+		U				SS, flat face, cleft palate, generalized skeletal dysplasia	Uncertain	HSPG2	(173)
Simopoulos			+									Hydrocephalus, polydactyly	AR	Unk	(174)

Table 6-1 (Continued)

Syndromes	Urinary tract abnormalities											Other associated anomalies	Other associated anomalies	Gene(s)	Ref.

Table 6-2

Well-known syndromes associated with occasional urinary tract anomalies

Syndromes	Renal agenesis	Ectopia/ horseshoe	Cystic/ dysplasia	Duplication	Hypoplasia	Hydro-nephrosis/ ureter	Diverticulae	Atresia/ stenosis	Reflux	Nephritis/ sclerosis	Tumor/ nephro-megaly	Other Associated Anomalies	Inheritance Pattern	Gene(s)	Reference.
Aase								Ua				Triphalangeal thumb, hypoplastic anemia	AD,AR	RPS19, 24	(200)
Achondrogenesis				+		+						Micromelic dwarfism, short trunk, fetal hydrops	AR	COL2A1	(201)
Acrocallosal	1		+									ACC, macrocephaly, polymicrogyria, polydactyly, CHD	AR	GLI3	(202)
Acro-facial dysostosis		H			+							Abnormal thumb/toe, facial bone defect,ear anomalies	AR	Unk	(203)
Acromelic frontonasal dysplasia		E		+								Polydactyly, ACC, encephalocele, Dandy-Walker anomaly	Sporadic	Unk	(204)
Adrenogenital	1			+		+						Ambiguous genitalia, vomiting,salt losing,UPJ obstruction	AR	CYP11,21	(205)
Adrenal hypoplasia-MR						+		U	+			Aminoaciduria, MR, muscular dystrophy, visual abnormality	X-linked	NROB1	(206)
Antley-Bixler		H		+								Craniosynostosis, radio-humeral synostosis, cardiac defects	AR	FGFR2	(207)
Apert (acrocephalo-syndactyly)			+			+						Acrocephaly, craniosynostosis, syndactyly	AD	FGFR2	(208)
Bloom											+	Short stature, telangiectasias, leukemia, lymphoma	AR	BLM	(209)
Bowen-Conradi		H		+								Micrognathia, arthrogryposis, cloudy cornea, brain anomaly	AR	Unk	(210)
Brachydactyly type E	1				+							Vertebral anomalies, narrow auditory canal	Uncertain	HOXD13	(211)
3C (Ritscher-Schinzel)						+						SS,Dandy-Walker anomaly,typical face, CHD	AR	Unk	(212)

C-trigonocephaly	1											Polysyndactyly, abnormal ear, hypospadias, dislocated joints	AR	CD96	(213)
Campomelic dysplasia	1		+			+						Tibial bowing, pretibial dimples, ambiguous genitalia	AD	SOX9	(214)
Carbohydrate deficient glycoprotein			+									FTT, abnormal fat pad, hepatosplenomegaly, neurodegeneration	AR	PMM2, MPI	(215)
Carpenter										+		Aminoaciduria, polysyndactyly, craniosynostosis	AD	RAB23	(216)
CHILD	1,2					+						Unilateral erythroderma, ipsilateral limb defect	X-linked	NSDHL	(217)
Chondrodysplasia punctata, non-rhizomelic			+									Flat face, microcephaly, cataract, short femora/humeri, stippled epiphyses	AR	Unk	(218)
Coffin-Siris	1					+						MR,sparse scalp hair, hirsutism,coarse face, thick lips	AR	Unk	(219)
Cutis la+a type I							B					GI tract diverticulae, emphysema, diaphragmatic defect	AR	FBLN5	(220)
Disorganization-like	+											Polydactyly, duplication of lower limbs, skin appendages	Sporadic	Unk	(221)

Prevalence of Urinary Tract Anomalies

The true incidence of urinary tract anomalies is difficult to ascertain because many anomalies are asymptomatic and therefore undetected. Many reported statistics have apparent bias of ascertainment because they are derived from symptomatic individuals. Furthermore, inconsistent terminology and clustering of data have decreased the power of much of the epidemiologic data. Long-term analysis of data collected through major national birth defect registries showed increasing prevalence of reported statistics for many congenital birth defects, not only from an actual increment but also from increased tendency to report several isolated and associated anomalies (1–4). For this reason, the practical use of the derived prevalence seems not to be meaningful. However, there currently are quite a number of reliable estimates for prevalence of specific isolated anomalies and of those associated with a specific syndrome. A large number of European birth cohorts during 1996–1998 (EUROSCAN) was prenatally studied and recently reported (4). *Table 6-4* shows a comparison of prevalence figures among various studies.

Approach to the Child with a Urinary Tract Anomaly

The approach to the child with a urinary tract anomaly is similar to that for other birth defects. The initial step is to make a specific diagnosis based on history taking, physical examination, and laboratory investigation. A thorough *family history* for both urinary tract anomalies and for any other type of congenital or developmental anomalies that may have occurred in the family must be obtained. Many genetic disorders have variable expression even within the same family. A careful *physical examination* looking specifically for major and minor anomalies should be performed. Sometimes, a pattern of multiple anomalies can be recognized immediately as a well-described syndrome. Patterns of anomalies that cannot be recognized may require a literature or database search, or referral to an expert in syndrome recognition, such as a clinical geneticist. The search for a specific diagnosis is optimally accomplished by identifying the least common and most distinctive anomalies, for which the list of differential diagnoses is limited. Many excellent textbooks, atlases, and databases are available (5–7). To aid

in this effort, refer to *Tables 6-1–6-3* in addition to a table listing the differential diagnosis that accompanies the description of each of the major urinary tract anomalies below (*Tables 6-5–6-15*). For example, it is preferable to search for syndromes with urethral agenesis (22 syndromes) rather than renal dysplasia (more than 80 syndromes) when the two anomalies coexist. A search based on the more common anomalies can be performed if the first search does not reveal a match. Even after careful evaluation, a substantial number of children with multiple congenital anomalies remain undiagnosed.

When a suspected syndrome is known to be caused by a gene mutation, confirmatory molecular genetic testing can be performed. DNA-based test is currently available on either a clinical service or research basis. Knowledge regarding a pathogenic mutation specific for each

proband may potentially be useful for genetic counseling and future reproductive option in order to avoid intrafamilial recurrence. *Tables 6-1* and *6-2* list currently known causative gene(s) for each of the disorder.

A chromosome analysis is indicated in any child who has at least two major congenital anomalies or one isolated anomaly that is a pertinent feature of a chromosome abnormality, such as aniridia (microdeletion 11p). Growth or developmental delay and dysmorphic features or lack of familial resemblance should also prompt a chromosome analysis. Chromosome abnormalities are found in approximately 10–12% of all renal anomalies (3, 8). *Table 6-3* lists common and distinct chromosomal disorders with their reported urinary tract anomalies.

For a child with no known urinary tract anomaly, findings that should prompt an evaluation of the urinary tract are oligohydramnios, undefined abdominal mass, abnormal genitalia, aniridia, hypertension, preauricular pits or tags, branchial cleft cyst or sinus, imperforate anus, or symptoms indicative of renal dysfunction, urinary tract infection, or obstructive uropathy (3). For patients with known syndromes, the type of potentially associated urinary tract anomalies are listed in *Tables 6-1* and *6-2*.

The best initial evaluation to screen for urinary tract anomalies in general is an ultrasound examination because this study is noninvasive and gives good anatomic information about the urinary tract. It is also the only method routinely used for the prenatal diagnosis of urinary tract anomalies. Specific investigations such as intravenous pyelogram, voiding cystourethrogram, radionuclide renal and urinary system scan, and specialized genetic testing may then be used, depending on the working diagnosis. The type

of anomaly generally guides treatment. Corrective or reparative treatments are available for many anomalies (stenosis or atresia, bladder exstrophy, duplication. diverticula, and tumors). Symptomatic treatment for complications is often necessary.

Families who have a child with a urinary tract anomaly should be informed of the diagnosis when possible. A search for a related anomaly in first-degree relatives is automatically indicated only when the proband has renal agenesis by ultrasound examination (9). Otherwise, the decision to investigate family members should be based on a thorough family history and/or physical examination, and whether the child's disorder is a well described inherited syndrome. Genetic counseling should be provided to the family and should include a discussion of the manifestations of the disorder, the natural history, complications, available treatments, cause, and recurrence risk when these are known. Reproductive options should be discussed in a nondirective fashion. For an isolated anomaly without a family history of similar or related anomalies, an empiric risk can be provided. Accurate risk figures can be determined for Mendelian disorders, and estimated risks are available for associations.

All children with congenital anomalies need long-term, periodic follow-up to detect new abnormalities or complications of their birth defects. This is especially the case for children with undiagnosed multiple congenital anomalies, for whom follow-up examination may lead to a specific diagnosis. Additional relevant family information should be specifically sought for any newly affected member. Finally, for patients with a urinary tract anomaly who reach reproductive age, the recurrence risk for their offspring and reproductive options should be discussed.

The remainder of this chapter contains descriptions of the major types of urinary tract anomalies, including the etiology, pathogenesis, and associated disorders. First, a review of the embryology of the normal urinary tract

will be useful in understanding structural urinary tract abnormalities.

Overview of Normal Embryogenesis of the Urinary System

Renal organogenesis is reviewed in chapter 1. Embryogenesis of the lower urinary tract includes development of the mesonephric duct and urogenital sinus. The mesonephric duct from which the ureteric bud arose inserts into the lower allantois, just above the terminal part of the hindgut, the cloaca. During the fourth to seventh weeks, mesoderm proliferates and forms the transverse mesodermal ridge, the urorectal septum that divides the cloaca into the anterior portion, the primitive urogenital sinus, and the posterior portion, the cloacal sinus or anorectal canal. The mesonephric ducts open into the urogenital sinus and later become the ureters. The urorectal septum develops caudally and fuses with the cloacal membrane, dividing it into the urogenital membrane (anterior) and the anorectal membrane (posterior) by the end of the

seventh week. The primitive perineal body forms at the site of fusion.

The primitive urogenital sinus develops primarily into the urinary bladder. The superior portion, originally continuous with the allantois, later becomes a solid fibrous cord, the urachus or median umbilical ligament, which connects the bladder to the umbilicus. The inferior portion of the urogenital sinus in the male divides into a pelvic portion, containing the prostatic and membranous urethra, and the long phallic portion, containing the penile urethra. The inferior portion in the female forms a small portion of the urethra and the vestibule. At the same time, the distal portion of the mesonephric ducts is incorporated into the endodermal vesicoureteral primordium, forming the trigone of the bladder. A part of the distal end of both mesonephric ducts just proximal to the trigone develops into the seminal vesicles and ductus deferens in the male. Finally, at the end of the twelfth week, the epithelium of the superior portion of the prostatic urethra proliferates to form buds that penetrate the surrounding mesenchyme. In the male, these buds form

the prostate gland; in the female, they form the urethral and paraurethral glands.

Anomalies Involving the Urinary Tract

Kidney Defects

Renal Agenesis

By definition, renal agenesis refers to complete absence of one of both kidneys without identifiable rudimentary tissue. Renal agenesis is usually associated with agenesis of the ipsilateral ureter. The pathogenesis of renal agenesis is failure of formation of the metanephros. Causal heterogeneity has been shown, by both animal studies and human observations (10–12), including failure of ureteric bud formation, failure of the bud to reach the metanephric blastema, or failure of the bud and the metanephric blastema to create mutual inductive influence on one another. In addition, interruption in vascular supply and regression of a multicystic kidney can lead to renal agenesis in the fetal period (11).

Unilateral renal agenesis is usually asymptomatic and found incidentally, whereas bilateral renal agenesis results in severe oligohydramnios and fetal or perinatal loss. Renal agenesis can occur in either side without predilection. Birth prevalence in the United States for renal agenesis/hypoplasia ranges between 0.30 and 9.61 per 10,000 live births (3). Several studies have demonstrated that unilateral renal agenesis is associated with an increased frequency of anomalies in the remaining kidney (9, 13). Moreover, renal agenesis is often detected in conjunction with anomalies of other organ systems. These anomalies can occur both in contiguous structures (e, g., vertebrae, genital organs, intestines, and anus) and also in noncontiguous structures (e.g., limbs, heart, trachea, ear, and central nervous system). The diagnosis of renal agenesis is made by abdominal ultrasound. Care must be taken to exclude the possibility of ectopic kidney. Intravenous pyelography, computerized tomography scan, and radionuclide studies can be helpful in equivocal cases.

The recurrence risk for renal agenesis can be provided if the pattern of inheritance is known or if the proband has a recognizable syndrome. For nonsyndromic renal agenesis, an empiric risk of 3% can be used for families in which renal anomalies in first-degree relatives (siblings, parents) have been excluded (3). First-degree relatives of patients with nonsyndromic renal agenesis have an increased prevalence of related urogenital anomalies. In one study, 9% of first- degree relatives of infants with agenesis or dysgenesis of both kidneys had a related urogenital anomaly, and 4.4% had an asymptomatic renal malformation (13). In another recent retrospective review, empiric risks were 7% in offspring, 2.5% in siblings and 4.5% in parents (14). Moreover, offspring of an individual with unilateral agenesis is at a slightly increased risk for bilateral renal agenesis. Therefore renal ultrasound is recommended for the first-degree relatives of the proband unless renal agenesis in the proband is clearly sporadic or a specific cause without an increased recurrence risk is identified.

Tables 6-5 and *6-6* list the syndromes commonly associated with unilateral and bilateral renal agenesis, respectively. See also *Tables 6-1–6-3* for more information about these disorders and other less known conditions with renal agenesis.

Ectopic Kidney

The ectopic kidney derives from an error of ascent. Most are pelvic kidneys that fail to ascend out of the pelvic cavity. Rare case reports of thoracic kidney exist (15). Ectopic kidney can be unilateral or bilateral. In bilateral pelvic kidneys, the kidneys often fuse into a midline mass of renal tissue, with two pelves and a variable number of ureters, which is referred to as a pancake or discoid kidney. Fused pelvic kidney may in fact be due to fusion of ureteric buds or metanephric blastema. *Crossed renal ectopia* refers to an ectopic kidney whose ureter crosses the midline. It often fuses with the normal kidney. The embryogenesis of crossed renal ectopia is not well understood, but presumably involves abnormal migration of the ectopic kidney to the contralateral side. An ectopic kidney is usually hypoplastic, is rotated, and has numerous small blood vessels and associated ureteric anomalies. Ectopic kidneys may be asymptomatic and incidentally found, but complications from ureteral obstruction, infection, and calculi can occur. In a recent study, ectopic kidney without hypoplasia or hydronephrosis seems not to be associated with an appreciable increase frequency of associated anomaly and complication thus making further urologic investigation such as vesicourethrography unnecessary (16). *Table 6-7* provides a list of syndromes that include ectopic kidney. These are described in *Tables 6-1–6-3*.

Horseshoe Kidney

Horseshoe kidney refers to a condition in which both kidneys are fused at the lower poles with a renal parenchymal or, less commonly, fibrous isthmus.

The embryogenesis of horseshoe kidney with parenchymal isthmus is thought to be migration of nephrogenic cells across the primitive streak before the fifth gestational week. Horseshoe kidney with fibrous isthmus is believed to originate from mechanical fusion of the two developing kidneys at or after the fifth week before renal ascent (17). The concept of a narrow vascular fork leading to approximation and fusion of the two kidneys is no longer considered valid. Most horseshoe kidneys are located in the pelvis or at the lower lumbar vertebral level because ascent is further prevented when the fused kidney reaches the junction of the aorta and inferior mesenteric artery.

Complications of horseshoe kidneys include obstructive uropathy primarily related to ureteropelvic junction obstruction, calculi and urinary tract infection. Similar to other urinary tract anomalies, a horseshoe kidney is often associated with other genitourinary anomalies. In addition, there is an increased risk of various types of renal tumors developing in the horseshoe kidney compared with the normal kidney (18). Renal cell carcinoma is the most common, but Wilms' tumor, adenocarcinoma, transitional cell carcinoma, malignant teratoma, oncocytoma, angiomyolipoma, and carcinoid have all been reported. Horseshoe kidneys also carry an increased risk for renal pelvis carcinoma and higher proportion of squamous cell carcinoma than those in normal kidneys (19).

Table 6-8 lists syndromes associated with horseshoe kidney. See *Tables 6-1* and *6-2* for more details of these disorders.

Dysplasia and Polycystic Kidney

Renal dysplasia is the most common congenital urinary tract anomaly and the most common cause of an abdominal mass in children (3). Unilateral dysplasia is reported to occur in 1:1,000, whereas the prevalence of bilateral disease is estimated to be 1:5,000 (20). It may be unilateral or bilateral, and diffuse, segmental, or focal. Symptoms are variable from silent in unilateral or focal dysplasia to progressive renal dysfunction in diffuse or bilateral dysplasia. Dysplasia refers to abnormal differentiation or organization of cells in the tissue. Renal dysplasia is characterized histologically by the presence of primitive ducts and nests of metaplastic cartilage (20, 21). Although cysts are not always present in a dysplastic kidney, the dysplastic process often results in the formation of cysts that are variable in size and number. Several hypotheses are proposed for the embryogenesis of the dysplastic kidney. The most likely pathogenesis is an error of the mutual induction between the ureteric bud and the metanephric blastema. The molecular pathogenesis of cystic kidney, especially polycystic kidney, has been one of the most extensively studied aspects of nephrology and recent studies discovered few genes and pathways critical for renal cyst formation such as TCF2/hepatocyte nuclear factor 1ss (HNF1beta), PAX2 and uroplakins. Dysplastic kidneys are usually identified as enlarged bright kidneys on prenatal ultrasonography. If there is associated functional renal impairment, alteration in amniotic fluid volume could potentially be detected and signifies a poor prognosis. (22) Unilateral dysplasia carries an overall better postnatal prognosis than that of bilateral disease. However, up to 30–50% of those with unilateral dysplasia have associated contralateral urinary anomalies (22). Multicystic renal dysplasia is the most common among many causes of renal dysplasia and it is usually unilateral. Polycystic kidney diseases, both autosomal dominant (ADPKD) and autosomal recessive (ARPKD) forms, are in general far more common than other syndromic causes of renal dysplasia. *Table 6-9* summarizes well-known syndromes with renal dysplasia/cystic kidney. See also *Tables 6-1–6-3*.

Obstruction and Hydronephrosis

Urinary obstruction is a complication of a primary anomaly, which can be stenosis or atresia of the ureteropelvic junction, ureter, or urethra; a poorly functional bladder causing reflux; a malformed dilated ureteral end (ureterocele); or extrinsic compression by other structures, such as anomalous blood vessels or tumors. Hydronephrosis and pyelectasis (dilated renal pelvis) are the most common urinary tract abnormalities on prenatal ultrasound examination. Early diagnosis of collecting system dilatation can be achieved by ultrasound examination in the second trimester (23). Persistent dilatation almost always indicates an underlying anomaly. Isolated obstructive uropathies diagnosed prenatally may not require antenatal or immediate postnatal surgical intervention. Postnatally diagnosed obstructive uropathies are almost always symptomatic and require thorough investigation to delineate the anatomy of the urinary tract and to exclude associated anomalies.

Table 6-10 provides a list of syndromes commonly associated with obstruction and hydronephrosis. See also *Tables 6-1–6-3*.

Ureter Defects

Duplication

Double ureters or collecting systems are caused by duplication of the ureteric bud. Early duplication results in

duplicated kidney, which is usually smaller and fused with the ipsilateral kidney and has ureters that enter into the bladder separately. Duplication that occurs later results in double ureters that may have separate openings into the bladder or may join each other before the opening. On rare occasion, one of the ureters may have an ectopic opening into the vagina, vestibule, or urethra. In most double ureters, the two ureters cross each other, and that from the higher pelvis enters the bladder more caudally. Duplication anomalies are common but usually asymptomatic; therefore they often remain undetected. One autopsy study reported the prevalence of duplication anomalies to be as high as 1 in 25, with females about four times more likely to be affected than males (24). Unilateral duplication is five to six times more common than bilateral duplication (3). Double ureters are commonly associated with vesico-ureteral reflux due to their ectopic opening into the urinary bladder and/or the ureterocele (23). In addition, ureteric obstruction can occur at the level of vesico-ureteric junction or that of uretero-pelvic junction.

Table 6-11 summarizes syndromes associated with duplication, and *Tables 6-1–6-3* provide clinical information about these disorders.

Hydroureter

Hydroureter, or magaloureter, is caused by distal obstruction and is usually found with hydronephrosis, except in ureteropelvic junction obstruction. Hydroureter has the same etiology as hydronephrosis (see Obstruction and Hydronephrosis).

Bladder Defects

Anomalies of the bladder are rare. These include agenesis, hypoplasia, diverticulae, and dilatation or megacystis caused by distal obstruction or by non-obstructive causes. Agenesis of the bladder is usually associated with severe developmental anomalies of the urinary tract, such as in sirenomelia and caudal regression syndrome. Hypoplastic bladder can be found in conditions associated with bilateral renal agenesis because no urine is produced. Bladder diverticulae have heterogeneous causes. They result from an intrinsic defect in the bladder wall, such as in cutis laxa, or Ehlers-Danlos, Ochoa, occipital horn, and Williams syndromes. They can also be caused by increased intravesicular pressure from distal obstruction or by persistent urachus. See *Tables 6-1–6-3* for information about specific syndromes associated with bladder diverticulae.

Bladder Exstrophy

Bladder exstrophy refers to a urinary bladder that is open anteriorly because of the lack of an abdominal wall closure. It is usually associated with anomalies of the contiguous structures including epispadias and separation of the pubic rami. This anomaly is thought to result from an overdeveloped cloacal membrane that interferes with inferolateral abdominal mesenchymal closure. Therefore, when the cloacal membrane ruptures, the inferior abdominal wall has not completely closed and the bladder cavity is exposed. It has been suggested that bladder exstrophy belongs to the spectrum of omphalocele-cloacal exstrophy-imperforate anus-spinal dysraphism (OEIS) complex (25–27). The extent of anomalies is determined by the timing of the cloacal membrane rupture. Rupture that occurs after the separation of cloaca by the urorectal septum results in bladder exstrophy, whereas one that occurs before the separation results in the more severe cloacal exstrophy and OEIS complex. Bladder exstrophy is six times more common in males.

Table 6-12 lists syndromes associated with bladder exstrophy, and *Tables 6-1–6-3* provide information about these disorders.

Urethral Defects

Agenesis and Atresia

Urethral agenesis is rare, and its predominant occurrence in males probably reflects the greater complexity of embryogenesis of the male urethra. Urethral agenesis is often associated with bladder obstruction sequence. *Table 6-13* lists syndromes associated with urethral agenesis, and clinical information about these disorders is summarized in *Tables 6-1–6-3*.

Duplication

Duplication refers to complete or partial duplication of the urethra, which is a rare anomaly found only in a few syndromes. Those syndromes associated with urethral duplication are listed in *Table 6-14* and their findings are provided in *Tables 6-1–6-3*.

Posterior Urethral Valves

Posterior urethral valves refer to abnormal mucosal folds that function as a valve to obstruct urine flow. This is the

most common childhood cause of obstructive uropathy leading to renal failure. Posterior urethral valves can be suspected prenatally when a dilated bladder is seen in association with obstructive uropathy. A "keyhole" sign has been demonstrated in prenatal ultrasound of fetuses with subsequently confirmed posterior urethral valves (28). A voiding cystourethrogram or endoscopy is usually required for a definitive diagnosis. The embryogenesis of posterior urethral valves is unknown. Proposed hypotheses include an overdeveloped posterior urethral fold, a remnant of the mesonephric duct, and an anomalous opening of the ejaculatory duct. *Table 6-15* lists syndromes in which posterior urethral valves can be seen, and the other findings in these disorders are provided in *Tables 6-1*–*6-3*.

Associations and Sequences Involving the Urinary Tract

A number of associations and sequences involve anomalies of the urinary tract that may be important to both diagnosis and management. For this reason, such conditions are described in more detail in this section, in addition to the information presented in *Tables 6-1* and *6-2*.

VATER Association

VATER association is an acronym used to designate a non-random occurrence of Vertebral defects, imperforate Anus, Tracheo-Esophageal fistula, Radial and Renal anomalies (29, 30). An acronym VACTERL has been proposed to broaden the spectrum of VATER to include Cardiac defects and Limb anomalies. The term VATER is not a diagnosis per se, but the designation provides clues for potentially associated anomalies and for recurrence risk counseling when no specific syndromic diagnosis can be made. Patients with VATER association need a careful physical examination and investigation for potential multiorgan anomalies. A specific diagnosis should be sought. Causes of VATER association include: chromosomal disorders, such as trisomy 18; genetic syndromes, such as Goldenhar and Holt-Oram syndromes; and teratogenic exposures, such as infants of diabetic mothers and fetal alcohol syndrome. A family with a mitochondrial DNA mutation was identified in which the daughter was born with VACTERL association, and her mother and sister had classic mitochondrial cytopathy (31). Thus all patients suspected to have VATER association should have a chromosome analysis, a careful family and prenatal exposure history, and a thorough examination for dysmorphic features. The spectrum of anomalies seen in VATER is broad. Associated renal anomalies are usually agenesis, ectopy, or obstruction (29, 30).

Because there is apparent causal heterogeneity for VATER association, the inheritance pattern and recurrence risk vary with the cause. VATER association is usually sporadic with an empirical recurrence risk of 1 to 3% when a specific cause cannot be identified (32). Autosomal recessive and X-linked inheritance have been reported for subsets of patients, such as for VATER with hydrocephalus, and recurrence risk in these families can be as high as 25% (32).

CHARGE Syndrome (CHARGE Association)

CHARGE syndrome – previously designated as an association but now recognized to have a major causative gene- is an acronym used to designate an association of Coloboma of iris, choroid or retina, Heart defects, Atresia choanae, Retarded growth and development, Genital anomalies or hypogonadism, and Ear anomalies or deafness (33–36). In addition, unilateral facial palsy is a common finding. Renal anomalies occasionally found in CHARGE syndrome include ectopy, dysplasia, renal agenesis, and ureteric anomalies. The presence of two or more anomalies associated with CHARGE syndrome should prompt a search for the others. To prevent overuse of the term, it was suggested that at least three anomalies are required for the term CHARGE to be applied, and one of the anomalies should be either coloboma or choanal atresia (34). To date, consistent features in CHARGE syndrome have been ocular coloboma, choanal atresia and semicircular canal hypoplasia (37). Conditions with anomalies in the spectrum of CHARGE include trisomy 13, trisomy 18, and Wolf-Hirschhorn (deletion 4p), cat-eye, Treacher-Collins, velocardiofacial, Apert, Crouzon, and Saethre-Chotzen syndromes. Therefore, a careful physical examination for malformations and dysmorphic features should be conducted. Recently, *CHD7* mutation has been found by an array CGH study to be the cause of this syndrome in about 60 percent of typical patients thus making a molecular confirmation possible. In those without *CHD7* mutation, chromosome analysis including specific fluorescence in situ hybridization (FISH) probes for velocardiofacial syndrome (deletion 22q) and 4p deletion should be performed. Because most cases of CHARGE association are sporadic, the empirical recurrence risk in sibling is low (33, 36).

MURCS Association

MURCS association refers to a rare occurrence of Mullerian duct aplasia, Renal aplasia and Cervicothoracic Somite dysplasia (38). Anomalies include absence of the proximal two thirds of the vagina; uterine hypoplasia or aplasia; unilateral renal agenesis; ectopic kidney; renal dysplasia; C5-T1 vertebral anomalies (hypoplasia of vertebrae, fusion, hemivertebrae, and butterfly vertebrae); and short stature. Additional anomalies are common, including rib defects, facial asymmetry, limb anomalies, hearing loss, and brain anomalies, such as encephalocoele and cerebellar cyst (39).

The pathogenesis of MURCS association is unknown, but is thought to be related to defects in the paraxial mesoderm, which gives rise to the cervicothoracic somites and the adjoining intermediate mesoderm. Most patients are diagnosed because of primary amenorrhea or infertility associated with normal secondary sexual characteristics, followed by recognition of reproductive organ atresia. MURCS association is usually sporadic. A report of vertebral and renal anomalies associated with azoospermia was proposed to represent the male version of MURCS association (40).

Oligohydramnios Sequence

Oligohydramnios of whatever cause leads to a recurrent pattern of abnormalities that has been called the oligohydramnios sequence (3, 6). Oligohydramnios may be caused by decreased production of fatal urine from bilateral renal agenesis or dysplasia or by urinary obstruction, or it can result from amniotic fluid leakage. When the oligohydramnios is prolonged and severe, the condition is lethal because of pulmonary hypoplasia. Moderate oligohydramnios from amniotic fluid leakage may result in a liveborn child with multiple congenital anomalies. These anomalies are both malformations and deformations. Intrauterine constraint leads to mechanical compression that leads to the characteristic flat facial profile (Potter's facies), limb deformities (e.g., talipes equinovarus), and intrauterine growth retardation (IUGR). Decreased fetal movement as a result of intrauterine constraint causes multiple joint contractures (arthrogryposis). Breech presentation is common. Pulmonary hypoplasia can be the consequence of compression of the chest cavity coupled with decreased inspiration of amniotic fluid. Liveborns have respiratory distress caused by pulmonary hypoplasia, and the lungs may have insufficient volume to support life.

Because the initial defect has many causes, recurrence risk is based on the underlying defect. When oligohydramnios is due to nonsyndromic bilateral renal agenesis or dysgenesis, related renal malformations occur at an increased frequency in first-degree relatives (13), and recurrence risk can be as high as 4–9%. The recurrence risk can be as high as 25% for an autosomal recessive disorder causing bilateral renal agenesis or dysplasia.

Urethral Obstruction Sequence

The initial defect in this sequence is obstruction of the urethra leading to dilation of the proximal urinary tract, bladder distension, and hydroureter (3, 6, 41). Obstruction of urine flow interferes with normal nephrogenesis, resulting in renal dysplasia. Other potential anomalies related to bladder distension include cryptorchidism, malrotation of colon, persistent urachus, and limb deficiency caused by iliac vessel compression. In addition, oligohydramnios results from lack of urine and leads to the oligohydramnios sequence.

Prune-belly syndrome (41, 42) is a rare entity referring to a constellation of anomalies that includes megacystis, abdominal wall muscle deficiency, hydroureter, renal dysplasia, and characteristic wrinkled abdominal skin. This condition, previously thought to be a form of urethral obstruction sequence, is in fact a non-obstructive cause of bladder distension that results from a malformation, thus now being properly designated a syndrome (28).

The most common cause of urethral obstruction is posterior urethral valves, but urethral agenesis/atresia or bladder neck obstruction can also be the cause. This anomaly occurs mostly in males, with a male: female ratio of 20:1. Survival is rare in fetuses with complete obstruction, and severe urinary tract dysfunctions are always present in those that are liveborn. Prenatal diagnosis by ultrasound examination can detect the abnormally dilated bladder at the beginning of the second trimester (43), and intrauterine urinary decompression procedures, such as vesicoamniotic shunts, are options for treatment in order to decrease the occurrence of pulmonary hypoplasia, although their benefits have not been unequivocally shown (44, 45).

Sirenomelia Sequence

Sirenomelia is a malformation characterized by the presence of a single lower extremity with posterior alignment of the knees and feet, sacral agenesis and other lower vertebral defects, imperforate anus and rectal agenesis,

and absence of external and internal genitalia (46). The current view of the embryogenesis is that sirenomelia results from a vascular steal phenomenon (47). This is supported by the presence of abnormal vasculature in the caudal part of affected embryos. A single large vessel originating from the aorta, a derivative of the vitelline artery complex, connects the iliac arteries to the placenta rather than the two normal umbilical arteries. The area caudal to the origin of this vessel has minimal blood supply because of the lack of aortic branches. Therefore, a "vascular steal phenomenon" is generated, leading to a vascular disruption sequence. Alternatively, since sirenomelia shares a number of anomalies with caudal regression syndrome, it is thought to potentially be causally similar and represent different patterns in the same spectrum.

Sirenomelia is a rare condition and has a broad spectrum of anomalies. Virtually any urinary tract anomaly can occur in sirenomelia sequence. Renal agenesis occurs in two-thirds of cases and a variable degree of renal dysplasia is present in one-third of cases (3). Absence of the ureter and bladder are common. All cases of sirenomelia are sporadic and almost uniformly fatal because of pulmonary hypoplasia. Sirenomelia has been noted with an increased frequency among monozygotic twins in which only one of the twins in usually affected.

Homeostasis

7 Sodium and Water

Howard Trachtman

Introduction

> "Wasted away again in Margaritaville, searching for my lost shaker of salt. . ."
>
> Jimmy Buffet

There must be something about the topic of sodium and water homeostasis that reaches deep within the human psyche and prompts authors to wax poetic in search of literary aphorisms (1, 2). In the past, the author looked to the ancients to demonstrate that human beings probably have an intuitive sense of the critical role played by salt balance and the integrity of the plasma compartment for the maintenance of life in terrestrial species. For the second time, the author turns to a contemporary voice for inspiration in this chapter that reviews the physiological mechanisms involved in the control of sodium and water homeostasis. Using this knowledge as a basis, there will be an analysis of the common diseases that arise when these systems malfunction and a discussion of the optimal therapy for these conditions.

Body Fluid Compartments and their Composition

Total Body Water and its Compartments

Water is vital for the maintenance of life and has several key physiological functions including providing an aqueous environment for cytosolic chemical reactions, a solvent for elimination of waste products, a medium for transport of nutrients, key molecules and gases, and thermoregulation via sweat production (1). On average, water comprises 60% of total body weight in adults. This proportion is higher in infants and even greater in babies born prematurely and very low birth weight neonates. It declines during early infancy and reaches the adult value by the end of the first year (3). The percentage of body weight, i.e., water, is lower in postpubertal girls because they have a higher percentage of body mass, i.e., fat. In addition, it may be altered in disease states that are associated with altered salt handling such as cystic fibrosis and endocrinopathies.

Total body water is divided into two principle components – the intracellular (ICW) and the extracellular water (ECW) spaces (4). These spaces are apportioned in a 2:1 ratio. When there is an increase in the total body water, this is clinically manifested by an increase in the ECW space, because the ICW compartment is not accessible to direct assessment. The ECW compartment is further divided into the interstitial and intravascular spaces, which are separated in a 3:1 ratio. Thus, the intravascular space constitutes 1/12 of the total body water, i.e., ⅓ × ¼ (*Fig. 7-1*). A component of the ECW, namely the interstitial fluid in skin and connective tissue, may serve as a reservoir that can mobilize water into the plasma volume to sustain circulation during conditions of hypovolemia (5). Finally, there are transcellular water compartments, such as the gastrointestinal lumen or cerebrospinal fluid, which need to be considered as a distinct category. They are not in direct contact with the rest of the fluid spaces and are separated by an epithelial membrane. Water and electrolytes enter these spaces via tightly regulated active transport processes.

Composition of Body Water Compartments

All of the major fluid compartments in the body are separated by semipermeable membranes (4, 5). This type of barrier permits free passage of the aqueous solvent but limits movement of selective solutes across the membrane. Water always moves down its concentration gradient to ensure that the osmolality of the solution is the same on both sides of the membrane. Water channels called aquaporins are a group of proteins that are selectively expressed in specific cell membranes such as the erythrocytes and distinct nephron segments, which facilitate water movement in response to an osmotic gradient (6).

Because of the presence of active transporters and selective channels for various solutes within the cell membrane, there is an uneven distribution of solutes in the ICW and ECW compartments. The presence of the Na-K ATPase pump in localized cell membrane domains ensures that potassium and sodium are the principle

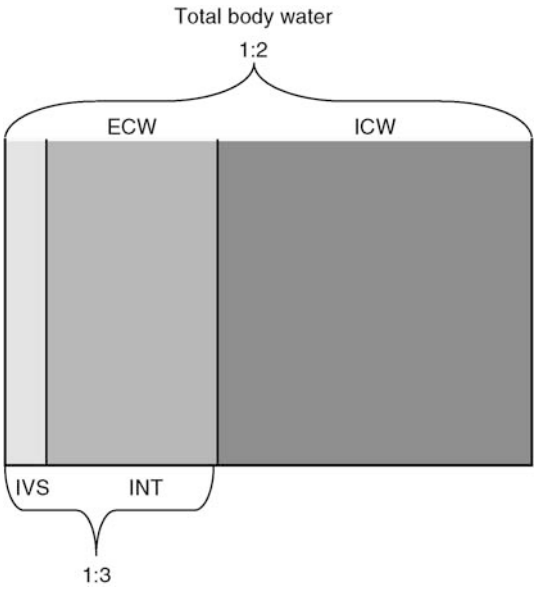
Figure 7-1

Graphic illustration of the total body water compartments and the relative size of the intracellular water (ICW) to the extracellular water (ECW) spaces, and intravascular (IVS) to interstitial water space.



cations in the ICW and ECW spaces, respectively (7). The secondary movement of Na^+ and K^+ through other pathways such as the amiloride sensitive epithelial sodium channel (ENaC) or ROMK channel is driven by the primary operation of the Na-K-ATPase (8). Limitations in membrane permeability to chloride and bicarbonate confine these anions almost exclusively to the ECW space, while proteins and phosphate comprise the major intracellular anions. The differences in cell permeability and binding characteristics of specific ions are reflected in the coefficients that are used to determine the volume of distribution for individual solutes. For example, because of the permeability of cell membranes to water, the volume of distribution for sodium is equal to the entire body water compartment even though sodium is confined to the ECW space. In contrast, the volume of distribution of bicarbonate is 0.3 × total body water. These considerations are important in formulating therapeutic regimens to treat specific disorders of sodium and water homeostasis (9).

Besides distinctive membrane permeability characteristics for specific solutes, the unequal distribution of ions across the membrane is in part due to the Gibbs–Donnan effect, which arises because of the presence of impermeant, negatively charged proteins, primarily albumin, in the intravascular space (3). Although there are significant differences in the composition of cationic and anionic solutes in various body water compartments, under equilibrium conditions, there is electroneutrality and tonicity or osmolality, i.e., the sum of all osmotically active particles is equal in all body water compartments.

Under normal conditions, the serum osmolality is 286 ± 4 mosm/kg water. Because sodium is the major cation in the ECW, osmolality can be closely estimated by the formula:

$$\text{Serum osmolality} \approx 2 \times [\text{serum sodium concentration}] \quad (1)$$

A reflection coefficient of 1.0 indicates a totally nonpermeant solute, while freely permeable molecules have a reflection coefficient of zero. The reflection coefficient for urea is approximately 0.4. Similarly, in the absence of insulin, the reflection coefficient for glucose is 0.5. Thus, when there is a pathological elevation in the serum urea nitrogen, e.g., acute renal failure, or glucose concentration, e.g., diabetic ketoacidosis, these solutes will also contribute to osmolality, albeit less than sodium. Therefore, the following formula should be used to calculate serum osmolality:

$$\begin{aligned}\text{Serum osmolality} &= 2 \times [\text{serum sodium concentration}] \\ &\quad + [\text{serum urea nitrogen}]/2.8 \\ &\quad + [\text{serum glucose concentration}]/18\end{aligned} \quad (2)$$

This formula is based on the molecular weights of urea nitrogen (28 Da) and glucose (180 Da) and the standard practice of reporting the serum concentrations as mg/100 mL. The calculated serum osmolality is normally within 1–2% of the value obtained by direct osmometry in clinical chemistry laboratories. If the calculated serum osmolality is significantly lower than the value obtained by measurement with an osmometer, this indicates the presence of an "osmolal gap" and reflects the accumulation of unmeasured osmoles. Clinically relevant examples are the organic solutes that are produced after an ingestion of ethanol or ethylene glycol (antifreeze) (10, 11).

Maintenance Sodium and Water Requirements

Sodium

Sodium is an essential dietary component that is required for normal growth. Wassner et al. (12) demonstrated

that somatic growth of experimental animals is impaired if they are fed a sodium-deficient diet. This effect is independent of the protein or calorie content of the diet. Interestingly, in contrast to chronic potassium deficiency induced by diuretics, compromised sodium intake does not cause structural damage to the kidney (13).

Balance studies indicate that the daily sodium requirement is 2–3 mmol/kg body weight. This quantity is nearly two- to threefold higher in term and very low birth weight premature infants (14). This reflects the immaturity in renal tubular function coupled with the increased need for sodium to achieve the high rate of growth during the first few years of life. It will be exaggerated by intrinsic (diarrhea, increased losses via chronic peritoneal dialysis, genetic defect in tubular sodium transport) or exogenous (administration of diuretics) factors that promote sodium loss. In most developed countries, the daily sodium intake is in excess of the amount needed to promote growth or maintain body function. Under normal circumstances, the principal anion that accompanies sodium is chloride. The identity of the anion that is present with sodium and a variety of other dietary constituents impacts on the adverse consequences of excessive sodium intake, such as hypertension (15). In certain disease states such as renal tubular acidosis, metabolic acidosis associated with chronic renal insufficiency, or urolithiasis, it may be advisable to provide a portion of the daily sodium requirement as the bicarbonate or the citrate salt.

Water

The daily requirement for water is traditionally expressed as mL per metabolic kg (16). However, in clinical practice, this is a very cumbersome and impractical method and all calculations are based on body weight and size. There are three methods that are currently used to estimate the daily fluid requirement. The first is a direct extension of the use of metabolic kg and utilizes the following formula:

(1) Daily water requirement
= 100 ml/kg for a child weighing less than 10 kg
+50 ml/kg for each additional kg up to 20 kg
+20 ml/kg for each kg in excess of 20 kg

The second method is based on body surface area and utilizes the following formula:

(2) Daily water requirement
= 1500 mL/m^2 body surface area (BSA)

The last method is a refinement of the second and utilizes the following formula:

(3) Daily water requirement = Urine output
+ insensible water losses

Based on clinical experience, under normal circumstances, urine output is approximately 1,000 mL/m^2/day and insensible losses amount to 500 mL/m^2/day.
Thus, for a child weighing 30 kg and 123 cm in height with a BSA of 1.0 m^2, according to the first method the daily water requirement is 1700 mL while the second method yields 1500 mL/day. The first method is easier to apply, but it tends to overestimate the water requirement as body weight increases. The third method is the most precise and should be applied in more complicated circumstances such as the patient in the intensive care unit with oliguria, secondary to acute kidney injury or the child with increased insensible losses, e.g., diarrhea, increased ambient temperature, tachypnea, burns, or cystic fibrosis (17). In addition to the daily energy requirement and insensible losses that are represented in the formulas, the amount of water excreted by the kidney on a daily basis is dependent upon the solute load. Because urine has a minimum osmolality, approximately 50 mosm/kg H_2O, even in the absence of arginine vasopressin (AVP), increased dietary intake of solute will result in a larger obligatory urine volume to accommodate the larger solute load (18, 19).

The daily sodium and water requirement are generally provided enterally. Intravenous administration of fluids and electrolytes should be resorted to only under clinical circumstances that interfere with normal feeding such a persistent vomiting, gastrointestinal tract surgery, or states of altered consciousness.

In recent years, there has been an ongoing controversy about which fluid is most appropriate for the administration of daily maintenance of water and sodium requirements. The standard recommendation is to use hypotonic fluids containing approximately 50–75 mmol NaCl/L (0.33–0.5% normal saline), based on the original studies done by Holliday that linked fluid requirements to metabolic needs. This guideline has been repeated in several recent reports (20, 21, 22a). However, there are nephrologists who have questioned the risk:benefit ratio of this prevailing practice, based on the occurrence of hyponatremia and neurological complications in

hospitalized children who receive hypotonic fluids parenterally (23, 24). To prevent cerebral edema and neurological consequences of hyponatremia, they advocate routine administration of isotonic saline to all pediatric patients who must receive maintenance fluids intravenously (25b). There are a number of gaps that need to be filled in to clarify this important issue, including the incidence of hyponatremia in large unselected patient populations studied prospectively, the frequency of neurological complications arising from hyponatremia, and the results of a randomized trial comparing safety and efficacy of the two fluid regimens, i.e., hypotonic and isotonic solutions. In the interim, it is important to emphasize that in the face of clinically significant acute ECW contraction, there is universal agreement that isotonic fluids are necessary to replete the intravascular compartment. Careful clinical and laboratory monitoring is a key to ensure good outcomes in all children who are given maintenance fluids and electrolytes parenterally (25a).

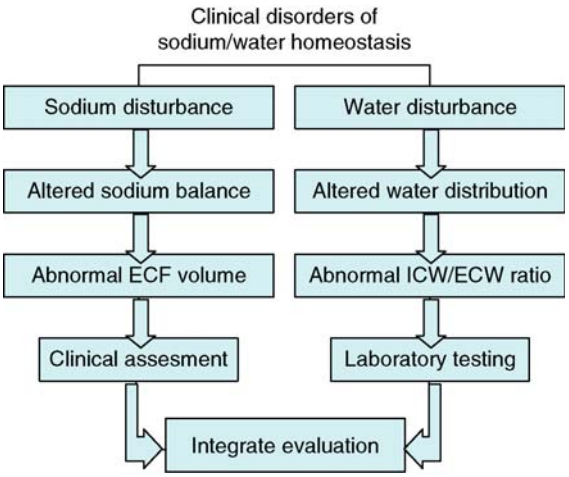
Distinct Roles of Sodium and Water in Body Fluid Homeostasis

Sodium and water are inextricably linked in the determination of the serum sodium concentration. However, it is critical to recognize that sodium and water serve two distinct functions within the body. Sodium is instrumental in the maintenance of the size of the extracellular fluid (ECF) space and the vascular perfusion compartment, while water is critical to the maintenance of the size of individual cells. The regulation of sodium and water homeostasis represents two distinct processes with discrete sensing and effector mechanisms. Although these systems overlap from a physiological and clinical perspective, a complete understanding of body fluids and electrolytes mandates separate evaluation of sodium and water (*Fig. 7-2*).

As mentioned earlier, sodium is confined primarily to the ECW compartment as a consequence of active transport mechanisms in the cell membrane. Because sodium is the principal cation in this space, disturbances in total body sodium content are reflected by expansion or contraction in the ECW compartment. Adequacy of the ECW compartment is essential to maintain the intravascular space and sustain perfusion of vital organs. In terrestrial mammals living in an environment where ECW volume depletion is a constant threat, the kidney is designed for maximal sodium reabsorption as the default mode unless physiological signals instruct it to respond otherwise. This contrasts with potassium, in which the threat is an elevated serum concentration and for which the default mode is tubular secretion of the cation.

Figure 7-2

This scheme illustrates the importance of independent assessment of sodium and water handling in managing patients with clinical disorders of sodium-water homeostasis.



The primary step in the pathogenesis of disturbances in ECW compartment size is a perturbation in sodium balance. When total body water and sodium content are within the normal range, net sodium balance is zero and the daily intake of sodium is matched by losses in the urine, stool, and insensible losses. Provided kidney function is normal, the dietary sodium intake can be as low as 0.1 mmol/kg or in excess of 10 mmol/kg without any derangement in ECF compartment size. If the alterations in diet are not abrupt, then sodium balance is maintained even when kidney function is markedly impaired (26). In contrast, if the daily input of sodium exceeds losses, there is expansion of the ECF space that manifests as edema while if the input does not match the daily losses, there will be symptoms and signs related to ECW space contraction. These disturbances are not associated with any obligatory parallel changes in the serum sodium concentration.

Water homeostasis is a prerequisite for the normal distribution of fluid between the ICW and ECW

compartments. Cell function is dependent on stabilization of cell volume in order to keep the cytosolic concentration of enzymes, co-factors, and ions at the appropriate level. Perturbations in water balance result in fluctuations in serum osmolality. Because cell membranes are semipermeable and permit free movement of water down its osmolal gradient, this causes obligatory shifts in water between the cell and the ECW space. Any disorder that alters the 2:1 ratio of water volume in the ICW:ECW spaces will be reflected by changes in cell size and subsequent cellular dysfunction. Under hypoosmolal conditions, water will move from the intravascular compartment into the cell, causing relative or absolute cell volume expansion. Conversely, if the serum osmolality is elevated, water will exit from the cell to the ECW space resulting in absolute or relative cellular contraction (27).

Disturbances in cell function related to abnormalities in cell size are most prominent in cerebral cells. There are two reasons for this phenomenon. First, the blood–brain barrier, which is constituted by tight junctions between adjacent endothelial cells, limits the movement of solute between the ICW and ECW compartments, while permitting unrestricted flow of water down an osmolal gradient (28). Second, the brain is contained within the skull, which is a closed, noncompliant space, and is tethered to the cranial vault by bridging blood vessels, which limits its tolerance of cell swelling or contraction. Thus, alterations in water balance and serum osmolality are dominated by clinical findings of central nervous system dysfunction, including, lethargy, seizures, and coma (27).

In the same way that disturbances in sodium balance do not necessarily predict specific abnormalities in serum sodium concentration, the presence of a disturbance in water balance and serum osmolality is not linked to a specific abnormality in the ECW compartment size. The independent nature of disturbances in sodium and water balance is illustrated in *Table 7-1*. Alterations in ECW size can occur in patients with hypotonicity, isotonicity, or hypertonicity. Similarly, each alteration in serum osmolality can develop in patients with contraction or expansion of the ECW compartment.

The presence of disturbances in sodium and water homeostasis must be addressed separately in the clinical evaluation of patients with derangements in ECF volume or tonicity. This must then be integrated to obtain a comprehensive view of what is abnormal, and determine how to restore sodium and water homeostasis effectively and with minimal side effects (*Fig. 7-2*). The clinical approach to these problems will be outlined later.

Sensor Mechanisms: Sodium and Water

For both sodium and water homeostasis, the sensor mechanisms that maintain the equilibrium state are primarily designed to be responsive to the consequences of abnormalities in sodium or water balance, i.e., changes in ECW and cell size, respectively, rather than measuring the primary variable. In this regard, they differ from a recently described acid-base sensor that is directly responsive to changes in pH (29). They operate using negative feedback loops in which deviations from normal are detected, counter-regulatory mechanisms are activated that antagonize the initiating event, and the system is restored to its original state.

Sodium

The detection of abnormalities in sodium balance is based on systems that sense the consequences of these changes. Thus, net sodium deficit is detected as a decrease in ECW space size, while net sodium excess is perceived as an obligatory expansion of the ECW space. These receptors, which are influenced by the filling pressure within the circulation, are called baroreceptors or mechanoreceptors. These signals are supplemented in certain instances by chemoreceptors that respond directly to changes in the serum sodium concentration and trigger adaptive modifications in renal sodium handling. These receptors may effect change by altering nervous system activity or by activating upstream promoter elements and stimulating the expression of relevant genes (30).

Atrial Receptors

There are ECW volume receptors on the venous (low pressure) and arterial (high pressure) sides of the circulation. Within the right atrium, sensors possess the distensibility and compliance needed to detect alterations in intrathoracic blood volume provoked by increasing negative intrathoracic pressure or head-out water immersion. Both of these maneuvers, which increase the central blood volume and raise central venous and right atrial pressures, are followed by a brisk natriuresis and diuresis (31). These relative changes are triggered even in the absence of a concomitant change in the total ECW space size. Neural receptors that respond to mechanical stretch or changes in right or left atrial pressure convey the signal via the vagus nerve (31, 32).

Table 7-1

Clinical diseases of sodium and water homeostasis: relationship between ECW size and tonicity

Tonicity ECW volume	Low	Normal	High
Low	Addison's disease	Isotonic diarrheal Dehydration	Hypertonic diarrheal Dehydration
	Salmonella diarrhea		Diabetes insipidus
	Mannitol infusion		
Normal	SIADH	No disease	Acute sodium bicarbonate infusion
High	Acute renal failure	Nephrotic syndrome	Salt intoxication
	Nephrotic syndrome		Salt water drowning
	Cirrhosis		
	Congestive heart Failure		

Hepatic Receptors

The enhanced renal sodium excretion, triggered by saline infusions, directly into the hepatic vein versus the systemic circulation suggests that there are low-pressure sensors within the portal vein or hepatic vasculature. The hepatic responses to changes in sodium balance have been divided into two categories (33). The "hepatorenal reflex" involves direct activation of sodium chemoreceptors and mechanoreceptors in the hepatoportal region, via the hepatic nerve, and causes a reflex decrease in renal nerve activity. The "hepatointestinal reflex" utilizes chemoreceptors to respond to changes in sodium concentration and modulate intestinal absorption of sodium via signals conveyed along the vagus nerve. Activation of these hepatic volume sensors may contribute to the sodium retention and edema states that develop secondary to chronic liver disease and cirrhosis with the associated intrahepatic hypertension.

Pulmonary Receptors

There may also be pressure sensors within the pulmonary circulation that are activated by changes in pulmonary perfusion or mean airway pressure (34). The receptors in the lung may be located in the interstitial spaces and influence the physical forces that modulate paracellular absorption of sodium and water. They resemble receptors in the renal interstitium that also influence paracellular absorption of fluid and solutes along the nephron, especially in the proximal tubule segment (35).

Carotid Arch Receptors

There are also volume-dependent sensors on the high-pressure side of the circulation including the carotid arch, the brain, and the renal circulation. Thus, occlusion of the carotid leads to increased sympathetic nervous system activity and alterations in renal sodium handling (32). The responsiveness of the carotid arch receptors may be modulated by chronic changes in ECF volume. For example, a head-down bed position and a high salt diet blunt carotid baroreceptor activity (36).

Cerebral Receptors

Increases in the sodium concentration of the CSF or brain arterial plasma promote renal sodium excretion (37). Lesions in discrete anatomic areas of the brain such as the anteroventral third ventricle alter renal sodium reabsorption, confirming that there are central mechanisms of sensing changes in sodium balance and ECF volume. Derangements in the sensing system within the brain in patients with long-standing central nervous system diseases may contribute to the cerebral syndrome. Intracerebral expression of angiotensin converting enzyme (ACE) isoforms contribute to peripheral sodium and water handling (38).

If the arterial sensors perceive underfilling of the vascular space, this activates counter-regulatory mechanisms to restore the ECW compartment size even if the receptors in the venous system detect adequate or even overfilling of the venous tree. This implies that despite normal or even excess total body sodium and net positive sodium balance, there are conditions in which the body perceives

an inadequate circulating plasma volume. This has given rise to the notion of the "effective" intravascular volume, a concept that is applicable in the edema states such as congestive heart failure, cirrhosis, and nephrotic syndrome (39). For example, in patients with cardiac pump failure, perceived underfilling of the arterial tree may occur despite significant venous distention (25b). Similarly, women who develop edema during pregnancy may have primary peripheral vasodilatation and excess total body sodium (39).

In summarizing the sensor mechanisms that are involved in the regulation of sodium balance, the primary ones are those that are directly linked via mechanoreceptors to the status of the ECF volume. These sensor systems are activated by a decreased size of the ECW compartment and respond to "underfilling" of the vasculature tree. However, there are secondary mechanisms that are activated by chemoreceptors or localized intra-organ disturbances in perfusion that are dissociated from the ECF volume. These sensors can cause overfilling of the vascular compartment by stimulating renal sodium reabsorption. Correct interpretation of the balance between these two processes involved in sodium balance is critical to the proper diagnosis and management of the edema states.

Water

The receptors that are responsible for regulating water homeostasis are primarily osmoreceptors and are sensitive to alterations in cell size (40). These osmoresponsive cells are located in the circumventricular organs and anterolateral regions of the hypothalamus, adjacent to but distinct from the supraoptic nuclei. They shrink or swell in response to increases or decreases in plasma tonicity and this change in cell size triggers the release of AVP and/or the sensation of thirst. The anatomic configuration of these cells enables them to be exposed to circulating peptides that are involved in water homeostasis.

AVP

AVP is a peptide containing nine amino acids and has a molecular weight of 1,099 Da. It is synthesized by the cells in the hyopothalamus, transported down the axon, and stored in the posterior pituitary in conjunction with larger proteins, called neurophysins (41). The gene for AVP is located on chromosome 20 and has a cAMP response element in the promoter region. Prolonged stimulation of AVP release leads to upregulation of the AVP gene; however, synthesis does not keep up with the need for the peptide because pituitary levels of AVP are usually depleted in states such as chronic salt loading and hypernatremia (42).

The principle solute that provokes the release of AVP is sodium. Infusion of sodium chloride to increase plasma osmolality results in increased secretion of AVP in the absence of parallel changes in ECW volume. This underscores the primary role of plasma osmolality per se in stimulating AVP release (40). Mannitol, an exogenous solute that is used in clinical practice to treat increased intracranial pressure, is nearly as effective as sodium in stimulating AVP release. Urea and glucose are <50% as effective as sodium in provoking AVP secretion because they are more permeable than sodium and cause less pronounced changes in osmoreceptor cell volume. However, in disease states such as acute renal failure or diabetic ketoacidosis, in which urea or glucose, respectively, act as osmotically active molecules or following the exogenous administration of mannitol, these solutes also stimulate increases in AVP release. There is coupling between mechanical changes in membrane structure and hormone release. However, the exact mechanism and the neurotransmitters that mediate the actions of the osmoreceptors on the cells of the posterior pituitary have not been identified.

A variety of nonosmotic stimuli to AVP release may contribute to water handling in various disease states (40). Vomiting and acute hypoglycemia promote AVP release by neural–hormonal pathways that are not well defined. Stress associated with pain or emotional anxiety, physical exertion, high body temperature, acute hypoxia, and acute hypercapnia are other conditions that lead to increased secretion of AVP in the absence of a primary disturbance in water balance. Numerous drugs directly influence the hypothalamic release of AVP including carbamazepine, cyclophosphamide, and vincristine. Finally, hemodynamic changes arising from primary alterations in sodium balance and the ECW space can trigger AVP release. If the ECW volume disturbance is mild, then the stimulation of AVP release is modest. However, in the face of severe ECW volume contraction, there is marked secretion of AVP. Under these circumstances, the imperative to protect the effective circulating blood volume takes precedence over the need to maintain plasma osmolality and ECW volume is restored at the expense of hypoosmolality. This clinical observation indicates that despite rigorous intellectual attempts to separate sodium and water homeostatic mechanisms, these two factors are closely linked in vivo and there can be significant overlap in sensor and effector mechanisms in the regulation of ECW and ICW compartment size. *Table 7-2* summarizes the factors that modulate AVP release.

Table 7-2
Factors that increase AVP release

↑Plasma osmolality
Hemodynamic
↓Blood volume
↓Blood pressure
Emesis
Hypoglycemia
Stress
Elevated body temperature
Angiotensin II
Hypoxia
Hypercapnia
Drugs

In addition to AVP release, the osmoreceptor cells also respond to the changes in serum osmolality in an independent manner to stimulate thirst and increase drinking (43). The stimuli for thirst are generally the same as those for AVP release, with hypernatremia being the most potent trigger. The osmotic threshold for thirst in humans appears to be higher than for AVP secretion, i.e., 295 mosm/kg. The sensing mechanism that leads to this increase in water intake is even more obscure than that for AVP release. It is likely that changes in ECW volume are also involved in this process because angiotensin II, which rises in states of ECW volume contraction, is a potent dipsogen (44). Recent studies suggest that the day-to-day regulation of thirst by osmoreceptors is under the control of dopamine-mu opioid neurotransmitters in the brain while angiotensin II may be activated under more stressful conditions (1).

Efferent Mechanisms: Sodium and Water

The efferent mechanisms involved in maintaining sodium and water balance include the neural and endocrine-humoral systems. There often is an overlap in the action of these effectors, with an individual effector having distinctive effects on both sodium and water balance.

Sodium

Renin–Angiotensin–Aldosterone Axis

The major components of this system – renin, angiotensinogen, and ACE – are found within the kidney and the vasculature of most organs. These elements are linked in a large feedback loop involving the liver, kidney, and lung as well as smaller loops within individual organs. This accounts for the often-disparate data about plasma renin activity (PRA) and the expression of individual components within the kidney during disturbances in ECW compartment size.

Angiotensin II is the major signal generated by this axis (45). There are two distinct forms of ACE and the ACE2 isoform may metabolize angiotensin II to nonpressor breakdown products that react with specific receptors and that are less likely to promote the development of hypertension (46). This introduces another layer of complexity in the regulation of sodium balance by the renin–angiotensin axis. Angiotensin II interacts with two different receptors, and most of its biological activity is mediated by the angiotensin type 1 (AT1) receptor. The AT2 receptor is more prominently expressed in the fetal kidney; however, interaction of angiotensin II with the AT2 receptor postnatally stimulates the release of molecules such as nitric oxide (NO) that counteract the primary action of the peptide (47). In addition, angiotensin I can be processed to the heptapeptide angiotensin 1–7, which interacts with a separate mas receptor and modulates the biological effects of angiotensin II (46). More research is needed to elucidate the role of alternate forms of angiotensin such as angiotensin 1–7 on sodium and water balance in children.

The best-known effects of angiotensin II include peripheral vasoconstriction to preserve organ perfusion and stimulation of adrenal synthesis of aldosterone to enhance renal sodium reabsorption. These two actions restore the ECW space to normal. However, angiotensin II also has direct actions on tubular function and stimulates both proximal and distal sodium reabsorption. The proximal tubule cells contain all of the elements needed to synthesize angiotensin II locally and the peptide increases the activity of the sodium–hydrogen exchanger (48). In the distal tubule, angiotensin II modulates this exchanger as well as the amiloride-sensitive sodium channel (45). The effects of aldosterone on the renal tubule include an immediate effect to increase apical membrane permeability to sodium and more extended effects that involve enhanced gene transcription and de novo synthesis of Na-K ATPase. Aldosterone stimulates the synthesis of other enzymes involved in renal cell bioenergetics such a citrate synthase that are needed to sustain maximal tubular sodium transport (49). Finally, aldosterone induces a state of glucose-6-phosphate dehydrogenase deficiency in endothelial cells which may contribute to oxidant stress and altered reactivity of blood vessels in response to disturbances in sodium balance (50).

Endothelin

This vasoactive molecule is part of a family of three peptides of which endothelin-1 (ET-1) is the most important in humans (51). It is converted in two steps from an inactive precursor to a biologically active 21-amino acid peptide. Endothelins react with two receptors, ETA and ETB, and cause vasoconstriction, resulting in a decrease in renal blood flow and glomerular filtration rate (GFR). With regard to sodium balance, the primary effect of endothelin is sodium retention mediated by the reduction in GFR. This suggests that endothelin acts in concert with angiotensin II to protect ECW compartment size under conditions of sodium deficit. However, the situation may be more complicated because direct exposure of proximal tubule and medullary collecting duct cells to endothelin in vitro inhibits sodium absorption.

Renal Nerves

There is abundant sympathetic nervous innervation of the renal vasculature and all tubular segments of the nephron (52). The efferent autonomic fibers are postganglionic and originate in splanchnic nerves. The renal innervation is primarily adrenergic and involves α1 adrenoreceptors on blood vessels and both α1 and α2 receptors along the basolateral membrane of the proximal tubule. Renal sympathetic nervous system activity contributes to preservation of ECF volume by (1) promoting renal vasoconstriction and lowering GFR and (2) increasing sodium reabsorption. Among the catecholamines involved in adrenergic transmission, norepinephrine exerts an antinatriuretic effect. Dopamine, another sympathetic nervous system neurotransmitter, promotes a natriuresis, suggesting that there is internal regulation of the effect of nerve activation on renal sodium handling (53).

Renal sympathetic nervous activity is inversely proportional to dietary salt intake (52). Drug-induced sodium retention and volume-dependent hypertension, e.g., with the use of cyclosporine, is mediated in part by activation of the sympathetic nervous system (54). Increased adrenergic nervous signaling within the kidney is instrumental in the initiation of hypertension in experimental animals by causing a right-shift in the pressure–natriuresis curve (52). However, sodium balance is normal and ECF volume is maintained in the denervated transplanted kidney, implying that the role of the sympathetic nervous system in maintaining sodium homeostasis is redundant and can be taken over by other regulatory mechanisms (52).

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is a 28-amino acid peptide that is a member of a group of proteins that includes C-type natriuretic peptide (55). It is synthesized as a prohormone that is stored in granules in the cardiac atria. There are other molecular isoforms of the hormone including brain natriuretic peptide (BNP) whose circulating levels are altered and which can be monitored at diagnosis and in response to treatment in conditions such as congestive heart failure (56).

Increases in right atrial pressure provoke cleavage and release of the mature peptide. For each 1 mm Hg rise in central venous pressure, there is a corresponding 10–15 pmol/L increase in circulating ANP levels. Conversely, declines in atrial pressure secondary to sodium depletion or hemorrhage inhibit ANP release. There are two receptors for ANP and both are coupled to guanylate cyclase. The activation of this enzyme results in cytosolic accumulation of cGMP, which in turn diminishes agonist-stimulated increases in intracellular calcium concentration. The principle effects of ANP are to promote an increase in GFR, diuresis, and most importantly, natriuresis. The augmented renal sodium excretion is, in part, mediated by an increased filtered load secondary to the rise in GFR. However, ANP also exerts direct actions on renal tubular cells to diminish sodium reabsorption including inhibition the Na-K-Cl co-transporter in the loop of Henle and the amiloride-sensitive sodium uptake in the medullary collecting duct. Finally, ANP antagonizes the action of several antinatriuretic effectors, including sympathetic nervous system activity, angiotensin II, and endothelin. The overall effects of ANP to counteract increases in ECW compartment have been demonstrated by short-term studies in which acute infusions of ANP improved cardiac status in patients with congestive heart failure and promoted a diuresis in patients with acute renal failure (57). However, despite the potent actions of ANP on fluid balance, clinical trials assessing its efficacy in chronic congestive heart failure have been disappointing and may be associated with an increased risk of kidney failure (58).

Prostaglandins

The kidney contains the enzymes required for constitutive (COX-1) and inducible (COX-2) cyclooxygenase activity that convert arachidonic acid to prostaglandins (59). The major products of these pathways are PGE_2, $PGF_{2\alpha}$, PGD_2, prostacyclin (PGI_2), and thromboxane (TXA_2).

In the cortical regions, PGE_2 and PGI_2 predominate, while PGE_2 is the major prostaglandin metabolite in the medulla. These two compounds increase GFR and promote increased urinary sodium excretion. In addition, they antagonize the action of AVP. These actions may mediate the adverse effects of hypercalcemia and hypokalemia on renal tubular function (59). The natriuretic effects of prostaglandins, in response to normal alterations in dietary sodium intake are unclear. The role of prostaglandins as efferent signals is more apparent in conditions associated with increased vasoconstrictor tone such as congestive heart failure or reduced renal perfusion, where prostaglandins counteract the vasoconstrictor and sodium-retaining effects of angiotensin II and norepinephrine. Inhibition of prostaglandins with cyclooxygenase inhibitors is associated with dramatic declines in GFR and profound sodium retention and edema (60).

Kinins

Kinins are produced within the kidney and act via B_1 and B_2 receptors. Because the half life of kinins in the plasma is very short, in the range of 20–40 s, it is likely that their actions in the kidney are regulated locally through production and proteolytic processing in the tissue (61). Their principal action is to promote renal vasodilatation and natriuresis. The kinins act primarily in the distal tubule to reduce sodium reabsorption (61, 62).

Nitric Oxide

The kidney contains all three isoforms of nitric oxide synthase (NOS) – neuronal NOS in the macula densa, inducible NOS in renal tubules and mesangial cells, and endothelial NOS in the renal vasculature – involved in NO synthesis. The neuronal and endothelial isoforms are calcium-dependent enzymes and produce small, transient increases in NO synthesis. The inducible isoform is upregulated by various cytokines and inflammatory mediators, resulting in large sustained elevations in NO release.

Activation of eNOS within the kidney increases the activity of soluble guanylate cyclase and causes vasodilatation and an increase in GFR. In addition to its effect on renal blood flow and GFR, NO directly inhibits Na-K ATPase in cultured proximal tubule and collecting duct cells (63, 64). The specific isoform of NOS that is responsible for modulating urinary sodium excretion is not well defined. Studies with inducible NOS, neuronal NOS and endothelial NOS knockout mice suggest that only the first two isoforms are involved in the regulation of sodium and water reabsorption in the proximal tubule (63). A role of NO in maintaining sodium balance under normal conditions is suggested by the observation that alterations in dietary salt intake are associated with parallel changes in urinary excretion of nitrite, the metabolic byproduct of NO (65). In normotensive Wistar-Kyoto rats and spontaneously hypertensive rats, increased dietary sodium intake is associated with a modest increase in urinary nitrite excretion (66). This effect is not well-documented in pediatric patients. Along with ANP and bradykinin, NO is part of the defense system against sodium excess and expansion of the ECW compartment. Derangements in renal NO synthesis and responsiveness to cGMP may be instrumental in the pathogenesis of salt-dependent hypertension in experimental animals (67).

Adrenomedullin

Adrenomedullin is a 52-amino acid peptide that was isolated from human pheochromocytoma cells (68). It reacts with a G-protein cell receptor and causes vasodilatation, an effect that may be mediated by increased synthesis of NO. The resultant natriuresis secondary to the increase in GFR is accompanied by direct inhibition of tubular sodium reabsorption. Its role in sodium balance is under investigation.

Water

AVP

The primary efferent mechanism in the maintenance of water homeostasis is AVP. This peptide fosters water retention by the kidney and stimulates thirst. The plasma AVP concentration is approximately 1–2 pg/mL under basal conditions (40). It is not known whether there is tonic release of AVP or whether there is pulsatile secretion in response to minute fluctuations in plasma osmolality. The set point, or osmotic threshold for AVP release, ranges from 275–290 mosm/kg H_2O. The circulating hormone concentration rises approximately 1 pg/mL for each 1% increase in plasma osmolality. The sensitivity of the osmoreceptors in promoting AVP release varies from person-to-person with some individuals capable of responding to as small as a 0.5 mosm/kg H_2O increase in osmolality and others requiring greater than a 5 mosm/kg H_2O increment to stimulate AVP release. Patients with essential hypernatremia possess osmoreceptors that have

normal sensitivity, but the osmotic threshold for AVP release is shifted to the right. Because the relative distribution of water between the ECW and ICW compartments is undisturbed, these patients are unaffected by their abnormally high serum sodium concentration. Although there may be sex-related differences in AVP secretion in response to abnormal water homeostasis with increased sensitivity in women, this is not a relevant clinical concern in prepubertal children.

Angiotensin

Angiotensin II serves as an efferent system in water homeostasis primarily by acting as a potent dipsogen and stimulating drinking (44). Its role in water handling within the kidney is minor and may be related to modulation of the renal response to AVP.

Thirst

Thirst, or the consciously perceived desire to drink, is a major efferent system in water homeostasis (43). It is estimated that for each 1 pg/mL increase in the circulating plasma AVP level, there is parallel rise of 100 mosm/kg H_2O in urinary concentration. If the basal plasma osmolality and AVP concentration are approximately 280 mosm/kg H_2O and 2 pg/mL, respectively, and the steady state urine osmolality is 200 mosm/kg H_2O, then as soon as the plasma osmolality and AVP concentration reach 290 mosm/kg H_2O and 12 pg/mL, respectively, the urine is maximally concentrated. Beyond this point, the only operational defense against a further rise in plasma osmolality is increased free water intake, underscoring the essential role of thirst as an efferent mechanism in water homeostasis. It highlights the increased risk of hyperosmolality in patients who do not have free access to water such as infants, the physically or mentally incapacitated, or the elderly (69).

Thirst is a difficult biological function to quantitate because it is an expression of a drive rather than an actual behavior. At present, visual analog scales using colors or faces are the most useful tools for quantitating thirst under controlled condition. There can be dissociation between water intake and the sensation of thirst as in patients with psychogenic polydipsia (e.g., schizophrenia, neurosis). It is not known whether specific drugs directly stimulate the dipsogenic response. The role of diet, e.g., high salt intake, in the regulation of thirst is also unknown. The osmotic control of thirst may be suboptimal in newborn infants and in the elderly (69).

Thirst and drinking behavior are stimulated by significant contraction of the ECF space or by hypotension. In addition, thirst and drinking behavior are modulated by signals that originate in the oropharnyx and upper gastrointestinal tract. Animals with hypernatremia who are given access to water as the sole means of correcting the hyperosmolal state stop drinking sooner than animals corrected in part with supplemental intravenous fluid. This is most likely due to oropharyngeal stimuli that curtail drinking prior to complete normalization of plasma osmolality (70).

Effector Mechanisms: Sodium and Water

The kidney is the principal organ that acts in response to sensory input, delivered via neural or humoral signals, to restore ECW volume size to normal following the full range of clinical problems. Although absorption of sodium and water across the intestinal epithelium may be modulated by chemoreceptors in the hepatic vasculature, the role of the gastrointestinal tract in the control of sodium balance is clearly secondary to the function of the kidney.

Sodium

GFR

In children with normal kidney function, changes in GFR are generally associated with parallel alterations in sodium balance. This is accomplished by glomerular-tubular balance in which proximal tubule sodium absorption and delivery of filtrate to the distal tubule is modulated in response to GFR (71). Tubular sodium reabsorption increases in parallel with an increase in GFR, which reflects the load-dependent nature of sodium reabsorption in the proximal tubule. In addition, changes in GFR lead to changes in the oncotic pressure in the peritubular capillaries that influence sodium reabsorption (72). Thus, an increased GFR is associated with higher hydrostatic pressures in the peritubular capillary network that retard fluid and solute reabsorption in the proximal tubule. Finally, tubuloglomerular feedback is activated by alterations in solute delivery to the distal nephron to bring GFR in line with alterations in tubular function. Many of the efferent signals including renin, angiotensin, NO, adenosine, and prostaglandins participate in this particular pathway. The release of these effector molecules is activated via myogenic stretch receptors

and chemoreceptors located in the macula densa region of the distal nephron. Even in children with compromised renal function (GFR < 20–30 mL/min/1.73 m^2), in whom there are adaptive changes in tubular function, e.g., increased fractional excretion of sodium (FENa), glomerulotubular balance is maintained in the face of gradual changes in GFR. However, patients with chronic kidney disease are unable to respond to abrupt changes in sodium balance and ECF volume changes as rapidly as in healthy children and are susceptible to volume contraction or hypervolemia if sodium intake is substantially reduced or increased over a short period of time (26).

Most of the neural and humoral factors described previously can modulate GFR. Agents that lower GFR act predominantly on the vascular tone of the afferent arteriole and reduce renal blood flow and the filtration fraction. Agents in this category include adrenergic nerve stimulation and endothelin. In contrast, angiotensin II acts primarily on efferent arteriolar tone. This tends to preserve GFR more than renal blood flow and the filtration fraction (RBF/GFR) is increased. This pattern is most evident in states of compromised effective perfusion such as congestive heart failure, cirrhosis, and nephrotic syndrome (39, 73, 74). The critical role of angiotensin II in maintaining GFR and sodium excretion in these conditions is manifested during the reversible functional decline in GFR that occurs after the administration of ACE inhibitors (75). This phenomenon also explains the reduction in kidney function and sodium retention that are observed in patients with a critical renal artery stenosis in a kidney transplant following initiation of ACE inhibitor therapy (75) and which are corrected by discontinuation of the medication.

Proximal Tubule

Nearly 60–70% of the filtered sodium and water load are reabsorbed in the proximal tubule. Sodium and fluid reabsorption are isosmotic in this nephron segment. These processes are driven by Na-K ATPase activity along the basolateral membrane surface with secondary active transport of solute across the apical membrane. The bulk of sodium reabsorption is driven by the sodium–hydrogen exchanger, with a lesser contribution by other co-transport systems for glucose, phosphate, organic anions and amino acids. The linkage between disturbances in ECF volume and sodium reabsorption in the proximal tubule is created, in part, by changes in the physical forces that govern fluid and solute movement. These include changes in peritubular capillary hydrostatic pressure, peritubular capillary protein concentration and oncotic pressure, and changes in renal interstitial pressure that modulate water and solute movement across cells (transcellular) and along the paracellular pathway.

Sympathetic nervous stimulation, norepinephrine release, and both filtered and locally synthesized angiotensin II stimulate the activity of the sodium–hydrogen antiporter and promote sodium reabsorption in conditions associated with decreased ECF volume. Conversely, ANP and the kinins act on proximal tubular cells to inhibit sodium reabsorption and limit expansion of the ECW space.

Distal Nephron Including Collecting Duct

This portion of the nephron is responsible for the reabsorption of approximately 10–25% of the filtered sodium and water load. Under most circumstances, it adapts to changes in delivery arising from alterations in proximal tubule function. This segment of the nephron is responsive to virtually all of the humoral efferent signals and accomplishes the final renal homeostatic response to fluctuations in sodium balance. Sodium reabsorption in the distal tubule and connecting segment is responsive to circulating levels of aldosterone (49). In the collecting tubule, mineralocorticoid-responsive sodium reabsorptive pathways achieve the final modulation of sodium excretion in response to alterations in sodium intake. Aldosterone enhances sodium reabsorption by inducing a number of transport proteins whose synthesis is triggered by activation of SGK1, serum and glucocorticoid-inducible kinase (76). The most prominent of these is the ENaC. This transepithelial protein is composed of three distinct chains – α, β, and γ – each of which is encoded by a separate gene (54). The complete protein has two membrane-spanning domains with an amino and carboxyl terminus within the cell. The α-chain appears to constitute the actual sodium conducting pathway while the β- and γ-chains may represent regulatory components that control the open/closed status of the channel. Genetic defects in each individual component have been described and linked to human disease. Thus, pseudohypoaldosteronism has been mapped to mutations in the α, β, and γ chains, and Liddle's syndrome has been attributed to truncation in the β-chain with increased ubiquitinylation and proteasomal degradation of the abnormal protein (76, 77, 78).

Water

AVP

AVP acts along several segments of the nephron. However, its primary site of action for maintenance of water homeostasis is the collecting tubule (66). In that segment of the nephron, AVP reacts with the V2 receptor, a 371-amino acid protein that is coupled to a heterotrimeric G-protein, along the basolateral membrane of the distal tubule and collecting duct cells. The V2 receptor gene has been localized to region 28 of the X chromosome. This epithelial cell receptor is distinct from the V1 receptor in the vasculature that is linked to Ca-activation of the inositol triphosphate cascade and which mediates vasoconstrictor response to the hormone (66).

Binding of AVP to the V2 receptor activates basolateral adenylate cyclase and stimulates the formation of cAMP within the cytosol. This intracellular second messenger then interacts with the cytoskeleton, specifically microtubules and actin filaments, and promotes fusion of intramembrane particles that contain preformed water channels with the apical membrane of principal cells in the collecting duct. The AVP-induced entry of preformed water channels involves clathrin-coated pits. Withdrawal of AVP leads to endocytosis of the membrane segment containing the water channels into vesicles that are localized to the submembrane domain of the cell, which terminates the hormone signal. Recycling of water channels from vesicles to the apical membrane and then back into vesicles has been demonstrated in freeze-fracture studies of cells exposed to AVP (66). The importance of the V2 receptor in water homeostasis is confirmed by genetic mutations and corresponding abnormalities in protein structure in children with X-linked congenital nephrogenic diabetes insipidus (79).

The water channels that mediate transmembrane movement of water across the collecting tubule in response to AVP are called aquaporins (80). There are nine known members of this group of proteins, all of which contain six membrane-spanning domains. The first member to be identified was aquaporin-1 (AQP-1) (originally called channel-forming integral membrane protein of 28 kDa or CHIP-28), which mediates water movement across the erythrocyte membrane and along the proximal tubule. Mice that do not express AQP-1 have a normal phenotype and concentrate their urine normally. AQP-2 is the major AVP-sensitive water channel in the collecting tubule (81). Immunogold electron microscopy studies have confirmed that AQP-2 represents the water channel in the cytosolic vesicles which fuse with the apical membrane following exposure of principal cells to AVP. The contribution of AQP-3 and AQP-4 to the normal urinary concentrating mechanism has been confirmed in mice that have been genetically manipulated and which do not express these two proteins (82).

The importance of AQP-2 in mediating the normal response to AVP has been verified by the discovery of mutations in the AQP-2 gene in children with non-X-linked, autosomal recessive forms of nephrogenic diabetes insipidus (83). Moreover, alterations in AQP-2 protein expression have been documented in other states associated with a urinary concentrating defect such as lithium exposure, urinary tract obstruction, hypokalemia, and hypercalcemia (80).

Water reabsorption in the collecting duct is not completely dependent upon the presence of AVP. In animals that are genetically deficient in AVP (Brattleboro rats) or in patients with central diabetes insipidus, urinary osmolality increases slightly above basal levels in the face of severe ECF volume contraction. This may be the consequence of reduction in urinary flow rate along the collecting duct that enables some passive equilibration between the luminal fluid and the hypertonic medullary interstitium.

Although the collecting duct is the primary site of regulation of net water reabsorption, the proximal tubule contributes to water balance under circumstances of decreased ECW compartment size. Whereas the proximal tubule normally reabsorbs approximately 60% of the filtered water load, this proportion may exceed 70% when the ECF volume is diminished. Furthermore, by decreasing fluid delivery to the distal nephron, this enhances the AVP-independent reabsorption of water along the collecting tubule. These combined effects may explain the clinical benefit achieved by the administration of thiazide diuretics to patients with nephrogenic diabetes insipidus (84).

Countercurrent Mechanism

The primary locus of the urinary concentrating mechanism is the medulla and involves the thin descending limb of Henle, medullary thick ascending limb of Henle, cortical thick ascending limb of Henle, and collecting duct (85). Sodium and water reabsorption are isosmotic in all segments of the nephron proximal to the loop of Henle. In order to concentrate or dilute the urine, water and solute must be separated to enable excretion of free water or

urine that is hyperosmolal relative to plasma. This process begins in the medullary and cortical thick ascending limb of Henle where NaCl is reabsorbed independently of water, generating a hypotonic luminal fluid. This action is linked in series to the low water permeability of the distal tubule and the connecting segment, which together with continued sodium reabsorption, enhances the hypotonicity of the urine in this segment. In a secondary step, the permeability to water along this segment of the nephron is much lower than in the descending limb of the loop of Henle. This enables water to move down its osmolal gradient from the tubule lumen into the interstitium as it enters the medulla in the descending limb. Finally, the third critical component of the countercurrent mechanism is the presence of vasa recta, which perfuse the inner medulla via vascular bundles that contain hairpin loop-shaped blood vessels. This facilitates efficient removal of water that exits the descending limb of Henle from the medullary interstitium without washing out the solute gradient that passively drives water reabsorption in the collecting tubule. The final effector mechanism is the alteration in the water permeability of the collecting tubule in response to AVP and the generation of a concentrated urine or the excretion of solute free water in the absence of AVP (*Table 7-3*).

Osmoprotective Molecule (Compatible Osmolytes)

Besides the presence of effector mechanisms to maintain water balance, cells possess a wide range of adaptive mechanisms to counteract the undesirable movement of water between the cell and the ECW during hypotonic and hypertonic states and to prevent neurological dysfunction. These include early response genes that mediate the prompt accumulation of chaperone molecules to counteract the adverse effects of altered cell size on protein function (27). This is followed temporally by the uptake or extrusion of electrolytes as an acute response to altered size cell. Because there are inherent limits on the ability to regulate cell volume exclusively with inorganic electrolytes, the more extended response involves membrane transport and/or synthesis/degradation of a variety of compatible solutes, called osmolytes, whose cytosolic concentration can be safely altered without perturbing enzymatic activity and cell function. These osmoprotective molecules include carbohydrates (sorbitol, myo-inositol), amino acids (taurine, glutamate), and methylamines (betaine, glycerophosphorylcholine) (27). They accumulate in the cytosol to preserve cell function during chronic osmolal disturbances. The cell volume regulatory response can be activated by electrolytes such as sodium or neutral molecules, e.g., urea and glucose (27a). The adequacy of the cell volume regulatory response and the accumulation of osmoprotective molecules in cerebral and renal cells depend on the rate of rise in osmolality as well as the magnitude of the absolute change (86).

Experimental data in animals and clinical experience in premenopausal women suggest that estrogens may impair the cell volume regulatory response to disturbances in plasma osmolality. This increases the risks associated with both the untreated abnormalities and therapy (87). The cell volume regulatory adaptation is fully operational during maturation. The accumulation of osmoprotective molecules in the face of chronic hypernatremia is normal in preweanling rats with a higher set-point to preserve the increased brain cell water content (88).

Failure to adequately account for the cell volume regulatory response to osmolal disorders contributes to some of the adverse effects associated with inappropriate correction of abnormalities in plasma osmolality. These include neurological dysfunction, specifically seizures, during the treatment of hypernatremia, osmotic demyelinating syndrome following rapid reversal of hyponatremia, dialysis dysequilibrium syndrome after the initiation of dialysis in patients with acute or chronic renal failure, and cerebral edema and brain herniation in patients with a first episode of acute diabetic ketoacidosis (89, 90).

Table 7-3

Factors that contribute to the countercurrent mechanism

Na-Cl-K-mediated solute absorption in the medullary thick ascending limb of Henle
Low water permeability of the distal tubule and connecting segment
High water permeability in the descending limb of Henle
Vasa recta and elimination of interstitial water volume
AVP-responsiveness of the collecting tubule

Laboratory Assessment of Sodium and Water Balance

There are no normal values for sodium and water intake or excretion, a reflection of the wide range of normal daily dietary intake for both sodium and water. Healthy individuals are in balance and the excretion of sodium and water matches the daily intake. Therefore, laboratory

assessment of sodium and water homeostasis is confined to disease states in which the clinician must determine whether renal sodium and water handling are appropriate for the clinical circumstances, will maintain external balance, and prevent disturbances in ECF volume or water distribution between the ICW and ECW compartments.

Sodium

The urine sodium concentration is not a valid index of sodium balance because the value may vary depending upon the volume and concentration of the sample. Therefore, the renal handling of sodium is best evaluated using the FENa. After obtaining a random urine sample and a simultaneous blood sample and measuring the sodium and creatinine concentrations in both specimens, the FENa is calculated using the following formula:

$$\begin{aligned}\text{FENa} &= \text{Excreted sodium}/\text{Filtered sodium}\\ &= \text{Urinary sodium concentration}\\ &\quad \times \text{urine flow rate}\\ &\quad / \text{ Plasma creatinine concentration}\\ &\quad \times \text{GFR}\\ &= \frac{\text{Urine sodium concentration}\,/\,\text{Plasma sodium concentration}}{\text{Urine creatinine concentration}\,/\,\text{Plasma creatinine concentration}}\\ &= \frac{\text{Urine sodium concentration}\times\text{Plasma creatinine concentration}}{\text{Plasma sodium concentration}\times\text{Urine creatinine concentration}}\end{aligned} \tag{3}$$

This formula is based on the insertion of the creatinine clearance as a measurement of GFR in the second equation and the cancellation of the urine flow rate term in the numerator and denominator. Therefore, the determination of the FENa is an especially useful test in clinical practice because it can be done using spot samples and does not require a timed urine collection. In healthy individuals, the FENa varies depending upon the daily sodium intake. However, in patients with ECF volume contraction who are responding appropriately to retain sodium, the FENa is $<1\%$ ($<3\%$ in neonates). Conversely, patients with expansion of the ECW compartment, the FENa will exceed 3% unless there is concomitant renal disease.

Water

Determination of the urine specific gravity or osmolality in a random sample varies depending upon the water intake in past 2–4 h. Therefore, the assessment of water handling is best judged by determining these values under more controlled conditions such as in the water-deprived state or following administration of a water load (10–20 mL/kg body weight) to evaluate the urinary concentrating or diluting capacity, respectively.

The functional aspects of renal water handling are best assessed by determining the free water clearance. This represents the amount of solute-free water excreted by the kidney. It is calculated using the following formula:

$$\begin{aligned}\text{Free water clearance} &= \text{Urine volume} - \text{osmolal clearance}\\ &= \text{Urine volume} - [\text{Urine osmolality}\\ &\quad \times \text{urine flow rate}]/\text{Plasma osmolality}\end{aligned} \tag{4}$$

If the free water clearance is a positive number, then the urine/plasma osmolality ratio is <1, the urine is dilute, and the kidney is in a diuretic mode. When a water diuresis is maximal, the free water clearance measures the capacity of the kidney to excrete free water. Under these circumstances, urine volume is directly related to the dietary solute intake (19). In contrast, patients who are in an antidiuretic mode and can concentrate the urine have a urine/plasma osmolality ratio >1 and a negative free water clearance. As the solute excretion rate increases, both the maximum values for free water clearance and free water reabsorption increase. At any given solute excretion rate, the free water clearance greatly exceeds the free water reabsorption. This indicates that the renal water homeostatic mechanisms designed to protect against overhydration and dilution of the ECW are more robust than those used to defend against water deficit and dehydration.

Overview of the Evaluation of Fluid and Water Abnormalities

In practice, the clinical information and laboratory data used to evaluate patients overlap with one another. However, in view of the different physiological roles of sodium and water balance in body fluid homeostasis, the distinct regulatory mechanisms activated to control these factors, and the varied therapeutic strategies that must be employed to restore sodium and water balance in disease

states, it is essential that disturbances in sodium and water balance be evaluated separately. In real-time, these separate assessments are done in parallel, a reflection of the body's own method of operation.

When confronted with a child with a sodium and water disturbance, the first question that must be addressed is whether the size of the ECF volume is altered to the extent that perfusion of vital organs or pulmonary gas exchange is jeopardized. Thus, it is necessary to clarify whether the ECF volume is decreased or expanded, which represents a clinical assessment of sodium balance. Depending on the severity of the problem, such patients have a life-threatening condition and may require emergency therapy such as volume resuscitation or acute dialysis.

After making this acute determination and instituting appropriate emergency therapy, it is important to grade the magnitude of the disturbance in ECF volume. There is no single or combination of laboratory tests that can substitute for clinical judgment. Because acute changes in body weight always reflect alterations in sodium balance and ECW compartment size, serial measurements in body weight are the most reliable indicator of the presence and severity of disturbances in ECF volume. However, these measurements are often unavailable or will have been done in different locations using different equipment. Therefore, the evaluation of sodium balance is based upon a wide range of clinical findings including changes in mental status, level of alertness, irritability, presence of thirst, pulse rate, blood pressure, orthostatic changes, fullness of the anterior fontanelle in infants, the presence of tears, dryness of the mucus membranes, skin color, elasticity of the skin or tenting, capillary refill or turgor, peripheral edema, shortness of breath, and the presence of rales on auscultation of the chest. Capillary refill may be the most useful test to rapidly and accurate assess ECF volume and the response to treatment (91). Other findings on clinical examination include urinary specific gravity, and central venous pressure. Laboratory investigations include BUN, serum creatinine and bicarbonate concentrations.

It is important to emphasize that assessment of ECF volume is a *clinical determination*. There is no single or combination of laboratory tests that is a valid surrogate marker. Moreover, despite the frequency of clinical disturbances in sodium balance, especially ECF volume contraction, no suitable scoring has been devised to accurately and reliably distinguish different degrees of ECF volume contraction or expansion. This contrasts to the Glasgow coma score or the APACHE score that have been successfully applied to the initial assessment of patients with acute neurological or multisystem organ failure.

The third step in the evaluation of a patient with a sodium and water disturbance is to measure the plasma osmolality, which indicates an abnormal distribution of water between the ECW and ICW compartments. The most likely symptoms in affected patients arise secondary to central nervous dysfunction and include confusion, irritability, lethargy, obtundation, and seizures. These manifestations overlap significantly in patients with hyperosmolality or hypoosmolality. Moreover, there is no obligatory change in ECF volume. In contrast to disorders of ECF volume, disturbances in water balance and distribution require a laboratory determination for confirmation and grading. The steps involved in the initial evaluation of a child with a disturbance in sodium and water balance are summarized in *Table 7-4*. The following sections will describe the individual clinical entities responsible for derangements in sodium and water balance and outline the general treatment of these conditions.

Sodium Balance Disturbances: Deficit and Excess

Sodium Deficit

Diagnosis and Evaluation

In children with normal kidney function, steady consumption of a diet that is low or high in sodium does not cause a net negative or positive sodium balance because the kidney can adaptively modify sodium reabsorption in parallel with salt intake if the changes are not too abrupt or massive in nature.

Sodium deficits and ECF volume contraction are dangerous because decreased size of the intravascular space leads to reduced perfusion and ischemia of vital organs

Table 7-4

Steps in the initial evaluation and treatment of a child with a disturbance in sodium and/or water balance

Step 1: Determine if there is a life-threatening alteration in ECF volume
• Volume resuscitation if there is ECF volume contraction
• Consider dialysis if there is ECF volume expansion
Step 2: Grade severity of defect in sodium balance
• Clinical determination of ECF volume
Step 3: Determine if there is a defect in water balance
• Laboratory measurement of plasma osmolality

such as the brain, heart, and kidneys. In children, the absence of concomitant atherosclerosis disease or endothelial dysfunction secondary to essential hypertension, smoking, hyperlipidemia and diabetes, decreases this risk. However, there are groups of pediatric patients who may be more susceptible to the adverse consequences of hypovolemia. These include newborn babies in whom high circulating levels of vasoconstrictor hormones and impaired autoregulation render the glomerular microcirculation sensitive to reduced perfusion (92). In addition, underlying diseases or medications may hinder the counterregulatory responses to ECF volume contraction and heighten the risks of hypovolemia.

Diseases that cause sodium deficiency can originate outside the kidney or within the kidney. It is unfortunate that the word dehydration is routinely used to describe these states because it deflects attention from the primary defect, namely a net negative sodium balance and suggests that water deficit is the major pathophysiological problem in these conditions (93, 94). The critical role of the ECF space and sodium balance in the pathogenesis of states of volume contraction is highlighted by comparing the situation that occurs in patients with diabetes insipidus. When sodium balance is perturbed, >30% of the fluid loss is derived from the ECW compartment provoking the rapid onset of symptoms. In contrast, only 1/12 or 8% of the pure water loss that occurs in diabetes insipidus is derived from the ECF (⅓ × ¼), accounting for the rare evidence of ECF volume contraction in children with central or nephrogenic diabetes insipidus (*Fig. 7-1*). Use of the term "denatration" may provide a more accurate depiction of what is occurring in patients with primary deficits in sodium balance and contraction of the ECF volume (93).

Extrarenal causes can occur from losses of sodium in any body fluid or across any epithelial surface including the CSF, pleural fluid, biliary tree, gastrointestinal losses, or skin. They can be the result of a disease process or they may be iatrogenic. Chronic kidney disease can cause sodium deficit because the lower GFR compromises the homeostatic capacity of the renal tubules. Alternatively, there may be primary renal sodium loss that is not the consequence of a decrease in kidney function. Finally, renal sodium reabsorption may be diminished because of reduced circulating levels of aldosterone or unresponsiveness to the hormone. The major causes of sodium deficiency are summarized in *Table 7-5*.

The diagnosis of the cause of a disturbance in sodium balance is made based on a thorough history and physical examination. In most cases, this information is adequate to identify the source of the sodium losses. Previously, the degree of ECF volume contraction was categorized as mild, moderate, or severe if the changes in body weight were estimated to be <5, 5–10, or >10%, respectively. Life-threatening ECF volume contraction was thought to represent >15% decrease in weight. Recent data, based upon systematic body weights at the time of hospitalization and immediately after correction of the sodium deficit, suggest that these numbers overestimate the degree of sodium deficit and that the ECF volume contraction is better estimated to be <3, 3–6, and >6% with >9% change in body weight representing an emergency (95).

If the losses are primarily extra-renal, then renal sodium reabsorptive mechanisms will be activated and the urinary specific gravity will be >1.015 and the FENa will

Table 7-5

Causes of net sodium deficit

Renal causes
Compromised GFR
Acute decrease in sodium intake or increased losses
Tubular disorders
Osmotic diuresis
Diabetic ketoacidosis
Renal tubular acidosis
Pseudohypoaldosteronism
Obstructive uropathy
Bartter's syndrome
Renal dysplasia/hypoplasia
Central nervous system
Cerebral salt wasting
CSF drainage procedures
Hepato-biliary system
Biliary tract drainage
Gastrointestinal tract
Infectious diarrhea
Chloride diarrhea
Laxative abuse
Malignancy (carcinoid, tumor-related)
Adrenal diseases
Salt-losing congenital adrenal hyperplasia
Addison's disease
Skin losses
Cystic fibrosis
Neuroectodermal diseases
Burns

be low, generally <1% except in infants. Failure to increase the urine concentration and lower FENa in the face of clinical signs of ECF volume contraction points towards a renal or adrenal cause for the disorder. A renal ultrasound documenting the presence of small, misshaped kidneys or hydronephrosis may be indicative of congenital abnormalities of the kidney such as dysplasia or obstructive uropathy. Adrenal insufficiency is suggested by concomitant hyponatremia and hyperkalemia in a child with ECF volume contraction.

Treatment

If the ECW compartment size is so severely contracted that vital organ perfusion is compromised, based upon an altered mental status, orthostatic changes, and azotemia, then fluid resuscitation must be initiated on an emergent basis. This is necessary to prevent the development of acute kidney injury, which may occur if there is sustained hypotension and renal ischemia secondary to ECF volume contraction. This term has been introduced to replace acute tubular necrosis which implies the presence of pathologic changes that are usually absent in kidney biopsy samples (9). The risk of acute kidney injury is higher in children with preexisting renal disease, who are receiving nephrotoxic medications or who have hemoglobinuria or myoglobinuria, e.g., crush injury or compartment syndrome. If there is no evidence of cardiac or pulmonary disease, then the optimal therapy under these conditions is infusion of isotonic crystalloid (0.9% NaCl, Ringer's lactate), 20 mL/kg body weight. While transfusion of whole blood is optimal for treatment of hemorrhagic shock, infusion of crystalloid solutions avoids difficulties caused by extravasation of the colloid into the interstitial compartment. Moreover, a systematic review of the literature does not support the use of colloid solutions for volume replacement in critically ill patients (96). This fluid is appropriate regardless of what the initial serum sodium or osmolality is and concerns about infusing Ringer's lactate are misplaced in view of the low potassium concentration (4 mmol/L) in this solution. A catheter should be placed in the bladder to facilitate monitoring of urine output. The infusion should be as rapid as possible and the fluid dose should be repeated as often as necessary to achieve some evidence of clinical improvement such as improved mental status, decrease in pulse, rise in blood pressure, or improved capillary refill.

After correcting life-threatening hypoperfusion, a fluid repletion plan should be initiated as soon as possible. Preference should be given to correcting sodium and electrolyte deficits with oral rehydration solutions (ORS). In general, patients can be repleted with a rapid (1–2 h) intravenous infusion to restore ECF volume followed immediately by initiation of ORS (97). The only conditions that represent contraindications to the use of ORS are impaired neurological status, persistent vomiting, or diseases associated with mucosal damage in the gastrointestinal lumen.

ORS fluids introduced by the World Health Organization contain sodium 90, potassium 20, bicarbonate 30, chloride, and glucose 111 mmol/L (20 g/L). The sodium and glucose are present in a molar ratio that maximizes the secondary active uptake of these solutes via the sodium–glucose co-transporter across the gastrointestinal epithelium. Water is absorbed passively down its osmolal gradient. The presence of other solutes such as potassium and bicarbonate are not critical to the successful utilization of ORS. These fluids have been utilized for over 30 years. They can be administered ad libitum in response to the child's own thirst and they are effective and safe with minimal occurrence of hypernatremia or hyperkalemia. Various alternatives to glucose such as rice-syrup or amylase-resistant starch may facilitate sodium and water reabsorption from ORS, decrease fecal fluid loss, and shorten recovery time after an episode of cholera (98, 99). Clinical studies are needed to confirm the utility of these additives because they may increase the cost and decrease the shelf life of ORS. These are important considerations in developing countries, where there is a high incidence of infectious diarrhea in infants and children.

When parenteral therapy is required to correct sodium and water deficits, the following guidelines can be applied when devising a therapeutic plan. First, in the absence of reliable data regarding the acute weight loss, it is easiest to calculate maintenance and deficit therapy based on the clinical estimate of the percentage decrease in body weight. Second, it is advisable to discount any emergency fluid therapy, such as bolus infusions of isotonic saline, in computing the fluid prescription. Third, if the clinical problem has developed in <48 h then it should be considered an acute process and the sodium and fluid losses are derived from the ICW and ECW in the ratio of 80:20%. If the patient has been ill for more than 48 h and the process is chronic, then the sodium and fluid losses are derived from the ECW and ICW in the ratio of 60:40%. Under most conditions in which the sodium and water losses are isotonic, the ECW portion of the loss, in liters, can be multiplied by 140 mmol/L to determine the sodium loss. Similarly, the ICW portion of the loss, in

liters, can be multiplied by 140 mmol/L to determine the potassium deficit. If the ECW and ICW fluid losses together with the respective sodium and potassium deficits are added to the maintenance requirements, then a total fluid volume can be determined. After selecting a fluid that most closely approximates the total sodium and water losses, the total fluid volume is divided by the time frame of the correction to determine the intravenous infusion rate.

As an example, if a child weighing 10 kg is judged to have a 5% decrease in body weight over 36 h, then the total fluid deficit of 500 mL can be divided into two components – 400 mL ECW with 56 mmol sodium and 100 mL ICW containing 14 mmol potassium. The daily maintenance water and sodium requirements are 1,000 mL and 30 mmol sodium. Adding these two quantities together results in a fluid that closely resembles 0.33–0.45% saline (61 mmol NaCl/L) containing 30 mmol KCl/L, and the infusion rate is approximately 60 mL/h if the correction is designed to occur over 24 h. In all cases, it is important to monitor and replace ongoing losses to insure that there is full resolution of the underlying clinical problem.

Sodium Excess

Diagnosis and Evaluation

These conditions, which generally are less common than sodium deficit, are evidenced by clinical signs of ECF volume expansion. They can arise secondary to exogenous addition of sodium or abnormal retention of endogenous sodium. Because the normal kidney has the adaptive capacity to rapidly excrete a sodium load, in order for the excess sodium to cause clinical symptoms and signs, there must be a concomitant factor that limits natriuresis.

Common causes of excess exogenous sodium are salt-water drowning, ingestion of a diet abnormally high in sodium, or therapeutic infusion of sodium-containing intravenous solutions, such as sodium bicarbonate during the resuscitation after a cardiopulmonary arrest. Examples of dietary excess of sodium include errors in the preparation of infant formulas. The widespread use of premixed baby formulas may decrease the incidence of these accidents.

Conditions associated with excessive endogenous sodium retention include acute renal failure and the edema states, namely nephrotic syndrome, cirrhosis, and congestive heart failure. In the first condition, which may occur due to glomerulonephritis or tubular necrosis, the sodium retention is directly related to the decrease in GFR and diminished filtration of sodium. In the latter three states, renal sodium and water reabsorption are activated by a combination of mechanisms that are termed, underfill and overfill. A critical review of the evidence in patients with nephrotic syndrome suggests that those diseases that are associated with an inflammatory infiltrate in the kidney develop primary sodium retention and overfilling of the ECF volume. This histopathological feature is absent in minimal change nephrotic syndrome and the underfill mechanism predominates (100). Thus, in nephrotic syndrome, total body sodium excess may be coupled with a diminished, normal, or expanded effective ECF volume. This explains the normal distribution of PRA values and wide range of measured plasma volume in these patients. The causes of net total body sodium excess are summarized in *Table 7-6*.

The major clinical problems that accompany these conditions are related to pulmonary venous congestion, impaired gas exchange, and dyspnea. In idiopathic nephrotic syndrome, the intra-alveolar pressure is often sufficient to prevent frank pulmonary edema. However, in other circumstances, intrinsic capillary leak together with lowered plasma oncotic pressure promotes the development of pulmonary interstitial fluid. Peripheral edema may be associated with skin infection, peritonitis, or thromboembolic events.

Conditions associated with sodium excess should be evident on physical examination. The FENa will be high if there is sodium loading and renal function is normal. In contrast, in the states characterized by retention of endogenous sodium, the FENa will be very low. The FENa is more useful than the urinary specific gravity because it is likely to be elevated in all cases of sodium excess.

Table 7-6
Causes of net sodium excess

Exogenous sodium
Salt-water drowning
Errors in formula preparation
Infusion of hypertonic sodium solutions
e.g., after cardiopulmonary arrest
Endogenous sodium
Acute renal failure (glomerulonephritis, ATN)
Nephrotic syndrome
Cirrhosis
Congestive heart failure

Therapy

The optimal therapy is targeted at correcting the underlying disease. This is most important in patients with cirrhosis or congestive heart failure. Ancillary therapies include administration of diuretics to facilitate urinary sodium excretion. Although thiazide diuretics may be adequate, more potent loop diuretics may be required if the GFR is diminished. Supplemental oxygen may be necessary to alleviate shortness of breath and hypoxemia. Patients with nephrotic syndrome may require combinations of diuretic agents that act in the proximal (e.g., metolazone) and distal (e.g., furosemide) segments of the nephron to promote an adequate natriuresis and diuresis. Infusions of albumin (1 g/kg bodyweight) can augment the medication-induced diuresis, especially in those with severe ECF volume contraction, reduced GFR, and azotemia (101). In the most severe cases, acute dialysis using peritoneal or hemodialysis techniques may be necessary to foster rapid clearance of the excess sodium. Finally, hemofiltration may be a safe and effective means to rapidly remove sodium and water in severely ECF-overloaded children with nephrotic syndrome (102).

Water Balance Disturbances: Deficit and Excess

Hyponatremia

Diagnosis and Evaluation

Patients with hyponatremia have relative or absolute expansion of the ICW compartment. If renal function is normal, then excess free water is eliminated within 2–4 h. Therefore, for this problem to occur two conditions must be satisfied – there must be continued AVP release that is inappropriate to the serum sodium concentration and the patient must have continued access to free water. The symptoms and signs of hyponatremia, which generally involve central nervous system dysfunction, are vague and nonspecific. Laboratory confirmation is required to diagnose this abnormality. The presence of hyponatremia has no predictive value about the status of the ECF volume and this later issue must be assessed clinically to determine whether the child has hypovolemic hypotonicity, isovolemic hypotonicity, or hypervolemic hypotonicity.

The laboratory measurement of serum sodium concentration is no longer susceptible to technical artifacts. In the past, laboratory analyzers measured sodium concentration in the total supernatant obtained after centrifugation of blood samples, including lipids and proteins. Because these molecules are not water soluble, they displace sodium into a smaller aqueous phase leading to a spurious reduction in the serum sodium concentration. All biochemical analyzers currently in use at large medical centers assay sodium concentration solely in the aqueous phase and yield an accurate determination of the serum sodium level. Therefore, the entity called pseudohyponatremia is no longer clinically relevant. In contrast, the reduced serum sodium concentration noted in patients with increased circulating levels of an impermeant solute such as mannitol, urea, contrast media, or glucose in patients with diabetic ketoacidosis is valid and reflects osmotic redistribution of water from the ICW to the ECW space. The phenomenon is reflected in the following formula which enables adjustment of the serum sodium in patients with severe hyperglycemia:

$$\begin{aligned}&\text{“Physiological” sodium concentration}\\&\quad = \text{measured serum sodium concentration}\\&\qquad + 1.6 \times [\text{Each 100 mg/dl increment in}\\&\qquad \text{serum glucose above 100 mg/dl}]\end{aligned} \tag{5}$$

The most common clinical causes of hyponatremia are classified by the concomitant ECF volume status in *Table 7-7*. In some diseases, such as congestive heart failure, the degree of hyponatremia may be a reflection of circulating AVP levels and sympathetic nervous system activation and provide a marker of disease severity. This relationship has not been demonstrated in patients with nephrotic syndrome or cirrhosis.

The syndrome of inappropriate AVP or ADH (SIADH) release causes hyponatremia with mild to modest ECF volume expansion. It can occur as a consequence of central neurological lesions, pulmonary disease, or tumors. In addition, numerous drugs can result in abnormal secretion or action of AVP and lead to chronic hyponatremia. A list of these agents is provided in *Table 7-8*. The diagnosis of SIADH requires confirmation that the urine is excessively concentrated relative to the plasma osmolality without any evidence of ECF volume contraction, or adrenal or thyroid insufficiency. These two hormones are required to maintain the low water permeability of the collecting duct in the absence of AVP. Deficiencies of either hormone impair free water clearance leading to euvolemic hyponatremia. In practice, diagnosing SIADH requires comparison of the urine specific gravity or osmolality with the concurrent serum

Gastrointestinal suction
Intestinal fistula
Laxative abuse
Transcutaneous
Cystic fibrosis
Heat exhaustion
"Third space" loss with inadequate fluid replacement
Burns
Major surgery, trauma
Septic shock
Euvolemic: Normal ECF volume
Glucocorticoid deficiency
Hypothyroidism
Mild hypervolemia: ECF volume expansion
Reduced renal water excretion
Antidiuretic drugs
Inappropriate secretion of ADH
Hypervolemic: ECF volume expansion
Acute renal failure (glomerulonephritis, ATN)
Chronic renal failure
Nephrotic syndrome
Cirrhosis
Congestive heart failure
Psychogenic polydipsia/compulsive drinking

osmolality. The urine should normally be maximally dilute if the serum sodium concentration is <130 mmol/L or the plasma osmolality <270 mosm/kg H_2O. A urinary sodium concentration >40 mmol/L is adequate evidence against ECF volume contraction.

Table 7-8
Drugs that cause water retention and the syndrome of inappropriate AVP release (according to mode of action)

Increasing water permeability of the nephron
AVP (arginine or lysine vasopressin)
Vasopressin analogs, e.g., 1-deamino, 8-D-arginine vasopressin (DDAVP)
Oxytocin
Promoting AVP release
Barbiturates
Carbemazepine
Clofibrate
Colchicine
Isoproterenol
Nicotine
Vincristine
Inhibition of prostaglandin synthesis
Salicylates
Indomethacin
Acetaminophen (paracetamol)
Other nonsteroidal anti-inflammatory drugs
Potentiation of the action of AVP
Chlorpropamide
Cyclophosphamide

Treatment

In all cases, the first line of therapy should be directed at the underlying cause of the low serum sodium concentration. However, hyponatremia often warrants specific corrective treatment. Much ink has been spilled in detailing the appropriate therapy of this electrolyte abnormality. At times, this issue has been quite contentious and the world has been divided into two supposedly distinct camps – those who advocate "rapid" versus "slow" correction of hyponatremia. The former group asserts that hyponatremia has direct adverse effects on central nervous system function including impaired oxygenation that can lead to seizures or cardiopulmonary collapse prior to initiation of therapy (103). Such a sequence of events has been documented in experimental animals with acute hyponatremia (104). This risk may be especially prominent in premenopausal women. In contrast, there are others who emphasize the cerebral cell volume regulatory response to hyponatremia and highlight the risk of brain cell dehydration and osmotic demyelinating syndrome in patients who are corrected too quickly (105).

Taking into account the entire literature on the subject, current evidence suggests that the risk of hyponatremia is more closely related to the acuity of the change rather than the absolute size of the drop in serum sodium concentration (106). Thus, therapy should be guided by the time frame in which hyponatremia has developed. If the hyponatremia is acute, i.e., <12 h in duration, then the brain will behave as a perfect osmometer leading to potentially life-threatening cerebral cell swelling. Under these circumstances, there is an urgent need to rapidly reverse the hyponatremia to counteract cell swelling. Clinical experience indicates that infusion of a 3% NaCl solution (513 mmol/L) in a volume designed to raise the sodium concentration by 3–5 mmol/L is sufficient to halt central nervous system dysfunction (107). The benefits and lack of adverse effects of acute correction have been confirmed in a series of 34 infants and children with acute water intoxication caused by the ingestion of dilute infant formula (108). After this is achieved, the hyponatremia can be corrected more slowly. For example, if a 6-year old child weighing 20 kg develops a seizure after a tonsillectomy and is noted to have a serum sodium concentration of 115 mmol/L, then 36–60 mmol of sodium are needed to raise the sodium concentration by 3–5 mmol/L. This is accomplished by infusing 72–120 mL of the hypertonic saline infusion.

If hyponatremia has developed over more than 12 h or the duration of the problem is unclear, especially if the patient has no signs of neurological dysfunction, then slow correction is the prudent course of action (105, 106). The current definition of slow correction includes two features: (1) the rate of rise in serum sodium concentration should be <0.6 mmol/L throughout the correction phase; and (2) the total increment and/or the final serum sodium concentration after 48 h of treatment should not exceed 25 or 130 mmol/L, respectively. The more cautious criterion should be applied depending on the initial serum sodium level. If a child develops acute changes in mental status or new neurological findings, during or shortly after the fluid treatment, then a serum sodium concentration should be checked. Imaging studies, specifically an MRI of the brain, may reveal the changes of osmotic demyelinating syndrome.

There are several therapeutic options for patients with SIADH whose underlying cause cannot be corrected. Restriction of free water intake to match insensible losses and urine output may be adequate to stabilize the serum sodium concentration. If this is not well-tolerated, then administration of furosemide 1–2 mg/kg/day to promote a hypotonic diuresis together with oral administration of NaCl 1–2 g/day may correct the hyponatremia. If these measures fail, consideration can be given to treatment with lithium or demeclocycline, two drugs that interfere with AVP-action in the collecting tubule to foster excretion of free water and raise the serum sodium concentration (109). Finally, nonpeptide vasopressin receptor antagonists have been developed that may be introduced into clinical practice for the treatment of chronic hyponatremia (110, 111). Conivaptan is the only FDA-approved agent in this class and is useful for short-term intravenous use. Tolvaptan is an oral agent that has been demonstrated to safely correct hyponatremia in several dose response studies involving adults with euvolemic hyponatremia or hypervolemic hyponatremia (112). Safety and efficacy of these drugs have not been assessed in pediatric patients.

Hypernatremia

Diagnosis and Evaluation

Hypernatremia may arise due to excessive intake of sodium and ECF volume expansion. However, excessive water loss relative to the sodium deficit with hypovolemia is far more common. In a recent survey of hypernatremia in hospitalized children, the vast majority had significant underlying medical problems and 76% of the cases were secondary to inadequate water intake (113). The prevalence of this electrolyte abnormality is much lower than hyponatremia. One of the common causes is diarrheal illness in infants; however, the reduction in the sodium concentration of most baby formulas to match the level in human breast milk has resulted in a dramatic decrease in the incidence of hypernatremic dehydration. Nonetheless, changes in medical practice with early discharge of newborn infants after delivery have resulted in the steady occurrence of hypernatremic dehydration in breast-fed babies (114). Patients with hypernatremia have relative or absolute contraction of the ICW compartment. Similar to the situation with hyponatremia, the clinical clues to the presence of hypernatremia are nonspecific and laboratory confirmation is mandatory to diagnose this abnormality. Moreover, the hypernatremia must be evaluated in light of the clinically determined ECF volume status.

Patients with hypernatremia and ECF volume expansion are easy to diagnose. The children who represent a serious problem are those with hypovolemia. They may have some distinct features including marked irritability, a high-pitched cry, and a doughy skin texture. Because the hyperosmolality of the ECW compartment provokes movement of water from the ICW down its osmolal gradient, these patients preserve ECF volume until

Table 7-9
Causes of hypernatremia

Hypovolemic: ECF volume contraction
Gastrointestinal (diarrhea and vomiting)
Evaporative (high fever, high ambient temperature)
Hypothalamic diabetes insipidus (ADH deficiency)
Head trauma
Infarction (Sheehan's syndrome)
Tumors (e.g., craniopharyngioma)
Histiocytosis
Degenerative brain diseases
Infections
Hereditary central diabetes insipidus (usually dominant)
Idiopathic
Nephrogenic diabetes insipidus (ADH resistance)
Chronic renal failure
Hypokalemia
Hypercalcemia
Damage to renal medulla
Sickle cell disease
Nephronophthisis
Renal papillary necrosis
Chronic pyelonephritis (reflux nephropathy)
Euvolemic: Normal ECF volume
Unconscious patients
Infants
Lack of access to water (lost in the desert)
Primary adipsia
Essential hypernatremia (osmoreceptor destruction or malfunction)
Hypervolemic: ECF volume expansion
Inappropriate IV fluid therapy
Salt poisoning
Mineralocorticoid excess

late in the disease course. Thus, their illness is usually chronic and there is a greater contribution of the ICW to the water and electrolyte deficits. Assessment of the FENa is useful in assessing the ECF volume in these patients. The causes of hypernatremia are listed in *Table 7-9*.

Treatment

Because children with hypovolemic hypernatremia are usually very ill, they often require bolus infusions of isotonic saline to restore organ perfusion. Once this is accomplished, then the fluid regimen should include the maintenance fluids, the estimated deficit with the assumption that 60% is derived from the ECW and 40% from the ICW. In addition, there is a free water deficit. This can be calculated from the following formula:

$$\text{Water deficit (in ml)} = 0.6 \times \text{Body weight} \times [\text{Actual serum sodium concentration}/140 - 1] \quad (6)$$

This formula may overestimate the water deficit and it has been recommended that the following alternative equation be used to estimate the increase in serum sodium concentration that will be achieved following the infusion of 1 L of a given solution (115):

$$\text{Change in sodium concentration} = [\text{Infusate } Na^+ - \text{serum } Na^+]/\text{total body water} + 1 \quad (7)$$

Finally, with regard to the rate of correction, the standard practice is to correct hypovolemic hypernatremia gradually over at least 48 h. After the groundbreaking work of Finberg et al. (116), the risk of cerebral edema following rapid correction of chronic hypernatremia is now attributed to the inability of brain cells to extrude the osmoprotective solutes that accumulate during sustained hyperosmolal conditions in parallel with the decline in plasma osmolality during fluid therapy (117, 118). Therefore, the osmolal gradient will be reversed with plasma osmolality lower than cerebral cell osmolality leading to ICW expansion and clinical signs of cerebral edema, findings that have been confirmed in NMR spectroscopy studies of the brain (119). The experimental observations were confirmed in a randomized trial, which demonstrated that the safest and most effective fluid therapy for hypovolemic hypernatremia is 0.18% NaCl given slowly over 48 h compared to 0.45% saline given slowly or rapidly over the same time period (120). Because hyperosmolality impairs insulin and PTH release, patients should be monitored for hyperglycemia and hypocalcemia during the correction period.

8 Potassium

Lisa M. Satlin

Potassium is the most abundant intracellular cation. Approximately 98% of the total body potassium content is located within cells, primarily muscle, where its concentration ranges from 100–150 mEq/L; the remaining 2% resides in the extracellular fluid, where the potassium concentration is tightly regulated within a narrow range (3.5–5.0 mEq/L in the adult). The ratio of the intra- to extracellular potassium concentration determines, in large part, the resting membrane potential, and is thus critical for normal function of electrically excitable cells, including nerve and muscle. Maintenance of a high intracellular potassium concentration is essential for many cellular processes, including DNA and protein synthesis, cell growth and apoptosis, mitochondrial enzyme function, and conservation of cell volume and pH (1–7). Because of the many vital processes dependent on potassium homeostasis, multiple complex and efficient mechanisms have developed to regulate total potassium balance and distribution.

Potassium Homeostasis

Total body potassium content reflects the balance between intake and output, the latter regulated primarily by renal and, to a lesser extent, fecal excretion; the amount of potassium lost through sweat is negligible. The homeostatic goal of the healthy adult is to remain in zero potassium balance. Thus, ~90% of the daily potassium intake, which typically averages 1 mEq/kg body weight, is eliminated by the kidneys and the residual ~10% lost through the stool (8).

Total body potassium content increases from approximately 8 mEq/cm body height at birth to >14 mEq/cm body height by 18 years of age (9, 10) (*Fig. 8-1*), with the rate of accumulation of body potassium per kilogram body weight in the infant exceeding that in the older child and adolescent. The increase in total body potassium content correlates with an increase in cell number and potassium concentration (at least in skeletal muscle) with advancing age (10–12). This robust somatic growth early in life requires the maintenance of a state of positive potassium balance (13, 14), as has been demonstrated in growing infants greater than approximately 30 weeks gestational age (GA) (15, 16). The tendency to retain potassium early in postnatal life is reflected, in part, in the higher plasma potassium values in infants, and particularly in preterm neonates (16, 17).

Thirty to fifty percent of very low birth weight and premature infants < 28 weeks GA exhibit nonoliguric hyperkalemia, defined as a serum potassium concentration of >6.5 mEq/L, during the first few days of life, despite the intake of negligible amounts of potassium (18–22). This phenomenon, not observed in mature infants or VLBW infants after 72 h (20, 21), has been proposed to reflect principally an intra- to extracellular shift of potassium (20, 21, 23). Prenatal steroid treatment may prevent this nonoliguric hyperkalemia via induction of sodium-potassium-adenosine triphosphatase (Na-K-ATPase) activity (see below) in the fetus (24, 25).

Studies in rats suggest that the accumulation of potassium in the growing fetus is facilitated by the active transport of potassium across the placenta from mother to fetus (26). This notion is further supported by studies in dog (27) and rat (28) that show that fetal plasma potassium concentrations are maintained during maternal hypokalemia, an adaptation proposed to be due to an increase in the ratio of maternofetal-to-fetomaternal unidirectional potassium transport.

Regulation of Internal Potassium Balance

The task of maintaining potassium homeostasis is challenging because the daily dietary intake of potassium in the adult (~50–100 mEq) approaches or exceeds the total potassium normally present within the extracellular fluid space (~70 mEq in 17 L of extracellular fluid with a potassium concentration averaging ~4 mEq/L). To maintain zero balance in the adult, all the dietary intake of potassium must be ultimately eliminated, a task performed primarily by the kidney. However, excretion of potassium by the kidney is sluggish. Only 50% of an oral or intravenous load of potassium is excreted during the first 4–6 h after it is administered (29, 30). Life-threatening

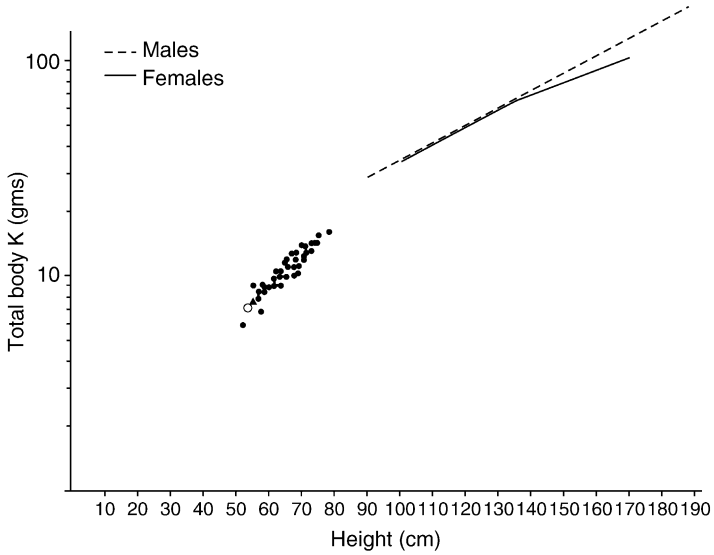
Figure 8-1

Relationship between total body potassium (gm) and height (cm) for infants and children. The rate of accretion of body potassium in the neonate is faster than in later childhood, likely reflecting both an increase in cell number and potassium concentration, at least in skeletal muscle, with advancing age (10).



hyperkalemia is not generally observed during this period because of the rapid (within minutes) hormonally mediated translocation of ~80% of the retained potassium load from the extracellular space into cells (31). The buffering capacity of the combined cellular storage reservoirs, which includes muscle, bone, liver, and red blood cells (RBCs), is capable of sequestering up to approximately 3,500 mEq of potassium and is vast compared with the extracellular pool (8).

Cells must expend a significant amount of energy to maintain the steep potassium (and sodium) concentration gradients across their cell membranes. This is accomplished by the ubiquitous Na-K-ATPase which transports 3 sodium ions out of and 2 potassium ions into the cell at the expense of the hydrolysis of cytosolic ATP. The unequal cation exchange ratio produces a charge imbalance across the cell membrane, and thus the Na-K-ATPase is defined as an electrogenic pump. Positively charged potassium ions, present in high concentration within the cell, passively leak out of cells down a concentration gradient through ubiquitously expressed potassium-selective channels. A steady state is reached at which the outward movement of positively charged potassium is opposed by the negative cell potential. At this cell equilibrium potential, the net transmembrane flux of potassium is zero.

The basic functional unit of the Na-K-ATPase is comprised of a catalytic α and a β subunit; the β subunit acts a molecular chaperone that directs the correct membrane insertion of the α subunit (32). The α/β-heterodimer complexes with phospholemman (PLM, FXYD1) in heart and skeletal muscle (33); the latter interaction modulates pump activity (33). The cardiac glycoside digoxin binds to the catalytic α subunit of the enzyme, inhibiting its activity. Thus, digoxin overdose may thus be associated with hyperkalemia, especially in the presence of a concomitant perturbation of potassium homeostasis.

Na-K-ATPase is regulated by changes in its intrinsic activity, subcellular distribution, and cellular abundance. Long-term stimulation of pump activity is generally mediated by changes in gene and protein expression, whereas short-term regulation typically results from changes in the intracellular sodium concentration, alterations in the phosphorylation status of the pump and/or interaction with regulatory proteins, or changes in membrane trafficking of preexisting pumps (33–35). Regulation of internal potassium balance in the neonate may be influenced by developmental stage-specific expression of potassium transporters, such as Na-K-ATPase, as well as channels, receptors, and signal transduction pathways (36, 37).

The chemical, physical, and hormonal factors that acutely influence the *internal* balance of potassium are listed in *Table 8-1*, and are discussed below. Potassium uptake into cells is acutely stimulated by insulin, β_2-adrenergic agonists, and alkalosis and is impaired by α-adrenergic agonists, acidosis, and hyperosmolality. Generally, deviations in extracellular potassium concentration

Table 8-1

Factors that regulate internal potassium balance and their effects on cell uptake of potassium

Physiologic factors	
Plasma K concentration	
Increase	Increases uptake
Decrease	Decreases uptake
Insulin	Increases uptake
Catecholamines	
α-Agonists	Decreases uptake
β-Agonists	Increases uptake
Pathologic factors	
Acid-base balance	
Acidosis	Decreases uptake
Alkalosis	Increases uptake
Hyperosmolality	Enhances cell efflux
Cell breakdown	Enhances cell efflux

arising from fluctuations in internal distribution are self-limited as long as the endocrine regulation of internal balance and mechanisms responsible for regulation of *external* balance are intact.

Plasma Potassium Concentration

Active basolateral cellular potassium uptake by the ubiquitous Na-K-ATPase in large part determines the intracellular pool of potassium. An increase in potassium input into the extracellular fluid space, which may arise from exogenous or endogenous sources or result from a chronic progressive loss of functional renal mass, decreases the concentration gradient against which the Na-K-ATPase must function and thus favors an increase in cellular potassium uptake. Sources of exogenous potassium input may not be readily apparent and include not only diet, but also potassium-containing drugs (potassium penicillin G), salt substitutes, protein-calorie supplements, herbal medications and packed RBCs (38). The extracellular fluid potassium concentration can also increase in response to endogenous release of potassium as accompanies tissue breakdown (rhabdomyolosis, tumor lysis syndrome) and exercise, the latter mediated by adenosine triphosphate (ATP) depletion and opening of ATP-dependent potassium channels. In those epithelial cells of the kidney and colon specifically responsible for potassium secretion, the resulting increase in intracellular potassium maximizes the concentration gradient between cell and lumen, thereby promoting potassium diffusion into the tubular lumen and thus potassium excretion.

Hormones

Insulin, the most important hormonal regulator of internal potassium balance, stimulates Na-K-ATPase-mediated cellular potassium uptake and thus the rapid transfer of potassium from the extracellular to the intracellular fluid space of insulin-responsive cells in liver, skeletal muscle, adipocytes, and brain, a response that is independent of the hormonal effects on glucose metabolism (39). The mechanism of insulin action in these tissues differs, in part, because of differences in the isoform composition of the catalytic α-subunit of the pump. Insulin stimulates Na-K-ATPase activity by promoting the translocation of preformed pumps from intracellular stores to the cell surface (40–44), and/or increasing cytoplasmic sodium content (45–47) or the apparent affinity of the enzyme for sodium (48).

Basal insulin secretion is necessary to maintain fasting plasma potassium concentration within the normal range (29). An increase in plasma potassium in excess of 1.0 mEq/L in the adult induces a significant increase in peripheral insulin levels to aid in the rapid disposal of the potassium load, yet a more modest elevation of approximately 0.5 mEq/L is without effect (29, 49, 50). In the setting of insulin deficiency, i.e., diabetes, there is a reduction in uptake of potassium by muscle and liver (31, 51).

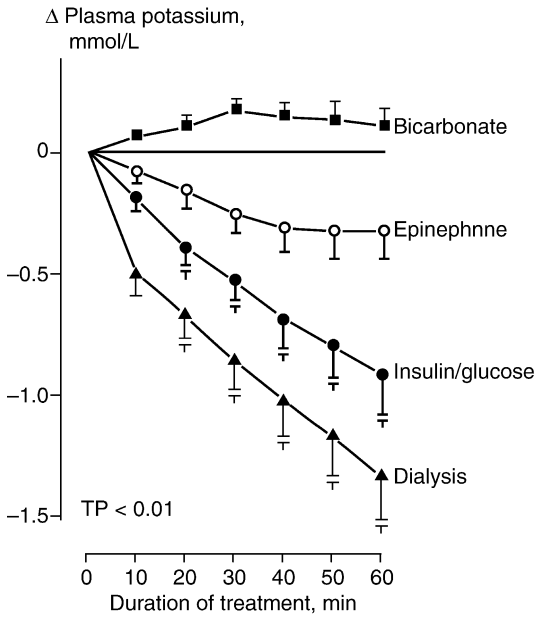
Catecholamines enhance the cell uptake of potassium via stimulation of Na-K-ATPase activity in skeletal muscle and hepatocytes through β_2-adrenergic receptors (52, 53). The effect of epinephrine on potassium balance in the adult is biphasic and is characterized by an initial increase, followed by a prolonged fall in plasma potassium concentration to a final value below baseline. The initial transient rise in plasma potassium results from α-adrenergic receptor stimulation which causes release of potassium from hepatocytes and impairs cell uptake of potassium (51, 54–56). β_2-Receptor stimulation, via stimulation of adenylate cyclase leading to generation of the second messenger cyclic adenosine monophosphate (cAMP) and activation of downstream protein kinases, stimulates the sodium pump and thus promotes enhanced uptake of potassium by skeletal and cardiac muscle, effects that are inhibited by nonselective β-blockers including propranolol and labetalol (51, 55, 57–60). The observation that the potassium-lowering effects of insulin and epinephrine are additive suggests that their responses are mediated by different signaling pathways.

The effects of these hormones on the distribution of potassium between the intracellular and extracellular compartments have been exploited to effectively treat disorders of homeostasis (*Fig. 8-2*). Administration of β_2-adrenoreceptor agonists (albuterol or salbutamol via nebulizer), which promote potassium uptake by cells, has been to treat hyperkalemia in neonates, children and adults (62–64). A single dose of nebulized albuterol can lower serum potassium by as much as 0.5 mEq/L (65, 66). Transient side effects associated with this class of drugs include mild tachycardia, tremor and mild vasomotor flushing (67). Administration of glucose alone (to induce endogenous insulin release) or glucose plus insulin is efficacious, although patients must be monitored for complications of hyperglycemia (without insulin) or hypoglycemia (with insulin), especially in neonates (68–70). It should be kept in mind that the treatment options discussed thus far are only temporizing. To remove potassium from the body, renal potassium excretion must be enhanced, either by stimulating potassium secretion in the distal nephron (see below) or, in the presence of renal insufficiency, by dialysis.

Aldosterone is best known for its effect on transporting tissue, increasing potassium secretion in distal segments of the nephron and colon (see below). Triiodothyronine (T3) also promotes Na-K-ATPase-mediated potassium cellular uptake in skeletal muscle (34). Whereas T3 had been thought to act as a direct transcriptional activator of target genes, recent studies emphasize the importance of nongenomic effects, including the stimulation of translocation of Na-K-ATPase to the plasma membrane by a pathway that requires activation of MAPK and phosphatidylinositol 3-kinase (PI3K) (71, 72). The postnatal increases in Na-K-ATPase expression in kidney, brain, and lung depend on normal thyroid hormone status (73).

Figure 8-2

Changes in plasma potassium concentration (mmol/L) during intravenous infusion of bicarbonate (8.4%), epinephrine, or insulin and glucose, and during hemodialysis in adult patients on maintenance hemodialysis (61).



Acid–Base Balance

It is well known that the transcellular distribution of potassium and acid-base balance are interrelated (74–77). Whereas acidemia (increase in extracellular hydrogen ion concentration) is associated with a variable increase in plasma potassium secondary to potassium release from the intracellular compartment, alkalemia (decrease in extracellular hydrogen ion concentration) results in a shift of potassium into cells and a consequent decrease in plasma potassium. However, the reciprocal changes in plasma potassium that accompany acute changes in blood pH differ widely among the four major acid-base disorders; metabolic disorders cause greater disturbances in plasma potassium than do those of respiratory origin, and acute changes in pH result in larger changes in plasma potassium than do chronic conditions (74).

Acute metabolic acidosis after administration of a mineral acid that includes an anion that does not readily penetrate the cell membrane, such as the chloride of hydrochloric acid or ammonium chloride, consistently results in an increase in plasma potassium. As excess extracellular protons, unaccompanied by their nonpermeant anions, enter the cell where neutralization by intracellular buffers occurs, potassium is displaced from the cells, thus maintaining electroneutrality and leading to hyperkalemia. However, comparable acidemia induced by acute organic anion acidosis (lactic acid in lactic acidosis, acetoacetic and β-hydroxybutyric acids in uncontrolled diabetes mellitus) may not elicit a detectable change in plasma potassium (74, 78, 79). In organic acidemia, the associated anion diffuses more freely into the cell and thus does not require a shift of potassium from the intracellular to the extracellular fluid.

In respiratory acid-base disturbances, in which carbon dioxide and carbonic acid readily permeate cell membranes, little transcellular shift of potassium occurs because

protons are not transported in or out in association with potassium moving in the opposite direction (74).

Changes in plasma bicarbonate concentration, independent of the effect on extracellular pH, can reciprocally affect plasma potassium concentration (80). Movement of bicarbonate (outward at a low extracellular bicarbonate concentration and inward at a high extracellular bicarbonate concentration) between the intracellular and extracellular compartments may be causally related to a concomitant transfer of potassium. This relationship may account for the less marked increase in plasma potassium observed during acute respiratory acidosis, a condition characterized by an acid plasma pH with an elevated serum bicarbonate (leading to inward net bicarbonate and potassium movement), as compared with acute metabolic acidosis with a low serum bicarbonate concentration (leading to outward net bicarbonate and potassium movement). Though recommended as a mainstay of therapy, alkalinization of the extracellular fluid with sodium bicarbonate to promote the rapid cellular uptake of potassium may not be useful in patients on maintenance hemodialysis for end stage renal disease (61) (*Fig. 8-2*). However, this maneuver remains valuable if metabolic acidosis is at all responsible for the hyperkalemia. The major toxicities of bicarbonate therapy include sodium overload and precipitation of tetany in the face of preexisting hypocalcemia.

Other Factors

A number of other pathologic perturbations alter the internal potassium balance. An increase in plasma osmolality secondary to severe dehydration or administration of osmotically active agents causes water to shift out of cells. The consequent increase in intracellular potassium concentration exaggerates the transcellular concentration gradient and favors movement of this cation out of cells. The effect of hyperosmolality on potassium balance becomes especially problematic in diabetic patients with hyperglycemia, in whom the absence of insulin exacerbates the hyperkalemia.

Succinylcholine, a depolarizing paralytic agent and an agonist of nicotinic acetylcholine receptors, which are found predominantly in skeletal myocyte membranes, may lead to efflux of potassium from myocytes into the extracellular fluid under certain pathologic states associated with upregulation and redistribution of the receptors, including states characterized by physical or chemical upper or lower motor neuron denervation, immobilization, infection, muscle trauma or inflammation and burn injury (81, 82).

Finally, parenteral administration of cationic amino acids such as lysine, arginine or epsilon-amino caproic acid (used to improve hemostasis in patients undergoing cardiac surgery) may lead to electroneutral exchange of cell potassium for the cationic amino acid in skeletal myocytes (83–85).

Regulation of External Potassium Balance

Renal Contribution

The kidney is the major excretory organ for potassium. In the adult, urinary potassium excretion generally parallels dietary intake. However, the renal adaptation to variations in dietary intake is rather sluggish. Extreme adjustments in the rate of renal potassium conservation cannot be achieved as rapidly as for sodium, nor are the adjustments as complete; whereas urinary sodium can be virtually eliminated within 3–4 days of sodium restriction, there is a minimum urinary potassium loss of about 10 mEq/day in the adult, even after several weeks of severe potassium restriction (86). An increase in dietary potassium intake is matched by a parallel increase in renal potassium excretion within hours, yet maximal rates of potassium excretion are not attained for several days after increasing potassium intake. In adults, renal potassium excretion follows a circadian rhythm, presumably determined by hypothalamic oscillators, and it is characterized by maximum output during times of peak activity (87). It is unknown whether a circadian cycle of urinary potassium excretion prevails in infancy.

Children and adults ingesting an average American diet that contains sodium in excess of potassium excrete urine with a sodium-to-potassium ratio greater than one (16, 88). Although breast milk and commercially available infant formulas generally provide a sodium-to-potassium ratio of approximately 0.5–0.6, the urinary sodium-to-potassium ratio in the newborn up to 4 months of age generally exceeds 1. This high ratio may reflect the greater requirement of potassium over sodium for growth. In fact, some premature (<34 weeks GA) newborns may excrete urine with a sodium-to-potassium ratio greater than 2, a finding suggesting significant salt wasting and a relative hyporesponsiveness of the neonatal kidney to mineralocorticoid activity (16).

Net urinary potassium excretion in the fully differentiated kidney reflects the sum of three processes:

glomerular filtration, reabsorption along the proximal tubule and the loop of Henle, and bidirectional transport (secretion and reabsorption) in the distal nephron (8, 89). Most of the factors known to modulate potassium excretion do so by altering the rate of potassium secretion.

Renal potassium clearance is low in newborns, even when it is corrected for their low glomerular filtration rate (16, 17). Infants, like adults, can excrete potassium at a rate that exceeds its glomerular filtration, reflecting the capacity for net tubular secretion. However, they are unable to excrete an exogenously administered potassium load as efficiently as the adult (90); specifically, the rate of potassium excretion normalized to body weight or kidney weight is less in newborn than older animals (91, 92). Comparison of the fractional delivery of potassium to the early distal tubule with that present in the final urine reveals that the distal nephron of the young (2-week-old) rat secretes approximately fivefold less potassium than the older (5-week-old) rat (93). Similarly, clearance studies in saline-expanded dogs also provide indirect evidence of a diminished secretory and enhanced reabsorptive capacity of the distal nephron to potassium early in life (94). Furthermore, premature neonates studied weekly after birth exhibited a 50% reduction in the fractional excretion of potassium between 26 and 30 weeks GA, in the absence of significant change in absolute urinary potassium excretion (15). To the extent that the filtered load of potassium increased almost threefold during this same time interval, the constancy of renal potassium excretion could be best explained by a developmental increase in the capacity of the kidney for potassium reabsorption (15). Please note that, in general, the limited potassium secretory capacity of the immature kidney becomes clinically relevant only under conditions of potassium excess.

Sites of Potassium Transport along the Nephron

Proximal Tubule

Potassium is freely filtered at the glomerulus. Thus, the concentration of potassium entering the proximal convoluted tubule (PCT) is similar to that of plasma. Approximately 65% of the filtered load of potassium is reabsorbed along the initial two-thirds of the proximal tubule, a fractional rate of reabsorption similar to that of sodium and water (95–97) (*Fig. 8-3*). A similar fraction (50–60%) of the filtered load of potassium is reabsorbed along the proximal tubules of suckling (13–15 days old) rats (93, 99).

Reabsorption of potassium along the early proximal tubule is passive, closely following that of sodium and water (100), and has been proposed to occur via solvent drag via the paracellular pathway and diffusion (101–103). Solvent drag depends on active sodium reabsorption, which generates local hypertonicity in the paracellular compartment, providing an osmotic force driving water reabsorption that entrains potassium in the reabsorbate. Potassium diffusion is driven by the lumen-positive transepithelial voltage in the second half of the proximal tubule, and the slightly elevated concentrations of potassium in the lumen (104).

In the proximal tubule, as in all other nephron segments discussed below, transepithelial sodium reabsorption requires the coordinated function of apical sodium transport proteins and the basolateral Na-K-ATPase which actively extrudes intracellular sodium into the interstitium, and thereby maintains the low intracellular sodium concentration and steep sodium concentration gradient critical to the driving force for apical sodium entry (*Fig. 8-3*). There is no evidence for specific regulation of potassium reabsorption along the proximal tubule, and most observed modulation of proximal reabsorption of this cation can be accounted for by alterations in sodium transport.

Electrogenic sodium-coupled entry of substrates such as amino acids and glucose across the luminal cell membrane of the proximal tubule as well as bicarbonate exit across the basolateral cell membrane are driven by the potential differences across the respective cell membranes, which are maintained by potassium flux through potassium channels (105). Electrophysiological studies in isolated perfused proximal tubules suggest that potassium movement from the cell to lumen maintains the electrical driving force for sodium-coupled cotransport in the proximal tubule. Immunohistochemical studies reveal that KCNE1 and KCNQ1, which together constitute the slowly activated component of the delayed rectifying potassium current in heart, also colocalize in the luminal membrane of the proximal tubule in mouse kidney, as does the cyclic nucleotide-gated, voltage-activated potassium channel KCNA10 (106, 107). The observation that KCNE1 knock-out mice exhibit an increased fractional excretion of fluid (with accompanying volume depletion), sodium, chloride, and glucose compared to their wild type littermates supports the critical role of KCNE1 in repolarizing the membrane potential in proximal tubule in response to sodium-coupled transport (107).

Notably, mutations in KCNQ1 give rise to the long QT syndrome (108).

Thick Ascending Limb of the Loop of Henle (TALH)

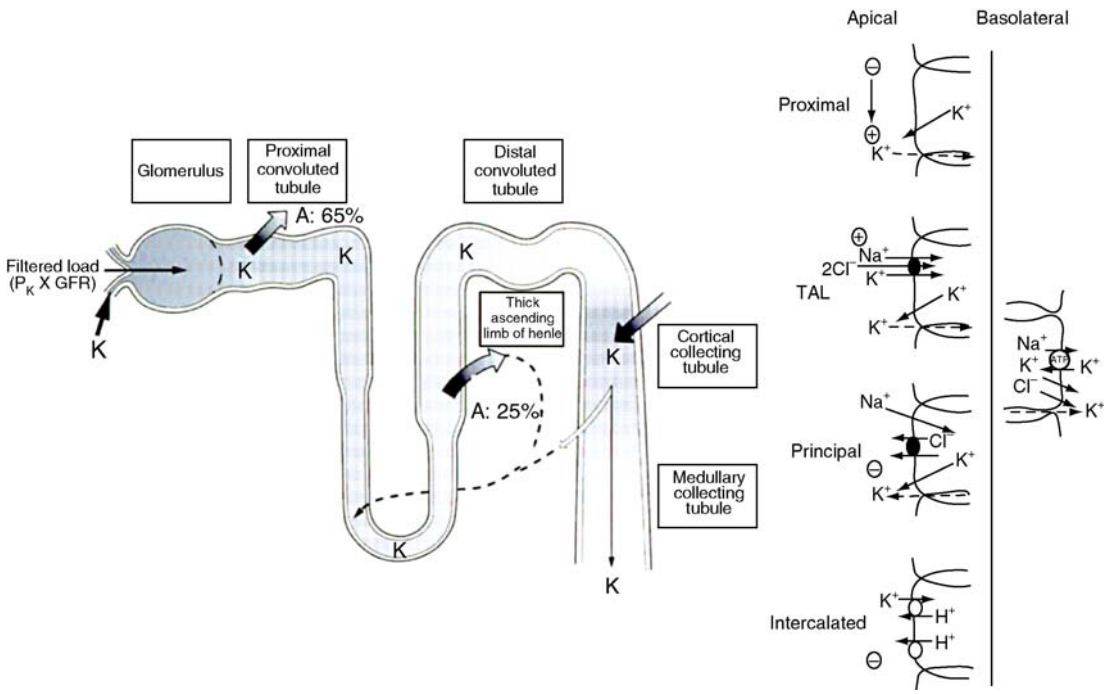
Approximately 10% of the filtered load of potassium reaches the early distal tubule of the adult rat (96), an observation that implies that significant reabsorption of this cation occurs beyond the proximal tubules. The site responsible for this additional avid potassium reabsorption is the TALH where potassium reabsorption is mediated, at least in part, by the apical Na-K-2Cl cotransporter (NKCC2) that translocates a single potassium ion into the cell accompanied by one sodium and two chloride ions (*Fig. 8-3*). This secondary active transport is ultimately driven by the low intracellular sodium concentration, established by the basolateral Na-K-ATPase, which drives sodium entry from the lumen into the cell. The diuretics furosemide and bumetanide specifically inhibit NKCC2 and thus block sodium, potassium and chloride reabsorption at this site.

Critical to the function of NKCC2 is the presence of a secretory potassium channel in the urinary membrane which provides a pathway for potassium, taken up into the cell via the cotransporter, to recycle back into the lumen. This "recycling" of potassium ensures that a continuous supply of substrate is available for the apical cotransporter. Potassium secretion into the urinary space creates a lumen positive transepithelial potential difference, which in turn provides a favorable electrical driving force that facilitates paracellular reabsorption of sodium, potassium, calcium and magnesium.

The luminal potassium secretory channel in the TALH has been identified as ROMK, a channel originally cloned from the TALH in the rat outer medulla (109–111); this low-conductance ATP-sensitive potassium channel is encoded by the KCNJ1 gene. Loss-of-function mutations in ROMK lead to antenatal Bartter syndrome (type 2),

Figure 8-3

Potassium transport along the nephron. (left panel) The percentages of filtered potassium reabsorbed along the proximal tubule and thick ascending limb of the loop of Henle (TALH) are indicated for the adult (A). *Arrows* show direction of net potassium transport (reabsorption or secretion). GFR = glomerular filtration rate. (right panel) Simplified cell models of potassium transport along the nephron, showing apical transporters unique to discrete nephron segments and cells therein, and basolateral transporters which are similar in all nephron segments (adapted from 98).



also known as the hyperprostaglandin E syndrome, which is characterized by severe renal salt and fluid wasting, electrolyte abnormalities (hypokalemia, hypomagnesemia, and hypercalciuria), and elevated renin and aldosterone levels (112). The clinical picture observed is similar to that of chronic administration of loop diuretics. The typical presentation of antenatal Bartter syndrome includes polyhydramnios, premature delivery, life threatening episodes of dehydration during the first week of life, and profound growth failure (113). It should be noted that mutations in NKCC2 (SLC12A1) or the basolateral chloride channel CLC-Kb (CLCNKB) can also give rise to Bartter syndromes type 1 and 3, respectively (114, 115).

In contrast to the situation in the adult, up to 35% of the filtered load of potassium reaches the early distal tubule of the young (2-week-old) rat (93), suggesting that the TALH undergoes a significant postnatal increase in its capacity for reabsorption. Consistent with this premise are the observations from studies in rats of significant increases in the (i) fractional reabsorption of potassium along the TALH, expressed as a percentage of delivered load, between the second and sixth weeks of postnatal life (93), and (ii) osmolarity of early distal fluid between the second and fourth weeks of life (116). While these findings provide compelling evidence for a developmental maturation of potassium absorptive pathways and diluting capacity of the TALH, respectively, direct functional analysis of the transport capacity of this segment in the developing nephron has not been performed.

Molecular studies in rat kidney indicate that mRNA encoding NKCC2, absent at birth, is first expressed on postnatal day 8 in rat, coincident with completion of nephronogenesis (37), and increases, at least in medulla, between postnatal days 10 and 40 (117). Na-K-ATPase activity in the TALH of the neonatal rabbit is only 20% of that measured in the adult when expressed per unit of dry weight (118). The postnatal increase in pump activity is associated with a parallel increase in expression of medullary Na-K-ATPase mRNA (117). Although the balance of the studies summarized above identifies a functional immaturity of the TALH early in life and would thus predict limited effects of inhibitors of NKCC2 on transepithelial transport, administration of furosemide (2 mg/kg) to newborn lambs leads to a natriuretic response equivalent to that observed in adult animals (119).

Distal Nephron

Within the distal nephron of the fully differentiated kidney, the late DCT, CNT and the CCD are considered to be the primary sites of potassium secretion, and thus urinary potassium excretion, which can approach 20% of the filtered load (96, 97, 120, 121) (*Fig. 8-3*). The DCT secretes a constant small amount of potassium into the urinary fluid (122). Regulated bidirectional potassium transport occurs in the CNT and CCD, comprised of two major populations of cells, each with distinct functional and morphologic characteristics. CNT/principal cells reabsorb sodium and secrete potassium, whereas intercalated cells regulate acid-base balance but can reabsorb potassium in response to dietary potassium restriction or metabolic acidosis (123, 124) (*Fig. 8-3*). Thus, the direction and magnitude of net potassium transport in these segments depend on the metabolic needs of the organism and reflect balance of potassium secretion and absorption, processes mediated by CNT/principal and intercalated cells, respectively.

Potassium Secretion

Potassium secretion in the CNT and CCD is critically dependent on the reabsorption of filtered sodium delivered to these segments. Sodium passively diffuses into the CNT/principal cell from the urinary fluid down a favorable concentration gradient through the luminal amiloride-sensitive epithelial Na channel (ENaC) and is then transported out of the cell at the basolateral membrane in exchange for the uptake of potassium via the basolateral Na-K-ATPase (*Fig. 8-3*). The accumulation of potassium within the cell and the lumen-negative voltage, created by movement of sodium from the tubular lumen into the cell and its electrogenic extrusion, creates a favorable electrochemical gradient for intracellular potassium to diffuse into the urinary space through apical potassium-selective channels. The magnitude of potassium secretion is determined by its electrochemical gradient and the apical permeability to this cation. Basolateral potassium channels in these same cells provide a route for intracellular potassium ions to recycle back into the interstitium, thereby maintaining the efficiency of the Na-K pump. Any factor that increases the electrochemical gradient across the apical membrane or increases the apical potassium permeability will promote potassium secretion. An apical electroneutral potassium-chloride cotransporter has also been functionally identified in the CCD (125, 126).

Two apical potassium-selective channels have been functionally identified in the distal nephron: the small-conductance secretory potassium (SK) channel and the high-conductance maxi-K channel. The density of these channels appears to be greater in the CNT than in the CCD (127).

The SK channel, restricted to the CNT/principal cell, mediates baseline potassium secretion (128, 129). ROMK, originally cloned from the TALH (described in the section above on the TALH), is considered to be a major functional subunit of the SK channel. A complex interplay of hormones, second messengers and kinases/phosphatases regulate the SK/ROMK channel in the distal nephron, thereby allowing the kidney to respond appropriately to the metabolic needs of the organism (130, 131). Protein kinase A (PKA)-induced phosphorylation of the channel is essential for its activity (129, 132), and may account for the well-documented stimulatory effect of vasopressin on renal potassium secretion (133). Protein tyrosine kinase (PTK) mediates the endocytosis of ROMK channels in the rat CCD in the face of dietary potassium restriction (134, 135). Tyrosine phosphorylation of ROMK enhances channel internalization and thus the removal of channels from the plasma membrane (136), leading to a reduction in number of apical channels and net potassium secretion. Tyrosine phosphorylation of ROMK channels decreases in response to dietary potassium loading (137).

The "with-no-lysine-kinases," or WNKs, comprise a recently discovered family of serine/threonine kinases that act as molecular switches that direct differential effects on downstream ion channels, transporters, and the paracellular pathway to allow either maximal sodium chloride reabsorption or maximal potassium secretion in response to hypovolemia or hyperkalemia, respectively (138). WNK4 inhibits sodium and chloride absorption in the DCT by reducing the surface expression of the apical thiazide-sensitive NaCl cotransporter NCCT (139), an effect that would be expected to increase sodium delivery to and reabsorption by the CCD, in turn augmenting the driving force for potassium secretion. However, WNK4 decreases surface expression of ROMK by enhancing endocytosis of this channel (140), thereby negating the effect of the augmented electrochemical gradient on stimulation of net potassium secretion. Mutations in WNK1 or 4 lead to pseudohypoaldosteronism type II (PHA II; Gordon's Syndrome), an autosomal dominant disorder characterized by hypertension sensitive to thiazide diuretics, hyperkalemia, and metabolic acidosis (141). Loss-of-function mutations in WNK4 lead to increased apical expression of the NaCl cotransporter and stimulation of sodium absorption in the DCT (139, 142). The consequent reduction in sodium delivery to the CNT and CCD would be expected to reduce potassium secretion. However, the same mutations in WNK4 that relieve the inhibition of NCCT further decrease surface expression of ROMK, reduce potassium secretion in the CCD, and likely are the cause of hyperkalemia in patients with Gordon's Syndrome. WNK1 suppresses the activity of WNK4. Therefore, a gain-in-function mutation in WNK1 will also produce the clinical signs and symptoms of PHA II (141).

The maxi-K channel, present in CNT/principal and intercalated cells, is considered to mediate flow-stimulated potassium secretion (143, 144). In the CNT and CCD, the density of conducting maxi-K channels is greater in intercalated than CNT/principal cells (145, 146). The maxi-K channel is comprised of two subunits: a channel pore-forming α subunit and a regulatory β subunit. This channel is rarely open at the physiologic resting membrane potential, but can be activated by cell depolarization, membrane stretch, and increases in intracellular Ca^{2+} concentration, as accompany increases in urinary flow rate (146–149). The proposed role of the maxi-K channel in flow-stimulated urinary potassium secretion has been confirmed in a mouse model with targeted deletion of the β1 subunit; the fractional excretion of potassium in maxi-K $\beta1^{-/-}$ mice subjected to acute volume expansion was significantly lower than that in wild type mice (150).

The maxi-K channel appears to assume great importance in regulating potassium homeostasis under conditions where SK/ROMK channel-mediated potassium secretion is limited. Thus, adult animals with targeted deletion of ROMK (i.e., Bartter phenotype) are not hyperkalemic, as would be expected in the absence of a primary potassium secretory channel, but instead lose urinary potassium (151). The sensitivity of distal potassium secretion in this rodent model of Bartter syndrome to iberiotoxin, a specific inhibitor of maxi-K channels, presumably reflects recruitment of the latter channels to secrete potassium in response to high distal flow rates as accompany loss-of-function of the TALH NKCC2 cotransporter (151). Similarly, although infants with antenatal Bartter syndrome due to loss-of-function mutations in ROMK may exhibit severe hyperkalemia during the first few days of life (152), the hyperkalemia is not sustained. In fact, these patients typically exhibit modest hypokalemia beyond the neonatal period (153, 154).

Potassium Absorption

In response to dietary potassium restriction or metabolic acidosis, the distal nephron may reverse the direction of net potassium transport from secretion to absorption. Potassium reabsorption is mediated by a H-K-ATPase, localized to the apical membrane of acid-base transporting intercalated cells, that couples potassium reabsorption to proton secretion (*Fig. 8-3*) (123, 155–157). Two isoforms of the H-K-ATPase are found in the kidney: the gastric isoform, HKAg, is normally found in gastric parietal cells and is responsible for acid secretion into the

lumen whereas the colonic HKAc isoform is a structurally related H-K-ATPase found in distal colon that mediates active potassium reabsorption (156). Expression of the apical gastric-like H-K-ATPase in the rat and rabbit intercalated cell is increased in response to dietary potassium restriction and metabolic acidosis (123, 155, 158, 159).

A reduction in potassium intake leads to a fall in potassium secretion by the distal nephron within 5–7 days in rat (160). This adaptation is associated with a decrease in the number of apical SK/ROMK (161) and maxi-K (162) channels and stimulation of H-K-ATPase-mediated potassium reabsorption in intercalated cells in the distal nephron (163). The reduction in number of SK/ROMK channels in potassium-restricted animals is mediated by the effect of dietary potassium on circulating levels of aldosterone and other effectors, such as PTK, as described above. Stimulation of luminal H-K-ATPase activity in intercalated cells results not only in potassium retention, but also in urinary acidification and metabolic alkalosis.

Developmental Regulation of Distal Potassium Transport

Potassium secretion in the distal nephron, and specifically in the cortical collecting duct (CCD) studied in vitro, is low early in life and cannot be stimulated by high urinary flow rates (121). Indeed, basal potassium secretion can not be detected in the rabbit CCD until after the third week of postnatal life, with potassium secretory rates increasing thereafter to reach adult levels by 6 weeks of age (121). Consistent with the relatively undifferentiated state of the newborn CCD are the ultrastructural and morphometric findings in neonatal principal cells of few organelles, mitochondria and basolateral infoldings, the site of Na-K-ATPase (164, 165).

The limited capacity of the CCD for potassium secretion early in life could be explained by either an unfavorable electrochemical gradient across the apical membrane and/or a limited apical permeability to this ion. Cumulative evidence suggests that the electrochemical gradient is not limiting for potassium secretion in the neonate. Activity of the Na-K-ATPase, present along the basolateral membrane of corticomedullary collecting ducts in the neonatal rabbit (166), is 50% of that measured in the mature nephron; the observation that the intracellular potassium concentration in this segment is similar in the neonate and adult presumably reflects a relative paucity of membrane potassium channels in the distal nephron early in life (118, 165, 167). Concordant with the measurements of sodium pump activity, the rate of sodium absorption in the CCD at 2 weeks of age is approximately 60% of that measured in the adult (121). However, electrophysiologic analysis has confirmed the absence of functional SK/ROMK channels in the luminal membrane of the neonatal rabbit CCD with the number of open channels per patch increasing progressively after the second week of life (168). Thus, the postnatal increase in the basal potassium secretory capacity of the distal nephron appears to be due primarily to a developmental increase in number of SK/ROMK channels, reflecting an increase in transcription and translation of functional channel proteins (168–170).

The appearance of flow-stimulated net potassium secretion is a relatively late developmental event. Flow-stimulated potassium secretion can not be elicited in rabbit CCDs until the fifth week of postnatal life, which is approximately 2 weeks after basal net potassium secretion is first detected (121, 171). The absence of flow-stimulated potassium secretion early in life is not due to a limited flow-induced rise in net sodium absorption and/or intracellular calcium concentration, each of which is required for flow stimulation of potassium secretion and is equivalent to that detected in the adult by the second week of postnatal life (171). The observation that mRNA encoding the maxi-K channel α-subunit and immunodetectable channel protein can not be demonstrated until the fourth and fifth weeks of postnatal life, respectively (171) suggests that flow-dependent potassium secretion is determined by the transcriptional/translational regulation of expression of maxi-K channels.

While the neonatal distal nephron is limited in its capacity for potassium secretion, indirect evidences suggests that this nephron segment absorbs potassium. As indicated above, saline-expanded newborn dogs absorb 25% more of the distal potassium load than do their adult counterparts (91). Functional analysis of the rabbit collecting duct has shown that the activity of apical H-K-ATPase in neonatal intercalated cells is equivalent to that in mature cells (123). The latter data alone do not predict transepithelial potassium absorption under physiologic conditions, as the balance of transport will depend on the presence and activity of apical and basolateral potassium conductances and the potassium concentration of the tubular fluid delivered to this site. The high distal tubular fluid potassium concentrations, as measured In vivo in the young rat, may facilitate lumen-to-cell potassium absorption mediated by the H-K-ATPase (93).

Luminal and Peritubular Factors Affecting Potassium Transport

The major factors that influence the external balance of potassium are listed in *Table 8-2* and are discussed in the following sections.

Table 8-2

Factors that regulate external potassium balance

Renal factors
Distal sodium delivery and transepithelial voltage
Tubular (urinary) flow rate
Potassium intake/plasma potassium concentration
Hormones (mineralocorticoids, vasopressin)
Acid-base balance
Gastrointestinal tract factors
Stool volume
Hormones (mineralocorticoids)

Sodium Delivery and Absorption

The magnitude of sodium reabsorption in the distal nephron determines the electrochemical driving force favoring potassium secretion into the luminal fluid, as described above. Processes that enhance distal sodium delivery and increase tubular fluid flow rate, such as extracellular volume expansion or administration of a variety of diuretics (osmotic diuretics, carbonic anhydrase inhibitors, loop and thiazide diuretics), lead to an increase in urinary excretion of both sodium and potassium. The kaliuresis is due not only to the increased delivery of sodium to the distal nephron, but also to the increase in tubular fluid flow rate, which maximizes the chemical driving forces, as described below, favoring potassium secretion.

Processes that decrease sodium delivery to less than 30 mM in the distal tubular fluid (172, 173) and/or sodium reabsorption sharply reduce potassium secretion in the CCD and can lead to hyperkalemia. In vivo measurements of the sodium concentration in distal tubular fluid generally exceed 35 mEq/L both in healthy adult and suckling rats and thus should not restrict distal sodium secretion (93, 116, 172, 174). However, in edema-forming states, including congestive heart failure, cirrhosis and nephrotic syndrome, the urinary sodium concentration typically falls to less than 10 mEq/L; a reduction in potassium excretion in these patients may be ascribed to the low rates of distal sodium delivery as well as urinary flow. The potassium-sparing diuretics, amiloride and triamterene, inhibit ENaC and thus block sodium absorption, thereby diminishing the electrochemical gradient favoring potassium secretion (175). Trimethoprim and pentamidine can also limit urinary potassium secretion via the same mechanism (177, 178).

Sodium delivered to the distal nephron is generally accompanied by chloride. Chloride reabsorption occurs predominantly via the paracellular pathway. The movement of the negative charged chloride out of the lumen dissipates the lumen negative potential, creating a less favorable driving force for luminal potassium secretion (179). When sodium delivered to the distal nephron is accompanied by an anion less reabsorbable than chloride, such as bicarbonate (in proximal renal tubular acidosis), β-hydroxybutyrate (in diabetic ketoacidosis), or carbenicillin (during antibiotic therapy), luminal electronegativity is maintained, thereby eliciting more potassium secretion than occurs with a comparable sodium load delivered with chloride (180).

Tubular Flow Rate

High rates of urinary flow in the mature, but not the neonatal or weanling, distal nephron, as elicited by extracellular fluid volume expansion or administration of diuretics or osmotic agents, stimulate potassium secretion (121). There are a number of factors responsible for the flow-stimulation of potassium secretion. First, increases in tubular fluid flow rate in the distal nephron enhance sodium reabsorption due to an increase in the open probability of ENaC (time the channel spends in the open state), which augments the electrochemical gradient favoring potassium secretion (176, 181). Second, the higher the urinary flow rate in the distal nephron, the slower the rate of rise of tubular fluid potassium concentration because secreted potassium is rapidly diluted in urine of low potassium concentration (182). Maintenance of a low tubular fluid potassium concentration maximizes the potassium concentration gradient (and thus the chemical driving force) favoring net potassium secretion. Finally, increases in luminal flow rate transduce mechanical signals (circumferential stretch, shear stress, hydrodynamic bending moments on the cilium decorating the apical surface of virtually all renal epithelial cells) into increases in intracellular calcium concentration, which in turn activate apical maxi-K channels to secrete potassium, thereby enhancing urinary potassium excretion (143, 144, 171).

Potassium Intake and Cellular Potassium Content

The kidney adjusts potassium excretion to match input, in large part by regulating the magnitude of potassium secretion and reabsorption in the distal nephron. Thus, for example, an increase in dietary potassium intake

stimulates whereas a decrease in intake reduces net potassium secretion (97). An increase in potassium concentration in the extracellular fluid space increases potassium entry into principal cells via the basolateral Na-K-ATPase, which in turn maximizes the concentration gradient favoring apical potassium secretion into the urinary fluid. Simultaneously, the increase in circulating levels of plasma aldosterone that accompanies potassium loading enhances the electrochemical driving force favoring potassium secretion in the distal nephron by stimulation of ENaC-mediated sodium absorption and its electrogenic absorption via the Na-K-ATPase. Within 6 h of an increase in dietary potassium intake, the density of apical ROMK channels increases in principal cells in rats due to activation of a previously "silent" pool of channels or closely associated proteins (183). Chronic potassium loading also increases maxi-K channel message, apical protein, and function in the distal nephron (162). Finally, the inhibition of proximal tubule and loop of Henle salt and water reabsorption in response to a potassium load (184, 185) increases tubule fluid flow rate which in turn stimulates potassium secretion via activation of maxi-K channels and increased distal of delivery of sodium to the distal nephron.

The trigger for the renal adaptation to dietary potassium loading remains uncertain. It is now believed that after a potassium-rich meal, a reflex increase in potassium excretion is initiated by sensors in the splanchnic bed (gut, portal circulation, and/or liver) that respond to local increases in potassium concentration that occur in the absence of or before changes in plasma potassium concentration are detected (87, 186). In support of the notion of potassium sensing, intraportal delivery of potassium chloride to rats leads to an increase in hepatic afferent nerve activity and urinary potassium excretion, responses that are unaccompanied by increases in plasma potassium concentration (187). Increases in the intraportal concentration of glucagon, as follows ingestion of a protein- and potassium-rich meal, also increases renal excretion of potassium (188, 189), a response proposed to be due to the release of cAMP, the second messenger of glucagon in the liver, into the circulation and its uptake by kidney (186).

Chronic potassium loading leads to *potassium adaptation,* an acquired tolerance to an otherwise lethal acute potassium load (8). Potassium adaptation, which begins after a single potassium-rich meal, includes increases in the rate of skeletal muscle uptake of potassium from the extracellular fluid (53) due to stimulation of Na-K-ATPase activity (190) and secretion of potassium by the distal nephron and colon. The process is facilitated by the increase in circulating levels of aldosterone elicited by the increase in serum potassium concentration (191). A similar adaptive response is seen in renal insufficiency such that potassium balance is maintained during the course of many forms of progressive renal disease, as long as potassium intake is not excessive (192). The molecular mechanisms underlying this adaptation in the distal nephron (and colon) include not only an increase in the density of apical membrane potassium channels, but also an increase in the number of conducting ENaC channels and activity of the basolateral Na-K pump. The latter two processes result in increases in transepithelial voltage and the intracellular potassium concentration, events that enhance the driving force favoring potassium diffusion from the cell into the urinary fluid.

Hormones

Mineralocorticoids are key regulators of renal sodium absorption and potassium excretion, and thus of circulating volume, blood pressure and sodium and potassium homeostasis. The major stimuli for aldosterone release from the zona glomerulosa in the adrenal gland are angiotensin II and elevations in serum potassium concentrations (193). ACE inhibitors, by reducing the conversion of angiotensin I to angiotensin II and thus aldosterone secretion by the adrenal gland, may lead to hyperkalemia as the ability of the distal nephron to secrete potassium is impaired. Angiotensin receptor blockers (ARBs), by competitively binding to angiotensin II type 1 (AT1) receptors and thus antagonizing the action of angiotensin II on aldosterone release, may have similar effects.

Aldosterone stimulates sodium reabsorption and potassium secretion in principal cells of the fully differentiated aldosterone-sensitive distal nephron (ASDN) (194, 195). Circulating mineralocorticoids bind to their cytosolic receptors in the ASDN; the aldosterone antagonist spironolactone competitively inhibits this binding. The hormone-receptor complex translocates to the nucleus where it promotes the transcription of aldosterone-induced physiologically active proteins (e.g., Na-K-ATPase). Among the cellular and molecular effects of an increase in circulating levels of aldosterone are increases in density of ENaC channels, achieved by the recruitment to and retention of intracellular channels at the apical membrane, de novo synthesis of new ENaC subunits, and activation of preexistent channels, as well as and stimulation of Na-K-ATPase activity by translocation of preformed transporters to the membrane and translation of new sodium pump subunits (196–201). The sum effect of the stimulation of apical

sodium entry and Na-pump-mediated reabsorption is an increase in lumen negative transepithelial voltage and thus electrochemical driving force favoring potassium exit across the apical membrane (199, 200, 202).

The effects of aldosterone on ENaC and, to some extent, the Na-K pump appear to be indirect, mediated by aldosterone-induced proteins, including serum and glucocorticoid-inducible kinase (sgk). Aldosterone rapidly induces Sgk1 in the distal nephron (203). Phosphorylated Sgk stimulates sodium reabsorption, in large part by inhibiting ubiquitin-ligase Nedd4-2-mediated endocytic retrieval of ENaCs from the luminal membrane (204). Renal water and electrolyte excretion is indistinguishable in sgk1-knockout ($sgk1^{-/-}$) and wild-type ($sgk1^{+/+}$) mice fed a normal diet (205), indicating that the kinase is not necessary for basal sodium absorption. However, dietary sodium restriction reveals an impaired ability of $sgk1^{-/-}$ mice to reduce sodium excretion despite increases in plasma aldosterone levels and proximal tubular sodium and fluid reabsorption (206). $Sgk1^{-/-}$mice exhibit an impaired upregulation of renal potassium excretion in response to potassium loading, presumably due to the impact of the mutation on ENaC and/or Na-K-ATPase activity and thus the electrochemical gradient favoring potassium secretion (207). Corticosteroid hormone induced factor (CHIF) is another aldosterone-induced protein that is expressed in the basolateral membrane of the collecting duct where it increases the affinity of Na-K-ATPase for sodium (208–211).

Plasma aldosterone concentrations in premature infants and newborns are higher than those measured in the adult (16, 212). Yet, clearance studies in fetal and newborn animals demonstrate a relative insensitivity of the immature kidney to the hormone (16, 213–215). The density of aldosterone binding sites, receptor affinity, and degree of nuclear binding of hormone-receptor are believed to be similar in mature and immature rats (215).

The transtubular potassium gradient (TTKG) provides an indirect, semiquantitative measure of the renal response to mineralocorticoid activity in the aldosterone-sensitive cortical distal nephron and is calculated using the equation:

$$\text{TTKG} = \frac{[K^+]\text{urine}}{[K^+]\text{plasma}} \times \frac{\text{plasma osmolality}}{\text{urine osmolality}}$$

where $[K^+]$ equals the potassium concentration in either urine (U) or plasma (P), as indicated (216–218). Measurements of TTKG have been reported to be lower in 27 than 30-week GA preterm infants followed over the first 5 weeks of postnatal life (219). The low TTKG has been attributed to a state of relative hypoaldosteronism (219), but may also reflect the absence of potassium secretory transport pathways (i.e., channel proteins).

Acid-Base Balance

Disorders of acid-base homeostasis induce changes in tubular potassium secretion in the distal nephron (179). In general, acute metabolic acidosis causes the urine pH and potassium excretion to decrease, whereas both acute respiratory alkalosis and metabolic alkalosis increase urine pH and potassium excretion (179, 220). Chronic metabolic acidosis has variable effects on urinary potassium excretion.

Acute metabolic acidosis reduces cell potassium concentration and leads to a reduction in urine pH, which in turns inhibits activity of the SK/ROMK channel and thereby limits potassium secretion in the distal nephron (220–223). The effect of chronic metabolic acidosis on potassium secretion is more complex and may be influenced by modifications of the glomerular filtrate (e.g., chloride and bicarbonate concentrations), tubular fluid flow rate, and circulating aldosterone levels (8, 179). The latter two factors may lead to an increase rather than a decrease in potassium secretion and excretion.

The alkalosis-induced stimulation of potassium secretion reflects two direct effects on principal cells: an increase in net sodium absorption (224), which enhances the electrochemical gradient for net potassium secretion, and (74) an increase in the permeability of the apical membrane to potassium resulting from an increase in duration of time the potassium-selective channels remain open (8). Alkalosis also decreases acid secretion in intercalated cells, thereby reducing H-K-ATPase-mediated countertransport of potassium.

Potassium deficiency stimulates proton secretion in the distal nephron, increases the production of the urinary buffer ammonia (225), and may stimulate bicarbonate generation by increasing expression H-K-ATPase in the distal nephron (226).

Contribution of the Gastrointestinal Tract

Under normal conditions in the adult, 5–10% of daily potassium intake is excreted in the stool. The colon is considered to be the main target for regulation of intestinal potassium excretion (227). Potassium transport in the colon represents the balance of secretion and absorption (228). Under baseline conditions, net potassium secretion predominates over absorption in the adult, whereas the neonatal gut is poised for net potassium absorption (227).

Potassium secretion requires potassium uptake by the Na-K-ATPase and furosemide-sensitive Na-K-2Cl cotransporter located in the basolateral membrane of colonocytes; potassium is then secreted across the apical membrane through potassium channels, including a calcium-activated maxi-K channel similar to that found in the distal nephron (229–233). Potassium absorption is mediated by two H-K-ATPases localized to the apical membrane of the distal colon (234).

Stool potassium content can be enhanced by any factor that increases colonic secretion, including aldosterone, epinephrine, and prostaglandins (31, 235, 236). Indomethacin and dietary potassium restriction reduce potassium secretion by inhibiting the basolateral transporters and apical potassium channels. Diarrheal illnesses are typically associated with hypokalemia, presumably due to the presence of nonreabsorbed anions (which obligate potassium), an enhanced electrochemical gradient established by active chloride secretion, and secondary hyperaldosteronism due to volume contraction (237).

Potassium adaptation in the colon is demonstrated by increased fecal potassium secretion after potassium loading and in the face of renal insufficiency. Fecal potassium excretion may increase substantially to account for 30–50% of potassium excretion in patients with severe chronic renal insufficiency (31, 238–240). The enhanced colonic potassium secretion characteristic of renal insufficiency requires induction and/or activation of apical maxi-K channels in surface colonic epithelial cells (241).

Net colonic potassium absorption is significantly higher in young compared to adult rats (227). The higher rate of potassium absorption during infancy is due to robust activity of apical K-ATPases and limited activity of the basolateral transporters that mediate secretion (227, 231, 242).

9 Acid-Base Homeostasis

Elizabeth Ingulli · Kirtida Mistry · Robert H. K. Mak

Introduction

Acid-base homeostasis operates to maintain extracellular arterial pH between 7.35 and 7.45, and intracellular pH between 7.0 and 7.3 in order to provide an optimal milieu for enzymatic and metabolic processes. Since pH is equal to –log [H^+], with the concentration of hydrogen ions in Eq/L (or mol/L), this normal extracellular pH correlates with a hydrogen ion concentration of 35–45 nEq/L, or 35×10^{-6} to 45×10^{-6} mEq/L. Thus, hydrogen ion concentration is maintained within extremely narrow limits, and is just a tiny fraction, roughly one millionth, of the concentration of sodium, potassium and chloride. Deviations in either direction outside the physiological range could impair cardiopulmonary or neurologic function or even lead to death. Several regulatory processes enable the body to efficiently dispose of physiologic daily load of carbonic acid (as volatile CO_2) and nonvolatile acids; and defend against the occasional addition of pathologic quantities of acid and alkali. Chemical buffers within the extracellular and intracellular compartments serve to blunt changes in pH that could occur with retention of either acid or bases. In addition, the control of CO_2 tension (PCO_2) by the central nervous system and the respiratory system and the control of HCO_3^- by the kidneys constitute the complex regulatory processes that act in concert to maintain the arterial pH within a very narrow range.

Buffering Systems

An acid is a proton donor and a base is a proton acceptor. An acid dissociates reversibly into a conjugate base (A^-) and a proton, H^+.

$$HA \rightleftarrows A^- + H^+$$

The acidity of the solution is calculated from the Henderson-Hasselbach equation:

$$pH = pKa + \log[(A^-)/(HA)]$$

pKa indicates the pH at which HA = A^- and $\log[(A^-)/(HA)] = 0$. A strong acid has a low pKa and dissociates freely in solution because its conjugate base has a weak affinity for protons; whereas a weak acid has a high pKa and dissociates poorly because its conjugate base has a strong affinity for protons. A weak acid only partially dissociates and forms a solution which contains both the acid and base forms, enabling it to partially resist changes in pH when a strong acid or base is introduced. This dampening of pH changes is called buffering and is maximal when the pKa is close to the physiological pH.

The major extracellular buffer is the CO_2-HCO_3 system:

$$H_2O + CO_2 \rightleftarrows H_2CO_2 \rightleftarrows H^+ + HCO_3^-$$

Although the pKa of the CO_2-HCO_3 buffer system (6.1) is well below 7.4, this buffer is very effective because of its abundance and because $PaCO_2$ is rapidly regulated by the lungs. Pulmonary participation in acid-base homeostasis relies on the excretion of CO_2 by the lungs. The reaction is catalyzed by the enzyme carbonic anhydrase. Large amounts of CO_2 (10–12 mol/day in adults) accumulate as metabolic end products of tissue metabolism. This CO_2 load is transported in the blood to the lungs as hemoglobin-generated HCO_3^- and hemoglobin-bound carbamino groups.

Introduction of a strong acid HA is rapidly (within minutes) distributed within the extracellular fluid and results in the titration of plasma HCO_3^-:

$$HA + NaHCO_3 \rightleftarrows NaA + H_2O + CO_2$$

The resulting changes in HCO_3 are ultimately corrected by the kidneys. Other buffers include plasma proteins and hemoglobin and intracellular proteins and phosphates. Intracellular buffering follows extracellular buffering and takes up to hours. Approximately 60% of a nonvolatile acid load is buffered outside the extracellular fluid by bone and soft tissues (1) *Table 9-1*.

Renal Acidification

The kidneys play major roles in acid-base homeostasis. Two renal processes are essential: reabsorption of filtered bicarbonate and secretion of acid generated from the metabolism of dietary protein as well as from bone formation, the latter especially significant in the growing child. About 4,000–4,500 mmoles of bicarbonate are filtered per day in

© Springer-Verlag Berlin Heidelberg 2009

the adult depending on glomerular filtration rate. Normally almost all of the filtered bicarbonate is reabsorbed. The proximal tubule accounts for the majority of this reabsorption (about 80%). The thick ascending limb of the nephron reabsorbs ~10% and the distal nephron reabsorbs the remaining 10% such that very little filtered HCO_3^- is excreted in the urine. The second function of the kidney is to secrete acid by generating new bicarbonate, to cope with dietary or endogenous metabolic acids. Dietary and endogenous acids amount to about 1 mEq/kg body weight per day in adults on a typical western diet (2). This is accomplished by excretion of titratable acid (TA) and excretion of NH_4^+. The production of new bicarbonate, which is not filtered, by the kidney is quantitated by urinary net acid excretion (NAE), calculated as:

$$NAE = NH_4^+ + TA - HCO_3^-$$

TA refers to acid excreted that has titrated urinary buffers. It equals the amount of acid (H^+) that is added to the tubular fluid by the nephron and is a function of both urine pH and buffering capacity (3). Urinary NH_4^+ excretion produces new bicarbonate from the metabolism of glutamine to bicarbonate and NH_4^+ (4). Addition of bicarbonate to plasma accomplishes acid secretion whereas loss of bicarbonate in the urine is equivalent to gain of acid.

Table 9-1

Summary of response of an acute nonvolatile acid load, including buffering, increased ventillatory rate, and increased renal acid excretion, resulting in ultimate correction of the acidemia

	Response	Time course
	Extracellular buffering by HCO_3	Immediate
Acid load	Respiratory buffering by pCO_2	Minutes to hours
Response	Intracellular and bone buffering	2–4 h
	Renal acid excretion	Hours to days

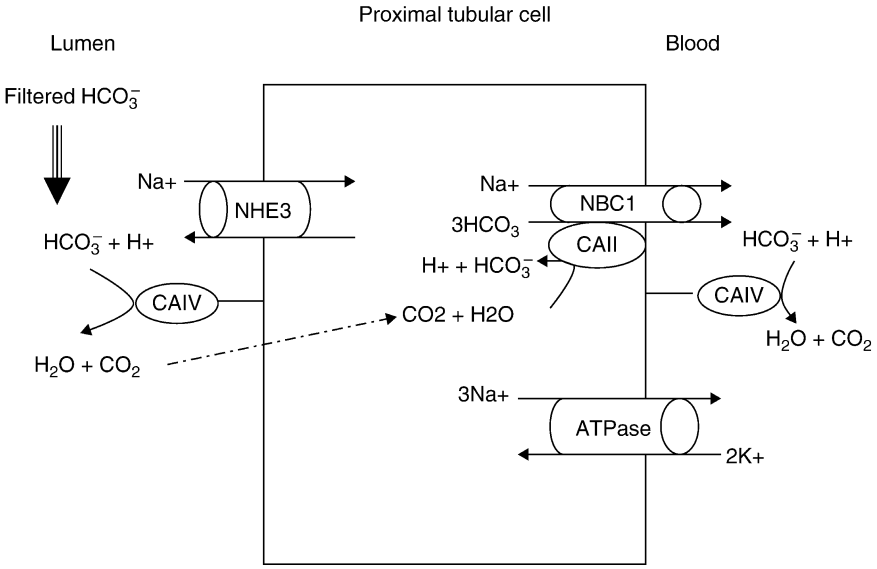
Modified with permission from (133)

Proximal Mechanisms

The proximal tubule of the nephron is responsible for reabsorbing approximately 80% of the bicarbonate that is filtered by the glomerulus. The ability of the proximal tubular cell to reclaim filtered bicarbonate is achieved indirectly by the secretion of hydrogen ions into the tubular lumen. There is no evidence for direct bicarbonate

Figure 9-1

Model for acid base homeostasis in the proximal tubular cell. Filtered bicarbonate is reabsorbed via secreting protons into the tubular lumen. H^+ secretion is achieved via the sodium hydrogen exchanger (NHE3) on the brush border and by electrogenic ($3HCO_3$:1Na) sodium bicarbonate cotransport (NBC1) on the basolateral surface. Carbonic anhydrase (CAIV and CAII) facilitates bicarbonate entry and efflux.



reabsorption (5) (Fig. 9-1). The rate of bicarbonate reabsorption can vary along the proximal segment, with a lower rate in the terminal S3 segment compared with the proximal S1 segment (6, 7). The major mechanism used to secrete H^+ into the lumen is through the Na^+/H^+ exchanger (NHE) located on the luminal surface of the cell (8–11).

Na^+/H^+ Exchanger (NHE)

To date, nine NHE isoforms have been described varying in their tissue expression and cellular location (12). NHE1 is the "housekeeping" isoform that is ubiquitously expressed in virtually all tissues within the plasma membrane. The isoforms NHE2-NHE5 are also located within the plasma membrane but are more restricted in their tissue distribution, while the NHE6-NHE9 isoforms are also ubiquitously expressed but are usually located intracellularly (12). NHE3, an integral membrane protein, is the predominant isoform in the proximal tubular cell and is located at the apical surface (13–19). Like other isoforms, NHE3 facilitates movement of one sodium molecule into the cell in exchange for secreting one hydrogen molecule into the tubular lumen. In addition, NHE3 regulates intracellular pH and cell volume and is responsive to growth factors (20–23). This exchanger is sensitive to amiloride and its analogs (10, 24, 25). Recent studies have identified a second transporter, NHE8, within the proximal tubule (24, 26, 27) that may play a role in acid base homeostasis (28).

Na^+/K^+ ATPase

Hydrogen ion secretion within the proximal tubule is sodium dependent (29). Sodium moves passively into the proximal tubular cell by the concentration gradient generated within the cell. The luminal concentration of sodium is maintained throughout the length of the proximal tubule and resembles that of isotonic sodium chloride. The sodium concentration gradient within the cell is generated by the basolateral Na^+/K^+ ATPase located on the basolateral surface of the tubular cell. This is an active process, which extrudes three sodium ions in exchange for two potassium ions. Within the proximal tubule, the Na^+/K^+ ATPase pump indirectly provides the energy that allows most of the transport proteins to translocate filtered solutes. Murine studies have suggested that two-thirds of the bicarbonate reabsorption in the proximal tubule is achieved through the NHE (15–19). The remaining one third is achieved through a ATPase similar to those in the distal nephron (30). The H^+-ATPase (15–19) is an apically located, multi-subunit vacuolar-type (31–33) ATPase that is blocked by DCCD (N,N'-dicyclohexylcarbondiimide), NEM (N-ethylmaleimide) and bafilomycin (34, 35). Studies have shown that there is a maturational increase in both NHE activity (36–40) and basolateral Na^+/K^+-ATPase activity (41, 42) resulting in an increase in proximal tubule acidification during development. Thus, most of the H^+ secreted by the proximal tubule is used to reclaim bicarbonate. The remaining secreted H^+ will be combined with phosphate as titratable acid.

Carbonic Anhydrase (CA)

The filtered bicarbonate combines with the secreted hydrogen ions within the lumen to form carbonic acid (H_2CO_3). The dehydration of H_2CO_3 to CO_2 and H_2O is catalyzed by the zinc metalloenzyme, carbonic anhydrase isoenzyme type IV (CA IV), which is tethered to the luminal membrane of the proximal tubular cells. The CO_2 that is produced by this reaction rapidly diffuse into the tubular cells. Within the cells it combines with intracellular H_2O to produce intracellular H_2CO_3. Soluble cytoplasmic carbonic anhydrase isoenzyme type II (CA II) catalyzes the conversion of intracellular H_2CO_3 to H+ and HCO_3^- (43). Currently, there are 15 identified CA isoenzymes that enhance H^+/HCO_3^- transport (44). CA II accounts for 95% of the CA activity in the kidney and resides primarily within the cytosol. CA IV and CA XII account for the remaining 5% and are membrane-associated. CA II interacts with a number of transporters that facilitate movement of HCO_3^- (45).

$Na^+/HCO3^-$Cotransporter (NBC)

In general, there are three main groups of bicarbonate transporters: chloride-bicarbonate exchangers, sodium bicarbonate cotransporter (NBC), and sodium dependent chloride bicarbonate exchanger (NDCBE). These transporters are part of the solute-linked carriers (SLCs) and are members of the SLC4 family (46). The sodium bicarbonate cotransporter 1 (NBC1), otherwise known as SLC4A4, is an electrogenic sodium bicarbonate transporter located on the basolateral cell membrane of the proximal tubule (47). In the proximal tubule, NBC1 is responsible for transporting three bicarbonate molecules and one sodium molecule into the blood (48). Although dependent on Na^+, NBC1 appears to be independent of chloride. The electrogenic Na^+/HCO_3^- cotransporter is blocked by disulfonic stilbenes SITS and DIDS (21).

NBC1 appears to be the dominant pathway for HCO_3^- reabsorption in the S1 and S2 segments of the proximal tubule but a basolateral Cl-HCO_3 exchanger plays a role in the S3 segment (49–51). Thus, both the secretion of H^+ within the tubular lumen and the movement of HCO_3^- into the blood are sodium-dependent.

Distal Mechanisms

The distal nephron is responsible for net acid excretion. As in the proximal tubule, processes are at work to reabsorb the remaining filtered bicarbonate. In addition, protons are actively transported to the tubular lumen where they combine with NH_3 and HPO_4^{2-} to form $H_2PO_4^-$ and NH_4^+ resulting in urinary acidification.

Loop of Henle and Thick Ascending Loop (TAL)

The loop of Henle is responsible for reabsorbing the HCO_3^- that escapes proximal tubular reabsorption. This can be as much as 15% of the total filtered HCO_3^- and mostly occurs in the TAL (52–54). HCO_3^- reabsorption in the thick ascending loop is dependent on the concentration of HCO_3^- in the lumen and, like the proximal tubule, on luminal H^+ secretion (55). H^+ secretion in the TAL is mediated by Na^+/H^+ exchange at the luminal surface (56). The NHE3 isoform is predominantly involved (57–59) although, NHE2 has also been demonstrated to be present (60). The driving force mediating the exchange is the Na^+/K^+-ATPase (3Na:2K) on the basolateral surface (55). Efflux of HCO_3^- across the basolateral membrane into the peritubular fluid occurs via the electroneutral (1:1) basolateral Na^+/HCO_3^- isoform (NBCn1) (61–63), but other mechanisms such as Cl^-/HCO_3^- exchange (AE2) and K^+/HCO_3^- transport have been suggested to play a role (64–66).

Renal synthesis and excretion of ammonia is an important function of the kidney in maintaining acid base homeostasis. Ammonia is synthesized in the proximal tubule from the metabolism of glutamine (67, 68), which enters the proximal cell on the basolateral surface via the glutamine amino acid transporter, SNAT3 (69). NH_3 produced from the metabolism of glutamine enters the tubular lumen by diffusion where it combines with H^+ to produce NH_4^+. The TAL reabsorbs NH_4^+ allowing its secretion in the thin descending loop facilitating acid secretion distally. The TAL participates in generating the high NH_4^+ concentration in the medulla and the establishment of countercurrent multiplication system (70). NH_4^+ absorption in the TAL occurs by both active transport and passive diffusion and a number of transporters have been described. NH_4^+ is carried across the apical membrane by a $Na^+/K^+/2Cl^-$ cotransporter (NKCC2) that is sensitive to furosemide and bumetanide (71). Other cellular transport pathways on the luminal surface of the TAL include a K^+/H^+ (NH_4^+) antiport (NHE3 and/or NHE2), which exchanges NH_4^+ for H^+ and nonselective cation conductance (72). Basolateral carriers that transport NH_4^+ into the interstitium are $Na^+/K^+(NH_4^+)$-ATPase, NH_4^+ (K+)/Cl^- cotransport (KCC4), NH_4^+ conductance and Na^+/K^+ (NH_4^+) antiport (NHE1) (73–75). The final excretion of NH_3/NH_4^+ into the lumen of the collecting duct may be mediated by carrier proteins. RhBG and RhCG have been suggested as candidates (76, 77).

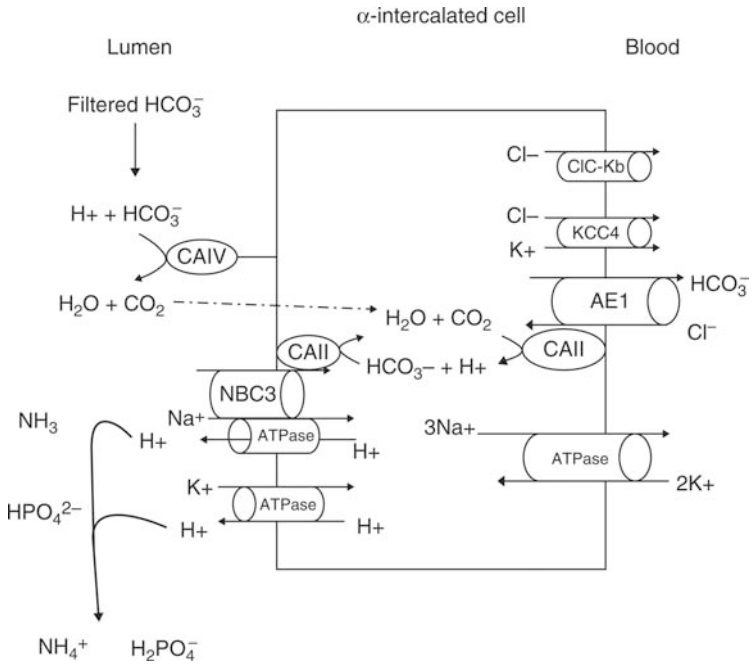
Collecting Duct

Urine acidification occurs mainly in the collecting duct (78). Two major cell types are found interspersed in the collecting duct: the principal cell and the intercalated cell. The principal cell is primarily involved with Na^+ reabsorption and K^+ secretion and plays little role in acid base balance. The intercalated cell is primarily involved in acid base transport and regulation. There are two types of intercalated cells that display different functions. The α-intercalated cells secrete protons while the β-intercalated cells secrete bicarbonate. The cortical collecting duct contains both α- and β-intercalated cells while the outer medullary collecting duct contains mostly α- intercalated cells.

The α-intercalated cell (*Fig. 9-2*) actively transports H^+ into the urine via a vacuolar H^+ -ATPase and to a lesser extent a H^+/K^+-ATPase on the luminal surface (79). Mutations in either the β1 or α4 subunits of the human H^+-ATPase can cause clinical acidosis (80–82). The distal tubule H^+-ATPase isoform differs from the proximal tubule isoform (83). Intracellular CAII is required to generate intracellular H^+ for active transport. An apical Na^+/H^+ exchanger (NHE2) also secretes H^+ into the tubule (59, 84). Proton secretion in the collecting duct serves to reabsorb the remaining HCO_3^- that has evaded earlier transport mechanisms of the nephron. In addition, secreted H^+ combines with HPO_4^{2-} to form $H_2PO_4^-$ and NH_3 to trap NH_4^+. HCO_3^- is transported from the cell to the interstitium via a basolateral Cl^-/HCO_3^- anion exchanger (AE1). AE1 exchanges one bicarbonate ion for one chloride ion. Mutations in AE1 can also cause a metabolic acidosis (85). Chloride returns to the peritubular space via a conductive pathway thereby continuing to drive

Figure 9-2

Model for acid base homeostasis in the α-intercalated cell of the collecting duct. α-intercalated cells acidify the urine by (1) secreting protons via the H^+ ATPase and less so via H^+/K^+-ATPase, (2) reabsorbing residual filtered HCO_3^- via electroneutral sodium bicarbonate cotransport (NBC3) and chloride bicarbonate exchange (AE1). Carbonic anhydrase (CAII) facilitates bicarbonate efflux.



HCO_3^- extrusion. Other exchangers such as AE2, AE4 and SLC26A7 (pendrin) have been identified on the basolateral membrane of selective cells within the inner or outer medullary collecting cells contributing to HCO_3^- exchange (65, 86–89). Mutations in the K^+/Cl^- cotransporter, KCC4, in mice have also been shown to result in acidosis (90).

The β-intercalated cell is opposite in polarity to the α-intercalated cell. The function is to actively secrete HCO_3^- into the urine coupled to Cl^- reabsorption but independent of Na^+. $HCO_3^-$is moved from the lumen into the cell through a Cl^-/HCO_3^- exchanger on the apical membrane. Pendrin (SLC26A4) is thought to be this exchanger. Mice deficient in pendrin are unable to secrete HCO_3^- by their collecting ducts (91–93). On the basolateral surface, acetazolamide sensitive H^+-ATPase pumps H^+ into the peritubular space assisting in HCO_3^- secretion (94).

Genetics of Renal Tubular Acidosis (RTA)

Renal tubular acidosis (RTA) is classified according to the location of the defect in acid-base balance. Molecular and genetic advances have identified various mutations in the transporters of the nephron that can result in metabolic acidosis and alkalosis. Inherited disorders of acidosis and alkalosis are listed in *Tables 9-2* and *9-3*.

Inherited Distal Renal Tubular Acidosis

Distal RTA is diagnosed when the kidney fails to acidify the urine in the setting of systemic metabolic acidosis or after an induced acid load. The inability to acidify the urine is usually associated with hypocitraturia, hypercalciuria, and nephrocalcinosis. The nephrocalcinosis can result in chronic interstitial disease, electrolyte abnormalities, and urinary concentration defects. Severe hypokalemia can result in muscle weakness, periodic paralysis, or cardiac arrhythmias. Affected children usually present with failure to thrive and growth retardation.

Both dominant and recessive forms of inherited distal RTA have been described. Mutations in either the basolateral AE1 transporter or the apical H^+-ATPase of the α-intercalated cell results in an inability of

Table 9-2

The inherited renal tubular acidosis

Type of RTA	Subtype and inheritance	Age at presentation	Clinical features	Protein	Gene(s)	OMIM
Distal (type 1)	Dominant	Older/adult	Mild/compensated metabolic acidosis	AE1	*SCL4A1*	179800
			Hypokalemia (variable)			
			Hypercalciuria			
			Hypocitraturia			
			Nephrolithiasis			
			Nephrocalcinosis			
			Sometimes rickets/ osteomalacia			
			Secondary erythrocytosis			
	Recessive	Childhood	Metabolic acidosis with hemolytic anemia	AE1	*SCL4A1*	602722
			Only reported in Southeast Asian populations			
	Recessive with early onset hearing loss	Infancy/ childhood	Metabolic acidosis	B1 subunit of H^+-ATPase	*ATP6V1B1*	267300
			Early nephrocalcinosis			
			Vomiting/dehydration			
			Growth retardation			
			Rickets			
			Bilateral sensorineural hearing loss, from childhood			
	Recessive with later onset hearing loss	Infancy/ childhood	As above, but later onset hearing loss in some (a few with normal hearing)	A4 subunit of H^+-ATPase	*ATP6V0A4*	602722
Proximal (type 2)	Recessive with ocular abnormalities	Infancy	Metabolic acidosis	NBC1	*SLC4A4*	604278
			Hypokalemia			
			Ocular abnormalities (band keratopathy, cataracts, glaucoma)			
			Growth retardation			
			Defective dental enamel			
			Intellectual impairment			
			Basal ganglia calcification			
Combined proximal and distal (type 3)	Recessive with osteopetrosis	Infancy/ childhood	Metabolic acidosis	CA II	*CA2*	259730
			Hypokalemia			
			Osteopetrosis			
			Blindness			
			Deafness			
			Early nephrocalcinosis

the distal nephron to acidify the urine (95). E1 is the Cl^-/HCO_3^- exchanger on the basolateral surface of the α-intercalated cell. The gene that encodes for the AE1 protein is SLC4A1 is located on human chromosome 17q21–22. AE1 is expressed in the kidney and in red blood cells. Mutations in the red blood cells isoform result in deformities such as hereditary spherocytosis and Southeast Asian ovalocytosis. Eight different mutations in the kidney isoform of AE1 have been reported to cause distal RTA (96–101). Dominant and recessive mutations of AE1 that result in distal RTA have been found (102). The defect does not appear to be abnormal anion exchange but rather the mutations appear to alter the polarity of the cell causing intracellular retention of the AE1 transporter or misplacement of the transporter to the apical surface (101, 103–107).

The renal proton pump is a member of the vacuolar multisubunit ATP-dependent proton pumps (108, 109). The pump has a soluble cytoplasmic domain, that displays the ATPase activity, and a membrane-associated domain that displays the proton translocation pathway. Two genes responsible for recessive distal RTA have been identified: ATP6V1B1 (on chromosome 2p13) and ATP6V0A4 (on chromosome 7q33–34) (110–112). Their expression is restricted to the kidney (111, 112). Bilateral sensorineural hearing loss is associated with mutations in the β1 subunit and not the α4 subunit. Hearing loss is thought to be due to impaired proton secretion which thought to be required for normal cochlear development and hair cell survival (111).

Inherited Proximal Renal Tubular Acidosis

Inherited mutations in the proximal tubule that result in isolated RTA are rare and characterized by impaired proximal tubular bicarbonate reabsorption with preservation of other proximal reabsorption functions, such as those for glucose, amino acids, phosphate, and citrate. Inherited isolated autosomal recessive proximal RTA can present with growth retardation alone, or together with mental retardation and ocular abnormalities such as

band keratopathy, cataracts, and glaucoma. Calcification in the basal ganglia has been described (113).

Sodium bicarbonate cotransport across the basolateral membrane of proximal tubular cells is required for proximal bicarbonate reabsorption. Two missense mutations were initially found in human kidney NBC1 isoform (SLC4A4) gene to be associated with reduced NBC1 activity (114). Other NBC1 mutations have since been found (113, 115, 116) and have been associated with intracytoplasmic retention and aberrant localization (117). The NHE3 deficient mouse exhibits reduced proximal tubular HCO_3 reabsorption with distal tubular compensation and a mild metabolic acidosis (118). Human NHE3, encoded by SLC9A3, is a candidate gene for proximal RTA. However, mutations have not been reported.

Genetics of Metabolic Alkalosis

Mutations in six genes have been found to cause Gitelman's and Bartter's syndromes (131) (*Table 9-3*). In the clinic, Gitelman's and Barter's syndromes are characterized by hypochloremic metabolic alkalosis, hypokalemia with increased fractional excretion of potassium and normal to low normal blood pressure. In the newborn period Bartter's syndrome presents with polyuria and polydipsia, and hypercalciuria with associated nephrocalcinosis. In childhood, classic Bartter's syndrome presents with polyuria and polydipsia along with vomiting and failure to thrive but nephrocalcinosis is not usually seen. Both forms demonstrate increased urinary prostaglandin E2 concentration. Gitelman's syndrome is usually diagnosed later in life where only mild laboratory abnormalities (mild hyokalemia and alkalosis) are observed. Patients may develop muscle weakness, cramps and tetany.

Classification of the syndromes as described below is based on the genetic mutations that have been reported (131). *Type I Bartter's syndrome* is caused by mutations of the sodium potassium chloride cotransporter (NKCC2) expressed on the apical surface of the TAL (120). The cotransporter is encoded by the SLC12A1 gene located on chromosome 15q15-q21 and is responsible for Na^+ reabsorption (121). *Type II Bartter's syndrome* is caused by mutations of the voltage-dependent potassium channel ROMK expressed on the apical surface of the TAL and the cortical collecting duct (122). The channel is encoded by the KCNJ1 gene on chromosome 11q24–25 and facilitates NKCC2 activity by providing the intraluminal potassium. *Type III Bartter's syndrome* is caused by mutations of a chloride channel (ClC-Kb) expressed in the basolateral surface of the TAL, the distal convoluted tubule, the connecting tubule and the α-intercalated cell of the collecting duct (123). The channel protein is encoded by the CLCNKB gene located on chromosome 1p36 and is responsible for transporting chloride across basolateral membrane (123–125). *Type IV Bartter's syndrome* is caused by mutations of barttin, a β-subunit of the ClC-Kb channel and is expressed in the basolateral surface of the TAL and in the cochlea (126, 127). The protein is encoded by the Bartter syndrome and sensorineural deafness (BSND) gene located on chromosome 1p31 (126, 128, 129). *Gitelman's syndrome* is caused by mutations of the renal thiazide-sensitive sodium chloride cotransporter (NCCT) in the apical membrane of the distal convoluted tubule. The cotransporter is encoded by the SLC12A3 gene located on chromosome 16q13 and is responsible sodium reabsorption in the distal tubule (130, 131).

Physiologic Response to Nonvolatile Acid Loads

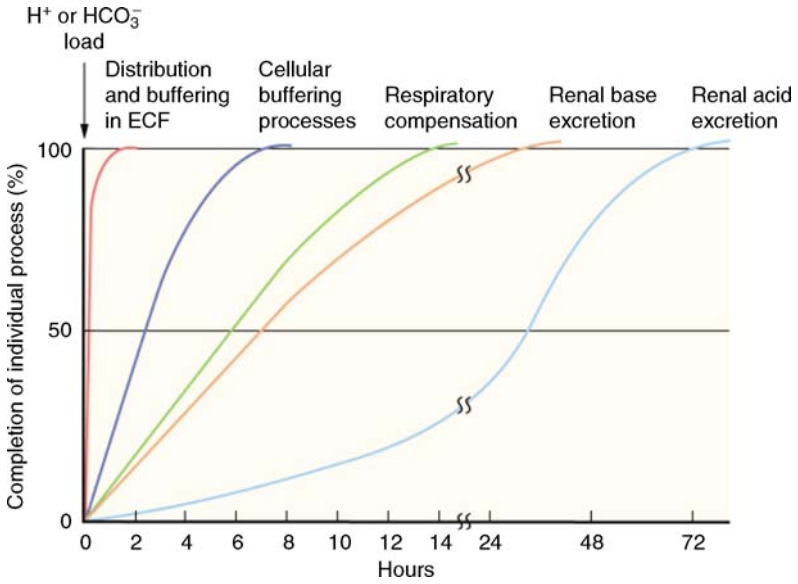
Acute non-volatile acid loads are distributed rapidly and attenuated by extracellular buffers within 30 min. A second phase of buffering by intracellular processes then occurs. Approximately two-thirds of this intracellular buffering is through Na^+/H^+ exchange and one-third through either K^+/H^+ or Cl^-/ HCO_3^- exchanges (132). These intracellular processes function to restore arterial pH within 6–8 h. This is followed by respiratory compensation and renal acid excretion. The time course of these physiologic compensatory mechanisms is summarized in *Fig. 9-3*.

An important response to an acid load is the neurorespiratory control of ventilation. A fall in the systemic arterial pH is sensed by chemo-receptors which stimulate ventilation and reduce $PaCO_2$. The fall in arterial pH is therefore blunted. Approximately 12–24 h is required for full respiratory compensation for metabolic acidosis (*Fig. 9-3*).

In response to a HCO_3^- load, the kidneys efficiently retain all filtered base and attempt to generate enough new bases to normalize the arterial pH. Acidosis enhances proximal HCO_3^- absorption, decreasing delivery of HCO_3^- out of the proximal tubule and enhances distal acidification. Net acid excretion is increased by stimulation of $NH4^+$ production and excretion. In addition, hyperaldosteronism and the effect of nonreabsorbable anions can act synergistically to strengthen the renal defense to an acid challenge (133).

Figure 9-3

Time course of acid-base compensatory mechanisms. In response to a metabolic acid or alkaline load, component approaches to completion of the distribution and extracellular buffering mechanisms, of cellular buffering events and of respiratory and renal regulatory processes are presented as a function of time. *ECF* extracellular fluid. (Reproduced with permission from reference 133.)



Physiologic Response to Alkaline Loads

The physiologic response to an alkaline load is dependent on the same three responses for defense of an acid challenge: cellular buffering, distribution within the ECF, respiratory and renal excretion. The cellular defense against a base load is somewhat less effective than the defense against an acid load. There is also poorer stabilization of intracellular pH in the alkaline than in the acid range (133).

An acute alkaline load in the form of a HCO_3^- load is rapidly distributed in the extracellular fluid within 25 min. This is followed by cellular buffering, which has a half life of about 3 h. The volume of distribution of the HCO_3^- load is inversely proportional to the preexisting serum HCO_3^- concentration. Two thirds of the HCO_3^- load is retained in the ECF. One third of the HCO_3^- load is buffered by cellular processes, principally by Na^+/H^+ exchange. A small amount is buffered by Cl^-/HCO_3^- exchange and increased lactate production (134). Modest hypokalemia also results. Neutralization of the HCO_3^- load by buffers results in an increase in PCO_2, which stimulates ventilation acutely. However, if the respiratory system is compromised, dangerous hypercapnia may ensue.

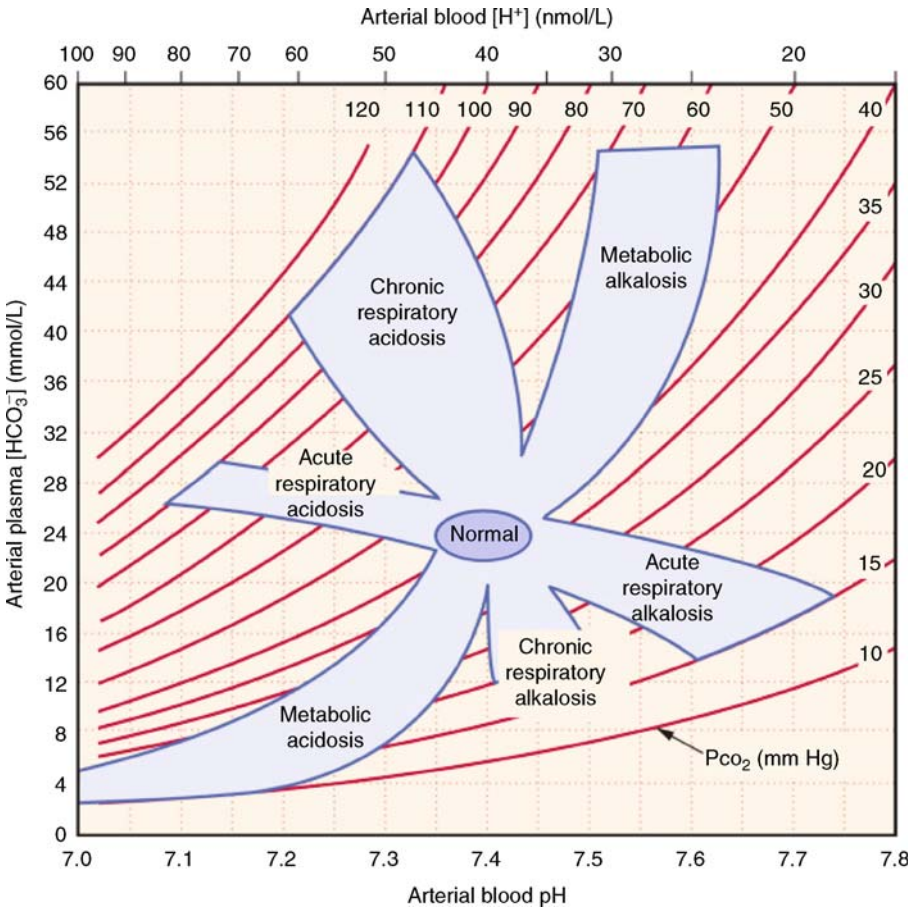
The kidney excretes HCO_3^- more rapidly than acid. A base load is excreted almost entirely within 24 h. The proximal tubule is responsible principally for HCO_3^- excretion when blood HCO_3^- increases. Glomerular ultrafiltrate HCO_3^- rises in conjunction with higher serum HCO_3^- but absolute proximal HCO_3^- reabsorption does not increase because of suppression of proximal acidification processes by alkali. The most sensitive renal response to an alkaline load is a decline in the excretion of NH_4^+. In addition, there is a rise in the excretion of unmeasured anions. Excretion of citrate and 2-oxoglutarate is increased significantly with modest base loads. Bicarbonaturia is quantitatively important only with the large alkaline loads. This process of limiting changes in urine pH without sacrificing acid-base balance lessens the risk of kidney stone formation (135).

Acid-Base Map

A convenient approach to acid-base disorders is an acid-base map. Although not always reliable, this defines the 95% confidence limits in acid-base disorders (*Fig. 9-4*).

Figure 9-4

Acid-base normogram (or map). Shaded areas represent the 95% confidence limits of normal respiratory and metabolic compensations for primary acid-base disturbances. Data falling outside the shaded areas denote a mixed disorder if a laboratory error is not present. (Reproduced with permission from reference 133.)



If the arterial HCO_3^- and H^+ values fall within one of the shaded areas, a simple acid-base disturbance is present. Two broad types of acid-base disorders are metabolic and respiratory. Metabolic acidosis and alkalosis are characterized by primary disturbances of plasma HCO_3^-. Common examples of metabolic acidosis and alkalosis are listed in *Tables 9-2*, *9-3* and *9-4*. On the other hand, respiratory disorders of acid-base balance are characterized by primary disturbance of $PaCO_2$. Common examples of respiratory disorders of acid-base balance are listed in *Tables 9-5*–*9-7*.

Primary metabolic acid-base disorders evoke secondary respiratory responses and primary respiratory acid-base disorders evoke secondary metabolic responses. Compensation is a predictable physiologic consequence of the primary disturbance and does not present a secondary acidosis or alkalosis. Mixed acid-base disorders are situations which exceed the physiologic limits of compensation. Values that fall outside the shaded areas in *Fig. 9-4* indicate mixed disorders. Common examples of mixed disorders of acid-base balance are listed in *Tables 9-8* and *9-9* (136).

Physiologic Response to Changes in Carbon Dioxide Tension

Respiratory acidosis (*Tables 9-6* and *9-7*) which follows hypercapnia, is initiated by an increase in $PaCO_2$ and elicits acidification of body fluids. An acute increase in plasma HCO_3^- occurs and is complete within 5–10 min. This results in acidic titration of non-bicarbonate buffers,

Table 9-4

Causes of metabolic acidosis

Mechanism	Class of agents	Clinical conditions
↑ Production of acid	β-Hydroxybutyric acid andacetoacetic acid	Fasting or starvation
		Insulin deficiency
		Ethanol intoxication
		Ketotic hypoglycemia with hypoalaninemia
	Lactic acid	Hypoxia
		Muscular exercise
		Ethanol ingestion
	Type 1 glycogen storage disease	Fructose-6-diphosphate deficiency
		Leukemia
		Diabetes mellitus
		Pancreatitis
		Cirrhosis
	Incompletely identified organic acids	Ethylene glycol ingestion
		Paraldehyde intoxication
		Salicylate intoxication
		Methanol intoxication
		Methylmalonic aciduria
		Propionyl coenzyme A carboxylase deficiency
	Acidifying salts	Arginine hydrochloride
		Ammonium chloride
		Lysine chloride
		Hyperalimentation
	Sulfuric acid	Methionine
		Neutramigen
		High-protein milk formula
↑ Extra renal losses of base	Bicarbonate (or combustible base)	Diarrhea
		Ureterosigmoidostomy
		Drainage of pancreatic, biliary, or small bowel secretion
		Ingestion of calcium chloride, cholestyramine, and magnesium sulfate
Dilutional acidosis	Infusion of bicarbonate-free isotonic or hypertonic solutions	Impaired renal acidification
		Oliguria or salt-retaining states
		Renal tubular acidosis
Impaired renal acidification	Accumulation of fixed, nonmetabolizable acids	Polycystic kidney disease
		Hyperparathyroidism
		Adrenal insufficiency
		Pseudohypoaldosteronism
		Leigh's syndrome

Table 9-5

Causes of metabolic alkalosis

Mechanism	Class of agents	Clinical conditions
Excessive loss of acid with volume contraction	Chloride deficiency syndromes	Normal blood pressure, high rennin and aldosterone, low potassium: vomiting of gastric juices, gastric drainage fistula; diuretic and laxative abuse; Bartter's syndrome; chloride-deficient infant formula
		Cystic fibrosis; villous adenoma of the colon; Congenital alkalosis with chloride diarrhea (Darrow)
Excessive gain of base	Base overload	Iatrogenic, especially in the context of renal
		insufficiency; milk alkali syndrome
	Conversion of lactate, acetate to base	Iatrogenic; dialysis excess
	Nonmetabolizable acid into cells	Glucose-induced alkalosis in fasting
	Excess proximal tubular bicarbonate reabsorption	Posthypercapnic state
	Hypoparathyroidism	Phosphate excess
Increased (distal) bicarbonate reabsorption	Volume expansion, mineralo-corticoid excess	Hypertension, high renin and aldosterone; secondary nonedematous aldosteronism (e.g., renal artery stenosis, intrarenal vascular disease, accelerated hypertension)
		Renin-secreting tumors
		Hypertension, low rennin, high aldosterone: primary hyperaldosteronism; dexamethasone-suppressible hyperaldosteronism; adrenal carcinoma
		Hypertension, low rennin, low aldosterone: adrenocorticosteroid excess; deficiency of 11-hydroxylation/17-hydroxylation; adrenal carcinoma; Liddle syndrome; licorice (glycyrrhizic acid) excess

such as phosphates, hemoglobin and intracellular protein buffers. When respiratory acidosis is chronic, renal adjustments exacerbate the acidemia by a further increase in plasma HCO_3^-. This chronic adjustment phase takes 3–5 days to complete and involves upregulation of the renal acidification mechanisms.

Respiratory alkalosis is initiated by a decrease in $PaCO_2$ from different causes (*Table 9-6*). Respiratory alkalosis causes alkalinization of body fluids. The acute response consists of a decrease in plasma HCO_3^- and is complete within 5–10 min from the onset of hypocapnia. It occurs by alkaline titration of nonbicarbonate buffers of the body as well as increased production of organic acids. When respiratory alkalosis is chronic, renal adjustments worsen the alkalemia by an additional decrease in plasma HCO_3^-. This adaptation takes 2–3 days to complete and involves downregulation of renal acidification mechanisms. Chronic but not acute respiratory acidosis stimulates activity of H^+-ATPase and H^+ K^+-ATPase in the proximal tubule, medullary thick ascending limb and collecting duct. In contrast, both acute and chronic respiratory alkalosis decrease both H^+-ATPase and H^+K^+-ATPase proton pumps. The stimulatory effect of respiratory acidosis and the inhibitory effect of respiratory alkalosis appear to be potassium and aldosterone independent. Although the precise mechanisms are not known, direct of PCO_2, pH or HCO_3^- delivery may be involved (137).

Molecular and Cellular Renal Regulation in Acid-Base Disorders

The proximal tubule responds to systemic changes in acid base balance to restore homeostasis. An acute acid load (decrease in peritubular pH) will result in increased H+ secretion and HCO_3^- reabsorption while an acute base load (increase in peritubular pH) will result in decreased H^+ secretion and HCO_3^- reabsorption by the proximal tubule (138–140). Metabolic acidosis results in increased insertion of NHE into the apical membrane as well as an

increase in its activation. On the basolateral surface there is an increase in posttranslational modifications of NBC resulting in increased HCO_3^- reabsorption (141). The amount of HCO_3^- reabsorbed depends upon the luminal concentration of HCO_3^- and the luminal flow rate (142, 143).

The distal tubule responds to acidosis by increasing H^+ secretion and HCO_3^- reabsorption in the superficial distal and inner medullary tubules. A decrease in peritubular HCO_3^- stimulates basolateral Cl^-/HCO_3^- exchange and stimulates insertion of vesicles containing H^+-ATPase in the apical membrane to enhance H^+ secretion. A decrease in luminal pH will inhibit H^+-ATPase activity. In the collecting duct, acidosis has been shown to result in loss of apical Cl^-/HCO_3^-exchange but acquired basolateral function. It is well understood that Na^+ delivery to the distal nephron with or without volume depletion results in increased H^+ secretion (144–146), while potassium depletion increases HCO_3^-reabsorption in the superficial distal tubule and collecting duct (147, 148).

Chronic acid loading (7 days) is associated with an increase in apical NHE-3 in the renal proximal tubule. Because NHE-3 mediates both proton secretion and sodium reabsorption, compensatory changes in sodium handling develop, involving decreases in the abundance of the thiazide-sensitive Na^+/Cl^- transporters of the distal convoluted tubule and both the β and γ subunits of the amiloride-sensitive epithelial sodium channel of the

Table 9-8
Causes of respiratory alkalosis

Mechanism	Conditions
Reflex excitation of respiratory center via pulmonary stretch receptors	Pulmonary edema, cardiopulmonary disease

collecting duct. In addition, the renal cortical abundance of the proximal type 2 Na-dependent phosphate transporter is markedly decreased (147). The adaptation of renal $NH4^+$ synthesis and transport is mediated by key enzymes of ammoniagenesis (mitochondrial glutaminase and glutamine dehydrogenase) and gluconeogenesis (phosphoenolpyruvate carboxykinase) in the proximal tubule and the apical $Na^+/K^+(NH4^+)$-2 Cl^- cotransporter of the medullary collecting ducts. An acid pH and glucocorticoids are the two major factors which control the expression of these transporters and act in concert to coordinate the adaptation during metabolic acidosis (148).

A variety of hormones (e.g., endothelin-1, cortisol, and angiotensin II) can influence proximal tubular function by increasing NHE3 and/or NBC1 activity. Endothelin-1 (ET-1), produced by proximal tubular cells in response to acidosis, binds to its receptor and increases levels of NHE3 in the apical membrane of proximal tubular cells (151–156). The increased ET-1 levels have also been suggested to stimulate distal tubule acid secretion by increasing Na^+/H^+ exchange and decreasing HCO_3^- secretion (157, 158). Acidosis also increases cortisol levels, which increase NHE3 insertion into the apical membrane (159–162) and increases both NBC1 levels and activity (163, 164). Mineralocorticoids have also been shown to enhance H^+ secretion by directly stimulating H^+-ATPase in the distal nephron (165, 166). Angiotensin II is produced by the proximal tubule and increases insertion of NHE3 into the apical membrane as well as enhances its activity (167–169). Basolateral NBC activity is also increased (170, 171) by decreasing cAMP, activation of PKC and activation of src/MAPK pathways (172–175). This results in net H^+ secretion and HCO_3^- reabsorption. In the distal nephron angiotensin II has opposing effects by increasing HCO_3^- reabsorption in the superficial tubules but decreasing it in the outer medullary duct (176–178).

Concept of Serum Anion Gap

All solutions of dissolved salts contain equal number of dissociated positive and negative charges. This simple principle was used by Gamble as a means of analyzing clinical acid-base disorders (179). A practical approach takes advantage of the fact that most plasma ions normally exist at relatively low concentrations. The three ions with the highest plasma concentrations and the largest variances are Na^+, Cl^- and HCO_3^-. The plasma concentration of Na^+ normally exceeds the sum of Cl^- and HCO_3^- and such comparisons therefore yield what is called the anion gap:

$$Na^+ - (Cl^- + HCO_3^-)$$

The anion gap is a virtual and entirely arbitrary measurement and is a function of the specific ions incorporated in, or excluded from the equation. Anion gap calculations can also include potassium:

$$(Na^+ + K^+) - (Cl^- + HCO_3^-)$$

Since the potential absolute changes in plasma K^+ is small compared to the other 3 ions, most clinicians do not include this ion.

Usually when metabolic acidosis (or chronic respiratory alkalosis) reduces the plasma HCO_3^-, the concentration of another anion increases, and the magnitude of that increase is similar to that of the HCO_3^- reduction.

Table 9-9

Causes of mixed acid-base disorders

Mechanism	Disorders	Adaptation	Blood pH
Inadequate response	Mixed metabolic acidosis and respiratory acidosis	$PaCO_2$ ↑↑ HCO_3 ↓↓	Depressed
	Mixed metabolic alkalosis and respiratory alkalosis	$PaCO_2$ ↓↓ HCO_3 ↑↑	Elevated
Excessive response	Mixed metabolic acidosis and respiratory alkalosis	$PaCO_2$ ↓↓ HCO_3 ↓↓	Normal or decreased or increased
	Mixed metabolic alkalosis and respiratory acidosis	$PaCO_2$ ↑↑ HCO_3 ↑↑	Normal or increased or decreased
Triple acid-base disorders	Mixed metabolic alkalosis (diuretics or Cl-deficient intake) metabolic acidosis (lactic acids of sepsis to hypoxemia, hypotension), and respiratory acidosis or alkalosis	$PaCO_2$ inappropriate, HCO_3 inappropriate, anion gap exceeds 20 mEq/L	Variable
Chronic respiratory acidosis obstructive lung disease, superimposed acute respiratory acidosis from pneumonitis or congestive heart failure, acute respiratory alkalosis (intubation) mechanical ventilation	HCO_3 inappropriate	$PaCO_2$ inappropriate	Variable

This simple calculation separates the acid-base disorder into two groups, thereby restricting the diagnostic possibilities. When the anion gap remains normal and increased Cl^- is the dominant change, the clinical situation is designated a normal-anion gap disorder or hyperchloremic metabolic acidosis (or compensated chronic respiratory alkalosis). Alternatively, if the HCO_3^- reduction is associated with an increased concentration any other anion (such as lactate or ketoacid anion) an elevated anion gap metabolic acidosis is diagnosed. Furthermore, when anion gap acidosis exists, the increase in anion gap should quantitatively mirror the fall in HCO_3^-. Disruption of this expected relationship is indicative of certain mixed acid-base disorders. For example, if the anion gap increases from normal to a far greater degree than the HCO_3^- decrease, this may indicate that the initial HCO_3^- was supranormal (pre-existing metabolic alkalosis) or that additional HCO_3^- was generated or administered during or after the metabolic acidosis. Both these possibilities define mixed anion-gap metabolic acidosis and metabolic alkalosis. Occasionally, the anion gap is abnormally small or even has a negative value. If the possibility of laboratory error is eliminated, the small or negative anion gap is likely to result from reduced concentration of a normal unmeasured anion such as albumin, pseudohyperchloremia (from hyperlipidemia) or increased concentration of unmeasured cations such as charged globulins (multiple myeloma) or lithium (as in lithium poisoning). Recognition of an unexpected abnormal anion gap is helpful in consideration of common as well as obscure disorders (179).

Normal anion gap in children is less than 12 mmol/L. Hypoalbuminemia reduces the anion gap by about 2–3 mmol/L (180). An anion gap of 12 mmol/L could represent clinically important lactic acidosis in a hypoalbuminemic patient. The normal range is higher for children younger than 2 years, 16 ± 4 mEq/L.

In recent years, another method of acid-base interpretation was introduced by Stewart, called "strong ion difference analysis" (181). This approach is similar to the anion-gap concept but requires many more quantitative measurements and calculations which makes it complicated and cumbersome for routine clinical utility. However, research in this area may help elucidate several unusual acid-base and electrolyte disorders.

Common examples of high and normal plasma anion gap acidosis are listed in *Table 9-9*.

Concept of Urine Anion Gap

In chronic metabolic acidosis, urine ammonium excretion should be elevated if renal tubular function is intact. Because ammonium is a cation, it should balance part of the negative charge of chloride. Therefore, the urine anion gap (UAG) should become progressively negative as the rate of ammonium excretion increases in response to acidosis or acid loading. UAG could therefore be used as a surrogate estimation of urinary ammonium. UAG is calculated as:

$$\mathrm{UAG} = [\mathrm{Na}^+ + \mathrm{K}^+]_{\mathrm{urine}} - [\mathrm{Cl}^-]_{\mathrm{urine}}$$

In the assessment of patients with normal serum anion-gap or hyperchloremic metabolic acidosis, a negative urine anion gap suggests gastrointestinal loss of bicarbonate whereas a positive urine anion gap suggests the presence of altered distal urinary acidification (182). The detailed approach to the clinical assessment and diagnosis of renal tubular acidosis will be discussed in a subsequent chapter (*Tables 9-10* and *9-11*).

Nutrition and Acid-Base Balance

Dietary intake, daily generation of organic acids (lactic acid, pyruvic acid and acetic acid) and excretion of bicarbonate in the stool results in net daily acid production of approximately 1 mEq hydrogen ions per kilogram body weight in adults (183). Dietary intake contributes to the majority of this daily acid production, with the latter two processes making a minimal contribution. During human evolution, with the development of agriculture and animal husbandry, our diets changed from net base or alkali-producing to net acid-producing. This occurred as net acid-producing animal foods and cereal grains replaced alkali-rich fruits and vegetables (184).

The typical modern western diet produces a net acid load or hydrogen ion in an adult of approximately 50–100 mEq/day (185, 186). Vegetarian diets that consist of vegetables, fruits and nuts generate net base, whereas non-vegetarian diets including meat, seafood and dairy products generate net acid (187). This load is markedly increased in infants who are solely fed cow milk based infant formula, which produces a net acid load of approximately 2 mEq/kg/day compared to about 0.8 mEq/kg/day when fed human milk (188). The dietary net acid load in children in the west is roughly 15–80 mEq/day, or roughly 1–3 mEq/kg/day, data obtained from population based studies, being higher in adolescents than younger children, and in males compared to females (189–192).

Metabolism of sulfur-containing amino acids cysteine and methionine, cationic amino acids arginine and lysine, and phosphorus produce acid. These substances are found in high concentrations in animal proteins, cereals,

Table 9-10
Causes of decreased and increased anion gap

Decreased anion gap	Increased anion gap

nuts and dairy products. Conversely, metabolism of anionic amino acids aspartic acid and glutamic acid, found in wheat, soy protein, cow's milk and vegetables; and potassium and magnesium containing foods like fruits, vegetables, nuts and dairy products, consume hydrogen ion (191).

Physiologically, two types of acid are important. Carbonic acid, which is a volatile acid, and produced by the metabolism of dietary carbohydrates and fats, and non-carbonic acids, produced from the metabolism of proteins. Metabolism of dietary carbohydrates and fats results in generation of carbon dioxide that can be excreted by alveolar ventilation. Approximately 15,000 mmol of volatile acid is produced per day (193). On the other hand, renal urinary excretion eliminates excess non-carbonic or non-volatile acids, mainly sulfuric acid (H_2SO_4) that is generated endogenously or from dietary intake of sulfur-containing amino acids.

Intracellular and extracellular acids and alkali are initially buffered. This process serves to neutralize the acid or base in order to minimize change in pH. Buffering does not remove acid or alkali from the body.

Two subsequent processes play an important role in maintaining normal acid-base balance: (1) the respiratory excretion of volatile acid as carbon dioxide, and (2) the ability of the kidney to excrete net acid. The non-volatile acid produced from metabolism and dietary intake is balanced with renal net acid excretion, thus maintaining acid-base equilibrium. The normal healthy kidney easily handles dietary net acid, but in the setting of reduced renal function, excess dietary load provides a challenge for excretion. In fact, there is evidence that even with normal aging, gradual reduction in glomerular filtration rate results in metabolic acidosis on a normal diet (193).

Goodman et al. demonstrated that despite minor daily fluctuations, the cumulative acid balance in normal individuals is approximately zero (194). Typical acid production in adults, estimated from extrapolation of urinary sulfate and organic anion, is equal to urinary acid output. With chronic renal insufficiency, serum CO_2 content reaches the acidotic level over a period of 6 days after withdrawal of bicarbonate therapy. Net acid production exceeds compromised or reduced net acid excretion, resulting in a positive balance of 21–30 mEq of acid per day (195). Withdrawing the alkaline therapy of a patient with chronic kidney disease may lead to metabolic acidosis resulting primarily from hydrogen ion retention.

Acid-Base Balance in Neonates, Infants and Children

Newborns and infants have a lower serum bicarbonate of about 20 mEq/L compared to older children and adults, whose serum bicarbonate is 24 mEq/L. The imbalance between increased acid load and decreased ability for net acid excretion, results in increased susceptibility of neonates and infants to development of metabolic acidosis.

The acid load from diet and metabolism in infants is approximately one hundred percent higher than that of adults, adjusted for body weight. The increased acid load is exaggerated in infants fed cow's milk formula. In small preterm babies, renal acid excretion capacity is low compared to term newborns. In both preterm and term infants, maximum renal net acid excretion improves rapidly during the first few weeks of life (189) (*Fig. 9-5*).

Insipient late metabolic acidosis is common in premature infants in the first year of life and its pathophysiology is multifactorial (189) (*Fig. 9-6*).

The growing bones of neonates and children results in production of additional acid as a result of hydroxyapatite production for bone mineralization. Approximately 0.92 mmol of protons are released into the extracellular circulation for every 1 mmol of calcium incorporated into the skeleton (196).

Broadly speaking, renal regulation of hydrogen ion balance involves (1) glomerular filtration, (2) reclamation of filtered bicarbonate, thus repleting body stores, and (3) excretion of hydrogen ion as titratable acid or ammonium, which excretes the non-volatile acid from metabolism, dietary intake, and in children, bone growth. Net urinary acid excretion consists of the sum of titratable acid (hydrogen ion buffered by phosphate and sulfate) plus ammonium.

Since the beginning of the twentieth century, it was observed that urine pH is higher in preterm and term neonates and gradually decreases after several weeks. When preterm and term infants fed human milk or formula were challenged with acute or chronic acid loading using ammonium chloride or calcium chloride, to determine maximal net renal acid excretion, the results revealed lower net acid excretion in preterm compared to term infants (188). Furthermore, there was an increase in maximum net renal acid excretion during the first few weeks in term and preterm infants (188) (*Fig. 9-3*).

Animal studies point to decreased activity and immaturity of almost every transporter involved in bicarbonate reabsorption and acid secretion as a cause for the reduced ability of the neonatal kidney to excrete acid. While it may not be possible to study these mechanisms in humans, animal studies have provided substantial insights into potential mechanisms. Less bicarbonate reclamation occurs in the proximal convoluted tubule of infants compared to adults. Whereas in adults, approximately 85% of filtered bicarbonate is reabsorbed proximally, only 65% of the bicarbonate is reabsorbed proximally in infants (189).

Studies in rabbit proximal convoluted tubules show that the lower neonatal bicarbonate transport is due to lower activities of all the transporters involved in proximal bicarbonate reabsorption, that is, the apical Na^+/H^+ antiporter, apical H^+-ATPase, the basolateral $Na^+/3HCO_3^-$ transporter, and the basolateral Na^+-K^+-ATPase (197–200). The activity of all these transporters reached adult levels by the age of 6–7 weeks in these studies. One of the major hormones that stimulate the development of bicarbonate transport is glucocorticoids. Neonates

are relatively glucocorticoid-deficient during the first weeks of life. There is a developmental increase in glucocorticoids which precedes the increase in bicarbonate transport. Indeed, if glucocorticoids are administered to pregnant animals prior to giving birth, the neonates have proximal tubular bicarbonate transport rates which are comparable to those in adults (197). Thyroid hormone also affects the development of bicarbonate transport but plays a much less important role.

The limited ability for urinary acidification may in part be due to carbonic anhydrase II deficiency in immature renal tubules. This isoform of carbonic anhydrase is found in the cytoplasm of proximal and distal tubular cells. Karashima et al. found that carbonic anhydrase II levels increased from 14% of adult levels in 1 week old rats to 40% at age 3 weeks and 97% at age 7 weeks (200). Carbonic anhydrase IV is the isoform that is membrane bound on the luminal surface of tubular cells. There is decreased activity of carbonic anhydrase IV in neonatal rabbit kidneys compared with adults (201, 202).

However, human studies provided contradictory data. Studies of kidney tissue from human embryos showed positive staining for carbonic anhydrase in proximal and distal tubules from 12 to 15 weeks gestation. The catalytic activity and the amount of carbonic anhydrase increased as gestational age increased from 19 to 26 weeks, being comparable to those of adult renal cortex at 26 weeks (203). Thus, in humans, carbonic anhydrase may not play a major role in the maturational changes associated with renal acid-base homeostasis.

Intercalated α and β cells in the collecting duct are responsible for distal urinary acidification. There are fewer intercalated cells in the rabbit neonatal kidney and the activity of the apical H^+-ATPase is reduced (204). Additionally, the capacity for ammonium excretion is reduced in newborn animals (205, 206). Thus, the ability for distal urinary acidification by excreting hydrogen ions is limited in newborns.

Therefore, maturational deficiencies in almost every transporter involved in acid-base homeostasis throughout the renal tubule puts the neonate at higher risk for developing metabolic acidosis. This limited capacity for acid excretion, in conjunction with increased acid load from the diet and bone formation in growing children are important factors in acid-base homeostasis.

Mechanisms of Growth Retardation in Chronic Acidosis

Poor growth occurs in many chronic disorders such as chronic kidney disease, cystic fibrosis, rheumatologic

conditions and inflammatory bowel disease. Growth retardation is a frequent, long-recognized complication of chronic metabolic acidosis (207).

Studies in acidotic children with classic renal tubular acidosis have shown a blunted release of growth hormone in response to provocative stimuli. The growth retardation associated with acidosis can be reversed by systemic bicarbonate therapy (208). The release of growth hormone under acidotic conditions has been studied (209). Exploration in rats with normal anion gap acidosis from ingestion of ammonium chloride demonstrated aberrant GH secretion. Significant inhibition of pulsatile growth hormone secretion was present in the acidotic rats such that both the amplitude of the GH secretory pulse and the area under the curve were significantly smaller than in controls. These reductions in pulse amplitude and area were correlated to decreased growth (weight) in the acidotic rats (209). Using in situ hybridization histochemistry in combination with immunocytochemistry, the expression of GH/insulin-like growth factor (IGF)-I in the tibial epiphyseal growth plate has been examined. Evaluation of tibial epiphyseal growth plate (IGF-I) gene expression in acidotic and control rats revealed that IGF-I messenger RNA abundance was lower in the acidotic growth plates. IGF-I peptide was predominantly localized to the hypertrophic zone of chondrocytes and was weakly detectable in the proliferative zone in both the acidotic and control rats' growth plates. Anthropomorphic measurements demonstrated that acidotic rats grew less than did control rats in both length and weight, and these physical measurements were reflected in the size of the tibial epiphyseal growth plates being significantly smaller in the acidotic rats compared with the control group (210). Taken together, these observations suggest that metabolic acidosis reduces IGF-I message abundance and induces resistance to IGF-I peptide action within the tibial epiphyseal growth plate. The use of growth hormone to stimulate growth in normal anion gap acidosis has been ineffective experimentally, despite enhancement of IGF-I and IGF binding protein immunoreactivity within the stem cell chondrocyte zone of the tibial epiphyseal growth plate (210).

Effect of Acidosis on Bone and Calcium Homeostasis

The renal response to acidosis, which consists of hydrogen ion excretion, is relatively slow and takes days. The initial response to acidosis is buffering by extracellular bicarbonate and by cellular and bone buffers. This role of the skeleton as buffer occurs at the expense of bone mineral content resulting in loss of calcium and phosphate (211). Bone sodium and potassium is lost in exchange for hydrogen ion, and carbonate consumed as a buffer. Positive acid and negative calcium balance (due to hypercalciuria) occurs in healthy individuals made chronically acidotic by ammonium chloride loading (212, 213). A similar profile is found in patients with renal tubular acidosis. Correction of the metabolic acidosis with bicarbonate therapy results in return of acid balance to zero and less negative calcium balance (214). Furthermore, bicarbonate administration corrects bone mineral loss in patients with acidosis (215, 216).

Acutely, bone resorption is primarily due to physicochemical mineral dissolution, while cell-mediated mechanisms predominate after 24 h (211). Chronic metabolic acidosis stimulates calcium efflux from bone due to increased osteoclastic bone resorption and decreased osteoblastic activity. The negative calcium balance observed in acidotic patients is due to calcium mobilization from bone, resultant hypercalciuria (217, 218), and lack of concomitant increase in intestinal calcium absorption (215, 219). There is net loss of body calcium. The hypercalciuria predisposes to osteoporosis, nephrocalcinosis and nephrolithiasis. The latter renal effects result in renal impairment as evidenced in the study by Goodman et al., in which few adult patients with RTA had normal glomerular filtration rate (194).

Patients with chronic kidney disease with concomitant metabolic acidosis and hyperparathyroidism are at increased risk for skeletal demineralization. Krieger et al. studied the effect of acidosis with and without parathyroid hormone on calvariae (211). They found that acidosis and PTH independently stimulated calcium efflux from bone, inhibited osteoblastic collagen synthesis and stimulated osteoclastic beta-glucuronidase secretion. Furthermore, the effects of acidosis and PTH on bone resorption were additive.

10 Calcium and Phosphorus

Anthony A. Portale · Farzana Perwad

Calcium

Calcium Homeostasis

Calcium Distribution in the Body

Calcium is the most abundant electrolyte in the human body, and in healthy adults, accounts for about 2%, or 1,300 g, of body weight. Approximately 99% of body calcium is in the skeleton mainly in the form of hydroxyapatite crystals [$Ca_{10}(PO_4)_6(OH)_2$]; the remainder is in teeth, soft tissue, and extracellular fluid. By contrast, at birth calcium accounts for only about 0.9% of body weight (1). From birth to approximately 20 years of age, when the skeleton reaches its full size and density, calcium content increases by some 40-fold (2). During this period, the increase in skeletal weight and calcium content requires the net retention of about 150–200 mg of calcium per day. Thus, in growing individuals, calcium balance must be positive to meet the needs of skeletal growth and consolidation. In adults, calcium balance is zero after peak bone mass is attained and becomes slightly negative as bone is slowly lost with aging.

Calcium Chemistry

Calcium in plasma exists in three fractions: protein-bound calcium (40%), which is not filtered by the renal glomerulus, and ionized calcium (48%) and complexed calcium (12%), which are filtered (3). Complexed calcium is that bound to various anions such as phosphate, citrate, and bicarbonate. Albumin accounts for 90% of the protein binding of calcium in plasma; globulins the remainder. Conditions that affect the concentration of albumin in plasma, such as nephrotic syndrome or hepatic cirrhosis, will affect the measurement of total serum calcium concentration. A decrease in albumin concentration of 1 g/dl results in a decrease in protein-bound and hence total calcium concentration of about 0.8 mg/dl. Binding of calcium to albumin is strongly pH-dependent between pH 7 and pH 8; an acute increase or decrease in pH of 0.1 pH units will increase or decrease, respectively, protein-bound calcium by about 0.12 mg/dl. Thus, in hypocalcemic patients with metabolic acidosis, rapid correction of acidemia with sodium bicarbonate can precipitate tetany, due to increased binding of calcium to albumin and a consequent decrease in the ionized calcium concentration.

Extracellular Calcium Homeostasis

Calcium homeostasis is maintained by the interaction between three major organ systems, bone, intestine, and kidney, and is regulated principally by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), and to a lesser extent, by calcitonin. In healthy adults, net intestinal absorption of calcium is approximately 20–25% of dietary intake. To meet the demands of rapid skeletal growth, fractional calcium absorption in infants is higher, 40–45%, reaching values as high as 80% in low-birth-weight, breast-fed infants (4, 5). The efficiency of calcium absorption also is increased during adolescence, during pregnancy, and with administration of vitamin D metabolites, and is decreased with vitamin D deficiency, in the elderly, and with estrogen deficiency. Calcium is absorbed principally in the duodenum and proximal jejunum, both by a saturable, active transport mechanism that requires stimulation by $1,25(OH)_2D$, and by a nonsaturable, passive diffusion mechanism. A small amount of calcium is secreted into the intestinal lumen, presumably by paracellular diffusion. An overall schema of calcium metabolism is depicted in *Fig. 10-1*.

Absorbed calcium enters the extracellular calcium pool, which is in equilibrium with the bone calcium pool; the latter includes a rapidly exchangeable pool which plays an important role in maintaining extracellular calcium concentration, and a more stable bone mineral pool. Calcium is filtered by the renal glomerulus and is nearly completely reabsorbed by the renal tubule. In subjects in zero calcium balance, the amount of calcium excreted by the kidney is equal to the net amount absorbed by the intestine, and in growing children is less than the net amount absorbed due to deposition of calcium in bone.

Figure 10-1

Calcium fluxes between body pools in the normal adult human in zero calcium balance.

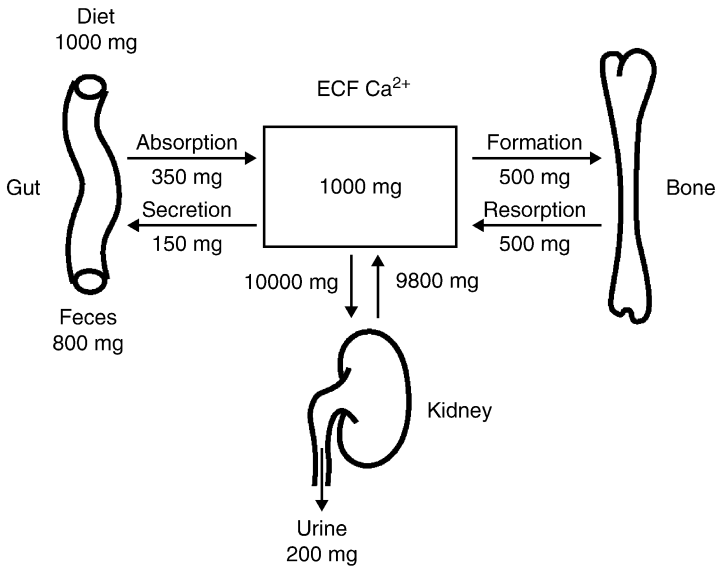

Figure 10-2

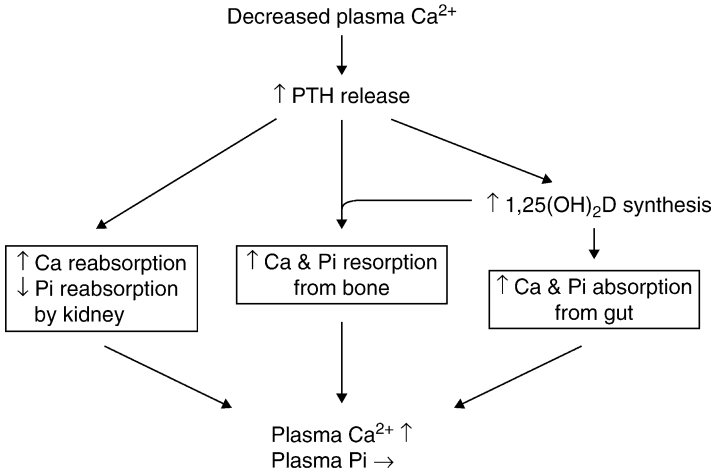
The homeostatic response to hypocalcemia.



In response to a decrease in extracellular concentration of ionized calcium, secretion of PTH from the parathyroid gland is increased (*Fig. 10-2*). PTH acts on the kidney to decrease excretion of calcium, to increase excretion of phosphate (Pi), and to stimulate the production of $1,25(OH)_2D$. $1,25(OH)_2D$ acts on the intestine to stimulate active absorption of calcium and Pi, and together with PTH, acts on bone to stimulate release of calcium and Pi into the extracellular fluid. PTH action on bone is thought to occur in two phases, an initial rapid mobilization of bone mineral that occurs within hours, is associated with increased metabolic activity of osteoclasts, and does not require protein synthesis, and a later phase that occurs after 12–24 h of exposure to PTH, is associated with an increase in both activity and numbers of osteoclasts, and does require protein synthesis (6). The combined

effects of PTH and $1,25(OH)_2D$ on their target tissues result in an increase in extracellular calcium concentration toward normal values, with the serum Pi concentration being little changed. Conversely, in response to an increase in blood ionized calcium concentration, secretion of PTH and production of $1,25(OH)_2D$ are decreased, and release of calcitonin is stimulated. The exact physiologic role of calcitonin in reducing hypercalcemia is unknown (7). The combined effects of these hormonal changes on bone, kidney, and intestine are opposite to those occurring with hypocalcemia, resulting in a decrease in calcium concentration toward normal values.

The total serum calcium concentration exhibits a circadian rhythm characterized by a nadir at 1–3 am and a peak at 12–1 pm, with amplitude (nadir to peak) of about 0.5 mg/dl (*Table 10-1*) (8–10). This rhythm is thought to reflect hemodynamic changes in serum albumin concentration that result from changes in body posture (11). Prolonged upright posture or venostasis can cause hemoconcentration and thus increases of about 0.5 mg/dl in serum calcium concentration. There is little difference between values taken in fasting and non-fasting states.

Normal values for serum total calcium concentration differ among clinical laboratories, and in general range from 9.0 to 10.6 mg/dl. In children, the calcium concentration is higher than in adult subjects, being highest at 6–24 months of age, mean ~10.2 mg/dl, decreasing to a plateau of ~9.8 mg/dl at 6–8 years and decreasing further to adult values at 16–20 years (*Table 10-2*) (12). In men, the calcium concentration decreases from a mean of ~9.6 mg/dl at age 20 to ~9.2 mg/dl at age 80 years; the decrease can be accounted for by a decrease in serum albumin concentration (13). In women, no change is observed with age. Ionized calcium is the fraction of plasma calcium that is important for physiologic processes such as muscle contraction, blood coagulation, nerve conduction, hormone (PTH and $1,25(OH)_2D$) secretion and action, ion transport, and bone mineralization. Measurement of the blood ionized calcium concentration is most useful in critically ill patients, particularly those in whom serum protein levels are decreased, acid–base disturbances are present, or to whom large amounts of citrated blood products are given, such as with cardiac surgery or hepatic transplantation. A decrease in the blood ionized calcium concentration can occur due to increased binding of calcium to albumin, such as with metabolic alkalosis, or due to increased complexing with other anions. For example, in severe uremia, the ionized fraction of calcium can decrease due to increased complexing with Pi, sulfate, and citrate (14). Based on in vitro studies of human serum (15), an increase in serum Pi concentration of 3.7 mg/dl was required to induce a decrease in ionized calcium of 0.1 mg/dl, the smallest decrease thought necessary to stimulate release of PTH (16, 17).

In normal individuals, values of ionized calcium will vary somewhat among laboratories depending on which technique is employed and whether the measurement is made in serum, plasma, or heparinized whole blood. In healthy infants, ionized calcium levels decrease from ~5.8 mg/dl (1.4 mmol/l) at birth to a nadir of 4.9 mg/dl (1.2 mmol/l) at 24 h of life (18), and increase slightly during the first week of life (*Table 10-2*) (19). Values in young children are slightly higher (~0.2 mg/dl) than those in adults until after puberty. In adult men and women, normal serum ionized calcium concentrations range from 4.6 to 5.3 mg/dl (1.0–1.3 mmol/l), without significant sex differences (20, 21). The blood ionized calcium concentration exhibits a circadian rhythm characterized by a peak at 10 am and a nadir at 6–8 pm, with an amplitude of 0.3 mg/dl (*Table 10-1*) (8). Specimens must be obtained anaerobically to avoid spurious results due to ex vivo changes in pH.

Calcium-Sensing Receptor

The calcium-sensing receptor (CaR) plays a central role in regulating calcium homeostasis. Extracellular ionized calcium concentration is maintained within a tight range (1.1–1.3 mM) by activation and inhibition of the CaR

Table 10-1

Characteristics of the circadian rhythms in blood mineral concentration in humans

	Concentration (mg/dl)		Amplitude (mg/dl)	Phase (hour)	
	Fasting	24-h mean	(Nadir to peak)	Nadir	Peak
Total serum calcium	9.6	9.4	0.5	03:00	13:00
Blood ionized calcium	4.67	4.52	0.3	19:00	10:00
Serum phosphorus	3.6	4.0	1.2	11:00	02:00

Data are from references (8, 10)

Table 10-2

Representative normal values for concentrations of blood ionized calcium, serum total calcium and phosphorus at various ages

	Age	Blood ionized		Serum total	
		Calcium		Calcium	Phosphorus
	(yr)	(mg/dl)	(mM)	(mg/dl)	(mg/dl)
Infants	0–0.25	4.9–5.6	(1.22–1.40)	8.8–11.3	4.8–7.4
	1–5	4.9–5.3	(1.22–1.32)	9.4–10.8	4.5–6.2
Children	6–12	4.6–5.3	(1.15–1.32)	9.4–10.3	3.6–5.8
Men	20	4.5–5.2	(1.12–1.30)	9.1–10.2	2.5–4.5
	50	4.5–5.2	(1.12–1.30)	8.9–10.0	2.3–4.1
	70	4.5–5.2	(1.12–1.30)	8.8–9.9	2.2–4.0
Women	20	4.5–5.2	(1.12–1.30)	8.8–10.0	2.5–4.5
	50	4.5–5.2	(1.12–1.30)	8.8–10.0	2.7–4.4
	70	4.5–5.2	(1.12–1.30)	8.8–10.0	2.9–4.8

Data are from references (12, 13, 18, 19, 21, 239, 240, 403)

located on the plasma membrane of parathyroid cells. When serum ionized calcium concentrations are increased, the CaR is activated, leading to a decrease in PTH synthesis and secretion and suppression of parathyroid cell proliferation; the opposite occurs when serum ionized calcium concentrations are decreased (22). The CaR has been cloned from bovine, human, and rat parathyroid tissue (23–25), from rat kidney (26), and from several other mammalian and non mammalian organisms (27–29). The nucleic acid and amino acid sequence of CaR is highly conserved throughout evolution, with retention of functionally important structural features and limited divergence (22).

The CaR has a predicted molecular weight of ~120 kD and is a member of family C II of the superfamily of guanine-nucleotide-regulatory (G) protein-coupled receptors (GPCRs). CaR activates many intracellular signaling pathways including phospholipase A2, C and D, and mitogen activated protein kinase (MAPK) pathways (22), with phospholipase C being the major downstream mediator of the biological response. Activation of the CaR results in increased activity of phospholipase-C, which catalyzes the hydrolysis of the membrane-bound phospholipid, inositol 4,5-bisphosphate, to two second messengers, inositol 1,4,5-trisphosphate (IP3) and diacylglycerol. Intracellular accumulation of IP3 induces release of calcium from storage pools and thereby a rapid increase in cytosolic calcium concentration, and possibly an increase in movement of calcium from the extracellular to the cellular compartment. In parathyroid cells, the increase in cytosolic calcium concentration is associated with a decrease in PTH secretion. Thus, CaR enables the parathyroid gland to tightly regulate PTH secretion in response to changes in serum calcium levels. CaR is also widely expressed along the entire nephron in the kidney, in bone, cartilage and intestine. The physiology and pathophysiology of CaR and the role of calcimimetic drugs in human disorders of calcium homeostasis are detailed in several comprehensive reviews (22, 30, 31).

Vitamin D

Vitamin D exists as either ergocalciferol (vitamin D_2) produced by plants, or cholecalciferol (vitamin D_3) produced by animal tissues and by the action of near ultraviolet radiation (290–320 nm) on 7-dehydrocholesterol in human skin. Both forms of vitamin D are biologically inactive pro-hormones that must undergo successive hydroxylations at carbons #25 and #1 before they can bind to and activate the vitamin D receptor. The 25-hydroxylation of vitamin D occurs in the liver, catalyzed by one or more enzymes including the microsomal cytochrome P450 enzyme, CYP2R1 (32). The activity of hepatic 25-hydroxylation is not under tight physiologic regulation, and thus circulating concentrations of 25-hydroxyvitamin D (25OHD) are determined primarily by dietary intake of vitamin D and exposure to sunlight. Although 25OHD is the most abundant form of vitamin D in the blood, it has minimal capacity to bind to the vitamin D receptor and elicit a biologic response. Circulating 25OHD is almost entirely bound to vitamin D binding

protein (DBP). In DBP knockout mice, serum 25OHD concentrations are low due to increased catabolism of 25OHD in the liver and its increased excretion in the urine (33). 25OHD bound to DBP is filtered by the glomerulus and reabsorbed by the proximal tubule where its uptake at the apical membrane is mediated by two endocytic receptors, megalin and cubulin. Mice with megalin or cubulin deficiency develop vitamin D deficiency due to increased urinary losses of 25OHD (34–36), as occurs in DBP-null mice. Therefore DBP, megalin and cubulin are responsible for targeted delivery of 25OHD to the renal proximal tubule cells for further bioactivation.

The active form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), is produced by the 1α-hydroxylation of 25OHD by the mitochondrial enzyme, 25-hydroxyvitamin D-1α-hydroxylase (1α-hydroxylase or P450c1α) in the renal proximal tubule. The circulating concentration of $1,25(OH)_2D$ primarily reflects its synthesis in the kidney; however, 1α-hydroxylase activity also is found in keratinocytes, macrophages, and osteoblasts (37–39). The 1α-hydroxylation is the rate-limiting step in the bioactivation of vitamin D, and enzyme activity in the kidney is tightly regulated. $1,25(OH)_2D$ is one of the principal hormonal regulators of calcium and Pi metabolism and thus is critically important for normal growth and mineralization of bone. The classical actions of $1,25(OH)_2D$ are to stimulate calcium and Pi absorption from the intestine, thereby maintaining plasma concentrations of these ions at levels sufficient for normal growth and mineralization of bone. $1,25(OH)_2D$ also has direct actions on bone, kidney, parathyroid gland, and on many other tissues unrelated to mineral metabolism (reviewed in (40)).

The other important vitamin D-metabolizing enzyme, the 25-hydroxyvitamin D-24-hydroxylase (24-hydroxylase), is found in kidney, intestine, lymphocytes, fibroblasts, bone, skin, macrophages, and possibly other tissues (41). The enzyme can catalyze the 24-hydroxylation of 25OHD to $24,25(OH)_2D$ and of $1,25(OH)_2D$ to $1,24,25(OH)_3D$; both reactions are thought to initiate the metabolic inactivation of vitamin D via the C24-oxidation pathway. The kidney and intestine are major sites of hormonal inactivation of vitamin D by virtue of their abundant 24-hydroxylase activity.

The synthesis of $1,25(OH)_2D$ in the kidney is subject to complex regulation by PTH, calcium, Pi, fibroblast growth factor 23 (FGF-23), and $1,25(OH)_2D$ (40, 42, 43, 346). Synthesis of $1,25(OH)_2D$ can be stimulated by PTH, insulin-like growth factor 1, and phosphorus deficiency, and suppressed by plasma ionized calcium, FGF-23, and $1,25(OH)_2D$ itself. The renal 1α-hydroxylase enzyme is a mitochondrial cytochrome P450 mixed-function oxidase that requires the presence of two electron transport intermediates for catalytic activity, a flavoprotein termed ferredoxin reductase and an iron/sulfur protein termed ferredoxin (44); these two proteins mediate the transfer of electrons from NADPH to the 1α-hydroxylase. The complementary DNA (cDNA) for the 1α-hydroxylase has been cloned from human, rat, mouse, and pig (45–50). The human 1α-hydroxylase cDNA is 2.4 kb in length and encodes a protein of 508 amino acids with a predicted molecular mass of 56 kDa (45). The human gene for 1α-hydroxylase, designated CYP27B1, is single copy, comprises nine exons and eight introns, and is located on chromosome 12 (46, 51). Although it is a substantially smaller gene, 5 kb, than those for other mitochondrial P450 enzymes (51), its intron/exon organization is very similar, especially to that of P450scc (51, 52). This strongly suggests that although the mitochondrial P450 enzymes retain only 30–40% amino acid sequence identity with each other, they all belong to a single evolutionary lineage. The mouse P450c1α gene also has been cloned (53, 54).

Loss-of-function mutations in the human CYP27B1 gene result in the autosomal recessive disease, vitamin D 1α-hydroxylase deficiency (45, 55–62), also known as hereditary pseudo-vitamin D deficiency rickets (PDDR) (63), vitamin D dependency (64), or vitamin D-dependent rickets type I. As of this writing a total of 36 different mutations have been found in 54 patients since the first description of gene mutations in 1997 (45, 60).

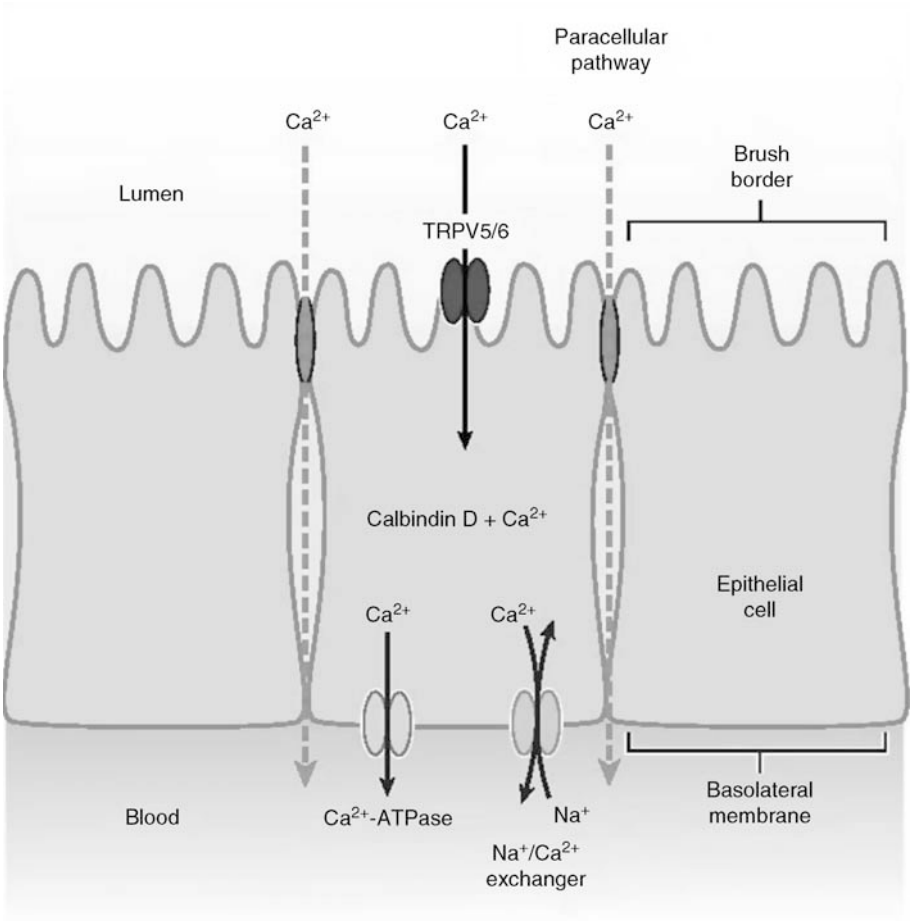
Transepithelial Calcium Transport

Transport of calcium across the plasma membrane of calcium-absorbing epithelia such as the intestine and renal tubule occurs via either the paracellular (between cells) or the transcellular (across cells) pathway, or via both pathways (*Fig. 10-3*). Paracellular transport is passive, linked to the net paracellular absorption (lumen-to-interstitium) of water, a process termed solvent drag or convection. Paracellular transport of calcium also can occur by passive diffusion driven by a chemical gradient, as occurs in the proximal convoluted tubule (PCT), or a lumen-positive transepithelial potential difference that results from sodium chloride reabsorption, as occurs in the thick ascending limb of Henle's loop.

Transcellular transport of calcium in the intestine and kidney is a three-step process (*Fig. 10-3*). Calcium enters the cell across the apical membrane via the epithelial calcium channels, TRPV5 in the kidney and TRPV6 in the intestine (65). It is then ferried across the cytosol by

Figure 10-3

Mechanism of epithelial Ca^{2+} absorption in the intestine and kidney. In the intestine, the TRPV6 epithelial Ca^{2+} channel, which is expressed in the brush border membrane, mediates the first step in transepithelial Ca^{2+} absorption. Within the epithelial cell, Ca^{2+} binds to calbindin-D9k. Ca^{2+} exits the cell at the basolateral membrane via the Ca^{2+}-ATPase, PMCA1b, and possibly the Na^+/Ca^{2+} exchanger, NCX1 (SLC8A1). Ca^{2+} reabsorption in the renal distal convoluted tubule proceeds in a similar fashion but with the following variations: (a) Ca^{2+} entry at the luminal membrane is mediated predominantly by the epithelial Ca^{2+} channel, TRPV5. (b) Ca^{2+} is shuttled to the basolateral membrane via both calbindin-D9k and calbindin-D28k. (c) Ca^{2+} exit proceeds via PMCA1b and NCX1 (SLC8A1). Under high luminal Ca^{2+} conditions, Ca^{2+} is absorbed, via the paracellular route, through the tight junctions down the transepithelial Ca^{2+} gradient. (Data from (65)).



calcium binding proteins – calbindin-D9k (in the intestine) and calbindin-D28K (in the kidney). Active extrusion across the basolateral membrane is mediated by a high affinity Ca^{2+}-ATPase (PMCA1b) and Na^+–Ca^{2+} exchanger (NCX1) (66).

Calcium Entry

Calcium channels. Although calcium entry across the luminal membrane is favored by both electrical and chemical gradients (67, 68), the physical chemical properties of lipid bilayer membranes prevent passive diffusion of the positively charged calcium ion (Ca^{2+}) across cell membranes. Thus, calcium entry across the luminal membranes of the kidney and intestine is thought to occur through Ca^{2+} channels. Studies using a variety of approaches including Ca^{2+} channel agonists and antagonists, patch-clamp analysis, and cell-attached electrophysiological techniques, have shown the presence of Ca^{2+} channels in proximal and distal nephron segments and in cultured distal renal tubule cells (69). Using

an expression cloning strategy, Hoenderop et al. (70) cloned and characterized the rabbit cDNA encoding a new epithelial Ca^{2+} influx channel, which was named ECaC/ECaC1 by analogy with the amiloride-sensitive, aldosterone-dependent epithelial sodium channel, ENaC (71, 72). The rabbit ECaC cDNA encodes a protein of 730 amino acids with a predicted molecular mass of 83 kDa (70). ECaC has been identified from several species including rabbit, rat, mouse, and human (69, 73). The amino acid sequence and predicted structure of ECaC closely resemble those of the superfamily of transient receptor potential (TRP) proteins, and hence ECaC was renamed TRPV5. Shortly after identification of the renal epithelial calcium channel, an expression cloning strategy was used to clone and characterize the cDNA for calcium transport protein (CaT1/ECaC2) from rat duodenum (74). CaT1 showed 75% homology to ECaC and was later renamed TRPV6. Studies in puffer fish show the presence of a single gene encoding a calcium channel (FrECaC) that closely resembles TRPV6, suggesting that early in the evolution of vertebrates, TRPV5 and TRPV6 evolved from a single ancestral gene (75, 76). Thus, the epithelial Ca^{2+} channels TRPV5 in the kidney and TRPV6 in the intestine are the gatekeepers of Ca^{2+} entry into the cell.

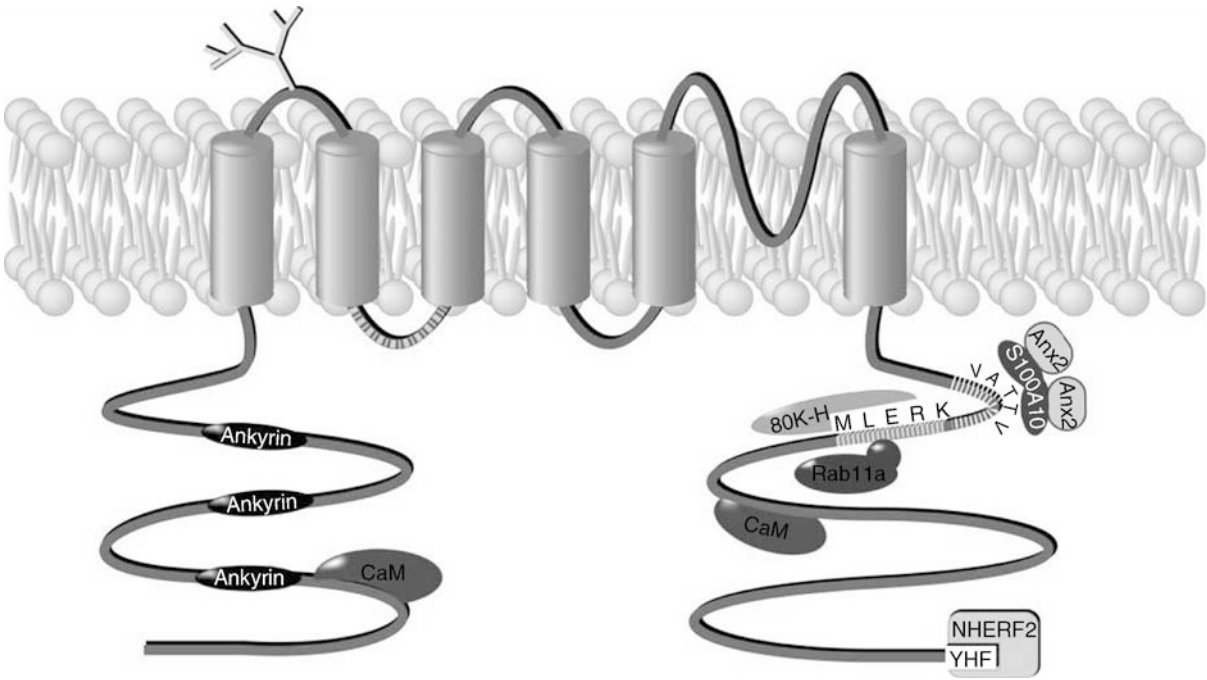
The TRP family of proteins is a diverse group of voltage-independent, cation-permeable channels that are organized into six protein subfamilies. TRPV5 and TRPV6 belong to the subgroup, TRPV (named after the founding member, vanilloid receptor) and are highly selective for Ca^{2+}. TRP channels possess six transmembrane domains with N- and C-termini located in the cytoplasm (*Fig. 10-4*) (77). TRPV5 and TRPV6 share typical topological features with other members of the TRP family. A hydrophobic loop region between transmembrane regions five and six is predicted to form the cation pore. The large intracellular N- and C-terminal domains contain putative regulatory regions that regulate channel activity and trafficking (69). Some of the regulatory sites identified are phosphorylation sites, postsynaptic density protein (zona occludens) motifs, and ankyrin repeat domains. Electrophysiological studies in HEK 293 cells show that both TRPV5 and TRPV6 are permeable to monovalent and divalent cations with a high selectivity for Ca^{2+}. A single aspartic residue in the pore region at position number 542 (D542) is critical for Ca^{2+} permeation (78, 79). TRPV5 and TRPV6 can form homo- and hetero-tetrameric ion channels, suggesting that the four aspartic residues form a negatively charged ring that selectively filters Ca^{2+} (80). The current–voltage relationship of TRPV5 and TRPV6 show inward rectification (unlike other TRPV channels which show outward rectification) and exhibit a Ca^{2+}-dependent feedback mechanism of regulating channel activity (81, 82). However, TRPV5 and TRPV6 exhibit different channel kinetics with respect to Ca^{2+}-dependent inactivation and recovery (82, 83). They also are differentially expressed in mammalian tissues as described below.

TRPV5 and TRPV6 are coexpressed in several tissues such as duodenum, jejunum, colon, kidney, pancreas, prostate, mammary, salivary, and sweat glands (84). However, the relative mRNA expression of TRPV5 and TRPV6 differ in various tissues; in the kidney, TRPV5 is 100 times more abundant than TRPV6, whereas in the intestine, TRPV6 is the major Ca^{2+} channel expressed. In rabbit kidney, TRPV5 is expressed exclusively in the distal nephron, specifically in the apical membranes of the distal convoluted tubule (DCT), connecting tubule (CNT), and cortical collecting duct, where it colocalizes with calbindin-D28k (70, 85). The distal nephron is the major site of regulation of Ca^{2+} reabsorption by PTH and $1,25(OH)_2D$, and TRPV5 is thought to play a major role in such regulation. In the intestine, TRPV6 is the predominant calcium channel that facilitates Ca^{2+} absorption, and it also is regulated by PTH and $1,25(OH)_2D$.

Mouse models of targeted disruption of the TRPV5 and TRPV6 genes have provided insights into the important physiological role of these Ca^{2+} channels in maintaining calcium homeostasis. Ablation of the TRPV5 gene induces severe hypercalciuria, increased serum $1,25(OH)_2D$ levels, and decreased bone mineral density (86). The increase in $1,25(OH)_2D$ induced a compensatory increase in duodenal TRPV6 and calbindin-D9k expression to maintain normocalcemia (87). However, despite high serum $1,25(OH)_2D$, which stimulates distal nephron calcium reabsorption, no compensatory increase in Ca^{2+} reabsorption was observed due to lack of TRPV5 expression. Therefore, TRPV5 channel activity was established as the rate-limiting step in renal tubular Ca^{2+} reabsorption. Surprisingly, TRPV6 knockout mice displayed a more severe phenotype than did the TRPV5 knock out mice, in that TRPV6-null mice developed growth retardation, reduced fertility, alopecia, and dermatitis in addition to decreased bone mineral density. These mice also exhibit impaired intestinal calcium absorption, hypercalciuria on a normal (1%) calcium diet, and hypocalcemia on a restricted (0.25%) calcium diet. The lack of TRPV6 expression resulted in failure to appropriately increase intestinal and renal Ca^{2+} reabsorption despite high PTH and $1,25(OH)_2D$ levels (88). Thus, TRPV6 was established as the rate-limiting step in intestinal Ca^{2+} absorption, but it also plays a significant role in other tissues such as skin and gonads.

Figure 10-4

Predicted topology of TRPV5/6 including the various binding sites identified for each associated protein. The extracellular loop between transmembrane domain (TM) 1 and TM2 is glycosylated. At the COOH terminus, Rab11, 80K-H, and S100A10 bind within a 30-amino acid-containing helical stretch juxtaposed to TM6. The S100A10-annexin 2 (Anx2) complex interacts with a conserved region within this stretch containing the VATTV amino acid sequence, whereas Rab11a and 80K-H share a COOH terminal binding site that flanks this sequence. Na^+/H^+exchanger regulatory factor 2 (NHERF2) specifically interacts with TRPV5 at the extreme COOH terminus of this channel. Calmodulin (CaM) has multiple binding sites present in the NH2 terminus, COOH terminus, and transmembrane region. The region between TM2 and TM3 of TRPV6 (indicated by vertical lines) is functionally linked to the fast Ca^{2+}–dependent inactivation of this channel, suggesting the binding of an unidentified protein to this region. (Data from (401)).



Transcytoplasmic Calcium Movement

Calbindins. Calcium diffusion through the cytoplasm is currently thought to be facilitated by the calcium binding proteins, calbindins-D, whose synthesis is dependent on $1,25(OH)_2D$. Calbindins also are proposed to act as an intracellular Ca^{2+} buffer to keep the otherwise tightly regulated cytosolic calcium concentration within physiologic levels during periods of stimulated transcellular Ca^{2+} transport (89–93). Two forms of calbindin-D have been described; a 28 kDa protein (calbindin-D28k) found in highest concentration in avian intestine and avian and mammalian kidney, brain, and pancreas, and a 9 kDa protein (calbindin-D9k) found in highest concentration in mammalian intestine, placenta, and uterus but also present in kidney, lung, and bone (94, 95). Much is now known about the amino acid sequence, X-ray crystal structure, and biophysical and calcium-binding properties of the calbindins. Calbindin-D28k is highly conserved in evolution, with a high degree of sequence homology observed among the various mammalian and avian D28k-calbindins (96). By contrast, calbindin-D9k is not highly conserved, and there is no amino acid sequence similarity between calbindin-D28k and calbindin-D9k. The genes for both rat calbindin species and for chicken calbindin-D28k have been cloned and sequenced and their transcriptional regulation by $1,25(OH)_2D$, glucocorticoids, and other factors has been investigated (reviewed in (94, 95, 97, 98)).

The calbindins belong to the superfamily of EF-hand helix-loop-helix, high affinity calcium binding proteins (K_d of 10^{-8} to 10^{-6} M) which contains more than 250 proteins. Calbindin-D28k binds four moles of calcium per mole of protein and calbindin-D9k, two moles of calcium

per mole protein. In the intestine, $1,25(OH)_2D$ stimulates both the synthesis of calbindin and the transfer of calcium across the luminal brush-border membrane. The rate and time course of active calcium absorption correlate well with the amount of calbindin D over a wide variety of physiological conditions (99, 100), providing strong support for the role of calbindin-D28k and calbindin-D9k in vitamin D-dependent active calcium transport. Calbindin D may play a similar role in mediating active renal tubular reabsorption of calcium (101, 102). In several mammalian species, both calbindin-D28k and TRPV5 have been localized in the DCT and CNT (70, 85, 103, 104), which are the major sites of active calcium reabsorption. Calbindin-D9k also has been localized to the distal nephron in the rat and mouse (105, 106). The creation of knockout mouse models has elucidated the relative importance of the calcium transport proteins in maintenance of calcium homeostasis. Calbindin-D28k knockout mice showed no change in serum concentrations of calcium, Pi, PTH and $1,25(OH)_2D$ when compared to wild type mice (107, 108). No compensatory increase in gene expression of other calcium transport proteins was observed in kidney or intestine (108). Similarly, calbindin-D9k knockout mice showed no significant difference in phenotype when compared to wild-type mice (109). In summary, the phenotypic findings in calbindin-D28k and calbindin-D9k knockout mice were not different from those in wild type mice, unlike the marked disturbances in calcium homeostasis observed in TRPV5 and TRPV6 knockout mice, which suggests that the role of calbindins in cellular transport of calcium is not rate-limiting.

Calcium Exit

At the basolateral membrane, calcium is actively extruded from the cell against its electrochemical gradient, mediated via a high affinity, magnesium-dependent Ca^{2+}-ATPase or an electrogenic $3Na^+/1Ca^{2+}$ exchanger.

Ca^{2+}-ATPase. The plasma membrane Ca^{2+}-ATPase (Ca^{2+} pump/PMCA) is an obligatory component of eukaryotic plasma membranes that mediates efflux of calcium from the cell. It is thought to play the most important role in maintaining the cytosolic calcium concentration within the normal range. PMCA belongs to the family of P-type ATPases in that it forms a phosphorylated intermediate (an aspartylphosphate) during the reaction cycle. PMCA has a high affinity for calcium, with an estimated K_m of 0.2 mM, and an apparent molecular weight of 120,000–140,000 daltons (reviewed in (110–116)). The pump is activated by direct interaction with calmodulin, a specific calcium receptor protein present in the cytosol, resulting in an increase in both the pump's affinity for calcium and its maximum transport velocity (Vmax). The pump also is activated by cAMP-dependent and protein kinase C-dependent phosphorylation of the pump protein, by limited proteolysis, and by exposure to acidic phospholipids. Transport of calcium from the cell is balanced by countertransport of hydrogen ion (H^+), and thus the activity of the Ca^{2+} pump can be either electroneutral ($Ca^{2+}/2H^+$) or electrogenic (Ca^{2+}/H^+).

The Ca^{2+} pump is located exclusively in the basolateral portion of the plasma membrane of renal tubule cells (117, 118). In earlier studies, activity of the Ca^{2+} pump was found along the entire length of the rabbit nephron, with the activity highest in the distal tubule where the majority of active calcium reabsorption occurs (119). In later studies using monoclonal antibodies against the erythrocyte plasma membrane Ca^{2+} pump, an epitope of this enzyme was identified in human and rat kidneys in the basolateral portion of only the distal convoluted tubule (117, 120). The purified Ca^{2+} pump protein colocalizes with calbindin-D28k in this nephron segment (117, 120). Analysis of different nephron segments of rat kidney using reverse transcription-polymerase chain reaction (RT-PCR) revealed that the Ca^{2+} pump is expressed in both the distal and proximal nephron (121). In the intestine, the Ca^{2+} pump is stimulated by calmodulin and by $1,25(OH)_2D$, which acts to increase pump activity by increasing its Vmax (122).

Four isoforms (PMCA1–4) of the plasma membrane Ca^{2+} pump have been identified and their cDNAs cloned (123–127). In humans and rats, the isoforms are encoded by a family of four genes (ATP2B1–4) that have been mapped to chromosomes 12, 1, 3, and X; additional isoforms of the enzyme (denoted by letters a, b, etc.) are created by alternative RNA splicing of the primary gene transcript (115). The isoforms exhibit 81–85% amino acid homology among themselves, and a single isoform exhibits about 99% homology among different species (128, 129). The deduced amino acid sequences of rat and human isoforms of the plasma membrane Ca^{2+} pump predict a secondary structure that contains ten transmembrane domains, with four main units containing most of the pump mass protruding into the cytoplasm (110, 111, 129). PMCA1b is the predominant isoform found in abundance in the small intestine and in the CNT and CCD of rabbit kidney (130). The expression and activity of PMCA1b is higher in enterocytes from the villus tip as compared to those from the villus crypt, which supports the idea that mature enterocytes have the greatest capacity for transcellular Ca^{2+} movement (131).

Na^+/Ca^{2+} exchanger. The Na^+/Ca^{2+} exchanger is an integral membrane protein that normally exports calcium from the cell, although under some circumstances it mediates calcium influx. The exchanger is a low-affinity, high-capacity transport system for calcium, which is driven by the inwardly directed transcellular electrochemical Na^+ gradient that is normally maintained by the basolateral Na^+/K^+-dependent ATPase. Activity of the exchanger is regulated by intracellular calcium, by changes in the transmembrane voltage being inhibited by sodium ionophores and ouabain which reduce the transmembrane sodium gradient, and by ATP (reviewed in (132–137)).

Complementary cDNAs encoding functional Na^+/Ca^{2+} exchangers have been isolated from heart, kidney, and brain from a variety of species (138–144), suggesting that the protein plays an important role in different physiologic processes in various cell types. Three mammalian isoforms of the Na^+/Ca^{2+} exchanger (NCX), designated NCX1, NCX2, and NCX3 have been cloned and are the products of separate genes (145–148); NCX1 is expressed most abundantly in heart but is found in most tissues including kidney, whereas expression of NCX2 and NCX3 is restricted to brain and skeletal muscle (148, 149). A number of alternative splicing variants of NCX1 are expressed in a tissue-specific fashion (149). The three NCX proteins share 68–75% amino acid sequence identity, and all are predicted to share the same topology of 11 membrane-spanning segments with a large hydrophilic cytoplasmic loop located between membrane-spanning segments 5 and 6. In NCX1, the cytoplasmic loop is thought to be a regulatory region and contains the binding site for Ca^{2+} and the location of the exchanger inhibitory peptide (XIP) sequence.

In the kidney activity of the Na^+/Ca^{2+} exchanger is found only in basolateral membrane preparations of renal tubules (150) and is localized exclusively to the distal tubule in the rabbit and rat (151). In rabbit kidney, immunolocalization was detected predominately along the basolateral plasma membrane of cortical connecting tubules, with weak staining of principal cells of the collecting duct; no staining was detected in other cell types in either the cortex or medulla (152). Using PCR to localize the exchanger in microdissected segments of rat nephron, NCX1 expression was observed in the DCT with little or no expression in other segments (153). Thus, the distal nephron exhibits Ca^{2+} pump and Na^+/Ca^{2+} exchanger activity, mRNA expression, and protein expression, consistent with the important role of this nephron segment in hormone-regulated calcium reabsorption. In the intestine, the Na^+/Ca^{2+} exchanger has been detected in rats (154), mice (155) and chicks (131), but not in rabbits (85). This transporter can operate in either a forward mode (Ca^{2+} exit) or in a reversed mode (Ca^{2+} entry), which depends on the Na^+ and Ca^{2+} gradients and the potential across the plasma membrane (156). The relative contribution of PMCA vs NCX1 in the extrusion of Ca^{2+} from the cytoplasm is unknown as there are no known inhibitors for NCX1, and its gene deletion results in fetal death (157, 158).

Renal Calcium Transport

Physiology and Tubular Localization

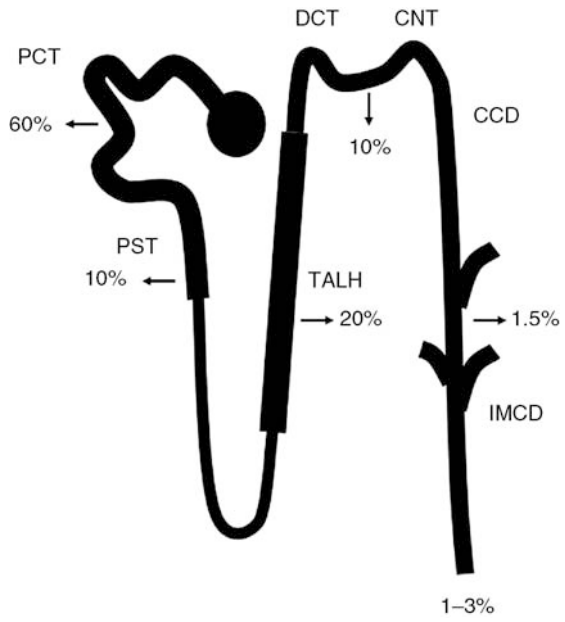
Approximately 60% of plasma calcium is freely filtered by the glomerulus, as shown by a glomerular filtrate to plasma (GF:P) ratio for calcium that ranges between 0.63 and 0.70 (159, 160). The fraction of plasma calcium that is filterable represents ionized calcium and complexed calcium. To maintain zero calcium balance, 98–99% of the filtered load of calcium, estimated at about 8 gm/day in the adult, must be reabsorbed by the renal tubules. Clearance studies in humans and experimental animals show that an increase in the filtered load of calcium, as occurs with calcium infusion, results in an increase in both urine excretion and absolute tubular reabsorption of calcium (161–165). Thus, there is no apparent maximum tubular reabsorptive rate (T_m) for calcium within the normal physiologic range (166).

Approximately 70% of filtered calcium is reabsorbed in the proximal tubule, about 20% is reabsorbed between the late proximal and early distal tubule, primarily in the thick ascending limb of Henle's loop (TALH), 5–10% is reabsorbed in the distal tubule, and less than 5% is reabsorbed in the collecting duct (*Fig. 10-5*) (159, 167–169). Thus, 1–3% of filtered calcium is excreted in the urine. As discussed below, the site of physiologic regulation of renal calcium reabsorption is the distal nephron.

Proximal tubule. The majority of filtered calcium is reabsorbed in the proximal tubule, with approximately 60% being reabsorbed by the end of the accessible portion of the superficial proximal tubule and an additional 10% reabsorbed in the proximal straight tubule. In the early proximal convoluted tubule (PCT) (S1 and S2 segments), calcium is reabsorbed passively principally via the paracellular pathway, in parallel with the reabsorption of sodium and water, mediated by convection (solvent drag) across the tight junctions. Evidence for passive reabsorption of calcium in the early PCT is the finding that in several species studied by micropuncture, the ratio of

Figure 10-5

Profile of calcium reabsorption along the nephron, as derived from micropuncture data. PCT, proximal convoluted tubule; PST, proximal straight tubule; TALH, thick ascending limb of Henle's loop; DCT, distal convoluted tubule; CNT, connecting tubule; CCD, cortical collecting duct; IMCD, inner medullary collecting duct. (Modified from (168)).



calcium concentration in tubular fluid to that in glomerular ultrafiltrate is approximately 1.0 (169). In the late S1 segment, reabsorption of calcium lags slightly behind that of sodium, thus creating a favorable chemical gradient for reabsorption downstream. In the S2 segment of the PCT, the transepithelial voltage is the lumen positive, thus the electrical gradient is positive for passive calcium reabsorption. In rabbit early S2 segments, net flux of calcium was zero in the absence of both water transport and an electrochemical gradient (170), providing further evidence for passive calcium reabsorption. There also is evidence that calcium reabsorption is active in the proximal nephron, particularly in the earliest segments of the PCT where the transepithelial voltage is lumen-negative (169). Calcium reabsorption also appears to be active in the S3 segment of the proximal tubule, as it is not dependent on sodium, occurs against an electrochemical gradient, and is not inhibited by ouabain (171).

Henle's Loop. In the thin descending and ascending limbs of Henle's loop, calcium transport is negligible (171, 172). However, in the TALH approximately 20% of the filtered calcium load is reabsorbed (169). In isolated, perfused segments of TALH, calcium reabsorption is passive, driven by the large lumen-positive transepithelial voltage in this segment (173–175) that results from the secondary-active transport of NaCl out of tubular fluid. An increase in NaCl reabsorption is attended by an increase in luminal positivity, which leads to stimulation of calcium reabsorption. Inhibition of NaCl transport with furosemide reduces the transepithelial voltage and thus increases calcium excretion. In some studies, however, calcium transport in the TALH is found to be active (172, 176, 177). It has been proposed that axial heterogeneity may account for some of the differences observed in the studies reported (178). Calcium transport in the cortical TALH can be increased by addition of PTH to the bath (179) and in medullary segments, by addition of calcitonin or cyclic adenosine monophosphate (cAMP) (180).

Distal Convoluted Tubule and Connecting Tubule. Physiologic regulation of calcium excretion occurs in the distal convoluted tubule (DCT), which reabsorbs up to 10% of the filtered calcium load. The capacity for calcium transport in this segment appears to be high and to be limited mainly by the availability of transportable ions. Although calcium transport in the DCT normally occurs in parallel with that of sodium, it is not dependent on either sodium or the transepithelial voltage and occurs against an electrochemical gradient; thus, it is active and presumably transcellular. Reabsorption of calcium in the DCT can be dissociated from that of sodium by administration of thiazide diuretics, which increase reabsorption of calcium and decrease that of sodium. As discussed above, luminal calcium entry in the DCT is thought to be mediated via the apical Ca^{2+} channel TRPV5, which is the rate-limiting step for Ca^{2+} entry from the tubular lumen. Both vitamin D-dependent calbindin-D28k, and the Ca^{2+} pump PMCA1b, co-localize in the DCT and are thought to facilitate transcellular movement and basolateral extrusion of calcium, respectively. The Na^{+}/Ca^{2+} exchanger NCX1 also is localized, perhaps exclusively, to the basolateral membrane of the DCT and connecting tubule (106, 151–153), although its physiologic role in these segments remains to be defined.

Collecting Tubule. Net reabsorption in the collecting tubule accounts for less than 5% of filtered calcium (169). In the cortical collecting tubule, calcium transport probably is active, as TRPV6 and calbindin-D28k in mice, and NCX1, calbindin-D28k, and the plasma membrane Ca-ATPase in humans, are found in this nephron segment (169). In the medullary collecting tubule, about 1% of the filtered load may be reabsorbed (181).

Regulation of Renal Calcium Transport

A number of factors can influence renal tubular reabsorption and urine excretion of calcium (*Table 10-3*) (166, 169).

Parathyroid hormone. PTH stimulates renal calcium reabsorption and is thought to be the principal hormonal determinant of urine calcium excretion. PTH acts to decrease calcium excretion in part by decreasing GFR via a reduction in glomerular capillary ultrafiltration coefficient, K_f (182), thus decreasing the filtered load of calcium. PTH receptors are found throughout the nephron (183, 184), and PTH increases tubular calcium reabsorption in the cortical TALH, DCT, and connecting tubule of the rabbit, with the principal effect being on the DCT (173, 179, 180, 185–188). PTH action is attributed to activation of both the cAMP-protein kinase A (PKA) and phospholipase A-protein kinase C (PKC)-dependent signaling pathways (168). The PTH-induced increase in calcium reabsorption is associated with an increase in the cytosolic calcium concentrations in cortical TALH, DCT, and connecting tubule (188–190). Recently, the molecular regulation of renal calcium transport proteins by PTH was studied in vivo and in vitro. In parathyroidectomized rats, the mRNA abundance of TRPV5, Calbindin-D28k, and NCX1 were decreased, and continuous infusion of PTH restored the expression to near normal levels (191). In addition, in primary cultures of rabbit connecting tubule/cortical collecting duct cells, PTH induced an

Table 10-3

Factors affecting renal calcium excretion

Factor	Ca excretion	Mechanism/nephron site
Dietary		
Volume expansion	↑	↓ Distal reabsorption
Sodium chloride	↑	Undefined
Protein	↑	↑ Net acid and sulfate excretion
Phosphorus	↓	↓ Production of $1,25(OH)_2D$ ↓ Intestinal absorption of Ca ↑ Distal reabsorption
Metabolic		
Acidosis	↑	↓ Proximal and distal reabsorption
Hypercalcemia	↑	↑ Filtered load of Ca ↓ Proximal and distal reabsorption (PTH)
Glucose	↑	↓ Proximal and distal reabsorption
Alkalosis	↓	↑ Proximal and distal reabsorption
Hormones		
Insulin	↑	↓ Proximal and distal reabsorption
Glucagon	↑	↑ RBF and GFR
Growth hormone	↑	Undefined
Thyroid hormone	↑	↑ Filtered load of Ca, ↓PTH
Glucocorticoids	↑	? ↓ Bone resorption, volume expansion
PTH	↓	↑ Reabsorption TALH, DCT and CNT
Vitamin D	↓	↑ Distal reabsorption; other sites
Calcitonin	↓	↑ Reabsorption TALH?
Estrogens	↓	↑ Distal reabsorption
Diuretics		
Mannitol	↑	↓ Proximal reabsorption
Furosemide	↑	↓ Reabsorption TALH
Thiazides, amiloride	↓	↑ Proximal reabsorption

increase in apical Ca^{2+} entry that was associated with increased mRNA expression of TRPV5, Calbindin-D28k, and NCX1 (191). These data support the critical role of PTH in regulating renal calcium reabsorption independent of vitamin D.

Vitamin D. The effect of vitamin D on renal calcium reabsorption is variable, depending on vitamin D status, activity of PTH, and species studied (66). Although vitamin D has no detectable effect on calcium transport by the proximal tubule (192), $1,25(OH)_2D$ stimulates Ca^{2+} transport in distal nephron segments, including DCT of the dog and CNT and cortical collecting duct of the rabbit (66, 193). The effect of $1,25(OH)_2D$ on expression of TRPV5 was studied in vitamin D-deficient rats. Administration of $1,25(OH)_2D$ induced an increase in the abundance of TRPV5 mRNA and protein in the distal part of the DCT and in CNT (194). The human TRPV5 promoter contains several putative vitamin D responsive elements, suggesting that $1,25(OH)_2D$ stimulates TRPV5 expression at least in part at the transcriptional level (194). Administration of $1,25(OH)_2D$ to vitamin D-deficient mice also stimulates the mRNA expression of Calbindin-D28k and NCX1 in the kidney (195). Thus, it is thought that $1,25(OH)_2D$ acts on the distal nephron to increase calcium reabsorption by increasing the expression of the calcium transport proteins in this nephron segment.

Other hormonal factors. Urine calcium excretion is increased by exposure to the following: insulin, glucose, glucagon, growth hormone, thyroid hormone, and corticosteroids; urine calcium is decreased by calcitonin and estrogens (169). Estrogen plays an important role in calcium homeostasis, and estrogen deficiency results in negative calcium balance as occurs in post-menopausal osteoporosis (196, 197). The negative calcium balance is attributed to increased renal excretion and intestinal malabsorption of calcium due to estrogen deficiency, which is corrected by estrogen therapy (198–201). Estrogen regulates intestinal and renal calcium absorption via TRPV6 and TRPV5 channels respectively (202–204), and this regulation is transcriptionally mediated and independent of vitamin D.

Dietary Factors. Changes in dietary calcium within the normal range have only a modest effect on urine calcium excretion. A high calcium diet decreases intestinal and renal calcium absorption, and a restricted calcium diet has the opposite effect. These changes are mediated by changes in expression of TRPV5, TRPV6, Calbindin-D28k, PMCA1b, and NCX1 by unknown mechanisms that are independent of vitamin D (205). A linear relationship exists between dietary protein intake and urine calcium excretion (206), an effect that is exaggerated in patients with recurrent nephrolithiasis. An increase in either oral or parenteral intake of phosphorus is associated with a decrease in urine calcium excretion, an effect mediated in part by increased calcium reabsorption in the distal nephron (207). Phosphorus loading can reduce intestinal calcium absorption and stimulate PTH secretion, both in part by decreasing the renal production and serum concentration of $1,25(OH)_2D$ (10, 208). Conversely, phosphorus restriction increases urine calcium excretion (166, 169). This effect is independent of vitamin D and PTH and is attributed to a reduction in tubular calcium reabsorption, principally in distal nephron segments.

Volume Status. Expansion and contraction of the ECF volume induces an increase and decrease, respectively, in excretion of both calcium and sodium. Acute infusion of sodium chloride increases urine calcium excretion, an effect attributed to inhibition of calcium reabsorption in both the proximal and late distal tubule (209). An increase in dietary sodium chloride induces an increase in urine calcium, although the intrarenal mechanisms responsible have not been defined.

Acid–base Status. Both acute and chronic metabolic acidosis, as induced by ammonium chloride loading in humans and experimental animals, is attended by an increase in urine calcium excretion (210–212). This increase is irrespective of a change in filtered load of calcium or in circulating PTH and is attributed to a decrease in calcium reabsorption in the distal nephron (210). Hypercalciuria is reversed when the acidosis is corrected with administration of alkali (210, 213, 214). Recently, the molecular mechanism of this regulation was studied in wild type mice administered ammonium chloride to induce metabolic acidosis. Hypercalciuria was associated with a concomitant decrease in TRPV5, Calbindin-D28k, and NCX1 mRNA and protein abundance in the kidney (215). Conversely, metabolic alkalosis is associated with a decrease in calcium excretion (216, 217). The effect of respiratory acid–base changes are similar to those of metabolically-induced changes (218, 219). Hypercalcemia, by increasing the filtered load of calcium, is associated with an increase in its excretion. This effect is mitigated to some extent by hypercalcemia-induced reduction in the ultrafilterability of calcium and Pi (220) and in GFR (221); the reduction in GFR is attributed to a PTH-dependent decrease in K_f. Hypercalcemia can decrease calcium reabsorption in the PCT, TALH, and distal nephron (166); the effect on this latter segment requires the presence of parathyroid glands (222).

Diuretic Agents. Loop diuretics (furosemide and ethacrynic acid) which act on the TALH, induce an increase in sodium excretion by inhibiting the apical Na^+–K^+–$2Cl^-$ cotransporter, NKCC2. Such inhibition reduces the

lumen-positive transepithelial voltage, leading to a decrease in paracellular reabsorption of calcium. Therefore, administration of loop diuretics induces both natriuresis and hypercalciuria (169). By contrast, thiazide diuretics, which inhibit the apical sodium chloride cotransporter, NCC, in the DCT, decrease the excretion of calcium (223). The molecular mechanisms for the hypocalciuric effect of thiazide diuretics are reviewed in (224). Recent studies (225–227) support the hypothesis that chronic administration of thiazide diuretics induces an increase in calcium reabsorption in the proximal tubule. In TRPV5 knockout mice, chronic administration of thiazide diuretics induces hypocalciuria, even though active calcium transport in the distal nephron is absent (225). Furthermore, in normal rats the hypocalciuric effect of thiazides can be reversed when extracellular volume (ECV) contraction is prevented by sodium repletion (226). Thus, the thiazide-induced ECV contraction leads to a compensatory increase in proximal tubular reabsorption of sodium. The electrochemical gradient thus generated drives paracellular calcium reabsorption in the proximal tubule.

Phosphorus

Inorganic phosphate (Pi) is fundamental to cellular metabolism and, in vertebrates, to skeletal mineralization. To accomplish these functions, transport systems have evolved to permit the efficient transfer of negatively charged Pi ions across hydrophobic membranes. Ingested Pi is absorbed by the small intestine, deposited in bone, and filtered by the kidney where it is reabsorbed and excreted in amounts that are determined by the specific requirements of the organism. The kidney is a major determinant of phosphorus homeostasis due to its ability to increase or decrease its Pi reabsorptive capacity to accommodate Pi need. Accordingly, significant advances have been made in our understanding of the molecular mechanisms involved in renal tubular Pi reabsorption and its hormonal regulation and modulation by dietary Pi intake. This section will focus on Pi homeostasis and the cellular and molecular aspects of intestinal and renal Pi transport and their regulation. For a more detailed discussion of renal Pi wasting disorders in humans, see chapter 11.

Phosphorus Homeostasis

Phosphorus Distribution in the Body

Phosphorus accounts for about 0.6% of body weight at birth and about 1% of body weight, or 600–700 gm, in the adult (1). Approximately 85% of body phosphorus is in the skeleton and teeth, approximately 15% is in soft tissue, and the remainder (~0.3%) is in extracellular fluid. Pi is an important constituent of bone mineral, and in growing individuals, the balance of Pi must be positive to meet the needs of skeletal growth and consolidation; in the adult, Pi balance is zero. Pi deficiency results in osteomalacia in both children and adults.

Phosphate Chemistry

Phosphorus exists in plasma in two forms, an organic form consisting principally of phospholipids and phosphate esters, and an inorganic form (228). Of the total plasma phosphorus concentration of approximately 14 mg/dl (4.52 mM), about 4 mg/dl (1.29 mM) is in the inorganic form. Of this, about 10–15% is protein bound and the remainder, which is filtered by the renal glomerulus, exits principally either as the undissociated or "free" Pi ions or as Pi complexed with sodium, calcium, or magnesium. At physiological pH, only HPO_4^{2-} and $H_2PO_4^{-}$ are present at significant concentrations in plasma. The ratio of the divalent to monovalent forms can be determined by the Henderson-Hasselbalch equation, pH = pKa+ log (HPO_4^{2-} /$H_2PO_4^{-}$). The dissociation constant, pKa, for Pi is 6.8. Thus, at a pH of 7.4, the ratio of divalent (HPO_4^{2}) to monovalent ($H_2PO_4^{-}$) Pi anions is essentially 4:1, and the composite valence of Pi in serum (or intravenous solutions) is 1.8. At this pH, 1 mmol Pi is equal to 1.8 meq. In clinical settings, only the inorganic orthophosphate form of Pi is routinely measured.

The terms "phosphorus concentration" and "phosphate concentration" are often used interchangeably, and for clinical purposes the choice matters little. Phosphorus in the form of the phosphate ion circulates in blood, is filtered by the renal glomerulus, and is transported across plasma membranes. However, the content of "phosphate" in plasma, urine, tissue, or foodstuffs is measured and expressed in terms of the amount of elemental phosphorus contained in the specimen, hence use of the term "phosphorus concentration."

Extracellular Phosphate Homeostasis

In the adult in zero Pi balance, net intestinal Pi absorption (dietary Pi minus fecal Pi) is approximately 60–65% of dietary intake. To satisfy the demands of rapid growth of bone and soft tissue, intestinal Pi absorption in infants is higher than in the adult and can exceed 90% of dietary intake (229, 230). Metabolic balance studies in normal adult humans reveal that over the customary range of

dietary Pi, net absorption is a linear function of intake (231), with no indication of saturation. Thus, inadequate Pi absorption results primarily from decreased Pi availability rather than from changes in the intrinsic capacity of intestinal Pi transport. A small amount of Pi is secreted into the intestinal lumen in digestive fluids. Absorbed Pi enters the extracellular Pi pool, which is in equilibrium with the bone and soft tissue Pi pools. Pi is filtered at the glomerulus and is reabsorbed to a large extent by the renal tubule. In subjects in zero Pi balance, the amount of Pi excreted by the kidney is equal to the net amount absorbed by the intestine, and in growing children is less than the net amount absorbed due to deposition of Pi in bone. An overall schema of Pi metabolism is depicted in *Fig. 10-6*.

Renal tubular reabsorption of Pi plays a central role in the regulation of plasma Pi concentration and Pi homeostasis. In response to a decrease in the extracellular Pi concentration, urine Pi excretion decreases promptly due to an increase in Pi reabsorption by the proximal tubule (*Fig. 10-7*). This acute response reflects a decrease in the filtered load of Pi, an adaptive increase in proximal tubule Pi reabsorption induced by hypophosphatemia or decreased dietary Pi intake, and a decrease

Figure 10-6

Phosphorus fluxes between body pools in the normal human adult in zero phosphorus balance.

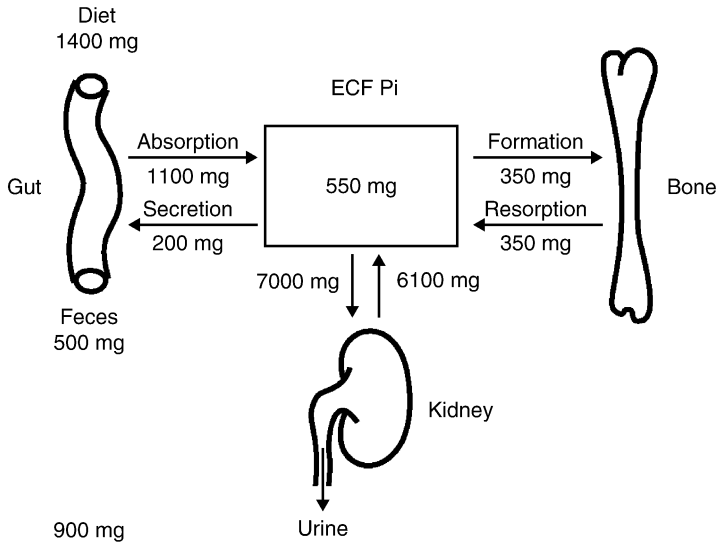


Figure 10-7

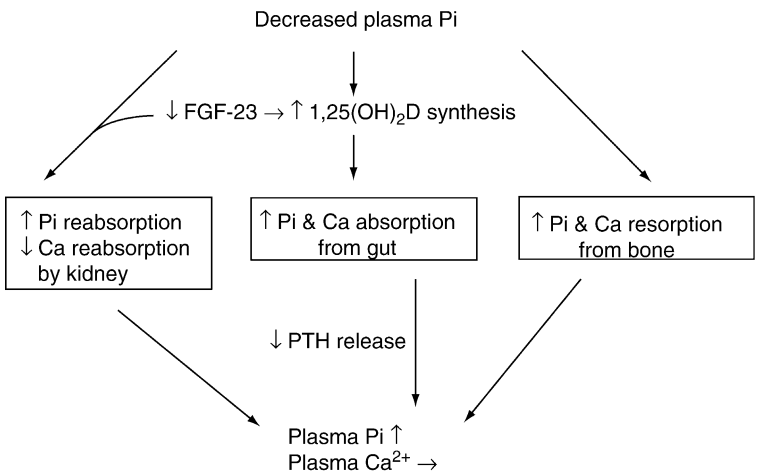
The homeostatic response to hypophosphatemia.



in circulating FGF-23 (discussed below). Hypophosphatemia also is a potent stimulus for the renal synthesis of $1,25(OH)_2D$ (208, 232–236). The resulting increase in serum $1,25(OH)_2D$ acts to stimulate intestinal absorption of Pi and calcium and their mobilization from bone. Hypophosphatemia itself also can directly promote mobilization of Pi and calcium from bone. With an increase in plasma calcium concentration, PTH is suppressed which leads to a further decrease in urine Pi excretion but an increase in calcium excretion. These homeostatic adjustments result in an increase in extracellular Pi concentration toward normal values, with little change in serum calcium concentration. Conversely, in response to an increase in plasma Pi concentration, production of $1,25(OH)_2D$ is decreased and release of PTH and FGF-23 are increased. The effect of hyperphosphatemia on bone, kidney, and intestine are opposite to those occurring with hypophosphatemia, the net result being a decrease in Pi concentration toward normal values.

In healthy subjects ingesting typical diets, the serum Pi concentration exhibits a circadian rhythm, characterized by a rapid decrease in early morning to a nadir shortly before noon, a subsequent increase to a plateau in late afternoon, and a small further increase to a peak shortly after midnight (8, 10) (*Table 10-1*). The amplitude of the rhythm (nadir to peak) is approximately 1.2 mg/dl, or 30% of the 24-h mean level. Restriction or supplementation of dietary Pi induces a substantial decrease or increase, respectively, in serum Pi concentrations during the late morning, afternoon, and evening, but induces less or no change in the morning fasting Pi concentration (10). To minimize the impact of changes in dietary Pi on the serum Pi concentration, one should obtain specimens for analysis in the morning fasting state. Specimens obtained in the afternoon are more likely to be affected by diet and thus may be more useful to monitor the effect of dietary Pi on serum Pi concentration, as in patients with renal insufficiency receiving Pi-binding agents to treat hyperphosphatemia.

Other factors can affect the serum Pi concentration. Presumably because of movement of Pi into cells, the serum Pi concentration can be decreased acutely by intravenous infusion of glucose or insulin, ingestion of carbohydrate rich meals, acute respiratory alkalosis, or by infusion or endogenous release of epinephrine. The decrease in Pi concentration induced by acute respiratory alkalosis can be as great as a 2.0 mg/dl (237). Serum Pi concentration can be increased acutely by metabolic acidosis and by intravenous infusion of calcium (238).

There are substantial effects of age on the fasting serum Pi concentration (*Table 10-2*). In infants in the first 3 months of life, Pi levels are highest (4.8–7.4 mg/dl, mean 6.2 mg/dl [2 mM]) and decrease at age 1–2 years to 4.5–5.8 mg/dl (mean 5.0 mg/dl [1.6 mM]) (239). In mid-childhood, values range from 3.5 to 5.5 mg/dl (mean 4.4 mg/dl [1.42 mM]) and decrease to adult values by late adolescence (12, 240). In adult males, serum Pi is ~3.5 mg/dl at age 20 years and decreases to ~3.0 mg/dl at age 70 (13, 240). In women, the values are similar to those of men until after the menopause, when they increase slightly from ~3.4 mg/dl at age 50 years to 3.7 mg/dl at age 70.

Intestinal Phosphate Absorption

Cellular Aspects

Dietary Pi is absorbed in the small intestine, primarily in the duodenum and jejunum with minimal absorption in the ileum. Pi absorption occurs via two mechanisms, nonsaturable, passive diffusion through the paracellular pathway and an active transcellular process that has been localized to the mucosal surface. Under usual conditions of excess dietary intake, Pi absorption occurs primarily via paracellular diffusion which is largely unregulated, whereas active transport plays an important role when luminal Pi concentration is low, as when dietary Pi is restricted (241, 242). The active absorption of Pi across the mucosal membrane is saturable, sodium-dependent, and driven by a Na^+-gradient (outside > inside) that is maintained by the basolateral membrane-associated Na^+, K^+-dependent ATPase. The exit of Pi at the serosal (basolateral) surface occurs down an electrochemical gradient and has not been well characterized. However, evidence suggests that the process is carrier-mediated, Na^+-independent, and electrogenic.

Regulation

Active transport of Pi across the mucosal membrane is the rate limiting step in intestinal Pi absorption and is regulated by $1,25(OH)_2D$ and dietary Pi intake (243). Administration of $1,25(OH)_2D$ to either vitamin D deficient or replete animals induces a significant increase in net Pi absorption which is associated with a corresponding increase in sodium-dependent Pi (Na/Pi) cotransport Vmax across the mucosal brush border membrane (BBM). The increase in intestinal Pi transport induced by $1,25(OH)_2D$ is dependent on protein synthesis, occurs several hours after its administration, and apparently

occurs after weaning. In a pig model in which mutant animals exhibit defective renal synthesis of $1,25(OH)_2D$, intestinal BBM Na/Pi cotransport Vmax in mutants is similar at birth but significantly reduced after weaning when compared to age-matched wild-type animals (244). Administration of $1,25(OH)_2D$ had no effect on mucosal Pi transport in newborn mutants but it corrected the Pi transport defect in weanling mutants (244). Low dietary Pi intake also induces an increase in mucosal Na/Pi cotransport. However, the response to dietary Pi restriction is likely mediated by $1,25(OH)_2D$. Renal synthesis of $1,25(OH)_2D$ is stimulated by hypophosphatemic states (232–234), and the adaptive intestinal response to Pi restriction is blunted in vitamin D deficient animals (245).

Molecular Mechanisms

In an effort to identify intestinal Na/Pi cotransporters, a full-length cDNA was generated from an EST clone and found to exhibit sequence homology with the renal type II Na/Pi cotransporter (discussed below) (246). When expressed in Xenopus oocytes, the cDNA induced Na/Pi cotransport that was electrogenic, with a pH-dependence that resembled that of intestinal BBM Na/Pi cotransport, i.e., higher transport at pH 6 than at pH 7.4 (246). Based on its high homology to the renal type II transporter, it was designated type IIb (NPT2b) (solute carrier series SLC34A2) and the renal isoform was renamed type IIa (NPT2a). The NPT2b/Npt2b genes map to human and mouse chromosome regions 4p15.2 and 5C1, respectively (247–249). NPT2b mRNA is expressed in a variety of tissues including small intestine, but not in kidney (246). NPT2b protein is localized to the apical membrane of enterocytes (246), and western blotting and immunohistochemical analysis revealed that its expression in the small intestine is regulated by dietary Pi intake (250). In mice, chronic Pi restriction induces an increase in small intestinal BBM Na/Pi cotransport and a corresponding increase in apical membrane NPT2b protein abundance. In contrast, with chronic feeding of a high Pi diet, Na/Pi cotransport was decreased, and NPT2b protein was no longer detectable in the intestinal apical membrane (250). The correlation between BBM Na/Pi cotransport and NPT2b protein expression in these studies is consistent with the notion that NPT2b plays an important role in intestinal Pi absorption and its regulation by dietary Pi intake.

Small intestinal NPT2b expression also is regulated by vitamin D. In mice, injection of cholecalciferol elicits comparable increases in small intestinal BBM Na/Pi cotransport and apical abundance of NPT2b protein (250). However, corresponding increases in intestinal NPT2b mRNA were not evident, suggesting that the effect of vitamin D cannot be explained by increased NPT2b gene transcription. In the rat, however, administration of $1,25(OH)_2D$ stimulated Na/Pi cotransport and increased both NPT2b mRNA and protein (251). In addition, in cultured intestinal epithelial cells, $1,25(OH)_2D$ induced an increase in NPT2b mRNA abundance and in NPT2b promoter activity (251). Both intestinal Na/Pi cotransport and apical NPT2b mRNA expression decrease with age in rats, being approximately fourfold higher in immature (2-week old) than in adult (14 weeks) rats, in the absence or presence of vitamin D (251).

Methylprednisolone induces a significant decrease in small intestinal BBM Na/Pi cotransport and a concomitant decrease in NPT2b mRNA and protein expression (252). The inhibition by methylprednisolone was evident in mice ranging from 14 days to 9 months of age, although apical transport activity and intestinal NPT2b expression were significantly higher in the suckling mice than in adult animals (252).

Renal Phosphate Transport

Physiology and Tubular Localization

Much of the material discussed here is covered in greater detail in review articles (253–260).

The proximal tubule is the major site of Pi reabsorption, with approximately 70% of the filtered load reclaimed in the proximal convoluted and approximately 10% in the proximal straight tubule. In addition, a small but variable portion (<10%) of filtered Pi is reabsorbed in the distal segments of the nephron (238) (*Fig. 10-8*). Clearance studies in humans and experimental animals show that when the filtered load of Pi is progressively increased, Pi reabsorption increases until a maximum tubular reabsorptive rate for Pi, or TmP, is reached, after which Pi excretion increases in proportion to its filtered load. The measurement of TmP varies among individuals and within the same individual, due in part to variation in GFR. Thus the ratio, TmP/GFR, or the maximum tubular reabsorption of Pi per unit volume of GFR, is the most reliable quantitative estimate of the overall tubular Pi reabsorptive capacity and is considered to reflect the quantity of Na/Pi cotransporters available per unit of kidney mass (241). The serum Pi concentration at which Pi reabsorption is maximal is called the "theoretical renal Pi threshold";

Figure 10-8

Profile of phosphate reabsorption along the mammalian nephron, as derived from micropuncture data. PCT, proximal convoluted tubule; PST, proximal straight tubule; TALH, thick ascending limb of Henle's loop; DCT, distal convoluted tubule; CCD, cortical collecting duct; IMCD, inner medullary collecting duct. (Data from (238)).

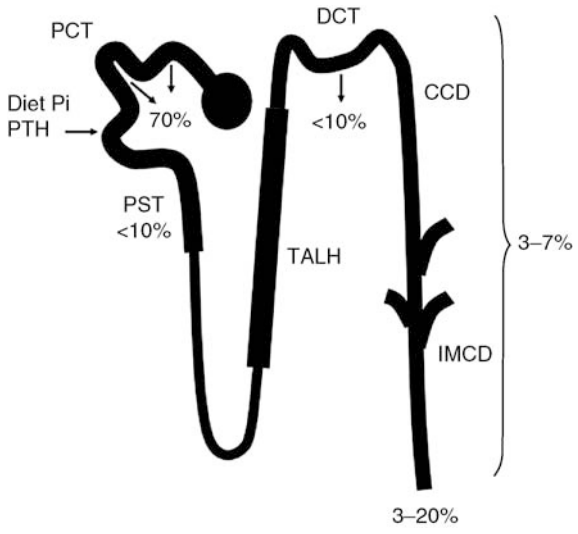


Figure 10-9

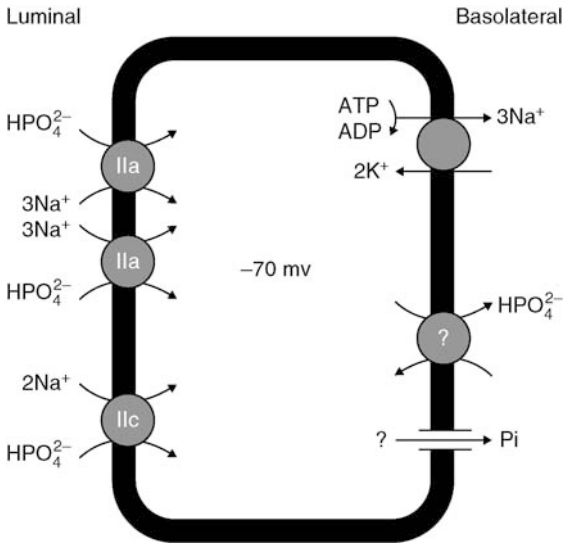
Location of identified and postulated type II Na^+-dependent Pi cotransporters in the proximal tubule cell. Available data indicate that most proximal tubule Pi reabsorption occurs via type IIa (NPT2a) and type IIc (NPT2c) cotransporters, which are localized to the brush border membrane and are the major target for physiologic regulation of renal Pi reabsorption. (Modified from (402)).



this value is equal to the ratio, TmP/GFR, and closely approximates the normal fasting serum Pi concentration. Thus, the renal reabsorptive capacity for Pi is the principal determinant of the serum Pi concentration.

Proximal tubule. Approximately 70% of the filtered load of Pi is reabsorbed by the proximal convoluted tubule (PCT). Reabsorption rates in early convolutions (S1 segment) normally are as much as four times greater than those in late convolutions (S2 segment) and the pars recta (S3 segment) (261–263). Due to this axial heterogeneity in Pi transport, most of the Pi reabsorption by the PCT occurs within the first 25% of its length. Internephron heterogeneity in Pi reabsorption also is present in the proximal tubule, with proximal tubules of juxtamedullary nephrons having a greater capacity to both reabsorb Pi (264–267) and adapt to changes in its filtered load (268, 269), as compared with proximal tubules of superficial nephrons. In the absence of PTH, up to an additional 10% of filtered Pi can be reabsorbed in the proximal straight tubule (PST) (*Fig. 10-8*).

Henle's Loop, distal convoluted tubule and connecting tubule. Little or no transport of Pi is thought to occur in Henle's Loop except for the PST segment (238). Up to 10% of the filtered Pi load is reabsorbed by the DCT in the absence of PTH, with the possibility of an additional 3–7% being reabsorbed beyond the accessible late DCT, presumably by the connecting tubule (238).

Collecting tubule. Although some investigators have failed to demonstrate Pi reabsorption in isolated perfused cortical collecting tubules (270), others have demonstrated a small but significant net efflux of Pi in this nephron segment (271, 272).

Cellular and Molecular Aspects

Transepithelial Pi transport in the nephron is essentially unidirectional and involves uptake across the BBM, translocation across the cell, and efflux at the basolateral membrane (*Fig. 10-9*). Pi uptake at the apical cell surface is the rate-limiting step in overall Pi reabsorption, the major site of its regulation, and is mediated by Na/Pi cotransporters that depend on the basolateral membrane-associated Na^+/K^+-dependent ATPase. Na/Pi cotransport is either electrogenic (NPT2a) or electroneutral (NPT2c) and is sensitive to changes in luminal pH, with 10- to 20-fold increases observed when the pH is raised from 6 to 8.5. Little is known about the translocation of Pi across the cell except that Pi anions rapidly equilibrate

with intracellular inorganic and organic Pi pools. There are little data regarding the mechanisms involved in the efflux of Pi at the basolateral cell surface. It has been proposed that in the proximal tubule, a Na^+-dependent electroneutral anion exchanger is at least partially responsible for Pi efflux (273).

Three classes of Na/Pi cotransporters have been identified by expression and homology cloning. The type I Na/Pi cotransporter (NPT1, *SLC17A1*) is expressed predominately in BBMs of proximal tubule cells (274). The NPT1 transporters are approximately 465 amino acids in length with seven to nine membrane spanning segments. NPT1 exhibits broad substrate specificity and mediates the transport of Cl^- and organic anions as well as high affinity Na/Pi cotransport. Its pH profile differs significantly from that of the pH-dependence of Na/Pi cotransport in isolated renal BBM vesicles. Furthermore, conditions that physiologically regulate proximal tubule Pi transport such as dietary Pi or PTH do not alter type I Na/Pi cotransporter protein or mRNA expression. Thus, the physiological role of NPT1 will require further study. The human gene encoding the type I Na-Pi cotransporter (*SLC17A1*) is located on chromosome 6p21.3-p23.

The type II family of Na/Pi cotransporters, whose cDNA shares only 20% homology with that of NPT1 (275,276), is comprised of three highly homologous isoforms: type IIa (NPT2a, *SLC34A1*) and type IIc (NPT2c, *SLC34A3*) (277,278), which are expressed exclusively in the BBM of the renal proximal tubule (*Fig. 10-9*), and type IIb (NPT2b, *SLC34A2*), which is expressed in several tissues including small intestine and lung, but not in kidney, and is responsible for intestinal absorption of Pi (246). Human NPT2a and human NPT2c are comprised of 635 and 599 amino acids, respectively; both proteins are predicted to have eight membrane-spanning segments (*Fig. 10-10*). The human genes encoding NPT2a and NPT2c are located on chromosomes 5q35 and 9q34, respectively (279). NPT2a-mediated Na/Pi cotransport is electrogenic and involves the influx of three Na^+-ions and one Pi-anion (preferentially divalent) (280). NPT2b-mediated cotransport also is electrogenic, whereas the NPT2c isoform mediates electroneutral transport of two Na^+-ions with one divalent Pi-anion.

In the mouse, Npt2a and Npt2c are detected exclusively in the BBM of proximal tubular cells. At the mRNA level, NPT2a is approximately one order of magnitude more abundant than NPT2c. The abundance of Npt2c mRNA and protein are both significantly higher in kidneys of 22-day-old rats than in those of 60-day-old rats, suggesting that Npt2c has a particularly important role during early post-natal development (277). However, several different homozygous and compound heterozygous mutations in the gene encoding NPT2c, *SLC34A3,* have been found in patients affected by hereditary hypophosphatemic rickets with hypercalciuria (HHRH) (281–283), indicating that at least in humans, this cotransporter has a more prominent role than initially thought. Hybrid depletion studies suggested that Npt2c accounts for approximately 30% of Na/Pi co-transport in kidneys of Pi-deprived adult mice (278).

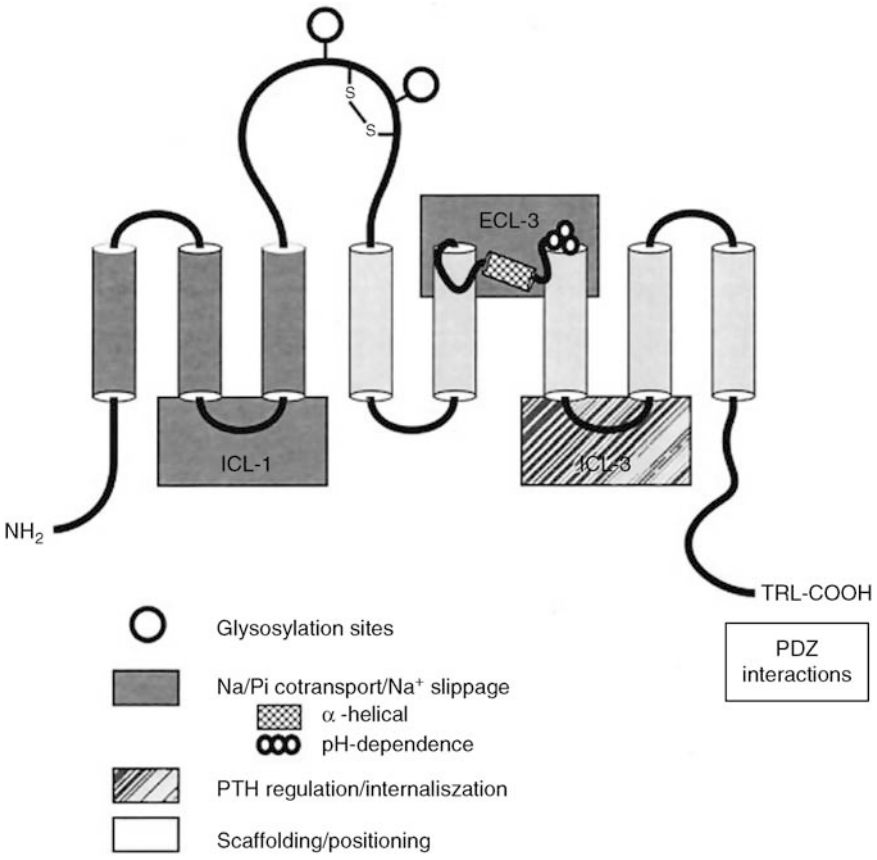
Type III Na/Pi co-transporters are cell-surface retroviral receptors [gibbon ape leukemia virus (Glvr-1, Pit-1, *SLC20A1*) and murine amphotropic virus (Ram-1, Pit-2, *SLC20A2*)] that mediate high affinity, electrogenic Na/Pi cotransport when expressed in oocytes and mammalian cells (257, 284). Glvr-1 and Ram-1 show no sequence similarity to NPT1 or NPT2a. Both Glvr-1 and Ram-1 proteins are widely expressed in mammalian tissues including the kidney and have been considered to function as "housekeeping" Na/Pi cotransporters to maintain cellular Pi homeostasis. However, recent studies report immunohistochemical evidence that Pit-2 is localized to the BBM of the rat proximal tubule, and its protein abundance is strongly up-regulated by dietary Pi restriction, but with a slower adaptation rate compared to Npt2a (285). The authors suggest that Pit-2 is a novel mediator of Pi reabsorption in the proximal tubule, and that its role in overall renal Pi handling should be re-evaluated (285).

Regulation of Renal Phosphate Transport

Regulation of NPT2a and NPT2c. Regulation of renal Pi reabsorption has been the subject of intense investigation. The major regulators of renal Pi reabsorption are thought to be dietary Pi intake, PTH, and FGF-23, although many hormonal and non-hormonal factors also are known to regulate this process (*Table 10-4*). Both NPT2a and NPT2c are the targets of regulation. Dietary Pi, PTH, and FGF-23 regulate renal Pi reabsorption primarily by inducing alterations in the abundance of NPT2a protein in the BBM of proximal tubular cells, which is accomplished either by insertion of existing transporters into the membrane or retrieval of transporters from the membrane with subsequent lysosomal degradation. Dietary Pi, PTH, and FGF-23 also regulate the abundance of NPT2c protein in the BBM (286); however, in contrast to NPT2a, NPT2c does not appear to undergo lysosomal degradation but instead may get recycled and re-inserted into the apical membrane. The mechanisms underlying

Figure 10-10

Model of the secondary structure of the rat type IIa Na-Pi cotransporter, derived from a variety of analytical approaches (reviewed in (256)). A large extracellular loop, stabilized by a disulfide bridge, separates the transporter into two domains. There is intramolecular homology within the ICL1 and ICL3 domains, and these domains are thought to form an important part of a "permeation pore" that participates in both "cotransport" and "Na^+-leak" function. Three amino acid residues between the fifth and sixth transmembrane domain are suggested to determine the pH dependence of the transporter. Two basic amino acid residues in ICL3 are important for PTH-dependent internalization. The COOH terminus contains information important for brush border membrane expression, i.e., a terminal PDZ-binding motif and a membrane internalization signal. (Reprinted with permission from (256)).



membrane trafficking of NPT2a and NPT2c proteins are complex and involve interaction of the transporters with various scaffolding and signaling proteins such as NHERF1, NHERF2, NHERF3 (PDZK1), NHERF4 (PDZK2), and Shank2E (287, 288).

Dietary Phosphate. Dietary intake of Pi is a key physiologic determinant of renal Pi handling. An increase or decrease in dietary Pi predictably induces an increase or decrease, respectively, in urine Pi excretion; with severe Pi restriction, urine Pi is negligible. This adaptation is independent of changes in the filtered load of Pi, in ECF volume, plasma calcium, growth hormone, vitamin D status, or parathyroid activity, and appears to reflect changes in the rate of Pi reabsorption by the proximal tubule, specifically, an increase or decrease in the Vmax of Na/Pi cotransport activity. The adaptation can be demonstrated both in vivo and in isolated perfused PCT segments and BBM vesicles taken from animals maintained on differing dietary intakes of Pi (289–294). Renal tubular adaptation to changes in either Pi intake or plasma Pi concentration occurs rapidly; an increase in BBM vesicle Na/Pi cotransport was observed after 2–4 h of Pi restriction in the rat (295–297); conversely, a decrease in Pi transport was induced after 1 h of Pi infusion (298). Similarly, exposure of cultured renal epithelial cells (LLC-PK1) to a low Pi concentration in the medium

Table 10-4

Factors affecting renal phosphate excretion

Factor	Urine Pi excretion	Mechanism/nephron site
Dietary		
Volume expansion	↑	↑ Filtered load of Pi ↓Proximal and distal reabsorption
High Pi intake	↑	↓ Proximal reabsorption
Phosphorus restriction	↓	↑ Proximal reabsorption
Metabolic		
Acidosis	↑	↓ Tubular reabsorption

Immaturity	↓	↑ Proximal and distal reabsorption

induced both short-term (minutes) and long-term (hours) adaptations in Na/Pi cotransport (299–301).

Such dietary Pi-induced regulation of Pi reabsorption is achieved primarily by alterations in the abundance of type IIa Na/Pi cotransporter protein in the BBM of proximal tubule cells. Short-term (hours) exposure of rats to a Pi restricted diet induced an increase in both BBM Na/Pi cotransport activity and NPT2a protein abundance but no change in NPT2a mRNA (302). Chronic (days) restriction of dietary Pi in mice, rats, and rabbits leads to an adaptive increase in BBM Na/Pi cotransport and in the abundance of NPT2a protein and mRNA (303–309). The acute increase in Pi transport induced by Pi deprivation is mediated by microtubule-dependent recruitment of existing NPT2a protein to the apical membrane (302). In contrast, exposure to high dietary Pi leads to internalization of cell surface NPT2a protein into the endosomal compartment by a microtubule-independent mechanism (302). Internalized NPT2a protein is then delivered to the lysosome by a microtubule-dependent process, for degradation (310).

A Pi response element (PRE) was identified in the mouse *NPT2a* promoter by DNA footprint analysis (311). The PRE was shown to bind a mouse transcription factor, TFE3, and the renal expression of TFE3 is increased in response to Pi deprivation (311). On the basis of these results, it was suggested that TFE3 participates in transcriptional regulation of the NPT2a gene by dietary Pi.

NPT2c also is regulated by dietary Pi. Dietary Pi restriction induces an increase in NPT2c immunoreactive protein in the apical membrane of proximal tubule cells, whereas feeding a high Pi diet induces a decrease (286, 312). Internalization of NPT2c was slightly delayed relative to that of NPT2a after acute exposure to high dietary Pi. Internalized NPT2c is, however, not degraded in the lysosomes.

Parathyroid Hormone. PTH is a major hormonal regulator of renal Pi reabsorption (166, 313). PTH acts directly on proximal tubular cells to inhibit Na/Pi cotransport through mechanisms that involve rapid internalization of cell surface NPT2a protein (314) and its subsequent lysosomal degradation (315). A prolonged increase in

PTH also can induce a decrease in type II Na/Pi cotransporter mRNA abundance (314).

PTH binding to the PTH/PTHrP receptors on the basolateral membrane activates PKA- and/or PKC-dependent signaling pathways, whereas PTH binding to apical receptors activates the PKC pathway (316). The extracellular signal-regulated kinase (ERK)/MAPK pathway also participates in PTH-induced signaling (317), and recent studies have shown that the PKA and PKC signaling pathways converge on the ERK/MAPK pathway to internalize NPT2a protein (318). Although the downstream targets for ERK/MAPK-mediated phosphorylation remain unknown, changes in the phosphorylation state of NPT2a are not associated with its PTH-induced internalization (319). Rather, it has been postulated that the phosphorylation of proteins that associate with NPT2a may determine its regulation. AKAP79, an A kinase anchoring protein (320), and RAP, a receptor-associated protein (321), were shown to participate in the PTH-mediated retrieval of NPT2a from the plasma membrane of proximal tubular cells. In opossum kidney (OK) cells, AKAP79 associates with NPT2a and the regulatory and catalytic subunits of PKA, and this process is necessary for PKA-dependent inhibition of Na/Pi cotransport (320). In RAP-deficient mice, PTH-induced internalization of NPT2a is significantly delayed whereas its regulation by dietary Pi is not affected (321).

PTH-dependent regulation of NPT2c is less well understood. In response to PTH, NPT2c disappears from the surface of the BBM at a much slower rate than does NPT2a, and NPT2c does not seem to undergo lysosomal degradation (286, 322–324). Indeed, preliminary evidence suggests that NPT2c may be recycled and re-inserted into the BBM (325). In rats fed a low Pi diet, NPT2a and NPT2c undergo different regulation by PTH. PTH(1–34) failed to decrease NPT2a expression in BBM vesicles from rats on a low Pi diet, consistent with the blunted phosphaturic effect of PTH observed in hypophosphatemic humans or rodents (326). In contrast, PTH was able to efficiently reduce the expression of NPT2c (323). Furthermore, whereas NPT2a is expressed in segments S1 through S3 of the proximal tubule, NPT2c is expressed only in the S1 segment.

Fibroblast Growth Factor 23. FGF-23 is a newly discovered, bone-derived circulating peptide that plays an important role in regulating Pi and vitamin D metabolism. Through a positional cloning approach, FGF-23 was first identified as the gene disrupted in patients with autosomal dominant hypophosphatemic rickets (ADHR) (327–329), a disorder characterized by hypophosphatemia due to renal Pi wasting, inappropriately low or normal serum concentrations of $1,25(OH)_2D$, and rickets or osteomalacia (330). Affected patients harbor mutations that alter the peptide's furin cleavage site (residues 176 through 179), thereby preventing the normal proteolytic processing of FGF-23 (331) and resulting in its accumulation in the plasma. Excess FGF-23 also is implicated in the pathogenesis of two related hypophosphatemic disorders, tumor-induced osteomalacia (TIO) (332–334), and X-linked hypophosphatemia (XLH) (330). FGF-23 is abundantly expressed in tumors that cause TIO (335, 336), and serum concentrations of FGF-23 are greatly increased in TIO patients and also in some patients with XLH (337, 338). With surgical removal of the tumor, FGF-23 concentrations decrease to normal values and the disorder resolves. Extracts from these tumors inhibit Pi transport in renal proximal tubule cells in vitro (339, 340), consistent with the notion that FGF-23 is responsible for this inhibition.

The human *FGF-23* gene consists of three exons spanning 10 kb of genomic sequence that encode a 251 amino acid precursor protein comprising a hydrophobic amino acid sequence (residues 1 through 24), which likely serves as a leader sequence (*Fig. 10-11*). Unlike most other fibroblast growth factors, FGF-23 appears to be efficiently

Figure 10-11

secreted into the circulation. FGF-23 binds, albeit with relatively low affinity, to most of the different splice variants of the known FGF receptors (341). However, in the presence of Klotho, a membrane bound protein with β-glucuronidase activity, FGF-23 can bind with high affinity to FGFR1(IIIc) (342, 343), suggesting that Klotho plays an important role in mediating the actions of FGF-23. Thus, it is currently thought that FGF-23 acts through known FGFRs but only in those tissues in which Klotho is also expressed, including kidney (344, 345).

FGF-23 acts on the kidney to impair Pi reabsorption and inhibit the synthesis of $1,25(OH)_2D$. In mice, administration of FGF-23 induces a decrease in serum Pi concentration, increased renal Pi excretion, inhibition of BBM Na/Pi cotransport, and decreased renal Npt2a expression (336, 346–349). Mice transplanted with cell lines stably expressing FGF-23 or transgenic mice that over-express FGF-23 display hypophosphatemia due to renal Pi wasting, low serum $1,25(OH)_2D$ concentrations, and abnormal bone development (336, 348, 350–352). FGF-23 suppresses the renal production and serum concentration of $1,25(OH)_2D$ by suppressing 25-hydroxyvitamin D-1α-hydroxylase mRNA and protein expression in vivo and in vitro and stimulating 24-hydroxylase mRNA expression (336, 347, 349, 352). Findings opposite to those in Fgf-23 transgenic animals were observed in mice homozygous for ablation of the Fgf-23 gene (*Fgf23*-null). These animals develop hyperphosphatemia and increased serum $1,25(OH)_2D$ concentrations, abnormal skeletogenesis, and they die prematurely, partly due to renal failure secondary to renal calcification (353–355). The findings in *Fgf23*-null mice overlap significantly with those in *Klotho*-null mice (356–360), even though *Klotho*-null animals show greatly increased serum levels of biologically active FGF-23 (357). These observations provide further evidence that Klotho plays an important role in mediating the actions of FGF-23.

Other Hormonal Regulators: Administration of $1,25(OH)_2D$ to vitamin D-deficient rats induces an increase in BBM Na/Pi cotransport that is accompanied by an increase in renal NPT2a mRNA and protein abundance (361). While these results are consistent with direct effects of $1,25(OH)_2D$ on NPT2a-mediated renal Na/Pi cotransport, the effects may result from a $1,25(OH)_2D$-dependent decrease in PTH levels. However, the finding that $1,25(OH)_2D$ increased the activity of a NPT2a promoter-luciferase reporter gene construct suggests a direct effect of this hormone on NPT2a gene transcription (361). In vitamin D receptor (VDR)-null mice, in which serum levels of PTH and $1,25(OH)_2D$ are greatly increased, the abundance of NPT2a protein in renal BBM vesicles was significantly decreased, whereas the abundance of NPT2c protein was unaffected (362). This finding suggests that $1,25(OH)_2D$ has little direct effect on NPT2c expression.

Growth hormone acts to increase renal Pi reabsorption, independently of PTH (363, 364). In growth hormone-deficient subjects, the serum Pi concentration and the TmP/GFR are reduced; both increase with administration of growth hormone (365, 366). In patients with acromegaly, serum Pi concentrations are increased (367). Growth hormone stimulates proximal tubular Na/Pi cotransport (368–371) which is mediated, at least in part by increased production and release of insulin-like growth factor 1 (IGF-1) (363, 372). Receptors for growth hormone are present on the basolateral membrane of proximal tubule cells and appear to activate the phospholipase C pathway. Receptors for IGF-1 also have been identified in proximal tubule membranes and their effects may involve tyrosine kinase activity (363).

Fibroblast growth factor 7 (FGF7), which is produced by a TIO-causing tumor, was recently shown to inhibit Pi uptake in OK cells, thus suggesting that FGF7 can also cause phosphaturia and may be responsible for TIO in those patients who have no elevation in circulating FGF23 levels (373). Secreted frizzled-related protein 4 (sFRP4), which, like FGF-23, is highly expressed in tumors from patients with TIO (374), has also been tested for its phosphaturic action. sFRP-4 induced a specific increase in the renal fractional excretion of Pi and hypophosphatemia when infused in rats and inhibited Na/Pi cotransport in vitro when added to OK cells (374).

Stanniocalcin is a peptide hormone that counteracts hypercalcemia and stimulates Pi reabsorption in bony fish, and is also produced by humans. Infusion of stanniocalcin in rats stimulates renal Pi reabsorption and BBM Na/Pi cotransport (375), suggesting a role for stanniocalcin in the maintenance of Pi homeostasis in mammals as well as fish. 5-hydroxytryptamin (5-HT) is synthesized in the kidney, and locally generated 5-HT was shown to interfere with PTH-mediated inhibition of renal Na/Pi cotransport (376), suggesting that 5-HT is a paracrine modulator of renal Pi transport. The increase in BBMN Na/ Pi cotransport induced by thyroid hormone is associated with an increase in NPT2a mRNA (377), whereas both hypercalcemia (378) and epidermal growth factor (379) decrease NPT2a mRNA abundance. Neither thyroid hormone nor hypercalcemia has an effect on NPT2a promoter-reporter gene expression (see (380)), suggesting that transcriptional mechanisms are not involved. Other factors which inhibit Pi reabsorption are: PTH-related peptide, calcitonin, atrial natriuretic factor,

epidermal growth factor, transforming growth factor-β, and glucocorticoids (for review see (238, 255, 260)).

Effect of Npt2a and NPT2c Gene Disruption. The critical role of NPT2a in the maintenance of Pi homeostasis has been clearly demonstrated in mice in which the *Npt2a* gene (lower case refers to the mouse gene) was knocked out by targeted mutagenesis (381). Mice that are null for *Npt2a* exhibit decreased renal Pi reabsorption, an ~80% loss of BBM Na/Pi cotransport, hypophosphatemia, an appropriate adaptive increase in the renal synthesis and serum concentration of $1,25(OH)_2D$ (246, 381) and associated hypercalcemia, hypercalciuria, and hypoparathyroidism, and an age-dependent skeletal phenotype (381, 382). Dietary Pi intake and PTH were without effect on renal BBM Na/Pi cotransport in *Npt2a*-null mice (383, 384), demonstrating that NPT2a is a major regulator of renal Pi handling. In the BBM of Npt2a null mice, the abundance of Npt2c protein was shown to be increased significantly (385), likely accounting for at least some of the residual Na/Pi cotransport in the mutant mice.

In preliminary studies, mice that are null for *Npt2c* exhibit, at different ages, only a small increase in blood ionized calcium and some increase in urinary calcium excretion, but not hypophosphatemia or increased urinary Pi excretion (386), suggesting that Npt2c may be of limited functional significance in rodents. However, the combined ablation of Npt2a and Npt2c exhibits a more severe phenotype than the ablation of Npt2a alone, suggesting that the Npt2c is likely to have more significant role than suggested by the Npt2c-null animals.

Non-Hormonal Regulators*: *Volume Status. Expansion of the extracellular fluid volume results in an increase, and volume contraction a decrease, in urine Pi excretion (*Table 10-4*) (166, 238). The effect can be attributed in part to changes in the filtered load of Pi and rate of Pi reabsorption by the proximal tubule, and to changes in plasma ionized calcium, the latter affecting secretion of PTH. A direct effect of volume expansion on tubular Pi reabsorption also has been reported.

Acid–base Status. Changes in acid–base status can significantly effect renal handling of Pi (166,313). Acute respiratory acidosis results in a decrease in renal Pi reabsorption; this effect may depend on an increase in pCO_2 tension but does not depend on an increase in filtered Pi load, expansion of the extracellular fluid volume, or change in PTH or blood bicarbonate concentration (387). Conversely, acute respiratory alkalosis induces an increase in renal Pi reabsorption and resistance to the phosphaturic action of both PTH and cAMP; these effects may depend on changes in pCO_2 tension but are independent of changes in plasma Pi concentration (388).

Although acute metabolic acidosis has minimal effects on urine Pi excretion (389), chronic metabolic acidosis can impair renal Pi reabsorption, independently of PTH and even when dietary Pi is severely restricted (390, 391). The suppressive effect of metabolic acidosis on Na/Pi cotransport is observed in BBM vesicles and is attributed to a decrease in Vmax of the transporter (391, 392). In rats fed ammonium chloride for 10 days, the 60% decrease observed in BBM Na/Pi cotransport activity was associated with a threefold decrease in BBM Npt2 protein abundance and a twofold decrease in mRNA (393). With a shorter duration of acidosis (<24 h), the changes were of lesser magnitude, with no change in Npt2 mRNA observed with very acutely-induced (6 h) acidosis. The inhibitory effect of metabolic acidosis on Pi transport was independent of endogenous PTH activity but was greatly attenuated in rats fed a low (0.1%) Pi diet (393). In recent studies of mice fed ammonium chloride, the renal abundance of Npt2a mRNA was reduced at 2 but not 7 days of acidosis, whereas Npt2c mRNA was reduced at both time points (394). However, the protein abundance of Npt2a and Npt2c in BBM were both paradoxically increased (394), suggesting that with acidosis, phosphaturia might be induced by direct interactions between protons and the type IIa and IIc Na/Pi cotransporters, thereby reducing transport activity (394). Acute metabolic alkalosis induced by infusion of sodium bicarbonate reduces Pi reabsorption when the prior dietary intake of Pi is high, but increases Pi reabsorption when dietary Pi is normal (166, 395–398). Chronic metabolic alkalosis predictably increases renal Pi reabsorption (313).

Growth and Development. As noted above, the serum Pi concentration is considerably higher in newborn infants and young children than in older children and adults. This finding is not due to a limitation of the immature kidney's ability to excrete Pi but rather reflects a higher rate of tubular Pi reabsorption in infants and immature animals, as demonstrated by their higher values for TmP/GFR compared with values in adults (399). In newborn animals as compared with adult animals, Pi reabsorption is greater, both in the early PCT and in more distal nephron segments, presumably the pars recta and segments beyond the DCT. In BBM vesicles, the Vmax for Na/Pi cotransport is higher in newborn than in adult guinea pigs, a finding that cannot be accounted for by differences in plasma Pi concentrations, ionized calcium, PTH, thyroxine, or calcitonin. The higher capacity for Pi reabsorption by the immature kidney also may reflect its relatively greater number of juxtamedullary nephrons, which have a higher

capacity to reabsorb Pi. Newborn animals demonstrate a blunted phosphaturic response both to Pi loading and to administration of PTH, the latter despite a normal increase in urine cAMP. In Pi restricted rats, the adaptive increase in Pi reabsorption is much greater in immature than in adult animals. Growth hormone may play an important role in mediating the increased renal reabsorption of Pi during development. Also, as noted above, the higher abundance of Npt2c mRNA and protein in the kidneys of young rats might contribute to their higher rate of Pi transport as compared to that in older animals (277). Thus, through a variety of mechanisms, Pi handling by the immature kidney is regulated such that Pi retention is promoted, presumably to meet the increased needs for Pi of the growing organism (399, 400).

Diuretic Agents. Although their mechanisms and sites of action differ, the following diuretic agents predictably induce phosphaturia: mannitol, acetazolamide, thiazide diuretics, and loop diuretics. Urine phosphorous excretion is little affected by amiloride, spironolactone, and triamterene (238).

11 Genetic Disorders of Calcium and Phosphate Homeostasis

Amita Sharma · Rajesh V. Thakker · Harald Jüppner

Introduction

The regulation of calcium and phosphate homeostasis involves several different hormones that act on the kidney, intestine, and bone. Parathyroid hormone (PTH) is the primary regulator of extracellular calcium ion concentration; while fibroblast growth factor 23 (FGF-23) is likely to be the most important regulator of extracellular phosphate concentration. In response to a decrease in the extracellular calcium concentration, secretion of PTH from the parathyroid glands is increased. PTH acts on the distal renal tubules to decrease excretion of calcium and it stimulates the production of the 1,25-dihydroxy vitamin D ($1,25(OH)_2D$) in the proximal tubules. The biologically active $1,25(OH)_2D$ in turn acts on the intestine to enhance the absorption of calcium and phosphorus. Together with PTH, this steroid hormone furthermore acts on the bone to increase the release of calcium and phosphorus into the extracellular fluid. PTH and $1,25(OH)_2D$ thus help maintain extracellular calcium concentration within the normal limits, but also increase the extracellular phosphorous concentration, which can be a problem, particularly in patients with chronic kidney disease. To limit the PTH- and $1,25(OH)_2D$-dependent increase in blood phosphorous level, PTH enhances the urinary excretion of phosphate by reducing the expression levels of two sodium-dependent phosphate co-transporters, NPT2a and NPT2c, in the proximal renal tubules.

Disorders with an abnormal regulation of calcium homeostasis can be classified according to whether they arise from an excess or deficiency of PTH, defect in the PTH-receptor (i.e., the PTH/PTHrP receptor), or insensitivity to PTH that is caused by defects down-stream of the PTH/PTHrP receptor. Recent advances in understanding the biological importance of key proteins involved in the regulation of PTH secretion and the responsiveness to PTH in target tissues has led to the identification of molecular defects in a variety of disorders, and thus have enabled the characterization of some of the mechanisms involved in the regulation of parathyroid gland development, parathyroid cell proliferation, PTH secretion, and PTH-mediated actions in target tissues.

Recent progress has also provided important new insights into the regulation of phosphate homeostasis. In particular, the molecular definition of rare inherited disorders of phosphate homeostasis has resulted in the identification and characterization of several proteins that contribute to the normal regulation of phosphate homeostasis; these include fibroblast growth factor 23 (FGF-23), phosphate-regulating protein with homologies to endopeptidases on the X chromosome (PHEX), dentin matrix protein 1 (DMP-1), FGF receptor 1c (FGFR1c), the longevity factor Klotho, the glycosyltransferase GALNT3 (which is responsible for initiating mucin-type O-linked glycosylation), and the two sodium-dependent phosphate co-transporters, NPT2a and NPT2c. In addition, proteins such as matrix extracellular phosphoglycoprotein (MEPE), soluble frizzled-related protein 4 (sFRP4), and FGF7 may have a direct or indirect role in the regulation of phosphate homeostasis. It remains largely unknown, however, whether and how the different phosphate-regulating proteins interact with each other. Furthermore, it is almost certain that additional molecules contribute to these regulatory events, and that molecular genetic studies will continue to be of pivotal importance for the identification of genes encoding novel regulators of phosphate homeostasis.

Regulators of Calcium and Phosphate Homeostasis

Parathyroid Hormone (PTH) and PTH-related Peptide (PTHrP)

The mature secreted form of PTH peptide comprises 84 amino acids, which is derived from a longer pre-pro peptide (for review see (1)). The gene encoding PTH gene is located on chromosome 11p15. PTH gene transcription (as well as PTH peptide secretion) is regulated by the extracellular concentration of calcium and phosphate

© Springer-Verlag Berlin Heidelberg 2009

(2, 3), and through a vitamin D response element upstream of the transcription start site (4, 5). After secretion, PTH is cleared from the circulation with a short half-life of about 2 minutes, via non-saturable hepatic and renal uptake (6).

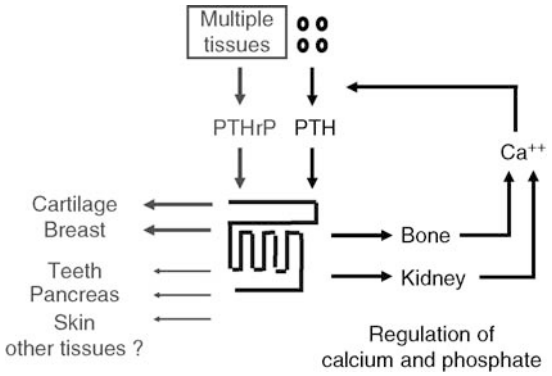
PTH secretion by the parathyroid glands is regulated through the calcium-sensing receptor (CaSR) and even small perturbations in blood calcium concentration lead to remarkable changes in PTH secretion. Besides being expressed in the chief cells of the parathyroid glands, the CaSR is expressed in the kidneys and in several other tissues, albeit at a lower abundance, which are not directly involved in the regulation of calcium homeostasis. In addition to regulating PTH secretion, the CaSR plays an important role in regulating renal divalent mineral transport by both direct and indirect mechanisms (7).

The PTH-related peptide (PTHrP also known as PTHrH, PTH-related hormone), which was first isolated from tumors that cause the humoral hypercalcemia of malignancy syndrome, shares significant amino acid sequence homology with PTH (8–10). The human PTHrP gene is located on chromosome 12p12.1–11.2, which is a region analogous to that containing the human PTH gene (11, 12). PTH and PTHrP, although distinct products of different genes, exhibit considerable functional and structural similarities, including equivalent positions of the boundaries between some of the coding exons and of the adjacent introns; both may have evolved from a shared ancestral gene (11, 12). PTHrP is a larger, more complex protein than PTH and it is synthesized in different organs and tissues. It functions as an autocrine/paracrine rather than an endocrine factor with a little influence on calcium homeostasis except when secreted in large concentrations (13). One of its most prominent functions is the regulation of chondrocyte proliferation and differentiation, and consequently of bone elongation and growth (14).

PTH and PTHrP both mediate their actions through a common receptor (15, 16) (*Fig. 11-1*). This PTH/PTHrP receptor is a member of a subgroup of G protein-coupled receptors; its gene is located on chromosome 3p21.3 (17, 18). The PTH/PTHrP receptor is abundantly expressed in the kidney and the bone, where it mediates the endocrine actions of PTH. However, the most abundant expression of the PTH/PTHrP receptor occurs in chondrocytes of the metaphyseal growth plate where it mediates predominantly the autocrine/paracrine actions of PTHrP, i.e., it delays the hypertrophic differentiation of growth plate chondrocytes (6, 14, 19). A second receptor, the PTH2 receptor, shares more than 50% homology with the PTH/PTHrP receptor (20). The human, but not the rodent PTH2 receptor is activated by PTH. The PTH2 receptor is not activated by PTHrP and its primary ligand is TIP39 (tubuloinfundibular peptide of 39 residues), appears to be involved in nocireception and reproduction (21–24).

Figure 11-1

Parathyroid hormone (PTH) mediates its endocrine actions through the PTH/PTHrP receptor expressed in the kidney and the bone to regulate mineral ion homeostasis and bone metabolism. In numerous other tissues, this G protein-coupled receptor mediates the paracrine actions of PTHrP; particularly important is its role in the growth plate.



Vitamin D and Its Metabolites

Most of the vitamin D in healthy individuals is derived via cutaneous synthesis by ultraviolet light from the precursor 7-dehydrocholestrol (25, 26). Vitamin D (D_2 and D_3) is a prohormone, which is stored in muscle or fat. It undergoes hydroxylation in the liver to form the 25-hydroxyvitamin D metabolite (25(OH) D). In the proximal convoluted tubular cells of the kidney, 25(OH)D is further hydroxylated by the enzyme 25-hydroxyvitamin D, 1α hydroxylase (1α hydroxylase) to yield the biologically active metabolite 1,25 dihydroxyvitamin D ($1,25(OH)_2D$) (25, 26). The activity of the 1α hydroxylase is regulated by extracellular concentrations of ionized calcium, inorganic phosphate, PTH, and FGF-23 (27). $1,25(OH)_2D$ binds in target organs (e.g., intestine, bones, kidneys and parathyroids) to the intracellular vitamin D receptor (VDR) (28), and thereby activates the transcription of genes in the bone, kidney and enterocytes that help increase gut absorption of calcium, reduce urinary calcium losses, and increase bone resorption, thereby ensuring adequate extracellular concentration of calcium and phosphate (26, 28). Mutations in the genes encoding the 1α hydroxylase and the VDR are associated with rickets (25, 26).

Fibroblast Growth Factor 23 (FGF-23) and Other Proteins with Phosphaturic Properties

Fibroblast growth factor 23 (FGF-23) belongs to a large family of structurally related proteins. Its role in the regulation of blood phosphorous homeostasis was first predicted when a positional cloning approach to determine the cause of autosomal dominant hypophosphatemic rickets (ADHR) led to the identification of several different, heterozygous mutations in the gene encoding FGF-23 (29). FGF-23 mRNA and protein were furthermore found to be markedly overexpressed in tumors that cause oncogenic osteomalacia, and in vivo findings indicated that this hormone promotes, either directly or indirectly, renal phosphate excretion (30, 31). The FGF-23 gene consists of 3 exons that encode a 251 amino acid precursor protein comprising a hydrophobic leader sequence (residues 1 through 24), thus allowing its secretion into the blood circulation (*Fig. 11-2*). FGF-23 protein undergoes O-linked glycosylation and it is proteolytically cleaved between Arg^{179} and Ser^{180} by the subtilisin-like proprotein convertase SPC2 (32); the intact FGF-23 appears to be the biologically active hormonal form (33).

FGF-23 is most closely related to fibroblast growth factors 21, 19, and 15, but shows limited homology also with other fibroblast growth factors (29, 31). FGF-23 mRNA could not be detected by Northern blot analysis in normal tissues, but it has been identified by reverse transcriptase (RT)-PCR in heart, liver, thymus, small intestine, and brain (29, 31). However, the most abundant expression of FGF-23 occurs in bone cells, particularly in osteocytes, which represent the largest population of bone cells (34–36). Its regulation remains not thoroughly understood, but recent studies in humans and mice that are null for DMP1 have suggested that this bone matrix protein reduces expression of FGF-23 (37, 38). However, the 57 kDa C-terminal fragment of DMP1 appears to be sufficient for this regulatory role (39).

In the presence of Klotho, a protein associated with longevity (40, 41), FGF-23 binds with high affinity to the FGFR1 splice variant FGFR1c (41, 42) (*Fig. 11-3*). Consistent with the role of Klotho in the regulation of phosphate homeostasis, mice that are "null" for Klotho develop severe hyperphosphatemia due to diminished urinary phosphate excretion. Furthermore, these animals show elevated 1,25 $(OH)_2D$ levels i.e., findings that are similar to those observed in the FGF-23-null mice (35, 36, 43). Distinct from the latter animals, however Klotho-null mice have dramatically elevated FGF-23 levels (42). In the absence of Klotho, FGF-23 can bind, albeit with low affinity, to several other FGF receptors, but the biological consequences of these interactions remain to be determined (44).

Mice receiving the recombinant FGF-23 intraperitoneally and nude mice transplanted with cell lines stably expressing FGF-23 develop hypophosphatemia due to increased urinary phosphate excretion, which is caused by a reduction in the expression of the sodium-dependent phosphate cotransporters NPT2a and NPT2c (31, 33, 45–48). PTH and FGF-23 thus have similar effects on the apical expression of these two important renal transporters, but the time courses of these hormonal effects appear to differ. Besides hypophosphatemia, animals with increased circulating FGF-23 levels show an increase in alkaline phosphatase activity, a marked increase of unmineralized osteoid, and a significant widening of growth plates leading to deformities of weight bearing bones. Furthermore, there is a

Figure 11-2

Schematic presentation of the FGF-23 precursor, which comprises a signal peptide for efficient secretion (amino acid residues 1–24; stripped area). The mature FGF-23 is glycosylated at amino acid residue 178 (and most likely other residues), and it undergoes cleavage at the RXXR through subtilisin-like protein convertases to generate fragments that appear to be devoid of phosphaturic activity.

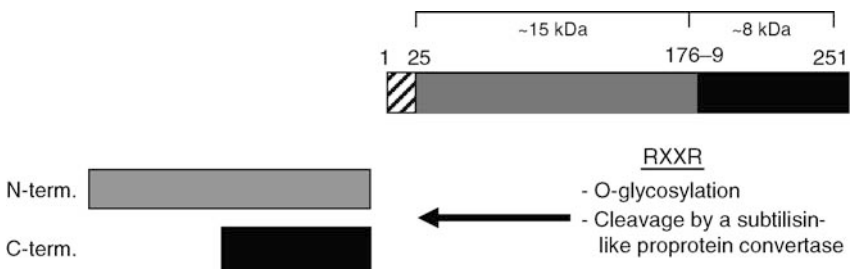


Figure 11-3

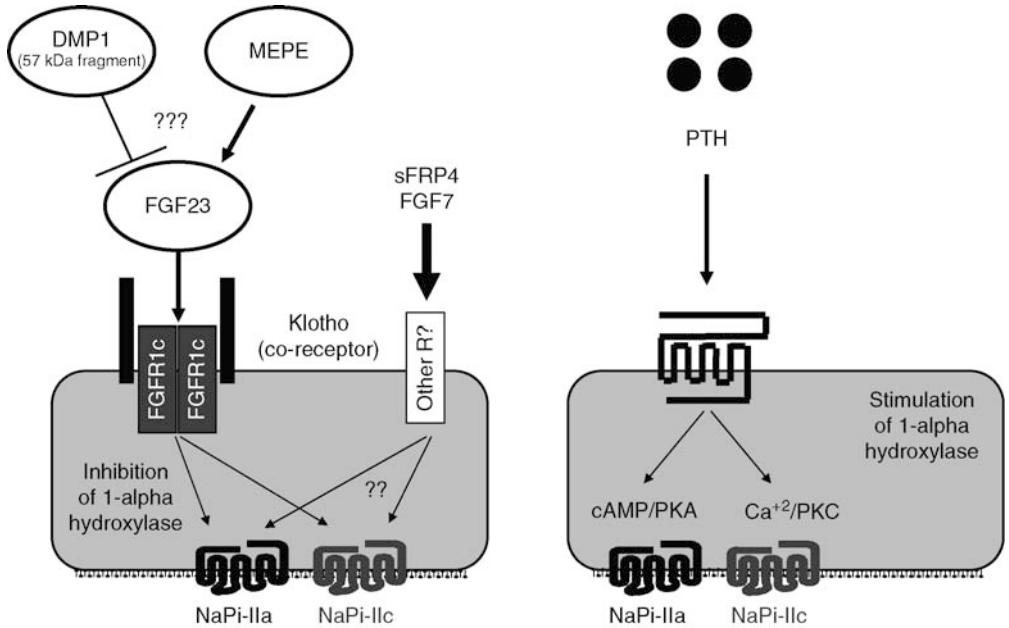
Production of fibroblast growth factor 23 (FGF-23) by osteocytes is regulated by matrix extracellular phosphoprotein (MEPE) and dentin matrix protein 1 (DMP1). Parathyroid hormone (PTH) is produced by the parathyroid glands. Both hormones activate their specific cognate receptors, FGFR1c with co-receptor Klotho and PTH/PTHrP receptor (PTHR1), respectively, on the proximal renal tubules to reduce the apical expression of the sodium-dependent phosphate co-transporters NaPi-IIa (NPT2a) and NaPi-IIc (NPT2c); PTH increases expression of the 1-alpha hydroxylase, while FGF-23 inhibits this mitochondrial enzyme. The potential role of other factors, such as soluble frizzled-related peptide 4 (sFRP4) and fibroblast growth factor 7 (FGF7), in the renal regulation of phosphate homeostasis remains to be investigated further.



FGF-23-dependent reduction in the activity of the 1-α hydroxylase in the proximal renal tubules leading to a reduction in serum $1,25(OH)_2D$ levels (49–51).

In contrast to the findings made in animals with increased FGF-23 levels, Fgf-23-null mice (*Fgf-23*$^{-/-}$) develop hyperphosphatemia and elevated serum $1,25(OH)_2D$ concentration, and they die prematurely, secondary to renal failure because of glomerular capillary calcifications (35, 43, 52). *Fgf-23*$^{-/-}$ animals furthermore show reduced bone turnover, an unexpected increase in osteoid, diminished osteoblast and osteoclast number and activity (43).

Besides FGF-23, MEPE, sFRP4, and FGF-7 were also shown to be overrepresented in cDNA libraries derived from tumors that cause oncogenic osteomalacia (53, 54). All three proteins have been implicated in phosphate handling in vivo and/or in vitro, suggesting that "phosphatonins" other than FGF-23, may be involved in the renal regulation of phosphate homeostasis; however, specific receptors mediating their actions have not yet been identified (54–56) (see *Fig. 11-3*).

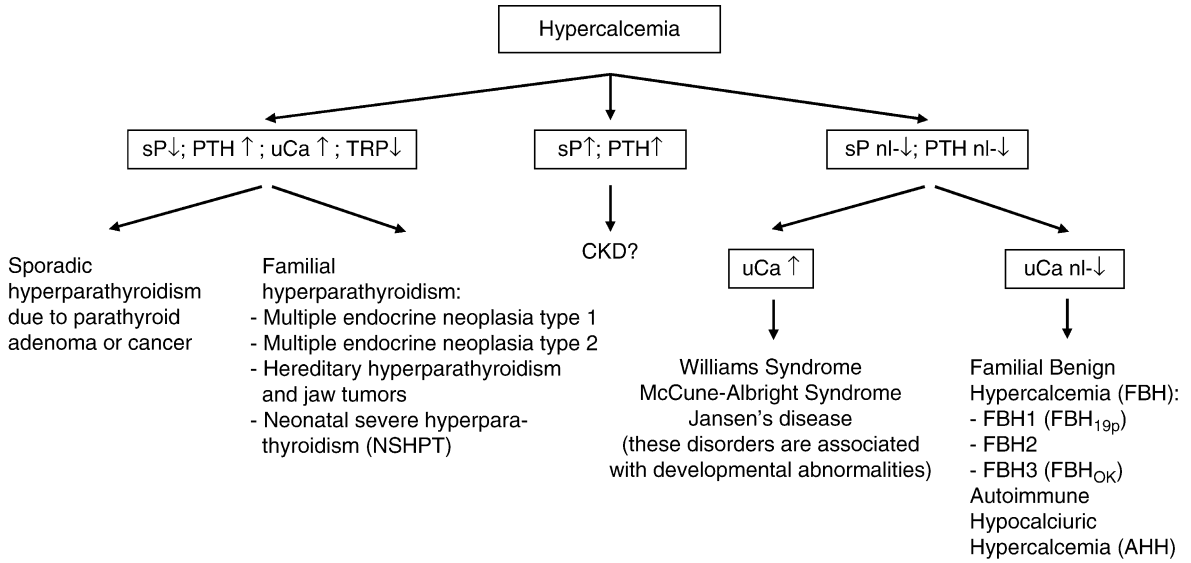
Hence to summarize, protein purification and molecular cloning techniques, and particularly the exploration of rare genetic disorders through positional cloning or candidate gene approaches have provided important new insights and unique molecular tools, which will help in determining the pathogenesis of common and uncommon disorders associated with an abnormal regulation of calcium and phosphate.

Hypercalcemia and Hypophosphatemia due to Increased Parathyroid Gland Activity

Hypercalcemia can be observed in several different sporadic or familial disorders, which requires besides physical examination and a careful review of the family history, the evaluation of several additional laboratory parameters (*Fig. 11-4*).

Figure 11-4

Flow-diagram for the work-up of patients with hypercalcemia.



In children, parathyroid tumors are rare (57), but as in adults two principal defects can lead to the development of parathyroid tumors: (1) a heterozygous mutation that enhances the activity of a gene (gain-of-function mutation), which is therefore referred to as a proto-oncogene, or (2) homozygous loss-of-function mutation in a tumor-suppressor gene, which is therefore referred to as a recessive oncogene. Parathyroid tumors usually occur as an isolated and sporadic endocrinopathy, or as part of inherited tumor syndromes (58) such as the multiple endocrine neoplasias (MEN) or hereditary hyperparathyroidism with jaw tumors (59, 60). Sporadic parathyroid tumors can be caused by single somatic mutations that lead to the activation or overexpression of proto-oncogenes such as PRAD1 (*pa*rathyroid *a*denoma *1*) or RET (mutations of which result in MEN2), or by mutations in tumor suppressor genes - predicted to be located on several different chromosomes, e.g., 1P, the location of RIZ1 and 11q13, which is the location of the MEN1 gene - that allow for the clonal expansion of a single parathyroid cell and its progeny (61) for detailed review of this topic in adults).

Chronic overstimulation of the parathyroid glands frequently occurs in patients with chronic kidney disease (CKD), which may lead to the development of tertiary hyperparathyroidism due to the clonal expansion of one or several parathyroid cells, as described for adults (62), through a process possibly involving the reduced expression of different cyclin-dependent kinase inhibitors (63). Furthermore, the development of hyperparathyroidism may be enhanced by frequently dramatically increased levels of circulating FGF-23, particularly in patients with CKD stage V. However, even in patients with earlier stages of CKD, FGF-23 levels can be elevated considerably, presumably due to intermittent hyperphosphatemia, leading to a reduction in $1,25(OH)_2D$ levels, which may contribute the development of secondary hyperparathyroidism and possibly the clonal expansion of some parathyroid cells (51, 64, 65). Recently, it was furthermore shown that FGF-23 can inhibit PTH secretion by normal parathyroid glands (66, 67), but it remains uncertain, why the dramatically elevated FGF-23 levels in CKD stage V cannot prevent the development of hyperparathyroidism.

PTH structural changes as the cause of hyperparathyroidism appear to be rare. However, recently an adult patient was reported, to have had hypercalcemia and hypophosphatemia, yet undetectable levels of PTH in the circulation. A single parathyroid adenoma was identified that secreted a mutant PTH molecule, which is truncated after amino acid residue 52, thus explaining why different two-side immunometric PTH assays had been unable to detect elevated circulating levels of this hormone (68). After surgical removal of the adenoma, clinical symptoms and biochemical abnormalities were resolved. These findings raise the question whether the lack of the C-terminal portion of PTH contributed to the development of the parathyroid adenoma and whether

this part of the molecule has unknown tissue-specific effects that remain to be characterized.

Hypercalcemic Disorders with Normal Parathyroid Gland Activity

Disorders of the Calcium-Sensing Receptor (CaSR)

CaSR is a G-protein coupled receptor located on chromosome 3q21.1 (69). Three hypercalcemic disorders are caused by mutations in the gene encoding the calcium-sensing receptor (CaSR) (70–76). There appears to be a gene-dosage effect associated with many of the inactivating CaSR mutations. Heterozygous mutations cause familial benign hypercalcemia (FBH), also referred to as familial hypocalciuric hypercalcemia (FHH), with mild hypercalcemia, while homozygous mutations result in neonatal severe hyperparathyroidism (NSHPT), a severe phenotype characterized by hypercalcemia early in life, bone demineralization and failure to thrive. Another form of hypocalciuric hypercalcemia is caused by acquired autoantibodies against the CaSR (AHH) and is associated with other autoimmune defects (see *Fig. 11-4*).

Familial Benign Hypercalcemia (FBH) and Neonatal Severe Hyperparathyroidism (NSHPT)

FBH may be inherited as an autosomal dominant trait, although patients may often not have a family history as they could have developed a *de novo* mutation. Affected patients are usually asymptomatic or have non-specific symptoms such as fatigue, weakness, painful joints and headache, and the diagnosis is often only suspected after a routine biochemical screening showing high calcium levels.

Mutational analyses of the humans have revealed different mutations that result in a loss-of-function of the CaSR in patients with FBH and NSHPT (70–75). Many of these mutations cluster around low affinity calcium-binding sites (that are similar to calsequestrin) containing aspartate- and glutamate-rich regions (codons 39–300) within the extracellular domain of the receptor (76, 77). Extracellular calcium has a steep inverse sigmoidal relationship to PTH secretion; the 'set point' of parathyroid cells is defined as the calcium concentration at which PTH secretion is half-maximal. Approximately two thirds of the affected members of investigated FBH kindreds were found to have unique heterozygous mutations that cause a loss of CaSR function thus increasing the set point (70, 75, 78, 79). Patients with severe neonatal hyperparathyroidism usually have homozygous or compound heterozygous CaSR mutations that are inactivating. However, recently a novel heterozygous mutation (F180C, TTC > TGC) was described in exon 4 of the CaSR gene, which led in the affected individuals to symptomatic hyperparathyroidism, yet low urinary calcium excretion. Vitamin D deficiency was documented in these patients, which probably impaired CaSR expression, thus leading to increased PTH secretion; consistent with this conclusion, vitamin D supplements resulted in the normalization of PTH levels (80). Another CaSR mutation (L137P) previously identified in FBH families was recently found to be involved in the development of chronic pancreatitis, when combined with a mutation (N34S) in the pancreatic secretory trypsin inhibitor gene (*SPINK1*). In fact, numerous patients with chronic pancreatitis, who carry the N34S mutation in *SPINK1,* were found to also have CaSR mutations suggesting that mutations in the latter gene can increase the susceptibility for pancreatitis (81).

Some FBH families in whom a mutation within the coding region of the CaSR could not be demonstrated may either have an abnormality in the promoter of the gene or a mutation at one of the other two FBH loci that have been revealed by family linkage studies. One of these FBH loci is located on chromosome 19p and is referred to as FBH_{19p}. Studies of another FBH kindred from Oklahoma that also suffered from progressive elevations in PTH, hypophosphatemia and osteomalacia (82, 83) demonstrated that this variant, designated FBH_{OK}, was linked to chromosome 19q13 (84). Numerous different CaSR mutations related to FBH, NSHPT, or ADH or to *de novo* disease have been reported (188 missense, 17 nonsense, six insertion and/or deletion, one silent and one splice mutation) (for more details see: *http://www.casrdb.mcgill.ca*).

NSHPT occurring in the offspring of consanguineous FBH families has been shown to be due to homozygous CaSR mutations that usually result in a complete loss of CaSR function causing severe hypercalcemia due to parathyroid bone disease within the first 6 months of life, often necessitating parathyroidectomy (70, 71, 73, 85–87). Infants with NSHPT may exhibit polyuria, dehydration, hypotonia, and failure to thrive (88). However, some patients with sporadic neonatal hyperparathyroidism have been reported to carry *de novo* heterozygous CaSR mutations (72), thereby suggesting the involvement of factors other than mutant gene dosage (85). A novel heterozygous *de novo* mutation (R551K) was shown recently to

cause NSHPT, which gradually reverted to asymptomatic FBH without the need for surgical intervention (89).

Autoimmune Hypocalciuric Hypercalcemia (AHH)

Some patients with clinical features of FBH, who lack CaSR mutations, may have AHH, which is an acquired disorder with circulating antibodies to the extracellular domain of the CaSR. Some of these antibodies stimulate the release of PTH when tested with dispersed human parathyroid cells in vitro, probably by inhibiting the activation of the CaSR by extracellular calcium (90). For patients, in particular who have hyperparathyroidism in combination with other autoimmune disorders, AHH should be considered (90, 91). Such an autoimmune PTH-dependent hypercalcemia was initially described in four individuals from two unrelated kindreds. Of these, three patients had anti-thyroid antibodies and one had celiac sprue with anti-gliadin and anti-endomyseal antibodies (90).

Recently, an IgG4 blocking autoantibody against CaSR has been isolated and reported to cause AHH, which is phenotypically similar to familial hypocalciuric hypercalcemia but is not associated with any mutations in the CaSR gene. The autoantibody inhibits CaSR signaling pathways, inositol phosphate (IP) accumulation and ERK phosphorylation, by binding to specific CaSR sites. AHH patients with this antibody presented with autoimmune dysregulation, including psoriasis, adult-onset asthma, Coombs-positive hemagglutination, rheumatoid arthritis, ureitis and autoimmune hypophysitis and symptoms regressed following glucocorticoid treatment. These findings suggested that the blocking autoantibody against CaSR was in fact responsible for the AHH in this patient (91).

CaSR is known to activate two signal transduction mechanisms, the phospholipase C and ERK1/2 phosphorylation pathways dependent on Gq and Gi coupling respectively. An autoantibody, isolated from a patient with AHH, was shown to enhance calcium-stimulated IP accumulation but inhibited calcium-stimulated ERK1/2 phosphorylation, suggesting that the CaSR when incubated with the patient's autoantibody adopts a distinct active conformation favoring coupling to Gq and uncoupling from Gi. This autoantibody did not interact with representative epitopes in the N-terminal domain of the CaSR, but shifted the concentration-response curve for Ca^{2+} to the left indicating that it causes allosteric changes at a site in close proximity to the binding site for calcimimetics and requires Ca^{2+} for its effect (92).

Jansen's Metaphyseal Chondrodysplasia (JMC)

JMC is an autosomal dominant disease that is characterized by short-limbed dwarfism caused by an abnormal regulation of chondrocyte proliferation and differentiation in the metaphyseal growth plate (*Fig. 11-5*), and associated usually with severe hypercalcemia and hypophosphatemia, despite normal or undetectable serum levels of PTH or PTHrP (93). These abnormalities are caused by heterozygous mutations in the PTH/PTHrP receptor that lead to constitutive, PTH- and PTHrP-independent receptor activation (94–96). Since the PTH/PTHrP receptor is most abundantly expressed in the kidney and the bone, and in the metaphyseal growth plate, these findings provided a likely explanation for the abnormalities observed in mineral homeostasis and for the associated defects in the growth plate

Figure 11-5

Patient with a severe form of Jansen's metaphyseal chondrodysplasia. (From Frame and Poznanski (370), with permission).

development. Three different, heterozygous mutations of the PTH/PTHrP receptor have been identified in the severe form of JMC; these involve codon 223 (HisArg), codon 410 (Thr→Pro), and codon 458 (Ile→Arg). Expression of the mutant receptors in COS-7 cells resulted in constitutive, agonist-independent accumulation of cAMP, while the basal accumulation of inositol phosphates was not measurably increased; the H223R mutation appears to be the most frequent cause of JMC (94–96). Transgenic mice in which expression of a PTH/PTHrP receptor carrying the H223R mutation was targeted to the growth plate by the rat alpha1(II) collagen promoter showed a significant delay in chondrocyte differentiation supporting the conclusion that the defect in endochondral bone formation in JMC patients is caused by the constitutively active mutant receptor (97). The slowed differentiation of growth plate chondrocytes was associated with an upregulation of cyclin- and E2F-dependent gene expression, indicating that the PTH/PTHrP receptor controls the timing of cell cycle exit and the onset of differentiation of chondrocytes (98). Another heterozygous PTH/PTHrP receptor mutation, Thr410Arg, was recently identified in a small Middle Eastern kindred, in which the three JMC patients showed less pronounced skeletal and laboratory abnormalities than previously described individuals affected by this disease, i.e., only mild skeletal dysplasia and relatively normal stature, high-normal plasma calcium concentration associated with normal or suppressed serum PTH levels and with hypercalciuria leading to nephrolithiasis in two individuals (*Fig. 11-6*) (99). In comparison to PTH/PTHrP receptors with the Thr410Pro mutation, the Thr410Arg mutation showed less pronounced agonist-independent cAMP accumulation in vitro (95, 100).

Williams Syndrome

Williams syndrome (WS) (also referred to as Williams-Beuren Syndrome, WBS) is an autosomal dominant disorder characterized by supra-valvular aortic stenosis, hypertension, elfin-like faces, psychomotor retardation and occasionally infantile hypercalcemia. It can be caused by different hemizygous deletions involving 25–30 genes on chromosome 7q11.23. Genetic analyses in four familial and five sporadic cases of WS have demonstrated hemizygosity at the elastin locus in over 90% of patients with the classical Williams phenotype (101), and a series of 235 WS patients revealed submicroscopic deletions detectable by FISH involving the elastin gene in 96% of the investigated individuals (102); however, the presence of two copies of the elastin locus does not exclude WS (103). Interestingly, ablation of the elastin gene in mice results in vascular abnormalities similar to those observed in WS patients (104). Other microdeletions were identified genes that are expressed in the central nervous system, including LIM-kinase (105), the cytoplasmic linker protein-115 (CYLN2), and the transcription factors GTF2I and GTF2IRD1(106), and these may well contribute to some of the distinct neurological and cognitive deficits observed in WS patients. In addition, aneuploid neighboring genes some of which are located several megabases away from the deletion, may contribute to the phenotypic variation observed in WS patients (107, 108). Moreover, deletion of *NCF1* may protect against hypertension by reducing angiotensin II-mediated oxidative stress (109). This gene encodes the p47 (phox) subunit of the NADPH oxidase and is involved in superoxide anion production and protein nitrotyrosination. Hypercalcemia during infancy occurs in about 15% of the children with WS. Although it is clinically not severe in most cases, some affected individuals require therapeutic interventions with bisphosphonates (110). The calcitonin receptor gene, located on chromosome 7q21, is not involved in the deletions identified in WS (111). It is therefore likely that the hypercalcemia observed in some WS patients is caused by another as yet unknown gene within the contiguously deleted region.

Hypocalcemia and Hyperphosphatemia due to Reduced Parathyroid Hormone Activity

As for hypercalcemic disorders, patients who present with hypocalcemia require careful clinical evaluation, as well as the assessment of laboratory parameters in serum and urine, and a detailed review of the family history (*Fig. 11-7*).

Hypoparathyroidism

Hypoparathyroidism comprises a heterogeneous group of disorders, which includes both acquired and inherited causes, each presenting clinically with hypocalcemia. Idiopathic hypoparathyroidism may be sporadic or familial, and it may occur as an isolated defect or as a component of a disorder with additional manifestations, such as pluriglandular autoimmune disorder or various developmental abnormalities, e.g., DiGeorge syndrome

Figure 11-6

Radio- and photographs of patients with a relatively mild form of Jansen's disease (From Bastepe et al. (99), with permission).

(DGS). However, for the majority of hypoparathyroid patients no genetic mutation has yet been identified.

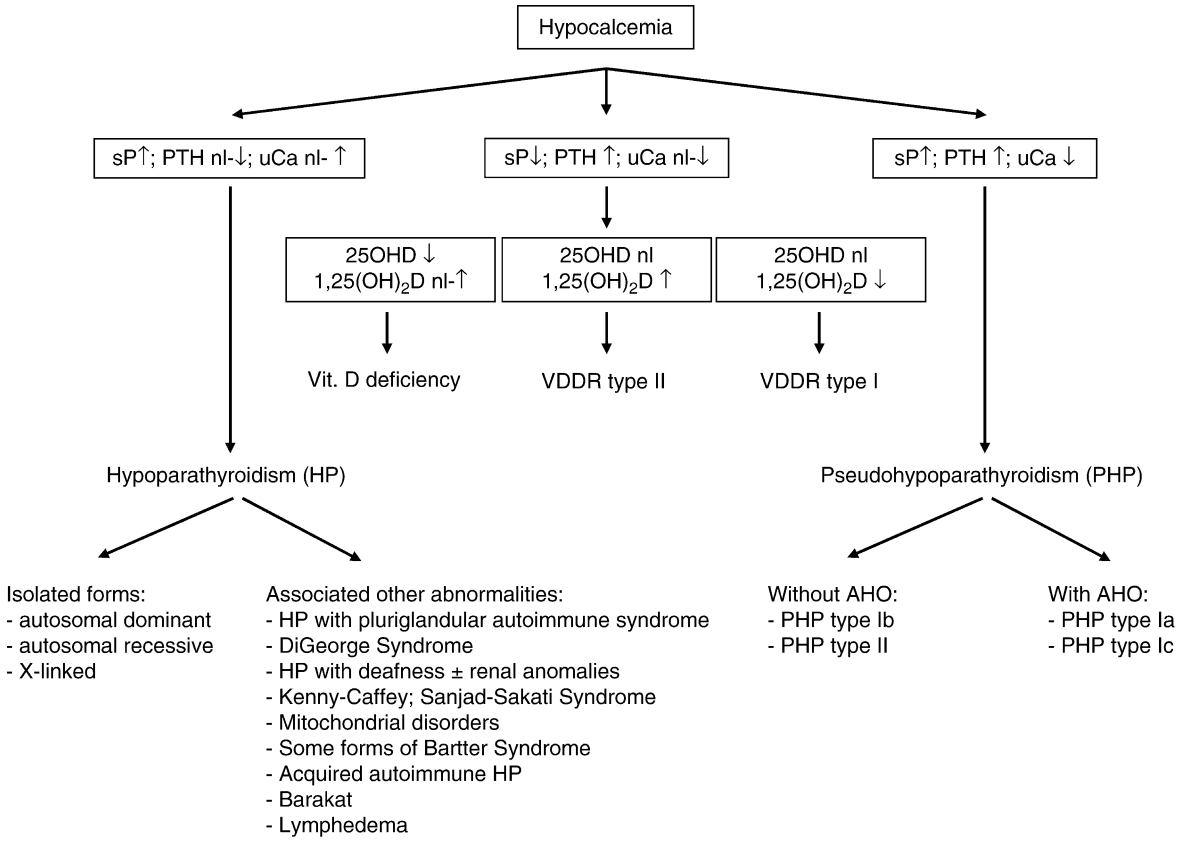
Parathyroid Hormone (PTH) Gene Abnormalities

Preproparathyroid hormone (preproPTH), the PTH precursor, contains a typical 25-residue amino-terminal signal sequence followed by a 6-residue pro-specific peptide and the mature hormone. The hydrophobic core of the human preproPTH signal peptide is composed of 12 contiguous uncharged amino acids (residues -5 to -16 of the signal peptide).

The coding regions, 5′ flanking regions, and splice junctions of the gene encoding PTH were sequenced in a patient with autosomal dominant familial isolated hypoparathyroidism (FIH). The mutant allele differed from the normal allele at only one nucleotide. This single base substitution (T→C) resulted in the substitution of

Figure 11-7

Flow-diagram for the work-up of patients with hypocalcemia.



arginine (CGT) at position 18 in the signal peptide for cysteine (TGT) thus disrupting the hydrophobic core of the signal sequence, which is required by the secreted proteins for efficient translocation across the endoplasmic reticulum. The charged mutant protein showed impaired processing from preproPTH to proPTH (112). Another patient with FIH was shown to have a single point mutation at the -8 position of the signal peptide changing a cysteine to an arginine. The mutant protein interfered with the normal targeting and processing of other secretory proteins, including the normal PTH precursor, suggesting that the mutant gene product exerts a dominant negative effect in vitro by trapping the hormone intracellularly, predominantly in endoplasmic reticulum (ER) (113), thereby causing stress-induced cell death (114). In another family, a single base substitution (T→C) involving codon 23 of exon 2 was detected. This resulted in the substitution of proline (CCG) for the normal serine (TCG) in the signal peptide (115). This mutation at the –3 position of the preproPTH protein cleavage site most likely disrupts cleavage of the mutant precursor molecule and prevents the efficient formation and secretion of PTH (115). The affected individuals of one other kindred with autosomal recessive, isolated hypoparathyroidism showed a single base transition (G→C) at position 1 of intron 2 of the gene encoding PTH. This mutation resulted in the deletion of exon 2, which encodes the initiation codon and the signal peptide, thereby causing parathyroid hormone deficiency (116).

GCMB Abnormalities

GCMB (*g*lial *c*ells *m*issing B), which is the human homologue of the Drosphilia gene Gcm, and of the mouse Gcm2 gene, is expressed exclusively in the parathyroid glands, suggesting that it may be a specific regulator of parathyroid gland development (117). Mice that were homozygous (−/−) for deletion of Gcm2 lacked parathyroid glands and developed the hypocalcemia and hyperphosphatemia as observed in hypoparathyroidism. However, despite their lack of parathyroid glands, Gcm2 deficient (−/−) mice did not have undetectable serum

PTH levels, but instead had levels indistinguishable from those of normal (+/+, wild-type) and heterozygous (+/−) mice. However, this endogenous level of PTH in the Gcm2 deficient (−/−) mice was too low to correct the hypocalcemia, but exogenous continuous PTH infusion could correct the hypocalcemia (117). Interestingly, there were no compensatory increases in PTHrP or $1,25(OH)_2$ vitamin D_3. These findings indicate that Gcm2 mice have a normal response (and not resistance) to PTH, and that the PTH in the serum of Gcm2 deficient mice was active. The auxillary source of PTH was identified to be a cluster of PTH-expressing cells under the thymic capsule. These thymic PTH-producing cells also expressed the CaSR, and long-term treatment of the Gcm2 deficient mice with $1,25(OH)_2$ vitamin D_3 restored the serum calcium concentrations to normal and reduced the serum PTH levels, thereby indicating that the thymic production of PTH can be down-regulated.

The gene encoding the human homolog of mouse Gcm2, namely *GCMB*, is located on chromosome 6p23–24. A large homozygous intragenic *GCMB* deletion was identified in the proband of extended kindred with an autosomal recessive form of isolated hypoparathyroidism (118). In addition, a homozygous mutation consisting of the substitution a glycine residue with a serine at position 63 (G63S) in the DNA binding domain of GCMB has been described; this mutation appears to cause a loss of transactivation capacity and was associated with some residual hormone secretion (119). Another homozygous GCMB mutation changes arginine at position 47 to leucine, which reportedly leads to the disruption of GCMB binding to the DNA binding site (120).

More recently, two closely related, heterozygous GCMB mutations were identified in two families in which hypoparathyroidism follows an autosomal dominant mode of inheritance (121, 122). Both mutations lead to a shift in the open reading frame and the replacement of a putative transactivation domain within carboxyl-terminal region by unrelated amino acid sequence, and both mutant proteins have a dominant negative effect on the wild-type GCMB protein. For a large number of patients with isolated hypoparathyroidism, however, no disease-causing mutation has yet been identified (123) making it likely that mutations in additional, as-of-yet unidentified genes can also cause hypoparathyroidism.

Anomalous expression of GCMB by some nonparathyroid cancers may be necessary for maintenance of the differentiated phenotype that allows sustained ectopic production of PTH. Intrathymic parathyroid adenomas that express GCMB are more likely to be derived from true parathyroid cells rather than from thymic epithelial cells as the thymus in humans does not serve as an auxiliary source of PTH, which is different from the findings in mice (124). Furthermore, GCMB expression was dramatically elevated in a parathyroid adenoma expressing a mutant PTH that is truncated after amino acid residue 52 (68). Conversely, compared to the findings in parathyroid adenoma, hyperplasia, and cancer, GCMB mRNA expression was lower in normal parathyroid glands and GCMB mRNA expression was down-regulated by lowering the extracellular calcium concentration (125). These findings indicate that the transcription factor GCMB may be directly or indirectly involved in mediating the effect of calcium on parathyroid hormone expression and/or secretion.

X-Linked Recessive Hypoparathyroidism

X-linked recessive hypoparathyroidism has been reported in two related multigenerational kindreds (126, 127). Relationship of these two kindreds was established by demonstrating an identical mitochondrial DNA sequence, inherited via the maternal lineage, in the affected males from both families (128). Affected males suffered from infantile onset of epilepsy and hypocalcemia (129). Linkage studies utilizing different X-chromosomal polymorphic markers localized the mutant gene to chromosome Xq26-q27 (130). This region mapped a 906-kb region on Xq27 that contains 3 genes (ATP11C, U7snRNA, and SOX3) but had no mutations were revealed. Further analysis of this region identified a novel molecular deletion – insertion [del(X) (q27.1) inv ins (X; 2) (q27.1; p25.3)], which involves a loss of 23–25 kb of noncoding Xq27.1 sequence and an inverted insertion of 305–340 kb from chromosome 2p25.3 to Xq27 and is approximately 67 kb downstream of SOX3 in X-linked recessive HPT patients resulting in an effect on the position on SOX3 expression. SOX3 may have a role in the embryonic development of the parathyroid glands. Identification of this deletion-insertion highlights the important role for genetic abnormalities that involve non-coding regions in causing disease, a feature that is likely to be of significance in the search for the molecular basis of other Mendelian inherited diseases for which coding region abnormalities have not been identified (131).

Autoimmune Pluriglandular Hypoparathyroidism Type 1 (APS1)

Autoimmune pluriglandular syndrome type 1 (APS1) or autoimmune polyendocrinopathy candiasis ectodermal

dystrophy (APECED) is an autosomal recessive disease with a high incidence in isolated subpopulations in Central and Eastern Finland (132). The diagnosis requires the presence of at least two of the three major components: hypoparathyroidism, candidiasis, and adrenal insufficiency. Hypoparathyroidism may, however, be the only manifestation of the syndrome. Data from 68 patients from 54 families in Finland reported hypoparathyroidism in 54 patients (79%) (133). In addition, the disorder has been reported to have a high incidence among Iranian Jews, although the occurrence of candidiasis is less common in this population (134).

Linkage studies of Finnish families mapped the APECED gene to chromosome 21q22.3 (135). Further positional cloning approaches led to the identification of AIRE (Auto Immune Regulator), a novel gene on chromosome 21q22.3 which encodes a 545 amino acid protein. Specific domains of AIRE protein indicate that it is involved in transcriptional processes, these domains include: (1) an amino-terminal HSR domain, (2) a nuclear localization signal (NLS), (3) a SAND domain, (4) two plant homeodomain (PHD) type zinc fingers, and (5) four LXXLL motifs (136). To date, more than 50 different APS1-causing mutations have been established in affected patients. The mutations are distributed throughout the coding region of the gene. Most of the mutations are, however, located in the amino-terminal HSR domain. The R257X mutation in SAND domain is the most prevalent mutation among Finnish patients, accounting for 83% of disease alleles (136–138). This particular mutation is also frequently found in Central and Eastern European and Northern Italian populations, indicating an early introduction of the mutation into Caucasian populations (137, 139). Another frequent mutation, the 979del13 bp is the most common mutation in North American, British and Norwegian APS1 patients (140–142). The Y85C mutation is typical for Iranian Jews (143) and R139X is found among Sardinian APS1 patients (144).

AIRE has been shown to regulate the elimination of organ-specific T cells in the thymus, and thus APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T cells, and thus failure to establish immunologic tolerance (145) by disrupting nuclear organization (146). In an Italian kindred with a unique G228W variant in the SAND domain, an autosomal dominant effect was documented. [G228]AIRE appeared to inhibit wild-type AIRE from reaching the sites of active transcription in medullary thymic epithelial cells. This resulted in a failure to delete T cells reactive against antigens specific for the thymus leading to autoimmunity. Thus, the AIRE mediated dominant negative effect may cause autoimmune predisposition to phenotypes distinct from APS (147). Further, in APS1 patients with hypoparathyroidism activation of the CaSR by antibodies directed to this receptor can decrease PTH secretion leading to hypocalcaemia (148). The NACHT leucine-rich-repeat protein 5 (NALP5), which is predominantly expressed in the cytoplasm of parathyroid chief cells, is the other autoantigen, and antibodies against this protein may be responsible for hypoparathyroidism. For NALP5-specific autoantibodies were detected in almost half of the patients with APS1 and hypoparathyroidism, but were absent in all APS1 patients without hypoparathyroidism (149). As the APS1 syndrome arises from a loss-of-function in the AIRE gene, mutations can be scattered throughout the entire gene and over 50 mutations in the gene have been described in APS1 subjects (150) therefore identification of the causative mutation in an individual patient may require the labor intensive process of sequencing the entire gene. Recently, high titer neutralizing IgG autoantibodies were found reactive to most IFN-α subtypes in 76 Scandinavian APS1 patients with high specificity for those patients with known AIRE mutations. APS1-specific high-titer neutralizing autoantibodies against type I interferons were also found in 100% of Finnish and Norwegian patients, who carry two prevalent AIRE truncations (151). These antibodies can be used as an additional criteria to establish the diagnosis of APS1 (152).

DiGeorge Syndrome

DiGeorge syndrome (DGS) is associated with a spectrum of malformations, including absence or hypoplasia of the thymus and the parathyroid glands, cardiovascular anomalies, and mild craniofacial dysmorphia (153). Most DGS cases that result from deletion of 22q11.2 are designated DGS type 1 (DGS1) (154). In some patients, deletions of another locus, which resides on chromosome 10p have been observed in association with DGS (155) and this syndrome is now referred to as DGS type 2 (DGS2). Approximately 17% of patients with the phenotypic features of DGS have no detectable genomic deletion (156). Mapping studies of the DGS1 deleted region on chromosome 22q11.2 have defined a 250 kb to 3,000 kb critical region that contains approximately 30 genes (157, 158). Studies of DGS1 patients have reported deletions of several of the genes (e.g., rnex40, nex2.2 – nex 3, UDFIL and TBX1) from the critical region (154, 159–161) and ablation of some genes in mice. (e.g., Udf1l, Hira and Tbx1) are associated with developmental abnormalities

of the pharyngeal arches (162–164). Interestingly, mice with deletion of Tbx1 have a phenotype that is similar to that of DGS1 patients (164). However, point mutations in DGS1 patients have only been detected in the TBX1 gene (165), which is therefore considered to be the gene causing DGS1 (166). TBX1, a DNA binding transcriptional factor of the T-Box family, has an important role in organogenesis and pattern formation. Tbx1-null mutant mice ($Tbx1^{-/-}$) had all the developmental anomalies of DGS1 (i.e., thymic and parathyroid hypoplasia; abnormal facial structures and cleft palate; skeletal defects; and cardiac outflow tract abnormalities), whilst Tbx1 haploinsufficiency ($Tbx1^{+/-}$) was associated only with defects of the fourth brachial pouch (i.e., cardiac outflow tract abnormalities). The spectrum of DGS1 malformations is thus elicited in a dose-dependent manner (167), suggesting that the Tbx1 dose, modified by specific genes, may cause the phenotypic variability observed in VCFS/DGS patients. Mice that are null for these modifying genes have similar defects as those observed in $Tbx1^{-/-}$ mutant animals (168).

Tbx1 is expressed in the ectoderm, mesoderm, and endoderm. In the mesoderm, Tbx1 activates the different members of fibroblast growth factor family as well as Pitx 2, a bicoid homeobox gene, which is co-expressed with Tbx1 in the secondary heart field and is required for establishing right-left asymmetry. $Pitx2^{+/-}$; $Tbx1^{+/-}$ double heterozygous embryos showed cardiovascular defects, albeit with reduced penetrance. Gbx2, a homeobox-containing transcription factor activated by Tbx1, interacts with Fgf8 during pharyngeal arch and cardiovascular development (169). In addition, Tbx1 together with Crkl negatively regulates activation of retinoic acid signaling pathways in all three germ cell layers. The gene encoding Crkl is located within the deletion DGS1 region. It encodes an adaptor protein of different activated Fgf8-Fgf receptor complexes, which enhances intracellular signaling in response to Fgf8 (170, 171). $Crkl^{+/-}$; $Fgf8^{+/-}$ mice have DGS1-related defects and compound heterozygosity for the loss of *Crkl* and *Tbx1* resulting in increased penetrance and expressivity of DGS1-related defects compared with $Tbx1^{+/-}$ or $Crkl^{+/-}$ mice (172). Furthermore, $Tbx1^{+/-}$; $Fgf8^{+/-}$; $Crkl^{+/-}$ triple heterozygous mice have more severe defects than double heterozygous mutants.

Genetic manipulation of retinaldehyde dehydrogenase 2 (RALDH2), a member of aldehyde dehydrogenase family, which converts retinaldehyde into retinoic acid were performed in mice. These experiments showed that animals carrying one hypomorphic allele of this enzyme and one null allele for RALDH2 ($Raldh2^{neo/-}$) also display the DGS1 phenotype (173). Retinoic acid effects the expression of Tbx1 and thus regulates the expression of Fgf8. Further, reducing retinoic acid signaling in $Tbx1^{+/-}$; $Crkl^{+/-}$ mice reduced the penetrance of thymic hypoplasia. Other genetic modifiers of DGS1 region are sonic hedgehog (Shh) and chordin. Shh binds to an upstream regulatory region in the Tbx1 locus (174) and it regulates Tbx1 expression through Fox family of transcription factors whereas chordin causes decreased expression of Tbx1and Fgf8 in the endoderm. Vascular endothelial growth factor (Vegf) has an important role in vasculogenesis and angiogenesis and mice expressing the $Vegf^{120/120}$ isoform exhibit DGS1-related cardiovascular malformations by reducing Tbx1 expression (175). Inactivation of transforming growth factor beta (Tgf-ß) by conditional inactivation of Tgf-ß receptor type II gene also resulted in DGS1-related defects by affecting Crkl phosphorylation in neural crest cells (176).

Individuals with 22q11.2 microdeletions show behavioral and cognitive defects and are at high risk of developing schizophrenia. An engineered mouse strain (Df(16)$A^{+/-}$) carrying a hemizygous 1.3 Mb chromosomal deletion spanning a segment syntenic to human 22q11.2 locus had abnormal brain structure and microRNA expression (177). Initially, prepulse inhibition (PPI) deficits caused by Tbx1 and *Gnb1l* haploinsufficiency has been reported in Df1/+ mice and in the affected members of a family with major depression and Asperger syndrome (178). In addition, altered expression of several 22q11 mitochondrial genes, particularly during early post natal cortical development may disrupt neuronal metabolism or synaptic signaling (179, 180).

Hence to summarize, most DGS1 patients have the same 1.5–3 Mb hemizygous deletion of chromosome 22q11.2. Loss of the *Tbx1* gene in the deleted region is likely to be responsible for the etiology of the syndrome. However, despite having the same size deletion, most patients exhibit significant clinical variability secondary to stochastic, environmental and genetic modifiers.

Hypoparathyroidism, Deafness and Renal Anomalies (HDR) Syndrome

The combined inheritance of hypoparathyroidism, deafness and renal dysplasia (HDR) as an autosomal dominant trait was reported in one family in 1992 (181). Patients had asymptomatic hypocalcemia with undetectable or inappropriately normal serum concentrations of PTH, and normal brisk increases in plasma cAMP in response to the infusion of PTH. The patients also had bilateral, symmetrical, non-progressive sensorineural

deafness involving all frequencies. The renal abnormalities consisted mainly of bilateral cysts that compressed the glomeruli and tubules, and lead to renal impairment in some patients. Cytogenetic abnormalities were not detected and abnormalities of the PTH gene were excluded.

However, cytogenetic abnormalities involving chromosome 10p14–10pter were identified in 2 unrelated patients with features that were consistent with HDR. These 2 patients suffered from hypoparathyroidism, deafness, and growth and mental retardation; one patient also had a solitary dysplastic kidney with vesicoureteric reflux and a uterus bicornis unicollis and the other patient, who had a complex reciprocal, insertional translocation of chromosomes 10p and 8q, had cartilaginous exostoses. Neither of these patients had immunodeficiency or heart defects, which are key features of DGS2 (see above), and further studies defined two non-overlapping regions; thus, the DGS2 region was located on 10p13–14 and HDR on 10p14–10pter. Deletion mapping studies in two other HDR patients further defined a critical 200 kb region that contained GATA3 (182), which belongs to a family of zinc-finger transcription factors that are involved in vertebrae embryonic development. DNA sequence analysis in other HDR patients identified mutations that resulted in a haploinsufficiency and loss of GATA3 function (182–184). GATA3 has 2 zinc-fingers, and the C-terminal finger (ZnF2) binds DNA, whilst the N-terminal finger (ZnF1) stabilizes this DNA binding and interacts with other zinc finger proteins, such as the Friends of GATA (FOG) (185). HDR-associated mutations involving GATA3 ZnF2 or the adjacent basic amino acids were found to result in a loss of DNA binding, whilst those involving ZnF1 either lead to a loss of interaction with FOG2 ZnFs or altered DNA binding affinity (184). These findings are consistent with the proposed 3-dimensional model of GATA3 ZnF1, which has separate DNA and protein binding surfaces (184, 186, 188, 189, 190, 191). Electrophoretic mobility shift assays (EMSAs) revealed three classes of GATA3 mutations: those that lead to a loss of DNA binding (over 90% of all mutations); those that lead to a loss of the carboxylterminal zinc finger and result in reduced DNA-binding affinity; and those (e.g., Leu348Arg) that do not alter DNA binding or the affinity but likely induce conformational change in GATA3 (191). No mutations were identified in patients with isolated hypoparathyroidism indicating that GATA3 abnormalities are more likely to result in two or more of the phenotypic features of the HDR syndrome and not in isolated disease affecting only the regulation of calcium homeostasis (191).

The HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle and parathyroids. However, GATA3 is also expressed in the developing central nervous system (CNS) and the haematopoietic organs in man and mice, and this suggests that GATA3 may have a more complex role. Indeed, homozygous GATA3 knockout mice have defects of the CNS and a lack of T-cell development. The heterozygous GATA3 knockout mice were initially reported to have no abnormalities (187). However, further studies have revealed that the latter mice have hearing loss that is associated with cochlear abnormalities, which consist of a significant progressive morphological degeneration that starts with the outer hair cells at the apex and eventually involves all the inner hair cells, pillar cells and nerve fibres (187a, 187b). These studies have shown that hearing loss in GATA3 haploinsufficiency commences in the early postnatal period and is progressive through adulthood, and that it is peripheral in origin and is predominantly due to malfunctioning of the outer hair cells of the cochlea (187a, 187b). It is important to note that HDR patients with GATA3 haploinsufficiency do not have immune deficiency, and this suggests that the immune abnormalities observed in some patients with 10p deletions are most likely to be caused by other genes on 10p. Similarly, the facial dysmorphism, growth and developmental delay, commonly seen in patients with larger 10p deletions were absent in the HDR patients with GATA3 mutations, further indicating that these features were likely due to other genes on 10p (182). These studies of HDR patients clearly indicate an important role for GATA3 in parathyroid development and in the etiology of hypoparathyroidism.

A *de novo* heterozygous missense mutation resulting in a non-conservative change of a single amino acid (R276P) in the GATA3 ZnF1 domain, which revealed reduced binding affinity to the GATA motifs, but normal interaction with FOG, was recently described in an HDR patient (188). Furthermore, a novel insertional mutation (405insC) in the GATA3 gene disrupting dual zinc fingers as well as one transactivating domain has been described (189). Three different *GATA3* mutations were furthermore described in several affected members of different Chinese HDR families. These are a single nucleotide deletion in codon 160 (478delG) and a donor splice site mutation at the exon 4/intron 4 boundary (IVS4 + 2 T to GCTTACTTCCC); both result in a shift in the open reading frame leading to a truncated GATA3 protein that lacks both N- and C-terminal zinc-containing fingers. The third missense mutation, R353S, is predicted to

disrupt the helical turn (190). In addition, 21 patients affected by HDR and 14 patients affected by isolated hypoparathyroidism were screened for GATA3 abnormalities. Thirteen different heterozygous germline mutations were identified in the HDR patients, and these consisted of three nonsense mutations, six frame-shift mutation leading to deletions, two frame-shifting insertions, one missense (Leu348Arg) mutation and one acceptor splice site mutation. Electrophoretic mobility shift assays (EMSAs) revealed three classes of GATA3 mutations; those that lead to a loss of DNA binding (over 90% of all mutations), those that lead to a loss of the carboxyl-terminal zinc finger, and those that result in reduced DNA-binding affinity. Additional mutations (e.g., Leu348Arg) do not alter DNA binding or the affinity but likely induce conformational change in GATA3. No mutations were identified in patients with isolated hypoparathyroidism indicating that GATA3 abnormalities are more likely to result in two or more of the phenotypic features of the HDR syndrome and not in isolated disease affecting only the regulation of calcium homeostasis (191).

The HDR phenotype is consistent with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle and parathyroids. However, GATA3 is also expressed in the developing central nervous system (CNS) and the hematopoietic organs in man and mice, and this suggests that GATA3 may have a more complex role. Indeed, homozygous GATA3 knockout mice have defects of the CNS and a lack of T-cell development, although the heterozygous GATA3 knockout mice appear to have no abnormalities (187). It is important to note that HDR patients with GATA3 haploinsufficiency do not have immune deficiency, and this suggests that the immune abnormalities observed in some patients with 10p deletions are most likely to be caused by other genes on 10p. Similarly, the facial dysmorphism, growth and developmental delay, commonly seen in patients with larger 10p deletions were absent in the HDR patients with GATA3 mutations, further indicating that these features were likely due to other genes on 10p (182). These studies of HDR patients clearly indicate an important role for GATA3 in parathyroid development and in the etiology of hypoparathyroidism.

Mitochondrial Disorders Associated with Hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: the Kearns-Sayre syndrome (KSS), the MELAS syndrome and a mitochondrial trifunctional protein deficiency syndrome (MTPDS). Both the KSS and MELAS syndromes have been reported to occur with insulin dependent diabetes mellitus and hypoparathyroidism (192, 193). A point mutation in the mitochondrial gene tRNA leucine (UUR) has been reported in one patient with the MELAS syndrome who also suffered from hypoparathyroidism and diabetes mellitus (77). Large deletions, consisting of 6741 and 6903 base pairs and involving $>$ 38% of the mitochondrial genome, have been reported in other patients who suffered from, hypoparathyroidism and sensorineural deafness (194). Rearrangements and duplication of mitochondrial DNA have also been reported in KSS. Mitochondrial trifunctional protein deficiency (MTPDS) is a disorder of fatty-acid oxidation that is associated with peripheral neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed with trifunctional protein deficiency (195, 196). The role of these mitochondrial mutations in the etiology of hypoparathyroidism remains to be further elucidated.

Kenny–Caffey and Sanjad–Sakati Syndrome

Hypoparathyroidism has been reported to occur in over 50% of patients with the Kenny-Caffey syndrome which is associated with short stature, osteosclerosis and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos and hyperopia (197). Initial description described female and male sibs, born of normal consanguineous parents, with typical findings of Kenny-Caffey syndrome making inherited characteristics autosomal dominant in most cases. Parathyroid tissue could not be found in a detailed post-mortem examination of one patient (198) and this suggests that hypoparathyroidism may be due to an embryological defect of parathyroid development. A recessive form of Kenny-Caffey syndrome was convincingly demonstrated in 16 affected children in 6 unrelated sibships, born to healthy, consanguineous parents of Bedouin ancestry (199). In 8 consanguineous Kuwaiti kindreds, linkage to a locus in the 1q42-q43 region was found for the autosomal recessive form of Kenny-Caffey syndrome (200).

In the Sanjad-Sakati syndrome, hypoparathyroidism is associated with severe prenatal and post natal growth failure and dysmorphic features and this has been reported in twelve patients from Saudi Arabia (201). The presenting complaint in all patients were hypocalcemic tetany or generalized convulsions, usually detected

in the first few days or weeks of life. Consanguinity was noted in 11 of the 12 patients' families, the majority of which originated from the Western province of Saudi Arabia. This syndrome, which is inherited as an autosomal recessive disorder has also been identified in families of Bedonin origin and homozygosity and linkage disequilibrium studies located this gene to chromosome 1q42-q43 (202). Sanjad-Sakati syndrome resembles the autosomal recessive form of KCS with similar manifestations but lacking osteosclerosis. Eight Sanjad-Sakati families from Saudi Arabia were genotyped with polymorphic short tandem repeat markers from the SSS/KCS critical region. A maximum multipoint LOD score of 14.32 was obtained at marker D1S2649, confirming linkage of Sanjad-Sakati syndrome to the same region as autosomal recessive Kenny-Caffey Syndrome. Haplotype analysis refined the critical region to 2.6 cM and identified a rare haplotype present in all the Sanjad-Sakati syndrome disease alleles, indicative of a common founder. In addition to the assignment of the Sanjad-Sakati syndrome in Saudi families and of the Kenny-Caffey syndrome in Kuwaiti families to overlapping genetic intervals, comparison of the haplotypes unexpectedly demonstrated that the diseases shared an identical haplotype. This finding, combined with the clinical similarity between the two syndromes, suggests that the two conditions are not only allelic but are also caused by the same ancestral mutation (203). Molecular genetic investigations led to the conclusion that mutations of the Tubulin-specific chaperone (TBCE) are associated with both syndromes (204). TBCE encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of α−β tubulin heterodimers. In addition, deletion and truncation mutations in the gene encoding a tubulin-specific chaperone cofactor E (TBCE) have been shown to cause the hypoparathyroidism, mental retardation and facial dysmorphism (HRD) syndrome which is associated with extreme growth failure. However, cryptic translational initiation at each of three out-of-frame AUG codons upstream of the genetic lesion can rescue a mutant HRD allele by producing a functional TBCE protein (208). The defect in the tubulin folding and assembly pathway also has grave consequences on growth and PMN functions (209).

Additional Familial Syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported. The inheritance of the disorder in some instances has been established and molecular genetic analysis of the PTH gene has revealed no abnormalities. Thus, an association of hypoparathyroidism, renal insufficiency and developmental delay has been reported in one Asian family in whom autosomal recessive inheritance of the disorder was established (205). An analysis of the PTH gene in this family revealed no abnormalities (205). The occurrence of hypoparathyroidism, nerve deafness and a steroid-resistant nephrosis leading to renal failure, which has been referred to as the *Barakat syndrome* (206), has been reported in 4 brothers from one family, and an association of hypoparathyroidism with congenital lymphoedema, nephropathy, mitral valve prolaps and brachytelephalangy has been observed in 2 brothers from another family (207). Molecular genetic studies have not been reported from these two families.

Calcium-Sensing Receptor (CaSR) Abnormalities

CaSR abnormalities are associated with 3 hypocalcemic disorders. These include autosomal dominant hypocalcemic hypercalciuria (ADHH), Bartter syndrome type V (i.e., ADHH with a Bartter-like syndrome), and a form of autoimmune hypoparathyroidism (AH) due to CaSR autoantibodies.

Autosomal Dominant Hypocalcemic Hypercalciuria (ADHH)

ADHH, although rare, in index cases may comprise a sizeable fraction of cases of idiopathic hypoparathyroidism, perhaps representing as many as one-third of such cases (210). CaSR mutations that result in a loss-of-function are associated with familial benign (hypocalciuric) hypercalcemia (FBHH) (70–76). It was therefore postulated that gain-of-function mutations in CaSR lead to hypocalcemia with hypercalciuria, and the investigation of kindreds with autosomal dominant forms of hypocalcemia have indeed identified such CaSR mutations (76, 211–215). The hypocalcemic individuals generally had normal serum intact PTH concentrations and hypomagnesemia, and treatment with vitamin D or its active metabolites to correct the hypocalcemia resulted in marked hypercalciuria, nephrocalcinosis, nephrolithiasis and renal impairment. Patients with this condition carry an activating CaSR mutation that changes the set-point of Ca^{2+}-regulated PTH secretion to the left and lowers renal tubular calcium re-absorption. Soon after the cloning of

the CaSR, investigators showed linkage of ADHH to a locus on chromosome 3q13 (212), i.e., the same locus as for the gene encoding the CaSR. Shortly afterwards, a heterozygous missense mutation, Q127A, was identified as a cause of ADHH (211). The majority (>80%) of CaSR mutations that result in a functional gain are located within the extracellular domain (76, 211–215), which is different from the findings in other disorders that are the result of activating mutations in G-protein coupled receptors. In addition, two deletion mutations have been described. Most ADHH patients are heterozygous for the activating mutation. In one family, a homozygous mutation was described but it was not associated with a more severe phenotype (216) and although there is a spectrum of phenotypic severity for a given genotype, the symptoms present in affected members of the same family tend to be similar.

Bartter Syndrome Type V

Bartter syndrome is a heterozygous group of autosomal recessive disorders of electrolyte homeostasis characterized by hypokalemic alkalosis, renal salt wasting that may lead to hypotension, hyper-reninemic hyperaldosteronism, increased urinary prostaglandin excretion, and hypercalciuria with nephrocalcinosis (217, 218). Mutations of several ion transporters and channels have been associated with Bartter syndrome, and 5 types are now recognized (218). The CaSR-related cases of Bartter's syndrome identified to date have been inherited in an autosomal-dominant manner, unlike other subtypes that are inherited as autosomal-recessive traits.

Bartter syndrome type V is due to activating mutations of the CaSR. Activating mutations of the *CaSR* gene in three patients; these mutations involved amino acid residues L125P, C131W and A843E. The mutant CaSR proteins inhibited the activity of the ROMK channel provided the missing link that explains why some activating mutations of CaSR can cause the Bartter's syndrome phenotype. Patients with Bartter syndrome type V have the classical features of the syndrome, i.e., hypokalemic metabolic alkalosis, hyper-reninemia and hyperaldosteronism (219, 220). In addition, they develop symptomatic hypocalcemia can, and an elevated fractional excretion of calcium leading to nephrocalcinosis (219, 220). Another recent report described monozygotic twins with a K29E mutation in the extra cellular domain of the CaSR; these patients presented with mild hypokalaemia, minimal aldosterone and renin production, absent alkalosis but notable hypocalcaemia (221). The K29E mutation also leads to cause agonist-independent activation of the CaSR (222) and buttresses previous observations that the phenotype of Bartter syndrome can be variable and is not directly related to the in-vitro potency of the known genetic changes associated with this syndrome (223).

Autoimmune Acquired Hypoparathyroidism (AH)

Twenty per cent of patients, who had acquired hypoparathyroidism (AH) in association with autoimmune hypothyroidism, were found to have autoantibodies directed against the extracellular domain of the CaSR (90, 91, 224). The CaSR autoantibodies did not persist for long; 72% of patients who had AH for less than 5 years had detectable CaSR autoantibodies; whereas only 14% of patients with AH for more than 5 years had such autoantibodies (224). The majority of the patients who had CaSR autoantibodies were females, a finding that is similar to that found in other autoantibody-mediated diseases. Indeed a few AH patients have also had features of autoimmune polyglandular syndrome type 1 (APS1). These findings establish that the CaSR can be an autoantigen in AH (90, 224).

Pseudohypoparathyroidism (PHP)

The term pseudohypoparathyroidism (PHP) was first introduced to describe patients with hypocalcemia and hyperphosphatemia due to PTH-resistance rather than PTH-deficiency (225). Affected individuals show partial or complete resistance to biologically active, exogenous PTH as demonstrated by a lack of increase in urinary cyclic AMP and urinary phosphate excretion; this condition is now referred to as PHP type I (226–228). If associated with other endocrine deficiencies and characteristic physical stigmata, now collectively termed Albrights's hereditary osteodystrophy (AHO), the condition is referred to as PHP type Ia. This latter syndrome is caused by heterozygous inactivating mutations within exons 1 through 13 of *GNAS* located on chromosome 20q13.3, which encode the stimulatory G protein ($G_s\alpha$) (for review see (229)). These mutations were shown to lead to an approximately 50% reduction in $G_s\alpha$ activity/protein in readily accessible tissues, like erythrocytes and fibroblasts, and explain, at least partially, the resistance towards PTH and other hormones that mediate their actions through G protein-coupled receptors (226–228). A similar reduction in $G_s\alpha$ activity/protein is also found in patients with

pseudopseudohypoparathyroidism (pPHP), who often show the same physical appearance as individuals with PHP-Ia, but lack endocrine abnormalities (226, 230–235). However, contrary to previous reports, recent studies have shown that not all AHO features are observed in pPHP patients. For example, obesity, which was thought to be a hallmark of both PHP-Ia and pPHP, was not evident in a large number of pPHP patients (236).

Patients affected by PHP-Ia or pPHP are typically found within the same kindred, but not within the same sibship. Furthermore, hormonal resistance is parentally imprinted, i.e., PHP-Ia occurs only if the defective gene is inherited from a female affected by either PHP-Ia or pPHP; pPHP occurs only if the defective gene is inherited from a male affected by either form of the two disorders (237, 238). Observations consistent with these findings in humans were made in mice that are heterozygous for the ablation of exon 2 of the *Gnas* gene. Animals that had inherited the mutant allele from a female showed undetectable $G_s\alpha$ protein in the renal cortex and decreased blood calcium concentration due to resistance toward PTH. In contrast, the offspring that had obtained the mutant allele lacking exon 2 from a male showed no evidence for endocrine abnormalities (239). Tissue- or cell-specific $G_s\alpha$ expression is thus almost certainly involved in the pathogenesis of PHP-Ia and pPHP. This provides also a reasonable explanation for the finding that heterozygous *GNAS* mutations result in a dominant phenotype.

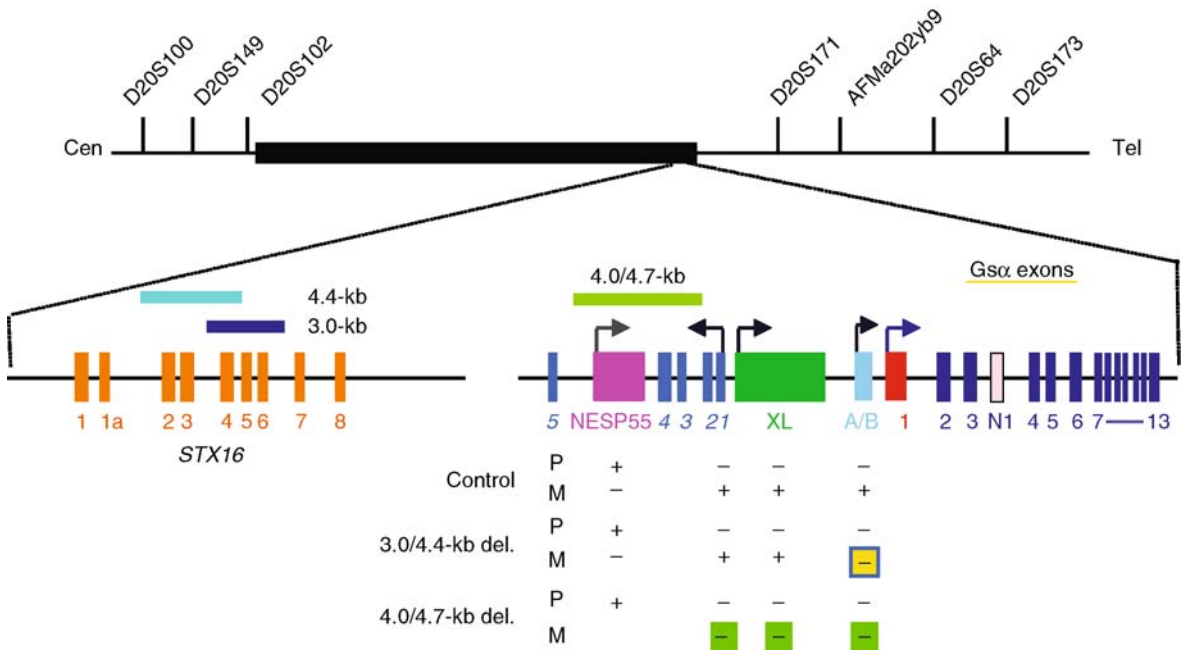
Progressive osseous heteroplasia (POH) was shown to be caused also by heterozygous inactivating mutations in the *GNAS* exons encoding $G_s\alpha$ (240–243). Interestingly, POH became only apparent when the $G_s\alpha$ mutation was inherited from a male, while inheritance from a female appears to have resulted in AHO, i.e., pseudopseudohypoparathyroidism (pPHP). This aspect of the findings was surprising since maternal inheritance of inactivating $G_s\alpha$ mutations usually leads to pseudohypoparathyroidism (PHP-Ia), i.e., AHO with hormonal resistance. However, PTH and TSH levels were not reported (242), and it is therefore conceivable that mild hormonal resistance may have been present in patients with maternally inherited $G_s\alpha$ mutations.

Mutations in the *GNAS* gene encoding $G_s\alpha$ have not been detected in patients with PHP type Ib (PHP-Ib), a disorder in which affected individuals show PTH-resistant hypocalcemia and hyperphosphatemia, but lack developmental defects. This variant of PHP was therefore thought to be caused by PTH/PTHrP receptor mutations; however, mutations in its gene and mRNA could not be identified (244–247). Recently, it was shown that there is an increased incidence of TSH resistance in PHP-Ib (227, 228, 248, 249), and that some patients affected by this disease variant show some shortening of the fourth metacarpals suggesting some overlap between the developmental features of PHP-Ia and PHP-Ib (250, 251).

A genome-wide search to identify the location of the "PHP-Ib gene" mapped the PHP-Ib locus to chromosome 20q13.3, which contains the *GNAS* locus (252), and it was furthermore shown that the genetic defect is parentally imprinted, i.e., it is inherited in the same mode as the PTH-resistant hypocalcemia in kindreds with PHP-Ia and/or pPHP (237, 238). Subsequently, it was shown that patients affected by PHP-Ib show a loss of methylation on the maternal allele, which is usually restricted to *GNAS* exon A/B (253, 254). In most families with the autosomal dominant form of PHP-Ib with parental imprinting (AD-PHP-Ib), the affected individuals and the healthy carriers were shown to carry a 3-kb deletion located with the syntaxin 16 (*STX16*) gene, which occurs between two 391-bp repeats about 220 kb up-stream of exon A/B (255–258) (*Fig. 11-8*). Affected members of one additional AD-PHP-Ib kindred, who show a loss of A/B methylation alone, were furthermore shown to have a 4.4 kb deletion within *STX16*, which overlaps with the 3-kb deletion by 1286 bp (259). In affected individuals with either mutation, the deletion is always found on the maternal allele, while it occurs on the paternal allele in unaffected healthy carriers. The affected members of two small families with broader methylation changes within the *GNAS* locus were shown to carry two distinct approximately 4 kb deletions on the maternal allele that remove *GNAS* exon NESP55 and the antisense exons 3 and 4 (260). Although indistinguishable broad methylation changes were observed in most patients with sporadic PHP-Ib, no deletions or point mutations have yet been identified in these individuals (261). Taken together these findings suggest that several different deletions upstream or within the *GNAS* locus lead to indistinguishable clinical and laboratory findings. However, it remains uncertain how the deletion affecting *STX16* results in a loss of exon A/B methylation alone, while deletion of NESP55 results in a broader loss of methylation. Furthermore, it remains uncertain how the different deletions affect signaling through the PTH/PTHrP receptor in the proximal renal tubules, but not in most other tissues. Mice lacking the murine homolog of exon A/B were recently shown to have biallelic and thus increased $G_s\alpha$ transcription (262). Loss of exon A/B methylation on the maternal allele allowing active transcription from this promoter therefore seems to have a prominent role in suppressing $G_s\alpha$ expression.

Figure 11-8

Location of the *GNAS* locus on chromosome 20q13.3 and of the microdeletions leading to autosomal dominant pseudohypoparathyroidism type Ib (AD-PHP-Ib). *GNAS* gives rise to multiple transcripts, some of which show allele-specific methylation in their promoters (P, paternal; M, maternal) and are expressed exclusively from the non-methylated allele (−). The $G_s\alpha$ specific promoter (exon 1) does not show differential methylation, and transcripts encoding this signaling protein are therefore biallelically expressed in most tissues. However, $G_s\alpha$ expression appears to occur predominantly from the maternal *GNAS* allele in the renal proximal tubules and a few other tissues. In AD-PHP-Ib kindreds, maternal inheritance of microdeletions affecting *STX-16* (gene encoding syntaxin 16; 3.0 or 4.4-kb deletion) are associated with loss of methylation at exon A/B alone, while deletions affecting NESP55 and two of the antisense exons (4.0 or 4.7-kb deletion) lead to the loss of all maternal methylation imprints; paternal inheritance of either deletion is not associated with imprinting defects and individuals carrying these deletions on the paternal allele are healthy. It has been suggested that in the renal proximal tubules a lack of exon A/B methylation and/or active transcription of A/B mRNA, both of which are normally seen on the paternal *GNAS* allele, mediate, *in cis*, the silencing of $G_s\alpha$ transcription. The maternal loss of exon A/B methylation in AD-PHP-Ib is therefore predicted to cause a marked reduction in $G_s\alpha$ expression and consequently resistance to PTH (and perhaps to few other hormones).

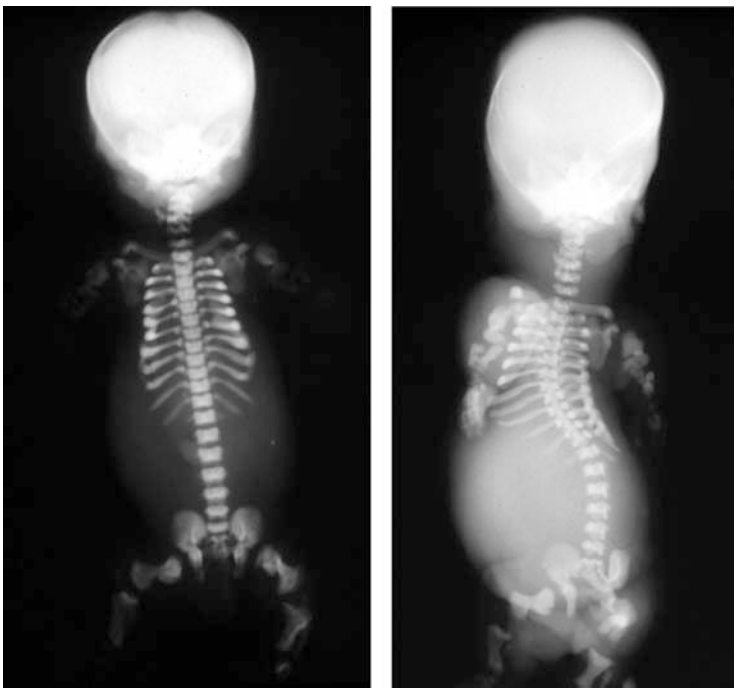


Blomstrand's Disease

Blomstrand's chondrodysplasia is an autosomal recessive human disorder characterized by early lethality, dramatically advanced bone maturation and accelerated chondrocyte differentiation (263). Affected infants are typically born to consanguineous healthy parents (only in one instance did unrelated healthy parents have two affected offspring) (264–268), show pronounced hyperdensity of the entire skeleton (*Fig. 11-9*) and markedly advanced ossification, particularly the long bones are extremely short and poorly modeled. Recently, PTH/PTHrP receptor mutations that impair its functional properties were identified as the most likely cause of Blomstrand's disease. One of these defects is caused by a nucleotide exchange in exon M5 of the maternal PTH/PTHrP receptor allele, which introduces a novel splice acceptor site and thus leads to the synthesis of a receptor mutant that does not mediate, despite seemingly normal cell surface expression, the actions of PTH or PTHrP; the patient's paternal PTH/PTHrP receptor allele is, for yet unknown reasons, only poorly expressed (269). In a second patient with Blomstrand's disease, the product of a consanguineous marriage, a nucleotide exchange was identified that

Figure 11-9

Radiological findings in a patient with Blomstrand's disease. (From (266), with permission). Note the markedly advanced ossification of all skeletal elements, and the extremely short limbs, despite the comparatively normal size and shape of hands and feet. Furthermore, note that the clavicles are relatively long and abnormally shaped.



changes proline at position 132 to leucine (270, 271). The resulting PTH/PTHrP receptor mutant showed, despite reasonable cell surface expression, severely impaired binding of radiolabeled PTH and PTHrP analogs, greatly reduced agonist-stimulated cAMP accumulation and no measurable inositol phosphate response. Additional loss-of function mutations of the PTH/PTHrP receptor have recently been identified in three unrelated patients with Blomstrand's disease. Two of these mutations led to a frame-shift and a truncated protein due either to a homozygous single nucleotide deletion in exon EL2 (272) or a 27 bp insertion between exon M4 and EL2 (273). The other defect, a nonsense mutation at residue 104 also resulted in a truncated receptor protein (274). Affected infants show besides the striking skeletal defects, abnormalities in other organs, including secondary hyperplasia of the parathyroid glands (presumably due to hypocalcemia). In addition, analysis of fetuses with Blomstrand's disease revealed abnormal breast development and tooth impaction, highlighting the involvement of the PTH/PTHrP receptor in the normal development of breast and tooth (275).

Hyperphosphatemic Disorders with Reduced Secretion of Biologically Active FGF-23

Tumoral Calcinosis With/Without Hyperphosphatemia

At least three variants of tumoral calcinosis have been described; an autosomal dominant form (276) and two apparently more common autosomal recessive forms that can be caused by mutations in two different genes. Patients affected by the autosomal dominant form usually have elevated serum 1,25-dihydroxyvitamin D levels, though classic findings of tumoral calcinosis may not always be present. The teeth are hypoplastic with short, bulbous roots and almost complete obliteration of pulp cavities, but they have fully developed enamel of normal color. The molecular defect of this autosomal dominant form of the disorder is not known.

The autosomal recessive forms of tumoral calcinosis can be severe, sometimes fatal disorder, and are typically characterized by hyperphosphatemia and often massive

calcium deposits in the skin and subcutaneous tissues; in some patients, however, only few minor abnormalities are noted (278). Recently, Topaz et al. mapped the gene causing one form of the disease to 2q24-q31 and revealed homozygous or compound heterozygous mutations in *GALNT3* (277), which encodes a glycosyltransferase responsible for initiating mucin-type O-glycosylation. Interestingly, the concentrations of carboxyl-terminal FGF-23 were significantly elevated in affected individuals. These findings implied that defective post-translational modifications of FGF-23 could be responsible for the abnormal regulation of phosphate homeostasis (see *Fig. 11-2*). Another form of tumoral calcinosis is caused by homozygous mutations in FGF-23, and patients affected by this disorder also showed dramatically elevated circulating concentration of carboxyl-terminal FGF-23, while the concentration of the intact protein were within normal limits (32, 279, 280).

Hyperostosis with Hyperphosphatemia

The combination of hyperostosis with hyperphosphatemia was first described in 1970 (281). Besides recurrent painful swelling of long bones, which can have features of tumoral calcinosis, affected patients present with elevated blood phosphate levels, yet normal renal function and usually normal serum calcium, 1,25-dihydroxy vitamin D, and PTH concentrations (282). Most cases appear to be sporadic, but consanguineous parents were described for some patients, implying that the disease can be recessive; the underlying molecular defect is not yet known. Recently, *GALNT3* mutations were also identified in the recessive form of this disease, indicating that one of the two forms of tumoral calcinosis and hyperostosis with hyperphosphatemia are allelic variants (283). As in patients with the autosomal recessive forms of tumoral calcinosis, carboxyl-terminal FGF-23 concentration appear to be significantly elevated (283).

Hypophosphatemic Disorders

The different forms of hypophosphatemia represent the most common cause of hereditary rickets, which can be divided into two main groups according to the predominant metabolic abnormality (284, 285). In the first group, hypophosphatemia is the result of a renal tubular defect, which may consist of either a single (isolated) defect in renal phosphate handling, as it occurs in the X-linked and autosomal dominant forms of hypophosphatemic rickets (XLH and ADHR, respectively), or of multiple tubular defects affecting phosphate, amino acids, glucose, bicarbonate and potassium handling as occurs in Fanconi syndrome's. In the second group, vitamin D metabolism is abnormal, either because of a defect in the 1α-hydroxylase enzyme or because of defects in the 1,25-dihydroxy vitamin D_3 receptor (VDR) leading to end organ resistance. The application of molecular genetic approaches has helped to elucidate some of the mechanisms underlying these disorders of hereditary hypophosphatemic rickets. Thus, XLH has been shown to be due to inactivating mutations of PHEX (*PH*osphate-regulating gene with homologies to *E*ndopeptidases on the *X* chromosome) (286, 287); Lowe's syndrome (oculocerebrorenal syndrome; X-linked recessive) is caused by mutations that result in a deficiency of a lipid phosphatase, which most likely controls cellular levels of the metabolite, phosphatidyl inositol 4, 5 bisphosphate ($P1P_2$) 5-phosphatase (288, 289); Dent's disease (X-linked recessive) results from loss of function mutations of a member of the voltage-gated chloride channel family, CLC-5 (290); vitamin D-dependent rickets type (VDDR type I; autosomal recessive) results from a deficiency of the renal 1a-hydroxylase enzyme (291, 292), which is a cytochrome P450 enzyme that forms part of the superfamily of hem-containing proteins that are bound to the membranes of microsomes and mitochondria and serve as oxidation-reduction components of the mixed-function oxidase system; and VDDR type II (autosomal recessive) is caused by mutations involving the VDR, which is closely related to the thyroid hormone receptors and represents another member of the transacting transcriptional factors that include the family of steroid hormone receptors. Furthermore, the molecular defect leading to ADHR was identified (29), which helped elucidate the role of a novel member of the fibroblast growth factor family, namely FGF-23, in the regulation of normal phosphate homeostasis (see *Figs. 11-2* and *11-3*) and in different acquired and inherited disorders of affecting the regulation of blood phosphate concentration (31, 33, 37, 38, 64, 293, 294).

Hypophosphatemic Disorders with Increased FGF-23 Activity

Autosomal Dominant Hypophosphatemic Rickets (ADHR)

ADHR is characterized by low serum phosphate concentrations, bone pain, rickets that can result in deformities of the legs, osteomalacia and dental caries (clinical and laboratory findings can be variable). ADHR and XLH

(see below) thus have marked clinical similarities but differ in their modes of inheritance. Genetic linkage studies mapped the ADHR locus to chromosome 12p13.3 (295) and defined a 1.5 Mb critical region that contained 12 genes. Mutational analyses of 6 of these 12 genes revealed the occurrence of missense mutations involving a new member of the fibroblast growth factor (FGF) family FGF-23 (29). Three missense FGF-23 mutations (see *Fig. 11-2*) have been identified in 4 unrelated ADHR families affecting codons 176 and 179. The affected members in two unrelated ADHR families have an identical mutation involving codon 176, in which the normal positively charged arginine residue is replaced by a polar but uncharged glutamine residue (Arg176Gln). The other two mutations involve codon 179, and in one ADHR family the normal arginine residue is replaced by a nonpolar tryptophan (Trp) residue (Arg179Trp) and in the other ADHR family, it is replaced by a glutamine residue (Arg179Gln). The clustering of these ADHR missense mutations that alter arginine residues has lead to the speculation that they may cause a gain of function. Mutational analysis of FGF-23 in 18 patients, who had hypophosphatemic rickets but did not have *PHEX* mutations, revealed no abnormalities, suggesting a role(s) for other genes in these hereditary disorders of hypophosphatemic rickets.

Oncogenic Osteomalacia (OOM)

OOM (also referred to as tumor-induced osteomalacia, TIO) is a rare disorder characterized by hypophosphatemia, hyperphosphaturia, a low circulating 1,25-dihydroxy-vitamin D_3 concentration and osteomalacia that develops in previously healthy individuals (296). Thus there are considerable similarities between OOM, XLH and ADHR. OOM is caused by usually small, often difficult to locate tumors, most frequently hemangiopericytomas. The clinical and biochemical abnormalities resolve rapidly after the removal of the tumor, whereas in XLH and ADHR these abnormalities are life long. However, the similarities between OOM, ADHR and XLH suggested that they may involve the same phosphate-regulating pathway, and it is important to note that OOM tumors do express PHEX (297, 298), which is mutated in XLH (see below). The possibility that FGF-23, which is mutated in ADHR, may be expressed in OOM tumors and that FGF-23 may be a secreted protein was therefore explored (30, 53, 294, 299). Indeed, OOM tumors were found by Northern and Western blot analysis respectively, to contain high levels of FGF-23 mRNA and protein. Consistent with this finding, FGF-23 plasma concentrations can be increased considerably in OOM patients, until successful tumor removal (64, 294, 300, 301).

Tumors responsible for oncogenic osteomalacia produce two molecular forms of FGF-23 (~32 and ~12 kDa), and both variants were also observed when assessing conditioned medium from cell lines, such as OK-E, COS-7 and HEK293 cells, expressing full-length, wild-type FGF-23 (30). When conditioned medium from cells expressing [R176Q]FGF-23 or [R179Q]FGF-23 was investigated by Western blot analysis only the larger protein band was observed (30, 33, 45). This implies that the known ADHR mutations, which affect a consensus cleavage site for furin-type enzymes, impair FGF-23 degradation thus enhancing and/or prolonging its biological activity.

X-Linked Hypophosphatemia (XLH)

XLH is the most frequent, inherited phosphate-wasting disorder. Just like ADHR, it is characterized by hypophosphatemia, hyperphosphaturia, low circulating 1,25-dihydroxy-vitamin D3 concentration and osteomalacia. This disorder is caused by inactivating mutations in PHEX, a gene located on Xp22.1 (286, 287). PHEX, which is expressed in kidney, bone and other tissues, shows significant peptide sequence homology to the M13 family of zinc metallopeptidases, which include neutral endopeptidase neprilysin (NEP), endothelin converting enzyme 1 (ECE-1) and 2 (ECE-2), and the Kell antigen. All of these are type II integral membrane glycoproteins that have endopeptidase activity and consist of a short N-terminal cytoplasmic domain, a single transmembrane hydrophobic region and a large extracellular domain. Thus, NEP functions as a membrane bound ectoenzyme that proteolytically inactivates a number of peptides that include atrial natruretic peptide, enkephalin, substance P and bradykinin, whilst ECE proteolytically activates endothelin. The substrate(s) for PHEX remains to be established, but several possible candidates can be considered. These are FGF-23, matrix extracellular phosphoglycoprotein (MEPE) (56, 302), and secreted frizzled related protein 4 (sFRP4) (53, 55). Amongst these proteins, FGF-23 was thought to be a likely substrate for PHEX, and consistent with this conclusion, serum FGF-23 concentrations were found to be elevated in about two third of patients with XLH (64, 249, 294) and they are unequivocally elevated in all Hyp mice, i.e., the murine homolog of XLH (52, 303). PHEX-dependent cleavage of FGF-23 was observed in one study in vitro (304), while another study failed to confirm these findings (32). However, genetic ablation of Fgf-23 in male Hyp mice, i.e., animals that are

null for Fgf-23 and Phex, leads to blood phosphate levels that are indistinguishable from those in mice lacking Fgf-23 alone (35, 36), indicating that FGF-23 resides genetically down-stream of PHEX/Phex. Furthermore, recent studies have shown that Hyp mice normalize their blood phosphate concentration and heal their rachitic changes, when injected with inactivating antibodies to FGF-23, indicating that FGF-23 is indeed the phosphaturic principle in XLH (305).

Autosomal Recessive Hypophosphatemia (ARHP)

Hypophosphatemic rickets in consanguineous kindreds was previously reported, suggesting an autosomal recessive form of hypophosphatemia (ARHP) (306–308). The clinical study of patients affected by ADHR or XLH, including rickets, skeletal deformities, and dental defects, show that affected individuals develop osteosclerotic bone lesions and enthesopathies later in life (see *Table 11-1*). Hypophosphatemia, which results from increased renal phosphate excretion, is accompanied by normal or low 1,25 $(OH)_2D$ levels and increased alkaline phosphatase activity. Patients affected by ARHP have FGF23 levels that are either elevated or inappropriately normal for the level of serum phosphorous (37, 38).

ARHP is caused by homozygous mutations, which affect the gene encoding dentin matrix protein 1 (DMP1). DMP1 belongs to the SIBLING protein family, which includes osteopontin, matrix extracellular phosphoglycoprotein, bone sialoprotein II, and dentin sialoprotein; the genes encoding these proteins are all clustered on chromosome 4q21. DMP1 is a bone and teeth specific protein (309), which is involved in the regulation of transcription in undifferentiated osteoblasts (310, 311). DMP1 undergoes phosphorylation during the early phase of osteoblast maturation and is subsequently exported into the extracellular matrix where it regulates the nucleation of hydroxyapatite. It undergoes post-translational modifications that yield a 94 kDa mature protein that is cleaved into a 37 kDa and a 57 kDa fragment. Preliminary studies suggested that the 57 kDa DMP1 fragment alone is sufficient to reverse the phenotype of *Dmp1*-null animals and to suppress FGF23 secretion (39).

Of the several different DMP1 mutations identified thus far, one mutation alters the translation initiation codon (M1V), two mutations are located in different intron-exon boundaries, and three are frame-shift mutations within exon 6. These mutations appear to be inactivating, suggesting that the loss of DMP1 results in hypophosphatemia. Accordingly, *Dmp1*-null mice show severe defects in dentine, bone, and cartalage, as well as hypophosphatemia and osteomalacia (312, 313). Furthermore, FGF23 levels in osteocytes and in serum are drastically elevated in these animals (38). Based on these findings, another role of DMP1 appears to be in the inhibition of FGF23 expression, thereby regulating phosphate homeostasis. Given the established importance of DMP1 in osteoblast function, loss of DMP1 actions in osteoblasts and extracellular matrix may also contribute to the phenotype of patients with ARHP. Consistent with this hypothesis, a high calcium/phosphate diet capable of rescuing osteomalacia in VDR-null mice does not seem to prevent the bone and dentine mineralization defect observed in Dmp1-null mice (39).

To summarize therefore, different molecular mechanisms, i.e., overexpression/production of FGF-23 by the tumors responsible for oncogenic osteomalacia, generation of a mutant FGF-23 that is resistant to cleavage in patients with ADHR, homozygous inactivating DMP1 mutations resulting in failure to suppress FGF-23 secretion, and inactivating mutations in PHEX that increase FGF-23 secretion through yet unknown mechanisms can all lead to renal phosphate-wasting and the resulting bone changes. FGF-23 thus has undoubtedly a central role in several hypophosphatemic disorders.

Hypophosphatemic Disorders with Normal or Suppressed FGF-23 Activity

Nephrolithasis and Osteoporosis Associated with Hypophosphatemia

Two different heterozygous mutations (A48P and V147M) in *NPT2a*, the gene encoding a sodium-dependent phosphate transporter, have been reported in patients with urolithiasis or osteoporosis and persistent hypophosphatemia due to decreased tubular phosphate reabsorption (314). When expressed in *Xenopus laevis* oocytes, the mutant NPT2a protein showed impaired function and, when co-injected, dominant negative properties. However, these in vitro findings were not confirmed in another study using oocytes and OK cells, raising the concern that the identified NPT2a mutation alone cannot explain the findings in the described patients (315). On the other hand, additional heterozygous NPT2a variations (in-frame deletion or missense change) have recently been identified upon analyzing a large cohort of hypercalciuric stone-forming patients in kindreds; however, these genetic variations do not seem to cause functional abnormalities (316).

Table 11-1

Biochemical findings in several inherited hypo- and hyperphosphatemic disorders and underlying genetic defects

	FGF-23	TRP or TmP/GFR	1,25(OH)2D	PTH	Serum Calcium	Urinary Calcium	Mutant gene
Hypophosphatemic disorders							
XLH	increased/ inappropriately normal	Low	Low/ inappropriately normal	Normal/ increased	Normal	Normal	PHEX
ADHR	increased/ inappropriately normal	Low	Low/ inappropriately normal	Normal	Normal	Normal	FGF23
ARHP	increased/ inappropriately normal	Low	Low/ inappropriately normal	normal	Normal	Normal	DMP1
HHRH	Low/normal	Low	High	Low	Normal	High	NPT2c
Hyperphosphatemic disorders							
Tumoral calcinosis	Intact: low C-terminal: very high	High	Normal-High	Low	Normal/ Increased	Increased	FGF23 or GALNT3 (glycosyltransferase)
	Extremely high (intact and C-terminal)	High	Normal-High	Elevated	Normal/ Increased	Increased	Klotho
Isolated hypoparathyroidism	Normal-increased	Elevated	Low-normal	Low-normal	Low	Increased or inappropriately normal	Calcium-sensing receptor, PTH, or GCMB, and unknown genetic defects
Pseudohypopara-thyroidism type Ia (PHP-Ia) or Ib (PHP-Ib)	Normal-increased	Elevated	Low-normal	High	Low	Low	PHP-Ia: *GNAS* exons encoding Gsα: microdeletions within or up-stream of *GNAS*

Hereditary Hypophosphatemic Rickets with Hypercalciuria (HHRH)

The homozygous ablation of *Npt2a* in mice ($Npt2a^{-/-}$) results, as expected, in increased urinary phosphate excretion leading to hypophosphatemia (317). Due to the hypophosphatemia $Npt2a^{-/-}$ mice show an appropriate elevation in the serum levels of 1,25-dihydroxyvitamin D leading to hypercalcemia, hypercalciuria and decreased serum parathyroid hormone levels, and increased serum alkaline phosphatase activity. These biochemical features are typically observed in patients with hereditary hypophosphatemic rickets with hypercalciuria (HHRH), which was presumed to bean autosomal recessive disorder affecting renal tubular phosphate reabsorption (318). HHRH patients develop rickets, have short stature, and increased renal phosphate clearance (TmP/GFR is usually 2 to 4 standard deviations below the age-related normal range), hypercalciuria despite normal serum calcium levels, increased gastrointestinal absorption of calcium and phosphorus due to an elevated serum concentration of 1,25-dihydroxyvitamin D, suppressed parathyroid function, and normal urinary cyclic AMP excretion. Long-term phosphate supplementation as the sole therapy leads, with the exception of persistently decreased TmP/GFR, to reversal of the clinical and biochemical abnormalities (318). Unlike HHRH patients, $Npt2a^{-/-}$mice do not have rickets or osteomalacia. Instead, they have poorly developed trabecular bone and retarded secondary ossification, and in older animals there is a dramatic reversal and eventual overcompensation of the skeletal phenotype. Consistent with these phenotypic differences, mutations in *SLC34A1*, the gene encoding the sodium-phosphate co-transporter NPT2a were excluded in several kindreds, including the one in whom this syndrome was first described (318, 319). However, subsequent studies have led to the identification of homozygous or compound heterozygous mutations in *SLC34A3*, the gene encoding the sodium-phosphate co-transporter NPT2c, in patients affected by HHRH (320–322). These findings indicate that NPT2c has a more important role in phosphate homeostasis than initially thought (323).

Vitamin D-Dependent Rickets (VDDR)

Patients with VDDR type I show clinical and laboratory findings that are similar to those observed in patients with vitamin D-deficient rickets. However, unlike in vitamin D-deficiency, patients with VDDR type I do not respond to treatment with vitamin D and treatment with 1,25 dihydroxy vitamin D is required instead. VDDR type I was therefore named *pseudovitamin D deficiency rickets* (324). Clarification of the abnormal vitamin D metabolism (325) led to the recognition that VDDR type I was due to a defect in the renal 1α-hydroxylase enzyme; consequently serum 1,25 dihydroxy vitamin D concentration is low. Subsequently another condition was recognized and called vitamin D-dependent rickets type II (VDDR type II). In this condition, which is due to end organ resistance to 1,25 dihydroxy vitamin D, the serum 1,25 dihydroxy vitamin D concentration is markedly elevated.

1-α Hydroxylase Deficiency (VDDR Type I)

Patients affected by VDDR type I (autosomal recessive) show almost all the clinical and biochemical features of vitamin D-deficient rickets. Typically, the child is well at birth and within the next two years develops hypotonia, muscle weakness, an inability to stand or walk, growth retardation, convulsions, frontal bossing and the clinical and radiographic signs of rickets - rachitic rosary, thickened wrists and ankles, bowed legs and fractures. A history of an adequate intake of vitamin D is usually obtained. Trousseau's and Chvostek's signs may be present. The permanent teeth show marked enamel hypoplasia, a feature not seen in X-linked hypophosphatemic rickets (326).

The pathogenesis of VDDR type I was first elucidated by studying vitamin D metabolism in affected patients, and it is shown that massive doses of vitamin D_3 and high doses of 25-hydroxy vitamin D_3 but only small doses of 1,25 dihydroxy vitamin D_3 were required to correct the clinical and biochemical abnormalities (325). This provided indirect evidence that the condition was due to an inborn error of vitamin D metabolism, i.e., a defect in the renal 1α-hydroxylase enzyme, the enzyme that converts 25-hydroxy vitamin D_3 to 1,25 dihydroxy vitamin D_3. The serum 25-hydroxy vitamin D_3 concentration was normal in untreated patients and high in patients treated with vitamin D whereas the serum concentration of 1,25 dihydroxy vitamin D_3 was low in untreated patients (327) and remained low or below-normal in patients treated with vitamin D_3 (328). The low serum concentrations of 1,25 dihydroxy vitamin D_3 despite the normal or high serum 25(OH)D_3 can be explained by a deficiency in the renal 1α-hydroxylase (328–330), and molecular genetic studies have later confirmed this conclusion. Indeed, genetic linkage studies in affected French-Canadian families mapped VDDR type I to a region on chromosome 12q13.3 (331), which comprises the gene encoding the 1α-hydroxylase. DNA sequence analysis of patients

affected by VDDR type I have identified more than 20 different mutations of this enzyme (291, 332–335) in 26 kindreds. All patients with VDDR type I were found to carry homozygous or compound heterozygous mutations, whilst their parents are healthy obligate carriers. Most mutations lead to a complete lack of the 1α-hydroxylase; only two mutations have been identified that maintain partial enzyme activity in vitro. These mutations were found in the two patents with only mild laboratory abnormalities, suggesting that such mutations contribute to the phenotypic variation observed in patients with 1α-hydroxylase deficiency suggesting that not all 1α-hydroxylase mutations lead to the development of the "classicial" laboratory findings in VDDR type II (336).

End Organ Resistance (VDR Mutations, VDDR Type II)

Vitamin D-dependent rickets type II (VDDR type II; autosomal recessive) is an autosomal recessive disorder caused by end-organ resistance to 1,25 dihydroxy vitamin D_3 (337–339). The laboratory and radiographic features of VDDR type II are similar to those found in VDDR type I, with one major exception; patients with VDDR type II have markedly elevated circulating concentrations of 1,25 dihydroxy vitamin D_3. The disease varies in its clinical and biochemical manifestations, which suggested heterogeneity in the underlying molecular defects (339). Most of the patients have an early onset of rickets but the first reported patient was a 22 year old woman who had skeletal pain for seven years (337) and another patient presented himself at the age of 50 (years) following five years of this symptom (340). Alopecia totalis occurs in some patients and it was suggested that the therapeutic response to the 1α-hydroxylated derivative of vitamin D_3 in patients with normal hair growth was better than in those with alopecia totalis (341), but this was not found to be a constant predictive sign (342). The severity of resistance to 1,25 dihydroxy vitamin D_3 is variable and some patients have improved following therapy with very large doses of vitamin D (343) or 1,25 dihydroxy vitamin D_3 (344–346). In patients who are refractory to vitamin D therapy, alternative treatments with oral calcium supplements have been tried with limited success. However, long term nocturnal intravenous calcium infusions followed by oral calcium supplementation have successfully healed rickets and promoted bone mineralization in VDDR II patients (347), though there are considerable practical difficulties with this therapy.

The elevated serum concentrations of 1,25 dihydroxy vitamin D_3 in patients with VDDR II suggested an abnormality in the mode of action of 1,25 dihydroxy vitamin D_3 within target tissues. The functions of 1,25 dihydroxy vitamin D_3 are mediated by an intracellular receptor that binds DNA and concentrates the hormone in the nucleus (348), analogous to the classical steroid hormones (349). The interactions between 1,25 dihydroxy vitamin D_3 and its intracellular receptor have been studied using cultured skin fibroblasts from control subjects and patients with vitamin D-dependent rickets type II (350, 351). Several defects were identified, including absent receptors, a decreased number of receptors with normal affinity, a normal receptor-hormone binding but a subsequent failure to translocate the hormone to the nucleus, and a post-receptor defect, in which normal receptors are present but there is a deficiency in the induction of the 25-OHD-24 hydroxylase enzyme in response to 1,25 dihydroxy vitamin D. Thus, the heterogeneity suggested from clinical observations in VDDR II patients could be demonstrated at the cellular level with various combinations of defective receptor-hormone binding and expression. The 1,25 dihydroxy vitamin D_3 receptor (VDR), which is closely related to the thyroid hormone receptors and represents another member of the trans-acting transcriptional factors including the steroid and thyroid hormone receptors is an intracellular protein, which has a molecular weight of 60,000 daltons. The binding site for 1,25 dihydroxy vitamin D_3 resides in the C-terminal part of the protein while the N-terminal part of the molecule possesses the DNA-binding domain (352). Zinc and other divalent cations are important in maintaining the DNA binding function of the receptor, possibly by determining the conformation of the protein and giving rise to processes that can interdigitate between the helices of DNA. This hormone-receptor complex binds to a DNA region, which is located upstream of the promoter of genes encoding calcium-binding proteins and other proteins.

The availability of cDNAs encoding the avian and human VDR (353) helped to clarify the molecular basis of VDDR type II (354). Nucleotide sequence analysis of genomic DNA revealed that the human VDR gene consists of 9 exons; exons 2 and 3 encode the DNA-binding domain, while exons 7, 8 and 9 encode the vitamin D-binding domain. The gene is located on chromosome 12q12-q14 in man (331), i.e., in a region that comprises the gene encoding the 1α-hydroxylase. Mutational analysis of the VDR gene in VDDR II patients demonstrated the presence of nonsense and missense mutations affecting different parts of the receptor. Expression of these

mutations in COS-1 monkey kidney cells demonstrated that these mutations result in a reduction or a loss of VDR function similar to the heterogeneous effects observed in cultured fibroblasts from VDDR II patients. Furthermore, null mutant i.e., "knockout" mice for VDR produced by targeted gene disruption (355, 356), were found to have growth retardation, skeletal deformities and an earlier mortality, and adult mice developed alopecia. In addition, biochemical investigations revealed that the VDR mutant mice were hypocalcemic and hypophosphatemic, with markedly elevated serum 1,25 dihydroxy vitamin D_3 concentrations. Thus, the VDR-null mutant mice have the features consistent with those observed in patients with VDDR type II.

Other Hypophosphatemic Disorders

There are several other genetic disorders associated with hypophosphatemia and often with other defects in proximal tubular function. These include, Dent's disease, an X-linked recessive disorder, which is caused by mutations in *CLCN5* encoding the voltage-gated chloride channel CLC-5 (290, 357) and Lowe syndrome (oculo-cerebro-renal syndrome) (358), another X-linked recessive disorder that is caused by mutations in OCRL1 (359, 360). Furthermore, Fanconi-Bickel syndrome, which is caused by homozygous or compound heterozygous mutations in GLUT2, can be associated with severe hypophosphatemia, but this feature is often not very prominent (361). Other rare hypophosphatemic diseases are osteoglophonic dysplasia (OGD) (362), an autosomal dominant disorder, which was recently shown to be caused by different heterozygous missense mutations in the FGFR1 (363, 364), linear nevus sebaceous syndrome (LNSS), also known as epidermal nevus syndrome (ENS) or Schimmelpenning-Feuerstein-Mims syndrome, in which elevated FGF-23 were observed (365, 366), and fibrous dysplasia, which is caused by heterozygous activating, post-zygotic mutations in exon 8 of *GNAS*, the gene encoding the alpha-subunit of the stimulatory G protein ($G_s\alpha$) (367, 368), that lead in the dysplastic regions to a cAMP-dependent increase in the production of FGF-23 by osteoblasts/osteocytes and fibrous cells (34, 369).

Concluding Remarks

Remarkable advances have been made in identifying key proteins that are involved, either directly or indirectly, in the regulation of calcium and phosphate homeostasis, the hormones that are involved in these mechanisms and receptors that mediate these hormonal actions in the different target tissues. Furthermore, the identification of mutations in several of these proteins provided a plausible molecular explanation for a variety of familial and sporadic disorders of mineral ion homeostasis and/or bone development. In addition to advances in further defining the biological role(s) of known proteins, genetic loci and/or candidate genes have been identified for many of the inherited disorders associated with an abnormal regulation of calcium and phosphate homeostasis. It is likely that the definition of these familial disorders at the molecular level, which is greatly aided by the rapid progress in the Human Genome Project, and the exploration of the underlying cellular mechanisms will provide further important insights into the regulation of calcium and phosphate.

12 Nutrition and Metabolism

Lauren Graf · Corina Nailescu · Phyllis J. Kaskel · Frederick J. Kaskel

Introduction

The effects of nutrition on the health and well-being of individuals is well described. The adverse effects of poor nutrition on children are amplified by their influence on the child's ability to grow and develop appropriately. Because of the kidneys' function on elimination of waste products from metabolism, the correlation between kidney disease and nutritional imbalance is well established, and this is most obvious in children with chronic kidney disease (CKD). Poor nutrition often complicates CKD and inevitably adversely affects weight gain, growth and development of these children. Conversely, abnormalities or reduction of renal function frequently lead to abnormalities of nutritional intake or metabolism, resulting in a complex inter-relationship of renal function and nutrition.

Nutrition in Children with CKD

The etiology of growth delay and cachexia in pediatric patients with CKD is thought to be multifactorial with inadequate caloric intake, uremic toxicity, anemia and metabolic and endocrine abnormalities among the leading causes (1, 2). Given the numerous causes of poor growth in CKD, identifying children with inadequate calorie and protein intake can be challenging. There is evidence that most infants and young children with CKD have suboptimal caloric intake (1). Foreman et al. found that mean caloric intake was 80 ±23% of the recommended dietary allowance (RDA) for age in these children (3); however, they found no correlation between caloric intake and height velocity. Calcium, vitamin B6, zinc, and folate intakes were also low. The mean protein intake in these children was 153 ±53% of the RDA. The same study suggested that the amount of energy per unit body weight (kcal/kg/day) consumed by children with CKD is comparable to that of age-matched healthy children, but because of their small size, children with CKD consume fewer total calories and have a lower %RDA for age (3). Nutritional supplementation in children with inadequate intake improves growth to some extent, but does not restore normal growth velocity. Further growth improvements have not been seen when energy intakes exceed 75% of the RDA (4, 5), suggesting that adequate calorie and protein intake are only part of a very complex mechanism involved in the etiology of poor growth and cachexia associated with CKD.

Current evidence suggests that dysregulation of hormones, particularly growth hormone, insulin, leptin and ghrelin, as well as inflammatory cytokines have a large impact on metabolism, body composition and growth (6–37). As a result, these compounds have been the focus of much recent research on the nutritional aspects of CKD. The abnormal regulation of multiple hormones and compounds creates an unfavorable state for growth and development. It is a great challenge for the medical team to promote adequate weight gain and growth given the powerful catabolic effects of many hormones and cytokines. These compounds have substantial impact on body composition and metabolism in CKD.

CKD creates a state of glucose intolerance (6). The anabolic effect of insulin is blunted, including the glucose metabolism, as are the amino acid uptake into cells and the lipoprotein lipase (LPL) activity. Clinically, this state usually consists of fasting euglycemia but abnormal glucose tolerance with a delayed decrease in blood glucose in response to insulin and hyperinsulinemia. The mechanisms responsible seem to be multiple but the most prominent metabolic disturbance in uremic patients is insulin resistance mainly due to a postreceptor defect (7, 8). Chronic metabolic acidosis (CMA), frequently associated with CKD, contributes to insulin resistance and its treatment increases insulin sensitivity (9). In addition to insulin resistance, there is abnormal insulin release attributable to reduced adenosine triphsophate content in the pancreatic islets, induced partially by high intracellular calcium, secondary to augmented parathyroid hormone (PTH)-induced calcium entry into the cells (7, 8). The abnormalities with insulin and CMA have negative effects on body composition and growth. Insulin resistance, acidosis and inflammation activate the ubiquitin-proteasome system (UPS), which degrade muscle protein leading to a catabolic state (10–14).

The dysregulation of growth hormone plays a major role in growth velocity and development in children. The

GH/insulin-like growth factor plays a fundamental role in the growth process during childhood. Although serum GH and IGF-1 levels are usually normal or high in growth-retarded children with CKD (15), uremic serum has a high IGF-1 blinding capacity, resulting in low IGF-1 bioactivity (16, 17). The mechanisms for this increased IGF-1 binding capacity seem to be related to decreased renal clearance of IGFBP (IGF binding proteins), because serum levels of IGFBP-1, -2, -4 and -6 were shown to correlate inversely with GFR (18, 19). In addition, uremia raises hepatic mRNA levels for IGFBP-1 and -2 by an unknown mechanism (20).

Secondary hyperparathyroidism has significant effects on longitudinal growth. High PTH levels are associated with mobilization of calcium from bone. PTH also causes proliferation of the fetal growth plates chrondrocytes, inhibits the differentiation of these cells into hypertrophic chondrocytes, and stimulates accumulation of cartilage-specific proteoglycans that are though to act as inhibitors of mineralization (21). However despite the high serum PTH level, there is "PTH resistance" at the level of growth plates, owing to intertwined factors affecting the PTH/PTH-related peptide receptors. This receptors mRNA expression was found to be downregulated in the kidney and growth plate of uremic rates, in the osetoblasts of patients with ESRD (22), and as a result of high-dose intermittent calcitriol therapy (23, 24). On the other hand, PTH/PTH-related peptide expression is upregulated by GH and physiologic doses of calcitriol (23).

Chronic metabolic acidosis may affect growth independently of uremia because diseases such as renal tubular acidosis are associated with growth defects, and catch-up growth can be achieved when patients are given alkali therapy. When the blood pH is less the 7.25, length gain is diminished earlier than weight gain. A reduction of weight gain is observed only for more severe acidosis with pH of less than 7.20 (25). This finding suggests that longitudinal growth of bone is more sensitive to acidosis than are such factors as protein synthesis, which influences body weight. The mechanisms appear to be profound in vitro-negative effect of CMA on the GH/IGF-1 axis, mainly through downregulation of the receptors for both hormones (26) plus a stimulation of osteoclastic and suppression of osteoblastic activity (27).

It was not until recently that the effects of cytokines and the hormones ghrelin and leptin have been understood. Cachexia and poor growth associated with kidney disease may be largely caused by the effects of proinflammatory cytokines and hormones (29–33). An understanding of this mechanism is the first step in the development of strategies to prevent or treat the symptoms of wasting in kidney disease. As kidney function declines, plasma levels of inflammatory cytokines increase. These elevated cytokines exert their effects on a number of sites throughout the body and likely contribute to cachexia in multiple ways (25–34).

Although the exact mechanism remains uncertain, studies have found that cytokines suppress appetite through actions on the central nervous system. Three cytokines whose effects on body composition have been well studies are interleukin 6 (IL-6), tumor necrosis factor alpha (TNF α and interleukin 1β (IL-1β)). IL-6 is present in both adipose tissue and the hypothalamus. It is the primary cytokine responsible for the activation of the acute phase response. The energy demands of the acute phase response are great, requiring large amount of essential amino acids. This overwhelming need for amino acids stimulates muscle breakdown (28). Animal studies have shown that infusion of IL-1β, and TNF-α lead to anorexia, weight loss and muscle wasting (4). In addition, IL-1β produces a delay in gastric emptying that may further contribute to poor nutrition. Cytokines also disrupt carbohydrate metabolism causing peripheral insulin resistance, which further contributes to wasting (28). Peripheral insulin resistance results in the transport of glucose away from muscle to the liver forcing skeletal muscle to use nonessential amino acids for energy. This process leads to negative nitrogen balance.

Leptin is a satiety hormone produced by adipose tissue that may have a large impact on appetite and weight in kidney disease (4, 35). In healthy individuals, leptin circulates in proportion to the amount of body fat. It inhibits appetite and food intake and increases energy expenditure. In healthy individuals, leptin circulates in proportion to the amount of body fat (4, 35). It reduces appetite and food intake and increases energy expenditure. During times of fat loss and decreased calorie intake, leptin levels decrease, which results in an increase in appetite and more efficient metabolism. Leptin functions as a regulatory hormone under healthy conditions and tends to preserve body composition at a relatively stable state. The kidneys are the main sites for clearing circulating leptin levels. As kidney function declines, excess leptin accumulates and becomes greatly out of proportion with the amount of body fat (30). It has been suggested that inflammation may also contribute to elevated leptin levels but this association is not clear. One study showed a significant association between C-reactive protein levels and leptin in patients with chronic kidney disease (36). However a more recent study showed no association between the two markers (36). One study even showed a positive correlation between plasma leptin and normalized protein

catabolic rate (nPCR), subjective global assessment score and midarm muscle circumference (37). This suggests that higher leptin levels may be a marker of good nutritional status.

Ghrelin is a second regulatory hormone that functions to maintain fat stores and body composition is. Ghrelin is produced primarily in the stomach but is also produced in smaller amounts in other tissues including the kidney. Ghrelin is elevated after fasting and its concentration is highest in lean people and lowest in obese people (29, 32). It stimulates growth hormone release, increases food intake, and promotes weight gain, particularly from fat. Ghrelin may make metabolism more efficient because increased body fat is seen in patients with hyperghrelinemia without extra calorie intake (29, 32). As kidney function deteriorates, ghrelin levels tend to increase. CKD patients often experience changes in body composition that lead to muscle wasting and preservation of fat mass. It is of interest that despite the already elevated ghrelin levels seen in patients with kidney disease, recent studies have found that treatment with exogenous ghrelin and ghrelin receptor antagonists actually improve body composition (34). A recent study performed on uremic rats has found that treatment with exogenous ghrelin and ghrelin receptor antagonists improves lean body mass, increased random GH levels and may decrease inflammation (34).

Nutritional Assessment and Interpretation of Anthropomteric Data in Children with CKD

It is important for the nutritional status and growth of children with even mild CKD to be assessed regularly by a skilled registered dietitian. The frequency of monitoring children with stage 2–5 CKD is dependent on the age of the child, stage of CKD and how well an individual child is thriving. Closer monitoring is indicated in children with growth delay, poor intake or low Body Mass Index. Nutritional assessments should include a method of estimating nutrient intake and measurement of growth parameters as well as growth velocity.

The two most clinically practical ways to assess energy and nutrient intake are the three-day food diary and 24-h recall (38, 39). For younger children, assessment of dietary intake can be done through a 3-day diet diary. Diet diaries have shown to provide accurate estimates of nutrient intake in normal weight children under the age of 10 (39). Similar accuracy has not been seen with adolescents keeping food records because they tend to underreport what they have consumed (40). A 24-h recall may be more suitable for adolescents who are not as inclined to comply with other methods of diet recording. This method has the advantage of being quick to carry out and can provide detailed information about specific foods.

The extent to which nutrition influences growth is highly dependent on the age of the child. The greatest benefit from correction in nutritional deficits is seen in infants. Growth occurs at the most rapid rate during the infancy stage and is driven predominately by nutrition (41). Infants use a much larger percentage of their daily energy for growth as compared with older children and adolescence. The first 6–12 months of life is normally considered the infancy stage, however in CKD the transition to the childhood phase is often delayed until 2–3 years of age (41, 42). Infancy is the most critical time for nutrition intervention in children with CKD. Infants with significant renal impairment frequently present with poor intake. Any signs of inadequate growth or weight gain are an indication for immediate initiation of nutritional supplements (*Table 12-1*) (41). Infants also may require gastrostomy tubes to meet their energy and fluid needs.

Growth retardation is also common in older children with CKD. However growth in those children is driven mainly by growth hormone during childhood and sex hormones during adolescence. Nutritional supplements have been shown to improve growth in infants but similar results have not been seen consistently in older children (41, 43–45). Poor growth in older children and adolescents has historically been attributed to poor calorie and protein intake; but given that numerous other factors are now known to be involved in inadequate growth and development including the dysregulation of hormones and cytokines, this conclusion is likely not accurate. The most recent KDOQI guidelines suggest that in older children poor intake may be the result of inadequate growth and not the cause (41). Determining whether inadequate growth is due to true undernutrition or another cause is crucial in providing the appropriate intervention.

Anthropometric measures, such as weight, height, head circumference and growth velocity should be monitored routinely. Infants and children with CKD should be measured and plotted on the length- or height-for-age curves and SD score calculated (41). In infants, length should be measured on a length board and in older children height should be assessed with a stadiometer. Growth velocity, defined as change in length per unit time should be assessed routinely. In children over age 2 years of age, height velocity is accurately assessed with intervals of 6 months of greater. Adequate linear growth is a good indicator of long-term nutritional status. However, weight

Table 12-1

Nutrition formulas for children with renal disease

	Manufacturer	Kcal/ml	Protein (g/L) sources	Fat (g/L) sources	Carbohydrates (g/L sources)	Na/K (mEq/L)	Ca/P (mg/L)	mOsm/Kg water

NeproCarb Steady	Ross products	1.8	81 (caseinates)	96 (high oleic safflower oil and soy oil)	167 (corn syrup, sucrose, FOS)	46/27	1,060/700	585

loss or poor weight gain may precede growth stunting (41). In the early stages of undernutrition, linear growth often continues at a normal rate until severe wasting occurs. Therefore, other indicators of nutritional status should be used. Assessing weight for age (in children 2 years of age and under) and BMI in older children can help determine the degree of wasting. BMI is determined as a ratio of weight to height and is calculated by dividing weight in kg by the square of the height in meters (BMI = Wt {kg}/[ht {M)}]^2. In healthy children, BMI is compared with reference values for a particular gender and age. Because many children and adolescents with kidney disease have delayed sexual maturation and linear growth, the most recent KDOQI guidelines recommend that plotting BMI against actual age may be misleading (41, 46). Body composition changes are related to pubertal growth as well as to age. Plotting BMI against actual age may falsely classify some patients as undernourished and it can be misleading for patients who are consuming adequate calories and protein but have delayed growth or sexual maturation due to non-nutritional causes. Therefore, plotting BMI against a particular child's height age (the age at which the height falls along the 50th percentile) may be more reasonable. These methods can be very accurate in assessing nutritional when fluid overload is not an issue. Extreme fluid overload as is seen with children with chronic nephrotic syndrome can make determining dry weight difficult and can mask weight loss (41). Estimating dry weight regularly (by means of physical exam and other clinical markers) is important to accurately track a child's weight gain.

Sophisticated body composition data are generally used for research purposes only, owing to the difficult of standardization (47). For determination of fat-free mass, the following methods can be used: total body water, total body potassium, total body nitrogen and calcium, bioelectrical impedance and electromagnetic scanning. Determination of body fatness can be done by densitometry, inert gas absorption or near-infrared interactance. Neuron activation or dual-energy x-ray absorptiometry can be used to determine the bone mineral content (48).

In the clinical setting, accurately detecting and treating malnutrition has been a challenge. Until recently, there has not been a clear or uniform definition of undernutrition for the CKD population. The definition of undernutrition set by the World Health Organization (WHO) for the general population is not suitable for children with CKD (41). The WHO defines undernutrition as weight-for-age, height-for-age, and weight-for-height $\geq$2 SD below the CDC reference range (41, 49). These guidelines are based on the fact that undernutition in a healthy child may lead to low weight-for-height as

well as low height-for-age (growth stunting). As discussed earlier, in children with CKD, many factors influence growth and stunting will often occur even with adequate nutrient intake. Therefore this definition of malnutrition should not be applied to children with CKD. Practitioners should be cautious in labeling a child with CKD as malnourished. Careful evaluation of height, weight, ratio of height to weight and BMI should be considered before a diagnosis of malnutrition is made. If a child is small for age (weight-for-age <5th percentile and height-for-age <5th percentile) but BMI for age of ≥50 percentile, and diet evaluation suggests adequate intake, it is reasonable to conclude that the growth delay is due to non-nutritional factors.

Table 12-2

Equations to estimate energy requirements for children at healthy weights

Age	Estimated energy requirement (EER) (kcal/d) = Total energy expenditure + Energy deposition
0–3 mo	EER = (89 × weight (kg) − 50) + 175
4–6 mo	EER = (89 × weight (kg) − 50) + 56
7–12 mo	EER = (89 × weight (kg) − 50) + 22
13–35 mo	EER = (89 × weight (kg) − 50) + 20
3–8 y	Boys EER = 88.5 – 61.9 × age (y) + PA × (26.7 × weight (kg) + 903 × height (m)) + 20
	Girls EER = 125.3 – 30.8 × age (y) + PA × (10 × weight (kg) + 934 × ht (m)) + 20
9–18 y	Boys EER = 88.5 – 61.9 × age (y) + PA × (26.7 × weight (kg) + 903 × height (m)) + 25
	Girls EER = 135.3 – 30.8 × age (y) + PA × (10 × weight (kg) + 934 × height (m)) + 25

Nutritional Support for the Child with CKD 1–4

Macro- and micro-nutrient guidelines for children with CKD before dialysis vary depending on the age of the child and stage of kidney disease (*Tables 12-2–10*). Equations for estimating energy needs differ with overweight versus normal weight children as well as activity level (*Tables 12-2–4*). Studies show that disturbances in nutritional intake, bone biochemistry and growth occur early in CKD and suggest the need for joint medical and dietary intervention in children even with mild and moderate CKD (50). A thorough nutrition assessment will ensure that poor growth or weight gain is detected and addressed early. To achieve the greatest benefit from nutrition intervention, it is imperative that it be started early.

Calorie and protein supplementation either orally or via a gastrostomy tube may be necessary if the child is unable to meet his energy needs through food. Vitamin and trace element supplementation may also be indicated the child's estimated intake is considerably less than the RDA. Iron supplementation is usually required in the predialysis period when depletion of iron stores is documented by laboratory studies. Patients receiving erythropoietin generally require iron supplementation owing to increased turnover of red blood cells and require regular

Table 12-4

Physical activity coefficients for determination of energy requirements in children ages 3–18 years

Gender	Sedentary	Low active	Active	Very active
	Typical activities of daily living (ADL) only	ADL + 30–60 min of daily moderate activity (e.g., walking 5–7 km/h)	ADL + ≥60 min of daily moderate activity	ADL + ≥60 min of daily moderate activity + an additional 60 min of vigorous activity or 120 min of moderate activity

checking of serum iron levels. Zinc administration is not routinely administered to children during the predialysis phase, but because foods rich in zinc are often limited due to poor appetite, supplementation by pharmacologic means on the basis of RDA standards may be recommended if there is reason to suspect zinc deficiency. Fluoride supplementation is provided only when the water supply is not satisfactory (51).

Nutritional Support for the Child Treated with Maintenance Hemodialysis

Chronic hemodialysis (HD) results in dialysate loss of amino acids and water-soluble vitamins. In addition, the HD procedure itself has catabolic effects (52). In adult studies, up to 8 g of free amino acids lost per HD session have been reported. This loss is further influenced by

Table 12-8

Recommended phosphorus intake for children with CKD

Information based on (41)

choice of membrane: Newer synthetic polyacrylonitrile membranes have decreased losses relative to cellulose membranes (53).

Children treated with maintenance HD require sufficient calorie intake not only for weight gain and growth but also to avoid the use of proteins as an energy source. Current recommendations based on KDOQI guidelines are that children treated with maintenance HD should receive a calorie intake based on the Estimated Energy Requirement (EER) plus an activity factor (*Tables 12-2–4*). This is based on the fact that there is no evidence to suggest that children on HD have higher calorie needs than healthy children (2). Ongoing adjustments should be made, depending on the child's growth velocity and rate of weight gain (54).

Recommendations regarding the dietary protein intake (DPI) in patients on maintenance HD are that DPI should be based on the DRI for chronologic age plus an additional increment of 0.1 g/kg/day to compensate for losses in the dialysate (*Table 12-5*) (41).

Children on maintenance HD often have insufficient intake of oral nutrients because of anorexia and dietary restrictions. The first attempt at improving energy intake is through oral supplementation (55) (*Table 12-1–3*). As discussed previously, nutrition is most important during periods when energy demands are the greatest- in the first 2 years of life and also during adolescence (56). When oral supplementation fails, enteral feeding through a gastrostomy tube is common and successful at achieving catch-up growth in infants and young children (57, 58).

In cases where the GI tract is not functional for any reason and the patient is at risk for developing malnutrition, intradialytic parentaeral nutrition (IDPN) can be initiated (59). The effectiveness of IDPN in children and adolescence is controversial and few clinical trails are available in this population. Several adult studies revealed morbidity and mortality were lower in patients receiving IDPN (60, 61). However one study failed to demonstrate a beneficial effect of IDPN (62). A study evaluating the use of IDPN in the pediatric population demonstrated a dramatic increase in oral caloric intake and eventual weight gain after 3 months secondary to improved dietary intake.

Pediatric IDPN indications and appropriate compositions are not well defined but involve the infusion of 5–6 mg/kg/min of glucose, 1.2–1.4 g/kg/day of protein, and possibly the addition of intralipids (63).

Possible side effects of IDPN are hyperglycemia associated with glucose infusion or rebound hypoglycemia when the infusion is suddenly terminated. A frequent complaint in patients receiving IDPN is painful cramps in the arm containing the fistula, an effect thought to be due to the rapid infusion of the hyperosmolar solution causing rapid fluid shifts from muscle cell to interstitium. A long-term complication of IDPN is the possible development of abnormal liver function tests due to fatty deposits in the liver and cholestasis. Therefore, patients on IDPN require close monitoring of glucose control, hepatic function and lipid profile (59).

IDPN provides minimal overall supplementation, usually between 500 and 1,500 kcal and is administered only three times per week. In addition, only approximately 70% of the infused amino acids are retained owing to rapid clearance by HD (59). In patients who are severely malnourished and expected to rely on parenteral nutrition for an extended period of time, IDPN would be unable to provide sufficient nutrients. In such cases, total parenteral nutrition (TPN) may be indicated. However, in patients with moderate malnutrition who are unable to be given enteral supplementation, a short course of IDPN may improve nutritional status (63).

Thus, short-term IDPN can be a safe and effective nutritional intervention in children treated with HD who are unable to receive sufficient nutrition from enteral feedings. However, IDPN is quite expensive, and generally restrictive criteria prevent reimbursement. As soon as the patient can tolerate an increase in oral intake or becomes a candidate for tube feedings, enteral supplementation should be initiated.

The practice of prescribing water-soluble vitamins has not been rigorously tested but probably does little harm. There are losses of water soluble vitamins in the dialysate fluid, particularly ascorbic acid (64). Vitamin B6 and folate are important supplements especially because they are useful in reducing the homocysteine levels (65). In view of the reports of peripheral neuropathy and hyperoxalemia with high dose vitamin B6 and vitamin C supplementation, megavitamin therapy with water-soluble vitamins should be given only when there is a clear indication because of the risk of toxicity. Vitamin A levels are invariably increased in the plasma of ESRD patients because of retinol-binding protein is increased in uremia (66).

Trace elements are indispensible components of many enzymes, and abnormalities are primarily the result of uremia and the dialysis procedure. Plasma trace element concentrations in adult HD patients are distinctly different compared to those of healthy controls. Elements such as cesium, magnesium, molybdenum, and rubidium are reduced and cadmium, and lead are accumulated in HD patients (67). Adequate water treatment, including reverse osmosis, prevents the accumulation of the majority of trace elements in HD patients. Zinc supplementation may be recommended for patients with proven zinc deficiency, but its use in all HD patients is questionable (68, 69). Selenium deficiency is to be suspected in dialyzed patients, and supplementation may be beneficial by increasing glutathione peroxidase activity, cardioprotective effect, and immunostimulatory properties (70).

Nutritional Support for the Child Treated with Maintenance Peritoneal Dialysis

Malnutrition in children receiving chronic peritoneal dialysis (PD) has specific etiologies and treatments (71). Benefits of this modality, such as more constant control of uremia, a liberalization of dietary restrictions, and an additional source of calories from the dialysate glucose absorption, are counterbalanced by losses of proteins, amino acids, vitamins and trace elements in the dialysate, anorexia possibly related to the pressure effect of dialysate in the abdomen, and to the hyperglycemia effects of absorption of glucose from dialysate (72). Finally, there is a catabolic effect induced by episodes of peritonitis (73, 74).

Adequate dialysis may be an important factor for obtaining and maintaining adequate nutritional status and growth (75, 76). The delta height velocity of children with a mean age at initiation of PD of 28.5 months was found to be significantly correlated with total creatinine clearance, residual global filtration rate (GFR), and Kt/V urea (77). On the other hand on a cautionary note, Schaefer et al. have also described an important inverse correlation between growth rates and overall clearance in children on PD perhaps attributable to dialytic losses of an essential factor (78). The analysis of change in height SDS over 18 months in children on PD revealed that high transporter state and total dialysate volume had a negative effect, whereas higher dialytic creatinine clearance had a positive effect (79). Alternatively, a Kt/V greater than 2.75 in PD patients had no effect on nutrition but resulted in increased albumin losses (80). Malnutrition in PD patients is multifactorial. Increased losses of amino acids, water-soluble vitamins and trace elements occur, whereas protein losses are inversely related to the patient's weight and peritoneal membrane total area (72). During peritonitis, the permeability of the peritoneum for proteins and amino acids increases significantly by 50–100%. Between 100 and 300 mg of protein/kg/day are lost in the drained peritoneal dialysate, which translates to up to 10% of total protein intake (72, 74). The main protein lost is albumin, but there are also losses of immunoglobulins, transferrin, opsonins, and water-soluble vitamins, such as vitamin B6, vitamin C, and folic acid (81, 82).

In addition the nonspecific factors contributing to decreases caloric intake in CKD, there are specific factors related to PD, such as abdominal fullness from the dialysate and the absorption of glucose from the dialysate. Whereas the glucose absorbed from the dialysate provides calories, it also contributes to the anorexia seen in PD patients (55, 83). The number of calories provided by

dialysate glucose absorption may be predicted by an equation developed from a study of adults (84). Pediatric studies reported dialysate glucose absorption ranging from 9 to 18 kcal/kg/day, representing 7–15% of the total daily caloric intake respectively (85).

Current recommendations for energy intake in children treated on PD should follow the RDA for chronological age, including calories derived from the dialysate glucose, adjusted accordingly (54). Malnourished children however may require additional "catch-up" energy supplementation. Supplemental G-tube feeding facilitates weight gain in infants and older children receiving PD, and arrests the decline in height SDS traditionally observed in infants with ESRD (86, 87). Gastrostomy feedings via a button in children on PD significantly improves BMI (88).

Current recommendations regarding DPI in patients on PD are also based on the DRI for chronological age, to which a supplement of 0.15–0.3 g/kg/day is added to compensate for peritoneal losses (*Table 12-5*) (41). Dietary recommendations for children on PD could be further defined using a series of nitrogen balance studies. The correlation between estimated DPI and nitrogen balance indicates that a DPI of more than 140% RDA and a total energy intake of more than 85% are required to obtain an estimated nitrogen balance of at least 50 mg/kg/day, which is considered adequate for metabolic needs in children (89). High biologic value protein (e.g., meat, milk, eggs) should constitute 60–70% of the DPI (85).

The use of special amino-acid based dialysis solutions in children on PD may compensate for losses into the dialysate (90). Furthermore, the potential complications related to the dialysate glucose load, such as hyperlipidemia, excessive weight gain, and glucose intolerance, could be ameliorated (90, 91). Usually, one exchange per day is replaced with the amino acid solution consisting of both essential and nonessential amino acids with electrolyte composition similar to that of standard dialysis solutions. Between 50 and 90% of the amino acids are absorbed without any changes in ultrafiltration compared with standard dialysis solutions (92, 93). Side effects include a rise in blood urea nitrogen, metabolic acidosis, anorexia, and nausea (94, 95). This nutritional intervention is still rather expensive and should be reserved for malnourished patients who fail more conservative nutritional support.

Dietary intake of water-soluble vitamins is lower than the RDA in the majority of children on PD and supplementation results in intakes that exceed the RDA (96–98). Hyperhomocysteinemia, an independent risk factor for cardiovascular disease in adults (99), is associated with deficiencies of folate, vitamin B6, and vitamin B12 (100). Elevated plasma homocysteine levels in pediatric patients on PD were significantly reduced after administration of 2.5-mg folic acid daily for 4 weeks (101). Supplementation of trace elements such as zinc is reserved for specific deficiencies (71, 102).

The Use of Albumin and Prealbumin and Normalized Protein Catabolic Rate in the Nutrition Assessment

Laboratory markers historically used to evaluate nutritional status (albumin and prealbumin) are now shown to be unreliable (41, 102–108). While albumin is strongly correlated with morbidity and mortality and remains an important part of the overall clinical picture, it is not an accurate measure of nutritional status. Albumin and prealbumin are known to be skewed in states of fluid overload or proteinuria. However, even in the absence of edema or proteinuria, albumin and prelabumin fail to be accurate markers of nutritional status. The decrease in albumin seen with chronic disease has been found to be related to the illness itself and is independent of calorie or protein intake. Albumin and prealbumin are negative acute phase proteins and decrease with inflammation and infection. There has been an increasing trend to shift away from the use of albumin as a nutritional marker (41, 102–108). The most up-to date pediatric KDOQI guidelines address this issue. There continues to be much confusion surrounding the term malnutrition, which is distinct from wasting or cachexia (41). To help alleviate some of confusion surrounding malnutrition and inflammation in the kidney disease population, the International Society of Renal Nutrition and Metabolism (ISRNM) met to establish uniform guidelines for wasting in chronic kidney disease (109). The term malnutrition implies abnormalities caused by insufficient calorie, protein or micronutrient intake. Since disruptions in body composition in patients with kidney disease are often driven by inflammation and metabolic changes, the term malnutrition can be misleading. The ISRNM panel recommends the use of the term "protein-energy wasting" (PEW) for loss of body muscle mass and reserve. This is distinct from energy wasting or malnutrition in that PEW might occur despite adequate nutrition and cannot be corrected by increasing energy intake alone. The diagnosis of protein energy wasting requires three criteria – low levels of serum albumin, transthyretin, or cholesterol, reduced fat mass and reduced muscle mass (109).

In malnutrition that is not complicated by a disease state, such as anorexia nervosa, albumin and prealbumin

levels usually remain normal (105). The loss of body mass that occurs in starvation can be corrected simply by increasing nutrients in the diet. PEW in kidney disease involves an increase in proinflammatory cytokines, tumor necrosis factor alpha and interleukin-6. It is this inflammatory response that results in poor protein anabolism and a decrease in albumin and prealbumin. Increasing calorie and protein intake alone will not be enough to reverse the catabolism associated with the inflammation. Albumin, prealbumin C-reactive protein can be used to assess degree of inflammation or illness. They should not be used as an indicator of nutritional status or as a means to assess adequacy of calorie or protein intake.

In adolescent and adult HD patients, the normalized protein catabolic rate (nPCR) may serve as a predictor of nutritional status (41). The nPCR is calculated as the change in BUN between dialysis treatments as an estimation of the urea generation rate. The most recent KDOQI guidelines recommend that the target nPCR for adolescents and adults receiving HD be set at $\geq$1 g/kg/day (41). This recommendation is based on research that demonstrated a direct relationship between nPCR values less than 1 g/kg/day and weight loss over a 3 month period (41, 110). To date studies on nPCR values have not been shown to predict weight loss in younger children (41). The exact reason for this is unclear but may be related to differences in protein catabolism and growth rate in younger children (41). However, given that regular measurement of nPCR is not of increased cost and does not pose any risk to the patient, it should be monitored monthly in all children receiving HD (41). In theory, changes in nPCR may be reflective of nutritional status.

Inflammation and poor intake often overlap and inflammatory cytokines can induce anorexia. Negative effects on health and body composition can stem from both poor intake and inflammation. Treating both of these problems will result in the best outcome for the patient.

Therapies for Treatment of Protein Energy Wasting Currently Under Investigation

In recent years, new research has brought a clearer understanding of the causes of poor growth and wasting in chronic and end-stage kidney disease. It is well documented that simply increasing calories and protein in the diet has limitations and is often ineffective (111). The challenge now is to develop ways to treat the inflammation and metabolic disturbances that may in turn improve body composition, growth and appetite. The etiology of growth delay and loss of lean body mass in kidney disease is very complex and likely includes many mechanisms. Therefore, it has been suggested in recent literature that wasting should be treated with multiple therapies including diet and pharmacologic components for the maximum benefit (111).

Much attention has been given to certain functional foods because evidence suggests they may have strong benefits in mediating the inflammatory response. Two of the dietary therapies currently being investigated for use in the chronic kidney disease and dialysis population are omega-3 fatty acids and soy protein. Omega 3 fats (DHA and EPA) found in fish have been shown to have antihypertensive, antiatherogenic, antithrombotic and anti-inflammatory properties in the general population (112). It is suspected that omega-3 levels in blood and tissue of dialysis patients are inadequate (113). Several current studies have investigated effects of omega-3 fatty acids or fish intake on specific makers of inflammation in dialysis patients. A pilot study by Saifullah et al. found that supplementing hemodialysis patients with 340 mg of EPA and 170 mg of DHA significantly decreased CRP values compared with controls (114). One perspective study of interest found that patients who reported regular fish consumption had higher serum albumins at baseline (112). The same study found patients who reported fish consumption were 50% less likely to die over a 3-year period (112). A double blind placebo controlled trail looking at the combined effects of gamma tocopherol and DHA on dialysis patients found significant reductions in interleukin-6 in the treatment group compared with controls (115). A recent quasi experimental study by Moriera et al. examined the effects of omega-3 fatty acids in the form of sardines on CRP levels in dialysis patients (116). CRP levels were stratified into tertiles. There was a significant reduction in CRP found only in study participants at the highest tertile of CRP. Still another study showed no benefit in administration of omega-3 fats on dialysis patients (117). Clearly more randomized placebo controlled trails in both the adult and pediatric kidney disease population are needed to better assess efficacy, safety and dosing before omega-3 fatty acids supplements can be recommended. Preliminary data of omega-3 supplementation does suggest positive clinical benefits however. The main risk associated with this treatment appears to be increased bleeding times with doses in excess of 3 g per day (113).

Soy protein is another compound that has been found to have protective effects on the kidney and may also have anti-inflammatory properties (118). Soy contains phytoestrogens, which may block inflammatory gene

expression (119). A recent study found an inverse correlation between blood levels of soy isoflavones and inflammatory markers in hemodialysis patients (120). In East Asian countries where consumption of soy products is significantly higher, the prevalence of inflammation and vascular disease among dialysis patients is lower than in Western countries (121). Asian diets are higher in fiber and fish, which may also offer benefits in reducing inflammation (111). Prebiotiics and probiotics may also play a role in regulating the immune response and protecting the gut barrier (111). These studies suggest that the nutrition therapies should focus more attention on the specific foods that are supplying energy in the diet and not just the number of calories, protein and fat being consumed. Although these therapies are in the early stages of investigation, they warrant discussion, as they will likely be the treatments of the future.

In addition to diet interventions to reduce inflammation, pharmacologic treatments may also have a role (111). Drugs that may have anti-cytokine properties include cyclooxygenase (COX)-2 inhibitors, which have been shown to reduce tumor mediated wasting. Other anti-inflammatory drugs under investigation include anti-TNF drugs such as etanercept and infliximab, which have recently been shown to be effective in rheumatoid arthritis and inflammatory bowel disease (122). studies in rats have shown that anti- TNF drugs improve both appetite and weight (123). These findings suggest a potential role for these drugs in inflammation associated with kidney disease as well.

Developing ways to treat inflammation is likely the cornerstone to improving body composition and linear growth in children with kidney disease. Standard nutritional supplementation is seldom effective when inflammation is present. In addition, the presence of inflammation may diminish the action of growth hormone.

Influences of Nutrition Disorders on Renal Function

Influences of Obesity on Renal Function

Obesity has been found to be an important risk factor for a certain number of diseases, including cardiovascular diseases, hypertension (124), lipid and lipoprotein abnormalities (125). The kidney is an organ that can be directly affected by obesity. In this section only those kidney problems that are considered to be direct effects of obesity will be discussed. Other kidney conditions that can also be associated with obesity, but related more to obesity co-morbidities, such as hypertension and type 2 diabetes will be discussed in other chapters.

The prevalence and severity of obesity is increasing in the pediatric population and this is becoming a severe health hazard. As a consequence, the prevalence of the sequelae of obesity is expected to be increasing, as well. Indeed, the rates of obesity among US children defined as BMI $\geq$95th percentile for age and sex, have increased dramatically, with a threefold increase since 1976 (126). The National Health and Examination Surveys (NHANES) have shown steady increases from the late 1970s to 2004 in the prevalence of overweight (BMI $>$95th percentile of the US growth reference) and at risk of overweight (a BMI between the 85th and 95th percentile) among children and adolescents. In 2004, 17.1% of American children and adolescents were overweight, and an additional 16.5% were at risk of overweight. Nearly 14% of 2–5-year old children and 19% of 6–11-year old children were overweight (127).

The association of obesity with proteinuria has been well described in adults as early as the 1970s and 1980s (128, 129). Obesity-associated proteinuria in adults is associated with focal segmental glomerulosclerosis (FSGS) (123). In addition, it is interesting to note that non-obese patients with increased BMI due to elevated muscle mass are also at risk of developing a secondary form of FSGS that resembles obesity-related glomerulopathy (130). However, the FSGS diagnosed in obese and non-obese patients with high BMI shares clinical features distinctive from those usually seen with primary FSGS: albumin levels tend to be higher, often above 3.0 g/dL, total cholesterol levels are only mildly elevated, often $<$300 mg/dL, proteinuria is moderate, blood pressure tends to be normal or only mildly elevated and edema may be minimal to absent (131). Histologic features of obesity-associated proteinuria in adults include focal segmental sclerotic changes often in a hilar location, mesangial proliferation and hypertrophy, foci of hyalinosis, and glomerulomegaly. In obesity-associated FSGS, on electron microscopy, the foot process fusion is often minimal and focal rather than diffuse, as opposed to idiopathic FSGS (123).

Despite the prevalence of childhood obesity, an association between obesity and renal abnormalities such as proteinuria had not been clearly reported until very recently. In one study seven obese African American adolescent patients had FSGS and significant proteinuria, but no edema, serum albumin levels were slightly low and total cholesterol was normal or mildly elevated. The histologic features included glomerular hypertrophy, FSGS, increased mesangial matrix and cellularity, relative preservation of foot process morphology, and absence of

evidence of inflammatory or immune-mediated processes (132). These clinical and histological characteristics resemble the descriptions of obesity-related FSGS found in the adult studies. In addition, even clinically healthy nondiabetic obese children and young adults have a higher degree of microalbuminuria than normal weight children, indicating early glomerular dysfunction as a consequence of childhood obesity (133, 134).

There is clearly a predisposition for African American children to develop obesity-related FSGS (132). Idiopathic primary FSGS is also much more common in African American children and carries a more severe prognosis compared with other races (135, 136). Epidemiologic data also suggest that there is a racial genetic component to susceptibility to renal injury as a complication of both chronic hypertension (137, 138) and type 2 diabetes (139) in African Americans compared with Caucasians. The pathophysiology of obesity-related FSGS is considered to be multifactorial. Potential etiologic factors seem to be hyperfiltration, hyperlipidemia, renal venous hypertension, and glomerular hypertrophy.

Based on the above clinical and pathological characteristics, the patients with obesity-related FSGS seem to share features with a very diverse group of patients whose initiating factor is a reduction in renal mass. The reduction in renal mass can be due to reflux nephropathy (140), solitary kidney (141), unilateral nephrectomy (142), or the more recently described oligonephropathy of prematurity (143). These reduced numbers of glomeruli are subjected to hemodynamic stress by taking on the filtration of a constant volume of plasma. This sets up a cascade of proteinuria, mesangial cell gene expression, and focal scarring. Similarly, in case of obesity there is increased plasma volume and cardiac output that translates into a relative deficit in the number of glomeruli (144). In severe obesity, renal plasma flow and GFR levels exceeded those of lean controls by 31% and 51%, respectively (145). In addition, obesity is associated with hypertension. Significant weight gain is also accompanied by excess renal sodium resorption, leading to increased systemic arterial pressure and glomerular hyperfiltration (146). All these changes result in glomerular capillary wall stress, leading to glomerular cell proliferation, matrix accumulation and glomerular sclerosis by the following mechanisms. Glomerular hyperperfusion, hyperfiltration, and hypertension lead to stretching of the capillary wall with subsequent injury of endothelial, epithelial, and mesangial cells. A high transforming growth factor-β (TGF-β) concentration in the glomeruli could result from cyclic stretching of the mesangium, as well as from elevated levels of angiotensin II (147).

Hyperlipidemia is another potential contributing factor, since the Zucker obese rat, a model in which FSGS develops, is hyperlipidemic and reduction in serum lipids appears to decrease or prevent development of FSGS (148). A clinical study performing autopsies in obese adults noted that those with FSGS had higher lipid levels and showed lipid deposits in renal tubular epithelial cells (149). In support of the importance of hyperlipidemia in the pathophysiology of obesity-related FSGS, it was recently suggested that low-density lipoprotein apheresis may be useful in maintaining long-term remission in adult (150) as well as pediatric FSGS (151).

Renal venous hypertension has been incriminated as another contributing factor to obesity-related FSGS. One study demonstrated that adult obese patients had increased plasma volume and increased right atrial pressure, which decreased with weight reduction along with parallel decreases in urinary protein losses (128). Other conditions also associated with increased right atrial pressure and presumed renal venous hypertension such as tricuspid atresia, constrictive pericarditis, and pulmonary hypertension have been associated with proteinuria and nephrotic syndrome (152, 153).

The glomerular hypertrophy theory postulated a sequence of changes that may occur in the genesis of obesity related FSGS from glomerular hypertrophy, stimulated in part by angiotensin II and other growth factors, leading to production of excess amounts of extracellular matrix in mesangial areas and the development of obesity related FSGS (154). Enhanced formation of angiotensin II additionally promotes tissue injury via inflammation, oxidative stress, and profibrotic actions (155).

Recent studies showed the connection between adipose tissue and kidney at molecular level mediated by leptin, a small peptide mainly produced in adipose tissue, therefore directly reflecting the amount of body fat. In glomerular endothelial cells, leptin stimulates cellular proliferation, (TGF-β) synthesis, and type IV collagen production. Conversely, in mesangial cells, leptin upregulates synthesis of the TGF-β type II receptor and stimulates glucose transport and type I collagen production through signal transduction pathways involving phosphatidylinositol-3-kinase. These data suggest that leptin triggers a paracrine interaction in which glomerular endothelial cells secrete TGF-β, to which sensitized mesangial cells may respond. Both cell types increase their expression of extracellular matrix in response to leptin. Infusion of leptin into normal rats produces the development of FSGS and proteinuria (155).

There is clear evidence that the treatment of obesity-related FSGS should include weight reduction. This

has been first shown in the 1980s in an animal model of obese Zucker rats, when a reduction in FSGS lesions occurred with reduced dietary intake and subsequent reduced weight (148). Several studies reported that extensive reduction of body weight, without use of any therapy, markedly reduced or eliminated proteinuria in obese adult patients (156–158). In the pediatric study, one patient showed a dramatic reduction in proteinuria in response to weight reduction (132). In general, patients who lost weight successfully showed marked decreases in proteinuria (159). However, unfortunately studies have shown that very few patients actually achieved a sustained weight loss, in which case the prognosis of obesity-related FSGS was poor, with almost one-half of patients developing advanced renal failure (160). This is why it was suggested that for refractory cases of obesity-associated renal disease in adults, when weight loss is not achieved by conventional methods such as diet and exercise, anti-obesity medication or bariatric surgery to be tried. Rimonabant, a new anti-obesity medication, showed beneficial potential effect in treating clusters of metabolic syndrome, which may ultimately suggest potential benefit in treating obesity-related glomerulopathy (161). Bariatric surgery has been evaluated in adults with extreme obesity and at 24 months after surgery, obesity-related renal alterations considerably improved (162). The effects of neither antiobesity medications, nor bariatric surgery have been studied in pediatric patients with obesity-related kidney diseases. The other treatment modality is the use of medications that have negative effects upon the renin-angiotensin system, such as angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers. In an animal model of obese Zucker rats, the use of an ACE inhibitor normalized proteinuria, cholesterol levels, glomerular lesions, and podocyte morphology (163). One study done in obese adults reported that patients with proteinuria who were given captopril had reductions in proteinuria similar to those seen with weight reduction alone (164). It is not clear whether the action of ACE inhibitors in such cases is related to hemodynamic changes in efferent arteriolar resistance or to non-hemodynamic factors. In two pediatric studies, patients with obesity-related FSGS who were given ACE inhibitors had significant reduction of proteinuria (132, 165).

Influences of Malnutrition on Renal Function

Extensive data already showed in the 1960s and 1970s that renal development is influenced by many factors, including nutrition. Maternal diet may influence nephrogenesis, with the result that individuals whose mothers have low protein intake during gestation may have a relatively lower total number of nephrons at birth (166, 167). After birth, the nutritional intake of an infant is a major stimulus to both renal growth and functional maturation. In early infancy, protein and amino acid intake can influence renal growth. GFR increases more rapidly in premature infants receiving a relatively high-protein diet than in those who do not. However, a high protein diet has been reported to be associated with metabolic acidosis, failure to thrive and even evidence of renal injury (168).

Later in life, renal function alterations are similar with diverse forms of malnutrition such as primary protein-calorie malnutrition, iatrogenic malnutrition or anorexia nervosa. These changes include decrease in GFR, decrease in renal plasma flow, poor urinary concentrating ability, decreased ability to excrete sodium and impaired acid excretion. In case of malnutrition, GFR can be as low as 50%. A low calorie diet and also a low protein diet can independently produce a fall in GFR or renal plasma flow (169). These changes are usually reversible, not associated by renal structural damage, and are not explained by hypoproteinemia or edema which can occur in these states (170).

13 Fluid and Electrolyte Therapy in Children

Michael J. G. Somers

Introduction

The prescription of fluid and electrolyte therapy is a common task for the pediatric clinician. The clinical situations requiring such therapy are myriad and range from the urgent in cases of children with circulatory collapse to the more mundane in children with mild dehydration from gastroenteritis. Superimposed on the simple provision of any set amount of water and salts are the changes in normal physiology and homeostatic mechanisms that accompany both acute and chronic illness. Recognition of each child's individual clinical situation and each situation's ultimate goal in respect to hydration or volume resuscitation is crucial for the provision of the correct combination of fluid and electrolytes in the proper amount of time.

In the eighteenth century, attempts to replace the profound enteral losses of salt and water from cholera infection led to an initial understanding of the morbidity and mortality that accompanies significant perturbations in fluid and electrolyte balance (1). The recognition that affected patients improved with repeated infusions of a saline solution became an impetus to define fluid and electrolyte needs in healthy individuals and to develop clinical parameters for fluid and electrolyte therapy. The understanding gained from clinical observations in epidemics of cholera and other diarrheal illness came to be generalized to other conditions in which there was an element of dehydration or poor circulation and ultimately helped to define the threshold for the minimum daily provision of fluid and electrolytes – so-called maintenance requirements – as well as a threshold of maximal tolerance.

By the early twentieth century, clinicians began more frequently to use such techniques as intraperitoneal injection of saline or intravenous infusion of isotonic solutions to try to restore circulation in children with volume compromise (2, 3). Additionally, spearheaded by Gamble and colleagues, fluid spaces in terms of intracellular and extracellular compartments were defined and the kidney's role in the regulation of overall body volume and specific gradients of solute between these fluid spaces were elucidated (4, 5). These early studies established the basis for all modern fluid and electrolyte therapies.

By the middle of the twentieth century, Holliday and colleagues devised simplified equations to link average daily metabolic rate to daily fluid requirements, and the practice of calculating daily fluid and electrolyte needs for an ill child based on continuing or "maintenance" needs and past and current losses or "deficits" was taught as the gold standard to minimize complications and improve clinical outcomes (6). Although the need to make exceptions to this approach in situations with reduced urine output or non-osmotic stimulated antidiuretic hormone activity was clearly stated, emphasis on these empiric equations led to relatively formulaic hydration protocols regardless of specific clinical condition. Moreover, in children requiring rehydration, a tradition of fluid therapy grounded on the so-called "deficit therapy" approach became widespread (7, 8).

Reassessment of this traditional approach, again spawned in large measure by Holliday's work, has come to appreciate that such elaborate maneuvers are often unnecessary and that reassessment of a child's response to any initial fluid therapy is crucial to the assessment of its adequacy and applicability (9). Moreover, increasing recognition that the use of oral rehydration solutions are a simple, safe, and efficacious alternative for most children in need of fluid and electrolyte therapy has also impacted this tradition of precisely calculated intravenous fluid volumes (10).

Nonetheless, there continues to be a place for such careful assessment and prescription of fluid and electrolyte therapy, especially in children with non-diarrheal illness (11). In more complex disorders of fluid and electrolyte pathophysiology, such as seen in critically ill children with sepsis, burns, trauma, or postoperatively, an understanding of the distribution of body fluids, usual fluid and electrolyte requirements, and the effect of disturbances in normal homeostatic balance remain vital to the correct prescription of therapy and the proper assessment of response. Such an understanding resonates

louder when approaching the care of a child with renal disease. Frequently, the presence of a preexisting renal condition or the development of acute kidney injury complicates the fluid and electrolyte management of the child. Standard approaches to fluid therapy assume that normal renal homeostatic mechanisms will come into play with the provision of adequate water and electrolytes. Such approaches are ill advised for the child with renal disease in whom such regulation may be deranged. Similarly, these approaches may have limited value with the critically ill child in whom normal fluid and electrolyte homeostasis may also be altered. In these circumstances, the clinician needs to approach fluid and electrolyte therapy systematically and with attention to individual clinical circumstance. Otherwise, in the absence of a customized prescription, the possibility arises that a therapeutic intervention may be deleterious, given preexisting reduced tolerance to alterations in body fluid volume, composition, or distribution.

Lastly, with improvements in long-term management strategies, many children with severe chronic disease are living longer lives, often surviving into adulthood. As a result, there is also an increasing population of children and adolescents with conditions such as chronic pulmonary disease, complex congenital cardiac disease, and chronic kidney disease who may require fluid and electrolyte therapy for support through an acute illness or during medical or surgical procedures when usual oral or enteral hydration may be contraindicated. For these children with more fragile clinical states, hydration must also be tailored to individual need and tolerance, and clinicians cannot rely on the formulaic prescription of water and electrolytes. In this regard, these children with significant chronic disease pose a special challenge to a medical community that often wishes to simplify or standardize approaches to care across a spectrum of patients. In addition, they also demonstrate why a well grounded understanding of volume balance and appreciation of both normal and aberrant physiology is critical to the clinician who is regularly prescribing fluid and electrolyte therapy.

Total Body Water

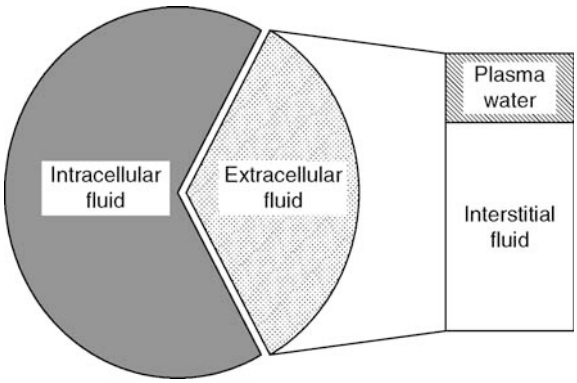
Extracellular and Intracellular Fluid Compartments

Although water makes up a large component of body weight, the exact proportion in each child varies with age, body size, and body composition. Early in gestation, 90% of the weight of the developing fetus may be water. By the first weeks of the third trimester, total body water (TBW) of the developing fetus approximates 80% of body weight in kilograms. This percentage falls to 70–75% in term infants, 65–70% in toddlers and young children, and eventually to 60% in older children and adolescents. Lean individuals have more body water than obese individuals and adolescent boys with increasing muscle mass tend to have more total body water than less muscular adolescent girls. Although 60% is the usual benchmark for estimating TBW in older children and adults, the actual percentage may be lower, especially in less well-conditioned individuals and the elderly (12).

Body water is found in both intracellular and extracellular compartments (*Fig. 13-1*). The intracellular compartment consists of the water within the cells of the body, comprising about two-thirds of TBW or 40% of body weight. The extracellular compartment comprises one-third of TBW or 20% of body weight. The extracellular compartment is divided into the interstitial fluid that bathes all cells and the plasma water that is carried intravascularly. The increased TBW seen in young children is the result of a relatively increased surface area as compared to body weight that accounts for an overall increased extracellular compartment (13).

The boundary between the intracellular and extracellular compartments is the cell membrane. Input or output from the body proceeds via some interface with the extracellular compartment. For instance, intravenous electrolyte solutions are infused into the extracellular intravascular space and their subsequent delivery intracellularly depends

Figure 13-1
Total body water: Fluid compartments and solute composition.



on a host of factors that influence transport across the cell membrane.

Since most cell membranes are readily permeable to water, the distribution of water between the intracellular and extracellular spaces reflects osmotic forces. In each body space there is a solute that is primarily sequestered within that compartment and that maintains its osmotic gradient (14, 15). For instance, activity of the sodium-potassium pump found in cell membranes leads to an increased concentration of potassium intracellularly and an increased concentration of sodium in the interstitial fluid. Thus, sodium serves as the effective osmole interstitially and potassium intracellularly. Similarly, plasma proteins, most notably albumin, exert an osmotic force to maintain water intravascularly. Hydrostatic perfusion pressure counterbalances this osmotic force by pushing water across the capillary from the lumen to the interstitium. Changes in the distribution of effective osmoles can result in redistribution of water between intracellular and extracellular spaces.

A dynamic equilibrium exists between the intracellular and extracellular spaces. Diffusional gradients, osmotic forces, and the activity of cellular transporters all combine to establish the composition differences between body compartments. Since the intracellular space cannot be directly accessed, its composition can be altered only by affecting the extracellular space and its subsequent communication with the cell. Any intake by ingestion or infusion into the extracellular space will result in a new equilibrium being established with the intracellular space as solute and fluid comes to be exchanged. Ultimately, the final equilibrium is a result of complex biochemical, electrical, and physical interactions.

Communication between the cellular spaces can be bidirectional. In other words, there can be exchange from the intracellular space to the extracellular space allowing for transfer or release of cell metabolites. In addition, since the extracellular space can communicate with the external milieu, output from the extracellular space to the external milieu results in effective excretion from the body. No direct communication exists, however, between the intracellular space and the external milieu. Any output from the cells themselves is mediated via the cell's direct ability to interface with the interstitial fluid or the plasma water.

Any impairment in the patient's normal homeostatic mechanisms regulating fluid and electrolyte balance will have a striking impact on the patient's total body water and its extracellular and intracellular constituents. An example of this disruption of normal balance is the development of hypertension frequently seen in individuals with progressive chronic kidney disease. As glomerular filtration rate falls, the ability of the kidney to excrete free water (CH_2O) also declines. Frequently, this change is in the setting of a decreasing number of effectively functioning nephrons with concomitant impairment of overall tubular solute excretion, most notably salt. Superimposed on this baseline tendency for dysregulation of solute and water balance may be clinical factors such as circulatory failure and decreased effective arterial volume leading to further renal salt and water retention. This salt and water overload leads to chronic expansion of TBW and mediates systemic hypertension with expansion of the extracellular volume compartment. Appropriate therapy in this instance would include use of diuretics to reduce the total body burden of salt and water and to restore the total body water to a more physiologic state. In this instance, failure to appreciate the preexisting expansion of the total body water because of chronic salt and water overload could prove deleterious to the patient if management did not include some measure to reduce the salt and water overload. This example also underscores the concept that fluid and electrolyte therapy may involve the removal of solute and water as well as the more usual notion that it is solely concerned with the correction of deficits of electrolytes and volume.

Effective Circulating Volume

Effective circulating volume is a more abstract concept than the division of body water into intracellular and extracellular fluid compartments. As the vascular volume circulates, oxygen and nutrients get delivered to the intracellular space and cellular metabolites get cleared from the intracellular space. The effective circulating volume refers to that portion of the extracellular vascular space that actually perfuses the tissues and accomplishes such an exchange.

Any compromise in this exchange proves deleterious to usual cell homeostasis and, as a result, the body constantly senses and regulates effective perfusion of fluid through the intravascular space. Homeostatic feedback mechanisms include baroreceptors that respond to the stretch of specialized areas of the carotid arteries and the atrium. Hypoperfusion of these areas decreases stimulation of the stretch receptors, triggering the secretion of vasopressin that increases water reabsorption in the most distal nephron and expands the vascular volume.

Similarly, in response to glomerular hypoperfusion, there is not only decreased afferent arteriolar stretch but also decreased glomerular filtration and delivery of sodium to the macula densa. These stimuli both can lead to the secretion of renin from the juxtaglomerular cells of the afferent arteriole. Renin release initiates a cascade resulting ultimately in increased aldosterone-mediated sodium and water reabsorption from the kidney as well as increased angiotensin-mediated vasoconstriction and sodium and water uptake.

Effective circulating volume should be considered the product of multiple factors, not the least of which include the size of the vascular space and the influence of various regulatory hormones. As a component of the extracellular body water, the size of the vascular space often parallels the size of the extracellular space. The size of the vascular space and the adequacy of the effective circulating volume do not, however, always vary coordinately. The extracellular space may be replete or expanded and the actual effective circulating volume decreased. For instance, children with significant liver disease are often edematous, due to sodium retention and expansion of the interstitial component of the extracellular space. The intravascular component of their extracellular space may also be expanded as a result of factors resulting in avid salt and water reabsorption by the kidney. But, because of portal hypertension, splanchnic vessel congestion, and multiple arteriovenous spider angiomas that are seen with this condition, much of the expanded intravascular volume is ineffective – it does not serve to perfuse the tissues and accomplish effective cellular exchange. Thus, these children act as if they are volume depleted: they avidly reabsorb any filtered sodium and excrete small volumes of urine and they vigorously continue to expand their already over expanded extracellular space by reabsorbing even more salt and water in response to the effects of renin and ADH. Similarly, this paradoxical state of sodium avidity and ADH-mediated water reabsorption characterizes children with nephrotic syndrome or with cardiac failure despite their preexisting expansion of the extracellular space.

In managing all aspects of a patient's fluid and electrolyte therapy, the clinician must accurately assess both the patient's current extracellular volume status and effective circulating volume and reconcile these with potential causes of volume loss. At all times, it is crucial to maintain an effective circulating volume and to make therapeutic decisions based on the unique clinical circumstances facing the patient. Such management may require rather disparate therapeutic interventions. For instance, expansion of the extracellular volume with vigorous rehydration may be called for in a child with poor perfusion secondary to gastroenteritis-induced dehydration whereas another child with equally poor perfusion due to cardiodynamic compromise may be intravascularly replete and require the initiation of pressor therapy and another child with edema from relapsed nephrotic syndrome may actually require fluid and salt restriction. These examples underscore that loss of effective circulating volume generally arises as a result of one or more broad perturbations in the extracellular fluid compartment that impacts effective perfusion (*Table 13-1*). In hospitalized children where there may be both aberrant disease related physiology and iatrogenic derangements of regulatory response, the causes of effective volume perturbations may be even more complex.

Clinical signs and symptoms of effective circulating volume loss may be subtle. At times, there may be preservation of effective circulating volume in the face of an overall depleted extracellular fluid compartment. Failure to initiate appropriate fluid and electrolyte therapy in such a circumstance may result in eventual compromise of the effective circulating volume. Important initial clinical signs to assess in any patient being evaluated for fluid therapy include pulse rate and capillary refill. Tachycardia and sluggish refill generally precede more obvious signs of ineffective circulation such as hypotension and oliguria. Clinical symptoms may also be non-specific and include fatigue and lethargy that are often attributed to an underlying illness rather than volume depletion. Proper restoration of effective circulating volume or extracellular fluid compartment depletion requires an understanding of baseline fluid and electrolyte needs as well as consideration of any extenuating clinical circumstances unique to the patient in question.

Table 13-1

Alterations in effective circulating volume

Cause	Mechanism
Contracted extracellular fluid space	Water or sodium chloride deficit
Massive vasodilatation	Loss of vascular tone sustaining perfusion pressure
Loss of intravascular osmotic pressure	Osmotic fluid losses into interstitium
Overfill of the intravascular space	Hydrostatic fluid losses into interstitium
Hemorrhage	Direct loss of blood and plasma water

Water and Electrolyte Requirements

Maintenance Therapy

The concept of maintenance therapy refers to that amount of water and electrolytes required to replace usual daily losses and to maintain an overall net balance of no water or electrolytes gained or lost. Such needs are a function of homeostatic and environmental factors and vary from day to day and from child to child. In the average child with adequate access to water and food, these maintenance needs are generally readily met (6, 16). In the ill or hospitalized child who requires therapeutic intervention and in whom there may be ongoing aberrant physiology, these needs must be considered when clinicians prescribe fluid therapy.

To assist in estimating maintenance needs, fluid and electrolyte requirements are typically calculated based on weight or surface area, but individual clinical circumstance must be considered when making such calculations (17). For instance, the 20-kg child who is well will require a far different "maintenance" quantity of fluid and electrolytes than the 20 kg child who is tachypneic and febrile or the 20 kg child who is anuric and on a ventilator in the pediatric intensive care unit. Careful clinical assessment of the patient's volume status and close attention to the balance of overall daily input and output will prove more useful at arriving at a correct estimate of daily fluid and electrolyte needs than merely using mathematical equations without clinical correlation. With these caveats in mind, it is nonetheless a common clinical practice to make certain empirical assumptions regarding daily needs for water and the major electrolytes.

Historically, daily maintenance water needs have been estimated based on energy expenditure (*Table 13-2*) (6, 16). For each kilocalorie of energy expended daily, 1 mL of water must be provided. Based on the computed energy expenditure of the average hospitalized patient, for the first 10-kg of body weight, 100 mL of water per kg is provided daily. For the next 10 kg of body weight, 50 mL of water per kg is provided daily, and for every kg of body weight in excess of 20 kg, 20 mL of water per kg is provided daily. In addition, in the process of oxidation of carbohydrate and fat, approximately 15 mL of water is generated for every 100 kcal of energy produced. This water of oxidation contributes significantly to overall water balance.

Maintenance water losses occur from urine output and from insensible sources that are almost exclusively evaporative and respiratory losses. In the child with average metabolic demands, for every 100 kcal of energy expended, 100 mL of water must be ingested. Oxidative metabolism generates 15 mL of water in the course of producing the 100 kcal of energy. Of this 115 mL of water, 40 mL is lost insensibly and 75 mL is lost as urine output. Overall, net water balance, composed of 100 mL ingested, 15 mL generated and 115 mL excreted, becomes equilibrated.

Table 13-2
Relationship of body weight to metabolic and maintenance fluid needs

Body Weight (kg)	Metabolic needs[a] (kcal/day)	Maintenance fluid needs[b]	
		mL/day	mL/h
5	500	500	20
10	1,000	1,000	40
15	1,250	1,250	50
20	1,500	1,500	60
30	1,700	1,700	70
40	1,900	1,900	80
50	2,100	2,100	90
60	2,300	2,300	95
70	2,500	2,500	105

[a]Based on 100 kcal/kg for first 10 kg of body weight + 50 cal/kg for next 10 kg of body weight + 20 cal/kg for next 50 kg of body weight
[b]Based on need of 1 mL of water to metabolize 1 kcal of energy
As described in (6)

Clinical factors can have a striking impact on insensible water losses (*Table 13-3*). Fever increases insensible losses by more than 10% per degree Celsius. Premature infants with relatively increased surface areas for size can have insensible losses two to threefold higher than baseline, especially if they are on open warmers or under phototherapy. On the other hand, children on ventilators providing humidified oxygen may have half the insensible losses of a non-ventilated child.

Similarly, urinary water output can vary tremendously. A child with a renal concentrating defect or ADH unresponsiveness may have urinary water losses of several liters per day, whereas an oligoanuric child will have no appreciable urinary water losses. In any child with normal renal function, even in the setting of maximal ADH stimulation, there is a minimal volume of urinary water obligatory to excrete the osmotic load ingested by the diet and generated by basal metabolism. As a result, even the child concentrating urine to 1,200–1,400 mOsm/L will lose nearly 25 mL of urinary water per 100 kcal of energy expended (6).

Table 13-3

Factors affecting insensible water losses

Increased losses	% Change	Decreased losses	% Change
Prematurity	100–300	Enclosed incubator	25–50
Radiant warmer	50–100	Humidified air	15–30
Phototherapy	25–50	Sedation	5–25
Hyperventilation	20–30	Decreased activity	5–25
Increased activity	5–25	Hypothermia	5–15
Hyperthermia	12%/°C		

Recent reports contend that the relationships between energy expenditure and water requirements demonstrated by hospitalized children at bed rest do not apply to anesthetized or critically ill children (18). For instance, in infants and children studied during general anesthesia, energy expenditure was half that of awake children at bedrest. On the other hand, water needs for cell metabolism was increased over baseline by about 60%, leaving the overall relationship between water needs and caloric expenditure similar in both situations. In some critically ill children, maintenance volumes may need to be reduced by 40–50% to prevent positive water balance (19).

Serum Osmolality

Water homeostasis maintains a stable serum osmolality. Serum concentrations of sodium, glucose, and urea nitrogen determine serum osmolality (20). Serum osmolality is estimated by the equation: (2 × serum Na) + (serum glucose/18) + (BUN/2.8), where the serum sodium is measured in mEq/L and the glucose and BUN in mg/dL. In the majority of children with no functional renal impairment and normal glucose metabolism, the contributions of BUN and glucose to the effective osmolality are small and the serum osmolality can be estimated by doubling the serum sodium concentration (21, 22). Thus, most children have a serum osmolality between 270 and 290 mOsm/L, corresponding to serum sodium values of 135–145 mEq/L.

Chemoreceptors in the hypothalamus constantly sense serum osmolality and respond to even small variations towards either limit of normal by adjusting ADH release from the posterior pituitary. Changes in osmolality in the setting of hypovolemia augment ADH release further. ADH effect on water permeability of the collecting tubule is a principal influence on the regulation of water balance.

Alterations in water intake or excretion result in the development of hypo- or hyperosmolality as the usual ratio of extracellular solute to water is perturbed. Since sodium is the largest component of extracellular osmolality, its concentration can be influenced profoundly by changes in water metabolism. An understanding of this link between water regulation and serum sodium values is crucial when prescribing fluid and electrolyte therapy. Most importantly, the clinician must recognize that hypo- or hypernatremia is usually a manifestation of impaired water regulation and that therapy must address regulation of water balance rather than alterations in body sodium stores.

Water Homeostasis in Acutely Ill Children or During the Perioperative Period

In ill children, there are multiple causes of both physiologic and aberrant vasopressin effect as listed in *Table 13-4* (23). As a result, if these children receive hypotonic intravenous fluids for prolonged periods of time or in volumes exceeding those generally recommended, there is the risk of acute hyponatremia. After volume resuscitation with isotonic fluids, most hospitalized children have traditionally been provided hypotonic fluids for their maintenance therapy. Given the tendency for ill children to have vasopressin effect independent of the usual osmotic and volume related stimuli, over the last decade some have suggested that isotonic fluids may be safer alternatives and should be continued as the source of maintenance fluid even after acute volume repletion (24).

Similarly, some have called for using isotonic saline as the intravenous fluid of choice whenever a maintenance infusion is needed in setting like the perioperative period when oral hydration has been held and when high ADH levels may come to be expected because of pain or anxiety. In these instances, children could receive intravascular volume expansion with an initial infusion of 20–40 mL/kg over a period of a few hours and then continued on isotonic saline as dictated by clinical circumstance, rather than the transition to fluids with more free water content.

Table 13-4
Common causes of vasopressin effect in hospitalized children

Category	Specific etiology
Physiologic	Hyperosmolar state, hypovolemia
Pulmonary	Pneumonitis, pneumothorax, asthma, bronchiolitis, cystic fibrosis
Drug effect	Narcotics, barbiturates, carbamazepine, vincristine, cyclophosphamide
Metabolic	Hypothyroidism, hypoadrenalism, porphyria
CNS	Infection (meningitis or encephalitis), tumor, trauma, hypoxia, shunt malfunction, nausea, pain, anxiety

Proponents of this routine believe it would decrease the overall numbers of hospitalized children who develop hyponatremia and prevent hyponatremia-related central nervous system damage (25).

Others have claimed that long term maintenance infusions of isotonic saline to all ill or perioperative patients may result in sodium loading in children who do not have triggers for water retention (8, 26). Moreover, hypernatremia has been described in some children receiving less sodium than that provided in these maintenance isotonic infusions (27). These cases of hypernatremia are often a result of an underlying renal concentrating defect, related to significant free water loss from sources other than urine, or resulting from aggressive fluid restriction (28). Children with certain renal or cardiopulmonary problems may be especially sensitive to such sodium loads and may more readily develop unintended sequelae of such sodium provision (29).

Several studies have shown that children with acute illness requiring emergency department evaluation or hospitalization do seem to be at risk for hyponatremia. In one study of 103 children admitted to a German pediatric hospital, nearly 80% had elevated serum ADH levels and increased plasma renin activity, independent of the underlying illness. As expected with ADH release, plasma osmolality was reduced significantly in comparison to a group of well children (23). In another report from a Canadian pediatric center, fewer than 5% of children were hyponatremic at presentation to the emergency department, but nearly 10% became hyponatremic after hospital admission, most as a consequence of excess free water provision by aggressive intravenous hydration with hypotonic fluid. Hospitalized children who became hyponatremic received on average three-times the volume of electrolyte free water than their hospitalized colleagues who remained eunatremic and were also three-times more likely to receive fluids at a rate that exceeded recommended maintenance rates (30).

A retrospective analysis of postoperative admissions to a pediatric ICU found that 11% of children manifested hyponatremia (serum sodium <130 mEq/L) during their ICU stay (31). Of those children with hyponatremia, although there was a trend towards an increased incidence in children receiving hypotonic fluids in comparison to children given isotonic solutions, there was no statistical difference demonstrated in the incidence of what the authors termed either moderate (<130 mEq/L) or severe (<125 mEq/L) hyponatremia. No children developed any neurologic sequelae or other morbidity. Children did have serum electrolytes assayed four times daily, however, so this vigilance likely resulted in clinical interventions to prevent exacerbating hyponatremia.

A prospective randomized study of 102 children with gastroenteritis at an Australian children's hospital demonstrated that the risk of developing hyponatremia decreased with provision of isotonic saline (32). Eunatremic children at presentation were most protected from subsequent falls in serum sodium when provided isotonic (0.9% NaCl) versus hypotonic (0.45% NaCl) intravenous solutions. Urinary biochemistry demonstrated that in the face of isotonic fluid provision hyponatremic children were more likely to retain sodium and bring their serum sodium values closer to normal, whereas children with normal serum sodium values already at presentation were able to excrete excess sodium appropriately and prevent hypernatremia.

A meta-analysis of six studies comparing hypotonic and isotonic maintenance intravenous solutions in children suggested that no single fluid composition or rate is ideal for all children but that an isotonic or nearly isotonic solution may prove less likely to cause symptomatic hyponatremia in acute illness and the perioperative period (33). Despite this growing body of literature to suggest that isotonic fluids may be preferable in many situations where non-osmotic ADH effect can be expected, children are still commonly prescribed hypotonic fluid therapy. A recent survey of anesthesiologists in the United Kingdom found that 60% were still prescribing hypotonic fluids for children intraoperatively, with 75% prescribing such fluids in the postoperative period (34).

Maintenance Electrolyte Therapy

Estimates for the maintenance requirements of the major electrolytes sodium, potassium, and chloride can also be

made based on metabolic demands and daily water needs (6). For sodium and chloride, approximately 2–3 mEq/100 mL of daily water requirement is needed with 1–2 mEq of potassium for each 100 mL of daily water need. Again, these estimates require adjustment based on clinical circumstance but the daily intake of most healthy individuals contains more than adequate electrolytes for maintenance needs. Although at times there can be significant electrolyte losses through the skin or the gastrointestinal tract, most electrolyte losses are urinary (17, 35). In the setting of anuric renal failure and no concomitant electrolyte losses from other sources, a much lower level of maintenance electrolyte supplementation is needed and patients may maintain adequate electrolyte balance with water supplementation alone to provide insensible fluid losses.

As with provision of water, in children who require electrolyte therapy their electrolyte prescription must be tailored to their individual needs. For the provision of sodium and chloride, this requires careful assessment of the extracellular fluid space, especially the effective circulating volume. Providing too little sodium chloride results in volume contraction and circulatory compromise; providing too much causes volume overload and sequelae such as hypertension and edema.

Similarly, inappropriate potassium supplementation may have significant clinical ramifications. In children with diminished renal function or who are at risk of hyperkalemia for other reasons, it is usually appropriate to forego any maintenance potassium supplementation. When supplementation is given acutely, it is important to monitor serum potassium values closely. When chronic potassium supplementation is needed, there should continue to be periodic assessments. A course of supplemental potassium administered orally is safer than a bolus intravenous injection; intravenous potassium supplements rarely need to exceed 0.5 mEq/kg/h (20).

Perturbations in Fluid and Electrolyte Homeostasis

Alterations in Water Balance, Serum Sodium, and Cell Volume

As discussed above, the regulation of osmolality is achieved by alterations in water intake and excretion. Serum sodium levels often vary with these alterations in water balance. Generally, serum sodium is kept regulated at levels between 135 and 145 mEq/L. A serum sodium value below 130 mEq/L or above 150 mEq/L is out of the range of normal homeostasis and most often indicates a problem with water balance.

Since sodium is the major extracellular osmole, alterations in serum sodium can result in water flux between the intracellular and extracellular spaces. Because significant water movement into or out of cells could prove deleterious to cell function, cell volume is closely regulated to minimize such shifts (36). For instance, with hyponatremia there is decreased effective osmolality in the extracellular space. As a result, water can shift from the plasma into the intracellular space and cell swelling will occur. To counterbalance such swelling, the cell acutely regulates its volume by transporting electrolytes, especially potassium, from the intracellular space into the extracellular space, thereby decreasing the osmotic gradient for water transfer. Over several days, when faced with chronic hyponatremia or chronic hypoosmolality, the cells will also achieve effective volume regulation by losing organic osmolytes such as taurine and inositol, thereby further diminishing the osmotic gradient for water transfer into the cell (37).

With hypernatremia, the osmotic gradient favors water movement out of the cells and into the extracellular space and, without protective mechanisms, cells will shrink. Again, there are both acute and chronic mechanisms minimizing these changes in cell volume. Acutely, there is transport of electrolytes intracellularly, whereas with time there is stimulation of the production of organic idiogenic osmoles (37, 38). Together, these act to blunt the loss of intracellular volume that would otherwise occur.

Changes in serum sodium values evolving slowly and reflecting chronic processes tend to be better tolerated clinically than acute alterations. Such slow changes allow for maximal counter-regulation and fewer clinical sequelae. On the other hand, profound sudden alterations – serum sodium values falling below 120 mEq/L or above160 mEq/L – are often accompanied by dramatic neurologic complications directly related to the acute changes in cell volume in the central nervous system.

These regulatory mechanisms must also be kept in mind when formulating specific therapeutic intervention. Acute perturbations can be corrected more rapidly than chronic conditions because the full gamut of responses to the imbalance has yet to come into play.

Hyponatremia: Initial Approach

Hyponatremia is usually defined as a serum sodium value less than 130 mEq/L. Depressed serum sodium values are likely to be the result of persistent ADH effect and a

relative surfeit of water for solute in the extracellular space; hyponatremia uncommonly arises secondary to depleted salt stores alone.

Infrequently, pseudohyponatremia may be seen. Pseudohyponatremia is not a depletion of sodium stores but a change in the usual make-up of the extracellular space such that the relative concentration of sodium is now depressed because of the pathologic elevation of another solute. Common etiologies of pseudohyponatremia include hypergylcemia, hyperlipidemia, and hyperproteinemia. In these clinical conditions, serum sodium values tend to be only modestly depressed. Since there is no underlying true anomaly in sodium or water stores in these conditions, the serum sodium need not be addressed with any therapeutic maneuvers. With the introduction of ion sensitive electrodes for the measurement of plasma sodium concentration, pseudohyponatremia related to the presence of confounding factors in the laboratory assay is much less commonly encountered.

To clarify the etiology of the hyponatremia, the clinician should assess the patient's extracellular volume status and determine if it is decreased, normal, or increased. Then, by measuring urine sodium excretion and determining the renal response to the hyponatremia, it becomes easier to determine if the patient should receive sodium and water or if sodium and water restriction is the appropriate therapy (*Table 13-5*).

Table 13-5
Etiology of hyponatremia

Circulating volume	Urinary Na (mEq/L)	
	≤ 20	≥ 20
Decreased	Burns	Adrenal insufficiency
	Cystic fibrosis	Diuretics –early
	Diuretics – late	Salt wasting
	Gastroenteritis	
Normal or Increased	Cardiac failure	Renal failure
	Hepatic cirrhosis	SIADH
	Nephrotic syndrome	Water intoxication

Hyponatremia: Decreased Volume Status and Urine Na ≤ 20 mEq/L

Decreased circulating volume is usually seen with states of significant sodium loss. The most common site of this loss is the gastrointestinal tract as a result of vomiting, diarrhea, or tube drainage. The renal response to the decreased effective circulating volume involves increased activity of the renin-angiotensin axis and relatively high levels of aldosterone and angiotensin. As a result, urine sodium values are generally low (<20 mEq/L) and water reabsorption in the distal nephron is facilitated by high levels of ADH. In the face of continuing sodium losses exceeding intake, this state of vigorous ADH effect leads to a relative excess of water and concomitant hyponatremia.

A similar clinical state of hyponatremia can also be seen in cystic fibrosis where there are increased skin losses of sodium and chloride, with bleeding, with burns, and with certain losses of fluid from the intravascular space of the extracellular fluid into the interstitial space ("third-spacing") as can occur post-operatively, in conditions of vascular leak such as sepsis, or with peritonitis. Such hyponatremia can also be seen following a period of diuretic therapy. In response to chronic diuretic-mediated volume contraction, the mechanisms outlined above come into play. Thiazide diuretics, especially in combination with a loop diuretic such as furosemide, are particularly prone to inducing such hyponatremia.

The appropriate therapeutic response to these conditions is the provision of sodium and water either by use of intravenous saline solutions or oral electrolyte solutions. This results in restoration of sodium balance and volume expansion.

Hyponatremia: Decreased Volume Status and Urine Na ≥ 20 mEq/L

Decreased circulating volume with a random urinary sodium excretion >20 mEq/L is indicative of renal salt wasting, either from an intrinsic tubulopathy or from early diuretic effect. Less commonly, adrenal insufficiency can cause sodium wasting from the cells of the distal nephron. Such a deficiency can arise from an intrinsic endocrine defect such as congenital adrenal hyperplasia related to 21-hydroxylase deficiency, from some secondary impairment of adrenal function caused by infection, bleeding, or malignancy, or from pharmacologic adrenal suppression without adequate replacement therapy. In the setting of adrenal insufficiency, provision of appropriate adrenal hormone replacement as well as adequate sodium and water proves therapeutic. With renal salt wasting, supplementation with sodium and any other electrolytes exhibiting impaired renal reabsorption is useful.

Hyponatremia: Normal or Expanded Volume and Urine Na ≤ 20 mEq/L

Normal or increased circulating volume and random urine sodium excretion <20 mEq/L can be seen in conditions where there is an excess of both total body water and total body sodium. The three major disorders that cause this type of hyponatremia are the nephrotic syndrome, hepatic failure related to cirrhosis, and cardiac failure. In all these conditions, there is a state of sodium and water avidity related to high levels of ADH and aldosterone. Most commonly, this is in the setting of preexisting total body sodium overload as evidenced by edema. In all of these conditions, despite the increased extracellular or circulating volume, the effective circulating volume is often depressed. As a result of this ineffective perfusion of the tissues, sodium and water avidity is only heightened by stimulation of the renin-aldosterone-angiotensin axis, further exacerbating the total body excess of salt and water. Appropriate therapy includes striking a balance between interventions promoting the maintenance of effective circulating volume and restricting the provision of excess water and sodium which will only contribute to further total body water and sodium overload.

Hyponatremia: Normal or Expanded Volume and Urine Na ≥ 20 mEq/L

Hyponatremia in the setting of normal or increased effective circulating volume is always related to persistent ADH effect (15). If the random urine sodium value is >20 mEq/L, the most common clinical scenario is the syndrome of inappropriate antidiuretic hormone secretion or SIADH. SIADH can arise from disparate clinical conditions including the postoperative child, the child with significant pain, or the child with pulmonary disease. As described earlier, ill children are at risk for both inappropriate ADH secretion and inappropriate ADH effect (39). In SIADH, despite a state of hypo-osmolality, the urine is inappropriately concentrated as a result of an inability to suppress ADH secretion and block ADH-mediated water reabsorption from the distal nephron. Appropriate therapy for SIADH includes restricting water intake and attending to any underlying clinical factors predisposing to this syndrome. Provision of fluids containing higher concentrations of sodium will not necessarily increase serum sodium without attention to concomitant water restriction.

Normal or increased extracellular volume and high urine sodium concentration can also be seen in the setting of renal failure as both glomerular filtration and water clearance falls while the fractional excretion of sodium rises. A more unusual cause of this form of hyponatremia is polydipsia, usually psychogenic in nature. Such water intoxication is rare in children but can occasionally be seen with emotional or psychiatric illness in older children or with infants inappropriately provided large volumes of water or very hypotonic fluid in a repetitive fashion by a caretaker. In both these circumstances, restriction of the volume of free water ingested on a daily basis may be beneficial.

Hypernatremia

Hypernatremia is defined as a serum sodium value greater than 150 mEq/L. Generally, even higher serum sodium values can be tolerated with the most significant clinical and neurologic effects not occurring until sodium values exceed 160 mEq/L. As with hyponatremia, it has long been recognized that hypernatremia is more commonly a reflection of a problem with water balance rather than a sodium imbalance (40). In most instances, the patient has a relative deficiency of water for normal extracellular solute content.

Since sodium is the major determinant of plasma osmolality, as serum sodium levels rise, serum osmolality concomitantly increases. Increases in serum osmolality are sensed by hypothalamic osmoreceptors, triggering ADH release from the posterior pituitary as serum osmolality increases over 280 mOsm (41). Increased serum osmolality also causes a sensation of thirst. Thus, in the normal state, as serum osmolality increases, there is increased fluid intake mediated by thirst in the setting of high ADH levels. This results in increased reabsorption of free water from the cortical collecting duct and re-equilibration of serum sodium levels and serum osmolality before clinically significant hypernatremia or hyperosmolality occurs.

Outside infancy, hypernatremia as a result of sodium excess or salt poisoning is infrequent. Its major cause is improper preparation of powdered or liquid concentrated formula resulting in a hypertonic, hypernatremic solution. Since infants do not have free access to water, they cannot respond to their increasing sense of thirst as they develop such hypernatremia. As caregivers continue to provide the same incorrectly prepared formula for further feedings, there is further salt loading. In addition, young

infants are unable to excrete sodium loads as efficiently as older children and this limits the intrinsic renal response. Iatrogenic sodium loading can also be seen in children who receive large doses of sodium bicarbonate because of persistent acidosis, during a resuscitation, or in children who have been given inappropriate amounts of sodium in peripheral nutrition. Iatrogenic sodium loading can also be seen in the child who has received repeated large volumes of blood products, generally isotonic or sodium-rich solutions.

Children who have hypernatremia from sodium excess should exhibit the physical signs and symptoms of an expanded extracellular space. They frequently have peripheral edema and may have hypertension or symptoms of pulmonary edema. These children can respond to therapy aimed at augmenting sodium elimination. The use of diuretics and the provision of adequate free water decrease the total body sodium burden. Rarely, dialysis may be necessary when the hypernatremia must be corrected rapidly (42, 43).

Hypernatremia as a result of salt loading is rare and the pediatric clinician is much more likely to see hypernatremia stemming from a free water deficit or a combined water and sodium deficit where the water losses exceed the sodium losses. Hypernatremia secondary to a water deficit arises in the setting of inadequate access to water or some impairment in ADH release or response. It is uncommon to see hypernatremia secondary to poor water intake except in infants or young children who cannot get water for themselves in response to their sense of thirst (44). As for ADH-related anomalies, there are many causes of central or nephrogenic diabetes insipidus (45). Again, given normal access to water, it is rare for the older child to develop hypernatremia even with an impairment in the ADH axis because of the strong drive to drink in response to thirst (46). In very young children with diabetes insipidus, however, the issue of access to water arises and hypernatremia may be a concern. Such hyponatremia can also be seen in the postoperative state in children with concentrating defects who are not allowed to drink by mouth and who are receiving a prescribed volume of fluid based on a presumed ability to concentrate urine and conserve water.

The most common etiology of hypernatremia in children is the loss of hypotonic fluid, that is fluid with a relative excess of water for its sodium content. In these situations, the total body water is decreased more than the total body sodium. The usual clinical scenario leading to such a condition is viral diarrheal illness in the setting of poor water intake or persistent vomiting. In this condition, there is loss of stool with a sodium content generally <60 mEq/L. These children tend to excrete small volumes of concentrated urine with urine sodium content <20 mEq/L, underscoring the fact that they are conserving both water and sodium. Their hypernatremia is not a manifestation of a total body excess of sodium but a depletion of sodium that is overshadowed by a larger relative depletion of body water. Therapy is aimed at restoring water and sodium balance by providing back the hypotonic fluid which was initially lost either by the use of intravenous saline solutions or with oral electrolyte therapy.

Fluid Replacement Therapy

Most commonly, the prime goal of fluid replacement therapy is restoration of an adequate effective circulating volume. In its absence, significant metabolic derangements can occur that then exacerbate perturbations in fluid and electrolyte homeostasis. The volume of fluid replacement required varies with the extent and etiology of the compromised circulation. In many children with acute illness, there may be an element of decreased effective volume that is mild and difficult to appreciate by clinical examination. Expansion of extracellular volume with infusion or ingestion of 20–40 mL/kg of fluid over a few hours often results in better perfusion and improved clinical appearance from presentation. Urine output tends to remain normal in these situations speaking against persistent non-osmotic ADH activity that would encourage volume overload (47).

Children with mild dehydration, manifesting with <5% weight loss, will usually respond to 30–50 mL/kg of fluid. In the setting of more significant compromise of effective volume such as with loss of vascular tone in sepsis or a systemic inflammatory response, more than 200 mL/kg may be needed to achieve hemodynamic stability and effective perfusion. In most situations other than outright shock, the clinician can approach fluid resuscitation with either intravenous or oral rehydration therapy.

Assessment of Volume Depletion

In estimating the severity of dehydration, a change in weight from baseline is the most objective measure (48). As rehydration proceeds, following weights on a serial basis becomes an important adjunct in assessing the efficacy of fluid repletion. If no baseline weight is known, the clinican

will use various parameters based on history and physical examination to judge the severity of dehydration (*Table 13-6*). Children with mild dehydration will have minimal clinical signs and only a modest decline in urine output. As dehydration becomes more significant, more classical findings such as dry mucous membranes, tenting skin, sunken eyes, and lethargy become prominent. With profound dehydration, there is anuria, marked alterations in consciousness, and hemodynamic instability.

A capillary refill time greater than 2 s has long been touted as a useful physical finding pointing towards effective volume depletion (49). Unfortunately, delayed capillary refill is neither a sensitive nor specific marker of dehydration (50, 51). It may be most useful if normal, as this does seem to exclude reliably severe dehydration. In a prospective cohort study of dehydrated Egyptian children between 3 and 18 months of age, the best correlation between clinical assessment of degree of dehydration and actual volume depletion came in children who had clinical parameters of significant dehydration such as prolonged skinfold tenting, a dry mouth, sunken eyes, and altered sensorium (52). Similarly, in a review of pre-school children with dehydration, the best clinical indicators of volume depletion – decreased skin turgor, poor peripheral perfusion, and Kussmaul breathing – accompanied more significant dehydration, underscoring the difficulty with which mild degrees of dehydration may be estimated by the clinician without access to prior weights (53).

A study of 97 American children given intravenous fluids in an emergency department for rehydration underscored the difficulty in assessing accurately even severe dehydration by standard clinical estimates (54). Physicians' initial estimate of dehydration compared to the actual percent loss of body weight varied dramatically, with a sensitivity of 70% for severe dehydration (>10% loss) but only 33% for moderate dehydration (6–10% loss). This study suggested that adding a serum bicarbonate level to the assessment may be useful, increasing the sensitivity of the clinical scales to 100% in severe dehydration and 90% in moderate dehydration if standard clinical features and a serum bicarbonate <17 mEq/L were found.

Other studies have found that laboratory studies by themselves are poor indicators of the degree of dehydration. In 40 children receiving intravenous fluids for dehydration, pre-hydration assessment of serum BUN, creatinine, uric acid, anion gap, venous pH, and venous base deficit were made as well as assessment of urinary specific gravity, urinary anion gap, and fractional excretion of sodium. Only the serum BUN/Cr ratio and serum uric acid significantly correlated with increasing levels of dehydration, but both lacked sensitivity or specificity for detecting more than 5% dehydration (55). Similarly, in a retrospective review of 168 dehydrated children, elevated serum urea levels and depressed serum bicarbonate levels were found to be useful adjuncts to clinical evaluation in accurately assessing the degree of dehydration but were not by themselves predictive (56).

In fact, with viral gastroenteritis, the most common cause of dehydration in children, there rarely is a significant laboratory anomaly despite clinically detected

Table 13-6

Clinical assessment of dehydration

	Degree of dehydration		
	Mild	Moderate	Severe
Vital signs			
Pulse	Normal	Rapid	Rapid and weak
Blood pressure	Normal	Normal to slightly low	Shock
Weight loss			
Infant	<5%	10%	>15%
Older child	<3%	6%	>9%
Mucous membranes	Tacky	Dry	Parched
Skin turgor	Slightly decreased	Decreased	Tenting
Eye appearance	Normal tearing	Decreased tearing ± sunken	No tears + very sunken
Capillary refill	Normal	Delayed (>3 s)	Very delayed (>5 s)
Urine output	Decreased	Minimal	Anuric

volume depletion, as underscored by a cohort of children from the United Kingdom admitted for rehydration due to viral gastroenteritis in whom only 1% of admitted children had an electrolyte derangement (57–59).

In children with volume depletion accompanying trauma, sepsis, surgery, or underlying renal dysfunction, it would be more likely to find perturbations in electrolyte and acid-base status. Thus, in the absence of a straightforward case of mild to moderate diarrheal dehydration, it is general consensus that blood should be obtained for assessment of electrolytes, bicarbonate, and renal function to help guide specific fluid and electrolyte therapy (60, 61)

As the child is volume resuscitated, it is important to reassess the child's clinical status. Initial estimates of degree of dehydration may need to be adjusted if the child is not showing progressive improvement. Most clinicians follow parameters such as general appearance and sensorium, change in weight from initiation of rehydration, and urine output and urine osmolality. In children with some types of renal dysfunction, there may often be an underlying chronic urinary concentrating defect. In these children, relatively dilute urine flow may be maintained even in the face of clinical dehydration and markers other than urine output and osmolality should be followed.

Oral Rehydration Therapy

Although oral rehydration with electrolyte solutions is a safe, efficacious, and convenient way to treat mild to severe volume depletion, parenteral fluid and electrolyte therapy has been the mainstay of medical treatment for most children presenting with fluid and electrolyte imbalances (62–65). Especially underutilized in North America, oral therapy has proved successful in clinical settings worldwide in resuscitating children of all ages with profound fluid and electrolyte anomalies, and short of significant circulatory compromise, can be used as first line therapy in all fluid and electrolyte aberrations (66, 67). An example of a situation calling for oral rehydration in the following clinical scenario:

A healthy 4-year old girl presents to her pediatrician's office following 3 days of a febrile illness. For most of this time, her appetite has been severely depressed and her parents estimate that she has only had a few cups of fluid in the last 12 h. Yesterday, she vomited once and today has had an additional episode of emesis. She has continued to urinate, although less frequently and with smaller volumes. On physical examination, the girl looks unhappy but non-toxic and alert. Initially, her pulse is 120 but, after acclimation to the examination, it has decreased to 100 beats per min. Her sitting blood pressure is 80/50 and she will not cooperate with attempts at orthostatic vital signs. Her mucous membranes are somewhat dry and her weight today is 15 kg, exactly the same as her weight at a well child examination 6 months previously. The parents are concerned that she is becoming dehydrated.

Primary care and emergency department physicians face such clinical scenarios regularly. An otherwise healthy child with an apparent viral illness causing mild to moderate dehydration will frequently be treated by intravenous therapy with the contention that oral rehydration will rarely succeed, will be too labor intensive, or will take too much time. In fact, such children are excellent candidates for oral rehydration. In most developed countries where a viral disease is thought to be the etiology of the dehydration and there is little concern about a cholera-like enteritis, solutions with sodium contents from 30 mEq/L to 90 mEq/L have been shown for years to be efficacious for oral rehydration (68–71).

With this girl, given the history and physical examination, it is unlikely that any clinically significant electrolyte perturbations will be found, so there is little indication for assaying electrolytes or renal function prior to starting oral rehydration (57–59). The family is given a commercially available oral rehydration solution containing 75 mEq/L Na, 20 mEq/L K, 30 mEq/L citrate, and 2.5% glucose. They are asked to provide 1 L of fluid (50 mL/kg) to the child over the next 4 h. The child should be offered small aliquots of fluid very often – 5 mL every 1–2 min at initiation. If this regimen is tolerated with no vomiting, the aliquots may be gradually increased in volume and the frequency reduced, aiming to deliver at least the prescribed total volume over about 4 h. After her rehydration, the child should subsequently continue to be provided free access to fluid and resume an age-appropriate diet. If, on the other hand, there are any further episodes of vomiting, then for each episode of emesis an additional 120–240 mL of oral rehydrating solution should be given, again with the goal to complete rehydration and resume usual fluid intake and nutrition.

The initial provision of oral fluid given often in small volumes is far more likely to be well tolerated by the dehydrated child than larger aliquots. If families are unwilling to provide the fluid in this manner, a nasogastric tube may be placed for continuous infusion of rehydrating solution.

Although occasional children may fail this approach and require intravenous rehydration, most children with mild to moderate rehydration can be rehydrated orally.

A guide for the volumes of fluid to provide and the duration of rehydration can be found in Table 13-7.

The first oral rehydration solutions were developed in the 1940s at academic medical centers. Within 10 years, a commercial preparation formulated as a powder meant to be mixed with water was available, but its use became associated with an increased incidence of hypernatremia (72). Several factors contributed to the development of this problem: the preparation was sometimes incorrectly administered as the powder itself or improperly diluted with too little water; when correctly reconstituted, the solution had a final carbohydrate concentration of 8% predisposing to an osmotic diarrhea; and it was a common practice at that time for parents to use high solute fluids such as boiled skim milk as an adjunctive home remedy. Taken together, these early experiences contributed to reluctance to use oral rehydration solutions on the part of many clinicians.

Over time, there came to be a better understanding of the physiology of water and solute absorption from the gut. Of prime importance was the recognition that many substances actively transported across intestinal epithelium had an absolute or partial dependence on sodium for absorption and that sodium itself was actually better reabsorbed in their presence (73–75). This led to the routine introduction of glucose into oral rehydration solutions in a fixed molar ratio of no more than 2:1 with sodium. Moreover, it became clear that the sodium/glucose cotransporter remained intact not only in the face of enterotoxic-gastroenteritis such as seen with cholera or *Eschericia coli* but also in more common viral and bacterial enteritides (66, 67).

The World Health Organization (WHO) and the United Nations Children's Fund have championed the use of a rehydrating solution that includes: Na 90 mmol/L, Cl 80 mmol/L, K 20 mmol/L, base 30 mmol/L, and glucose 111 mmol/L (2%). This WHO solution has proved useful in many clinical trials rehydrating children and has also been shown to reduce the morbidity and mortality associated with diarrheal illness regardless of its etiology (68, 69).

Most commercially available oral rehydration solutions differ from WHO solution in that they have a somewhat higher carbohydrate content, a lower sodium content, and a higher carbohydrate to sodium ratio (Table 13-8). Some preparations are available as powder and other as ready to drink formulations. Some manufacturers have also used rice solids as a carbohydrate source instead of glucose.

Many of these formulation changes arose from concerns that using an oral rehydrating solution with a sodium content >60 mmol/L would prove problematic in developed countries where most gastroenteritis is viral in nature and has a lower sodium content than the secretory diarrheas seen in less developed areas. Some clinicians

Table 13-7

Oral rehydration for previously healthy, well-nourished children

Type of dehydration	Rehydration phase	Rehydration duration	Replacement of ongoing losses	Nutrition
Mild (<5%)	30–50 mL/kg ORT	3–4 h	60–120 mL ORS for each diarrheal stool or episode of emesis[a]	Continue breast milk or resume age appropriate usual diet
Moderate (5–10%)	50–100 mL/kg ORT	3–4 h	As above	As above
Severe (>10%)	100–150 mL/kg ORT	3–4 h	As above with use of nasogastric tube if needed	As above
Evidence of shock	20 mL/kg 0.9% NaCl or Lactated Ringers IV	Repetitive infusions until perfusion restored then transition to ORT 100 mL/kg over 4 h	As above with use of nasogastric tube if needed or consideration of further IV therapy	As above
Accompanying Hypernatremia	Per type of dehydration	At least 12 h for ORT. Monitor fall in serum Na	As above	As above

ORT, Oral Rehydration Therapy with fluid containing 45–90 mmol/L Na, 90 mmol/L glucose, 20 mmol/l K, 10–30 mmol/L citrate; IV, Intravenous infusion

[a]For children >10 kg, aliquots for replacement of ongoing losses should be doubled to 120–240 mL rehydration solution for each stool or emesis

Table 13-8

Oral rehydration solutions

	Concentration (mmol/L)					
Product						
	Na	Sugar	K	Cl	Base	Osmolality (mOsm/L)
WHO ORS[a]	90	111	20	80	30	311
CeraLyte 90[a]	90	220[b]	20	80	30	275
Low-Na ORS[a]	75	75	20	65	30	245

feared that, if minimally dehydrated children losing small amounts of sodium in their stools were exclusively provided WHO solution, hypernatremia might ensue without provision of excess free water. A few early studies did document iatrogenic hypernatremia related to such rehydration techniques (76). In cases of mild dehydration stemming from causes other than secretory diarrhea, solutions with lower sodium contents may be as useful and, in fact, solutions with sodium content ranging from 30 to 90 mmol/L have proved quite effective in this setting (70, 71, 77). A more recent meta-analysis of studies focused on the safety and efficacy of oral rehydration solution in well nourished children living in developed countries documented little evidence that WHO solution was more likely to cause aberrations in serum sodium than lower sodium containing oral rehydration solutions (78). Why ingestion of lower tonicity oral rehydration fluids would be less problematic than infusion of similar tonicity intravenous fluid is not clear, but does again underscore the safety of oral rehydration.

Oral Rehydration with Fluids Other than ORS

Despite the efficacy and widespread availability of commercial oral rehydration solutions and the ease with which other electrolyte solutions can be mixed at home with recipes requiring few ingredients other than water, sugar, and salt, there are many children who are still given common household beverages in attempts at rehydration. In children with dehydration and electrolyte losses from vomiting or diarrhea, most common beverages do not contain adequate sodium or potassium supplementation. Moreover, the base composition and the carbohydrate source are often sub-optimal for the dehydrated child, especially in the setting of diarrheal illness (*Table 13-9*). Similarly, most beverages marketed as sports drinks for "rehydration" following exercise are also deplete of sufficient electrolytes given that the electrolyte composition of sweat is many fold lower than the composition of gastrointestinal fluid. In prescribing oral rehydration to children in an ambulatory setting, the clinician should be specific to the family as to the appropriate fluid and volume for the child to ingest, emphasizing the need to use a fluid with appropriate electrolye content if there is concern about evolving imbalances in sodium, potassium, or bicarbonate homeostasis.

Oral Rehydration and Serum Sodium Abnormalities

Although oral rehydration is often considered for children with modest dehydration and no presumed electrolyte anomalies, oral rehydration with WHO or WHO-like solution has also been used in cases of dehydration accompanied by hyponatremia or hypernatremia (79, 80). Although most children with severe hypernatremia (>160 mEq/L) can be successfully rehydrated orally, there have been reports of seizures, generally as a result of too rapid correction of serum sodium stemming from the

Table 13-9

Composition of common oral fluids[a]

Fluid	Na (mEq/L)	K (mEq/L)	Source of base	Carbohydrate (g/100 mL)
Apple juice	<1	25	Citrate	12

Tea	2	5	Citrate	10

[a]Adapted in part from data found in (74)

provision of supplemental water in addition to the glucose-electrolyte solution (79–81). In those cases, the average serum sodium fell by 10–15 mEq/L over 6 h rather than over 24 h as advised. In follow-up studies, no seizure activity was seen in a similar cohort of hypernatremic children who received 90 mmol/L Na rehydration solution alone at a rate calculated to replace the infant's deficit over 24 h (79). It is important for the practitioner to remember that once peripheral perfusion has been stabilized with initial volume expansion, there is no benefit to correcting any deficit rapidly and taking 24–48 h may be a more prudent course in the face of significant electrolyte anomalies.

Oral Rehydration Schemes

Several oral rehydration schemes have been shown to be quite effective and well tolerated. In one approach used extensively in developing countries, the patient's volume deficit is calculated on the basis of weight loss and clinical appearance (82). The volume deficit is doubled; this is the target rehydration volume to be given over 6–12 h. Two-thirds of this volume is given as a glucose-electrolyte solution containing 90 mmol/L Na over 4–8 h; once this has been ingested, the remaining volume is provided as water alone over 2–4 h. In cases of suspected or confirmed hypernatremia with serum sodium exceeding 160 mEq/L, the volume deficit would not be doubled and would be administered as 90 mmol/L Na glucose-electrolyte solution alone over 12–24 h. Patients who refuse to take fluids by mouth have nasogastric tubes placed. With this approach, successful oral rehydration is the rule; 95% of children are fully rehydrated without the need for intravenous therapy.

An alternative approach has been to have the child begin by taking 15 mL/kg/h of a 60–90 mmol/L Na rehydration solution by mouth or nasogastric tube (83). The solution is given in small frequent quantities and increased up to 25 mL/kg/h until hydration has improved at which point solid feedings are reintroduced and volumes of 5–15 mL/kg of rehydration solution offered after feeds until the volume deficit has been delivered.

Over two decades ago, the American Academy of Pediatrics issued guidelines for the treatment of fluid and electrolyte deficits with oral rehydration solutions (66). Children with acute dehydration and extracellular volume contraction were to be provided 40–50 mL/kg of a glucose-electrolyte solution containing in each liter 75–90 mmol Na, 110–140 mmol glucose (2–2.5%), 20 mmol potassium, and 20–30 mmol base. This volume was to be administered over 3–4 h and then once there has been amelioration of the extracellular volume contraction, the child would be changed to a maintenance solution with 40–60 mmol/L Na at half the rate. If the child was still thirsty on this regimen, there should be free access to supplemental water or low-solute fluid such as breast milk.

Based on much of this published clinical experience, an evidence-based guideline for treating dehydration in children from industrialized European countries was created in the late 1990s, recommending oral rehydrating solution containing 60 mmol/L of sodium, 90 mmol/L of glucose, 20 mmol/L of potassium, and 10–30 mmol/L

of citrate with rehydration occurring over 3–12 h utilizing from 30 to 150 mL/kg of fluid depending on the degree and type of dehydration (48).

In 2004, the American Academy of pediatrics updated its oral rehydration recommendations and endorsed guidelines promulgated by the Center for Disease Control and Prevention (84, 85). Minimal dehydration in children weighing less than 10 kg was to be treated with provision of 60–120 mL of oral rehydration fluid for each watery stool or each episode of vomiting. In larger children, twice this volume would be provided. For children with more moderate dehydration, 50–100 mL/kg of oral rehydration solution would be given over 2–4 h to account for estimated fluid deficit and ongoing losses would be treated with the 60–240 mL per stool or emesis depending on size. Nursing babies would continue to receive breast milk as desired and formula fed babies would be provided age appropriate diet as soon as they had been rehydrated. For severely dehydrated children, a combination of intravenous hydration with isotonic fluids and prompt transition to oral rehydration solution by mouth or nasogastric tube was recommended. Overly restricted diets were to be avoided during gastrointestinal illness and attention to adequate caloric intake emphasized (see *Table 13-7*).

Use and Acceptance of Oral Rehydration Solutions

Despite the availability of guidelines for oral rehydration and their endorsement by professional organizations, a minority of American academic pediatricians, private practitioners, and pediatric house staff acknowledged utilizing oral rehydration (70). Although oral rehydration schemes have been shown to be used significantly more frequently by emergency room physicians who were familiar with the American Academy of Pediatrics recommendations, even in this group oral therapy was underutilized in children with all degrees of dehydration. Worldwide, WHO estimates that fewer than 25% of patients who could benefit from oral rehydration are actually treated with such therapy (86). Moreover, even in areas of the world such as Bangladesh, where oral rehydration has been championed by both local and international medical agencies for decades, its use is still suboptimal (87, 88). Among practitioners, there may also be generational differences in the use of oral rehydration therapy. In a national survey of Amercian pediatric emergency department physicians, although there was no difference in the baseline knowledge of published data in this field or acceptance of its validity, recent graduates of training programs were much more likely to use oral rehydration for more advanced cases of clinical dehydration than their older colleagues (89).

When utilized according to these schemes, oral rehydration has been demonstrated to be almost universally successful in achieving some degree of volume repletion (90). Other advantages to oral therapy include the safety and stability of the product despite lengthy shelf storage, its ability to be administered readily by the child's caretaker in nearly any locale, and avoidance of the discomfort and potential complications associated with intravenous catheter placement (91). In developed countries, there has been the concern that some powdered ORS formulations may not be looked upon by parents as a convenient hydration solution since they involves preparation. In fact, in a randomized controlled trial of an urban pediatric clinic and a suburban medical practice in the United States, parents were as equally satisfied with the ease of administration and effectiveness of a powdered solution as a commercially prepared ready to drink solution (92).

Oral rehydration is somewhat less successful in hospitalized children than in children treated in an ambulatory setting (90). This difference may be directly related to the degree of dehydration or other complicating clinical issues leading to hospital admission. Moreover, the relatively labor intensive slower approach to oral rehydration may be problematic in medical facilities with time constraints or space limitations (91, 93).

Frozen flavored oral rehydration solutions may be more readily accepted than conventional unflavored liquid electrolyte solutions. Their use resulted in higher rates of successful rehydration in children with mild to moderate dehydration, even if these children initially failed conventional oral rehydration (91). Frozen flavored rehydration solution is now commercially available in many parts of the world, as is a variety of flavored rehydration solutions.

Another potential issue with oral rehydration is that its use does not alter the natural course of the child's illness. For instance, in gastroenteritis with dehydration, by far and away the most common illness requiring rehydration in children, oral rehydration does not lower stool output or change the duration of diarrheal illness (94). As a result, caretakers may abandon oral rehydration because the child continues to have symptoms, failing to appreciate the benefits of ongoing hydration. Oral rehydrating solutions have been formulated with lower electrolyte composition and different carbohydrate moieties with the goal to reduce the osmolarity of solutions and potentially augment fluid absorption from the small intestine (78). The rice based oral solutions have been studied most

extensively. In these solutions, glucose is substituted with 50–80g/L of rice powder. In a meta-analysis of 22 randomized clinical trials comparing rice based solution to conventional glucose containing solutions, stool output dramatically decreased in children with cholera given rice based hydration but did not change in children with other bacterial or viral enteritides (95).

There are some reports that suggest that providing children with non-cholera enteritis with reduced osmolarity rehydration solution may be beneficial. A study of 447 boys less than 2 years of age admitted for oral rehydration were assigned to either receive WHO solution (osmolarity 311 mmol/L) or a solution containing less sodium and chloride (osmolarity 224 mmol/L). Children who received the lower osmolarity solution had reduced stool output, reduced duration of diarrhea, reduced rehydration needs, and reduced risk of requiring intravenous fluid infusion after completion of oral hydration (96). A meta-analysis of 9 trials comparing WHO solution to reduced osmolarity rehydration solution concluded that children admitted for dehydration had reduced needs for intravenous fluid infusion, lower stool volumes, and less vomiting when receiving the reduced osmolarity solution (97).

Intravenous Therapy

Although absolute indications for parenteral intravenous therapy are limited, they do include significantly impaired circulation or overt shock. In addition, there are occasional children who are truly unable to sustain an adequate rate of oral fluid intake despite concerted effort or have such persistent losses that parenteral therapy comes to be necessary. The mainstays of fluid therapy in children are saline or buffered saline crystalloid solutions. Isotonic versions of these crystalloids are used for volume resuscitation and hypotonic saline solutions may be used in addition to provide supplemental maintenance hydration. In addition to crystalloid solutions, there are several colloid fluids that are also used by many clinicians. *Table 13-10* lists the electrolyte content of some of the more common intravenous solutions used for pediatric fluid therapy.

Table 13-10

Composition of common intravenous fluids

Fluid	Osmolarity (mOsm/L)	Na (mEq/L)	K (mEq/L)	Cl (mEq/L)	Buffer (source) (mEq/L)	Mg (mEq/L)	Ca (mEq/L)	Dextrose (g/L)
Chrystalloids								
0.9% Saline	308	154	0	154	0	0	0	0
Lactated ringers	275	130	4	109	28 (lactate)	0	3	0
D5 0.45% Saline	454	77	0	77	0	0	0	50
D5 0.22% Saline	377	38	0	38	0	0	0	50
5% Dextrose water	252	0	0	0	0	0	0	50
Normosol	295	140	5	98	23 (gluconate) 27 (acetate)	3	0	0
Plasma-Lyte	294	140	5	98	23 (gluconate) 27 (acetate)	3	0	0
Colloids								
5% Albumin	309	130–160	<1	130–160	0	0	0	0
25% Albumin	312	130–160	<1	130–160	0	0	0	0
Fresh frozen plasma	300	140	4	110	25 (bicarbonate)	0	0	0
3.5% Hemaccel	301	145	5	145	0	0	6	0
6% Hetastarch	310	154	0	154	0	0	0	0
Dextran 40 or 70	310	154	0	154	0	0	0	0

Choice and Volume of Parenteral Fluid

Children with significant extracellular volume contraction (greater than 10% acute weight loss in an infant or 6% weight loss in an older child) should receive an isotonic crystalloid solution such as 0.9% saline (154 mEq/L NaCl) or Lactated Ringer's (130 mEq/L NaCl) at a rate of 20 mL/kg over 30–60 min. In some children, even more rapid infusions or serial provision of such aliquots may be necessary to restore effective volume. Children with less pronounced dehydration may not exhibit signs or symptoms of volume contraction. In certain situations, however, it may be clinically warranted to provide them with an initial rapid intravenous bolus to initiate rehydration therapy.

Concomitant with the placement of intravenous access, blood should be obtained for determination of serum electrolytes, osmolality, and renal function. Given that dehydrated children often have high levels of vasoactive hormones and high vasopressin levels, it is most circumspect to establish baseline electrolyte levels since it is possible to alter electrolyte balance rapidly with intravenous therapy. In the face of inadequate tissue perfusion, a parenteral fluid infusion should begin immediately prior to the return of any pertinent laboratory results. If hemorrhagic shock is suspected, resuscitation with packed red blood cells is optimal. In cases of severe volume depletion, if the child does not improve with the initial 20-mL/kg crystalloid bolus, this should be repeated up to two additional times. In children who have not improved despite administration of 60 mL/kg of total volume over an hour or in children in whom underlying cardiac, pulmonary, or renal disease may make empiric aggressive rehydration more problematic, consideration should be given to placement of a central monitoring catheter to more accurately assess intravascular volume and cardiac dynamics (98). In some instances of profound ineffective circulating volume, such as might accompany certain cases of sepsis, initial volume resuscitation may require sequential infusions of fluid ultimately exceeding 100 mL/kg.

Within minutes of infusion of a crystalloid fluid, it becomes distributed throughout the extracellular space. Since this involves equilibration of the fluid between the two components of the extracellular space – the intravascular and interstitial spaces – actually only one-third to one-quarter of infused crystalloid stays in the blood vessels (99). This accounts for the need to give large volumes of crystalloid in the setting of circulatory collapse and leads some to suggest that colloid solutions such as 5% or 10% albumin should play a role in resuscitation (100, 101).

Colloid Solutions and Volume Resuscitation

The use of colloid solutions for volume resuscitation is controversial. Colloids were once included in a number of widely promulgated guidelines for the care of patients in emergency facilities and intensive care units both for hemorrhagic shock prior to the availability of blood and for non-hemorrhagic shock as an adjunct to crystalloid use (102). Types of colloid utilized included 5% albumin, fresh frozen plasma, modified starches, dextrans, and gelatins. These guidelines, generally aimed toward the fluid resuscitation of adults, were composed despite the prior publication of a systematic review of randomized controlled trials that demonstrated no effect on mortality rates when colloids were used in preference to crystalloids (103). Moreover, there is a distinct cost disadvantage to using colloid solutions.

Subsequent systematic reviews have looked at this issue anew. In one meta-analysis of 38 trials comparing colloid to crystalloid for volume expansion, there was no decrease in the risk of death for patients receiving colloid (102). In the other review, albumin administration was actually shown to increase mortality by 6% compared to crystalloid (104). Proposed mechanisms contributing to this worse outcome include anticoagulant properties of albumin (105) and accelerated capillary leak (106).

A drawback of all these systematic reviews, however, has been the limited number of studies that included children other than ill premature neonates. As a result, generalization of these results from ill adults may not be germane to all critically ill volume depleted children. For instance, a report of 410 children with meningococcal disease suggests that albumin infusion in this population may not have been harmful, as case fatality rates were lower than predicted (107). Overall, however, there seems to be no substantive data to support the routine use of colloid to complement or replace crystalloid in fluid resuscitation. Rather, repetitive infusions of large volumes of crystalloid seem to be well tolerated in volume depleted children, do not seem to predispose to excessive rates of acute respiratory distress syndrome or cerebral edema, and in some conditions such as sepsis, play an important role in improved survival (108). A recent survey of pediatric anesthesiologists in western Europe reported that colloid solutions are being used less frequently in infants and older children and suggested that familiarity with some of the issues raised in these systematic reviews are affecting practice patterns (109).

Repetitive infusions of crystalloid may also prove problematic in some children. Most notably, if very large volumes of 0.9% saline are used acutely for volume

resuscitation, it is not unusual for children to develop a hyperchloremic metabolic acidosis. This occurs as acidotic peripheral tissues begin to reperfuse and already depleted extracellular bicarbonate stores are diluted by a solution with an isotonic concentration of chloride (98, 110). This acidosis can be ameliorated by supplemental doses of bicarbonate as well as the addition of supplemental potassium as needed. There is sometimes a tendency for clinicians to react to the hyperchloremic metabolic acidosis with further saline bolus infusions. In the face of corrected hypoxia or hypovolemia, however, such maneuvers may only exacerbate the chloride driven acidosis (111). This hyperchloremic acidosis is seen less frequently when Ringer's lactate solution is used as the resuscitation fluid because of the metabolic conversion of lactate to bicarbonate. In the setting of significant preexisting acidosis or underlying hepatic dysfunction preventing the metabolism of lactate, infusion of Ringer's lactate solution may, however, exacerbate an acidosis.

With the recent suggestion that some children with acute illness or following surgery may benefit from a prolonged period of isotonic fluid infusion given high levels of ADH and the possibility for hyponatremia developing with hypotonic fluid therapy, some have expressed concern that a hyperchloremic acidosis may develop in these children. In a prospective randomized study of more than 100 children with gastroenteritis given isotonic intravenous rehydration and maintenance therapy, there was no tendency for the development of hyperchloremic acidosis even after a day of isotonic fluid provision. Although serum chloride levels did tend to increase in these children, serum bicarbonates also improved, potentially related to improved effective volume and subsequent better tissue perfusion (112). Similarly, in children post cardiac surgery who were given isotonic solutions for their maintenance fluid needs, although there was a tendency for a hyperchloremic acidosis to develop, there seemed to be no significant clinical ramifications and long-term outcomes were similar to children who did not develop hyperchloremic acidosis (113).

Large volume infusion of blood may also predispose to electrolyte anomalies as well as manifestations of citrate toxicity. If aged whole blood is infused, there is the possibility that a large potassium load will be delivered to the patient as potassium over times migrates down its concentration gradient from less viable erythrocytes into plasma. Since most patients receive packed red blood cells instead of whole blood, this potential problem is minimized since little plasma is infused and, thus, the relatively small amount of infused potassium can be accommodated by intracellular movement.

Citrate is used as the anticoagulant in stored blood. Since citrate complexes with calcium, there can be a fall in ionized calcium levels if large volumes of blood are infused rapidly or if there are concomitant perturbations in calcium homeostasis. Similarly, citrate may complex with magnesium and magnesium depletion may occur. The liver usually metabolizes infused citrate into bicarbonate. Alkalosis may, thus, occur if large volumes of citrate are metabolized. In the setting of hepatic dysfunction, however, citrate will not be metabolized and serves as an acid load and will help create an acidosis or exacerbate any underlying acidosis.

Regardless of the initial infusion with either colloid or crystalloid, once sufficient volume to restore circulatory integrity has been infused, less rapid volume expansion is necessary. During this phase, the rapidity of fluid repletion is most probably not a concern unless there are severe underlying aberrations in the serum sodium or serum osmolality. In the absence of these derangements or profound volume deficit, if the child has improved significantly with the initial parenteral volume expansion, attempts should be made to reinstitute oral rehydration. Prolonged intravenous therapy rarely should be necessary.

Rapid Rehydration

Over the last decade, a scheme of rapid intravenous resuscitation and follow-up oral rehydration has been adopted by many pediatric emergency departments to treat children with up to 10% dehydration secondary to vomiting and gastroenteritis (114). After infusion of 20–30 mL/kg on intravenous crystalloid, the child is allowed to take up to several ounces of a standard oral rehydration fluid, and if this intake is tolerated without vomiting for 30–60 min, then discharged home to continue rehydration, initially with a prescribed volume of standard rehydration solution.

If the child does not tolerate oral rehydration or if there are such significant electrolyte anomalies that there are concerns regarding potential adverse CNS sequelae of too rapid rehydration, then intravenous rehydration may be the best route for continued hydration. It is rare for children to become symptomatic from serum sodium aberrations until levels less than 120 mEq/L or greater than 160 mEq/L are reached. Children who have had very sudden fluxes in electrolytes may become symptomatic earlier. On the other hand, children whose severe sodium abnormalities are thought to be more chronic in nature must be treated in a more controlled fashion since they are at higher risk for developing CNS symptoms during treatment.

The vast majority of children treated in emergency facilities for volume repletion do well with such rapid rehydration. These children are generally healthy with normal cardiac and renal function and have developed extracellular volume depletion relatively rapidly. As a result, they suffer no ill effects from rapid rehydration. In fact, the clinical success of this aggressive restoration of extracellular volume underlies the calls to reexamine the traditional deficit therapy approach to rehydration with its tedious calculations of fluid and electrolytes losses and requirements (9, 115).

Symptomatic Hyponatremia

In the setting of symptomatic hyponatremia, especially if the child has seizures, it is important to raise the serum sodium approximately 5 mEq/L acutely. Generally, this results in stabilization of the clinical situation and allows for further evaluation and treatment of the child in a less urgent fashion. This is one of the few situations in which hypertonic saline (3% saline) should be utilized.

To calculate the proper volume of 3% saline to infuse, the child's TBW must be multiplied by the 5 mEq/L-desired increase in serum sodium to determine the amount of sodium (in mEq) to infuse. Since every mL of 3% saline contains 0.5 mEq of sodium, doubling the number of mEq of sodium needed results in the proper milliliter volume of 3% saline to infuse. Thus, in the 20 kg child, the TBW is approximately 12 L (0.6 L/kg × 20 kg) and the desired sodium dose would be 60 mEq (12 L × 5 mEq/L). If 120 mL of 3% saline were infused, the serum sodium would be expected to rise by approximately 5 mEq/L. The infusion should be given at a rate to increase the serum sodium by no more than 3 mEq/L/h and is often given more slowly over the course of 3–4 h (116). If the child continues to be symptomatic from hyponatremia after this infusion, additional 3% saline may be given until the symptoms improve or the serum sodium is in the 120 to 125 mEq/L range. At that point, further correction of the hyponatremia should consist of a slower infusion of more dilute saline to cover the sodium deficit, the sodium maintenance needs, and any volume deficit. Consideration of the role of ADH and prior excess free water provision should also be considered in determining the volume and tonicity of fluid to be provided.

Asymptomatic Hyponatremia

If a child has severe hyponatremia but is not symptomatic, there is no need to administer hypertonic saline based solely on a laboratory anomaly. With or without symptoms, in cases of severe hyponatremia the child should be carefully evaluated as to the etiology of the hyponatremia, keeping in mind that hyponatremia tends to result from an imbalance of water regulation. If this is the case, free water should be restricted and appropriate supplementation with intravenous saline solutions begun to provide maintenance sodium requirements of approximately 2–3 mEq/kg/day and any ongoing losses of sodium.

Besides these maintenance sodium needs, if the child has an element of dehydration, every kilogram of body weight lost from baseline represents a 1 L deficit of nearly normal saline from the total body water as well. These losses are often referred to as isotonic losses. These account for a sodium deficit of 154 mEq/L that also must be included in the calculations for sodium replacement.

In the setting of hyponatremic dehydration, there have been additional sodium losses as well. Generally, these occur as viral diarrheal stool losses with a sodium content $\leq$60 mEq/L are replaced with fluids with a lower sodium content. To estimate these sodium losses, the difference between the child's desired serum sodium and current serum sodium is multiplied by the child's estimated TBW. This product represents the hyponatremic sodium losses that must be added to the maintenance sodium needs, any ongoing losses, and the sodium losses that accompanied weight loss. An example of the calculations and therapeutic maneuvers that need to be considered with significant hyponatremia is presented in the following case study:

A girl who normally weighs 10 kg suddenly develops generalized seizures and is brought by ambulance to the emergency department. She has had a week of gastroenteritis, has felt warm to touch, and has been drinking water and apple juice only, refusing any other liquids or any solid food for several days. Intravenous access is placed and lorazepam is administered and the seizure activity stops. The emergency department physician orders serum chemistries and the child is weighed and found to be 8.8 kg. A bolus infusion of 200 mL of 0.9% NaCl is administered over the next 30–60 min after which the girl appears well perfused but she is still lethargic. The serum sodium is then reported to be 112 mEq/L. While further evaluation of the child's overall status is ongoing, it is important to begin correcting the symptomatic hyponatremia.

The child has actually already received approximately 30 mEq of sodium in the 0.9% NaCl bolus given because of her dehydration and poor perfusion. Given her TBW of roughly 5.5 L (wt in kg × 0.6 L/kg), this should result in an increase in her serum sodium by approximately 5 mEq/L.

Since the child has had hyponatremic seizures and is still exhibiting some central nervous system effect with her lethargy, it is prudent to raise the serum sodium by 5 mEq/L so that it will be in the 120–125 mEq/L range. Since she is hemodynamically stable, it is also best not to provide an excess of further volume until the child undergoes imaging to assess for cerebral edema, especially given the history of seizures, lethargy, and hyponatremia. By using a small volume of hypertonic saline, the serum sodium can be raised in a controlled manner while further evaluation of the child continues. It would take about 22 mEq of sodium (TBW × desired increase in serum sodium = 5.5 L × 5 mEq/L) to accomplish the desired elevation. Since each mL of 3% saline contains about 0.5 mEq of sodium, a total of 44 mL of 3% saline could be infused over approximately 3–4 h.

In addition to this acute management to restore initial circulation and perfusion and to raise the serum sodium to a safer level, plans must be formulated to attend to the patient's overall volume and sodium deficit. To prescribe the proper follow-up intravenous fluid, the patient's water and electrolyte deficits at presentation must be reconciled with his therapy thus far.

The child's water deficit is 1.2 L, reflecting the 1.2-kilogram weight loss. She has "maintenance" water needs of an additional 1 L/day based on her normal weight of 10 kg. She is having no other ongoing water losses and has already received nearly 250 mL in intravenous fluid in the form of 0.9% NaCl and 3% NaCl. Her current water needs are thus 1,950 mL.

The child's normal "maintenance" sodium needs are 30 mEq/day (3 mEq/kg/day). She has lost 1.2 kilograms of isontonic fluid in body weight that represents 185 mEq of sodium. In addition, she has hyponatremic sodium losses that have arisen as her diarrheal stool that contained sodium was replaced with water alone. To calculate these needs, her normal total body water needs to be multiplied by the difference in her serum sodium from a normal value of 135 mEq/L. Her TBW is 6 L (TBW = 0.6 L/kg × 10 kg) and the difference in serum sodium is 23 mEq/L (135 mEq/L − 112 mEq/L); her hyponatremic losses are therefore 138 mEq (6 L × 23 mEq/L). Total sodium needs are thus 30 mEq of maintenance, 185 mEq of isotonic losses, and 138 mEq of hyponatremic losses or a total of 353 mEq. She has already received 52 mEq of sodium from the 400 mL of 0.9% NaCl given in the emergency department. Her current sodium needs are thus just about 300 mEq.

To choose the proper solution for this child, the deficit of 1,950 mL of water should contain 300 mEq of sodium. This is best approximated by 0.9% NaCl with its NaCl content of 154 mEq/L NaCl. In the past, it has been suggested that half of the fluid and sodium deficit be replaced over 8 h and the remainder over the ensuing 16 h. Although such a plan can be followed, there is little evidence that more rapid correction of the hyponatremia is harmful except if the patient has been symptomatic with hyponatremia or has profound asymptomatic hyponatremia of chronic duration. In these cases, it is safest to plan to correct the serum sodium by no more than 12–15 mEq/L over 24 h. More rapid correction has resulted in osmotic demyelination injury to the brain with devastating long-term neurologic outcomes (116–118).

Severe Hypernatremia

With hypernatremia, therapy is again guided by the clinical situation and provision of intravenous fluid is usually reserved for those children with very elevated serum sodium values who are not considered candidates for oral rehydration therapy. In cases of hypernatremia due to salt poisoning, there should be signs of overhydration and volume expansion. Excretion of sodium should be enhanced by using a loop diuretic to augment urine sodium losses and by replacing urine output with free water. If the patient has significant underlying renal or cardiac compromise, dialysis and ultrafiltration may be necessary to correct the water and electrolyte imbalance (42, 43). With hypernatremia and volume expansion from salt excess, it will be detrimental to provide further intravenous saline.

In hypernatremia accompanied by volume loss, any significant alterations in effective circulation should be addressed with 20 mL/kg bolus infusions of an isotonic crystalloid solution until effective peripheral perfusion is restored. Then, further provision of water and sodium should be provided based on calculated water and sodium needs. In the majority of cases, with mild elevations in serum sodium and minimal degrees of dehydration, the actual calculation of deficits is probably unnecessary since the child will be hemodynamically stable and a candidate for exclusive oral rehydration. In situations where there is profound hypernatremia or circulatory compromise, it remains necessary, however, to be able to calculate a free water deficit to tailor intravenous rehydration therapy. An example of such a situation is outlined in the following clinical scenario:

After 2 days of refusing to nurse, a 5 kg infant boy with a viral syndrome presents to an emergency department in shock, 15% dehydrated with a weight of 4.25 kg and a

serum sodium of 170 mEq/L. He receives 300 mL of 0.9% NaCl urgently and further therapy is now planned.

The child has lost 750 g of weight. Since this is hypernatremic dehydration, there has been loss of water in excess to salt. Thus, part of the weight loss represents isotonic losses but a larger proportion represents free water loss. The child's free water deficit can be calculated by the equation:

$$[(\text{Serum Na actual})/(\text{serum Na desired}) \times \text{total body water}] - \text{total body water}$$

Substituting the appropriate data for this baby:

$$[(170/145) \times (0.6 \times 4.25)] - (0.6 \times 4.25) = [1.2 \times 2.55] - 2.55 = 0.51\text{L}]$$

Thus, of this baby's 750-mL fluid deficit due to dehydration, 510 mL is free water and 240 mL is normal saline.

Too rapid correction of the baby's serum sodium with free water could result in cerebral edema as the water infused into the extracellular space follows osmotic forces and moves into the intracellular space. In cases of hypernatremia where the serum sodium exceeds 160 mEq/L, it is considered safest to correct the serum sodium by no more than 15 mEq/day. In this boy's case, this would mean that correction to a serum sodium in the normal range would take about 2 days.

If the fluid and electrolyte therapy must be given intravenously, the appropriate prescription again depends on calculation of water and sodium requirements and deficits. His original fluid deficit was 750 mL and his maintenance water needs are estimated at 500 mL/day. Thus, over the next 2 days, the fluid needs to replace the deficit and provide maintenance would be 1,750 mL. Of this volume, sthe baby has already received 300 mL of fluid in the emergency department so a net deficit of 1,450 mL now exists.

The baby has maintenance sodium needs of 15 mEq/day (3 mEq/kg/day). His sodium deficit reflects only the isotonic fluid losses that have been estimated above at 240 mL of normal saline or 37 mEq of sodium. Thus, over the next 2 days, his sodium needs are 67 mEq of which he has already received more than 45 mEq in the emergency department due to initial volume expansion.

Initiating an infusion of 30 mL an hour of free water should result in the slow and steady correction of the hypernatremia over 2 days by providing the nearly 1.5 L of free water that the child requires to replace losses and provide ongoing needs. The serum sodium should be monitored every 4 h initially and if it is falling faster than desired (about 0.5 mEq/hour) then sodium should be added to the rehydration fluid.

Fluid and Electrolyte Therapy with Renal Dysfunction

Impact of Kidney Disease

Children with compromised renal function often manifest a reduced tolerance for changes in total body water as well as changes in the composition or distribution of volume between the intracellular and extracellular body spaces. Similarly, alterations in electrolyte balance are more likely problematic because normal homeostatic mechanisms are frequently perturbed. Especially in the child with marked nephrosis or significant impairment in renal clearance, it becomes vital to approach the provision of fluids and electrolytes with great care.

As far as fluid therapy is concerned, of utmost importance is the recognition that the concept of maintenance fluids or electrolytes pre-supposes normal renal function. Roughly two-thirds of any daily maintenance fluid prescription is to replace urinary water losses. Similarly, urinary electrolyte losses figure prominently in daily electrolyte balance. In the setting of oliguria or anuria, provision of maintenance fluids could contribute to and, potentially, exacerbate volume overload and maintenance electrolyte therapy could result in electrolyte anomalies.

Fluid and electrolyte needs of the child with renal dysfunction are better considered in the context of the child's current volume status and electrolyte needs. For instance, in symptomatic volume depletion with decreased circulatory perfusion, volume expansion would be initiated regardless of urine output. Once volume replete, the child's needs could be reassessed along with his current renal function. The child who is volume overloaded would best be managed by fluid restriction and provision of only insensible losses of approximately 300 mL/m^2. Insensible fluid losses should be considered essentially electrolyte free water. The child who is volume replete should be kept volume replete. This is most readily accomplished by providing a combination of insensible losses as free water and any other volume losses (urine output, diarrheal stool, surgical drain output, emesis) on an additional milliliter for milliliter basis. If there are significant ongoing losses from a single source, the electrolyte composition of this fluid can be assayed so that the replacement fluid may more accurately reflect the electrolyte losses. Otherwise, a solution of 0.45% NaCl can be used initially and altered as the clinical situation continues to develop and further electrolyte determinations are made.

If the child's volume status or the adequacy of renal function is difficult to discern initially, it is best to provide the child with replacement of both insensible and ongoing losses. This approach should maintain the child's current volume status and allow for further determination of the appropriateness of more vigorous hydration or conversely fluid restriction as the clinical situation clarifies. Monitoring the child's weight on at least a daily basis and documenting the child's total fluid intake and output will also assist in arriving at a proper hydration regimen.

Assessing the child's current electrolyte status and monitoring the loss of electrolytes in the urine or in any other source of significant output will help tailor the daily electrolyte prescription. An understanding of the pathophysiology underlying the child's renal dysfunction will also be useful. The child who has profound tubular electrolyte losses will require more sodium on a daily basis than the child who is edematous and total body salt overloaded from his nephrotic syndrome. The child with chronic renal insufficiency and hypertension mediated by long-standing salt and water overload may actually benefit from diuretic therapy to remove salt and water rather than any further volume expansion with saline.

Certainly the provision of supplemental potassium to the child with renal dysfunction must be done judiciously. The oliguric or anuric child should receive no potassium until it is well documented that serum potassium levels are low or that there are extrarenal potassium losses (for instance losses from diarrheal stool). The child with marginal renal function should receive small amounts of potassium (approximately 1 mEq/kg/day) with at least daily assessment of electrolyte balance to determine adequacy and appropriateness of continued potassium supplementation.

Fluid and Electrolyte Therapy in the Pediatric Intensive Care Unit

Critically ill children present a challenge to the clinician attempting to prescribe appropriate fluid and electrolyte therapy. Oftentimes, there may be acute kidney injury or multiorgan failure complicating management decisions. With such children, rote reliance on standard equations or practice guidelines to prescribe fluid and electrolyte therapy may create significant fluid and electrolyte anomalies. Rather than prescribing set maintenance requirement of fluid or electrolytes, the clinician should assess the patient's individual fluid and electrolyte needs in the context of the underlying pathophysiology, the current volume status, the efficacy of tissue perfusion, the current ventilatory requirements, and the current renal function. Whenever there is concern about incipient or exacerbating fluid overload, it is important to review the volume and type of fluids being provided. Maximizing the concentration of continuous medication drips and assessing medication compatibility for simultaneous infusions are important steps in limiting total daily fluid input. Initially, it is crucial in these critically ill children to ascertain that their intravascular space is replete to help maintain hemodynamic stability. Once a patient is felt to be intravascularly replete, maintaining euvolemia by providing insensible water losses as well as replacing any ongoing fluid and electrolyte losses should maintain fluid and electrolyte balance.

Oftentimes, despite a desire to limit fluids in the critically ill child, medication requirements, nutritional needs, and hemodynamic insufficiency may result in very large daily fluid loads. There may also be situations in which increased vascular permeability or "leak" causes a critically ill child to become massively volume overloaded but with a decreased effective circulating volume. In other words, renal and tissue perfusion may be sluggish because fluid has leaked from the intravascular space into the interstitial space. In this setting, there may be need to continue to administer large volumes of fluid to maintain circulatory integrity with the knowledge that such infusions will only exacerbate the total body fluid overload. Aggressive diuretic therapy may prove useful especially if renal function is not compromised. Combination diuretic therapy utilizing agents that work at separate sites along the renal tubule may be necessary. Ultimately, the use of either periodic or continuous ultrafiltration may be beneficial to these patients by allowing ongoing fluid administration but limiting the daily imbalance between fluid intake and output. Ultrafiltration may be accomplished via peritoneal dialysis, by intermittent hemodialysis with ultrafiltration, or by utilizing one of the slow continuous ultrafiltration techniques now known as continuous renal replacement therapy (CRRT)). The recognition that volume overload has a deleterious effect on many aspects of patient management and seems to be a strong prognostic indicator of poor ultimate outcome has led some to suggest that early ultrafiltration should be considered in critically ill patients (119).

If ultrafiltration is initiated, extreme vigilance is necessary to prevent exacerbation of intravascular depletion and the development of pre-renal azotemia or frank renal failure. Special care must be taken with the continuous modalities to insure that ultrafiltration rates are

periodically reassessed and readjusted. Furthermore, because the electrolyte losses that accompany the ultrafiltration of fluid are isotonic, the electrolyte content of infused fluids must be adjusted to match the composition of the ultrafiltrate, especially if there is no component of dialysis ongoing that may blunt the development of serum electrolyte anomalies. As a result, serum electrolyte values need to be followed in a serial fashion with periodic review and readjustment of the composition of supplemental intravenous fluids.

Abnormalities in Serum Sodium Complicated by Kidney Injury

Because of the important contribution of serum sodium to serum osmolality, alterations in serum sodium, especially coupled with alterations in BUN related to renal failure, can complicate the usual approach to a child with fluid and electrolyte anomalies. Generally, there are greater concerns with hypernatremia and renal failure since the need to correct the sodium in a slow fashion can be problematic when renal replacement therapy needs to be initiated for clearance of urea. Balancing the correction of sodium and the hyperosmolar state with the clearance of urea requires a carefully considered plan that is grounded in a firm understanding of fluid and electrolyte homeostasis.

In most cases of hypernatremia related to severe dehydration, some degree of acute kidney injury is present. This renal dysfunction is usually "pre-renal" in nature, a result of a decreased effective circulating volume rather than an intrinsic glomerular or tubular disorder. Most often, in the course of rapid restoration of perfusion and early rehydration, urine output increases and azotemia begins to resolve.

Alternatively, there are occasional cases in which due to intrinsic renal dysfunction or acute tubular necrosis, the renal insufficiency will not respond to volume infusion and, in fact, the provision of excess volume may contribute to significant volume overload. In these cases, there may be need to consider some form of renal replacement therapy to assist in the controlled correction of fluid and electrolyte derangements, especially if the renal failure is oliguric or anuric in nature. Such an example is detailed in the following case study:

A 15-year-old boy presents with several weeks of polyuria, severe weight loss, fatigue, and poor oral intake. He is diagnosed as having diabetes mellitus with ketoacidosis by his pediatrician and referred to an emergency department for management. At this point, his serum sodium is 154 mEq/L, his creatinine is 3.0 mg/dL, and his BUN is 30 mg/dL. In the emergency department, the child receives several bolus infusions of normal saline supplemented with sodium bicarbonate and is started on an insulin drip. He is admitted and continues to receive brisk intravenous hydration with normal saline with bicarbonate supplementation per a practice guideline for treating children with diabetic ketoacidosis. He is noted to be oliguric and this does not improve with several more h of hydration with normal saline following the guideline hydration recommendations. The next morning, laboratory values reveal a serum sodium of 165 mEq/L, a creatinine of 4.5 mg/dL, and a BUN of 50 mg/dL. He has made only 75 mL of urine in the last 8 h and is developing some mild peripheral edema.

In this case, the renal insufficiency and poor urine output have complicated the usual management of diabetic ketoacidosis and has exacerbated an underlying hypernatremia. Given the patient's evolving renal failure, it is not feasible to provide the necessary volume of free water to correct the hypernatremia without contributing to further volume overload. Because of the apparent progressive renal failure, it would also be useful to correct the hypernatremia in case dialysis becomes necessary for urea clearance. By performing controlled ultrafiltration on the patient and replacing back the volume ultrafiltered with free water, the serum sodium could be corrected without exacerbating the volume status.

With a serum sodium of 165 mEq/L and an estimated TBW of 42 L (70 kg $\times$ 0.6 L/kg), this boy has free water needs of 7.5 L to lower his serum sodium to the 140 mEq/L range ([165/140 $\times$ 42]–42). Since the patient is now significantly hypernatremic and has been subject to various fluid and electrolyte shifts as his diabetic ketoacidosis has been treated, it would be prudent to correct his serum sodium by no more than 10–12 mEq/day over the course of 3 days. Thus, if the boy undergoes ultrafiltration with a goal of 2.5 L removed daily, and the ultrafiltration volume each day is replaced back totally as free water, the serum sodium should be in the normal range in 3 days' time. The ultrafiltration goal could be achieved over the course of a few hours each day if the patient were hemodynamically stable or over a more prolonged period of time each day if there were concerns regarding hypotension. Thus, either a conventional hemodialysis set up could be used for relatively rapid ultrafiltration only or a continuous filtration circuit for either rapid or slow filtration.

Since the fluid removed in ultrafiltration is isonatremic to the serum sodium, the sodium concentration of each liter of ultrafiltrate should mirror the serum sodium

concentration at the time of ultrafiltration. Thus, on the initial day of ultrafiltration, each liter of ultrafiltrate would contain a sodium content of 165 mEq/L. By providing back the volume ultrafiltered each day as free water, the serum sodium content could be expected to fall, in this case, by about 8–10 mEq/L/day.

It is important to recognize that free water must be provided back to the patient to make up for the ultrafiltration losses. Otherwise, since the ultrafiltrate is isotonic, there will be no change in the serum sodium concentration and the ultrafiltration may potentially exacerbate the renal failure by depleting the intravascular space and the effective circulating volume.

Moreover, it is also important to recognize that the boy's overall daily fluid needs will be greater than the daily ultrafiltration volume alone since maintenance fluid requirements and any ongoing fluid losses must also be considered. Since the boy is in renal failure, his maintenance fluid needs can be scaled back to insensible losses of 300 mL/m^2/day and, in this case, there are no ongoing losses. Thus, each day for the next 3 days this 70-kg patient needs to receive approximately 500 mL/day of insensible losses and 2,500 mL/day of ultrafiltration replacement or a total of 3,000 mL/day. His maintenance sodium requirements are 3 mEq/kg/day. Although it may seem counterintuitive to provide a hypernatremic patient with maintenance sodium, disregarding these requirements will result in a more rapid correction of the hypernatremia than desired. If the child were to receive a saline infusion of 0.45% NaCl at a rate of 125 mL/h, this will provide just over 3 mEq/kg/day of sodium in a total volume of 3 L/day.

If the child with hypernatremia has profound renal failure and requires dialysis for urea clearance, the dialysis prescription must take into account the need to correct the serum sodium slowly. Normally, regardless of the modality of renal replacement therapy, most dialysate contains sodium isotonic to the normal serum sodium range. It may prove detrimental, however, to dialyze a patient who is very hypernatremic against a dialysate with a sodium concentration 30 mEq/L or more less than the patient's serum sodium concentration. The diffusional gradient during dialysis would lead to more rapid correction of the serum sodium than the desired drop of approximately 1 mEq every 2 h.

Although most hemodialysis machines can be readjusted so that the dialysate produced will have a sodium content as high as the low to mid-150s, this still may not reduce the gradient sufficiently in cases of severe hypernatremia. In those situations, by maximizing the sodium concentration of the dialysate and by performing dialysis for limited amounts of time, one could minimize the drop in serum sodium. Still, there would need to be frequent assessments of the serum sodium concentration, and overall clearance may need to be sacrificed to prevent too rapid correction of the serum sodium and a rapid concomitant decrease in the serum urea that may increase the chances for dialysis dysequilibrium.

Alternatively, a continuous hemodiafiltration technique such as continuous venovenous hemodiafiltration (CVVHDF) could be performed. By asking the hospital pharmacy to increase the sodium content of the dialysate and replacement fluid to within 10–12 mEq/L of the serum sodium concentration, the diffusional gradient for sodium clearance could be minimized. Then, by making appropriate adjustments in the sodium content of the dialysate as the serum sodium falls, the serum sodium levels could be reduced gradually by 10–12 mEq/L/day while at the same time adequate urea clearance and ultrafiltration for most situations would be achieved.

Peritoneal dialysis has also been used in cases of severe hypernatremia (120–122). Again, the concentration of sodium in the dialysate may need to be adjusted upwards in severe hypernatremia to prevent too rapid clearance of sodium. In addition, since the degree of clearance and ultrafiltration may not be as precisely controlled as with hemodialysis or hemodiafiltration, frequent assessment of electrolyte values will be necessary. Manipulation of dwell volumes and dwell times will also influence overall clearance and the use of smaller dwell volumes for longer periods of time will help to minimize sodium clearance.

In contradistinction to hypernatremia, since hyperosmolality is less common with hyponatremia, in some ways it is easier to employ renal replacement therapy in the setting of severe hyponatremia and concomitant renal insufficiency. Again, the focus needs to be on the rapidity of the correction of the serum sodium. In conditions of severe but asymptomatic hyponatremia of some chronicity, the rate of correction of serum sodium should parallel the rate of correction recommended in hypernatremia – approximately 10–12 mEq/L/day. Correction of chronic hyponatremia at a more rapid rate has been associated with the development of central pontine demyelinosis.

All of the manipulations described above for hypernatremia and renal failure can be utilized with hyponatremia and renal failure, with the understanding that the dialysate sodium concentration should now not exceed the serum sodium value by 10–12 mEq/L. Conventional hemodialysis machines can be adjusted to produce dialysate with a sodium concentration as low as the mid-120s. In the very rare situation in which a child with profound hypernatremia (<110 mEq/L) were being hemodialyzed,

brief hemodialysis runs may be necessary initially to prevent too rapid correction of the serum sodium level and the attendant risk of central pontine demyelinosis. If dialysate is being custom prepared for peritoneal dialysis or hemodiafiltration, precise alterations in the electrolyte content can be made more readily to reduce the sodium gradient.

The local resources, the training of ancillary staff, the unique circumstances of each patient, and the comfort of the clinician with different modalities of renal replacement therapy will guide the choice of therapy when faced with renal failure and significant serum sodium anomalies. The actual modality of renal replacement therapy utilized is less important than careful attention to the rate of correction of the electrolyte anomaly, to the rate of urea clearance being achieved, and to the clinical response of the patient to on-going therapy.

Research Methods

14 Molecular Biology

Francesco Emma · Luisa Murer · Gian Marco Ghiggeri

Introduction

The field of molecular biology developed initially between the 25 years from 1940–1965, through the efforts of scientists which led to the discovery of the genetic code and the establishment of the role of RNA in the synthesis of proteins (1, 2). Thereafter, efforts of an increasing number of researchers have provided an explosion of key technological innovations allowing recombinant DNA technology to be applied to a wide variety of biologic problems and to enter clinical practice. Major milestones include discovery of restriction nucleases and DNA ligases, development of DNA libraries, DNA cloning procedures, nucleic acid hybridization techniques, the polymerase chain reaction (PCR), rapid sequencing techniques, and the production of transgenic animals. These advances permitted detection, amplification and engineering of DNA sequences, and delineation of the role of genes in cellular physiology and pathophysiology.

This molecular revolution has affected all sciences, including medical and clinical research, and has culminated in the completion of the human genome project (3). It has provided new insight into the complexity of living organisms that are now been studied by functional genomic and proteomic approaches that involve microengineering, computer technology, and bioinformatics.

This chapter illustrates the basic concepts of molecular biology that underlie various strategies that have been developed for studying living cells and organisms and summarizes molecular biology techniques that are used in nephrology research and clinical practice. It is therefore necessarily limited in breadth and depth. For more information, the reader can refer to the many specialized reference textbooks that are available (1, 2).

Basic Concepts

From DNA to Proteins

In the mid-1950s, the "central dogma of molecular biology" was proposed soon after the discovery of the DNA structure in 1953. To date, this dogma remains one of the keystones that guides the study of genetic human diseases.

DNA sequences are transcribed into RNA molecules that carry the flow of genetic information out of the nucleus to be translated into proteins. These processes have been well defined and are detailed in most introductory cell biology texts (1, 2). This simple concept has been however thoroughly revised, as genetic information has been shown to be conveyed in both directions through a complex series of feedback loops.

The link between nucleic acids and proteins is contained in the genetic code. Sixty-one of the 64 codons correspond to amino acids, whereas three correspond to termination codons. The code is said to be "degenerate", as it contains redundancies. Codons corresponding to the same amino acid generally differ by the nucleotide in the third position.

As a practical consequence of the degeneracy of the genetic code, nucleotide substitutions (point mutations) in the third nucleotide of a given codon may not change the primary sequence of a protein and are frequently found in nature, as they are not subject to natural selection. Point mutations in the first and second position result in an amino acid substitution or in a termination codon, either of which can dramatically alter protein structure and function.

In principle, each messenger RNA (mRNA) can be translated in any of the three possible reading frames determined by overlapping triplet codes. With few exceptions, only one reading frame produces a functional protein because stop codons encountered in the other two reading frames terminate translation. As the only punctuation signal is located at the start codon (ATG), the reading frame is set at the beginning of the translation and proceeds until a termination codon is reached. Thus, finding the correct reading frame and locating the start codon are essential steps in the process of cloning genes and defining their protein products. Mutations causing deletion or insertion of one or two nucleotides result in a shift of the reading frame (frameshift mutations) and cause production of aberrant protein products.

Gene Structure

Complementary strands of chromosomal DNA are arranged in an anti-parallel fashion as dictated by hydrogen bond pairing of nucleotide bases. It is estimated that the human genome is composed of approximately 3 billion base pairs of DNA containing over 30,000 genes, arrayed on 23 pairs of chromosomes (4). Overall, the amount of DNA containing genes comprises a minority of nuclear DNA.

Traditionally, a gene is depicted as a "transcriptional unit" as illustrated in *Fig. 14-1*. The DNA double helix is represented as a line interrupted by rectangular boxes corresponding to exons, with its 5′ end on the left and its 3′ end on the right. Each gene is divided into two major regions, namely the promoter and the coding regions. The promoter region is located upstream near the 5′ boundary of the coding region and contains clusters of short sequences (less than ten base pairs) spread over a few hundred bases that bind transcription factors. These regulatory proteins mediate the attachment and activation of type II RNA polymerase, which mediates transcription along the DNA while unwinding the duplex and adding nucleotides to the growing RNA molecule. DNA sequences in the promoter region that bind to transcription factors are referred as *cis*-acting elements. In some

Figure 14-1

General organization and processing of a eukaryotic gene. A gene consisting of four exons and three introns is shown. The promoter region (black box) is located near the 5′ end of the gene. Transcription of the gene yields a primary mRNA transcript that contains both exon and intron sequences. Differential splicing of this mRNA transcript yields two mature mRNA species by inclusion or exclusion of exon 3 (hashed box). In order to be exported into the cytosol and translated, mRNAs need to be modified by polyadenylation of their 3′ end and capping of their 5′ end with methylated guanosines. Differential splicing results in two different protein isoforms which are encoded by a single gene.

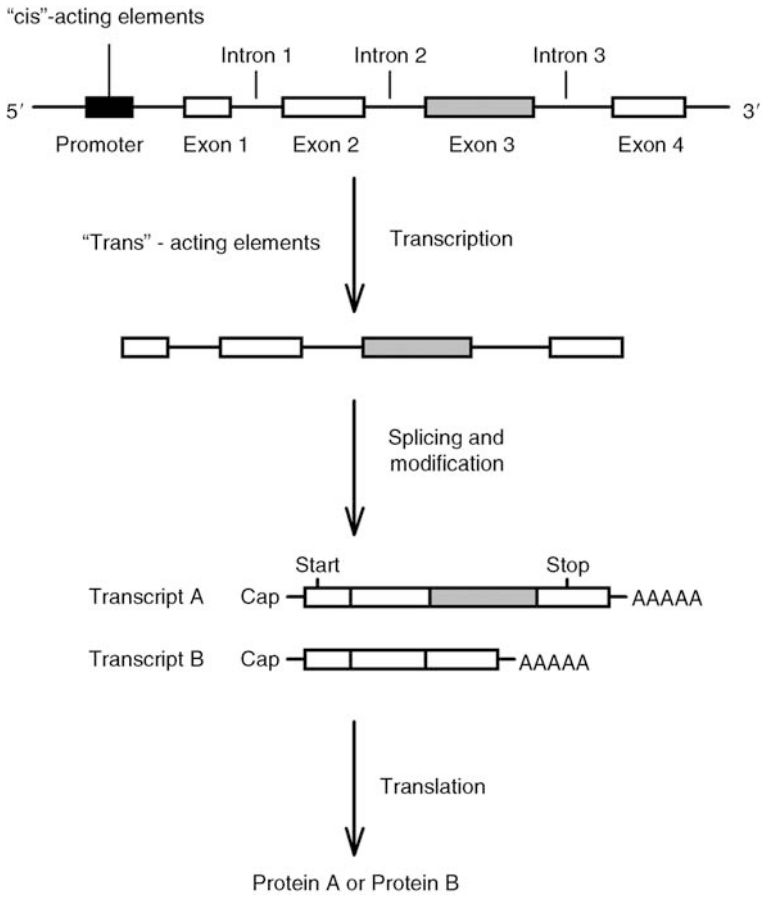

Figure 14-2

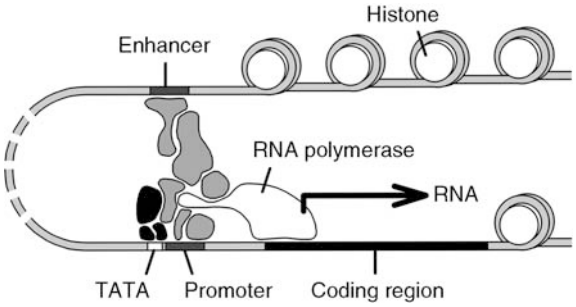
Transcriptional regulation in eukaryotes. Different transcription factors bind to the promoter and enhancer regions and position type II RNA polymerase at the starting point of transcription. General transcription factors shown in black interact with the TATA box and hold together the enhancer-promoter-RNA polymerase complex. When not activated, eukaryotic genes are hidden in nucleosomes which are composed of a central core formed by histones. Activation of eukaryotic genes requires remodeling of the chromatin in order to allow the transcriptional apparatus to interact with regulatory sequences.



cases, transcription factors also interact with other *cis*-acting elements (enhancers) that are located at a greater distance (up to a few thousand bases) from the promoter. The physical gap between the enhancer and the promoter explains the need for accessory factors that convey transcriptional signals to the RNA-polymerase through protein-protein interactions (*Fig. 14-2*). All molecules, generally proteins, which are physically involved in the regulation of transcription are referred to as *trans*-acting elements, because their DNA sequence resides in a different location of the genome (1, 2). The coding region contains information for protein synthesis. In this region, most genes are composed of a succession of exons and introns. Exons are coding sequences that ultimately transfer into mature mRNA, whereas introns are edited out of the newly synthesized transcript by a process called splicing.

Control of Gene Expression

As only a fraction of the available genes are expressed in a given cell at a given developmental stage, differential transcription and processing of genes provides for enormous diversity between cells within the same organism.

Although gene expression can be controlled at different levels, transcriptional regulation generally predominates. Information that governs transcription is located in DNA sequences that correspond to *cis*-acting elements or which encode for transcription factors. These sequences occupy a minimal portion of the entire genome but are key determinants of cell organization by ensuring a balanced expression of different genes that preserves phenotypic stability. They also provide for differences among cell types within the same organisms and are at the core of the evolutionary process.

Gene expression in eukaryote organisms is complex. Unlike prokaryotes, genes operating within the same metabolic pathway are not usually physically aligned along the genomic DNA and are often located on different chromosomes. The expression of functionally related genes is achieved by activation of shared classes of transcription factors that act on common structural motifs in DNA-binding domains (enhancers and promoters). Transcription factors are also often involved in developmental regulation. The eukaryotic type II RNA polymerase differs from its prokaryotic ancestor by the complexity of transcription factors that are required for its activation (5) (*Fig. 14-2*). This elaborate modular system allows forflexible and highly coordinated regulation of gene transcription. In transcription, DNA rearranges to allow interaction between transcription factors located at the promoter and at the enhancer site. The TATA box, which contains consensus sequences recognized by general transcription factors (TFIID, TBP, and TAF), is usually located approximately 24 bases upstream from the promoter and acts as a bridge that holds together the enhancer-promoter-RNA polymerase complex and positions the enzyme at the starting point of transcription (6). Although enhancers are not essential, they increase promoter efficiency.

A second characteristic of transcription in eukaryotic cells is related to the association of nuclear DNA with histones, forming nucleosomes. This particular organization prevents interaction between regulatory sequences and transcription factors unless conformational changes of the chromatin permit gene activation (*Fig. 14-2*).

Gene transcription can be chemically blocked in eukaryotic cells by methylation of specific DNA regions located near the promoter. Experimentally, the state of DNA methylation can be determined by inhibition of the nuclease activity of restriction enzymes that recognize non-methylated GC doublets.

Transcription Factors

The major characteristic of transcription factors is to contain specialized domains that allow for interaction with the DNA double helix.

Zinc fingers, helix-turn-helix (HTH) domains, helix-loop-helix domains, and leucine zippers are examples of DNA binding domains that are encountered in more than 80% of transcriptional factors (7). Zinc finger motifs are composed of a Zn ion holding together a peptide loop (the finger) through interaction with two histidines and two or four cysteines. The functional DNA binding domain is located in the amino acid residues at the base of the finger and recognizes specific consensus sequences that are generally located in the enhancer region. Steroid receptors are the most popular examples of this class of transcription factor, including glucocorticoid, mineralocorticoid, androgen, progesterone, thyroid hormone, and vitamin D receptors (8).

Similar DNA binding activity characterizes other classes of transcription factors. HTH domains are often found in proteins that have key roles during morphogenesis such as the homeobox group of transcription factors (9). Members of the helix-loop-helix class include proteins that control myogenesis, such as MyoD, that have been implicated in the transdifferentiation of myofibroblasts, which promote renal fibrosis (10). Leucine-zipper motifs are used by the Jun and Fos proteins. Both are members of the AP-1 heteromeric transcription complex that is involved in cell proliferation and regulation of cell matrix during fibrogenesis (11). An important transcription factor that is often implicated in renal diseases is nuclear factor-κB, which regulates many proinflammatory pathways and is itself under the control of other proteins, such as angiotensin II, known to promote inflammatory reactions in the renal parenchyma (12).

Transcriptional Control during Development

Transcriptional regulation plays a central role during development, by governing complex sequences of events that transform undifferentiated embryonic cells into highly specialized mature cells (1, 2). Three major classes of developmental regulatory genes have been identified. These include maternal, segmentation, and homeotic (Hox) genes. Each are expressed at different stages of cell maturation following complex sequences of activation in which gene products that are expressed at a given stage activate genes at a following stage. This highly sophisticated sequence of events creates a hierarchy according to which maternal, segmentation, and homeotic genes are expressed sequentially. Maternal systems activate expression of specific transcription factors, termed morphogens, that are responsible for the initial patterning of the embryo. Segmentation genes are zinc-finger proteins that control the boundaries of compartments, whereas Hox genes control the differentiation steps of each segment. Hox genes are characterized by a common HTH-type DNA-binding motif at their carboxy- terminus termed homeobox and are organized in the human genome in four different clusters (A,B,C,D) containing up to ten genes each. As the number of identified developmental transcription factors is rapidly increasing, their impact on renal development and involvement in congenital renal anomalies is a field of active research (13). Moreover, during the recovery phase of renal cell injury, cells reactivate several developmental genes in repair and restoration of function (14).

Modification and Splicing of mRNAs

During cleavage and processing of primary RNA transcripts, RNA molecules are capped at their 5′ origin by the addition of methylated G nucleotides, and a segment of poly-A residues is attached near their 3′ end (*Fig. 14-1*). These modifications are necessary to allow export of the transcript from the nucleus, to stabilize mRNA molecules, and to allow interaction with ribosomes. The presence of a poly-A tail is a major characteristic of mRNAs and constitutes a key tool to isolate mRNAs from other RNA molecules, mostly ribosomal, using complementary oligo-dT primers.

Before RNA is exported into the cytosol, splicing of intron segments is performed. As introns facilitate recombination events, they play a major role in the evolution of species and are often targeted in the process of generating knockout animals. Their physical structure may be more important than their actual nucleotide sequence, as these diverge more rapidly between species than exons (15, 16). Introns can range in size from 80 to several thousand nucleotides. They contain specific sequences at their extremities referred as the 5′ splice site (always ending with 5′-GU-3′) and the 3′ splice site (always ending with 5′-AG- 3′) that come together in the process of splicing. During splicing, a large catalytic heteromeric complex, termed spliceosome, is formed by the assembly of different ribonucleoproteins (1, 2). After RNA binding, spliceosomes bridge together two exons and excise their intron segment. Generally, each 5′ splice site pairs with the closest 3′ splice site in the spliceosome, producing only one form of mRNA. In some cases, however, splicing of RNA enables a single gene to produce different mRNA transcripts by jumping from a given 5′ splice site to a more distant 3′ splice site (*Fig. 14-1*). Each of these mRNAs yields different isoforms of the same protein that can be alternatively produced in different types of cells. Genome-wide analysis of

alternative splicing indicates that 40 to 60% of human genes have alternative splice isoforms (16, 17). Splicing of mRNA is an important regulatory step in the production of cell proteins that requires high degree of accuracy. In general, DNA mutations that involve splice sites (splice site mutations) do not prevent splicing but instead cause the normal partner to seek alternative splice sites, producing the synthesis of various abnormal proteins lacking one or more exons, as, for example, in Frasier syndrome (18). Constitution of gene banks containing thousand of gene transcripts has greatly facilitated the recognition of splicing variants of a given gene, which can be easily accessed online: (www.ncbi.nlm.nih.gov/IEB/Research/Acembly/).

Regulation of Proteins Synthesis

Mammalian ribosomes are the site of mRNA translation and composed of two asymmetric subunits - the 40S that binds mRNAs and the 60s that interacts with transfer RNAs. Eukaryotic cells can decrease their rate of protein synthesis in various conditions such as infections or heat shock. One important mechanism that mediates these types of nonselective responses involves phosphorylation of a repressor protein termed elF-2 that interacts with target regions containing the AUG start codon preventing ribosomal binding. A second gene-specific mechanism of translational regulation is termed attenuation and involves the formation of mRNA hairpins that block the translation. Similar mechanisms also regulate mRNA stability and degradation by RNases. Given the fact that each molecule of mRNA can serve as a template for multiple copies of proteins, the rate of mRNA degradation is a major determinant of protein abundance and is often the site of complex regulatory processes. In general, these processes operate primarily on unstable mRNAs (such as cytokines) that are stabilized under specific conditions by their interaction with *trans*-acting elements (19, 20). The stability of transferrin mRNA, for example, increases during iron deprivation, triggering the synthesis of more transferrin molecules (21).

Protein Sorting and Degradation

Newly synthesized polypeptides are processed by a complex network of cellular enzymes and other binding proteins that are arranged in a highly organized fashion in various organelles in the cell. Information resident in the primary amino acid sequence as well as the folded structure of the proteins allow each to be recognized and targeted to its ultimate destination (1, 2). Proteins which are synthesized in free cytosolic ribosomes are normally directed to the nucleus or the mitochondria, whereas membranous ribosomes are the site of synthesis for proteins that enter the reticuloendothelial system (co-translational transport) to be redirected to their final destination after being processed in the Golgi apparatus. An excellent example of this process is highly polarized epithelial cells in renal tubules. In these cells, transport proteins are located specifically on the apical or basolateral plasma membranes. This arrangement enables epithelial cells to perform net transport of solutes and water to either secrete or reabsorb fluid. Some proteins are able to self-assemble by spontaneous interaction among reactive amino acid groups, whereas other proteins, such as the V2 receptor, require assistance of molecules such as the Hsp70 system and chaperonins (22). These molecules control accessibility of reactive groups and maintain the peptide in a relatively flexible state until it reaches its final conformation. The final fate of most cell proteins is degradation into proteosomes. A process called ubiquitination that involves covalent linkage of small peptides called ubiquitins to target proteins precedes this step. Ubiquitination is also involved in important signal-transduction pathways, such as the nuclear factor- κB pathway - in which inhibitory subunits are degraded after stimulatory signals and activate various signaling cascades (23).

Recombinant DNA Technologies

Introduction

Until recently, molecular biology has addressed two major objectives; namely, to identify genes and analyze their function. With the completion of the human genome project, focus is shifting from the first to the second goal and to the more complex task of delineating complex patterns of gene expression. In the following sections, the more common recombinant DNA and protein analysis technologies are described, to illustrate common experimental procedures that are routinely used in molecular diagnostics as well as basic research.

Basic Recombinant DNA Technology

Hybridization and Detection of Nucleic Acids

Pairing of nucleotide bases in DNA and RNA allows a wide variety of specific recognition processes both *in vivo*

and *in vitro*. These not only form the basis of many critical cellular functions, but also provide the molecular biologist with tools to detect and study single genes.

The extraordinary specificity of nucleic acid-base recognition has been exploited in the process of hybridization of complementary DNA or RNA *in vitro*. Under appropriate conditions, a unique nucleotide sequence present within a complex mixture of nucleic acids can be identified with a resolution of greater than one part per million. Using standard techniques, DNA or RNA is isolated from cells or tissues, stripped of proteins, and denatured into single strands. When incubated under conditions favoring renaturation, complementary sequences reassociate. Experimental conditions (commonly temperature and salt concentration) can be altered to allow for only perfect or nearly perfect sequence matches. This is called stringency. Lowering stringency conditions is sometimes desirable to identify close relatives of particular nucleotide sequences. Thus, one can search for a gene or mRNA in kidney that is a close relative of a transcript expressed in other tissues as well as species. Nucleic acids are commonly fractionated by agarose gel electrophoresis. Under these conditions, the agarose acts as a molecular sieve, retarding larger strands while allowing smaller strands to migrate in the electric field placed across the gel. Fractionated DNA or RNA is then eluted from the gel or can be transferred to a filter and exposed to a labeled DNA probe. When the filter contains DNA, this process is called a Southern blot, whereas it is called Northern blot if it contains RNA (1, 2).

This same procedure has also been adapted to tissue sections to localize expression of mRNA transcripts by specific cell types within a complex organ such as the kidney. This technique is called *in situ* hybridization (1).

Restriction Endonucleases

The discovery by Arber in 1962 of bacterial nucleases that cut DNA molecules at specific locations constitutes one of the cornerstone in the development of recombinant DNA techniques (24).

Most restriction enzymes recognize palindromic DNA sequences, meaning that the 5′ to 3′ sequence in the upper strand is identical to the 5′ to 3′ sequence in the lower strand.

To date, nearly 1,000 different restriction enzymes have been purified. Each enzyme can produce defined DNA restriction fragments possessing specific nucleotide sequences at each end from any given DNA sample. With these enzymes, strings of DNA can be isolated, ligated into plasmid or phage genomes, and amplified (*Fig. 14-3*).

Historically, restriction nucleases have allowed construction of the first detailed maps of various genomes (restriction maps). They are commonly used for allelic discrimination by restriction fragment length polymorphism (RFLP). In this technique, DNA mutations which modify the recognition sequence for specific restriction enzymes can be identified by the length of the restriction reaction product.

DNA Amplification Using Procaryotic Systems

The possibility of replicating specific strings of DNA to obtain quantities sufficient for analysis and further manipulation is central to all recombinant DNA technologies. In the early 1970s, work by Boyer and by Cohen provided the first fundamental tools for DNA cloning with the discovery of DNA ligases and the characterization of bacterial plasmids.

Plasmids are circular molecules of DNA that replicate in the cytoplasm of bacterial cells (*Fig. 14-3*). Specific regions of plasmids not vital for vegetative growth under laboratory conditions can be engineered using restriction nucleases for insertion of exogenous DNA fragments. When inserted into *E. Coli* cells, plasmid genes encoding for antibiotic resistance are expressed, allowing selection of bacteria that have been transformed. During this process, the inserted DNA is replicated along with the rest of the bacterial genome. This technology enables amplification and characterization of virtually any DNA string of appropriate size.

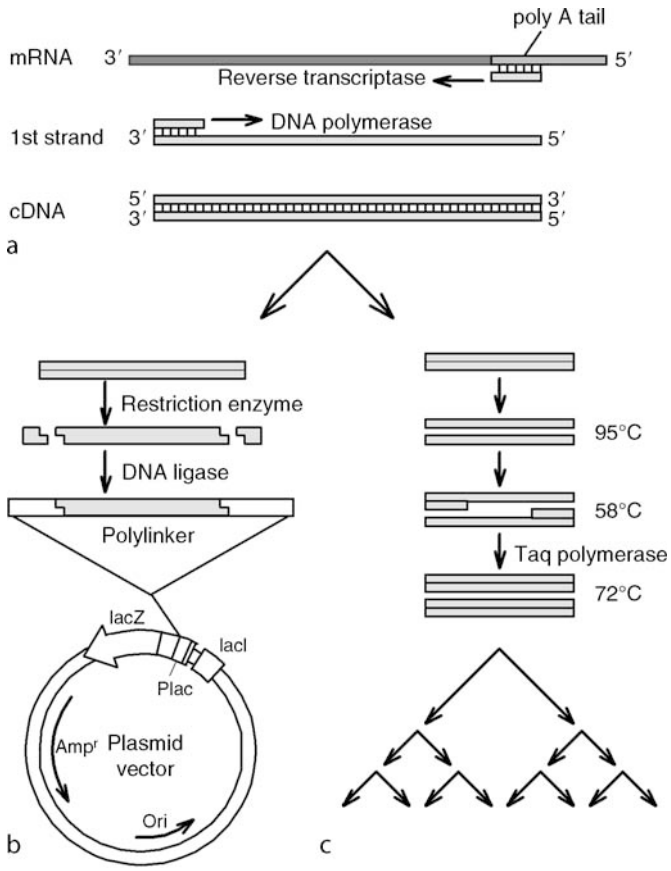
Because bacteria has a mean generation time of approximately 20 min during exponential growth and contains up to several hundreds copies of plasmids per bacterium, virtually limitless amounts of DNA can be grown and harvested routinely. Most available plasmids are engineered to incorporate a polylinker corresponding to a portion of DNA that contains multiple restriction sites that facilitate cloning of DNA fragments generated by various restriction enzymes.

Because of their simplicity, DNA is generally cloned into plasmids. The relatively low efficiency of bacteria transformation with plasmids limits their use however, when generating DNA libraries. In this case, bacterial viruses such as the *bacteriophage* λ, are more advantageously used.

The λ phages are composed of a head that contains the viral genome and a tail that infects bacterial cells with high efficiency. Phages can be packaged *in vitro* after insertion of exogenous DNA and are replicated in

Figure 14-3

Basic enzymes and techniques in recombinant DNA technology. The figure summarizes basic procedures used in routine laboratory experiments. a. mRNA molecules are reverse-trascribed into cDNA using enzyme reverse transcriptase in order to synthesize the 1st complementary DNA strand, which is then used to generate double-stranded complementary DNA (cDNA) using a DNA polymerase. Both enzymes require prior priming with complementary oligonucleotides. b. cDNA and other DNA molecules can be amplified in bacteria after insertion into plasmids using restriction enzymes and DNA ligase. Recombinant plasmids generally contain a polylinker that offers different restriction sites to facilitate insertion of exogenous DNA. In addition, they are engineered to contain antibiotic resistance genes (Ampr) for selection of transformed bacteria and often contain other useful genes like the lacZ in this example, which allows color detection of colonies transformed with "empty" plasmids. c. Alternatively DNA can be amplified by PCR with the Taq polymerase. Repeated cycles of DNA denaturation (95°C), primer annealing (58°C in this example), and DNA synthesis (72°C) allow for exponential replication of DNA strands encompassed by the two primers. When reverse-transcription and PCR are combined, the procedure is referred to as RT-PCR.



bacteria. Both λ phages and plasmids can amplify DNA fragments up to 20 kb. They are ideal for cDNA (see below) and other relatively small DNA molecules, but are insufficient for large strings of genomic DNA. In these cases, other vectors can be used. These include cosmid vectors, containing elements of both plasmids and λ phages that can accommodate up to 45-kb fragments or bacteriophage P1 housing up to 100 kb of exogenous DNA. If larger fragments need to be replicated, plasmid vectors based on the *E.Coli* F vector can incorporate up to 300 or 1,000 kb of DNA. The bacterial artificial chromosome (BAC) is a derivative of the F plasmid and is present in very few copies per *E.Coli* cell. Currently, BACs are the preferred vectors for genomic DNA libraries (1, 2). Yeast artificial chromosomes (YAC) can also be used for the same purpose.

DNA Amplification with Polymerase Chain Reaction

The second breakthrough in DNA amplification was achieved in 1985 by Mullis and coworkers who developed PCR (25).

PCR permits selective amplification of minute quantities of DNA, facilitating every aspect of molecular biology research and diagnostics including site-directed mutagenesis, labeling, and sequencing of DNA. Fixed tissues on slides or small tissue fragments, such as renal biopsy specimens, can also provide sufficient material for PCR amplification.

PCR reaction has nowadays replaced Southern and Northern blotting in most recombinant DNA applications.

PCR relies on the binding of two chemically engineered priming oligonucleotides (primers) that flank a region of DNA, to amplify the region located in between (*Fig. 14-3*). Primers are complementary to the opposite DNA strands. Addition of DNA polymerase results in the synthesis of new DNA. Repeated cycles of denaturation, annealing, and DNA synthesis are performed in a chain reaction such that the newly synthesized strands become templates for further DNA synthesis. This process exponentially increases the number of DNA copies containing the sequence of interest. This allows isolation of a given DNA string from the genomic DNA or from a pool of cDNA molecules (see below).

PCR reactions are performed using thermostable DNA polymerase species derived from the thermophilic bacterium Thermus aquaticus (Taq polymerase), which retain activity after being heated to 95°C. A number of modified enzymes that guarantee reliable DNA duplication or amplification of long DNA strings are commercially available.

Since the complete sequencing of the human genome, *in silico* PCR can now be performed to identify PCR products.

Amplification of mRNA with Reverse Transcription

In several experimental circumstances direct amplification of mRNAs is required.

mRNA transcripts reflect the actual genes that are activated in a cell system and contain nucleotide sequences which can be directly translated into proteins, obviating the tedious task of sorting exon segments from introns when working with genomic DNA.

This process is achieved with a reverse transcriptase derived from retroviruses, which is one major exception to the central dogma, as it harbors their genetic information in RNA molecules that are copied into DNA on infection of host cells.

The DNA obtained by reverse-transcription is called cDNA; it reflects the nucleotide sequences of mRNAs (*Fig. 14-3*). Similar to DNA polymerases, reverse transcriptase requires complementary oligonucleotide priming to begin transcription. Oligo-dT hybridizing to poly-A tails or random primers can be used to reverse-transcribe mRNA molecules (3, 9) in a non-selective manner.

Once converted into cDNA, nucleic acids can be ligated into vectors or directly amplified by the PCR reaction, a process that is referred as reverse transcription polymerase chain reaction (RT-PCR) (*Fig. 14-3*). In other circumstances, gene-specific primers are designed to amplify selected mRNA molecules.

As investigators are progressively turning their attention from genomic analysis to the analysis of gene expression, this process has become extremely important. It permits the generation of collections of "Expressed Sequence Tags" (ESTs), which provide extremely rapid tools to identify genes, evaluate their expression, and construct genome maps. ESTs are small DNA sequences that are generated by RT-PCR reactions and which when pooled together, represent a collection of DNA sequences that are expressed in a given cell or tissue. These "tags" can be used to identify specific portions of the genome that encode for a given gene, "fish-out" similar genes, or identify splicing variants of a given mRNA, using online collections of ESTs.

Sequencing Nucleic Acids

The highly specific binding of small oligonucleotides to DNA also lies at the heart of the dideoxy chain termination sequencing of DNA.

DNA sequences are obtained from a uniform population of DNA, obtained by PCR.

After DNA is denatured, complementary primers are added. In the traditional manual sequencing, synthesis of complementary radioactive DNA strands was initiated by DNA polymerase after addition of ^{35}S-labelled radioactive deoxy-nucleotides in four different reactions containing one of the four dideoxy-nucleotide analogs of G, A, T, or C. In each reaction, chain termination occurs if a dideoxy analog is inserted in the newly formed DNA strand, preventing further extension.

Modern automated sequencing machines apply these basic principles using fluorescence labeled deoxynucleotides. The reaction products are resolved on sequencing gels or electrophoresis capillary. As DNA advance along the electric gradient, a laser beam is used to excite their fluorescence, which is read and analyzed by a computer. Reliable DNA sequences can generally be obtained for more than 500 nucleotides per run, and multiple lanes can be read simultaneously.

Analysis of Gene Expression

A critical issue in normal physiology and renal pathophysiology is the determination of the expression of given genes under different cellular and environmental conditions.

Classically, gene expression analysis is performed by protein detection with specific antibodies in Western blotting or, when antibodies are not available, by measuring the amount of mRNA transcripts. Densitometric methods have been developed to compare the amount of expressed protein or mRNA, with respect to a control preparation. These semi-quantitative techniques however, have severe limitations. They require relatively large amounts of starting material, can only study a limited numbers of genes simultaneously, and require development of specific probes such as antisera. To overcome some of these limitations, other techniques have been developed and are briefly reviewed.

Real-Time RT-PCR

Unquestionably, RT-PCR is more sensitive than the traditional Northern blot analysis to measure levels of mRNA expression, and can be performed from limited amounts of mRNA.

The major difficulty in quantifying mRNA by RT-PCR however, is related to the exponential nature of the method, which tends to amplify differences when comparing levels of expression in different biological conditions or biological systems.

For this reason, competitive RT-PCR was initially developed and was based on the use of internal standards sharing the same priming sequences as the transcript of interest, which were added to the mixture to act as competitors during the reaction (26). This method was however time consuming and has now been replaced by real-time PCR and micro-array analysis when quantitative expression of multiple genes needs to be evaluated.

Real-time RT-PCR allows detection of PCR products as they are being formed (*Fig. 14-4*), using quenched fluorescent dyes linked to the 5′ end of one primer that are released by the 5′ nuclease activity of the Taq DNA polymerase. The emitted light is measured in real time during PCR reaction and is proportional to the amount of PCR product. The number of cycles required to cross a given fluorescence threshold is inversely proportional to the amount of mRNA present in the original reaction mixture. Multiplex real-time RT-PCR represents an extension of this technique and is based on differential fluorescent labeling of primers that amplify for different genes. This permits comparison within the same PCR reaction of the relative amount of up to 3–4 different transcripts (27). Generally, a house-keeping gene that is presumed to be stably expressed, serves as an internal control, allowing correction of the results for the amount of RNA that was loaded in the initial sample reaction.

Multiplex real-time RT-PCR allows determination of gene expression even from extremely small samples such as renal biopsies - and has been developed for example, to detect gene expression in human renal specimens (28) or quantify viral genome copies in biological samples.

Differential mRNA Display Using DNA Microarrays

DNA microarray technology has become a valuable technique for comparative gene expression analysis. Transcriptomic DNA chips are composed of thousands of known expressed sequence tags or synthetic oligonucleotides, which are deposited in gridded arrays by a robotic spotting device on a solid support such as a glass microscope slide or a membrane matrix (29).

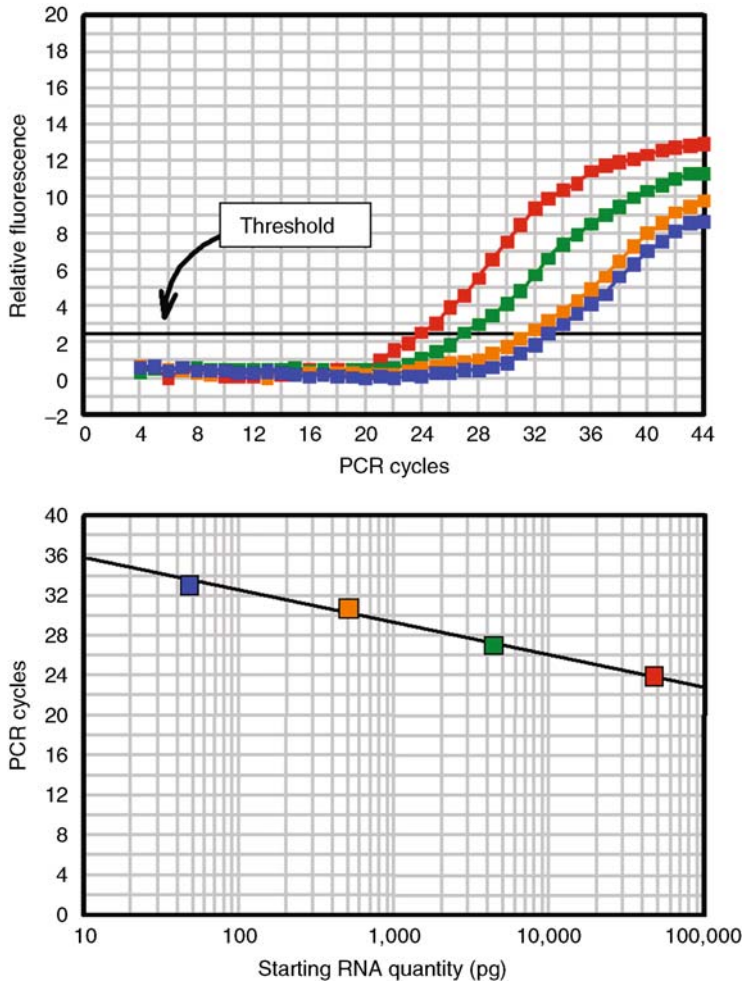
Oligonucleotide sequences are selected from databases such as GenBank, dbEST, or UniGene (30). Several thousand genes can be spotted on a single microscope slide for large screening. Other chips contain clusters of genes that are functionally related, as in oxidation chips or cell-cycle chips, for example. Two populations of mRNA are labeled with different fluorophores, hybridized to the same chip, and analyzed with a laser scanning device (*Fig. 14-5a*).

The intensity of the fluorescence emitted by each dye is proportional to the amount of RNA that has hybridized at a given location, reflecting the level of a gene expression represented by that spot.

Despite increasing developments, this technique has limitations, particularly in terms of chip reproducibility and variability in the efficiency of labeling and hybridization, which generally need to verify the obtained results by standard RT-PCR or real-time RT-PCR.

Figure 14-4

Real-time PCR. Figure illustrates an actin calibration curve. Total RNA was extracted from HK2 cells and loaded in increasing concentrations in the sample reaction. Fluorescence was measured in real-time as primers were incorporated in newly synthesized PCR fragments with an ABI Prism 7,700. The number of cycles required to cross a given fluorescence threshold shown in the upper panel is proportional to the initial amount of loaded mRNA as shown in the lower panel.



The enormous quantity of information generated by expression data from thousands of genes requires sophisticated computer analysis to generate meaningful results (31). Computer-based algorithms have been developed to recognize patterns of gene expression within complex genetic networks such as the human genome. The so-called cluster analysis is a powerful statistical tool, permitting grouping of genes in hierarchical clusters that follow similar patterns of expression (*Fig. 14-5b*). This information can then be used as a molecular fingerprint for diagnosis or monitoring response to therapy. It may allow detection of subtle changes of gene expression and may identify functions and interactions of uncharacterized proteins, by grouping them into clusters of genes whose function is known.

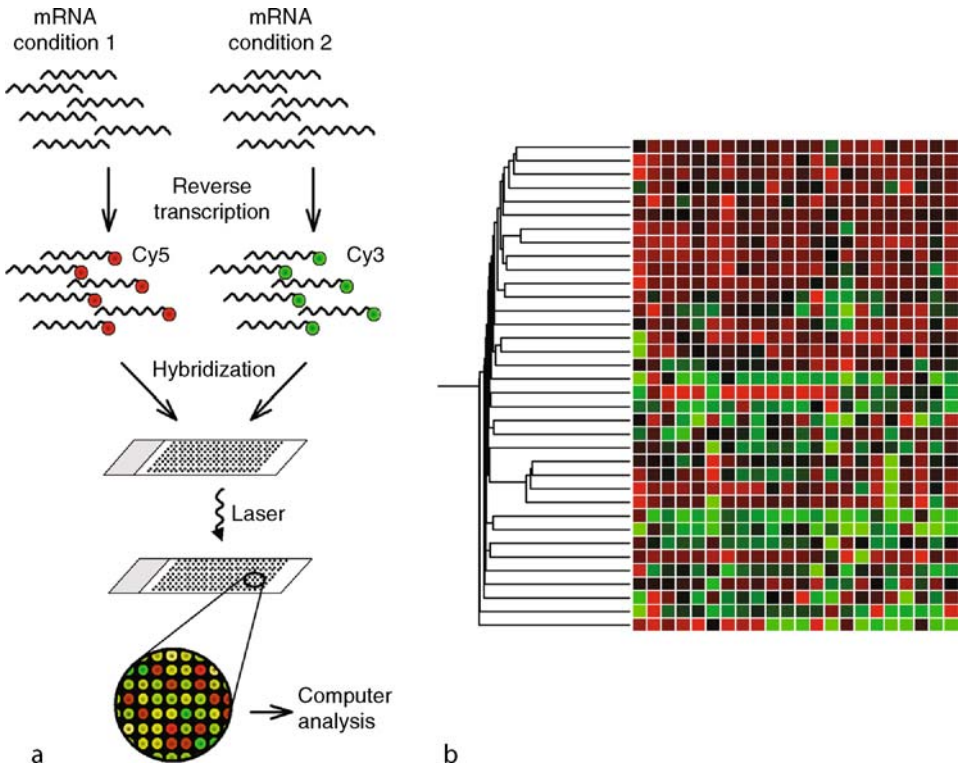
Microarray Technologies for Genomic Analysis

Similar approaches to the transcriptomic chips have also been developed for the analysis of genomic sequences.

In "comparative genomic hybridization" (CGH) for example, genomic gain or loss of particular genes can be detected, permitting identification of small deletions or duplications throughout the genome.

Figure 14-5

Differential display on DNA microarrays. (a) mRNA obtained from two different samples are labeled with two fluorescent cyanine dyes with one round of reverse-transcription. The fluorescent targets are then pooled and hybridized under stringent conditions to the clones on the microarray chip. The emission light is measured with a scanning confocal laser microscope at two different wavelengths that are specific for each dye. Monochrome images are then pseudo-colored, combined, and analyzed with a suitable computer software. (b) Cluster analysis of results obtained in a microarray experiment. Rows represent individual genes whereas columns indicate different experiments. Genes that are the most up-regulated are colored in red, while down-regulated genes are indicated in green. By analyzing patterns of gene expression, genes that behave similarly are grouped together in hierarchical order, to identify patterns of gene expression.



Microarray chips have also been developed to detect gene mutations. In this case, the target is limited to few genes. Sequential small fragments of the genes of interest are arrayed onto the chip, which detects even single nucleotide changes, when hybridized with amplified DNA obtained from patients carrying the mutation.

Likewise, microarrays can also be used to screen for single nucleotide polymorphisms (SNPs). Chips containing over 1.6 SNP markers have now been developed allowing whole-genome genotyping to search for associations of particular SNPs with given clinical conditions. Using this approach for example, genes that are involved in the pathogenesis of Systemic Lupus Erythematosus have been identified (32), and whole genome association studies can be done with large populations.

Gene Cloning and Analysis of Cloned Sequences

Until recently, one of the primary goals in molecular research was to clone genes responsible for diseases. This task has been largely accomplished for monogenic diseases, although several genes, mostly encoding for proteins involved in rare diseases, still need to be identified. Other diseases have a polygenic base of inheritance and a vast majority of these that regulate complex patterns of inheritances still need to be identified.

Cloning of genes responsible for genetic disorders can be achieved without prior knowledge of the molecular nature of the disease by a strategy termed positional cloning, which is based on the genomic localization of

the locus of interest using genetic markers present at a known chromosomal location.

Alternatively, gene cloning has been performed by screening tissue-specific collections of recombinant vectors containing sequences of cDNA, termed cDNA libraries. This basic approach can be refined by the use of subtractive libraries for example, that are obtained by subtracting unwanted mRNA species from the library before screening.

Currently, the process of cloning genes has been completely revolutionized by the creation of electronic databases. More than 100,000 partial ESTs sequences that cover most human genes have been collected (33), and thousand of putative genes that were generated by digitally sorting out and mending together potential exon regions of the human genome have been obtained.

These sequences are collected in databases that can be accessed online, which constitute virtual DNA libraries to be screened electronically using partial DNA or protein sequences. Tags sequences can be obtained from differentially expressed proteins or DNA molecules (identified by microarray analysis for example) or from sequences of related genes. Once a putative gene has been identified, its sequence can be directly amplified from mRNA or from genomic DNA, by RT-PCR or PCR, respectively. As already mentioned, ESTs databases also represent invaluable tools for "serial analysis of gene expression" (SAGE), which is considerably increasing our knowledge of the human transcriptome (33).

Other techniques that are used to identify genes include library screening with antibodies, functional assays, or by protein-protein interaction. Using expression plasmids, peptides encoded by exogenous cDNAs can be directly translated in the bacterial lawn and identified with specific antisera (34). With a similar approach, phage epitope libraries expressing randomly generated oligopeptides can be screened to find domains recognized by antibodies or by other proteins (35). The recognized epitope sequence generally corresponds to a partial amino acid sequence contained in the natural antigen or binding protein. From this sequence, the protein can be identified or cloned. This technique is particularly powerful for identifying autoantibodies or for cloning proteins by their reciprocal interactions such as in receptor-ligand association.

The two-hybrid system is an alternative strategy which permits investigators to fish for clones which code for peptide that interact with other proteins offered as bait in the screening process (1, 2).

The strategy of expression-cloning relies on screening cDNAs that produce functionally active proteins when expressed in a suitable system, such as Xenopus oocytes. Assays using oocytes are usually used to identify and study by electrode impalements, patch clamping, and flux techniques proteins involved in membrane transport. Large quantities of RNA (cRNA) can be synthesized *in vitro* and injected into oocytes (36).

Online programs provide important clues regarding the nature of newly cloned cDNAs and proteins, such as structural aspects, including membrane-spanning domains or antigenicity, presence of specialized amino acid sequences coding for functional domains such as phosphorylation, glycosylation, or targeting domains to specific cell compartments (www.ncbi.nlm.nih.gov/IEB/Research/Assembly/). Sequence alignment in databases helps define relationships with other genes and identify functional motifs, such as DNA-binding and protein-binding domains, that can give important clues to the biologic function of the newly cloned sequence (37). In addition, important information is also contained in the promotor region that can be identified and screened for consensus sequences that help defy the physiological role of the protein in the cell.

Gene Expression and Silencing in Cell Cultures (see also Chapter on In Vitro Metods in Renal Research by Dr. Wilson in this text, Chapter 15)

One important aspect of recombinant DNA technology is the demonstration of the biological role of a selected gene. The easiest and often first approach, is to express or suppress a given gene in cells that are cultured *in vitro*.

Cells can be obtained from tissues after disruption of the extracellular matrix with enzymes, such as trypsin or collagenase. Cells of the same type need thereafter to be purified using different techniques that are based on cell size, resistance to specific conditions, or expression of specific markers. In the latter case, cells are often isolated by fluorescence activated cell sorting (FACS) or with beads that bind to specific antigens. In highly organized tissues, such as the kidney, laser captured microdissection can help isolate fragment of tissues containing only few cell types, which greatly facilitates the following purification steps. These "primary cell cultures" are extremely powerful biological models, because they often retain much of their original phenotype. Unfortunately, they often grow slowly, their preparation is expensive and time consuming, and they tend to stop growing after few passages due to a process termed "replicative cell senecesce". This process is in part caused by the lack of telomerase, which prevents shortening of telomeres at each cell division. Introducing the catabolic sub-unit of the telomerase gene allows in some cases to obtain "immortalized cell lines". In most cases however,

mammalian cells stop dividing as they activate cell-cycle "check-point mechanisms". In order to inactivate these mechanisms, viral pro-oncogene genes are usually inserted to generate "transformed cell lines". These cells proliferate indefinitely, but unfortunately tend to loose their phenotype. To partially circumvent this phenomenon, strategies aimed at turning-off the pro-oncogene can be used. The thermo-sensitive Simian Vacuolating virus 40 T antigen (SV40 Tag) for example, promotes undifferentiated cell proliferation at 33°C, but is turned-off at higher temperatures. Conditionally immortalized cell lines can therefore be grown to confluence at 33°C, but will stop proliferating at 37°C and will, in most cases, recover part of their original phenotype (38).

To study the effects of a given gene, cell cultures and cell lines can be directly obtained from specimens of patients lacking a given gene. Alternatively, genes can be over-expressed or suppressed in cell cultures. Genes are usually inserted into expression vectors under the control of a potent viral promoter, like the CMV promotor. Cells are thereafter "transfected" with these vectors. Transient transfection allows for gene expression for a few days. Stably transfected cell lines can also be obtained by transfecting cells with a linearized vector that will insert itself randomly into the cell genome in few cells. As most of these vectors contain an antibiotic resistance gene, stably transfected cells can be selected and purified.

Vectors harboring mutated genes can also be engineered by site-directed mutagenesis techniques, which allow selective mutatation, deletion or insertion of peptide residues of a given protein. Once expressed, these mutated peptides produce information on the function of various domains of a single protein (39).

Specific cDNAs sequences can also be fused to sequences encoding for fluorescent proteins (GFPs). Once, these vectors are transfected into cells, it will prompt the synthesis of a fusion protein which is composed of the protein of interest and a GFP tag, which helps to follow the protein expression in the cell by fluorescence microscopy.

Similarly, gene regulatory regions such as promoters can be transfected. Their effects on a neighboring reporter gene can then be determined using a gene product that is easily assayed, such as chloramphenicol acetyltransferase or a luciferase.

In some cases, non mammalian cells are more advantageously used. *Xenopus* oocytes are popular systems to express membrane transport proteins. The cystic fibrosis gene was among the first gene to be isolated without knowledge of its actual function. Oocytes were used to demonstrate its function as an epithelial cell chloride channel (40). Other fundamental membrane transport proteins have similarly been cloned using Xenopus oocytes, including Na-H exchangers (41), bumetanide-sensitive Na-K-2Cl and thiazide-sensitive NaCl cotransporters (42), the renal outer medullary adenosine triphosphate–regulated potassium channel (43), multiple aquaphorin water channels (44), and the amiloride-inhibitable epithelial Na + channel, or ENaC (45).

These studies have provided molecular links between epithelial cell transport data and the expression of specific genes within individual kidney epithelial cells.

Detailed knowledge of these transporter proteins has also enabled the identification of specific gene abnormalities in humans that cause inherited disorders of renal tubular function including nephrogenic diabetes insipidus (46) and Bartter's (47, 48), Gitelman's (49), and Liddle's (50) syndromes.

Although gene suppression in animal model is probably the most powerful approach to study the function of a given gene, another approach is to inactivate its mRNA. This is achieved by a technique called RNA interference (RNAi, siRNA), in which double stranded RNA molecules matching the sequence of interest are introduced into cells, where they hybridize with their complementary mRNA, causing its degradation. Fragments of degraded RNA form other double-stranded RNA, which continues to eliminate more targeted mRNA. In addition, some RNA molecules enter the nucleus where they inhibit directly gene transcription by interaction with the targeted genomic sequence (51).

The range of applications of recombinant DNA technologies to protein expression expands well beyond the above mentioned techniques. Bacteria for example, can also be "transformed" with recombinant plasmids containing bacterial promoters that activate transcription of genes fused to specific detection sequences. These fusion proteins can then be purified in large quantities and used for functional studies or as immunogens to raise antisera. As mammalian proteins expressed in bacteria are not post-translationally modified, viral expression systems have been developed, allowing the production of recombinant proteins by viral infection of cultured insect cells (52). These proteins are then properly processed, glycosylated, and phosphorylated. A similar approach can be used in yeast. In fact, yeast cells have in fact become particularly interesting for the study of the cellular effect of given proteins. The 6,000 yeast genes have been fully sequenced, are particularly easy to mutate, and large collections of well characterized mutant strains are available. This is enabling researchers to perform functional genomics and proteomics studies in a simple organism and has

enabled dissection of genomic control mechanisms as well as identification of several proteins that regulate a variety of cell functions, including endocytosis and membrane fusion (53).

Expression and Suppression of Specific Genes in Animal Models

In vitro cell expression systems are very powerful tools, but have limitations when studying the role of genes in multicellular organisms in which a gene's expression or lack thereof has complex effects on an animal's development and physiology. In these cases, genetically engineered animals which are modified in genes that are homologous to their human counterparts, are used advantageously. Whenever the animal phenotype is similar to the human disease, it always represents an extremely powerful tool to understand the disease and test new treatments.

Likewise, scientists have studied genes which are responsible for different animal phenotypes or have been genetically manipulated to modify activity of given genes, for which the human homologue has not been associated with specific diseases. Most of these experiments have been performed in mice, but also in other organisms such as *S. Cervisiae, C. Elegans, Arabidopsis,* and *Drosophila*. This has led to the constitution of a collection of animal mutations that represent invaluable repertoire of candidate genes for human diseases which can be tested based on clinical phenotypes. This approach is referred as "reverse genetics", because instead of identifying a given gene using biological material obtained from patients, scientists begin their search from experimental gene mutation data, to identify by phenotypic homology human diseases.

While engineering animal models of a given disease, different strategies are used depending on the effects of the human mutations ("loss of function" or "gain of function") and the mode of inheritance (recessive, addictive or dominant).

In most cases the removal of a given gene, termed "knock out", is the first approach to reveal the function of its encoded protein. Other strategies are aimed at changing the levels of expressions of a given gene or changing its expression in specific tissues or in time. This latter approach, which is generally based on the use of inducible promoters, is particularly interesting when analyzing genes that are implicated during development or when the mutation is lethal in animals. In this case, the gene of interest can be "turned-off" only after birth, when the animal is fully developed. In some cases, researchers have adopted a dominant-negative strategy, when over-expression of a mutant protein can inhibit by competition, the activity of its wild-type homologue, which continues to be normally synthesized. In general, gene replacement or addition is more complicated and time-consuming than gene knock-out. Regardless of the strategy that is used, all these genetically modified animals are termed "transgenic" and their artificially modified genes are referred as "transgenes".

Introduction and disruption of specific genes into amphibians and insects such as *Xenopus* and *Drosophila* are particularly useful in the analysis of developmental genes and have been used extensively to characterize various developmentally specific transcripts governing tissue-specific differentiation, including in the kidney (1, 2). This research is greatly facilitated by the ability to manipulate easily, cells of the earliest embryo stages and have produced a fundamental understanding of pattern formation in these animals.

For most human diseases, mice have become the animals of choice, because their genes can now be easily manipulated, their genome has been fully sequenced, a full range of techniques have been developed to analyze their phenotype and they can be rapidly bred to produce heterozygous and homozygous mutants or compound transgenic animals, in which more than one gene has been modified (54–56).

In some cases, production of transgenic animals may be performed by injection of the transgene directly into the pronucleus of a one-cell stage embryo so that it can integrate into the genome. In mice, a vector carrying the transgene is introduced in embryonic stem cells (ES) which are allowed to proliferate *in vitro.* The rare cells where homologous recombination with the original gene has occurred are then selected, and injected with a micropipette into the embryo at its early stage. This leads to the formation of a chimeric animal that will carry the mutation in a significant percentage of its germ lines. Mice are then bred to produce heterozygous male and female off-springs, which, once mated together, will produce homozygous animals. Both heterozygous and homozygous animals can then be studied.

Conditional mutants allow for the disruption of genes in specific tissues at given times.

To express a specific protein in podocytes, for example, the nephrin promotor can be used, in order to activate the transcription of a given gene only in cells that can activate this promotor (56). Using this strategy for example, researchers have over-expressed the macrophage migration inhibitory factor (MIF) gene in podocytes, demonstrating the development of mesangial sclerosis in the presence of high levels of MIF (57).

To knock-out genes at a given time, site-specific recombinant systems are used, like the Cre/Lox system. For this purpose, a fully functional gene or a portion of this gene is flanked by small sequences of DNA corresponding to the "lox" sites, which are recognized by the Cre recombinase protein. Transgenic animals are then mated with mice expressing the Cre recombinase under the control of an inducible promotor that excise the gene of interest, when activated (56).

Protein and Peptide Analysis

Principles and Techniques

The principle of protein analysis has considerably evolved over the past years in parallel with key technological advancements, especially in the field of mass spectrometry.

The basic principle in proteomic analyses is that the digestion products of a given peptide create a fingerprint of the original protein, which permits its identification.

In most cases, identification of a protein requires a preparative step, to obtain a purified sample. Two-dimensional (2D) electrophoresis is frequently used for this purpose, while LC-Mass and MALDI-TOF are commonly used for the analysis of digestion products.

Denaturing and Non Denaturing 2D-Electrophoresis

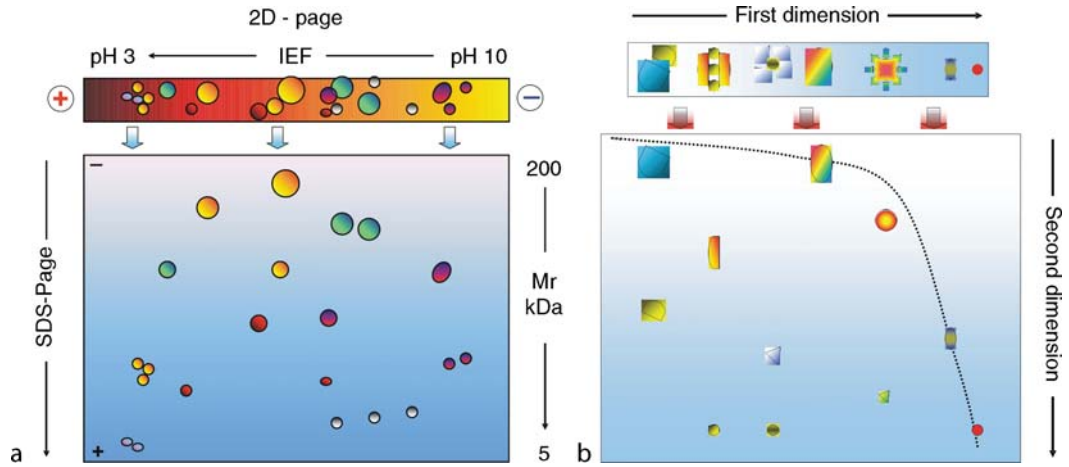
Classic 2D protein electrophoresis is the technique of choice for the analysis of plasma proteins or other complex biological samples. High-resolution is usually achieved by combining separation by charge and separation by size in denaturing conditions (IEF/PAGE) (*Fig. 14-6*) (58, 59). This can then be followed by micro-scale mass spectrometry that allows identification of individual spots. The development of soft gels has considerably improved the resolution of high molecular weight proteins, but requires denaturing conditions, which prevents the analysis of protein-protein interactions (*Fig. 14-6b*) (60). For this reason, new techniques that separate protein mixtures in low denaturing conditions have recently been developed. These include Blue-PAGE, which is performed on membranes, or the Nat/SDS PAGE, which is performed on a polyacrylamide substrate (61–63). This latter system helps to resolve protein aggregates and disclose protein interactions (*Fig. 14-6b*).

Protein Staining

Traditionally protein staining after electrophoresis has been performed with Coomassie R-250 and silver ions. New dyes allow differential protein expression analysis on

Figure 14-6

Schematic representation of a classical 2D-polyacrylamide gel electrophoreis (2D-PAGE) (a) and of a 2D electrophoresis in non- denaturing condition (Nat/SDS-PAGE) (b). In the former approach, proteins are first separated according to their charge in the presence of urea (IEF) and are then run in a polyacrylamide gradient that separates them on the basis of size. In Nat/SDS-PAGE protein complexes migrate unresolved in the first dimension and are then separated in denaturing conditions, in the second dimension.



2D-gels (DIGE). This technique is based on modification of selected aminoacid residues and has become a standard application of quantitative proteomics. Peptides are labeled with matched sets of fluorescent N-hydroxysuccinimidyl ester cyanines (NHS) that have different excitation-emission wave-lengths (64, 65). Use of thiol-based reagents (maleimide, iodoacetamide) increases specificity and reproducibility. Protein mixtures are label separately with different NHS dyes, combined and resolved on a single 2D gel that is analyzed with different fluorescence excitation wavelengths (66). The differential expression of individual proteins is by this means analyzed and quantified.

Mass Spectrometry

Proteins are generally characterized by mass spectrometry. As ionized molecules are accelerated through an electric field, they are separated, reaching the detector at different times, depending on their mass and charge. This "time-of-flight" (TOF) is specific to a given solute, allowing its identification. Whole proteins need to be first ionized by electrospray ionization (ESI) or matrix-assisted laser desorption/ionization (MALDI). The commonly used "MALDI-TOF" procedure indicates that the MALDI sample preparation is followed by TOF mass analysis, while in the Surface Enhanced Laser Desorption and Ionization (SELDI) procedure, proteins are immobilized on solid supports or customized protein chips.

In the so-called "top-down" strategy, intact proteins are ionized and resolved in the mass analyzer. Alternatively, proteins are pre-digested into smaller peptides before mass analysis; a procedure referred to as "bottom-up". In the latter case, the source protein is identified by its pattern of digestion that creates a "peptide mass fingerprinting" (PMF), or by "*de novo* sequencing", tracking back the protein sequence from the mass sequence data using protein databases. Often, both 'top-down" and ''bottom-up" strategies need to be used to optimize protein identification.

Research Applications

Protein-Protein Interaction

One important question in protein analysis is to identify interactions between proteins, as these are at the core of most intracellular signaling pathways and are critical to the assembly of functional peptides.

Recent developments of the Nat/SDS-PAGE technique permit identification of protein-protein interactions in biological fluids (63). If proteins are extracted from cells or tissues, strategies based on binding to targets linked to solid supports are more advantageously used. These approaches can be further refined using recombinant DNA techniques, in order to construct target protein fragments enabling identification of domains that mediate protein-protein interactions.

Alternatively, the yeast two-hybrid system is based on the modular structure of gene activation and may be used for the same purpose. In general, the GAL4 transcriptional activator is exploited. This transcription factor has a DNA-binding domain and an activation domain, both of which must be in close association to activate transcription. By DNA recombinant techniques, two protein sequences acting as bait and target are fused with sequences encoding with one of the GAL4 domains. When expressed in yeast cells, the activation domain and the DNA-binding domain are bridged together when the two proteins interact and promote transcription of a reporter gene. This system helps to study interactions between known molecules and to clone new proteins using cDNAs libraries.

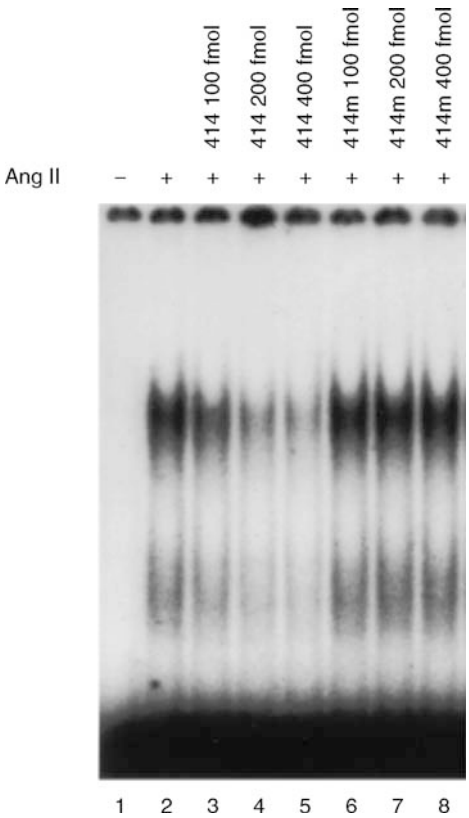
Similar prokaryotic systems have been developed based on the modular structure of bacterial RNA polymerases, in which target and bait cDNAs are fused to either the core enzyme or a Φ factor.

Protein-DNA Interaction

Techniques that analyze the regulation of DNA expression by transcriptional factors have helped to identify consensus DNA binding regions and their regulatory proteins. Most of these studies are based on the principle that protein-DNA complexes have high molecular weights and are therefore retarded when resolved by polyacrylamide gel electrophoresis. In addition, proteins interacting with DNA molecules tend to protect the nucleic acid regions to which they bind, from digestion with DNAse, which allows its identification (67). In *Fig. 14-1* for example, a nuclear extract of proteins obtained from cells stimulated with angiotensin II was co-incubated with strings of DNA that encode for the promoter of type III collagen. As shown, angiotensin II stimulation promotes synthesis of a protein that binds to the ^{32}P-labeled DNA target, forming macromolecular complexes that are retarded in the gel.

Figure 14-7

Gel retardation assay. Figure demonstrates binding of regulatory nuclear proteins to cis-elements in the COL3A1 promoter after angiotensin II (Ang II) stimulation. Nuclear extracts were obtained from Ang II stimulated cells (Ang II+) and incubated with a 32P-labelled oligonucleotide (414) that contains sequences +3 to +20 of the COL3A1 promoter. Ang II stimulates synthesis of a peptide that binds to the target DNA and retards its migration in the gel (lanes 2). This reaction can be competed with increasing amounts of non-labeled wild-type oligonucleotide (lanes 3–5) but not with a cold mutated analogue sequence (414m) (lanes 6–8). In the absence of Ang II stimulation (AngII −) no DNA-protein complex generating gel retardation is observed (lane 1).



The Building of the Podocyte Protein Map

Unquestionably, the completion of the human genome sequencing has expanded considerably our possibilities to understand and study cell molecular processes. Though over 30,000 genes are encoded in the human DNA however, only a portion is expressed in a give cell. Cell- and tissue-specific cDNA libraries have partially overcome this limitation but do not completely reflect the cell protein repertoire and the levels of expression of individual peptides. Recent advances in protein analysis have now helped to build protein maps. A podocyte protein inventory for example, will allow the study in depth of the signaling pathways regulating cell function in these highly specialized cells, which play a key role in many renal diseases. Definition of the podocyte protein map is in progress and should allow, when completed, to study changes observed under pathological conditions (*Fig. 14-8a*). Currently, podocyte cell lines are being used. Future studies may directly use podocyte expanded from kidney biopsies or from urines of patients with glomerular diseases.

Clinical Applications

Proteomic Analysis of Biological Fluids

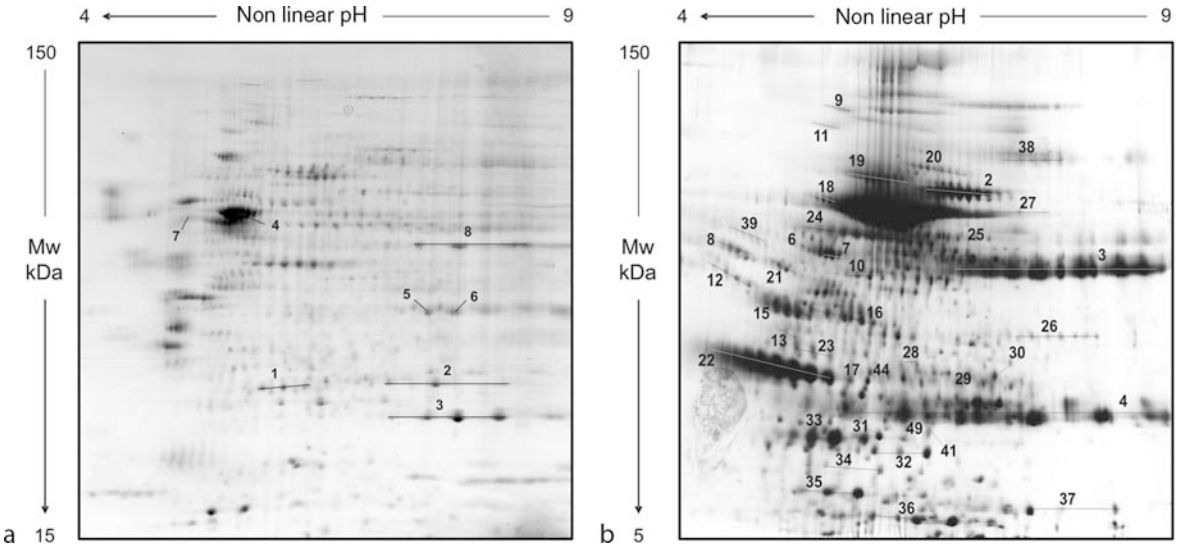
The plasma compartment contains important diagnostic markers and causative molecules of renal diseases. The expression of most plasma proteins cannot be assayed by recombinant DNA technologies, as these are generally not synthesized by circulating cells. Proteomic represents therefore a major tool to study plasma composition. In nephrotic syndrome for example, proteomic has been used to identify glomerular permeability factors and to characterize oxidized protein products. By Nat/SDS PAGE analysis, albumin and other proteins, such as the α1-antitrypsine, have been shown to undergo post-translational modifications that include fragmentation, polymerization, and formation of adducts in nephrotic states (63, 68). Role of these transformed peptide products in the pathophysiology of proteinuria is currently under study.

Likewise, proteomics can also be applied to urine samples (*Fig. 14-8b*). Until recently, urinary proteins were primarily characterized by classic single dimension electrophoresis. Alternatively, the excretion of individual proteins such as albumin, IgG or β2-microglobulin for example, were measured and used as markers for glomerular selectivity or low molecular weight proteinuria.

As the urine proteomic map is nearly completed, researchers are now attempting to use proteomic analysis to create a collection of urinary fingerprints that would allow diagnosis of more specifically renal diseases. Until now, studies in humans have been disappointing and have shown that even distantly related renal diseases can share very similar patterns of proteinuria. The current level of accuracy of urinary biomarkers reliably differentiate

Figure 14-8

Two-dimensional electrophoresis analysis showing a partial normal podocyte proteomic map (a) and a urine proteomic map (b) Identified proteins in Panel A correspond to (1) ubiquitin carboxy terminal; (2) Triosophosphato Isomerase; (3) superoxide dismutase; (4) HSP 60; (5) Glyceraldeyde 3P dehydrogenase; (6) aldose reductase; (7) secernin, (8) alpha enolase. All numbered proteins in Panel B correspond to known proteins that together represent a fingerprint of urinary protein excretion in normal and pathological conditions.



diseases with glomerular and non glomerular involvement, but is inadequate to distinguish between different types of glomerular lesions and to guide their treatment. Experimentally however, candidate disease markers such as haptoglobin in passive heymann nephritis or clusters of proteins in adriamycin nephropathy have been identified (69, 70).

Of notice, urine proteomic analysis also allows to detect factors such as C1qTNF, complement factor Bb or inter-α−trypsin inhibitor chain 4 (spots 50, 23, 52 in *Fig. 14-8b*), which are not detected in plasma because they are readily eliminated in the urine. These proteins also represent potential markers for renal diseases such as primary nephrotic syndrome, IgA nephropathy, or post-transplant proteinuria (71–73).

Peptidome and Degradome

Plasma and urine also contain very small peptides (<5 Kda). Several methodological hurdles still need to be overcome, before applying these analyses to human diseases. Specifically, results obtained by different techniques, such as SELDI and LC-ESI-MS/MS, are often not concordant and lack reproducibility.

Several, if not most of these small urinary peptides, originate from proteolysis of plasma proteins. It is still unclear if their urinary excretion correlates with significant biological events and represent surrogate biomarkers of diseases. Experimentally, a number of them have been shown to have biological activities and most are derived from digestion of urinary albumin.

Few studies have analyzed potentialities of small urinary peptide maps as fingerprints of diseases.

Recently, Decramer et al. have used capillary elctrophoresis followed by tandem mass analysis to characterize the peptide composition of urines obtained from infants born with hydronephrosis secondary to ureteric pelvis junction (74). They could show quantitative changes of a type V pre-procollagen α2 chain fragment that was predictive of the clinical evolution of hydronephrosis and subsequent need for surgery, with a reasonable sensitivity.

Similarly, by combined tandem mass spectrometry, protein chip immunoassay, and SELDI-TOF, O'Riordan et al. have identified two peptides of 4.7 and 4.4 Kda derived from defensin1 and α1antichymotrypsin respectively, and have shown that their ratio correlates with episodes of acute rejection (75). Likewise, they also identified a 4.1 urine peptide that correlates with clinical response in children with nephrotic syndrome (76).

Obviously, most of these findings need to be confirmed with large scale prospective studies. They represent nonetheless one of the forefronts of proteomic research in human diseases and may provide in the near future, less invasive diagnosis and monitoring tools for several renal conditions.

Metabolomics

Similar to proteomics, recent advances in Nuclear Magnetic Resonance (NMR) and Mass Spectrometry (MS) have helped in the search for patterns of recognition of specific conditions by analyzing non-peptidic products of the metabolism. By analogy to "genomics" and "proteomics", these approaches are now referred to as "metabolomics" and their description is beyond the scope of this chapter. The following few examples however suggest that metabolomics may complement proteomics and may provide in the future, new insights into the diagnosis and understanding of renal diseases. In murine models of cis-platinum tubulopathy for example, specific urinary metabolic spectra have been identify that precede the decline in renal function and normalize after treatment (77). Likewise, combined proteomic and metabolomic analysis have identified fingerprints which distinguish between different genetic forms of Fanconi syndrome (78) and specific metabolic profiles have been identified in patients with different glomerular lesions, which may help their diagnosis and monitoring of treatment (79).

15 *In Vitro* Methods in Renal Research

Patricia D. Wilson

Significant advances in the understanding of normal and disease-associated renal cell function, epithelial cell biology, and morphogenesis have been made in recent years by the application of in vitro techniques. The researcher today is presented with a wide choice of in vitro models, and the aim of this chapter is to provide not only an overview of techniques available but also sufficient information to allow insight into the advantages and limitations of each system. This provides the experimental pediatric nephrologist with an appreciation of the range of renal in vitro methods currently available and allows selection of the most appropriate in vitro system to adequately answer the questions posed. For a more complete methodologic review of isolation and culture techniques, the reader is referred to standard tissue culture texts (1–3).

Renal Cell Types

The kidneys are highly heterogeneous, predominantly epithelial organs containing one million nephrons in each human kidney. Each nephron is comprised of a glomerulus and a highly segmented epithelial tubule with specific functions and markers (*Fig. 15-1*; *Table 15-1*), supplied by a specialized vasculature. Detailed, studies of the properties of glomerular epithelia, endothelia and mesangial cells, and of the >15 different epithelial types in the renal proximal, distal and collecting tubules are needed for the fundamental understanding of the function and development of the normal kidney as well as effects of injury and disease. Substantial progress toward achievement of this goal has been made over the last 2 decades.

Specifically, techniques have been developed in mammalian species (predominantly human, mouse, rat and rabbit) for the isolation and culture of glomerular podocytes and mesangial cells; epithelial cells from proximal convoluted and straight tubules of the S1, S2 and S3 segments; medullary and cortical thick ascending limbs of Henle's loop; distal convoluted tubules, principal and intercalated cell types of the cortical, outer medullary and inner medullary (papillary) collecting tubules; as well as interstitial cortical and medullary fibroblasts and renal vascular smooth muscle cells. Recently, progress has also been made towards isolation and culture of specialized areas of the nephron such as the macula densa and juxtaglomerular apparatus (see *Table 15-2*).

Renal Cell Isolation Techniques

The first step and prerequisite for the establishment of a useful and informative renal cell culture system is the development of a reliable isolation technique for the individual renal cell type of interest. Several techniques have been used successfully, including physical microdissection, size discrimination by graded sieving, centrifugation through Ficoll or Percoll gradients or selection by immunoabsorption on to specific antibody or lectin-coated solid surfaces, beads or nanospheres (4, 5, 17, 50–56). Certain fundamental differences between these starting isolates should be stressed. The use of long periods of tissue disaggregation by incubation in collagenase, pronase, or other dissociative enzyme solutions is often detrimental to cell membrane integrity, receptor and adhesive function and thus viability and should thus be kept to a minimum necessary to generate tubule fragments. For these reasons, physical microdissection techniques with minimal or no enzyme pretreatment is often the preferred method. These techniques provide precision of specific segment selection and is suitable for isolation of many segments of the nephron since the ease of dissection can be increased by the use of pathogen-free animals or pre-perfusion of human kidneys in situ with sterile salts solutions. Although physical microdissection of tubules provides the most accuracy, only relatively small numbers of tubules can be obtained from a single isolate because of the limited period of tissue viability. This limitation can be alleviated to some extent by freezing tissue slices in 5% dimethyl sulfoxide-containing medium for subsequent use, but the technique remains time consuming and labor intensive.

If purity is less important than large quantities of cells, tissue mincing with or without mild enzymatic digestion and/or Percoll gradient centrifugation followed by immunoabsorption with cell-type specific antibodies provides potential for generation of large numbers of pure cells. In this case, the quality of the preparation is directly related

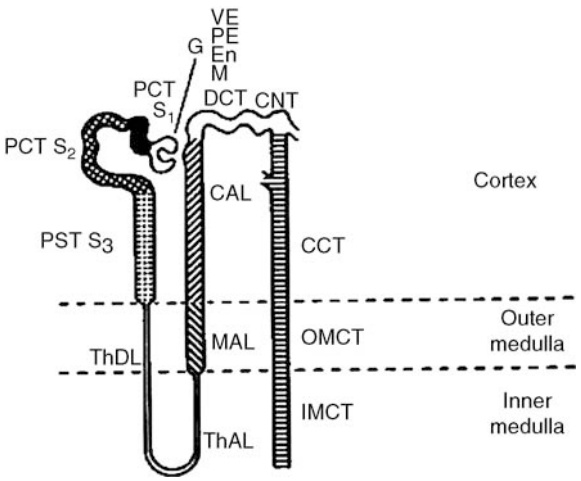
Figure 15-1

Schematic representation of distribution of cell types in the mammalian nephron. All tubule cell types can be isolated by microdissection techniques, and those shaded can be grown as primary culture monolayers in serum-free defined media. Glomeruli can be isolated by sieving and individual cell types grown in culture. Additional cells (not shown) include juxtaglomerular, vascular endothelia and smooth muscle cells, and interstitial fibroblasts of the cortical and medullary zones. CAL, cortical thick ascending limb of Henle's loop; CCT, cortical collecting tubule; CNT, connecting piece; DCT, distal convoluted tubule; En, endothelial cells; G, glomerulus; IMCT, inner medullary collecting tubule; M, mesangial cells; MAL, medullary thick ascending limb of Henle's loop; OMCT, outer medullary collecting tubule; PCT, proximal convoluted tubule; PE, parietal epithelial cells; PST, proximal straight tubule; ThDL, thin descending limb of Henle's loop; ThAL, thin ascending limb of Henle's loop; VE, visceral epithelial cells.



to the quality and specificity of the antibody used. Development of coated beads and nanoparticles offers the potential for significant improvement in separation techniques in the near future.

There are many obvious advantages to long-term study of defined cell populations in vitro. The ability to adapt culture conditions to permit the proliferation of isolated renal cells in vitro has led to a dramatic increase in the understanding of renal cell biology. Such techniques provide a powerful tool for study of renal tubule function, development, and disease. Most glomerular, tubular and interstitial isolation techniques have used adult kidneys as starting material, but increasingly, these basic techniques are being applied and adapted to the isolation, purification and culture of fetal kidney cells (2).

Renal Cell Culture Techniques

The ideal tissue culture method to use depends on the experimental question to be asked. The simplest form of cell culture is conducted in monolayers which can be derived from primary isolates or from immortalized cell lines. More elaborate culture systems may involve co-cultivation of different cell types in stratified culture systems, in 3-dimensional gels, or on synthetic scaffolds. For the system most closely resembling complex multi-cell type interactions, organ culture systems are the most appropriate choice. Each method provides advantages and disadvantages. For instance, primary cultures are likely to closely resemble the properties of the cells of origin *in vivo*, but are labor-intensive to generate and may not be feasible for the study of normal human samples or of rare diseases. Permanently growing cell lines are convenient, but may be transformed and possess abnormal characteristics. In such cases, single cell cloning may be an option to derive a homogeneous cell type with the desired property(ies). Several *in vitro* culture techniques are available to the renal researcher.

Primary Cell Cultures

Traditional explant techniques, in which small pieces of whole kidney (separated into cortex or medulla) are chopped and placed into tissue culture media- containing serum. Cell monolayer outgrowths of explants then studied in primary culture, are of little use in kidney research. The extreme heterogeneity of cell types derived from the explants and the nonselective nature of serum stimulation of growth are major limitations. Such concerns led to the development of cell type-specific isolation techniques which have contributed to significant advances in renal cell biology.

Glomeruli can be readily isolated from mammalian kidney cortex by graded sieving (57), and the differential supplementation of culture media and extracellular matrix to collagenase digests favors the primary outgrowth of epithelial, endothelial, or mesangial cells. Mesangial cells are the easiest to obtain because they grow on uncoated plastic in Roswell Park Medical Institute (RPMI) medium containing high levels (20%) of serum (9). Endothelial cells require gelatin for attachment and endothelial cell growth factor supplementation in the medium (8), whereas epithelial cells require collagen as matrix and supplementation of the medium with transferrin, insulin, dexamethasone, tri-iodothyronine, and prostaglandin E2 (6). The nature and degree of purity of primary cell populations can be determined by rigorous marker

Table 15-1

Markers of differentiated cell types from normal adult kidneys

Glomerulus	
Parietal epithelium	Cytokeratin, VCAM1
Visceral epithelium	Podocalyxin, podocin, nephrin, synaptopodin, WT-1, laminin α5, integrin α3, C3B receptor, angiopoietin,-1, VEGF, o-acetylated ganglioside
Endothelial cells	Tie-2, PDGFB, von Willebrand factor, Factor, Weibel-Palade bodies, angiotensin-converting enzyme, acetylated low-density lipoprotein uptake.
Mesangial cells	PDGF receptor β, angiotensin,II receptor, Actomyosin, contractility, desmin, dystrophin
Tubules	
Proximal	Abundant brush border, alkaline phosphatase, y-glutamyl transpeptidase, isomaltase, leucine aminopeptidase, meprin, aminopeptidase N, dipeptidylpeptidase, villin, megalin (GP330, Heymann nephritis antigen), parathyroid hormone receptors, Na-glucose transporter, Na- amino acid transporter, aquaporin-1, NHE3; GLUT-2, ClC5, CFTR, rBAT, PEX, NBC, hUAT, 1,25-hydroxy 2D3
Thin descending limb of Henle	Aquaporin-1, Ca-ATPase-3
Thick ascending limb of Henle	No brush border, abundant mitochondria, highest Na-K-ATPase activity, Tamm-Horsfall protein (uromodulin), pre-pro-epidermal growth factor (EGF), ROMK channel, NKCC2 (BSC1), NHE3 CaSR, glucocorticoid receptor, osteopontin
Juxtaglomerular apparatus	Renin
Macula densa	Anion exchanger AE2, NHE-2, NHE-4
Distal convoluted tubule	Epidermal growth factor, osteopontin, NHE2, NCC, Ca-ATPase,-2, CaSR, 28Kd CaBP, Na/Ca exchanger, ClC-K1, 2, claudin 16, Ca^{2+}, Mg^{2+}-ATPase, 11-hydroxysteriod dehydrogenase-2, mineralocorticoid receptor, calcitonin response
Connecting tubule	Kallikrein, 28kD CaBP, Na/Ca exchanger, 11-hydroxysteriod dehydrogenase-2, mineralocorticoid receptor, aquaporin-2
Collecting tubule	
Principal cells	Light cytoplasm, few organelles, calcium-binding protein, vasopressin, receptor V2 aquaporin-2, aquaporin-4, CFTR, ENaC 11-hydroxysteriod dehydrogenase-2, mineralocorticoid receptor, AE-1, AE-228kD CaBP, vasopressin receptors
Intercalated cells	Dense cytoplasm, many organelles, Cl-/HCO_3- exchanger (Band 3), H^+-ATPase, carbonic anhydrase II
Fibroblasts	
Cortical	Vimentin, FSP-1 I-CAM-1
Medullary	Vimentin, FSP-1, tenascin

It should be noted that species differences are common in segment distribution of some transporters

Abbreviation: CaSR, calcium sensing receptor; C1C5, chloride channel; ENaC, epithelial sodium channel; GLUT-2, Na-glucose cotransporter; hUAT, urate transporter; PDGF, platelet-derived growth factor; PEX, Na/phosphate transporter; NBC, Na-$HC0_3$ transporter; NCCT, Na^+ Cl^- transporter; NHE3, Na/H^+ exchanger; NKCC2 (BSC1), Na^+ K^+ Cl^{2-} transporter; rBAT, cystine and dibasic amino acid transporter; ROMK, renal outer medullary potassium channel; CAM, cell adhesion molecule 1; VEGF, vascular endothelial growth factor

analysis using immuno-detection techniques using cell-type specific antibodies (see *Table 15-1*).

Primary cultures of defined renal tubule epithelia have been derived from several mammalian species, using a wide variety of techniques. As discussed above, microdissected tubules provide maximum purity and allow discrimination between the S1, S2, and S3 portions of the proximal tubule (10–12, 58) as well as isolation of specialized regions such as the macula densa and the juxta-glomerular apparatus (21, 59–61). Commonly used, reliable techniques are available for the culture of proximal tubules, thick ascending limbs of Henle's loop, and collecting tubules of cortical and medullary origin. These techniques are used for the primary monolayer culture of cells of adult and fetal

Table 15-2

Mammalian renal cell and tissue cultures

Cell type	Species	References
Primary cultures		
Glomerular visceral epithelia (podocytes)	Human, rat, mouse, pig,	(4–7)
Glomerular endothelia	Human, bovine, rat	(8)
Glomerular mesangial cells	Human, bovine, rat	(9)
Proximal convoluted tubule S1, S2	Human, rabbit, mouse	(3, 10–12)
Proximal straight tubule S3	Human, rabbit, mouse	(3, 10–12)
Thick ascending limb of Henle's loop	Human, rabbit	(10, 11, 13, 14)
Distal convoluted tubule	Rabbit, rat, mouse	(14–16)
Collecting tubule	Human, bovine,dog, rabbit	(10, 11, 15, 17)
Intercalated cells	Rabbit	(16)
Principal cells	Rabbit	(18)
Outer medullary collecting tubule	Human, rabbit	(10, 11)
Inner medullary collecting tubule	Human, rabbit, rat	(10, 11, 19, 20)
Macula Densa	Mouse	(21)
Juxtaglomerular cells	Rat	(22–25)
Cortical interstitial fibroblasts	Human, rabbit, rat	(21, 26, 27)
Medullary interstitial fibroblasts	Rabbit, rat	(23, 27, 28)
Renal vascular smooth muscle cells	Rabbit	(24)
Spontaneous permanent cell lines		
Proximal-like: JTC-12, BSC-1, OK, LLC-PK1, PT	Monkey, opossum ,pig, mouse	(29–32)
Distal like: MDBK, MDCK, GRB-MAL, MmTAL-1C	bovine, dog, rabbit, mouse	(33–35)
Fetal kidney	Human	(33)
Immortalized/transformed cell lines		
Glomerular epithelia (podocytes)	Human, rat, mouse	(36, 37)
Proximal tubule	Human,	(38, 39)
Distal convoluted tubule	Mouse	(39, 40)
Cortical collecting tubule	Rabbit	(33, 41)
Inner medullary collecting tubule	Mouse	(29)
Fetal Kidney (HEK 293)	Human	(25)
Metanephric blastema (RSTEM-1)	Mouse (fetal)	(42)
Conditionally immortalized/differentiated cell lines		
Glomerular epithelial (podocytes)	Mouse	(43)
Proximal tubule	Human (fetal)	(44)
Proximal tubules	Human (adult), rat, mouse	(45–47)
Thick ascending limb of Henle	Human (adult)	(44)
Colllecting tubule	Human adult and fetal	(44, 48, 49)
Ureteric bud	Mouse fetal	(42)

Abbreviation: LLC-PK1, pig kidney; MDBK, Madin-Darby bovine kidney; MDCK, Madin-Darby canine kidney; MmTAL, mouse medullary thick ascending limb; OK, opossum kidney; PT, proximal tubule

origin. In addition to epithelial cells, renal interstitial fibroblasts can also be cultured with ease from the cortical or medullary explants (23, 24, 27, 28, 62). These are fairly easy to generate because fibroblasts proliferate rapidly in response to 10% serum stimulation, whereas renal epithelial proliferation is inhibited under these conditions. This means that the renal fibroblasts initially present in mixed cell populations in explants eventually overgrow the cultures. Subculture with trypsin results in the acquisition of pure preparations of fibroblasts by the third passage, because renal epithelia are more sensitive to the destructive effects of trypsin than fibroblasts (62).

To assess the validity and stability of any primary culture technique, rigorous marker analysis is essential and possible because each renal cell type expresses specific protein(s). This permits analysis of both the purity of the initial preparation and the maintenance of the differentiated state through subsequent passages in vitro. If these criteria are fulfilled, primary cultures are particularly useful for the study of normal cell function. Most cell cultures derived from glomerular or tubule preparations isolated from normal adults survive a few (three to five) passages but then die out. This is consistent with normal cell properties and is thought to represent the maximal repair capacity of renal cells in vivo. This contrasts with neoplastically transformed cells, which possess unlimited proliferative potential and produce tumors in vivo and immortal cell lines in vitro.

Permanent Cell Lines of Renal Origin

Renal Cell Lines

Several permanently growing renal epithelial cell lines have been identified and used to study many aspects of renal cell biology (*Table 15-2*). These cell lines can provide a convenient supply of large numbers of cells for the study of polarity, ion transport, hormone receptor interactions, ischemic injury and toxic responses (29–35). However, their limitations must be appreciated. Although LLC-PK1, OK, and JTC-12 cells have properties suggesting proximal tubule origin, and Madin-Darby canine kidney (MDCK) cells have some properties of distal tubules, the precise cells of origin of these spontaneously immortal lines is unknown. In addition, like all immortal cell lines, they have undergone genetic drift because of numerous passages. This has led to the loss of some normal and the acquisition of abnormal, anomalous properties. Some of these limitations can be overcome by recognition of unique subclones (i.e., MDCK-1 and MDCK-2 cells), and single cell cloning and restricted use of cells for study (i.e., with a maximum of 10 passages). For instance MDCK and LLC-PK1 cells have proven to be invaluable for the study of specific transport proteins, and for analysis of mechanisms controlling epithelial cell polarity.

Immortalized, Transformed Renal Cell Lines

An important advance in the generation of cell lines for renal research has been the successful application of immortalization techniques using recombinant viral vectors introduced into cells by infection or transfection. Initial studies used oncogenic viruses to deliver transforming oncogenes to cells in vitro, including Human Papilloma Viral (HPV)-immortalized HK2 cells; adenovirus/simian virus immortalized RCCT-28A cells and the adenovirus-5-transformed human embryonic kidney (HEK) 293 cell line (*Table 15-2*). The latter cell line has become widely used due to its permissiveness to transfection. But it should be cautioned that all of these cells are highly transformed and may therefore not be the cell line of choice for the study of normal cell functions. An additional successful strategy has been to isolate a variety of renal segmental cell lines from the SV40-large T antigen transgenic mouse, including podocytes, Macula densa, juxta-glomerular apparatus (JGA), mouse cortical collecting tubules (mCCT) and widely used mouse inner medullary collecting duct (mIMCD)3, M1 and K2 cells (see *Table 15-2*) (21, 24, 25, 33–41, 63). The advent of these cell lines has greatly improved the efficiency and options for *in vitro* study of renal genes and proteins, since they provide large numbers of cells of a single type amenable to transfection with specific genes. However, like any transformed cells, they suffer from the limitation that the permanently proliferative phenotype is conferred by the presence of the introduced oncogene rendering the cells abnormal. Thus the significant advantage conferred by a constantly renewable proliferative source of cells is counter-balanced by the disadvantage of abnormalities conferred by this transformation.

Conditionally Immortalized Renal Cell Lines

To date, the most successful advance made towards achieving the goal of production of large numbers of

permanently proliferating but normally differentiated renal cell cultures has been the introduction of a temperature-sensitive (tsA58) allele-containing Simian virus (SV-40) T antigen into defined renal cell types (42, 44, 47–49, 64, 65). This has permitted the immortalization by virtue of expression of the integrated SV-40 tsT antigen, and proliferation to confluence without loss of contact inhibition when cells are grown at the permissive temperature of 33°C. However when such cells are switched to a non-permissive temperature($\geq$37°C), they lose T antigen expression, cease proliferation and exhibit a fully-differentiated cellular phenotype. This technique has been widely and successfully applied to generate several conditionally immortalized human, mouse and rat renal segment specific cell lines including podocytes, proximal, thick ascending limb and collecting tubules, ureteric bud epithelial and renal fibroblasts of normal adult and fetal origin (see *Table 15-2*). This has been achieved utilizing two approaches: either by isolating specific renal cell types for culture from the SV-40tsA58 transgenic mouse (Immorto-mouse) (43, 64) or by in vitro retroviral delivery of pZIPtsA58U19 into microdissected primary cell cultures of specific renal cell types followed by selection of transfectants in neomycin (45). The latter technique has been used successfully to conditionally immortalize human renal epithelial cells of normal and diseased origin, to generate conditionally immortalized cell lines of normal human fetal and adult proximal tubules, thick ascending limbs and collecting tubules, as well as epithelial cell lines from patients with cystinosis, autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD) (44, 48, 49, 65–67). As required for understanding the utility of all cells in culture, these cells have been fully characterized by marker analysis and show maximal differentiation and characteristics of their segment of origin after 5–14 days at 37°C (*Table 15-3*). Conditional immortalization of microdissected primary renal cell cultures provides a homogeneous, renewable system to study specific cell types that closely resemble their cell type of origin, exhibit normal function and polarization of proteins, and are highly transfectable (*Fig. 15-2*). These techniques offer substantial promise for the study of cellular basis of disease and are being applied to many mouse models by crossing mutant diseased mice with the Immorto-mouse to facilitate the generation of conditionally immortalized renal cells after isolation applying micro-dissection, or immunodissection approaches (68).

Role of Extracellular Matrix

Studies in several in vitro systems have elucidated a major role for the extracellular matrix in the regulation of epithelial cell proliferation, adhesion, polarity, differentiation and gene expression (69). *In vivo*, the renal extracellular matrix is comprised of the tubular and glomerular basement membranes as well as peri-tubular interstitial matrix and contains an intricate network of collagens (types IV, I and III), laminin, fibronectin, entactin and heparan sulphate proteoglycans (HSPG). Confluent renal tubule epithelial cells in vitro have also been shown to secrete a basement membrane (10, 70, 71). To promote normal growth and differentiation, renal tubule epithelia are optimally seeded onto tissue culture plastic or membrane filters that have been pre-coated with an extracellular matrix protein or combination of proteins such as collagen type I or type IV; or Matrigel (derived from the EHS sarcoma) This not only facilitates adhesion via normal integrin-based receptors but also promotes proliferation, polarization and differentiation. Although renal tubule and glomerular epithelial cells have a strong preference for exogenous matrix for their optimal culture, this is not the case for renal cells of mesenchymal origin such as mesangial cells, smooth muscle cells or fibroblasts that grow on uncoated tissue culture plastic in the presence of serum.

Role of Growth Factors

Soluble growth factors have long been known to play a major role in the control of cell proliferation. In vitro, serum was first used to induce cell growth. However, serum is a complex mixture of proteins, and its detailed composition has not been fully elucidated. The value of serum in renal cell culture is that it favors the growth of fibroblasts at the expense of epithelia. In mixed epithelial and fibroblast cell populations, this enables the generation of fibroblast cell lines due to their differential survival in vitro. For instance, when human kidney cortex or medulla is grown without exogenous matrix in the presence of 10% serum, after three passages only fibroblasts are present. A significant advance for renal epithelial cell culture was the definition of serum-free growth factor-supplemented culture media that support the proliferation of renal epithelial cells (72). Modifications of the original formulation have led to optimization of the culture conditions for most renal epithelial cell types

Table 15-3

Characterization of conditionally immortalized human renal epithelial cell clonal lines

Abbreviation: weak signal; + /−, most clones positive, few clones negative; (A), apical; ADPKD, autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; (B), basal; (C), cytoplasmic; HFCT, human fetal collecting tubule; HFPT, human fetal proximal tubule; NHCT, normal human adult collecting tubule; NHPT, normal adult human proximal tubule; NHTAL, normal human adult thick ascending limb

in serum-free media. All epithelia have an absolute requirement for transferrin and proximal tubules are stimulated to proliferate by combinations of dexamethasone (or hydrocortisone) and insulin, although this requirement can be substituted by epidermal growth factor (EGF). Optimal proliferation of thick ascending limb epithelia requires additional supplementation with tri-iodothyronine, whereas collecting tubules require only dexamethasone and transferrin (12). It is thought that the different balance of growth factor and hormonal supplementation reflects the different complement of membrane transporters and receptors of the different epithelial segments.

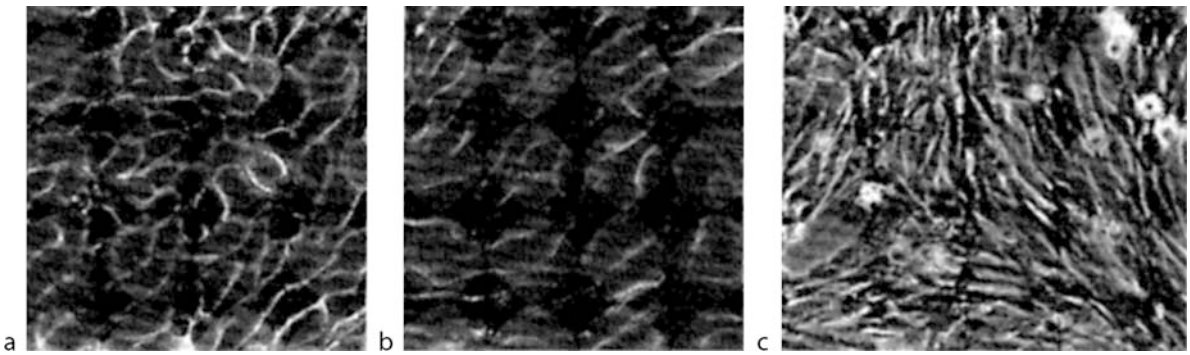
In vitro Techniques for the Analysis of Normal Renal Function, Development, Differentiation and Morphogenesis

Proliferation and Differentiation of Monolayer Cultures

The in vitro system can be utilized with great power to understand the role of individual components involved in normal and abnormal processes by controlled studies in which single components can be deleted or added at a time.

Figure 15-2

Phase-contrast light micrographs of confluent primary cultures. (a) Epithelial monolayer grown from individually microdissected human fetal proximal tubule explanted onto type I collagen-coated plastic plates in Click- RPMI (Roswell Park Medical Institute) medium supplemented with human transferrin, dexamethasone, insulin, and fetal bovine serum (1%). Note polygonal morphology. (b) Epithelial monolayer grown from individually microdissected human fetal collecting tubule expianted onto type I collagen-coated plastic plates in Click-Roswell Park Medical Institute medium supplemented with transferrin, dexamethasone, and fetal bovine serum (1%). Note polygonal morphology. (c) Renal fibroblasts derived from cortical explants plated onto uncoated tissue culture plastic in Dulbecco modified Eagle medium supplemented with 10% fetal bovine serum. Note elongated, spindle-shaped cell morphology.



Regulation by Matrix and Soluble Factors

The interactions of extracellular matrix proteins such as collagens I, III, IV, and V; laminin and proteoglycans with their specific αβ integrin matrix receptors are critically important in development and establishment of epithelial cell polarity as well maintenance of the differentiated state (73–75). In vitro techniques are ideally suited to analyze the roles of specific matrix proteins on proliferation, adhesion, polarization and differentiation of renal cell types and can be used to compare these in adult versus fetal epithelia (71). The action of a variety of soluble factors via their specific growth factor and hormone receptors also play important roles in renal cell proliferation and differentiation in development and maturity which cam also be readily assessed in renal cell culture systems (76).

Establishment of Epithelial Cell Polarity

The physiologic hallmark of the renal tubule epithelia is polarized reabsorption and secretory functions specific to each nephron segment, which is paralleled by and a consequence of the highly polarized and asymmetric distribution of specific ion transporters, channels, and receptor proteins on the apical versus basolateral membranes. Structural polarity is also seen in that only apical membranes elaborate brush borders and basal membranes elaborate a basement membrane. The maintenance of polarity is determined by the integrity of occluding tight junctional complexes that form a continuous belt between epithelial cells at the apical pole of renal epithelial cells. Renal epithelia in vitro also form tight junctions and polarized monolayers when grown on extracellular matrix. The MDCK cell line has been highly utilized to study mechanisms of polarization since it readily forms a tight monolayer. To maximize morphological and physiological polarization of normal renal epithelial cell types, growth on collagen coated membrane filters suspended in tissue culture wells (e.g., Transwell assemblies) is highly recommended. It appears that the feeding of cells from the basal (as well as the apical) cell surface facilitates maximal differentiation and polarization of epithelial cells in vitro. These techniques have been widely applied and are suitable to examine the polarization potential of developing and mature epithelia by marker analysis of specific membrane proteins (see *Table 15-4*). The analysis of cell polarization events in monolayer primary cultures derived from differentiated renal progenitors will in the future provide a temporal and spatial map of sequential events involved in tubule maturation during nephrogenesis.

Marker Analysis

The complex arrangement of the kidney into multiple nephrons comprising a filtering glomerulus and transporting

Table 15-4

Markers of membrane polarity in normal adult tubule epithelia

Apical	Basal and lateral
Influenza hemagglutinin	VSV-G
Alkaline phophatase	Na-K-ATPase
γ-Glutamyl transpeptidase	Ankyrin
5′-Nucleotidase	Fodrin
Meprin	E-cadherin
Diaminopeptidase-IV, meprin	Vasopressin-2 receptors
Aminopeptidases, M, N, P	EGF receptors
Maltase	IGF-1 receptors
H^+- ATPase	Laminin receptors
Trehalase	Type IV collagen receptors
Carcinoembryonic antigen	HSPG receptors
Na-glucose transporter GLUT2	Integrin α6
Na-amino acid transporter	Integrin α2
Na-H exchanger NHE3	Integrin β1
Aquaporin-2	Integrin β4
Na^+ K^+ $2Cl^-$ symporter	CI/HCO3, AEI transporters
Urate transporter	Aquaporin-4

Abbreviation AQP, aquaporin; ATPase, adenosine triphosphatase; HSPG, heparan sulfate proteoglycan

tubular epithelium divided into approximately 15 segments with distinct physiological functions, provides the basis for marker analysis due to the accompanying expression of segment and cell type-specific genes and proteins. As described above, this feature can be used to verify the validity and purity of a cultured cell population. In addition, it can be used to analyze the physiological and developmental regulation of specific proteins. *In vitro* cell systems are ideal to test the effects of potential hormonal agonists and antagonists on specific proteins and is widely used in studies of renal ion transporter and channel regulation. Much less is known about the underlying processes controlling the conversion of undifferentiated, nonadhesive, nonpolarized mesenchymal cells of the metanephric renal blastema into fully polarized, adhesive, highly specialized nephron (77). In vitro cell systems utilizing renal epithelia from fetal through to adult kidneys will elucidate the temporal and spatial characteristics and may shed light on developmental defects in renal function associated with sporadic or genetic malformations. To facilitate study of this complex array of events, a series of developmental cell- and stage-specific markers are becoming available due to studies conducted in developing kidneys (*Table 15-5*).

Table 15-5

Markers of renal development

Cell Type or Structure	Markers
Metanephric blastema (undifferentiated mesenchyme)	Vimentin; syndecan; integrins α1,α9; collagen I, III; laminin β1, y1, fibronectin; N-CAM; IGF-II; GDNF HGF; c-Met; NGFR; midkine; CRABP; BF2; tenascin; WT1, cadherin -11; Hox AII; Hox DII; Six-2; Sca-1;; FGF2; BMP4; PNA+; apoptosis
Condensates	Vimentin, syndecan, α8 integrin, N-CAM, N-myc, WT1, IGF-II, HGF, c-Met, NGFR, midkine, pax-2, wnt4, cadherin 6, E-cadherin
S-shaped bodies	Laminin, α1 integrin, E-cadherin, syndecan, tenascin, N-myc, NGFR, wnt4, Notch-1
Glomerular pole	Vimentin, WT1, α3 integrin, podocalyxin, C3b receptor, IGF-II, nephrin- B2
Tubular pole	γGT, MDR, α6 integrin, α1-dystroglycan
Fetal tubule epithelia	Cytokeratin, laminin α1, collagen IV, α6 integrin, E-cadherin, desmoplakin, HGF, c-Met, LIM-1, α1-dystroglycan
Proximal	Alkaline phosphatase, leucine aminopeptidase, renal peptidase, meprin, MDR, midkine, aquaporin 1, CFTR, cadherin 6
Thin descending limb	Aquaporin 1
Thick ascending limb	Na-K-ATPase-α1 β2, Tamm-Horsfall protein, osteopontin, L-myc, integrin β4, integrin α2, calcium-binding protein, E-cadherin, Brn 4/1
Collecting tubule/ureteric bud	Midkine, Wnt7b, PKD-1, polycystin-1, CFTR, Pax-2, carbonic anhydrase, H-ATPase, aquaporin 2, Hox B7, c-ret, calbindin, Pax-2, E-cadherin, DBA+
Fetal glomeruli	Vimentin; integrin α3, β1; podocalyxin; C3bR; WT-1; ACE
Fetal interstitium/stroma	Vimentin, tenascin, GD-3, ganglioside, IGF-II, FGFa, NGFR, RAR α, RAR β, BF-2

Assay Development in Tissue Culture Plates

Cell culture monolayer systems on multiwell tissue culture plates offer a highly manipulable system with the potential to develop high through-put, multi-variable assays to measure the effects of agonists, inhibitors, or gene modification on cellular responses including proliferation, apoptosis, matrix adhesion, cell-cell adhesion, motility and secretion. These systems are being utilized for analysis of therapeutic small molecule or antibody drugs and for toxicity testing (*Fig. 15-3*).

Transfilter systems are also particularly beneficial for the study of renal epithelial polarity and polarized function (*Fig. 15-3*). By establishment of a gradient of growth factor or ion in question by differential media supplementation in the apical and basal compartments, effects on polarized cell secretion or absorption, chemotaxis or directional cell migration can readily be analyzed. These types of assays have been productively applied to the analysis of altered functions of diseased (polycystic kidney) epithelia (78–80). In addition, important observations have been made to dissect the respective roles of soluble factors versus cell-cell contact in the inductive events leading to metanephric blastemal induction in response to the ureteric bud by separating the two components (81, 82). These types of assays also provide a strong potential for analysis of cell type interactions for instance between epithelial sheets and interstitial cells in normal development, function and disease (83, 84).

Morphogensis in Three-Dimensional Gels

Experimental confirmation of the role of mesenchymal and extracellular matrix induction on normal renal epithelia has also been shown by the ability of collagen or reconstituted basement membrane gels to promote the development of three-dimensional tubule-like structures from mouse inner medullary collecting ducts (mIMCD), dog (MDCK) collecting tubules and pig proximal tubules (LLC-PK1) (85–87). When initially seeded into type I collagen gels, MDCK (and LLC-PK1) cells form inside-out cysts and co-cultures with fibroblasts or the addition of fibroblast-conditioned media or hepatocyte growth factor (HGF) elicits a tubulogenic effect (87, 88) (*Fig. 15-4*). These surrogate tubulogenesis assay techniques are now widely utilized to study the effects of gene modulation by transfection or siRNA, or added soluble co-factors or specific inhibitors in development and disease (89–91). The utility of this system is that it provides a robust three-dimensional assay to analyze the roles of cell-cell, cell-matrix, and cell-soluble factor interactions. It should be cautioned, however, that MDCK cells may not be the ideal cell type to model a developing kidney and the use of ureteric bud or other fetal-derived cells should be explored to answer developmental questions.

Embryonic Organ Culture

The most sophisticated and directly relevant in vitro system to study renal development is organ culture of fetal kidneys. These techniques have the advantage that epithelial-mesenchymal tissue interactions are maintained, although vasculature does not develop as in would in vivo. Nevertheless, the branching morphogenesis of the ureteric bud and the induction and differentiation of glomeruli and nephron tubules can be studied for upto a 14-day period in these cultured organ explants (*Fig. 15-4*). Mouse embryonic kidneys from embryonic day (E) 11–16 embryos are dissected and placed on a stainless steel rafts or filter membranes in a culture well and specific serum-free, growth factor supplemented media is added to the lower compartment to allow a thin film of media to cover the explant. These types of assay have been instrumental in identifying important matrix and growth factors involved in the regulation of normal ureteric bud branching and metanephric blastemal progenitor cell production (81, 92–96).

For studies of renal development and nephrogenesis, the most important modification of organ culture, the transfilter technique, was first introduced by Grobstein (81) and continues to be used extensively. Metanephric blastemas are attached to a filter suspended above a tissue well and tissue fragments of ureter or spinal cord are applied to the undersurface of the filter to induce nephrogenesis. Alternatively, the natural inducer, the ureteric bud maybe removed from one E11 kidney and development compared with that of the paired kidney in which it was left in. Progressively refined analysis of the transfilter organ culture system has provided the basis for much of our present understanding of the cellular and molecular events associated with nephrogenesis. These include cell-cell contact and cell-matrix attachment, allowing regulated migration and cell shape changes as well as appropriate growth factor-receptor interactions that coordinately regulate proliferation, apoptosis, differentiation and epithelial polarization associated with renal tubule maturation.

More recent studies have focused on using these organ culture systems to understand cystic expansion and ureteric bud malformations associated with disease processes by the introduction or modulation of genes by direct

Figure 15-3

injection or incubation of inhibitory dominant negative or shRNA or activating viral constructs (80, 97–100). Although the majority of metanephric organ culture studies are carried out using mouse kidneys, studies of rat and human renal organ culture are also feasible (101, 102).

In Vitro Techniques for the Analysis of the Underlying Mechanisms and Modulation of Renal Cell Injury and Disease

Renal tubule cell injury in vivo can be induced by ischemia, nephrotoxins, genetic abnormalities, or cancer. An understanding of some of the cellular and molecular mechanisms involved is beginning to emerge, in large part because of the use of in vitro techniques, as summarized in *Table 15-6*.

Glomerular Disease

The availability of pure glomerular cell types in vitro has led to their use in elucidating cellular mechanisms of disease. For example, exposure of glomerular podocytes in culture to Heymann nephritis antigen provided experimental evidence for binding in coated pits, patching,

Table 15-6

In vitro techniques for the study of cell injury and diseases

Injury or disease	Cell type	Species	Reference
Ischemia (anoxia)	PT, PCT, PST CTAL, mTALCCT	Human, rat, rabbit	(103)
Gentamicin	LLC-PK1, PTPCT, PST, CCT	Human, dog, rabbit	(104–107)
Cyclosporine	LLC-PK1, PCT, PST, TAL, CCT, mesangial, endothelia, vascular, smooth muscle	Human, dog, rabbit	(108–111)
Nephropathie cystinosis	Proximal tubule	Human	(45)
ADPKD	Primary cystic epithelia	Human	(70)
	Interstitial fibroblasts	Human	(21)
	Conditionally immortalized:		
	Cystic epithelia	Human	(44, 48)
	Interstitial fibroblasts	Human	(112)
ARPKD	Primary cystic epithelia	Human, mouse	(44, 113–115)
	Conditionally immortalized:		
	Cystic epithelia	Human, mouse	(44, 48, 68)
	Organ culture	Mouse	(99)
Nephronophthisis	Primary monolayer	Human	(116)
Wilms' tumor	G401, SK-NEP, WIT 13, GOS-4	Human	(117)
Renal adenocarcinoma	A704, AHCN, RAG	Human, mouse	(118)
Renal carcinoma	CAKI-1, 2: A-498; RC-1; RCC; CCF-RC1, -2, OUR	Human	(119–122)

capping, and shedding from the cell surface (123) while glomerular epithelia from mice with puromycin aminonucleoside nephrosis exhibited loss of negative charge and adhesive properties More recently, the advent of well-differentiated, conditionally immortalized podocyte cell systems from normal mice and their genetically manipulated diseased counterparts has significantly contributed to the understanding of the roles of collagen IVα4 in Alport's syndrome, nephrin in Finnish-type nephropathy, and podocin in immunoglobulin A nephropathies (43, 124). In addition, these cell systems provide new opportunities to study the underlying mechanisms of immune and membranous glomerulonephritides (7) and to provide novel insights into podocyte cell properties (125).

Mesangial cell cultures have also been used as a model system to study diabetes by their isolation from streptozotocin-induced diabetic rat kidneys or by addition of glucose, transforming growth factor (TGF) -β interleukin-lβ or galectin-3 to their tissue culture media in vitro (94, 126, 127). Cell culture studies, utilizing proliferation, contractility, chemotaxis and migration assays are ideal to examine the mechanisms underlying mesangial proliferative disorders, and the effects of ageing (128, 129), although care must be taken to use cells in early passage to prevent loss of phenotypes by long-term adaptation to culture conditions.

Ischemic Injury

Periods of oxygen deprivation lead to ischemic injury and may result in acute renal failure. To fully understand the mechanims underlying hypoxic, anoxic and ischemic renal cell injury, cell culture approaches offer certain advantages and complement the short-term studies carried out in isolated tubule preparation (103, 130). Of the permanent renal cell lines, LLC-PK1 cells have been the most frequently used and have demonstrated apoptotic responses to ischemia, as well as alterations if heat shock proteins leading to necrotic cell death in response to ATP depletion (131–133). Although LLC-PK1 are thought to be of proximal tubule origin, the most susceptible segment to ischemic injury, permanent cell lines have adapted to the relatively hypoxic conditions of tissue culture rendering them abnormally resistant to ischemic damage. For this reason, the cell culture method of choice for studies would be of primary or conditionally immortalized origin. Primary cultures of rat, rabbit, and human

renal proximal tubule epithelial cells have been shown not only to retain their sensitivity to hypoxic, anoxic and ischemic injury and have been used successfully to demonstrate differential tubule cell sensitivity and attenuation of cell death by polyethylene glycol, extracellular calcium restriction, calcium channel blockers, and inhibitors of calmodulin and cysteine protease activities (103, 130). In addition molecular insights have been determined with regard to the integrin-based mechanisms of the loss of cell-matrix adhesion as well as induction of the cell-cell adhesion molecule I-CAM-1 (134, 135). Hypoxia studies have also been carried out on mesangial cells in culture where a role for osteopontin in the resultant proliferation response has been invoked (136).

Nephrotoxic Injury

Renal toxicity is an important topic of study with regard to exposure to environmental toxins, chemotherapeutic, antibiotic and anti-rejection drugs. LLC-PK1 cell lines and primary and conditionally immortalized cultures of rabbit and human proximal tubules have been most widely used to study the mechanisms underlying the toxic effects of a variety of metals (137–139) as well as those of aminoglycoside antibiotics, such as gentamicin where a major role for alterations in proximal tubule phospholipid profiles have been implicated (104–107, 140). Primary and conditionally immortalized renal proximal tubule cells have also been used to study mechanisms of sensitivity to the chemotherapeutic agent cisplatin and to define the relative contribution of epithelial versus microvascular effects of the anti-rejection drugs cyclosporine and FK506 (108–111). Cell culture approaches are highly suited to identification of the intracellular targets of toxicity and the subsequent testing of potential modulators. Primary porcine proximal tubules, LLC-PK1 and MDCK cells, have been used to study mechanisms of transepithelial drug transport (141, 142) and the effects of calcium oxalate crystal formation (143, 144). Interestingly, this was shown to be exacerbated by hypoxia and hypercapnia (145).

Congenital Renal Diseases

Hereditary and non-hereditary renal disease can readily be modeled in vitro by development of renal cell lines from human diseased tissues or from spontaneous or genetically engineered rodent models of disease.

The first cell culture system devised for the study of human autosomal dominant polycystic kidney disease (ADPKD) utilized a primary culture approach in which individual cyst epithelial linings were microdissected and grown in primary culture (65). Together with parallel in vivo studies, these were instrumental in delineating the aberrant cell biological characteristics of ADPKD cystic epithelia including excessive cell proliferation, hypersensitivity to epidermal growth factor (EGF), increased cell-matrix adhesion, alterations in apico-basolateral polarity and fluid secretion defects (146). Subsequently, several primary, immortalized, and conditionally immortalized monolayer systems for human ADPKD, human and mouse autosomal recessive polycystic kidney diseases (ARPKD), and nephronophthisis (44, 49, 68, 113–116) have been established (*Table 15-6*). The derivation of conditionally immortalized cell lines derived from human, rat and mouse models of ADPKD and ARPKD via retroviral delivery to cell cultures of the temperature-sensitive T antigen (*Table 15-4*) (44, 45, 48, 49, 80) or by crossing PKD1, PKD2 mutant mice with the Immortomouse (64) will clearly provide a valuable tool essential tool to analyze the precise function of polycystin-1, and polycystin-2 proteins and to allow development and testing of potential therapeutic interventions.

In addition to genetic cystic diseases, cell culture techniques have also been developed to study X-linked hypophosphatemia (147), nephropathic cystinosis (45) and hydronephrosis (148) and other developmental abnormalities. Although monolayer culture provides several advantages, these studies can be complemented by application of organ cultures of embryonic and postembryonic kidneys (99). Such approaches have been used to define specific defects in ureteric bud morphogenesis and tubule differentiation after inactivation of PKD1 or PKD2 (80). This then provides a 3-dimensional system to test the effects of gene replacement or modulation by delivery via viral transduction technology (100, 149) or of small molecule drugs or antibodies as potential therapeutics agents.

Renal Cancer

Kidney tumors arise predominantly either during early development (Wilms' tumor) or associated with advancing age (renal carcinomas).

Wilms' Tumor

Although it has been surprisingly difficult to culture primary cells from primary Wilms' tumors, some permanently

growing cell lines are available for study, the most widely used of which are G401 and SK-NEP (› *Table 15-6*) (117). The Wilms' tumor suppressor gene encodes a zinc-finger DNA-binding protein, WT-1 that is involved in normal renal development, and its deletion results in tumor formation.

Renal Cell Carcinoma

Numerous permanent cell lines have been established from human renal cell carcinomas including adenocarcinomas, non-metastatic and metastatic clear cell carcinomas with or without additional mutation of associated genes such as Von Hippel Lindau (VHL) (118–122) (› *Table 15-6*). These cell lines are important not only to provide insights into mechanisms of renal carcinogenesis, metastasis and resistance to apoptosis (120, 150, 151) but also to foster the development and testing of potential therapeutic approaches (152, 153).

Renal Fibrotic Disease

Interstitial fibrosis is an important manifestation of renal disease and exacerbates. Renal cell culture techniques employing primary and conditionally immortalized human, rat and mouse renal cortical and medullary fibroblasts have led to important mechanistic insights, including identification of increases in specific integrin (α_5/β_1 and α_v), nonintegrin and discoidin domain matrix receptors (27, 112). Cell culture techniques are also ideally suited to test the potential involvement of growth factors, cytokines and inflammatory mediators such as TGFβ and TNFα and nitric oxide in epithelial to mesenchymal transition (EMT) which is thought to play a role in the induction of fibrosis (27, 154). Co-culture techniques are likely to be particularly instructive with regard to the influence of diseased epithelia on fibroblasts and vice-versa. Mix and match experiments provide the potential to rescue defects and thus could lead to therapeutic insights.

Conclusion and Perspectives

The ability to culture pure populations of renal cells has provided important fundamental tools and has increased understanding of the renal cell biology of normal and diseased kidneys. Together with rapidly increasing molecular understanding of disease processes, due to sequencing of the human, rat and mouse genomes and the identification of many disease genes, it is to be predicted that the future will bring a rapid advancement in our understanding of disease processes. This will be facilitated with the ability to rapidly and efficiently transfect all renal cell types in culture, in a cell specific manner using efficient viral delivery systems. In addition, sophistication of monolayer cell culture techniques and development of clonal, conditionally immortalized cell lines will facilitate development of high-throughput testing of new drugs and potential therapies for a wide range of renal diseases. Finally, with advances in stem cell biology and the ability to derive, modify and deliver renal progenitor cells (155–157), long-term, cell-based regenerative therapeutic approaches to combat renal disease might become a viable option in the foreseeable future.

16 Animal Models

Jordan Kreidberg

Introduction

The use of animal models has been an essential aspect of nearly all areas of nephrological research since its earliest days. Research on kidney formation and malformation, physiology and pathophysiology, immunological injury, and tolerance or transplant rejection all depend on the use of animal experimentation. This chapter will emphasize genetic approaches that utilize animals, as this area has shown the great progress in the development of novel technologies, that have had great impact in all areas of nephrology.

Institutional Oversight

There is increasing public awareness of the use of animals in research, and with this comes increasing concern about the appropriateness of the use of animals, and whether much of the research that does involve animal models could be accomplished using non-animal models. Therefore it is important to note that all animal research in the United States and presumably in most other countries must be evaluated by institutional committees before any experimentation may commence. Furthermore, the United States Department of Agriculture (USDA) provides constant oversight through the use of frequent and usually unannounced visits to animal facilities with research institutions. These regulatory committees and agencies are charged with evaluating animal protocols to make certain that animals are used in an ethical manner, with proper use of anesthetics or analgesics to minimize or eliminate any source of pain during experimentation. They are also charged with verifying that animals are indeed required for the specific research in question, that large animals are not used when smaller ones would suffice, and that the investigators are trained and knowledgeable about proper use of animals. Despite these several layers of oversight, in the end it is up to the principal investigator to be thoughtful about whether their intended experimental approach will yield sufficiently important and worthwhile results to justify the use of laboratory animals.

Animal Models of Kidney Disease

The selection of an animal model for some aspect or type of kidney disease takes several factors into consideration. Most importantly, the similarity to human disease that can be observed in a particular model is taken into account. Other important factors include the cost of the animals involved: the cost of maintaining animals larger than rodents increases dramatically with size, and the numbers of animals that can be studied consequently decreases. For this reason, some studies may begin with a rodent model, and then progress to a larger model once the rodent model establishes the feasibility of the hypothesis under study. The size of an animal may be important to the extent that it affects the ability to perform surgical manipulations or physiological measurements. However, since it has become increasingly desirable to obtain physiological measurements on various strains of knockout mice, the equipment available to perform these measurements has improved and become commercially available.

Genetic Models

Animal models of disease that have a genetic basis may either result from spontaneous or induced mutations. Spontaneous mutations or phenotypes are those noticed either by chance or through the directed observation of large numbers of mice, that were not otherwise treated to induce a mutation. In contrast, induced mutations are those resulting from the treatment of mice with irradiation or mutagenic agents known to introduce point mutations or deletions into the genome.

The past 20 years have witnessed an explosion in the use of genetic approaches to understand development and physiology, and thus they will receive appropriate emphasis in this chapter. Several genetic approaches are available for use with animal model systems. A gene of interest may be mutated using gene targeting, or expressed in transgenic mice in such a way to interfere with its normal function. On the other hand, it is possible to start with a phenotype of interest, which could either be obtained as a spontaneous mutation or from mice treated with

a mutagen, and an effort is made to identify the mutated gene responsible for the phenotype. Genetic approaches using gene targeted or transgenic mice are useful for a wide variety of developmental and physiological studies in which there is a need to study the function of a known gene.

Genetic Approaches with known Genes-Genotype to Phenotype

Gene Targeting

Gene targeting was originally used to introduce a deletion or interruption into a gene of interest, using the scheme shown in *Fig. 16-1*, such that it could be determined whether mice would be able to develop in the absence of that gene's function. In cases where a gene was shown not to be essential for development, the homozygous mutant mouse might serve as a useful model in which to study the role of a specific gene in a physiological or disease process. For example, targeted deletions of the Wt1 (1), Pax2 (2), GDNF (3–5), Wnt4 (6), and BMP7 (7, 8), among others, showed these genes to be essential for various aspects of early kidney development. On the other hand, the absence of many immunology-related genes does not result in any developmental impairment, but these mice have served as useful models to study the role of the immune system in transplant rejection.

The advent of gene targeting was made possible through the use of two technologies developed mainly in the 1980s. The first was the development of tissue culture conditions that allowed embryonic stem (ES) cell lines to be grown indefinitely in culture while retaining their totipotency (9). ES cells grown in culture could then be introduced into mouse preimplantation embryos or blastocyts, and become fully integrated into those embryos such that their descendant cells would give rise to all developmental lineages that are found in adult mice (10). The second technology involved the use of homologous recombination to introduce mutations into mammalian genes (11–13). As shown in *Fig. 16-1*, when long stretches of genomic DNA in recombinant DNA constructs are introduced into cells in culture, this DNA will, at variable and often quite low frequency, recombine into the locus from which the genomic DNA was originally derived. Therefore homologous recombination of the correctly designed genomic fragment can be used to introduce a deletion or insertion into a genomic locus, that renders the gene unable to be expressed. This ES cell would in essence be heterozygous for a mutation in the targeted gene, and heterozygous ES cells can be isolated and expanded to provide a population for injection into blastocysts. Therefore, by combining the ES cell technology and homologous recombination, it became possible to target mutations into genes in ES cells, and then introduce ES cells carrying these mutations into blastocysts, finally obtaining a mutant adult mouse.

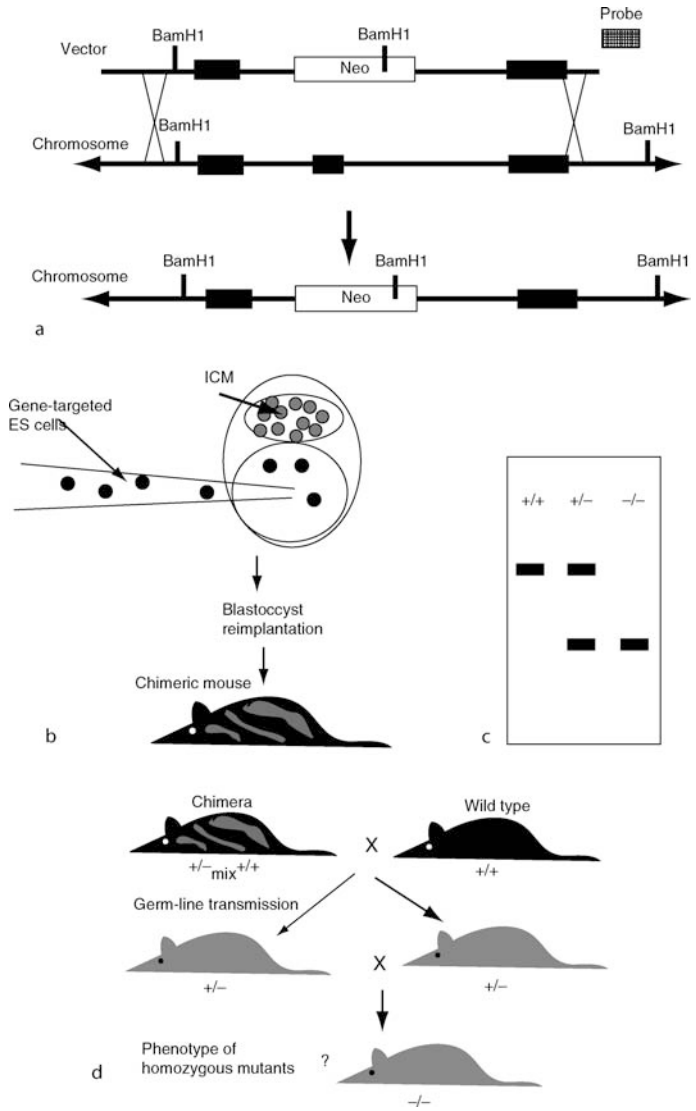
In a typical experiment, gene targeted ES cells would contain one mutated allele and one normal or wild type allele for the gene under study. The targeted ES cells would be injected into preimplantation blastocysts, and groups of these blastocysts would be introduced into female mice that were previously hormonally primed to allow implantation of the injected blastocysts into their uteri, to begin a pregnancy. The resultant mice from these injections are termed "chimeras," because any specific cell is either derived from an ES cells or the original injected embryo, i.e., the chimeric mouse essentially has four parents, the male and female that provided the blastocyst, and the male and female that provided the embryo from which the ES cell line in use was originally derived. In the best cases, a chimera might be nearly entirely derived from the ES cells. Among the tissues that ES cells contribute to are the germ cells: spermatocytes or oocytes. When ES cells heterozygous for a mutation are used to make a chimera, germ cells derived from the ES cells have a 50% chance of carrying the mutant rather than the wild type allele. Therefore, mating a chimeric and wild type mice can result in some of the offspring being true heterozygotes for the mutated gene. After obtaining both male and female heterozygotes, they can be mated to obtain homozygous mutant embryos or mice, depending on whether or not the gene is essential for development.

Conditional Gene Targeting

The process described in the preceding section results in the inactivation of a target gene from the beginning of embryogenesis. In this situation, an embryo will become non-viable at the first point at which expression of the inactivated gene becomes essential for survival. However, it may be highly desirable to study the function of a gene product in many later events during development or adult life. Conditional gene targeting allows the inactivation of a gene in particular tissues or at particular times during development or adult life (14–16). This technology has been developed more recently, and has proved more difficult to employ on a widespread basis thus far, for reasons that will be discussed.

Figure 16-1

Gene targeting in mice. (a) The scheme for targeting a deletion of an exon in embryonic stem cells. Exons are shown as black boxes along a chromosome. Restriction sites for restriction enzyme BamH1A are shown. The replacement vector is constructed such that the neomycin resistance gene (neo) is shown as an open box, in place of one of the exons. An external probe specifically does not overlap with the replacement vector. A double homologous recombination results in then integration of the vector into the chromosome, thus replacing the exon with the Neo gene. The BamH1 site within the neo gene results in a shorter BamH1 restriction fragment detected by probe after homologous recombination. (b) ES cells can be injected through a micropipette into a blastocytst, where they become part of the inner cell mass. The injected blastocyst is introduced into the uterus of a hormonally primed mouse, and gives rise to a chimeric mouse, partially derived from the ES cells, and partially from the original inner cell mass cells. If the ES cells and blastocysts are derived from strains with different coat colors, then the chimeric mouse will have a variegated coat color pattern on its fur, providing an indication of its overall extent of chimerism. In the best cases, the resultant mouse is nearly entirely derived from ES cells. (c) shows a possible pattern obtained in a Southern blot, based on the scheme shown in (a), using the external probe. A wild type mouse shows only the longer band. A heterozygous mouse shows both the wild type and gene targeted band, and the homozygous mutant shows only the shorter band, due to the presence of the BamH1 site in the neo gene. (d) the mating involved in obtaining germ line transmission of the mutation and subsequently obtaining homozygous mutant mice.



The general approach to conditional gene targeting is shown in *Fig. 16-2*. This is a variation on traditional gene targeting, in that it also relies on homologous recombination to introduce a segment of recombinant DNA into the locus of a gene in ES cells. However, whereas traditional gene targeting inactivates the gene, conditional gene targeting must modify the gene such that it can be expressed until such time as its inactivation is desired. The most commonly used approach involved the insertion of LOX sites, which are 34 base pair sites involved in site-specific recombination by Cre recombinase, and enzyme originally derived from a bacteriophage (15). Since LOX sites are rather small, it is usually possible to insert them in introns where they have no effect on gene expression. By placing two LOX sites in a gene to flank an exon, Cre can be used to inactivate a gene by recombining out the DNA segment containing the exon that was situated between the two LOX sites, thus inactivating the gene. There are experimental approaches for expressing Cre in temporally and spatially specific manners or both. Spatial or lineage specific expression of Cre is most often obtained by placing the Cre cDNA downstream of a known tissue specific promoter. Sometimes this is achieved by using homologous recombination to insert the Cre gene into the genomic locus of a gene with known tissue specific expression, such that Cre replaces the first exon of that gene. Temporally specific expression of Cre has proved more difficult to obtain. One approach is to regulate Cre using the tetracycline system for inducible gene expression (17). The other approach makes use of a fusion protein consisting of Cre and a portion of the estrogen receptor that confers steroid mediated nuclear localization (18, 19). The latter is modified to bind tamoxifen or tamoxifen-derivatives instead of estrogen. The Cre-modified estrogen receptor fusion protein will remain in the cytoplasm and therefore not be able to mediate site-specific recombination of LOX sites, until tamoxifen is administered to the mouse to induce nuclear translocation of the Cre fusion protein. This system can be used to induce recombination in embryos, when tamoxifen is administered to pregnant mice. The major obstacle to employing conditional gene targeting on a widespread basis is the availability of promoter/enhancer elements that are able to confer robust tissue or cell-lineage-specific expression of Cre recombinase. However, an increasing number of mouse strains are available that express Cre recombinase in various cell lineages within the developing and adult kidney (20). It is possible to obtain conditional knockouts restricted to nephron progenitor cells (21), podocytes (21, 22–24), proximal tubules (25–27), thick ascending limb (28), ureteric bud (29), juxtaglomerular cells, and collecting ducts (30). It is also possible to obtain vascular knockouts (31–33), though not restricted to the kidney.

As more tissue-promoter elements become available, conditional gene targeting promises to have a large impact on genetic approaches to kidney disease. As noted above, there are many genes expressed both in developing and adult kidney, where the knockout of the gene results in embryonic lethality. This precludes study of how that product of that gene might function in postnatal kidneys, or why a mutation in that gene leads to kidney disease in humans. It also raises the question of why humans carrying such mutations are able survive, albeit with a genetic disease, when mice carrying mutations in the same gene do not survive embryogenesis. Sometimes this is simply because mice and humans differ in their respective requirements for specific genes, but more often, it is because humans with genetic disease often have point mutations that lead to partial loss of function, whereas mouse knockouts often involve complete loss of function mutations. Conditional gene targeting can sometimes offer a solution to this problem, by allowing normal gene expression during embryogenesis, and then inactivating a gene in adult mice. Alternatively, there are variations on the Cre-LOX approach that allow the introduction of point mutations into mice. The introduction of point mutations into mice has been greatly facilitated by recent advancements that facilitate homologous recombination into BACs (Bacterial Artificial Chromosomes) in E. Coli (*Fig. 16-3*) (34–36). BACs are used as they contain large amounts of genomic DNA, and thus are ideal for use as gene targeting vectors. The longer length of BACs compared with shorter genomic clones should improve the frequency of homologous recombination in ES cells.

Animal Models using RNAi Approaches

RNAi technologies have had great impact across the breadth of molecular biology and the study of disease over the past 10 years (37). RNAi is based on a mechanism common to both plant and animals whereby a short strand of RNA, that is associated with a set of proteins known as the RISC complex, hybridizes to a complementary sequence in a mRNA, causes degradation or inhibition of translation of the mRNA (38, 39). In the natural setting, these small RNAs are encoded in the genome as microRNAs. The same molecular machinery used by microRNAs to inhibit expression of mRNAs can be

Figure 16-2

Conditional gene targeting. The targeting vector is different from the previous figure in that LOX sites flank the exon that will eventually be deleted, and the Neo gene is flanked by Frt sites. The vector is incorporated into the chromosome through homologous recombination, and ES cells with this knock-in are used to make chimeric mice, and germline transmission is obtained. Although the LOX sites should not interfere with expression of the gene, the Neo gene is likely to interfere with normal gene expression. However, in most cases mice will tolerate one inactive gene, as long as the other allele is functional. After obtaining heterozygous mice, they are mated with Flp – deleter mice, that express Flp recombinase in germ cells. Flp will recombine the FRT sites and eliminate the neo gene. Mice without the neo gene, but still containing the exon flanked by LOX sites, are mated with mice expressing Cre in a particular tissue or cell type, or expressing an inducible Cre, to obtain the conditional knockout. The breeding scheme shown in the figure is oversimplified. In the actual experiment, a more complicated breeding scheme is required to obtain a mouse that is homozygous for alleles with LOX sites, and that also has the Cre-expressing transgene. An alternative is to breed mice with the conditional allele with mice carrying a traditional knockout. This has the advantage that to obtain the conditional knockout, Cre must only recombine one, and not two, pairs of LOX sites in each cell.

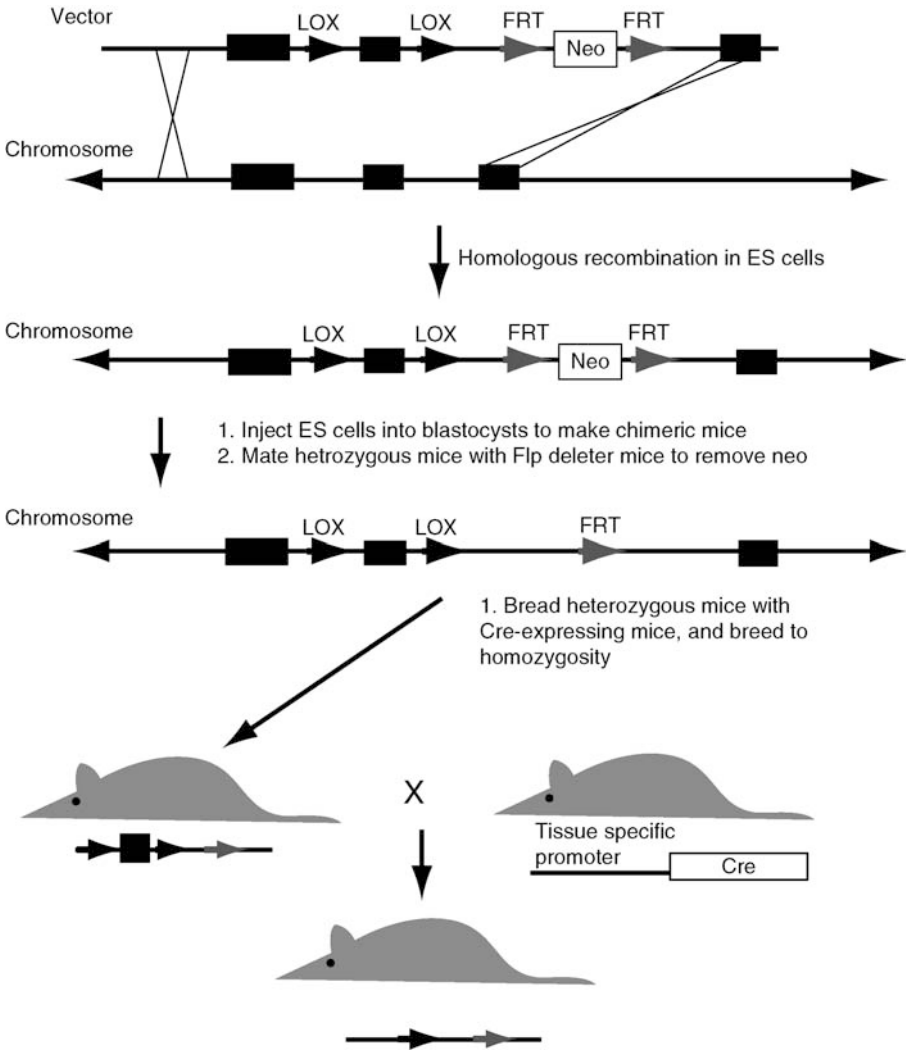


Figure 16-3

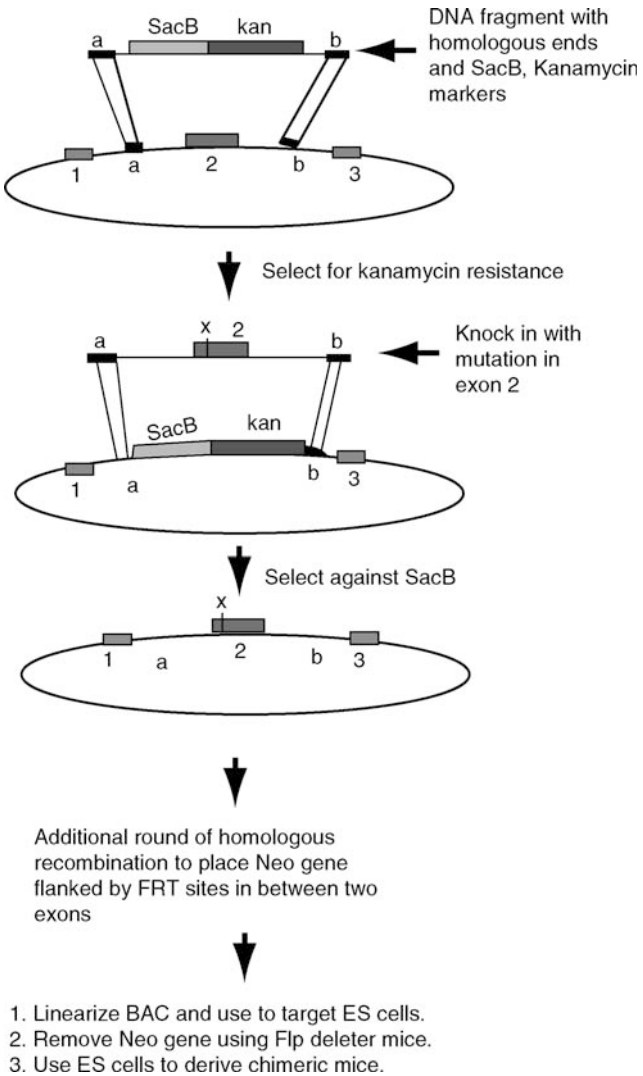
Gene targeting using BAC clones. Homologous recombination is done in E. coli instead of in ES cells. In the first step, a DNA fragment is prepared that contains the kanamycin resistance positive selectable marker and the SacB negative selectable marker, and which also contains homologous ends (A and B, each about 50–60 bp) is introduced into E. coli. This fragment can usually be prepared by PCR, using primers that contain the homologies to the genomic region, and also to a vector containing the selectable markers. Usually, a strain of E. coli is used that allows transient activation of the enzymes required for homologous recombination. Selection for kanamycin resistance will obtain BAC clones where the selectable markers have recombined into the BAC. In a second round of homologous recombination, A DNA fragment with the same homologous ends but containing a mutated exon 2, denoted by the "X," is introduced into the E. coli containing the BAC. Selection against SacB will obtain BACs in which the mutated exon 2 has replaced the selectable markers. A third round of homologous recombination is used to insert the neo gene, flanked by FRT sites, so that the BAC can be used for homologous recombination in ES cells. As shown, this scheme is used to introduce point mutations or small deletions into a gene. It can also be used to construct conditional knockout vectors, similar to those shown in *Fig. 16-2*. An additional use is to knock-in a Green Fluorescent Protein (GFP) or β-galactosidase (LacZ) reporter gene into a locus to obtain information about patterns of gene expression.



co-opted for use by siRNA (silencing RNA) or shRNA (short hairpin RNA) that are ectopically expressed in cells. siRNA refers to RNA duplexes that are usually obtained commercially and transfected into cells. shRNA refers to small RNAs that are expressed from plasmids or viral vectors that are introduced into cells. A major addition to the arsenal of approaches involving transgenic mice involves the derivation of transgenic mice that express shRNA molecules capable of reducing levels of mRNA for specific genes in specific tissues or cell lineages (38–41). shRNAs can be expressed either constitutively, or conditionally using the Cre-Lox system (*Fig. 16-4*). An advantage of shRNA technology over gene knockouts is that it is quicker and cheaper, as mice do not need to be bred to homozygosity and also to carry the Cre transgene. Instead, a resulting phenotype can be obtained by mating a Cre-expressing mouse with a mouse carrying a conditional shRNA transgene, and examining the first generation offspring carrying both transgenes. The major disadvantage in comparison with gene knockouts is that expression of the target gene may be variably reduced, and it may be necessary to examine several shRNA transgenic lines in order to obtain ones that demonstrate efficient knockdown of the desired gene.

Transgenic Mice

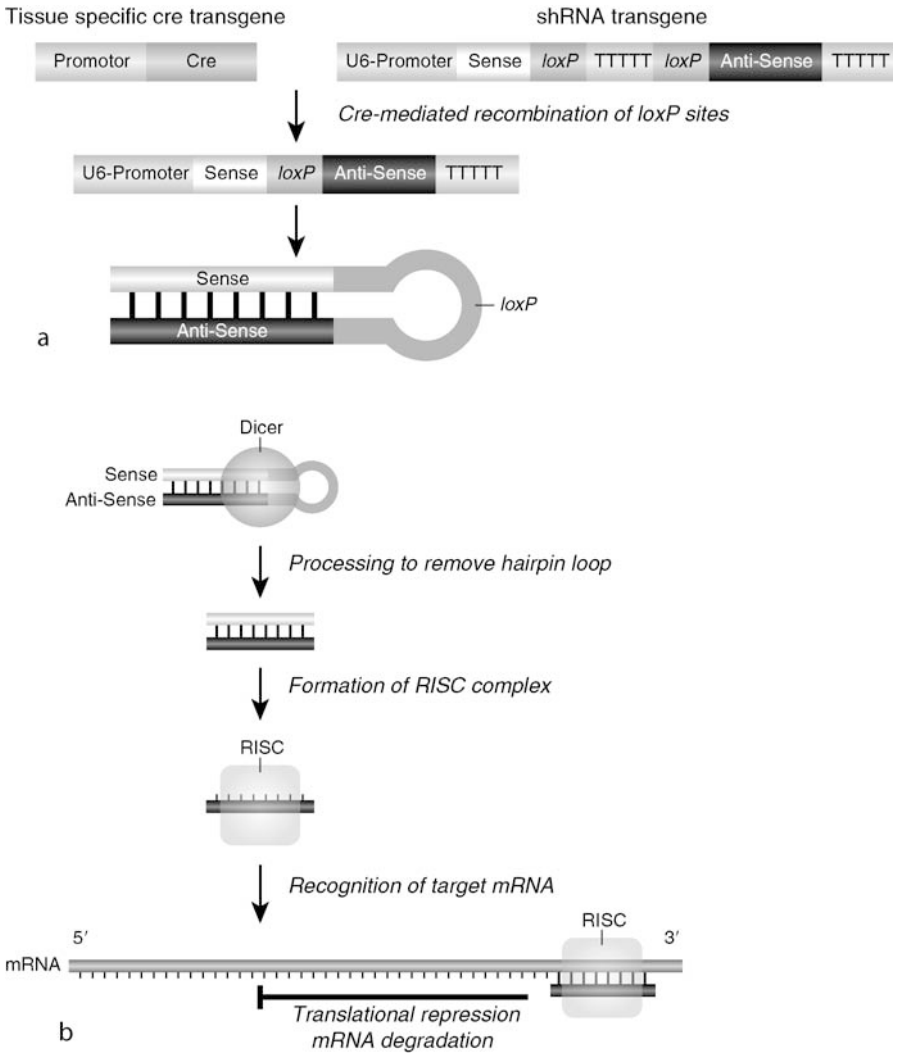
As mentioned above, many mutations that result in human disease are point mutations that result in "hypomorphic," or partial loss of function alleles of a gene. In this case a disease state may result from decreased activity of a gene product. In other cases, a point mutation or deletion mutation may produce a protein that interferes with the function of the normal gene; this is referred to as a dominant negative effect. This could occur in instances where a protein requires homodimerization for activity, and dimerization of a wild type and a mutant form of a protein leads to an inactive complex. Dominant-negative effects can also be found in cases where two proteins heterodimerize, and an inactive mutant protein is able to complex with its partner protein, but as before, the complex is inactive. Dominant – negative effects can be studied in animal models using transgenic mice. Although gene targeted mice discussed in the previous sections can also be considered to be transgenic, because foreign DNA is used to disrupt the endogenous gene, here the term "transgenic" is reserved for those mice in which foreign DNA has been inserted into the murine genome through pronuclear injection (42–45). In contrast to gene targeting schemes in which genes are modified in ES cells, and ES cells are then used to derive chimeric mice, transgenic strategies, DNA is directly microinjected into the pronucleus of a fertilized egg or zygote, and the injected zygotes are then reimplanted into the oviduct of a hormonally-primed female mouse. The injected DNA is able to recombine by non-homologous, or illegitimate recombination into random locations within the genome, and in variable amounts from zygote to zygote. Once mice are derived from the injected zygotes, they are tested to determine if they carry the injected DNA within their genomes as a transgene, and if they do, whether the transgene is expressed. By injecting DNA constructs that contain a tissue-specific promoter and a mutated gene of interest, it is possible to study whether expression of the mutant gene leads to an observable phenotype. In other instances, the gene to be expressed is not mutated, and the experiment is designed to determine if overexpression or de novo expression of the gene results in an observable phenotype or disease model. While the original transgenic studies used relatively short DNA constructs, more recent studies have used BAC (bacterial artificial chromsome) or YAC (yeast artificial chromosome)-based vectors whose much longer stretches of DNA containing promoters and other regulatory regions will hopefully confer more faithful patterns of expression of the transgene directed by those regulatory elements (42, 46). The great majority of transgenic work has been done in murine models, but there have been pioneering efforts in other species such as pigs and rats (47, 48).

Mutagenesis in Zebrafish

Possibly the single most important advancement in the development of novel animal models for kidney disease over the past 10 years is the establishment of zebrafish (*Danio rerio*) as a major model for understanding the genetic and physiological basis for disease. Zebrafish models of glomerular development and disease and polycystic kidney disease have been particularly useful models for study of human disease (49–55). Zebrafish are much less expensive to maintain than mice, and genetic tools to map zebrafish mutations nearly equal or in some cases extend beyond those available for mice (56–58). The zebrafish excretory system involves a pronephric duct and glomus that bears important similarity to mammalian nephrons, and has already been the subject of many research studies (49, 59–65). Two great advantages of Zebrafish are (1) their shorter

Figure 16-4

Conditional expression of shRNA transgenes. (a) Mice containing a Cre recombinase-expressing transgene and a shRNA transgene are crossed to obtain embryos or offspring mice containing both transgenes. The shRNA transgene contains a U6 promoter to direct RNA polymerase III mediated transcription, that is terminated by a poly-T sequence. It also contains a sense and anti-sense sequence, designed to target a mRNA, that will become the double stranded RNA that associates with the RISC complex to mediate the inhibitory effect on mRNA stability or translation. Therefore, transcription of the shRNA transgene is interrupted prior to Cre-mediated recombination of the first poly-T sequence. After removal of the first poly-T sequence by Cre-mediated recombination of the two LoxP sites, the transgene is fully transcribed and terminates at the second poly-T sequence. The resultant shRNA forms a hairpin loop by base pairing of the sense and ant-sense sequences. (b) The shRNA associates with DICER, an RNase III class enzyme that removes the hairpin loop. The double stranded RNA then associates with the RISC complex, the sense strand is removed, and the RISC complex with the anti-sense RNA finds its target mRNA and suppresses translation or decreases mRNA stability.



developmental timing, and (2) that development occurs in nearly transparent embryos that develop outside the mother, allowing for far greater observation and intervention than is possible with rodent embryos. The Zebrafish genome is presently being sequenced at the Sanger Center (66), and a full set of markers exists for gene mapping (57, 67, 68). Importantly, Zebrafish are not inbred like inbred mouse strains and there exists genetic

heterogeneity between isolates used in different laboratories. It is possible to make transgenic Zebrafish, though gene targeting is not yet possible (69–71). However, there have been large scale efforts to saturate the Zebrafish genome through insertional mutagenesis (72–74). An alternative to gene targeting is the use of morpholio oligonucleotides that inhibit expression of specific genes against which the morpholino is targeted; these can be injected into cells of early embryos, and phenotypes can be observed at various developmental stages thereafter (75, 76). In one sense, morpholinos have an advantage over gene knockouts, in that they can be designed to block expression of specific alternative splice forms (75), rather than all forms as is often the case with gene knockouts in mice.

Gene Identification- Phenotype to Genotype

Mutational Screens to Obtain New Phenotypes and Identify Genes

ENU mutagenesis: At present, several major efforts in several countries involve the use of N-ethyl-N-nitrosourea (ENU) to introduce small mutations throughout the mouse genome (77–82). Similar approaches have been used with Zebrafish and many interesting phenotypes have been obtained (83–87). These large genome-scale approaches, which can involve very large mouse or Zebrafish colonies, are justified by the following arguments: (1) Most disease-related human mutations are caused by point mutations, therefore a ENU-mutagenic approach may have a greater chance of producing a phenotype resembling a human disease than will gene-targeted mutations that usually completely inactivate a gene; (2) an ENU-based approach does not rely on previous identification or cloning of the gene, i.e., any gene is a theoretical target, and can be studied, to the extent that some degree of compromise in the gene product's activity will result in an observable phenotype. The obvious disadvantage in comparison with gene targeting is that a large amount of work lies between the observation of a phenotype and the final identification of the mutated gene. (3) Given a large enough effort, it should be possible to eventually "saturate" the genome with mutations, i.e., examination of several hundred thousand mutagen-treated mice or Zebrafish is likely to provide the opportunity to observe the effects of placing a mutation in every gene capable of causing an observable phenotype. However, one important point remains to be mentioned, that dramatically increases the labor and expense of an ENU-based effort. Most observable phenotypes tend to be genetically recessive instead of dominant, meaning that they are not apparent in the first generation offspring of mutagen-treated animals. Instead, it is necessary to breed a second generation and then backcross it to the first generation mice (or Zebrafish), resulting in a third generation (*Fig. 16-5*). Doing this on a large scale will result in many third generation animals that are now homozygous for mutations resulting from the original mutagenic treatment, and some will have observable phenotypes that can be studied for biological interest and to map the responsible gene.

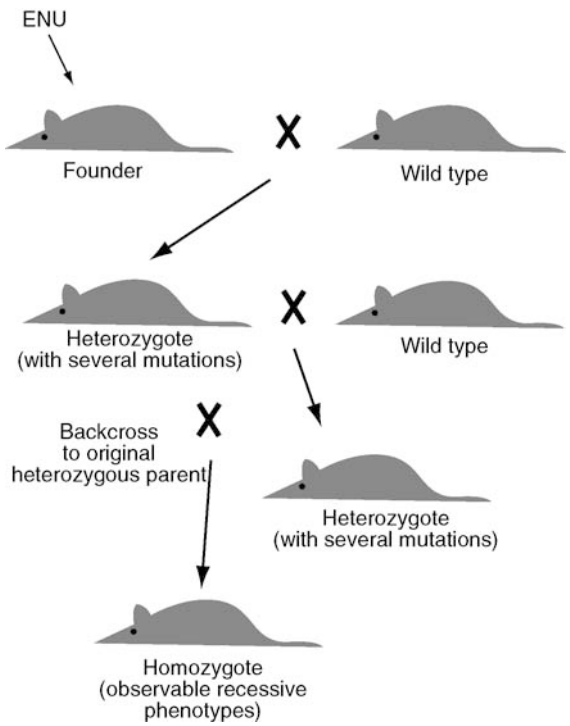
These large scale genetic approaches are not only suited to study developmental anomalies. Some of the large-scale efforts on mouse mutagenesis ongoing around the world will involve performing basic blood work and a urinalysis on each mouse from the group being screened for new phenotypes. Thus this approach has the potential to identify genes involved in disease progression, as well as those responsible for morphogenetic processes.

Gene Identification

Microsatellite repeats: Mapping sites of induced or spontaneous mutations in mice has been greatly aided by the development of sets of microsatellite repeat markers. Microsatellite repeats used in mapping are stretches of CA dinucleotide repeats that are found interspersed throughout mammalian genomes (88, 89). Typically, these CA repeats contain 10–20 CA dinucleotides. These CA repeats are flanked by unique sequences, and thus it is possible to design pairs of PCR primers that correspond to these flanking sequences, that will amplify the $(CA)_n$ sequence between the two primers. Within a genetically inbred strain of mice each individual mouse will contain the same number of CA dinucleotides at each repeat. However, similarly to the variation observed between human individuals, different inbred strains may differ in the number of CA dinucleotides at any particular repeat. Additionally, there are species of mice closely related to *mus musculus*, such as *mus spretus*, that provide even greater differences in the number of CA dinucleotides at many repeats than are found between the inbred strains of mus musculus. As depicted in *Fig. 16-6*, genetic mapping using microsatellite markers takes the following approach: A mouse (or mice) with a phenotype produced by induced or spontaneous mutagenesis is mated with a mouse from a different inbred strain, or from a different species, such as mus spretus to produce F1 mice that are now

Figure 16-5

ENU mutagenesis. A scheme is depicted for finding recessive phenotypes through ENU mutagenesis. Dominant phenotypes require a less complicated approach, as phenotypes will be apparent in the first generation derived from crossing founders with wild type mice. In this scheme, a mutagenized male founder that probably carries many mutations after mutagenesis, is mated with a wild type mouse to produce heterozygote offspring that carry a subset of these mutations. These heterozygotes are mated with wild type mice to produce a second generation, which will carry a smaller subset of the original mutations. These are then mated to the original heterozygous offspring of the founders, and 25% of the offspring of this cross will be homozygous for any particular mutation that was present in the second heterozygous generation.

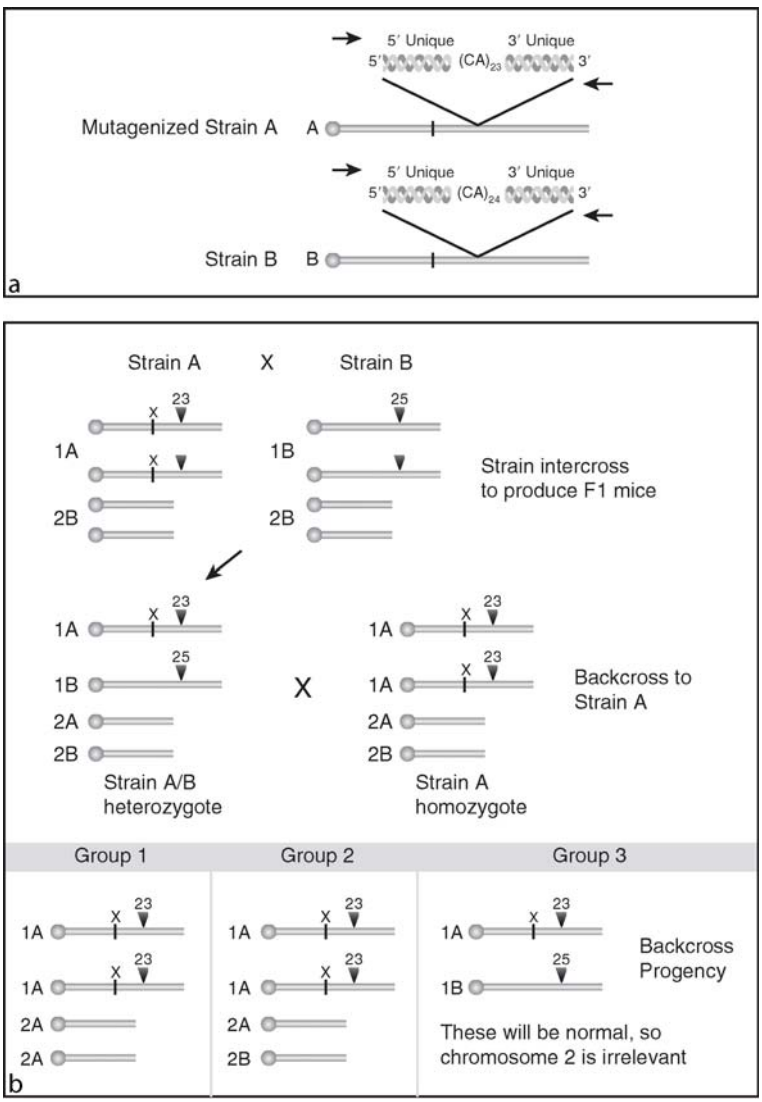


heterozygous at all loci, containing one allele from each of the two parental strains, and one mutant allele. In the case of a recessive phenotype, these F1 mice are now either backcrossed to the original mutant strain, or intercrossed among themselves, to produce approximately 100 progeny mice, about 25% of which can be expected to show the mutant phenotype. For dominant phenotypes, the backcross can be to a wild type mice of either parental strain, and 50% will display the phenotype. Importantly, during this back- or intercross, there is independent segregation of chromosomes, such that each individual of the 100 mice is genetically unique, in that at any given locus, it may be homozygous for alleles from a parental strain, or heterozygous, containing an allele from each strain. A set of PCR primers corresponding to about 40–50 microsatellite repeats (about 2–3 per mouse chromosome) are used in the first round of analysis. These are chosen such that the two parental strains are know to differ in the length of the CA repeat between each primer pair. DNA samples are now obtained from all the progeny, and are tested for the length of the CA sequence at each of the 40–50 microsatellites, and these results are correlated with the observed phenotypes (in practice, a computational result, called a LOD score is produced). Most of the microsatellites will not be genetically linked to the locus containing the mutation, and there will be no observable correlation between the strain genotype at a particular microsatellite and the presence or absence of the phenotype. In contrast, if a microsatellite marker is sufficiently closely linked to the site of a mutation causing a recessive phenotype, both alleles of the microsatellite marker are more likely to be derived from the parental strain originally containing the mutation. Thus, the goal of the first round of screening is to identify at least one marker that is linked to the mutation. Thereafter, subsequent rounds will use sets of markers linked to the original positive marker, with the expectation that it will be possible to identify a marker or pair of markers very closely linked to the mutation that will delimit the region of a single chromosome on which the mutation is located. This can then be used to initiate either a candidate gene approach or a chromosome walking approach to eventually identify the mutated gene.

SNPs and haplotype mapping: Newer more efficient approaches to mapping genetic elements are presently replacing the use of microsatellite repeats described in the previous section. Chief among these are the use of SNP microarrays. SNPs, or single nucleotide polymorphisms, are single base pair differences found between individuals within a species. Among the human population, SNPs tend to be found every 100–300 base pairs within the genome, and can be used as a measure of genetic relatedness among, for example, ethnic groups, or people in different geographic areas (90). SNPs are also found in comparing different inbred strains of mice and between the commonly used laboratory inbred strains that are all derived from *mus musculus* and other mouse strains that are "non-*musculus*" that can be intercrossed with mus musculus strains to aid in genetic mapping, as described above (91). In contrast, within a particular inbred strain of mice, there is by definition genetic homogeneity, and

Figure 16-6

A scheme for mapping a mutation to a genetic locus. (a) depicts the use of microsatellite CA repeats. Strains A and B are two inbred strains of mice, that differ in the length of many CA repeats, including the one shown here. Strain A has 23 CA dinucleotide repeats, whereas strain B has 25. They have the same unique 5′ and 3′ sequences flanking the CA repeats, thus the same PCR primers can be used for both strains, but amplification will yield a longer product from strain B than A. (b) The mating scheme to begin mapping the mutation. Only chromosome 1 and 2 are shown. Strain A has a homozygous mutation on chromosome 1, marked as an ''X,'' that is linked to the CA repeat, here designated by the black inverted triangle. This recessive mutation yields an observable phenotype. Strain A and B are mated to produce an F1 progeny, which will be heterozygous at all loci, including the one mutated in strain A. They will also be heterozygous for all CA repeats, including those on chromosome 2. Thus any CA repeats that differ between the two strains will yield two bands on a PCR reaction using the flanking unique primers for that CA repeat. F1 mice are backcrossed to Strain A homozygotes, and many offspring are examined. 50% of these offspring should be homozygous for X and have the observable phenotype. When these mice are analyzed for the CA repeat close to the locus for X, most mice with the phenotype will show only the strain A amplification product, whereas most of those without the phenotype will show both the strain A and strain B bands. In contrast, amplification of any CA repeats from chromosome 2 or any other chromosome, will not show any correlation of strain A homozyosity with the observed phenotype.



SNPs should not be present between individuals of the same strain. SNPs are also used to map genes in Zebrafish (68). See also *Fig. 16-7*.

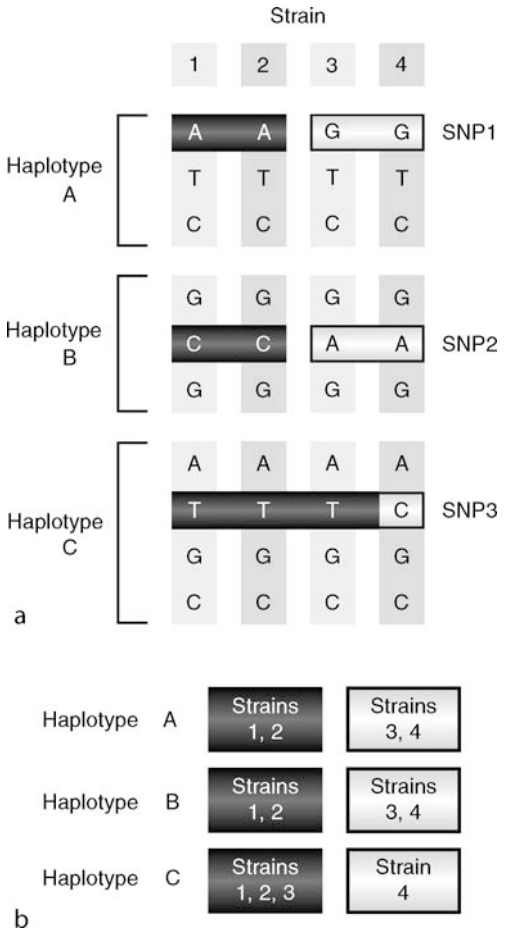
It is now possible to detect SNPs using microarrays (92, 93), such that thousands of oligonucleotides complementary to sequences containing known SNPs can be arrayed on a single microarray chip, and hybridized to an individual human or animal's DNA to determine which of thousands of particular SNPs that individual has in their genome (94). SNPs can be used as genetic markers similarly to the microsatellite repeats described in the previous section. Therefore, a single microarray can provide the same information as hundreds of PCR reactions. To be used in a genetic mapping experiment, the same type of inter-specific cross would be performed as described in the previous section, but instead of using PCR reactions to analyze the segregation of microsatellite repeats, a microarray is used for each individual to analyze the segregation of SNPs, to narrow the interval that contains the gene being mapped.

QTL and Haplotype Analysis

Almost all human disease has a genetic component, whether it is the relative susceptibility to an infectious agent, at one end of a spectrum, or a disease that is primarily due to a genetic mutation in a single gene, at the other end. Between these two extremes lies most human disease, whose etiology derives from a combination of genetic and environmental factors. In many instances, the genetic component is due to the effects of more than one gene. In other instances a single gene might be responsible, but the phenotype is not absolute, but rather of variable penetrance or severity. A genetic elements that contributes to a disease phenotype in a quantitative, as opposed to absolute, manner is referred to as a quantitative trait locus, or QTL (95). It is probably not an overstatement to say that most genetic components of disease occur as QTLs, and indeed, there are over 2,000 known QTLs that have been reported (96). Herein, however, lies the difficulty, as there are not standardized criteria for defining a QTL (95). Moreover, despite this enormous number of reported QTLs, only in the case of around 20–30 QTLs, depending on the criteria used to judge, have the responsible genes been identified and rigorously proven to be responsible for the disease phenotype (96). This is both due to the difficulty in identifying genes responsible for phenotypes in complex genomes, but also because in situations where a phenotype

Figure 16-7

SNPs and haplotypes. (a) A highly simplified of schematic of SNPs and haplotypes is depicted. Four mouse strains, labeled at top are compared. A three nucleotide stretch is shown for haplotypes A and B and four nucleotides for C, though in reality a haplotype may span megabases and be defined by hundreds or more SNPs. The sequences in haplotypes A, B and C are not necessarily contiguous and might even be on different chromosomes. In haplotype A, SNP1 is present at the first nucleotide, in haplotype B, SNP2 is present at the second nucleotide, and in haplotype C, SNP3 is present at the second nucleotide. (b) Haplotype grouping defined by the SNPs. For haplotypes A and B, strains 1 and 2 are the same haplotype, and 3 and 4 define a different haplotype. For haplotype C, strains 1, 2 and 3 are the same haplotype, and strain 4 is a different haplotype, suggesting that strain 3 might be more closely related to strains 1 and 2 than is strain 4. If strains 1 and 2 differ from 3 and 4 for a disease phenotype, it is more likely that the gene is within the area covered by haplotypes A and B, than within haplotype C, that is shared between strains 1, 2 and 3.



may be due to the combined actions of many genes, the contribution of any individual gene may be modest and difficult to prove in an experimental setting.

Nevertheless, many animal models of human disease appear to be caused by one or more QTLs, and the identification of the responsible gene(s) is a pursuit of many research laboratories. Importantly, comparisons of syntenic regions between human and rodent genomes has aided the search for genes at QTLs, as it is often apparent that a QTL identified in humans corresponds to a QTL for a similar phenotype in rodents (97). Comparisons of syntenic regions can also be complicated, as a region harboring a QTL in a rodent genome, if not already delimited to a narrow interval, may be syntenic with several regions of the human genome, that are found on different chromosomes.

The approach to identifying QTLs is similar to that used to detect monogenic phenotypes, that involved the detection of microsatellite repeats or SNPs described above. However, QTL analysis is much more complicated than the analysis of monogenic phenotypes, as one is likely to find multiple regions that appear to be linked to the phenotype, and no single region will stand out as the obvious candidate, until much larger numbers of individual animals or humans are analyzed to obtain statistically significant genetic data for each of several candidate genes.

Haplotype analysis has the potential to make gene identification by SNP mapping more efficient (97–99). Haplotypes are defined as a group of genetic markers that are physically linked on chromosomes and that tend to be inherited together more often than might be predicted if genetic recombination events were evenly distributed along chromosomes. Perhaps the best know examples are the major histocompatibility loci, HLA in humans and H2 in mice. It is now known that haplotype units exist throughout mammalian genomes, and that SNPs can be used as markers to define haplotypes (97–99). It then follows that inbred mouse strains that more closely genetically related are likely to have the same haplotype at a particular genomic location, whereas more distantly related strains would be more likely to have different haplotypes (97, 98). Thus, when SNPs are being analyzed in the progeny of a genetic cross in an attempt to narrow down the location of a candidate gene, haplotype analysis provides an alternative to considering each SNP individually. For example, if strains A and B are being studied with the aim of identifying a disease related QTL only present in strain A and strain B being normal, then genomic areas where strains A and B share the same haplotype are unlikely to harbor the disease locus, whereas areas of the genome where they have differing haplotypes are more likely to have the disease locus. Therefore, consideration of haplotypes, each of which may contain hundreds of SNPs, may allow a means of focusing on candidate genes within differing haplotypes, and ignoring those located within regions where the affected and unaffected strains share the same haplotype, that might otherwise be suggested for further study through a SNP analysis that did not take haplotypes into account. In practice, such an analysis may involve multiple strains of mice and crosses between them in an effort to narrow a genetic interval and physically locate a QTL (100, 101).

Implications of Genome Sequencing

Sequencing of the entire human genome was completed in 2001 (102, 103) and of the mouse genome in 2002 (104). These continue to be refined, with more detailed reports and annotations of the sequence of specific human chromosomes published from 2003 to 2006. As of this writing, the sequences of approximately 180 organisms, including bacteria, plants and animals have been reported. This rapidly expanding database has transformed modern biology and the study of disease, and newer high throughput sequencing technologies promise an even more rapid expansion in of sequence data in the near future (105). For example, in gene mapping studies described above, it is no longer the situation that a disease gene might be mapped to an area within a chromosome that had never been sequenced, and the hunt for the gene becomes a large scale sequencing project. Now, once an area is delimited, the candidate genes in that area are largely known from prior genome sequencing, allowing much more directed sequencing to be done in attempts to find disease-causing mutations. The genome sequences for most, if not all, animals used as disease models is also known, greatly accelerating studies such as those involving disease-related gene identification in animal models. A major frontier in genome sequencing related to disease models is not so much the sequencing of additional species as it is the sequencing of multiple genomes within a species, so that we can increase our understanding of intra-species genetic variation, and how it relates to disease susceptibility (105–107).

Other Animals in Nephrology Research

The emphasis on mice and Zebrafish thus far in this chapter is not meant to overlook the enormous benefit that has derived from the use of other species. Despite

some pioneering efforts, gene targeting technology has not been developed in rats. However, ENU mutagenesis has been used to obtain rat mutant models of disease and gene mapping of disease phenotypes in rats has yielded important insights (108–112). Rats have also been widely used in studies of nutrition as it related to kidney development and disease (113). Furthermore, their larger size makes rats more amenable to studies that require precise physiological monitoring or imaging, though the technology to perform such studies in murine models, to take advantage of knockout mouse models, has also improved dramatically (114–121).

Large animal research have also had an important legacy in nephrology that continues to this day. Historically, several animal models have been used to study renal physiology, including swine, sheep, guinea pigs, rabbits, rats and mice. Fetal lambs have been a particularly important model in which developmental aspects of physiology have been studied, particularly relating to obstructive uropathy (122–134). Studies in large animals are also vital in efforts to use tissue engineering to develop artificial tissues or in models of tissue regeneration (135–137). As in other situations, there is a constant need to balance the advantages of a large animal model with the lower costs of smaller animals models.

Models of Renal Failure

Approaches to the study of renal failure include acute and chronic models. Acute renal failure has been induced using pharmacological agents, antisera against kidney tissue or other antigens in which immune complex formation leads to glomerular disease (138–144). Ischemia-reperfusion models of acute renal failure are achieved by temporarily ligating a renal artery allowing study of the pathological processes involved in tubular damage, as well as the effect of various pharmacological treatments on the pathologic process (e.g., (145–165)). An alternate form of tubular injury involves temporary obstruction of a ureter (166–168). Combining these injury models with genetic models is an emerging frontier in nephrology research.

Models of Immunological Injury

There are many models of autoimmune injury to the kidney. A traditional model for a lupus-like autoimmune disease is the NZB mouse, that has been studied for many years (169–173). These mice develop autoantibodies similar to those observed in humans with systemic lupus erythematosis and other related autoimmune disorders. More recently, many strains of mice carrying mutations in genes involved in the regulation of the immune response have been used to increase our understanding of the role the immune system plays in the onset and progression of kidney disease (174–184). These knockout strains have allowed investigators to begin a genetic dissection of genes involved in autoimmune and other disorders. Transgenic technologies have also had an important impact in the development of new immunological models. One particular contribution is the use of live-cell imaging that exploits fluorescent transgenic reporter genes which mimic the expression of genes expressed in specific immunological cell types (185, 186). These can be used either to trace the location of these cells in animals, or to show evidence of gene expression in an in vivo setting.

Transplant Models

Animal models have been used extensively to study transplant rejection, and in efforts to understand how tolerance to transplanted tissue may be improved. Over the past 20 years there has been an extraordinary advancement in our mechanistic understanding of the immune function, and this has been brought to bear on the study of transplant rejection and tolerance (187–193). Important models under study include skin and heart transplants in mice, and kidney transplants in rats (194–201). Additionally, it is possible to produce "humanized" mice by transplanting human tissue into immunodeficient or irradiated mice whose immune system has been reconstituted with human lymphocytes, thus allowing the study of human immune function in an animal model (202–205). One area of research that remains controversial is that involving xenografts (206, 207). Since the supply of human kidneys and other organs for transplants continues to fall far short of the demand, there is a desirability of determining whether non-human animals provide an alternative source of organs for transplantation. The major concerns here include the strong immunological rejection to a xenograft that must be overcome, and the danger that xenografts might serve as vectors for the introduction of novel infectious agents into the human population.

Summary

Animal models are of increasing importance in the study of kidney disease. An important shift over the past 10 or

more years is the use of rodent models, and the use of genetic models. Large animal use remains an important aspect of these studies. The use of large versus small animals must take into account cost and ethical considerations.

17 Clinical Investigation

Susan L. Furth · Jeffrey J. Fadrowski

Clinical Research Question

How can we best evaluate, treat, and assess long-term risks for children with kidney disease? Who is at risk of developing end-stage renal disease (ESRD) in childhood or young adulthood? Clinicians are often faced with questions such as these with uncertain answers in the practice of pediatric nephrology. Parents ask, "Why did my child get this disease?" "What is the most effective method to treat this condition?" "What's the prognosis of this condition in my child?" Frequently, these answers are not known, and these questions are the inspiration for high-quality clinical research. The first step in developing a valuable clinical study is determining whether the initial query can be translated into a good research question.

Hallmarks of a Good Research Question

A good research question gives *useful* information, is interesting to the researcher, builds on what is known, and can be answered with available resources. Research is a labor of love, demanding attention to detail, perseverance, honesty, and imagination. Developing a good research question is an iterative process. One needs input from knowledgeable colleagues and collaborators. The researcher must become thoroughly familiar with what is already known about the topic by reviewing the literature and consulting with experts in the area. Investigating what is already known has several benefits. First, it can reveal that the candidate research question has already been answered adequately. Second, learning what is already known provides insight into potentially useful methods for addressing a research question. For example, previous studies may demonstrate good ways to measure a variable of interest or provide background information for determining sample size. Third, a literature review may suggest ways to frame the research question at hand. For example, a literature review may reveal that particular risk factors are consistently associated with a disease process, and an intervention to modify these risk factors may form a sound basis for a clinical trial.

Finally, a good research question needs to be answerable with available resources. These include subjects available for study, technical expertise of the research staff, and the time and money that can be devoted to the project. Once a question is framed, the researcher needs to outline the study protocol or methods, which include specifying the recruitment method, number of subjects and how they will be recruited, how each variable will be defined, and the plan for data analysis. A poorly designed study is worse than no study at all because, like imprecise measurements and an improper analytic plan, it can also lead to false conclusions.

Steps in Refining a Good Research Question

A good research question usually begins with a broadly stated concept. The initial question is then made more specific by identifying independent and dependent variables. Often, research questions are concerned with causal relationships. *Independent variables* are those conceptualized to be causes; *dependent variables* are those conceptualized to be effects. The research question can be modified to ask about the role of multiple potential causes in leading to the specific outcome. A simple research question asks whether x (independent variable) causes y (dependent variable). More complex research questions could assess the relative importance of x and other variables (e.g., a and b) as causes of y. A different research question might ask how strongly x predicts y in one population versus another.

The next step is to translate a research question into a hypothesis. In our simple example, the researcher may hypothesize that x causes y. In the actual research project, the information collected is examined to determine whether it is reasonable to conclude that x does cause y. In examining the data, the investigator tests the *null hypothesis* that x does not cause y versus the *alternative hypothesis* that it does.

Scientific Method

A study's potential value is determined by the relevance of the research question. Its ultimate worth is determined by

© Springer-Verlag Berlin Heidelberg 2009

the study methods. Methodologic issues concern the study design, subject selection, data collection techniques, and the analytic plan. Subsequent sections in this chapter discuss each of these aspects. As a foundation, this section describes the concepts of inference, generalizability, and validity.

Inference

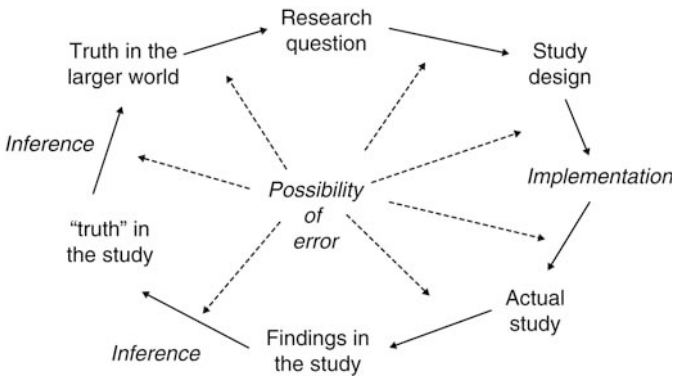
As *Fig. 17-1* shows, scientific research begins with the research question. It then moves (clockwise in the figure) to the controlled arena of the study design and then through the implementation of the actual study and findings. Inferences from the findings in the study approximate the "truth in the study." From these "truths" we attempt to infer the applicability of the findings to general clinical practice. Researchers describe and explain reality by sampling a portion of it, measuring characteristics of the sample, analyzing the measurements, and interpreting the results. Errors in the design or implementation of the study can lead to false conclusions. The strength of inference depends largely on the research methods used in the recruitment of study subjects (sampling) and in the choice and integrity of the study design. At any stage in study design and implementation, bias can occur. Bias is the result of any process that tends to produce results that depart systematically from the truth. Three broad categories of bias include selection bias, measurement bias, and confounding bias. Selection bias arises if the manner in which subjects with the outcome of interest and the comparison group were selected yields an apparent association when, in reality, exposure and disease are not associated. Measurement bias occurs when the methods of measurement systematically differ between groups. Confounding occurs when a factor is associated both with the exposure and the outcome and the effect of the main exposure under study is confused or distorted by the confounder.

Statistical inference depends on the methods used to define and sample the population. The researcher uses inferential statistics to *extrapolate* the sample findings to the larger population of children from which the sample was drawn. Inferential statistics assume that the studied sample is drawn by probability methods and can be used to make inferences about the larger population. The size of a probability sample determines the certainty of inferences from it. All other things being equal, the larger the sample size, the greater the certainty of inferences to the population.

The researcher's ability to make a *causal inference* from study results depends largely on issues of study design. Study designs are *observational* when the investigator does not manipulate the risk factor but merely selects children with and without disease and compares them in terms of the risk factor(s). Study designs are *experimental* when the investigator not only observes but actually manipulates the *relationship* between two variables. Observational designs provide somewhat weaker evidence of causation, because they fail to rule out explanations other than association between the variables studied. Experimental designs can provide much stronger evidence for causation. In an experimental study, the investigator controls the independent variable, which is the factor hypothesized to produce change in a dependent variable. In an experimental study, subjects are randomized to receive or not receive the independent variable. The goal of the process of randomization is to produce

Figure 17-1

The role of inference in drawing conclusions from clinical research studies.



study groups that are "balanced" in terms of other factors that could influence the dependent variable. Unfortunately, experimental designs often are not feasible, ethical, or desirable. Epidemiologic studies of disease preclude manipulation of risk factors in humans. Health services researchers studying the public health impact of changes in health policy rarely can control these changes.

Within the broad categories of observational and experimental designs, there are many variations. These variations, distinguishing characteristics, primary uses, strengths, and weaknesses are discussed in the section Study Design. Study design also influences the validity of study results.

Validity

Validity is the extent to which study findings correctly reflect and explain reality (Fig. 17-2). Validity can also be thought of as accuracy. Systematic bias undermines validity. As a research question's relevance increases, so does the need for validity. The clarity and rigor of study design as well as the careful implementation of the research plan increase the likelihood that inferences from the study are valid.

Cook and Campbell (1) define several *aspects* of validity. *Statistical validity* is the correctness of study conclusions regarding the existence of a relationship between two variables. A study lacks statistical validity when it concludes there is no relationship between variables when in fact there is one or when it concludes there is a relationship when in fact there is none. Statistical validity is jeopardized most often by inadequate sample size and by improper use of statistical tests.

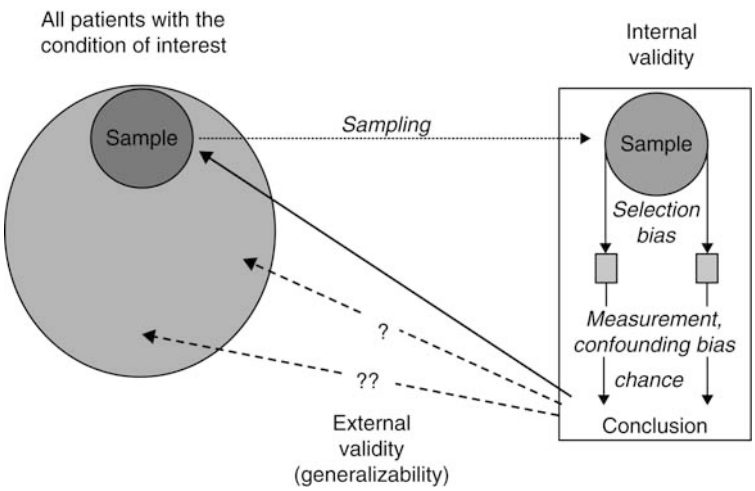
If there is a relationship between two variables, *internal validity* is the correctness of conclusions about whether the relationship between the independent and dependent variables is causal. Internal validity is jeopardized when a study design fails to control for factors that could confound the hypothesized causal relationship.

Finally, given a causal relationship between the independent and dependent variables, *external validity* is the correctness of generalizing to other persons, settings, and times. Poor choice of a study population and inadequate research procedures are common challenges to external validity.

Reliability. While validity is the degree to which data measure what they were intended to measure, reliability is the extent to which repeated measurements at different times and places, or by different people, are reproducible. An instrument measuring an assay may be accurate if, on average, the measures vary around the true value, but may not be reliable, because the measures are widely scattered around the true value. Reliability and precision are related concepts. A precise measure is one that has nearly the same value each time it is measured. It is very reliable. Precision can be described statistically using the standard deviation of repeated measures. The standard deviation

Figure 17-2

External and internal validity in experimental designs (from Fletcher RH, Fletcher SW, Wagner EH. Clinical Epidemiology: The Essentials, 3rd edn. Baltimore, Williams & Wilkins, 1996:12, with permission).



divided by the mean is the coefficient of variation. Small coefficients of variation imply precise measurements.

In summary, the scientific method involves extrapolating inferences from a study situation to the larger world. The value of research depends on the validity of such inferences, which in turn is determined by the researcher's choice of reliable methods. The following sections explain the strengths and weaknesses of the study designs available.

Study Design

Observational Studies

There are four major types of observational studies: case series, cross-sectional, case-control, and cohort. Observational designs are weaker than experimental designs in establishing causation, but they are useful when it is not feasible to manipulate the independent variable. Studies of disease etiology usually are observational. In these types of observational studies, risk factors or exposures are the independent variables, and disease is the dependent variable.

Case Series

In a *case series* study, a sample of cases is chosen, and the presence of the risk factor is measured. A case series study is easy to conduct and is useful as a preliminary study to reinforce anecdotal evidence, to generate hypotheses, or to establish variable distributions in planning future research. Case series can sometimes identify previously unrecognized constellations of symptoms or morbidities attributed to exposures to drugs or toxins. An example of a case series is the report by Furth et al. on diabetes associated with the use of tacrolimus in pediatric renal transplant recipients (2). The authors identified a number of pediatric transplant recipients treated with tacrolimus who developed diabetes. The authors summarized the case histories and reviewed existing literature regarding diabetes associated with immunosuppressive therapy in adult transplant recipients. A case series such as this can provide useful information for the clinician. However, as a method to determine the risk associated with a particular factor, this design is extremely weak because there is no means of comparison. Even if a risk factor is highly prevalent among the cases (in this example, all the cases of diabetes posttransplant had been treated with tacrolimus), there is no way of knowing whether the risk of the disease is greater with exposure to tacrolimus than with exposure to other immunosuppressive medications – for example, cyclosporine or steroids. The case series design cannot provide an estimate of risk.

Cross-Sectional Design

A cross-sectional study is one in which the disease and risk factors are measured at the same time in a sample of subjects. Subjects can be categorized as either having or not having the risk factor. Within each group, the presence of the disease can be determined. Analytically, the association between a particular risk factor and the disease is measured as the relative prevalence of the disease among those with, versus those without, the risk factor. The cross-sectional study design is superior to the case series in that it provides a means for comparison. Cross-sectional studies are relatively economic, easy to conduct, and allow simultaneous examination of multiple risk factors.

An example of a cross-sectional design is an analysis of hemoglobin levels among the first 340 children enrolled in the Chronic Kidney Disease in Children Prospective Cohort Study (CKiD) (3). Although the CKiD Study is a "cohort study," because hemoglobin in the present analysis was described in each subject at *only one time point*, the first study visit, it would be considered a cross-sectional design. As the CKiD Study progresses, serial hemoglobin measurements among the CKiD participants will be available, allowing for cohort study designs (see "*Cohort Design*"). *Table 17-1* from this cross-sectional study describes the prevalence of anemia. The prevalence of anemia increased as the severity of chronic kidney disease increased.

Cross-sectional studies have a number of limitations. Studying prevalent patients runs the risk of missing those patients who were "cured" or who died soon after

Table 17-1

Prevalence ratio of anemia by CKID stage in cross-sectional study of children with chronic kidney disease

KDDQI CKD stage[a]	*n*	% Anemic	Prevalence ratio	95% CI
2	39	21	1.0	–
3	217	39	1.9	1.0–3.6
4	82	73	3.6	1.9–6.7

[a]Based on GFR measured by plasma disappearance of iohexol (3)

developing the disease. Also, because in cross-sectional analyses the presence or absence of two factors is assessed at the same time, it is not possible to attribute causality.

Case-Control Studies

A case-control study starts with the identification of persons with the disease or other outcome variables of interest in the population at risk (*Fig. 17-3*). A suitable control group of persons without the disease or outcome is also selected from the population at risk. This is pictured on the right side of *Fig. 17-3*. To examine the possible relation of one or more exposures to the given disease or outcome, the researcher then looks back in time to compare the proportions of the cases and controls exposed and not exposed to the risk factor in question.

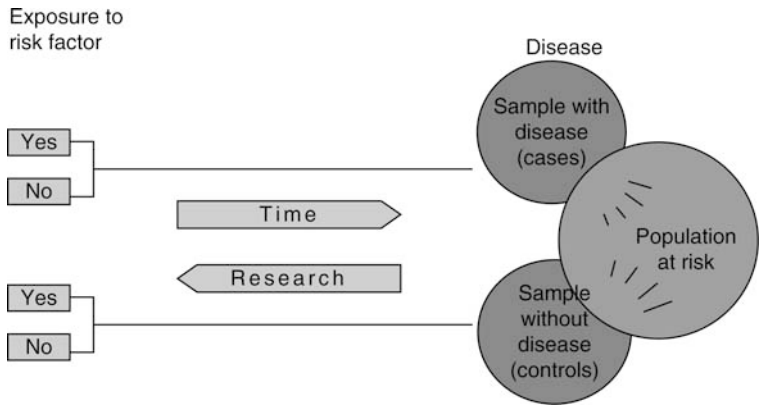
The case-control design has several advantages. It provides stronger evidence of causation than the cross-sectional design. In a cross-sectional study, outcomes and exposures are assessed simultaneously, and the investigator must infer cause and effect relationships because the temporal sequence cannot be established. In a case-control design, an attempt to establish a temporal relationship between the outcome and exposure is made by starting with a population of persons with and without the outcome and then working backwards to examine suspected exposures. Thus, compared to the cross-sectional design, the investigator is more confident that the exposure of interest came before the outcome, not as a result of the outcome. As compared to other study designs, case-control studies are efficient in the study of rare diseases or those with long latent periods between exposure and outcome. Whereas cross-sectional or cohort designs would require a large number of subjects and time to identify risk factors for a rare disease, a well-designed case-control study can identify similar risk factors with comparatively fewer subjects and much less time and expense. Also adding to the efficiency of the case-control design, several potential risk factors for a disease or outcome can be examined simultaneously.

A case-control study by Fored et al. confirmed the association of acetaminophen and aspirin with chronic renal failure (4). Adult Swedish patients with early-stage chronic renal failure were identified as cases ($N = 918$) from monthly reports of serum creatinine measurements from medical laboratories. Controls were randomly selected throughout the ascertainment period from the Swedish Population Register ($N = 980$). Aspirin and acetaminophen were used regularly by 37 and 25%, respectively, of the patients with renal failure and by 19 and 12%, respectively, of the controls. Regular use of either drug in the absence of the other was associated with an increase by a factor of 2.5 (odds ratio via logistic regression) in the risk of chronic renal failure from any cause.

Case-control studies yield an odds ratio as an estimate of relative risk. This measure is calculated by dividing the odds that a patient was exposed to a given risk factor by the odds that a control was exposed to the risk factor. It can also be obtained from logistic regression analysis. Logistic regression allows the investigator to obtain the odds ratio for a given risk factor independent of other potential risk factors or confounders using the technique of adjustment. Odds ratios are generally a good approximation of relative risk if the outcome is rare.

Figure 17-3

Design of a case-control study (from Fletcher RH, Fletcher SW, Wagner EH. Clinical Epidemiology: The Essentials, 3rd edn. Baltimore, Williams & Wilkins, 1996:213, with permission).



As with any study design, the case-control method has limitations. Case-control studies allow for the study of only one disease at a time, as opposed to cross-sectional or cohort studies. This design does not allow for the measurement of incidence, prevalence, or excess risk. Case-control studies are also subject to error, or bias, which can threaten the validity of the study. Selection and information biases, the two major categories of bias, are possible in the case-control design. Selection bias arises if the manner in which cases and controls were selected yields an apparent association when, in reality, exposure and disease are not associated. For example, cases, by definition, include only individuals who have been identified as having the disease and who are available for study. Those who have not been diagnosed, have been misdiagnosed, or have died are excluded. If diagnosis or availability is related to the exposure being studied, the sample of cases will be biased.

Avoiding selection bias can be even more challenging in the selection of controls. The control group must be comparable to the cases. They should not be chosen in such a way that important differences between cases and controls exist that might influence exposure history and thus limit the inferences derived from the study. A number of strategies exist to select a control group that is at risk for the disease and otherwise representative of the same population as the cases. These include sampling cases and controls in the same way (e.g., from the same clinical setting), matching controls to cases on key variables related to the disease (e.g., age), using multiple control groups, and using population-based samples of both cases and controls (e.g., using disease registries).

Information bias occurs when the case and control groups differ in terms of the quality of the data collected to measure risk factors. The retrospective approach to measuring an exposure in the case-control design introduces the possibility of differential recall between the cases and controls. Cases may have been asked more often about the presence of a given exposure and/or may be more circumspect in their recall of such exposures. This introduces *recall bias*, a form of information bias because of better, and sometimes exaggerated, recollection of exposures by cases as compared to controls.

It can be difficult for an investigator to remain objective in collecting exposure information. In interviewing subjects and in reviewing records, there may be a tendency to look more carefully or evaluate evidence differently for cases than for controls. Strategies for dealing with this problem include the use of objective measures and to ensure that the individuals collecting data are unaware of the subject's group status (*blinding/masking*). The more subjective the method for measuring the exposure, the more important it is to mask the observer. Blinding as to the specific exposure being studied or study hypothesis is useful and also can be used to attempt to control recall bias.

Nested case-control studies and nested case-cohort studies are alternative case-based hybrid designs that have many advantages. A nested case-control study involves selecting all cases and control subjects from a known cohort. In this design, the controls are free of the outcome or disease. Nested case-control studies eliminate the problem of recall bias, because the exposure information is obtained before the outcome has developed (cohort design). Also, the temporal sequence between exposure and outcome is defined. This design is also much more economical and efficient; the entire cohort need not be analyzed for a given exposure (e.g., via a laboratory specimen). Nested case-cohort studies also use the selection of cases and controls from a known cohort. However, in this design, controls are randomly selected from the initial cohort irrespective of outcome. This design permits the delineation of *relative risk* for an exposure.

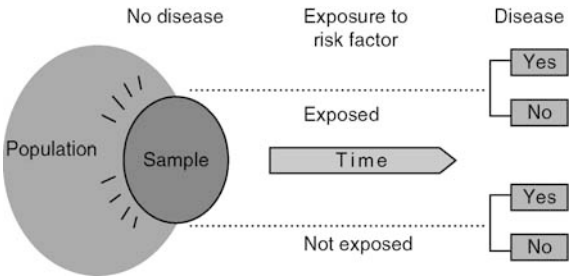
Cohort Design

Various names, including prospective, follow-up, and longitudinal, have been used to label cohort studies in the past, reflecting the temporal sequence of exposure and disease in this category of observational studies. The word *cohort* originated from the Latin word *cohors*, describing a group of warriors that marched together. Clinical investigators have adapted this term to a specific type of research study: a group of individuals free of the disease(s) of interest is assembled, their risk status is determined, and the group is followed over time to measure the incidence of disease. Comparison of the incidence of disease (or rate of death from disease) between those with and without the exposure of interest permits measurement of the association between the risk factor and the disease (*Fig. 17-4*).

The significance of the cohort design has been emphasized by the wealth of scientific data obtained from famous cohorts such as the Framingham Study or the Physicians Health Study. In the field of pediatric nephrology, the Chronic Kidney Disease in Children Prospective Cohort Study (CKiD) is ongoing and designed to improve the understanding of the occurrence and progression of chronic kidney disease and its multiple complications (5). Pediatric nephrology has previously benefited from studies

Figure 17-4

Design of a cohort study (from Fletcher RH, Fletcher SW, Wagner EH. Clinical Epidemiology: The Essentials, 3rd edn. Baltimore, Williams & Wilkins, 1996:102, with permission).



using the cohort design. For example, Wong et al. used the cohort design to demonstrate a 17-fold increase in the risk of hemolytic uremic syndrome (HUS) associated with antibiotic use in children with *Escherichia coli* 0157:H7 diarrhea infections (6). In this study, children with *E. coli* 0157:H7 were followed to assess risk factors for the development of HUS.

The cohort design has an obvious niche in clinical research. Ethical and practical considerations often do not allow for randomization of individuals to an exposure of interest. Cohort designs allow for the examination of exposure and disease associations under such circumstances.

Cohort studies can be classified as concurrent or nonconcurrent. In a concurrent cohort study (also referred to as a prospective or longitudinal study), the clinical investigator identifies the population and collects extant exposure information and then follows the cohort to a designated point in the future. Nonconcurrent cohort studies (i.e., retrospective, historical, and nonconcurrent prospective) require the investigator to identify a cohort that has been delineated in the past, along with information regarding the exposure(s) of interest. This population can then be followed for the development of a given disease in the more recent past, the present, or into the future.

Traditionally, the outcome of interest in cohort studies is the ratio of the incidence of disease in those with the exposure divided by the incidence of disease in those without the exposure. This can be interpreted as the *relative risk* for disease in many cases. When calculating and interpreting risks in the cohort design, the absence of randomization must be taken into account. Because the investigator is merely observing the exposure and not controlling for it via randomization, subjects with and without the risk factor might differ in terms of other characteristics that are related to the disease. If the characteristic is related to both the exposure being evaluated and the disease, it can lead to a misleading association between the exposure and the disease. Such a characteristic would be a *confounder*.

To avoid misinterpreting such an association, the investigator must measure potential confounders and adjust for them in the analysis. Multivariable analyses are examples of statistical tools used to adjust for confounders. However, unsuspected confounders might still jeopardize the validity of conclusions.

For example, Wong et al. (6) used a multivariate logistic-regression analysis to account for potential confounders in the association of antibiotic use for *E. coli* 0157:H7 associated diarrhea and HUS. Adjustments were made for the initial white blood cell count and the day of illness on which the initial stool culture was obtained for analysis. These factors had been previously associated with increased risk of HUS. A higher initial white blood cell count could be a potential confounder, for example, because it is associated with an increased risk of HUS (the outcome) and might make the physician more likely to prescribe antibiotics (the exposure), thus potentially falsely linking antibiotic usage with HUS. After adjustment for these factors, the multivariate analysis revealed a persistent association, reassuring the discerning reader.

Cohort studies have several advantages. Because risk factors are measured before disease, the temporal sequence of risk and disease is established, and the potential for biased risk measurement is avoided. Several diseases or outcomes can be measured, and disease occurrence can be measured in terms of incidence, not just prevalence. Cohort studies often require large sample sizes and are unsuitable for studying rare diseases. Large sample size and long follow-up periods can make cohort studies costly. A nonconcurrent cohort design can reduce cost, but it decreases the investigator's control over subject selection and risk factor measurement.

Experimental Studies

In an experimental study, the investigator controls the independent variable, also known as the intervention or treatment, and then observes the effect on an outcome or series of outcomes. The classic form of experimental design is the clinical trial.

Randomized Controlled Clinical Trials

Most investigators, clinicians, and patients are familiar with the "gold-standard" of experimental designs, the

randomized blinded controlled clinical trial. Such trials are considered "gold-standard" because the rigid design helps minimize the influence of confounding variables and bias, allowing the true effect of the intervention to be elucidated.

The IgA Nephropathy Study is an example of a randomized controlled clinical trial. In this study, eligible patients younger than 40 years with immunoglobulin A (IgA) nephropathy on kidney biopsy, estimated glomerular filtration rate $\geq$50 mL/min/1.73 m^2, and evidence of moderate to severe proteinuria are randomly assigned to receive alternate day prednisone, fish oil, or placebo (7). The goal of this study is to determine the relative benefits of fish oil or alternate day prednisone on the progression of IgA nephropathy. In this and other controlled clinical trials, randomization is the key feature of its experimental nature. Participants are *randomly* assigned to the group that will receive the intervention (the intervention, treatment, study or experimental group) or the group that will not receive the intervention (the control or placebo group) (*Fig. 17-5*). Through randomization, all potential confounders, both those recognized by the investigator and those that are not suspected, are likely to be balanced between the study groups. In other words, the three groups in this study are considered to be the same except for the treatment they receive. Differences in rates of progression of kidney disease in the three groups are attributable to the intervention, because the effect of confounders has been ruled out by the balance achieved by randomization. Therefore, experimental designs offer stronger evidence of causality than do observational designs.

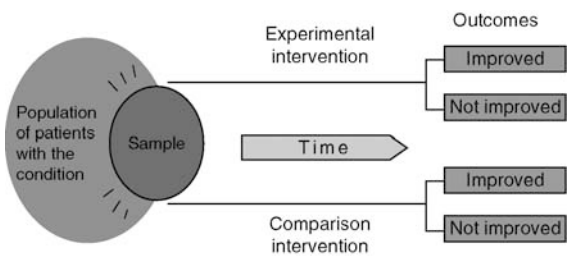
In an experimental study, it is important to ensure that subject assignment is truly random. This can be achieved by using random numbers, either through computer-assisted assignment or manually, with a table of random numbers. Sometimes *blocking* is used in conjunction with random assignment. A block of subjects is simply a set number of consecutive study enrollees. Within each block, a predetermined number of subjects are randomly assigned to each study group. For example, if the block size is set at six and two study groups of equal size are desired, then three subjects in each block of six are randomly assigned to one group and three to the other. Blocking is useful when study enrollment is expected to be prolonged. Over extended periods, both study procedures and outside conditions can change. Blocking ensures that the study groups will be balanced with regard to such changes. For example, given the prolonged enrollment period due to the relative rarity of IgA nephropathy in children and young adults, block randomization was used in the IgA Nephropathy Study.

Experimental studies, like observational studies, are subject to measurement bias. Research staff should be masked or *blinded* to the subject's group assignment during data collection, especially if any outcome measures are not strictly objective. In the IgA study, for example, both the research staff and the study subjects are unaware of which treatment they receive. In one arm of the study, placebo capsules are made to look exactly like fish oil capsules. In another arm, placebo tablets are distributed that are identical to prednisone. If outcomes are measured, without subject or staff knowledge of the subject's group status, they are less likely to be influenced by expectations about potential differences between treatment and control group outcomes. Studies in which both the participant and the staff are unaware of the treatment group status are known as "double-blinded." There may be situations in which blinding the clinical staff and patients is difficult or impossible. Clinical trials that are not blinded are known as open-label trials. Such designs are common in cancer clinical trials, as treatments being compared are often complex, with different side effect profiles and delivery protocols, and thus masking is not feasible.

Clinical trials typically provide the necessary medical evidence to bring a new treatment into use, and for drugs, such trials are referred to as "phases." A *phase I* trial is most often the first stage in testing a new drug in humans, and may include healthy participants and/or patients. In these trials, information on the distribution, metabolism, excretion and side effects of the drug is investigated. The optimal dose of the drug to deliver is also investigated. Such studies are typically not randomized or blinded.

Figure 17-5

Design of a randomized trial (from Fletcher RH, Fletcher SW, Wagner EH. Clinical Epidemiology: The Essentials, 3rd edn. Baltimore, Williams & Wilkins, 1996:139, with permission).



Phase II clinical trials are designed to evaluate the effectiveness and short-term safety and side effects associated with the drug. These trials are generally carried out in persons having the disease of interest. *Phase III* trials are expanded trials to prove the efficacy of a drug and provide the information necessary for physician labeling of the drug. These studies are most often randomized and blinded. Once completed, the pharmaceutical manufacturer may apply to market the drug for the indication(s) studied in the phase III trial. *Phase IV* clinical trials are postmarketing studies (post licensure) designed to delineate more information about the drug's risks, benefits, and optimal use in "real-world" conditions.

Alternative Designs

It is not always feasible to conduct a traditional randomized controlled clinical trial for every treatment. In such scenarios, multiple alternative experimental study designs are available and may provide useful information regarding the treatment under consideration. A few examples of such alternative designs follow. *Cross-over trials* randomly assign half of the study population to start with the control period and then subsequently switch to active treatment; the other half are on the opposite schedule. Such trials allow each participant to serve as their own control, allowing for increased statistical power and thus fewer participants. However, these studies generally take a longer period of time. The analysis and interpretation of the results may also be complicated if the treatment effects are thought to persist for a period of time even after the intervention has been ceased. A before-after trial compares the outcomes of different types of treatments in a group or groups of interest by taking advantage of calendar time. In such a study, outcomes in individuals receiving one type of treatment during a given period are compared with individuals at a subsequent time, who have received a different treatment. Although economical to perform, the results of such designs may be more prone to error as it may be difficult to know and/or control factors independent of the treatment that may have also influenced the outcome of interest.

Issues with Analysis in Experimental Designs

It is not uncommon in clinical trials to have patients who were assigned to one group switch to a different group. For example, a patient assigned to receive the active treatment under study may discontinue the treatment. Alternatively, a patient assigned to the control group may end up receiving active treatment. To avoid introducing bias in the results, it is common practice in clinical trials to analyze the results by "*intention-to-treat*." In such conservative analyses, every patient is grouped according to his/her original randomization assignment when analyzing the results, regardless of whether the patient actually received the assigned treatment or not. Intention-to-treat analyses may dilute the effect of the treatment of interest, but more importantly, likely minimize the introduction of bias into the study which may lead to erroneous conclusions.

To maximize the yield of arduous and costly clinical trials, investigators may perform *subgroup analyses*, defined as an evaluation for treatment effects within a subset of patients. For example, in the IgA Nephropathy Study, baseline proteinuria was found to be associated with "time to failure," defined as a decline in estimated GFR to $\leq$60% of baseline. The authors performed a subgroup analysis comparing the effects of the treatments and placebo among those with more severe proteinuria, defined as a first morning baseline urine protein/creatinine ratio between 1 and 3; no significant difference between the treatment groups or the placebo group in the time to failure was observed (7). Related to subgroup analyses, *post hoc analysis* refers to examining the data after the study has concluded for associations that were not specified a priori. Although subgroup analyses and post hoc analyses may provide additional useful information, due to analytic challenges, particularly in the area of sample size, results may be misleading. Given these statistical limitations, it is recommended that all hypotheses and intended analyses be stated prior to the initiation of the study, which may help in planning the design of the study, including the sample size. In the event that post hoc analyses are performed, they should be clearly labeled as such so that the reader is able to identify the potential limitations to any conclusions derived from such analyses. A recent report in the New England Journal of Medicine reviews the challenges of subgroup analyses, and provides guidelines for their use within the Journal (8).

In summary, many research designs are available to the investigator. No single design is best for all research questions. Although experimental designs are superior to observational designs in addressing threats to internal validity, they are not always feasible or ethical. The most appropriate design for a given research question is the design that maximizes internal validity within the constraints of the research environment.

Important Issues in Carrying out a Research Plan

Selection of Subjects

In any research study, one would like to extrapolate the findings to all patients with the condition of interest. The study population is the group that is meant to represent the target population from which a sample is drawn. Sampling decisions involve defining the study population and sample.

Defining the Target Population

Although there is no one single ideal target population, the investigator needs to consider the ramifications of one definition versus another. If the investigator were interested in studying risk factors for a specific disease, the target population could be defined as all children with this disease or a subset of them (e.g., children of a certain age). The broader the target population, the greater the generalizability of the study findings. On the other hand, the increased heterogeneity of a broadly defined target population could introduce variability among subgroups in terms of the importance of risk factors. For example, a particular characteristic could be a major risk factor in some population subgroups but not in others. Assessing the importance of risk factors within subgroups requires a larger study sample and perhaps a more complex sampling design.

Defining the Study Population

A practical consideration in defining the target population is availability of the population for study. The investigator could have all children available seen in a particular clinical setting. Insofar as children seen in this setting are representative of the target population, the clinical site would be a good choice for study; the experience of its enrollees could be considered *generalizable* to the target population. If children enrolled in the clinical setting differ systematically from the target population, *sampling bias* is introduced. For example, tertiary care pediatric nephrology centers might be more likely to serve children with advanced *stages* of the kidney disease or more severe or complicated cases. Studying only these cases may introduce bias toward only studying the most complex forms of a particular disease. Sampling bias impairs the generalizability of study findings. Representativeness, therefore, is a prime consideration in defining a study population. Investigators should evaluate the representativeness of candidate settings and the likely implications of potential biases. One possible approach to this in studies of patients with kidney disease is to compare the characteristics of participants in a study to known characteristics of the larger population to whom one would like to generalize the results.

Defining the Sampling Scheme

Just as we generalize from the study population to the target population, we generalize from the study sample to the study population. *Sample statistics* are measures that pertain to the samples that are studied. A sample mean, for example, is the sample's average score on a particular measure, and a sample standard deviation expresses the variability of the sample scores. The sample statistics are the investigators best estimates of the *population parameters*. The sample mean is the best estimate of the population mean; the sample standard deviation is the best estimate of the population standard deviation.

Extending beyond inference to hypothesis testing, sample statistics of the association between variables are the best estimates of these associations in the target population. The association between a hypothesized risk factor and the occurrence of disease in the study sample (perhaps measured by odds ratios or relative risks) is the investigator's best estimate of the association between the risk factor and disease in the target population.

Probability theory is the rationale for extrapolating inferences from a study sample to the reference population. A *probability sample* is one in which every subject, or element, in the study population has a known probability of being selected. A *nonprobability sample* is one in which the probabilities of selection are unknown. It is legitimate to extrapolate from a sample to its population only if probability sampling has been used.

There are several types of probability sampling. In *simple random sampling*, each element has an equal chance of being selected. In *systematic sampling*, each element in the population is assigned a consecutive number, and every *nth* element is sampled. Systematic sampling is easy to use, but it will generate a biased sample if the sampling fraction (e.g., every tenth case) is the same as some periodicity in the ordering of cases in the population. For example, if every tenth patient is sampled in a clinic where ten patients are seen each session and the most complex cases are scheduled first, then the sample will contain either all complex cases or no complex cases, depending on the first element drawn. *Stratified random*

sampling is useful when one believes that population subgroups differ in important ways. The population is divided into the subgroups, or *strata*, of interest. Simple or systematic random samples are then drawn from each stratum. *Cluster sampling* is useful when it is difficult or costly to sample elements in a population individually. Instead of elements, groups of elements are sampled. For example, in a study of school children, the investigator could take a probability sample of classrooms and then study all the students within each selected classroom. The selected classrooms, in combination, must be representative of the overall population. As with stratified sampling, formulas for calculating variance must be modified, and consultation with a statistician is recommended.

Nonprobability sampling techniques include *convenience sampling*, *quota sampling*, and *purposive sampling*. A convenience sample is one that is most readily obtained without the use of random sampling. A quota sample is a convenience sample drawn to assure specified numbers of subjects in specified strata, without the use of random sampling. A purposive sample is one in which subjects are selected because they are judged to be representative of the population of interest.

Probability sampling is preferred but not always possible. In clinical research, the investigator is often limited to a particular clinic population. If a clinic population is believed to be representative and if it is larger than the number of subjects needed for study, the investigator should use a probability sampling technique to draw the study sample.

An example of probability sampling using stratified sampling techniques can be seen in a recent survey study of adult and pediatric nephrologists (9). The authors created a survey containing ten case vignettes to assess whether increased experience with pediatric patients influenced nephrologists' recommendations for peritoneal or hemodialysis in otherwise identical patients with ESRD described in the vignettes. Because the authors wanted the survey respondents to represent the population of U.S. adult and pediatric nephrologists, they randomly selected a representative sample of nephrologists in five geographic regions of the United States. Each randomly selected nephrologist was mailed a survey containing ten case vignettes to assess what factors affected the nephrologists' dialysis recommendations.

Determining Sample Size

In any study, several factors determine the required sample size. This section describes those that come into play in several common types of investigations. Detailed sample-size formulas and tables are beyond the scope of this chapter, but several excellent references are listed in Suggested Reading. Briefly, to estimate sample size, the researcher needs to set the acceptable level of α (probability of type I error), β (probability of type II error), and determine the effect size that one is likely to see. In determining sample size, the probability of making a type I error, α, is usually set at 0.05. This is the probability of concluding that an association between two variables exists when it does not. β error is the probability of concluding that no association exists, when in fact it does. The reader will be more familiar with β error in terms of its relationship to "power." The power of a study is equal to 1-β. In many studies, β is customarily set at 0.2 for a power of 80%. If β is set to 0.1, the power of the study is 90%.

In addition to specifying α and β, the researcher must also determine an estimate of the response to treatment in one of the groups (in a clinical trial) or the rate of occurrence of disease (in a cohort study). The effect size is an estimate of how much better than the comparison group you expect a treatment group to be in a clinical trial or how increased the risk of a particular disease is in the setting of a particular risk factor (in a cohort study). An illustration of estimated sample sizes for given α, β, and effect sizes is shown in *Table 17-2* for a study comparing differences in proportions in two groups (10).

Table 17-2 illustrates how varying the acceptable levels of α, β, and effect size influences sample size. For example, if we designed a study to determine whether a new drug could "cure" 40% of patients compared to an old drug that "cured" 10% of patients, we would have 90% power to see such an effect with 95% confidence in a total sample of 96 patients (see row 2 in *Table 17-2*). In contrast, to obtain a significant result documenting a smaller effect size from the old drug cure rate of 10% to a new drug cure rate of 20% with the same $a = 0.05$ and 90% power, we would need to study 572 patients.

Attrition of Study Subjects

Sample size calculations determine the number of subjects needed at the study's conclusion. In determining the number of subjects to enroll, the investigator must estimate attrition rates and enroll a sufficiently large sample to compensate for study dropout.

Even if probability sampling is used to define the study, subject attrition could produce a biased sample at the study's conclusion. An attrition rate of more than 25% is cause for concern. In data analysis, subjects completing the study should be compared with those who drop out to

Table 17-2

Example illustrating how α, β, and effect size affect sample size

Confidence 1-α (%)	Power 1-β (%)	Effect size (%)	Total sample No.
95	80	10→40	76
95	90	10→40	96
95	90	10→20	572
95	99	10→40	156

Adapted from sample size calculator (Statcalc) in Epi-info Stat Calc (10)

determine whether the two groups differ in a clinically significant way. Such differences must be considered in interpreting the study findings.

Data Collection: Measurement

Decisions on what data to collect and how to do so begin with specifying the variables that need to be measured and operationally defining each. The investigator will need to evaluate the suitability of existing measures and determine whether to use an existing measure or develop a new one. The data sources for each variable must also be identified. Finally, the investigator should specify the level of measurement of each variable. An efficient way to document the data collection plan is to make a table with columns listing the variables to be measured, their definitions, the data source(s) for each variable, and level of measurement for each. This section describes issues pertaining to each of these tasks.

Identifying the Variables to Be Measured

Researchers are often tempted to collect as much information as possible. This can be costly, in terms of time, money, and data quality. The investigator should be able to justify each variable to be measured. Most important are the hypothesized independent and dependent variables. In addition, identified potential confounders should be mea\sured. Finally, data characterizing the study population and sample will be needed to describe the study's generalizability.

Types of Variables

Variables can be continuous or categorical. Age, height, and weight are examples of continuous variables. Categorical variables can be binary, with two possible outcomes such as male or female gender; nominal, i.e., nonordered categories such as race: White, African American, Asian, Native American or Pacific Islander; or ordinal, i.e., ordinal categories such as a pain rating scale: none, mild, moderate, severe.

Sources of Data

Study data can be collected from existing sources or can be generated specifically for the specific research hypothesis being tested, using surveys, interviews, or observations. Most studies combine both strategies.

An enormous variety of existing data sources is available, including medical records, vital records, national and local health surveys, and census data. Health programs often keep records of services provided, and billing records can be especially helpful. Examples of existing data sources in pediatric kidney disease include the United States Renal Data System (USRDS) (11) and data collected by the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) (12). Existing sources can provide data for time periods and individuals otherwise unavailable to the investigator. The number of studies published by the NAPRTCS and their tremendous contribution to our understanding of clinical outcomes in pediatric kidney transplantation and dialysis illustrate this point. The chief disadvantage of existing sources gleaned from registry data is that the data are often not collected as systematically as in a prospective research study. Important data elements are sometimes missing. Incomplete data and inaccuracies are also possible with registry data.

Primary data collection is expensive and is limited to subjects available to the investigator. On the other hand, the investigator's control over data collection makes data quality more certain. Many primary data collection strategies are available, including mail surveys, mass-administered questionnaires, telephone and in-person structured and unstructured interviews, direct observation, and videotaping and audiotaping. Choosing a strategy should be based on the research question, the sensitivity of the data to be collected, the literacy of the population to be studied, and the resources available for the study. The key factor should be data quality – that is, *which* method will provide the most complete and accurate information within budgetary constraints.

Assessing Data Quality

One strategy to enhance data quality is to train research staff thoroughly. Often, data collection staff works

independently. To ensure that they follow study procedures, the protocol for data collection should be detailed in a study manual. Training sessions should be held to explain the study's aim to staff, as well as how each one's role fits into the big picture. Staff should be given ample time to practice their data collection skills. Once the fieldwork of the main study begins, staff should be encouraged to bring problems to the attention of supervisory staff. Such problems should be resolved in a timely fashion, and the resolution should be documented and added to the study manual. In this way, research staff are kept apprised of changes in the study protocol and are impressed with the importance of adhering to it.

After the instrument pretesting and staff training, the investigator should pilot test the data collection activities. A pilot test is a dress rehearsal of the activities for selecting study subjects, contacting them, securing informed consent, and collecting and processing data. Activities that do not work as planned should be modified and the pilot testing continued until the fieldwork procedures run smoothly.

Data quality should be monitored during the main study. Interviews and questionnaires should be reviewed as they are completed to allow recontacting subjects to correct errors. The reliability of subjective measures and those requiring special technical skill should be assessed. For studies with unsupervised interviewing of subjects, it is wise to validate a portion of the completed interviews handed in by fieldworkers. This can be done by recontacting a random sample of subjects and then asking them to verify their responses to a subsample of the interview questions.

Analytic Plan

Data Analysis

Investigators often defer considering data analysis until the data have been collected. This is a serious mistake. Study planning should include an analytic plan of the steps needed to answer the *study* questions once the fieldwork is completed.

Use of Statistical Tests

As noted earlier, statistical validity is the correctness of study conclusions regarding group differences and variable relationships. A key threat to statistical validity is the use of inappropriate statistical tests. Variable types and variable distribution, as well as the hypothesis being tested, determine the correct type of statistical test. The important properties of a variable's distribution are its location, spread and shape. Measures of location include the *median* (middle observation), the *mean* (arithmetic mean or average) and the *mode* (most frequent value). Measures of spread of a distribution include the *range*, which equals the maximum minus the minimum value, the *interquartile range*, which equals the 75th minus the 25th percentile, the *variance*, which equals the average squared deviation from the mean, and the *standard deviation*. The shape of a distribution can be described by its skewness i.e., symmetry, and its kurtosis i.e., "peakedness." *Parametric statistical tests* are based on assumptions about parameters of the population and are the most powerful tests available in situations in which these assumptions are met. *Nonparametric statistical tests* are based on fewer assumptions about the population, so they are appropriate in situations in which the assumptions underlying parametric statistics are not met.

Assumptions vary by statistical test. If a test is used in a situation that violates its assumptions, it will be inaccurate, leading to a misleading measure of statistical significance. This, in turn, will lead to an incorrect estimate of the likelihood of a Type *I* error.

In developing the analytic plan, the investigator should consider the assumptions of candidate tests in determining which ones to use. A discussion of specific statistical tests is beyond the scope of this chapter, but a framework for deciding which tests to use can be given. In this framework, three factors determine the type of test to use: the major analytic question to be answered, the levels of measurement used, and the number and independence of comparison groups.

In preparing the analytic plan, the investigator needs to translate the research question into analytic terms. Three major analytic approaches are to describe characteristics of the sampled population, to compare groups of subjects, and to measure associations among variables.

Where group comparisons are to be made, the appropriate statistical test is also determined by the number of groups to be compared (two vs. three or more) and by whether comparison groups are independent or matched. Thus, in a study of cases matched with sibling controls, it would be inappropriate to use a statistical test for independent groups.

As decisions about level of measurement and the selection of study groups are part of study planning, it is easy to see how these decisions are better informed if their ramifications for data analysts are considered. Level of measurement, study group formation, and data analysis

Table 17-3
Bivariates Statistical Tests

Level of measurement	Two groups		Three or more groups	
	Independent (unpaired groups)	Paired groups	Independent (unmatched groups)	Matched groups
Nominal dichotomy	Chi-square of Fisher's exact test	McNemar's test	Chi-square	Cochran's test
More than two categories	Chi-square	McNemar's test	Chi-square	Cochran's test
Ordinal	Mann-Whitney test	Sign test	Kruskal-Wallis one-way analysis of variance ANOVA	Friedman two-way ANOVA
		Wilcoxon matched-pairs signed-ranks test		
Interval	*t* Test for groups	*t* Test for pairs	One-way ANOVA	ANOVA for repeated measures

are all interrelated, and should all be considered part of study planning.

When the study's purpose is to assess the relationship between two continuous variables, the degree of concordance can be expressed as a simple *correlation coefficient*. A related approach is the use of a *kappa statistic* which expresses the degree of concordance beyond that due to chance. *Chronbach's alpha* expresses internal consistency among three or more variables that measure the same general characteristic.

When the study's purpose is to describe a population, the investigator makes inferences from sample statistics to population parameters. Sample proportions and measures of central tendency (mean, median, and mode) and dispersion (standard deviation, range) are used to estimate these parameters in the population. *Confidence intervals* can be constructed around proportions and means to express the certainty of the sample-based population estimates. When the study's objective is to compare two or more groups, sample group differences in proportions and means are used to estimate such differences in the population. Statistical tests of significance can be used to assess the certainty of sample-based inferences about group differences in the population. The appropriate statistical test depends on the number of groups compared, whether subjects in the groups are matched, and the level of measurement of the variable on which the groups are being compared. *Table 17-4* displays bivariate statistical tests commonly used in assessing the significance of group differences. For a variable with a normal distribution, a *t-test* compares two means, while *ANOVA* can compare means in three or more groups. *Chi-square* compares proportions.

When normality assumptions cannot be made, the *sign test* can be used for a single sample or paired sample to assess whether the medians of the sample and a reference, or two samples being compared differ. The *Wilcoxan signed rank test* can be used when the data are on an interval scale, and makes use of the magnitudes of the differences between measurements and a hypothesized location parameter. If the variable of interest is measured on an ordinal scale, the *Mann-Whitney test* can be used to assess whether the two populations have different median values.

When the research aim is to measure the association between variables, sample statistics again are used to estimate population parameters. The variables' levels of measurement determine the appropriate statistical measure of the strength of their association, the appropriate test of the statistical significance of the association, and the certainty of estimates of its strength. For continuous data, Pearson's correlation coefficient is used to measure association. For dichotomous variables, the *odds ratio* and *relative risk* (RR) are measures of the degree of association between two factors. Analytic studies in the medical literature often are designed to determine whether there is an association between exposure to a factor and development of disease. If there is an association, the question is how strong the association is. To assess the strength of the association, we measure the ratio of the incidence of disease in exposed individuals to the incidence of disease in nonexposed individuals. This ratio is called the *relative risk*. If the risk in exposed individuals is equal to the risk in unexposed, the relative risk is 1.0 and there is no association. If the risk in exposed individuals is greater than in unexposed (RR $>$ 1.0), then there is an association that may suggest that the exposure

Table 17-4
Sensitivity and specificity of urinalysis components (13)

Test	Sensitivity % (range)	Specificity % (range)
Microscopy: WBCs	73 (32–100)	81 (45–98)
Microscopy: bacteria	81 (16–99)	83 (11–100)
Leukocyte esterase	83 (67–94)	78 (64–92)
Nitrite	53 (15–82)	98 (90–100)
Leukocyte esterase or nitrite positive	93 (90–100)	72 (58–91)
Leukocyte esterase or nitrite or microscopy positive	99.9 (99–100)	70 (60–92)

confers risk. If the risk in exposed is less than in unexposed (RR < 1.0), the exposure may be protective against risk. The relative risk can only be calculated in a prospective study, as it requires incidence of disease. In a case-control study, since we do not know incidence, we cannot calculate the RR directly. Instead of the proportion of the exposed population who develop disease compared to the proportion of the unexposed population who develop disease, in case-control studies, we have the proportion of the cases who were exposed and the proportion of the controls who were exposed. In case-control studies we utilize the concept of odds to define the odds ratio, which approximates the relative risk if the incidence of disease is low. We compare the odds of a case having been exposed to a particular factor to the odds of a control being exposed to that factor. As in the case of relative risk, if the exposure is not related to the disease, the odds ratio will equal 1.0. If the exposure is positively related to the disease, the odds ratio will be greater than one.

Studies of the combined and relative impacts of multiple independent variables, or the effect of an independent variable after controlling for other factors, will require multivariable analytic tests. The appropriateness of a multivariable technique is determined by the levels of measurement of the independent and dependent variables. Multiple linear regression analysis can be used to assess association between a putative exposure and a continuous outcome while adjusting for other possibly confounding factors. Multiple logistic regression analysis can be used to assess the association between a putative risk factor and a binary outcome measure, while adjusting for other potential confounding factors. These measures can be used to calculate an adjusted relative risk, or an adjusted odds ratio. The references cited at the end of this chapter describe the applicability and interpretation of the most commonly used multivariable statistical tests.

In addition to describing association between two variables, and assessing the risk associated with an exposure and an outcome, another common research question in the medical literature includes assessing the time from a particular exposure until an outcome such as death, or hospitalization or transplantation. A commonly used statistical tool to assess the time to an event is survival analysis, or *Kaplan Meier analysis*. Kaplan Meier analyses can be used to compare survival between two treatment modalities. When adjusting for other potential confounding variables in a survival or time to event analysis, Cox *proportional hazards methods* can be used, yielding a hazard ratio which can be thought of as comparable to a relative risk.

Statistical Significance and Confidence Intervals

Most readers of the medical literature will be familiar with the term *statistical significance*, which is most often referred to in clinical reports as a "p value $<.05$." This highly sought after result of a statistical test refers to the probability of α, or a type I error. A p value of .05 in a study means that there is a 5% chance that the results seen in the study could have occurred by chance. However, the authors have concluded that this probability is low enough for them to accept the alternative hypothesis (that there is a real difference between groups) and to reject the null hypothesis (there is no difference between groups). It is important to note that the p value in a study result depends on the size of the observed difference between the groups in question and the size of the sample of patients studied. Standing alone, the p value does not convey any sense of the magnitude of the treatment effect seen in the study or the precision of the estimate of the size of the treatment effect. *Confidence intervals*, in contrast to p values, can convey this information in a more meaningful way.

For any estimated value, it is useful to have an idea of the uncertainty of the estimate in relation to the true

value it is trying to approximate. For example, if we designed a study to estimate the beneficial effect of a new lipid-lowering medication in chronic kidney disease in adolescents, we would try to recruit a large representative sample of hyperlipidemic adolescents and randomize them to treatment with a new lipid-lowering medication. From our study, we might want to estimate the magnitude of lipid level reduction associated with the new medicine. We might also want to use this estimate as an approximation for the "true" reduction in lipid levels that would be seen in the "universe" of pediatric patients with hyperlipidemia and chronic kidney disease. To estimate the "true" reduction in lipid levels (which can never be directly measured), we can generate a confidence interval around our estimate.

In any study, construction of a *confidence interval* around the point estimate gives us a range of values in which we can be confident that the true value resides. A confidence interval gives a sense of the estimates precision; it extends evenly on either side of the estimate by a multiple of the standard error (SE) of the estimate. In our example, our study might yield an estimate of the drop in serum low-density lipoprotein cholesterol levels of the treatment group of 30% with a standard deviation of that estimate of 20%. One could then use this estimate to generate a confidence interval around this estimate. In the medical literature, one will most often see references to 95% confidence intervals. The general equation for a 95% confidence interval is equal to the estimate ± 1.96 times the SE of the estimate. The factor 1.96 comes from the standard normal distribution, in which 95% of estimates would fall within ± 1.96 SEs of the mean. If one wanted to increase the probability of including the true estimate in the confidence interval, one could generate a 99% confidence interval, which would equal the estimate ± 2.56 times the SE of the estimate. Because the SE of an estimate is equal to the standard deviation of the population divided by the square root of the sample size, n, one can see that a larger sample size is needed in a study to generate a precise estimate of a treatment's effect. Given the same standard deviation, the SE in our study would be smaller if we studied 100 children compared to 20 children. The larger study would generate a narrower 95% confidence interval. The strict interpretation of a 95% confidence interval is that this is the range of values for the true population estimate that is consistent with the data observed in the study. In our hypothetical example, the smaller study might give us the opportunity to conclude that the new lipid lowering is associated with a 30% reduction in low-density lipoprotein cholesterol with a relatively broad 95% confidence interval of 21–39%, whereas the larger study yields a more precise estimate. The 95% confidence interval around the same point estimate of a 30% reduction is 26–34% in the study with the larger sample size.

Topics Related to Clinical Decision Making

Clinicians are routinely faced with patients with unknown diagnoses, and patients expect that the clinician will know how to efficiently and accurately diagnose the problem with which they are presenting. Diagnostic acumen relies in large part in understanding the "epidemiology" of the possible diagnoses, as well as the strengths and limitations of the various tests that might be performed to diagnose such diseases. The following section provides an introduction to concepts and terms that are related to the science of clinical decision making.

The Disease

When describing the burden of a disease in a population, the terms incidence and prevalence are often used. *Incidence* is defined as the number of new cases of a disease that occur in a population at risk for developing the disease during a specified period of time. *Prevalence* is defined as the proportion of persons present in the population currently affected by the disease at a specified point in time. Distinguishing between these terms is important when considering the burden of given disease. When prevalence is reported, people affected by the disease for varying amounts of time are included; these are not necessarily all new cases. Those with severe forms of the disease may have died and thus depending on the time specified in the definition, may not be included in the prevalence. The incidence and prevalence of end-stage renal disease (ESRD) are routinely reported by the United States Renal Data System (USRDS). In 2005, the incidence was 347 (new) cases of ESRD per million population per year. This was only 1% higher than the incidence in 2001. The prevalence of ESRD in 2005 (also referred to as point prevalence) was 1,569 cases per million population (11). Based on these definitions, we know that 347 (22%) of the 1,569 prevalent cases of ESRD per million population in 2005 were new cases.

The Diagnostic Test

When utilizing a diagnostic or screening test to aid in the care of a patient, a clinician must know "how good" the test is. Terms used to describe "how good" a test is

include sensitivity and specificity. The *sensitivity* of a test describes the ability of the test to correctly identify those that have the disease. A sensitive test has a low *false-negative rate*, meaning the test result will not frequently be negative in those who have the disease. The *specificity* of a test describes the ability of the test to correctly identify those who do *not* have the disease. A specific test has a low *false-positive rate*, meaning the test result will not frequently be positive in those who do *not* have the disease.

Table 17-4 from the American Academy of Pediatrics' Practice Parameter for the diagnosis of initial urinary tract infections in children examines the sensitivity and specificity of various components of the urinalysis (13). For example, the sensitivity of nitrite is reported as 53%. Thus, among children with a urinary tract infection, this test will be positive approximately 53% of the time. Knowing the relatively low sensitivity of the nitrite test, a clinician would not be reassured that a urinary tract infection does not exist if the result is negative. The specificity of the nitrite test is 98%. Thus, among children *without* a urinary tract infection, this test is negative approximately 98% of the time. The high specificity of the nitrite test informs the clinician that a low false-positive rate exists. As can be observed in the figure, and as often happens in clinical practice, using a combination of diagnostic tests can significantly increase the overall sensitivity and specificity, and thus the accuracy of the diagnosis.

Often in clinical medicine, clinicians are faced with a positive test result, and the next question asked is, "among patients with a positive test result, what proportion will actually have the disease?" This is known as the *positive predictive value* of the test. The *negative predictive value* of a test relays the probability that if the test is negative, the patient does not have the disease. It is important to remember that the predictive value of a test is affected by both the prevalence of the disease in the population being considered, and, if the disease in uncommon, the specificity of the test being used. Higher disease prevalence generally leads to an increase in the positive predictive value of a test. However, as most diseases are rare, tests with higher specificity likely have a greater impact on increasing the positive predictive value for a given test. These values can be easily calculated as demonstrated in *Fig. 17-6*.

Likelihood ratios (LR) are another measure of test performance that helps the clinician utilize the results of a given test diagnostically. When presented with a patient with particular signs and symptoms, the clinician has an initial assessment of the probability, (pretest probability) of a particular disease. A diagnostic test ordered to help determine the presence of a disease may be positive or negative. LRs help inform the clinician as to how much the test result should shift his/her initial assessment of the probability (pretest probability) of the disease being present or absent to the posttest probability. Strong, conclusive tests yield very big or very small LR's. Weak, inconclusive tests yield modest LR's, close to 1.0. For example, following the results of a positive test result, if the positive LR is found to equal 1, then there is no change in the likelihood of the disease. If the LR was 10 after the positive test result, then the posttest odds of the disease is equal to the likelihood ratio multiplied by the pretest odds. The odds of disease can be calculated from the probability as probability/1- probability. The higher the LR, the better the test is for ruling in a diagnosis. These ratios depend upon the validity of the test being ordered in distinguishing who has

Figure 17-6

Calculation of sensitivity, specificity, positive and negative predictive values.

	Population	
Test results	**With disease**	**Without disease**
Positive	True positive (TP) = have disease and test result positive	False positive (FP) = no disease and test result positive
Negative	False negative (FN) = have disease and test result negative	True negative (TN) = no disease and test result negatve

$$\text{Sensitivity} = \frac{TP}{TP + FN} \qquad \text{Specificity} = \frac{TN}{TN + FP}$$

$$\text{Positive predictive value} = \frac{TP}{TP + FP} \qquad \text{Negative predictive value} = \frac{TN}{FN + TN}$$

the disease in question from who does not; hence these ratios may be derived from sensitivity and specificity of the test (see below). LR's may be more useful than sensitivity and specificity in certain situations. LR's can be calculated for tests without dichotomous results such as those that are resulted as "positive, intermediate, or negative." The results of several diagnostic tests may be combined to provide a single LR. Finally, with some relatively simple calculations, the posttest probability of a disease can be calculated using the LR and the pretest odds of the disease. Formulas for calculating LRs follow.

$$\text{Positive LR}: \frac{\text{probability of an individual with the disease having a positive test}}{\text{probability of an individual without the disease having a positive test}}$$

$$\text{Negative LR}: \frac{\text{probability of an individual with the disease having a negative test}}{\text{probability of an individual without the disease having a negative test}}$$

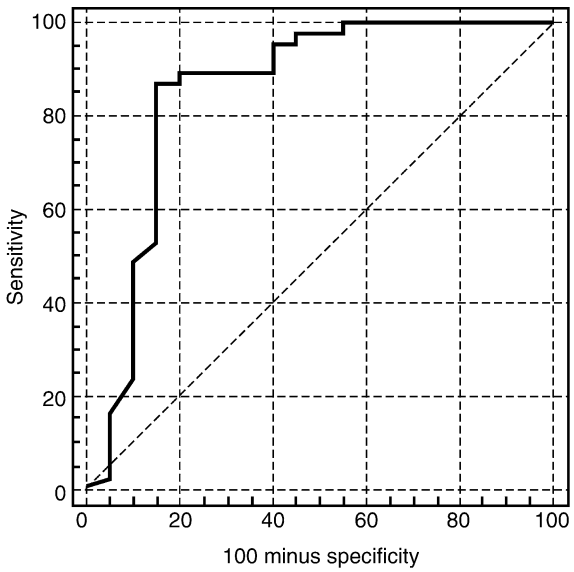
For dichotomous tests:
Positive LR: sensitivity/(1-specificity)
Negative LR: (1-sensitivity)/specificity

Receiver operator characteristic (ROC) curves, originally developed in the field of electronics, allow for a graphical display of the trade-off between sensitivity and specificity for diagnostic tests with ordinal or continuous results, in which several values of sensitivity and specificity are possible. Several cutoff points are determined and the sensitivity and specificity are determined at each point. The sensitivity (or true-positive rate) is graphed on the Y axis as a function of 1-specificity (the false-positive rate) on the X axis. Tests with values falling in the upper left corner of the graph are considered ideal (100% true positives and no false positives). If a test followed the diagonal line from the lower left corner to the upper right corner, it would be considered useless–on this diagonal line the true-positive rate equals the false-positive rate. The area under the ROC curve can range from 0.5 for a worthless test to 1.0 for a perfect test.

Filler et al. made use of both an ROC curve and LRs in a study examining nonminimal change nephrotic syndrome in children referred to a tertiary care medical center in Canada, as can be seen in the *Fig. 17-7* included from this study (14). The authors noted an increase in the incidence in focal segmental glomerulosclerosis (FSGS) over a 17 year study period. Based on the International Study of Kidney Disease in Children (ISKDC), the approach to a child with new-onset nephrotic syndrome has been to perform a kidney biopsy if the disease was unresponsive to a standard dose of corticosteroid therapy of at least 28 days in duration (15). Given the increased incidence of FSGS observed in their study, Filler et al. considered that kidney biopsies to distinguish FSGS from minimal change disease may need to be performed sooner after presentation with the nephrotic syndrome, and based on their data, investigated the ideal time to perform a kidney biopsy for the detection of nonminimal change nephrotic syndrome (i.e., FSGS). The clinical feature (as opposed to a "diagnostic" test) represented in the ROC curve is "time to remission after starting corticosteroid therapy." By plotting and comparing the various sensitivities and specificities of values for "time to remission," the authors concluded that the cutoff of 28 days was statistically the best point when a biopsy should be considered. At this cutoff point, the detection of "true positives" (nonminimal change nephrotic syndrome) was maximized, and the detection of "false-positives" (minimal change nephrotic syndrome) was minimized. The LRs for "time to remission" are also listed in the manuscript. The longer a patient took to enter remission, the

Figure 17-7

ROC curve for the detection of non-MCNS in relation to remission time (14). The graph plots the true-positive rate expressed as sensitivity (%) as a function of the false-positive rate (*100-specificity* [%]) at different cutoff points. Area under the ROC CURVE = 0.859; SE = 0.057; 95% confidence interval, 0.793 to 0.911.



higher the positive LR for the diagnosis of a nonminimal change pathology underlying the nephrotic syndrome.

Screening Programs

Screening programs are designed to detect or diagnose a disease as early as possible, in hopes of improving the prognosis. A common screening program is the use of mammography for the earlier detection of breast cancer. Detecting breast cancer early, before it is "symptomatic" or advanced, has been proven to improve outcomes and survival in older women. A sampling of the many factors that must be considered when evaluating the feasibility and effectiveness of a screening program follows.

Disease

Is there a preclinical phase of the disease – a time when the disease is present but clinical symptoms have not yet manifested? Does intervening earlier in the natural history of the disease make treatment easier and/or improve morbidity or mortality? Is the disease prevalence high enough to make a screening program cost-effective?

Test

Does a screening test exist with acceptable sensitivity and specificity for a screening program – are the false-positive and false-negative rates acceptable? Is the test acceptable to the population – will they consent to the test? Do the benefits gained from early diagnosis of the disease outweigh the cost of the test?

Person/Population

Does screening/early diagnosis improve outcomes for an individual and the population? Do those with earlier diagnosis of the disease comply with treatment recommendations and regimens – how many of those who screen positive receive a final diagnosis and treatment? Is there an improvement in the quality of life in those screened?

Ethics in Research

The foundation of medical research is to help improve the lives of patients. In keeping with this, it is important to be familiar with the various terms and concepts related to the responsible and ethical conduct of medical research.

Conflicts of interest may occur between a researcher's interest in advancing medical knowledge versus his/her self-interest in fame, prestige, academic or financial advancement. Transparency of contractual obligations and relationships is mandatory, and in some circumstances, these must be dissolved, or the researcher should not participate in a related project. For example, a conflict of interest would exist if a physician was paid by a pharmaceutical company as a medical consultant, and this physician also served as a primary investigator in a clinical trial of a medication produced by the same drug company. Conflicts of interest may also occur in the clinician-investigator role when a researcher is also the clinician for the research subject. In such situations, what may be best for the research project may not be best for the individual patient. In such conflicts, the physician is expected to do what is best for the patient.

Several types of scientific *misconduct* have been described. Scientists have a responsibility to report misconduct, and institutions have the responsibility to investigate the misconduct, and protect the person alleging the misconduct. *Fabrication/forgery* is the invention and reporting of data that does not exist from an experiment that was not performed. *Falsification/fraud* is the manipulation of research data such that what is reported misrepresents the actual findings. *Plagiarism* is the presentation of another person's words or ideas as one's own or without giving appropriate credit to the original author(s).

Research on *human subjects* requires special ethical considerations and protections. Respect for research participants requires investigators to obtain informed consent or assent, maintain privacy and confidentiality, and protect the vulnerable. *Informed consent* involves relaying an unambiguous description of the research project and allowing the subject to make an informed decision regarding participation. It must be clearly stated that the patient will be involved in a research project and participation is entirely voluntary. A clear description of the potential risks and benefits, and any compensation, should be provided. For pediatric patients participating in research, *assent* is also required. Children cannot legally give permission to participate in a research study, nor can they give "consent" as consent implies

full understanding. However, ethicists and medical and legal professionals have agreed that children should be routinely asked if they agree (assent) to participate in a research project, and their wishes should be respected. Other *vulnerable* populations that require special attention to ensure their safety include prisoners, pregnant women and their fetuses and embryos, and people with impaired capacity to make decisions, such as the mentally ill. During the consent process, *confidentiality and privacy* procedures utilized by the study should be outlined. The extent of confidentiality should be disclosed – the subject should understand who will and who will not have access to the data.

Evaluating the Literature: Rating the Strength of Scientific Evidence

Health care decisions should be based on research-based evidence. Whether the individual nephrologist is making a clinical decision or a national organization is developing clinical practice guidelines, efforts should be made to systematically assess the strengths of scientific evidence related to a particular clinical diagnostic or treatment plan. Guidelines first developed more than 20 years ago at the Department of Clinical Epidemiology and Biostatistics at McMaster University first introduced tools to allow clinicians to critically review original articles on etiology, diagnosis, prognosis, and therapy (16). In the following decade, the series was widely read and cited, was modified for use by the general public, and was published in clinical epidemiology texts (17). At the same time, clinicians at McMaster University and across North America continued to expand and improve the guidelines. Their focus has expanded to include clinicians' ability to access, summarize, and apply information from the literature to everyday clinical problems, transforming the Readers' Guides to Users' Guides (18–41).

Such systematic approaches have also been adapted to assess entire bodies of research on particular subjects. In 1999, the U.S. Congress directed the Agency for Health Care Policy Research and Quality to identify methods to assess health care research results. The results of that effort were published in a report entitled "Systems to rate the strength of scientific evidence." The goals of this project were to describe systems to rate the strength of scientific evidence, including evaluating the quality of individual articles that make up a body of medical evidence related to a particular disease, allowing for the most informed medical assessments and decision making. The report provides framework for the clinician regarding the evaluation of the various types of study design as described in this chapter (42).

In summary, the busy clinician can afford to be selective in reviewing the literature. In rating the strength of scientific evidence in evaluating a specific clinical problem or treatment, one needs to be selective. The simplest criteria for choosing which studies to read in detail or which to weigh heavily in evidence are clinical relevance and methodologic soundness. This chapter has introduced a simple framework for evaluating such features in the context of sound clinical research methodology and has outlined the most recent guidelines for assessing the strength of scientific evidence for making decisions in clinical care. These tools for systematic assessment of existing research can also guide the clinical investigator toward areas that require further study in which current evidence for treatment or outcomes is scant.

18 Genomic Methods in the Diagnosis and Treatment of Pediatric Kidney Disease

Karen Maresso · Ulrich Broeckel

The completion of the Human Genome Project (HGP) in 2003 has laid the foundation and driven the technological advancements necessary for the study of the genetics of complex, multi-factorial diseases, such as those affecting the kidney. The International HapMap Project has built upon the HGP through the systematic identification and cataloguing of genetic variation across human populations. Translating the mass of data generated by these studies into useful clinical knowledge is now a major undertaking in nearly all areas of medicine, including the field of Pediatric Nephrology. Much of this work will revolve around linking particular patient phenotypes to genomic and proteomic data, such as genotype, expression profile, and protein biomarkers. As evidenced by the etiological advances made in various kidney disorders resulting from the application of genome-wide linkage analyses in the 1990's, there are a number of unique aspects of Pediatric Nephrology that make it an area particularly suitable to genomic exploration with such novel technologies as genome-wide association and expression analyses. These aspects relate both to the clinical characteristics, as well as to public health and epidemiological concerns, of pediatric kidney diseases.

A number of pediatric kidney diseases are considered to have a multi-factorial pathogenesis, often reflected in their variable clinical presentations. Such diseases are often difficult to diagnosis; and invasive biopsies are often required. Genotype and/or expression information obtained from large-scale association or profiling studies may refine the diagnosis of a number of kidney diseases and even allow for individualized disease management and therapy. Additionally, there remains an urgent need for clinically useful biomarkers which can assist in the prevention and early diagnosis of both acute and chronic kidney diseases in children. Novel serum and/or urine biomarkers identified through the application of high-throughput proteomics offers another possibility for enhanced diagnosis and treatment. Moreover, from a public health standpoint, proper management of renal disease is expensive, particularly renal replacement and dialysis. The treatment of kidney patients based on genomic and proteomic data may help lessen this burden by enhancing disease risk prediction and creating disease subsets with associated prognostic and therapeutic implications. While these issues are relevant to all of nephrology in general, as well as to many other areas of medicine, they are particularly germane to the study of childhood kidney diseases where there can be high mortality, the need for expensive lifetime treatment, as well as serious growth and nutrition implications. The proper application of genomics in Pediatric Nephrology is well-suited to address the unique challenges posed by this field.

This chapter aims to provide an overview of the application of genomic technologies to the study of pediatric kidney diseases. We will begin with a discussion of the polygenic nature of complex diseases and the recent genomic advances enabling their study. This will include outcomes of the HGP and International HapMap Project. We will then discuss the application of various genomic methods to the more common pediatric kidney diseases, covering the range of both chronic and acute, with a focus on the DNA level. We will end with a discussion of the future prospects and recommendations for applying genomics to pediatric nephrology.

The Genomics Revolution

In 2003, the completion of the Human Genome Project brought the scientific community one step closer to identifying the genes underlying common, polygenic diseases. Prior to this achievement, the goal of identifying the genetic factors responsible for diseases presenting substantial public health burdens was elusive. Research efforts focused on monogenic disorders following Mendelian patterns of inheritance. Linkage analysis was the main tool for the identification of genes behind these monogenic diseases. Although linkage analysis proved to be an effective method for the mapping of numerous genes in monogenic disorders during the 1980's and 90's, including for familiar forms of various kidney diseases (1–5), it's subsequent application to complex diseases did not meet

© Springer-Verlag Berlin Heidelberg 2009

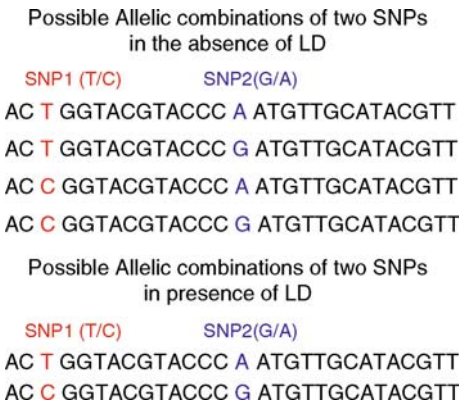
with the same success. As linkage analysis is more suitable for the identification of genes with relatively large effect sizes, its application to polygenic diseases, where the contribution of each locus or allele is believed to be relatively small, resulted in less than significant findings and results that could not be replicated. Only a handful of genes contributing to common diseases have been identified to date through linkage and subsequent positional cloning methods (6–9).

In 1996, Risch and Merikangas demonstrated the power of genome-wide association analysis (GWA) over linkage methods for the identification of the genes behind complex diseases (10). Association analysis relied upon the availability of a standardized dense set of markers covering the genome that could be easily and inexpensively typed, as well as sample sizes of thousands of cases and controls. Until the technology existed to identify, accurately map and then genotype such large numbers of markers in such great numbers of individuals, linkage analysis followed by fine-mapping remained the best option at that time for uncovering complex disease genes. However, the work of the HGP began to drive the technological breakthroughs needed to map polygenic diseases.

Analysis of the human genome sequence has demonstrated the abundance and uniformity of single nucleotide polymorphisms (SNPs), single base changes in DNA that occur in at least 1% of the population (This is in contrast to a mutation, which occurs in < 1% of the population). It is some of these common DNA variants that are believed to be responsible for at least some of the phenotypic variation observed within and between populations, including various diseases. The HGP contributed to developing technologies for the rapid, large-scale identification and scoring of SNPs and creating the intellectual resources needed to study sequence variation. The International HapMap Project built upon these discovery efforts by characterizing the patterns of linkage disequilibrium (LD) and haplotype structure across the human genome. LD occurs when two or more markers segregate together with significantly different frequencies than would be expected if they segregate independently from each other. LD is generally greater for SNPs in close physical proximity. As LD tends to reduce the number of possible haplotypes, or set of alleles, present in a population, it is useful for association mapping, in that knowing the genotype of one marker can predict the genotype of another marker in LD with it (*Fig. 18-1*). The work of the HapMap Project, along with others, has resulted in the identification, mapping, characterization, and the public availability of over four million validated SNPs to date (www.hapmap.org). The identification, mapping and cataloging of these SNPs in various human populations has helped make association studies a reality. In conjuction with the advent of mass throughput genotyping platforms, such data has potential to contribute extensively to our basic understanding of human biology and disease.

Figure 18-1

The Prinicipal of Linkage Disequilibrium. A Set of DNA sequences illustrating two SNPs. In the top half, the SNPs are not in LD with each other and segregate independently. With two SNPs in linkage equilibrium, four possible allelic combinations are possible. In the bottom half, two SNPs in the presence of LD are illustrated. Notice that LD reduces the number of possible allelic combinations, as the SNPs no longer segregate independently. Here, the 'T' allele of SNP1 segregates only with the 'A' allele of SNP2, while the 'C' allele of SNP1 segregates only with the 'G' allele of SNP2. In such a case, only one of these two SNPs would need to be genotyped, as the genotype at one SNP will provide the genotype information for the other.



The two types of association studies that are commonly used are the candidate-gene approach and the genome-wide approach (*Table 18-1*, *Fig. 18-2*). Candidate-gene association studies rely upon a specific hypothesis and are often limited by our current knowledge of biological and/or disease mechanisms. The strategy has been a frequently employed method in the study of numerous traits and diseases, including many related to nephrology. Nevertheless, replicable results have been difficult to achieve for various reasons, including the small, underpowered sample sizes characteristic of many of these types of studies (11).

In the second type of association study, the genome-wide strategy is hypothesis-free and does not make any assumptions regarding the mechanisms behind the phenotype being studied. Genome-wide association studies are ideally suited for common complex diseases, where

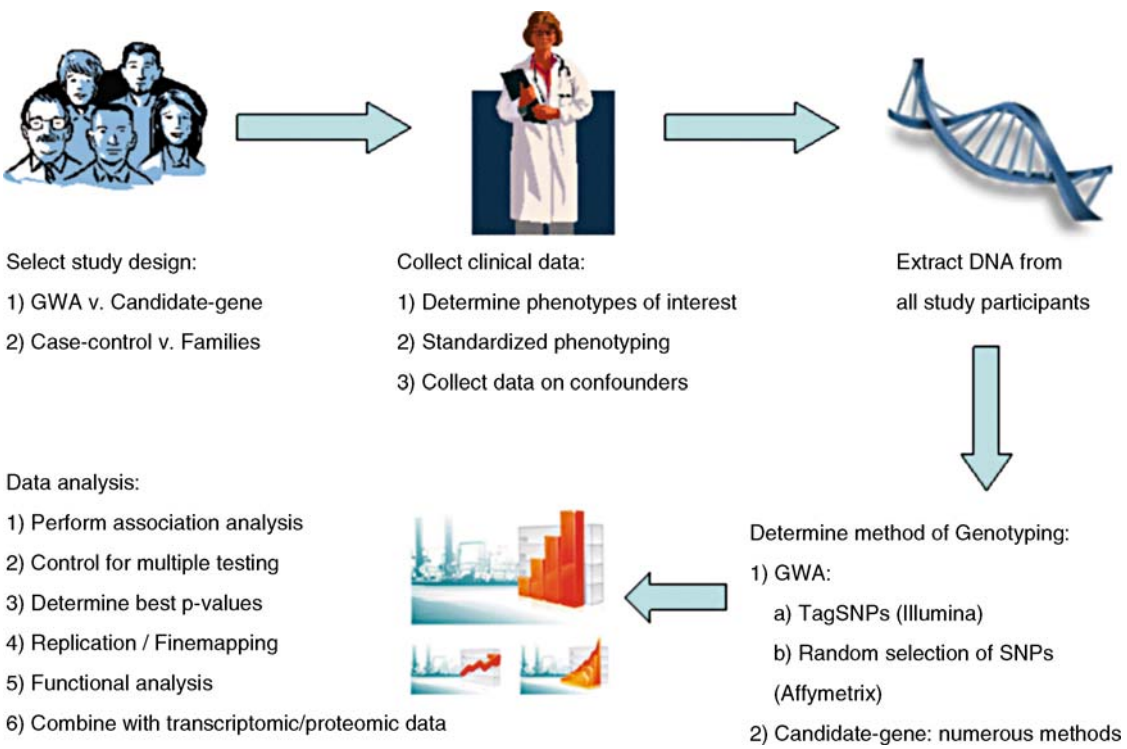
Table 18-1

Comparison of Genome-wide (GWA) and Candidate-gene Association Studies

Study design	Advantages	Disadvantages
GWA	Hypothesis-free	Genotyping more technically demanding
	May be more economical and efficient when large numbers of loci need to be worked-up	May be costly and time-consuming
	Ideal in cases where little is known regarding disease mechanisms	
	Often allow for collection of data relating to copy number polymorphisms (CNPs) in addition to SNPs – two genetic variants for the price of one.	Requires sophisticated bioinformatic approaches to data analysis and storage
Candidate-gene	Less costly and time-consuming if large numbers of loci do not need to be analyzed	Candidate-gene selection constrained by known disease biology
	Ideal in situations where evidence implicates particular disease mechanisms and related genes; or when following-up a QTL containing likely functional candidates	Less economical and efficient when testing great numbers of loci
	Straightforward data-handling and analytical approaches	
	Various methods of genotyping available; less technically demanding	

Figure 18-2

Workflow of a Genetic Association Study.



the physiological mechanisms and genetic factors that contribute to them are often not well understood. GWA studies are based on hundreds of thousands to millions of SNPs spread across the genome, each one tested for association with a particular outcome. There are currently two main approaches to this type of study. One type employs an LD-based selection strategy, as exemplified by the Illumina HumanHap-550 and Human1M sets of variants. The LD-based strategy exploits patterns of genomic LD to select a minimum number of SNPs (tagSNPs) to be assayed which captures the maximum amount of information across the genome. SNPs on these arrays serve as proxies for those not assayed. The second approach ignores patterns of LD and relies on the random selection of markers. This approach is the basis for the Affymetrix 500 K and 1 million SNP array products. A number of GWA reports have recently been published identifying novel genes for various diseases in adult populations, including many outcomes relevant to kidney disease, such as obesity and Type II Diabetes (12–14), as well as quantitative traits like urinary albumin excretion (15).

Within the field of Pediatric Nephrology, many of the known disease genes were initially identified through the study of familiar forms of a disease using linkage analysis followed by positional cloning methods (16–19). These genes have become obvious candidates to examine in the context of seemingly sporadic occurrence, where a patient has no prior family history of the disease, and which constitutes the majority of many childhood-onset kidney diseases. This is often done through mutation scanning in case series. While linkage analysis proved to be a useful tool for identifying the first disease genes in pediatric kidney disease, allowing for some of the first insights into the molecular pathogenesis of many of these diseases, these genes generally only account for a minority of cases. New methods which result in the identification of novel genes can assist in making further advances. While GWA studies are still relatively new, candidate gene studies have been an actively pursued approach in nephrology for novel gene identification. The popularity of this approach is illustrated by a review of the 2004 and 2005 abstracts of the American Society of Nephrology (ASN) and the European Renal Association/European Dialysis and Transplantation Association (ERA/EDTA), where over 180 studies encompassing 205 polymorphisms in 92 different genes were submitted (20). The genes most frequently studied were those of the renin-angiotensin system (RAS) and those related to inflammation (20). (The best evidence to date indicates minor statistical associations and a negligible clinical relevance of the most frequently studied RAS polymorphism, the insertion/deletion (I/D) variant of the angiotensin I-converting enzyme (ACE) gene (21–23). Despite their frequent study, a genetic association has yet to be convincingly demonstrated for any of the RAS genes. These genes will not be further discussed in the chapter. Of particular note, the authors highlight the extremely small sample sizes of the vast majority of these studies. In 2004, the average study size was 185 (cases and controls combined), with a slight increase in 2005 to 276. In addition, the authors found that while only 16% of these studies met the newly-adopted criteria for publishing candidate gene association studies in the Journal of the American Society of Nephrology (JASN) in 2004, this number jumped to nearly half in 2005 (20). These data highlight two important points. First, as it is unlikely that the often thousands of subjects needed for adequately-powered studies can be collected at a single site, there is a need for large-scale, multi-site collaborative studies. Large-scale candidate-gene association studies of novel genes in adult or pediatric populations are currently lacking. Second, by adopting strict publishing guidelines, journals can help assure the proper design and analysis of association studies. To address the first point, European investigators interested in nephrology and genetics established the Renal Genome Network (ReGeNet; www.regenet.eu) in 2003 to encourage large, collaborative clinical studies focused on the genetic epidemiology of renal disease (24). To date, a comparable formal renal network of investigators is lacking in the States. Such a network dedicated to studying the genetic basis of pediatric renal disease would greatly assist in establishing the infrastructure needed to design and implement adequately-powered association studies, whether those studies are candidate-gene-based or genome-wide.

When many genes are to be tested, or when one desires a hypothesis-free approach, it may be more efficient and economical to perform a GWA study. While these studies may assist in the identification of novel genes in acute kidney disorders, where currently half or less of all cases are explained by known mutations, GWA approaches in pediatric nephrology are likely to be most beneficial when applied to chronic kidney disease (CKD) and end-stage renal disease (ESRD) resulting from the increasing rate of hypertension, diabetes and obesity in children. The mechanisms leading to CKD and ESRD in these settings are likely to be polygenic in nature and the current lack of understanding regarding all disease mechanisms leading to these outcomes precludes a selection of appropriate candidate genes. In addition, the mechanisms of these disorders and their precipitating causes may be different from those occurring in adults. While some of the GWA findings from adult populations

may be relevant to pediatric populations as well, more work will be required to determine this. A more in-depth discussion on the application of candidate gene association and GWA approaches to the more common pediatric kidney diseases will be presented in the following section.

While much of this discussion has focused exclusively on the role of DNA sequence variation in disease outcomes, there are also extensive research efforts dedicated to the role of mRNA and proteins in the prevention, diagnosis and treatment of kidney disease. Expression profiling, as with high-throughput SNP genotyping, has benefited substantially from recent advances in microarray technology, which are allowing for the measurement of genome-wide expression levels, also called 'transcriptomics,' and their correlation with various disease states. As with cancer, the iden- tification of certain common expression 'signatures' through the simultaneous profiling of thousands of genes from kidney biopsy samples may help determine treatment course and patient prognosis in various renal diseases. The genome-wide study of proteins, or proteomics, has also benefited from recent technological breakthroughs in mass spectrometry, allowing for a greater number of proteins to be simultaneously analyzed. There is currently an urgent need in pediatric nephrology for clinically-relevant biomarkers which can be obtained non-invasively and which will eventually allow for earlier disease detection (25, 26). Because these two fields are closely aligned with the study of DNA sequence variation, in that changes affecting gene sequence can ultimately affect gene expression and protein production, we focus in the following section on the application of the study of DNA sequence variation to the various forms of pediatric renal disease. The application of all three fields to the study of pediatric nephrology can ultimately lead to enhanced prevention efforts, diagnoses and treatment options through the identification of novel genes and genetic markers, gene expression signatures and biomarkers associated with various renal disease states and outcomes in pediatric populations.

The Application of Genomic Methods to Pediatric Kidney Diseases

Acute Diseases

Table 18-2 provides a summary of the genes and loci implicated in the following conditions, as well as information on known genotype-phenotype correlations.

Nephrotic Syndrome (NS) NS as a heterogeneous collection of disorders represents an excellent example of where the application of genetic and genomic methods can assist in a greater understanding of disease pathogenesis and treatment.
