In children, minimal change nephropathy (MCN) is the overwhelming cause of NS, such that renal biopsies are often not performed before beginning treatment with potentially harmful immunosuppressive therapies (27). Corticosteroids are often prescribed first. The majority of children respond well to this treatment and they are said to have 'steroid-sensitive nephrotic syndrome' (SSNS). However, there is a subset of children who do not respond to this therapy and they are said to have 'steroid-resistant nephrotic syndrome' (SRNS). In such cases, a renal biopsy may be indicated and the underlying cause may be focal segmental glomerularsclerosis (FSGS). Current treatment strategies for MCN and FSGS are similar, however, they are generally less effective for FSGS; and children with the latter may go on to develop ESRD. Despite the existence of these therapeutic strategies, the underlying pathological mechanisms of these two histological classifications are poorly understood. It is a subject of debate in the literature as to whether or not these classifications represent distinct diseases or subtypes of a single condition (27). In addition to a need for a greater understanding of the disease processes involved in NS, less toxic therapies are also needed for treatment in children. In the last decade, much progress has been made in the area of NS genetics and more can be expected in the coming years with novel genomic technologies. These advances should help to clarify NS-related pathologies and offer a pharmacogenetic approach to the treatment of NS.

In the late 90's, genome-wide linkage analysis followed by positional cloning was a particularly successful method for the identification of the genes behind the familial form of NS, although sporadic cases, those without any previous family history, account for the majority of pediatric NS cases. In 1998, Kestila et al. identified the first NS-related gene, NPHS1 (nephrin), to be the cause of an autosomal-recessive form of congenital NS in the Finnish population (16, 17). This was a particularly severe form of NS, characterized by heavy proteinuria in utero, lesions of the glomerular filtration barrier, and often death within the first two years of life (17). These findings were quickly followed by the identification of the NPHS2 (podocin) gene and its mutations as the cause of autosomal recessive steroid-resistant NS in older children from families of Northern European and North African descent (18, 19). This form presented between three months and five years of age and was characterized by minimal glomerular changes on early biopsy samples, FSGS present at later stages and rapid progression to ESRD. Both nephrin and

Table 18-2

Genes and genotype-phenotype correlations in Selected Pediatric Renal Diseases

Disease	Gene(s)/Loci	Genotype-Phenotype Correlations	Comments
Nephrotic Syndrome (steroid-resistant)	NPHS1, NPHS2, LAMB2, WT1, PLCE1	NPHS1,NPHS2,LAMB2,WT1 commonly mutated in congenital onset & resistant to steroid treatment; Type & number of NPHS2 mutations correlates with age of onset.	Additional susceptibility genes and modifier genes likely. GWA studies may assist with their discovery.
Atypical Hemolytic Uremic Syndrome	CFH, CFI, CFB, MCP (complement regulatory genes)	CFH -severe clinical course, rapid progression to ESRD, earlier age at onset, disease recurrence after transplant; MCP -most favorable course, no recurrence post transplant; CFI – intermediate course.	Known complement genes account for ~50% of cases. Additional susceptibility genes likely. Modifier genes likely due to high incomplete penetrance. SNPs may also play a role along with known mutations.
Autosomal Dominant Polycystic Kidney Disease	PKD1, PKD2	PKD1 – more severe course & earlier onset; 5′ mutations may progress to ESRD earlier & be more susceptible to ICAs.	PKD1 accounts for ~85% of families. Most mutations in these genes are unique to single family. Genetic background may account for variability w/in a family. Medical re-sequencing can assist in increasing the numbers of particular mutational profiles. GWA studies may help to uncover modifier genes.
Autosomal Recessive Polycystic Kidney Disease	PKHD1	Presence of two truncating mutations results in neonatal death, regardless of position. Missense mutations associated with milder phenotype.	~33% of mutations are unique to a single family. Medical re-sequencing can assist in increasing the numbers of particular mutational profiles.
IgA Nephropathy	6q22–23; 4q26–31; 17q12–22; 2q36; megsin gene, uteroglobin, C1GALT1, E & L selectins, PIGR, IGHMBP2, TNFa, TGFb, IL-4, IFg, and HLA-DRA	Gene verification and discovery and genotype-phenotype correlations still needed.	No gene(s) yet identified in families. Many results from case-control studies need verification. GWA studies needed.
End-Stage Renal Disease	10p; 18q; See Iyengar, et al. for additional loci; D10S558, D10S1435, D6S281, D4S2937, D2S291, D17S515, CNDP1, ELMO1, PVT1	Gene verification and discovery and genotype-phenotype correlations in pediatric cohorts still needed.	Genes identified in adult populations and many in setting of DN. Verification in adults and children required. GWA studies needed.

podocin localize to the slit diaphragm and are key glomerular filtration barrier proteins.

Since the identification of these genes, numerous studies have investigated their role in all forms of NS. It is now well-established that 10–30% of sporadic NS cases with FSGS are due to mutations within NPHS2 (28). Mutations within the laminin-β-2 (LAMB2), Wilms' tumour 1 (WT1) and phospolipase C-ε (PLCE1) genes have also been reported in pediatric NS, although they are far less frequent (29–31). Hinkes et al. reported that in 89 patients from 80 families manifesting NS within the first year of life, mutations in one of four genes (NPHS1, NPHS2, WT1, and LAMB2) were identified in 66% of the cases, with nearly 38% and 23% due to NPHS2 and

NPHS1 mutations, respectively (32). When examined by age of onset, the proportion of congenital cases explained by mutations in one of the four genes was nearly twice that of infantile-onset cases. Also of note, the study reported that children with mutations in any one of the four genes did not respond to steroid treatment. The authors concluded that children with onset of NS during the first year of life should be screened for mutations within these four genes in order to guide therapeutic course; and that there are likely additional unknown genes playing a role in early-onset NS.

Previous studies have suggested both allelic and locus heterogeneity of NS. While nephrin mutations have been found only in patients with congenital onset, podocin mutations have been found in cases presenting at varying ages (32, 33). The reasons for this phenotypic variability are not yet completely understood, however, there is data supporting that the specific type or number of NPHS2 mutations may play a role (34, 35).

Perhaps the largest study to date on podocin mutations in sporadic cases best demonstrates the significant locus and allelic heterogeneity of NS. Using direct sequencing in 430 patients from 404 families from around the world, Hinkes, et al. was the first to document that patients with a specific type and number of mutations presented with symptoms at a significantly earlier age than patients without such mutations (33). Nevertheless, the authors did observe that identical mutations did result in different ages of onset within their study. Consequently, Hinkes, et al. concluded that there are likely to be additional modifying factors affecting the phenotype. It must also be noted that nearly 300 individuals in this study did not carry any mutation within the podocin gene, highlighting the likelihood of as yet undiscovered genes. This is the largest report to date, and the first to establish statistical significance of an important genotype-phenotype correlation. It serves as an example of the advantages of multi-national collaborations and demonstrates that further such studies are required in order to identify additional correlations with therapeutic and prognostic implications in the treatment of NS.

Currently, genetic screening is recommended for those children presenting with NS during their first year of life, as this could allow carriers of mutations in the NPHS1, NPHS2, LAMB2, and WT1 genes to be spared the potentially harmful treatments to which they have been shown not to respond (32, 36). Genetic testing may eventually become more widespread in children presenting with NS, regardless of age, as further studies establish links between currently known mutations and clinically-relevant phenotypic outcomes, as well as with the discovery of novel genes and variants. It should be noted that a different set of genetic variants may predispose to the steroid-sensitive form of NS (37), however, it has not been as intensively studied as SRNS due to its relatively benign clinical course. While there is currently much research focused on the genes and proteins of the slit diaphragm complex, further in-roads may be made in both SRNS and SSNS with the application of genome-wide association and expression studies to uncover novel susceptibility and modifying genetic variants. Such studies will require large-scale cohorts resulting from multi-institution and/or multi-national collaborations in order to further elucidate the pathogenetic mechanisms behind this rare and heterogenous syndrome.

Hemolytic Uremic Syndrome (HUS)

Hemolytic Uremic Syndrome (HUS) is similar to NS in that there are different manifestations of the disease and it appears to be genetically heterogenous. HUS occurs in its typical form following an infection associated with diarrhea, often from the E. Coli serotype 0157:H7. This form is relatively benign, and once resolved, complete renal function is generally restored. However, approximately 5–10% of HUS patients present with no previous infection. This atypical form, aHUS, can occur at any age, can be familiar or sporadic in nature and is associated with a poor clinical outcome, including a 25–30% mortality rate (38). While a number of environmental factors triggering aHUS have been reported (39–45), a genetic basis for this form has been suggested by familial cases (46–48). In 1998, the first aHUS-associated gene, complement factor H (CFH), was localized (49). Since then, aHUS has become largely recognized as a disease of complement alternative pathway dysregulation.

As with NS, some of the initial advances in understanding the etiology of aHUS were the result of genetic linkage and subsequent association studies. Using a candidate-gene linkage approach in three families, Warwicker et al. first demonstrated linkage of aHUS to a region on chr. 1 containing a number of genes involved in complement activation regulation (49). Subsequent mutational screening of the CFH gene identified two different mutations in one of the three families and in a sporadic aHUS patient. Since this first identification, numerous studies have reported various mutations within CFH associated with aHUS (49–54). Most mutations are missense mutations occurring in the C-terminal region of the protein; and functional analysis of CFH mutations show that they result in a reduced ability of CFH to protect cells from

complement lysis (55). Additional mutations within the complement regulatory genes of membrane co-factor protein (MCP) (56–58) and factor I (CFI) (59, 60), as well as within complement activating components factor B (CFB) (61) and C3 genes (62), have also been associated with aHUS. Together, these genes are estimated to account for approximately 50% of aHUS cases (39, 63–65). There is now an on-line database, www.fh-hus.org, which catalogues the various complement activation gene mutations associated with aHUS and provides a host of information regarding this disease and its genetic risk factors.

In order for complement gene mutation status to be translated into clinically useful information, a few reports have examined genotype-phenotype correlations in aHUS. Although each report is based on a small number of children, the results are consistent across studies. Carriers of CFH mutations have the most severe clinical course, demonstrating earlier age of onset, rapid progression to ESRD, and disease recurrence after kidney transplantation (63, 66). Those with MCP mutations show the most favorable prognosis, with no disease recurrence post-transplantation (39, 63, 66). CFI mutations carriers have an intermediate course, with 50% quickly progressing to ESRD, 50% recovering and a majority with disease recurrence post-transplantation (63, 66). These data demonstrate that aHUS presentation, response to treatment and long-term outcome are closely linked to genotype status. This should allow for more tailored management of children with aHUS and underscores the urgent need for new and improved therapies for those with CFH and IFH mutations.

An interesting feature of aHUS is its high rate of incomplete penetrance, approaching 50%, where disease-causing mutations are seen in those who do not present with the disease. It has been speculated that additional genetic factors may be required in addition to the known causative mutations in order for the disease to manifest itself. In addition, approximately half of aHUS patients do not carry a known causative mutation, suggesting as yet unidentified genetic variants. In this regard, a handful of polymorphisms, or SNPs, have also been associated with aHUS (50, 56, 65, 67,68). Caprioli et al. documented association of three SNPs in CFH with aHUS, concluding that they may predispose to the disease in those without CFH mutations, as well as contributing to the full manifestation of aHUS in CFH mutation carriers (50). Findings from Fremeaux-Bacchi, et al. support these data (56). A report by Esparza-Gordillo identified a SNP haplotype block spanning the complement activation gene cluster or chr.1q32 which was more frequent in aHUS patients, particularly those with CFH, MCP or F1 mutations, and which associated strongly with the severity of the disease (68). This same group later reported on a pedigree where three independent aHUS genetic risk factors were segregating, but only those members who inherited all three manifested aHUS (69). The authors hypothesize that multiple "hits" are required in complement activation genes in order to induce the aHUS phenotype. These data demonstrate the allelic heterogeneity and polygenic nature of aHUS.

Clearly, more work remains to be done, as only 50% of cases are explained by currently known mutations. It is likely that more genes and mutations await discovery. Moreover, the role of SNPs and their functional impact along side the currently known mutations needs to be better elucidated. As with NS, large-scale genomic association and expression studies may be helpful in this regard.

Chronic Kidney Diseases and End-Stage Renal Failure

As with the acute disorders, *Table 18-2* provides a summary of the genes, loci and genotype-phenotype correlations relevant to the below conditions.

Polycystic Kidney Disease (PKD) PKD represents a diverse collection of disorders of the tubules of the kidney, where healthy renal tissue is progressively replaced by fluid-filled cysts. Extra-renal manifestations are also seen in PKD, including hypertension, biliary ectasia and fibrosis leading to portal hypertension, hepatic cysts, abnormal heart valves, and intra-cranial aneurysms. Autosomal dominant PKD (ADPKD) is the most common form, with symptomatic onset usually during the third and fourth decades of life, although childhood onset has been documented (70, 71). Autosomal recessive PKD (ARPKD) is rarer, with symptoms often beginning *in utero* or during the neonatal period. Aside from palliative care, there are currently no known specific therapies for PKD. While the genetics of both ADPKD and ARPKD are well-established, additional advancements await through medical re-sequencing and the identification of genetic disease modifiers.

As with the aforementioned acute conditions, the genes for ADPKD, polycystin-1 (PKD1) and polycystin-2 (PKD2)/transient receptor potential channel (TRPP2), and the gene for ARPKD, fibrocystin (PKHD1), were identified through linkage analyses and subsequent positional cloning efforts (1–5). In ADPKD, the PKD1 gene accounts for approximately 85% of all families (72–74) and is associated with both a more severe clinical course and earlier onset (74–77). There is substantial allelic

heterogeneity of both PKD1 and PKD2, with most mutations unique to a family. The ADPKD database shows 314 and 91 likely pathogenic germ-line mutations within PKD1 and PKD2, respectively (http://pkdb.mayo.edu/; accessed 6/6/08).

As most mutations are private, genotype-phenotype studies must generally classify mutations in some way, usually based on type (missense v. truncating) and position within the protein. However, no strong correlations have yet been established between either type or position and phenotypic outcome for either gene. There is some evidence to suggest that patients with mutations in the 5' region of PKD1 progress to ESRD earlier and may be more susceptible to intra-cranial aneurysms (78, 79). While these two genes account for nearly all cases, the disease often presents with significant variability within families. While some of this variability is likely due to environmental factors, additional genetic factors are also suspected in modifying disease outcomes. Studies have estimated that 18–78% of the phenotypic variance in PKD1 and PKD2 populations may be attributable to genetic background (80–82). Many candidate gene studies have been performed in an attempt to identify some of these modifying factors; however, the results to date have been inconsistent (23, 83, 84). Because of the diversity of disease mutations and a lack of phenotypic correlations, the usefulness of genetic testing in ADPKD is limited, although it may be helpful in childhood cases with no previous family history. This may change as genotype-phenotype correlations and new therapies are eventually established.

In ARPKD, allelic effects play a greater role than in ADPKD. There are currently just over 300 mutations in the PKHD1 gene, according to the ARPKD database (http://www.humgen.rwth-aachen.de/; accessed 6/6/08). About 33% of mutations in this gene are unique to a single family (74). Although genotype-phenotype studies are limited by the substantial amount of allelic heterogeneity present within PKHD1, some conclusions can be drawn from these reports. In all studies to date, the presence of two truncating mutations has been shown to result in neonatal death, regardless of their position (85–87). All ARPKD patients which survive the neonatal period have been shown to carry at least one amino-acid substitution, as opposed to all chain-terminating mutations (85). While truncating mutations in general are associated with more severe disease, missense mutations have been shown to result in a milder phenotype (85). Larger cohorts of patients will be required to establish consistent and more detailed genotype-phenotype correlations that can be used to improve management of the disease, and in particular, to assist in the development of novel therapeutic approaches. As ARPKD is quite rare, and thus the numbers small, no candidate gene studies have been carried out to identify genetic modifiers, although some have been mapped in mouse models (74, 88).

In both ADPKD and ARPKD, the availability of fast, high-throughput medical re-sequencing, where patients are re-sequenced in-depth over long genomic regions in a matter of hours or days, offers a new opportunity for mutation detection, with a consequent increase in numbers of patients with specific mutational profiles. This should eventually aid in establishing clinically useful genotype-phenotype correlations. Moreover, the use of GWA studies in ADPKD, where the numbers are larger, may allow for the identification of novel genetic modifiers.

Primary IgA Nephropathy (IgAN) Primary IgAN is the most common form of glomerulonephritis in children worldwide, although its prevalence varies according to country (89–91). Some of this variance is attributable to geographic differences in the policies affecting renal biopsy in the young (92), while some may also be due to geographic differences in genetic and environmental factors (93, 94). Its incidence has been estimated as high as 25–30% in some Asian countries where children routinely undergo annual urinary screening, however, lower rates have been reported in Europe and the United States (95–98). IgAN is characterized by glomerular mesangial deposits of IgA and a widely-varying presentation (99). IgAN often presents with gross hematuria attendant to an upper respiratory tract infection (95, 98, 100, 101). However, it is estimated that in as many as half of all cases, there is only microscopic hematuria, which can continue for years before the development of proteinuria (95, 98, 101, 102). Because symptoms can be intermittent, and because in most countries there are no routine urinary screening programs, the diagnosis of IgAN can be missed.

IgAN was previously considered a benign disease, however, this outlook is changing based on the recognition of increased morbidity and mortality after long-term follow-up (95, 100, 103, 104), including the finding that approximately 10% and 20% of children progress to ESRD from ten and twenty years postdiagnosis, respectively (95, 100, 105–108). The disease progresses slowly over decades and with clinical symptoms often not presenting until years after onset, it is possible that many adult IgAN cases actually had a pediatric onset. Consequently, childhood IgAN may be considered an early stage of adult IgAN with life-long follow-up and evaluation required to detect the signs of disease progression (95). Enhanced detection of the disease in childhood may allow

for its earlier treatment and more aggressive management, offering a reduced risk of chronic kidney disease and ESRD at its later stages.

A complete understanding of the pathogenesis of IgAN is still lacking, although abnormally low glycosylation of IgAI molecules is a consistent finding in patients (109–111). Treatment of the disease is based upon symptoms, but ACE inhibitors are commonly prescribed due to their reno-protective effects. Some new drugs are currently under investigation, but more specific novel treatments are needed which can be used safely over the long-term in children. Obtaining a better understanding of this disease from a genetic standpoint should allow for insights into IgAN pathogenesis, as well as offering options for its improved diagnosis and treatment.

As with the diseases previously discussed, IgAN is genetically heterogenous, with familial aggregation identified in a subset of cases, while the bulk of cases present with seemingly sporadic onset. Currently, it is estimated that 15% of cases are "familial," however, it may actually be higher due to the difficulty in diagnosing the disease.

Within families, IgAN appears to follow an autosomal dominant inheritance pattern with incomplete penetrance. The most likely genetic model for IgAN resembles that of NS or aHUS, where there are a handful of primary susceptibility genes with additional modifying genetic and environmental factors also required. Yet the identification of genes for IgAN lags behind that of the acute kidney disorders, with no gene yet identified in familial cases. However, three genome-wide linkage studies have established a number of chromosomal regions linked to the disease. Gharavi, et al. identified a locus, termed *IGAN1*, on chromosome 6q22–23 as being linked to IgAN in 60% of the families from a Caucasian cohort (112). Using 22 informative Italian families from the IgAN biobank (113), Bisceglia, et al. reported linkage to *IGAN1* and also identified two suggestive loci on chromosomes 4q26–31 and 17q12–22(114). The most recent genome-wide linkage scan identified a locus on chromosome 2q36 in a Canadian family of Austrian-German descent with 14 affected subjects (115). These studies support the likely genetic heterogeneity of the disease. Review of the genes within these loci do not reveal likely candidates, however, this is not unexpected given the lack of understanding surrounding IgAN pathological mechanisms (116).

Not unlike the previous diseases, numerous smaller-scale case-control and family-based association studies have been undertaken for IgAN. Some of the genes studied to date, and for which significant associations have been reported, include the megsin gene, found in glomerular mesangium and upregulated in IgAN (117, 118); the uteroglobin gene, a multifunctional anti-inflammatory protein (119–121); and the C1GALT1 gene, an enzyme involved in the O-glycosylation process (122); and the E- and L- selectin genes, involved in endothelial and leukocyte cell-cell interactions, respectively (123). Associations have also been reported for a number of inflammatory candidates as well, including TNFα, TGFα, IL-4, IFγ, and HLA-DRA (124–127). In a partial genome-wide screen, a Japanese group has reported significant associations of the polymeric immunoglobulin receptor (PIGR) gene (128) and the immunoglobulin mu-binding protein 2 gene (129) using over 80,000 gene-based SNPs in a stepwise association design. Finally, while not associated with IgAN onset, a 32 bp deletion in the chemokine receptor 5 (CCR5) gene has been associated with increased renal survival in IgAN patients (130, 131). Results for many of the above genes require confirmation in larger, independent cohorts.

High-throughput genotyping of dense sets of SNPs within the currently known linkage peaks, now made possible through the HapMap Project and the commercial availability of mass-throughput SNP genotyping platforms, may assist in the identification of the genes responsible for the signals. GWA studies may also be useful and more economical in this regard. Once susceptibility genes are firmly established, the IgAN field can progress to identifying genotype-phenotype correlations to aid in diagnosis and treatment.

End-stage Renal Disease (ESRD) While many chronic kidney diseases can lead to ESRD, the causes of it differ between children and adults. Although hypertension and diabetes are the primary causes of ESRD in adult populations, FSGS and congenital structural kidney abnormalities are the primary causes in children. However, the well-documented worldwide increase in rates of childhood obesity, and its related complications of diabetes and hypertension, has the potential to significantly impact the rate of pediatric renal failure (132–137). The prevalence of ESRD in pediatric cohorts is generally less than that in adults, nevertheless, these children experience significant morbidity and mortality (138–140). In addition, ESRD disproportionately affects minorities, with African-American children having nearly double to triple the rates of Caucasian children within the same age categories (140).

Due to well-established statistics indicating a potentially catastrophic increasing public health burden of CKD and ESRD overall, the identification of genes related to these two outcomes represents a substantial opportunity for improvement in understanding the complex pathological mechanisms behind CKD progression.

A vast majority of the work in this area has been conducted in adult populations due to the higher prevalence of these outcomes, as well as to the availability of large cohorts of adults well phenotyped for the more common complex diseases which result in CKD and ESRD within this population. We will briefly review findings from the adult studies here, however, as the precipitating causes differ between adults and children, disease mechanisms leading to the end-point of ESRD may also differ. Therefore, genes identified in adults need to be tested for relevance in pediatric patients. Large, multi-institutional/multi-national cohorts of CKD and ESRD pediatric patients phenotyped in a standardized manner will be required to dissect the genetics of these complex and critical outcomes of various pediatric kidney diseases.

A number of groups have performed linkage analyses for ESRD in the context of one of its major precipitating causes in adults, diabetic nephropathy (DN) (141–153). Results from these linkage studies have identified numerous distinct loci, however, the best evidence supports DN susceptibility loci on chromosomes 10p and 18q (154). A susceptibility gene, carnosinase-1 (CNDP1), has been identified from the 18q locus. Two independent groups have demonstrated that diabetic patients harboring a particular leucine repeat polymorphism of CNDP1 are at a significantly reduced risk of developing nephropathy and ESRD (155, 156).

Although numerous association studies examining single genes have been published for ESRD, as in other cases, the small sample sizes and limited coverage of the candidate genes make results difficult to interpret (154). However, some larger-scale and more in-depth association scans, including a GWA study, have been published in this area and warrant discussion (15, 157, 158–160). In the first comprehensive, family-based screen of candidate genes for ESRD, Ewens identified twenty nominally significant genes, including twelve novel ones, in 72 type I diabetic trios (160). McKnight et al., used 6,000 microsatellites in 400 Irish patients with and without type I DN to identify two significant makers on chromosome 10, and four additional markers worthy of investigation on chromosomes 2, 4, 6, and 17 (159). A Japanese scan using over 80,000 SNPs in 87 type II diabetics with nephropathy and 92 diabetic controls without nephropathy identified the engulfment and cell motility 1 (ELMO1) gene as a DN susceptibility gene (158). In a recent GWA SNP association study, Hanson et al. found a significant association with the plasmacytoma variant translocation (PVT1) gene with ESRD in 207 type II diabetics with and without DN (157). Unfortunately, many of the above results still await verification (154).

It is noteworthy that the above studies all examined a qualitative outcome and were conducted in the setting of DN. However, there have been a number of both large-scale linkage and association studies published examining quantitative kidney function traits, such as glomerular filtration rate and urinary albumin excretion, in various populations (15, 141, 161, 162). Results from most of these studies require verification. A number of advantages have been suggested for the use of quantitative traits in the genetic dissection of complex diseases (163–165). The continued use of large and comprehensive linkage and association scans should assist in the further identification and replication of ESRD susceptibility loci. However, their relevance to children will have to be tested. The establishment of cohorts of children with ESRD is challenging given the small numbers, nevertheless, such cohorts can be collected through long-term collaborative efforts. Such cohorts are required to map genetic variation which may ultimately allow for more aggressive and tailored prevention and treatment efforts in this life-threatening disorder.

The Past, Present and Future Application of Genomic Methods in Pediatric Nephrology

With the application of genome-wide linkage analyses as one of the first genomic technologies, pediatric nephrology witnessed some of the first fundamental advances in the understanding of many chronic and acute kidney diseases. With the completion of the HGP and the availability of genome-wide SNP markers that were easily and inexpensively typed, the field witnessed the candidate-gene era, where one or a few genes were genotyped for a handful of SNPs in usually small to moderate size samples with inadequate statistical power for detecting true disease associations. The popularity of this method was due in large part to its ease of application; however, the current and widespread use of candidate gene studies has limited ability to result in the novel breakthroughs required to enable paradigm changes in the prevention, diagnosis and treatment of these often life-threatening conditions. In order for the field to take the next step in the understanding of such diseases, the application of the next generation of genomic technologies to pediatric renal diseases in required, including GWA studies with hundreds of thousands to millions of SNPs. In order for these studies to become a reality within the field, large, well-phenotyped cohorts of children are necessary. The sample sizes needed for GWA studies to be successful, those samples approaching

1,000 or more, cannot be collected at a single center due to the often modest number of cases of any particular kidney disorder. Consequently, it becomes apparent that investigators need to form inter-institutional and even international collaborations with standardized methods of phenotyping. This is being pursued to some extent with adult renal patients and it is just beginning in the pediatric case. More collaborations can be expected as the importance of genomic technologies in pediatric nephrology is increasingly recognized, as such technologies become more readily available to investigators and as the infrastructure required for such studies becomes more firmly established. GWA studies offer a hypothesis-free design to gene discovery and are therefore ideal for many complex kidney diseases where there is limited knowledge of disease mechanisms. Their analysis, in conjunction with the other genome-wide technologies of transcriptomics and proteomics, offers the best hope for future fundamental advances in the field of pediatric nephrology.

19 Tissue Engineering

Anthony Atala

Patients suffering from diseased or injured genitourinary organs are often treated with reconstructive surgery or transplants, but there is a severe shortage of donor tissue and organs. This shortage worsens yearly as modern medicine increases the human lifespan. The aging population grows, and the need for organs grows with it. Physicians and scientists have begun to look to the fields of regenerative medicine and tissue engineering to provide new options for these patients. These fields apply the principles of cell transplantation, material science, and bioengineering to construct biological substitutes that can significantly improve the quality of life of the urologic patient by eliminating the need for intensive grafting procedures or transplant surgery.

Tissue engineering, one of the major components of regenerative medicine, follows the principles of cell transplantation, materials science, and engineering to develop biological substitutes that can restore and maintain normal organ function. Tissue engineering strategies generally fall into two categories: the use of acellular matrices designed to direct the body's natural ability to use its own cells to regenerate damaged tissue, and the use of matrices seeded with cells in the laboratory to produce novel tissues and organs. Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds, or by removing cellular components from donor tissues via mechanical and chemical manipulation to produce collagen-rich matrices (1–4). These matrices slowly degrade after implantation and are replaced by the extracellular matrix (ECM) proteins secreted by the in growing cells. Cells themselves can also be used for therapy via injection, either with carriers such as hydrogels, or alone.

The most common way to use cells in tissue engineering is to obtain a small piece of donor tissue and dissociate it into individual cells in the laboratory. These cells are either implanted directly into the host, or are expanded in culture and attached to a support matrix. The cell/matrix construct is then reimplanted into the host. The source of the donor tissue can be heterologous (such as bovine), allogeneic (same species, different individual), or autologous. Ideally, autologous cells are used, because in this case both structural and functional tissue replacement will usually occur with minimal complications. To accomplish this, a biopsy of tissue is obtained from a host, the cells are dissociated and expanded in culture, and the expanded cells are implanted back into the same host (2, 5–12). The use of autologous cells, although it may cause an inflammatory response, avoids rejection and thus, the deleterious side effects of lifelong immunosuppression can be avoided.

However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous cells cannot be expanded from a particular organ, such as the pancreas. In these situations, stem cells are envisioned as an alternative source of cells from which the desired tissue can be derived. Stem cells can be derived from discarded human embryos (human embryonic stem cells), from fetal tissue, or from adult sources (bone marrow, fat, skin). However, there are ethical issues involved in the use of embryonic stem cells. Most human applications are currently banned in the United States, a policy that may be dramatically changed with the inauguration of a new President in January 2009. Despite this, the field of stem cell biology is advancing rapidly, and cutting-edge techniques such as therapeutic cloning and somatic cell reprogramming circumvent some of the ethical questions and offer potentially limitless sources of these cells for tissue engineering applications.

This chapter will review the major components of most tissue engineering techniques, and will describe how these techniques are being applied to the reconstruction and regeneration of the genitourinary system.

The Basic Components of Tissue Engineering

Cells

Native Cells

In the past, one of the limitations of applying cell-based regenerative medicine techniques to organ replacement was the inherent difficulty of growing certain cell types in

© Springer-Verlag Berlin Heidelberg 2009

large quantities. Even when some organs, such as the liver, have a high regenerative capacity in vivo, cell growth and expansion in vitro can be difficult. By studying the privileged sites for committed precursor cells in these organs, as well as by exploring the conditions that promote differentiation and/or self-renewal of these cells, it has been possible to overcome some of the obstacles that limit cell expansion in vitro. One example is the urothelial cell. Urothelial cells could be grown in the laboratory setting in the past, but only with limited success. Several protocols were developed over the past two decades that identify the undifferentiated cells in a mixed culture of cells isolated from the urinary tract, and keep them undifferentiated during their growth phase (11, 13–16). Using these methods of cell culture, it is now possible to expand a urothelial culture that initially covered a surface area of 1 cm^2 to one covering a surface area of 4,202 m^2 (the equivalent of one football field) within 8 weeks (11). These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the donor in sufficient quantities for reconstructive purposes (11, 14–19). Major advances in cell culture techniques have been made within the past decade, and these techniques make the use of autologous cells possible for clinical application.

Embryonic Stem Cells

In 1981, pluripotent cells were found in the inner cell mass of the human embryo, and the term "human embryonic stem cell" was coined (20). These cells are able to differentiate into all cells of the human body, excluding placental cells (only cells from the morula are totipotent; that is, able to develop into all cells of the human body). These cells have great therapeutic potential, but their use is limited by both biological and ethical factors.

The political controversy surrounding stem cells began in 1998 with the creation of human embryonic stem (hES) cells derived from discarded embryos. hES were isolated from the inner cell mass of a blastocyst (an embryo 5 days post-fertilization) using an immunosurgical technique. Given that some cells cannot be expanded ex vivo, ES cells could be the ideal resource for tissue engineering because of their fundamental properties: the ability to self-renew indefinitely and the ability to differentiate into cells from all three embryonic germ layers. Skin and neurons have been formed, indicating ectodermal differentiation (21–23) (24). Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation (25–27). Pancreatic cells have been formed, indicating endodermal differentiation (28). In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers while in culture, and can form teratomas in vivo (29). These cells have demonstrated longevity in culture and can maintain their undifferentiated state for at least 80 passages when grown using currently published protocols (30, 31).

However, in addition to the ethical issues surrounding the use of embryonic stem cells, their clinical application is limited because they represent an allogenic resource and thus have the potential to evoke an immune response. New stem cell technologies (such as somatic cell nuclear transfer and reprogramming) promise to overcome this limitation.

Therapeutic Cloning (Somatic Cell Nuclear Transfer)

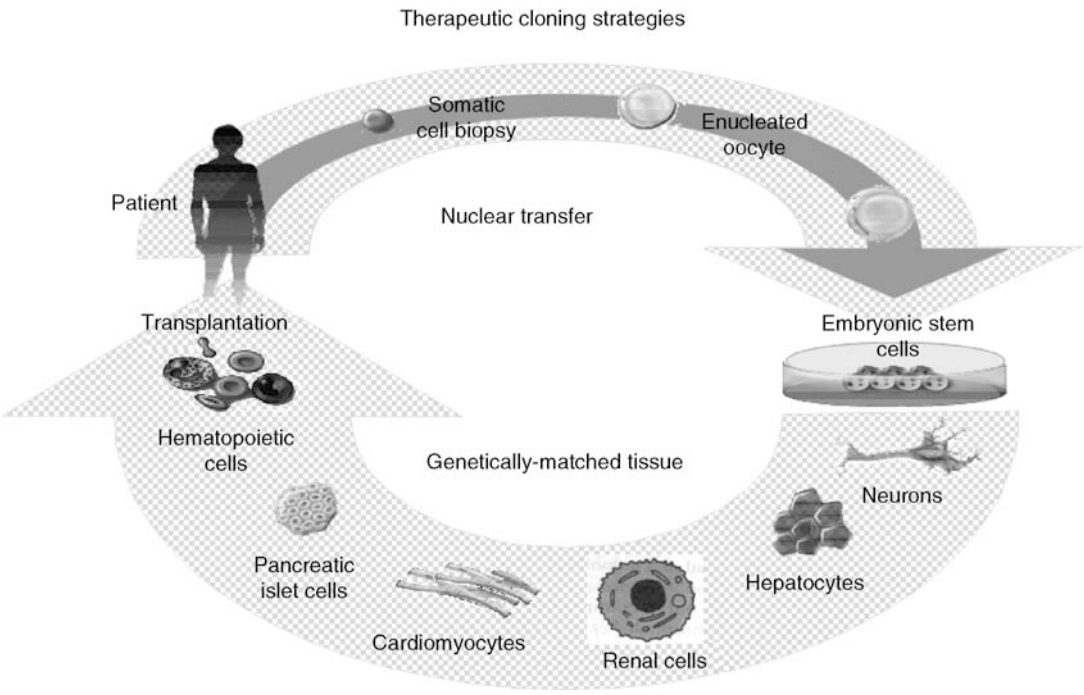
Somatic cell nuclear transfer (SCNT), or therapeutic cloning, entails the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. Activation with chemicals or electricity stimulates cell division up to the blastocyst stage.

At this point, it is extremely important to differentiate between the two types of cloning that exist – reproductive cloning and therapeutic cloning. Both involve the insertion of donor DNA into an enucleated oocyte to generate an embryo that has identical genetic material to its DNA source. However, the similarities end there. In reproductive cloning, the embryo is then implanted into the uterus of a pseudopregnant female to produce an infant that is a clone of the donor. A world-famous example of this type of cloning resulted in the birth of a sheep named Dolly in 1997 (32). However, there are many ethical concerns surrounding such practices, and as a result, reproductive cloning has been banned in most countries.

While therapeutic cloning also produces an embryo that is genetically identical to the donor, this process is used to generate blastocysts that are explanted and grown in culture, rather than in utero. Embryonic stem cell lines can then be derived from these blastocysts, which are only allowed to grow up to a 100-cell stage. At this time the inner cell mass is isolated and cultured, resulting in ES cells that are genetically identical to the patient. This process is detailed in *Fig. 19-1*. It has been shown that nuclear transferred ES cells derived from fibroblasts, lymphocytes, and olfactory neurons are pluripotetent and can generate live pups after injection into blastocysts.

Figure 19-1

Strategies for therapeutic cloning in regenerative medicine.



This shows that cells generated by SCNT have the same developmental potential as blastocysts that are fertilized and produced naturally (33–36). In addition, the ES cells generated by SCNT are perfectly matched to the patient's immune system and no immunosuppressive medications would be required to prevent rejection should these cells be used in tissue engineering applications.

Although ES cells derived from SCNT contain the nuclear genome of the donor cells, mitochondrial DNA (mtDNA) contained in the oocyte could lead to immunogenicity after transplantation. To assess the histocompatibilty of tissue generated using SCNT, Lanza et al. microinjected the nucleus of a bovine skin fibroblast into an enucleated oocyte (37). Although the blastocyst was implanted (reproductive cloning), the purpose was to generate renal, cardiac and skeletal muscle cells, which were then harvested, expanded in vitro, and seeded onto biodegradable scaffolds. These scaffolds were then implanted into the donor steer from whom the cells were cloned to determine if cells were histocompatible. Analysis revealed that cloned renal cells showed no evidence of T-cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA. This finding represents an important step in overcoming histocompatibility problems of stem cell therapy.

Although promising, SCNT has certain technical limitations that must be overcome prior to clinical application. There are also obvious etical concerns which must be resolved re: the potential abuses of therapeutic cloning. In addition, this technique has not yet been successful in humans. The initial failures and fraudulent reports of nuclear transfer in humans have reduced enthusiasm for human applications (38–40). However, it was recently reported that non-human primate ES cell lines were generated by SCNT of nuclei from adult skin fibroblasts (41, 42).

Before SCNT-derived ES cells can be used as clinical therapy, careful assessment of quality of the lines must be determined. For example, some cell lines generated by SCNT have contained chromosomal translocations and it is not known whether these abnormalities originated from aneuploid embryos or if they occurred during ES cell isolation and culture. In addition, the low efficiency of SNCT (0.7%) and the inadequate supply of human oocytes further hinder the therapeutic potential of this technique. Still, these studies provide promise that ES cell lines could one day be generated from human cells to produce patient-specific stem cells. Such cells would have the potential to cure many human diseases that are currently untreatable.

Reprogrammed Somatic Cells

Recently, exciting reports of the successful transformation of adult cells into pluripotent stem cells through specific genetic "reprogramming" has been published. Reprogramming is a technique that involves de-differentiation of adult somatic cells to produce patient-specific pluripotent stem cells, eliminating the need to create embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus, the patient who donated these cells) and would not be rejected. Yamanaka was the first to discover that mouse embryonic fibroblasts (MEFs) and adult mouse fibroblasts could be reprogrammed into an "induced pluripotent state (iPS)" (43). These iPS cells possessed the immortal growth characteristics of self-renewing ES cells, expressed genes specific for ES cells, and generated embryoid bodies in vitro and teratomas in vivo. When iPS cells were injected into mouse blastocysts, they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of ES cells. In addition, the epigenetic state of the iPS cells was intermediate between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

These results were improved significantly by Wernig and Jaenisch in July 2007 (44). In their study, DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of ES cells. Teratomas induced by these cells contained differentiated cell types representing all three embryonic germ layers. Most importantly, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germ line like ES cells, suggesting that these iPS cells were completely reprogrammed.

It has recently been shown that reprogramming of human cells is possible (45, 46). Yamanaka generated human iPS cells that are similar to hES cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Thompson's group showed that retroviral transduction of the stem cell markers *OCT4, SOX2, NANOG, and LIN28* could generate pluripotent stem cells. However, in both studies, the human iPS cells were similar but not identical to hES cells. Although reprogramming is an exciting phenomenon, our limited understanding of the mechanism currently limits the clinical applicability of the technique. The future potential of reprogramming is quite exciting.

Placental and Amniotic Fluid Stem Cells

Recently, it has been shown that pluripotent cells may be derived from the amniotic fluid and placenta. Both amniotic fluid and placenta are known to contain multiple partially differentiated cell types derived from the developing fetus. Stem cell populations have been isolated from these sources. Called amniotic fluid and placental stem cells (AFPSC), they express embryonic and adult stem cell markers (47). The undifferentiated stem cells expand extensively without a feeder cell layer and double every 36 h. Unlike human embryonic stem cells, the AFPSC do not form tumors in vivo. Lines maintained for over 250 doublings retained long telomeres and a normal complement of chromosomes. AFPSC are broadly multipotent, and human lines can be induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal and hepatic lineages. Examples of differentiated cells derived from AFPSC and displaying specialized functions include neuronal lineage secreting the neurotransmitter L-glutamate or expressing G-protein-gated inwardly rectifying potassium (GIRK) channels, hepatic lineage cells producing urea, and osteogenic lineage cells forming tissue engineered bone. In this respect, they meet a commonly accepted criterion for pluripotent stem cells, without implying that they can generate every adult tissue. The cells could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus, or from the placenta at the time of birth. They could be preserved for self use, and used without rejection, or they could be banked. A bank of 100,000 specimens could potentially supply 99% of the US population with a perfect genetic match for transplantation. Such a bank may be easier to create than with other cell sources, since there are approximately 4.5 million births per year in the USA (47).

Biomaterials

In the most common tissue engineering procedures, isolated cells are seeded onto a scaffold composed of an appropriate biomaterial. These biomaterials replicate the biologic and mechanical function of the native extracellular matrix (ECM) found in tissues in the body by serving as an artificial ECM. Biomaterials provide a three-dimensional space for the cells to develop into new tissues with appropriate structure and function. They can also allow delivery of appropriate bioactive factors (e.g., cell adhesion peptides, growth factors) to the developing tissue (48) to help regulate cellular function. As the majority of mammalian

cell types are anchorage-dependent and will die if no cell adhesion substrate is available, biomaterials provide this substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against in vivo forces so that the predefined three-dimensional structure of the engineered implant is maintained during tissue development.

The ideal biomaterial should be biodegradable, bioresorbable, and support the replacement of normal tissue without inducing inflammation. Incompatible materials are destined for an inflammatory or foreign-body response that eventually leads to rejection and/or necrosis. Degradation products, if produced, should be removed from the body via metabolic pathways at an adequate rate so that the concentration of these degradation products in the tissues remains at a tolerable level (49). The biomaterial should also provide an environment in which appropriate regulation of cell behavior (adhesion, proliferation, migration, and differentiation) can occur. Cell behavior in the newly formed tissue has been shown to be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell-adhesion ligands (50) and with soluble growth factors. Since biomaterials provide temporary mechanical support while the cells undergo spatial reorganization into tissue, the properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development, it should begin to degrade so that it does not hinder further tissue growth (48).

Generally, three classes of biomaterials have been utilized for engineering tissues: naturally derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). These classes of biomaterials have been tested for biocompatibility (51, 52). Naturally derived materials and acellular tissue matrices have the potential advantage of biological recognition. However, synthetic polymers can be produced reliably on a large scale with controlled properties such as strength, degradation rate, and microstructure, which would aid in the preparation of easily used, "off-the-shelf" scaffold material.

Naturally Derived Materials

Collagen is the most abundant and ubiquitous structural protein in the body, and may be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction (53). Collagen implants, under normal conditions, are degraded through a process involving phagocytosis of collagen fibrils by fibroblasts (54). This is followed by sequential attack by lysosomal enzymes including cathepsins B1 and D. Under inflammatory conditions, the implants can be rapidly degraded largely by matrix metalloproteins (MMPs) and collagenases (54). However, the in vivo resorption rate of a collagen implant can be regulated by controlling the density of the implant and the extent of intermolecular cross-linking – the lower the density, the greater the space between collagen fibers and the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell adhesion domain sequences (e.g., RGD) that may help to retain the phenotype and activity of many types of cells, including fibroblasts (55)and chondrocytes (56).

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle (57) and a cell immobilization matrix (58) owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is relatively biocompatible and is approved by the Food and Drug Administration (FDA) for human use as wound dressing material. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of polygluronic block in the alginate chains (57).

Acellular Tissue Matrices

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues. The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue (1–4). These matrices slowly degrade upon implantation, and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or in growing cells.

Synthetic Polymers

Polyesters of naturally occurring *a*-hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers are FDA-approved for a variety of applications, including sutures (59). The ester bonds in these polymers are hydrolytically labile, and they degrade by nonenzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are nontoxic natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water (59). The degradation rate of

these polymers can be tailored to theapplication by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Generally, the optimal degradation time ranges from several weeks to several years. Since these polymers are thermoplastics, they can be easily formed into a three dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion, solvent casting (60), phase separation techniques, and gas foaming techniques (61). Many applications intissue engineering often require a scaffold with high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(orthoesters), can also be used to fabricate scaffolds for tissue engineering with controlled properties (62).

Engineering Specific Tissues and Organs

Investigators around the world, including our laboratory, have been working towards the development of several cell types, tissues, and organs for clinical application. The following sections will describe this research in detail.

Urethra

Various biomaterials without cells, such as PGA and acellular collagen-based matrices derived from decellularized small intestine and bladder, have been used in animal models for the regeneration of urethral tissue (4, 63–67). Some of these biomaterials, like acellular collagen matrices derived from bladder submucosa, have also been seeded with autologous cells for urethral reconstruction. Our laboratory has been able to replace tubularized urethral segments with cell-seeded collagen matrices (68, 69).

Acellular collagen matrices derived from bladder submucosa by our laboratory have been used experimentally and clinically. In animal studies, segments of the urethra were resected and replaced with acellular matrix grafts. Histological examination showed complete epithelialization and progressive vessel and muscle infiltration, and the animals were able to void through the neo-urethras (4). These results were confirmed in a clinical study of patients with hypospadias and urethral stricture disease (70) (*Fig. 19-2*). Decellularized cadaveric bladder submucosa was used as an underlying matrix for urethral repair in patients with stricture disease and hypospadias. Patent, functional neo-urethras were noted in these patients with up to a 7-year follow-up. The use of a readily available, "off-the-shelf" matrix appears to be beneficial for patients with abnormal urethral conditions and obviates the need for obtaining autologous grafts, thus decreasing operative time and eliminating donor site morbidity.

Unfortunately, the above techniques are not applicable for tubularized urethral repairs. The collagen matrices are able to replace urethral segments only when used in specific physical contact with existing tissue. However, if a tubularized repair is needed, the collagen matrices should be seeded with autologous cells to avoid the risk of stricture formation and poor tissue development (68). Therefore, tubularized collagen matrices seeded with autologous cells can be used successfully for total penile urethra replacement.

Bladder

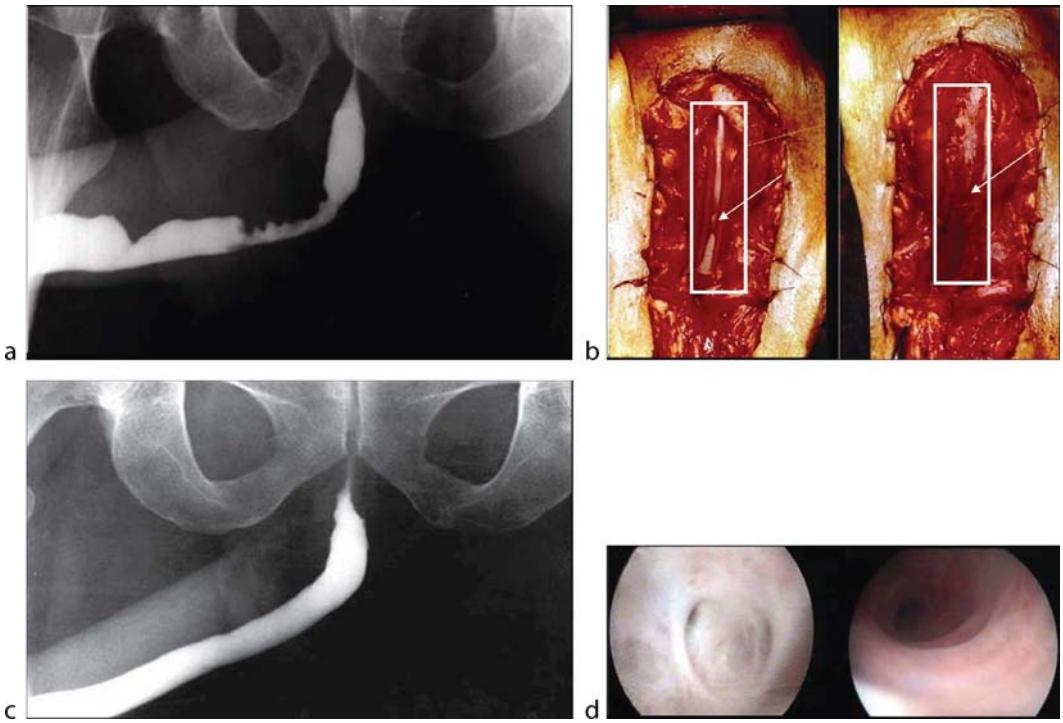
Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is designed for the excretion of solutes. Due to the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative materials and tissues for bladder replacement or repair.

The success of cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long term survival, differentiation, and growth. Urothelial and muscle cells can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells (71). These principles were applied in the creation of tissue engineered bladders in an animal model that required a subtotal cystectomy with subsequent replacement with a tissue engineered organ in beagle dogs (12). Urothelial and muscle cells were separately expanded from an autologous bladder biopsy, and seeded onto a bladder-shaped biodegradable polymer scaffold. The results from this study showed that it is possible to tissue engineer bladders that are anatomically and functionally normal. Clinical trials for the application of this technology are currently being conducted.

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1999. A small pilot study of seven patients was reported, using a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage (*Fig. 19-3*). The patients reconstructed with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds showed increased compliance, decreased end-filling pressures, increased capacities and

Figure 19-2

Urethral repair using a collagen matrix. (a): Representative case of a patient with a bulbar stricture. (b): During surgery, strictured tissue is excised, preserving the urethral plate on the left side, and the matrix is anastamosed to the urethral plate in an onlay fashion on the right. The boxes in both photos indicate the area of interest, including the urethra, which appears white in the left photograph. In the left photograph, the arrow indicates the area of stricture in the urethra. On the right, the arrow indicates the repaired stricture. Note that the engineered tissue now obscures the native white urethral tissue in an onlay fashion in the right photograph. (c): Urethrogram 6 months after repair. (d): Cystoscopic view of urethra before surgery on the left side, and 4 months after repair on the right side. (See color plate 5)



longer dry periods (72) (*Fig. 19-4*). Although the experience is promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. Further experimental and clinical work is being conducted.

Kidney

Renal tissue is arguably one of the most difficult tissues to replicate in the laboratory. The kidney is a complex organ and its unique structural and cellular heterogeneity creates many challenges. The system of nephrons and collecting ducts within the kidney is composed of multiple functionally and morphologically distinct segments, arranged in an elaborate architectonic pattern. For this reason, appropriate conditions must be provided to ensure the long-term survival, differentiation and growth of many types of cells. Recent efforts in kidney tissue regeneration have focused on the development of a reliable cell source (73, 74) (75, 76) (77, 78). Moreover, optimal growth conditions have been extensively investigated to provide adequate enrichment to achieve stable renal cell expansion systems (79, 80) (81–83).

Isolation of particular cell types that produce specific factors may be a good approach for selective cell therapies. For example, cells that produce erythropoietin could be isolated in culture, and these cells could eventually be used to treat anemia that results from end stage renal failure. However, total renal function would not be achieved using this approach. To create kidney tissue that would deliver full renal function, a culture containing all of the cell types comprising the functional nephron units should be used. Optimal culture conditions to nurture renal cells have been extensively studied and

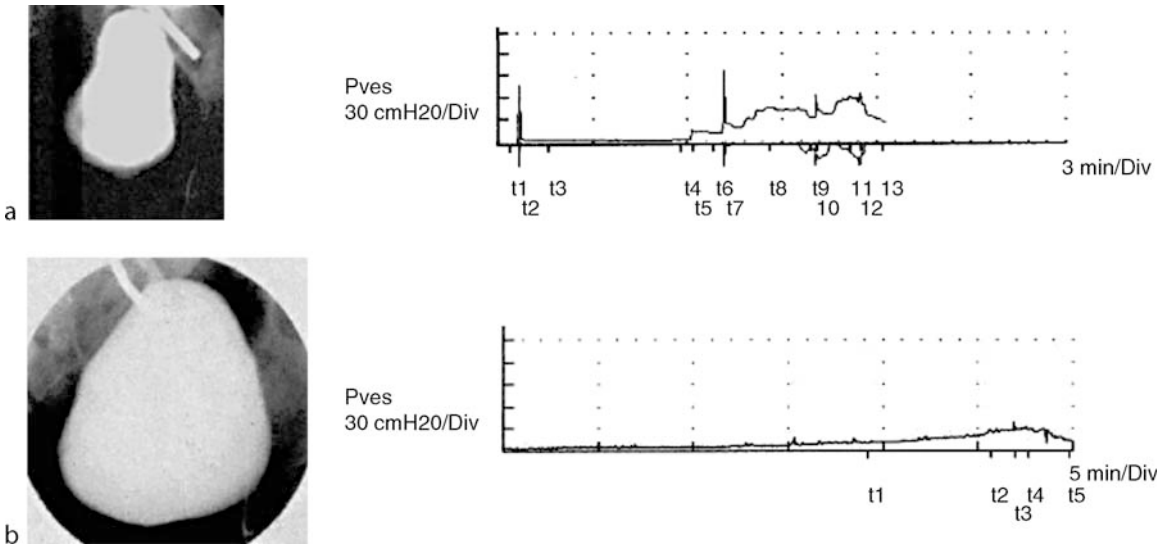
Cystograms and urodynamic studies of a patient before and after implantation of the tissue engineered bladder. (a): Preoperative results indicate an irregular bladder in the cystogram and abnormal bladder pressures as the bladder is filled via urodynamic study. (b): Postoperatively, findings are significantly improved.



cells grown under these conditions have been reported to maintain their cellular characteristics (84). Moreover, renal cells placed in a three-dimensional culture environment are able to reconstitute into renal structures.

Recent investigative efforts in the search for a reliable cell source have been expanded to stem and progenitor cells. Use of these cells for tissue regeneration is attractive due to their ability to differentiate and mature into the many specific cell types needed. This is particularly useful in instances where primary renal cells are unavailable due to extensive tissue damage. Bone marrow-derived human mesenchymal stem cells have been shown to be a potential source due to their ability to differentiate into several cell lineages (73, 74, 77). These cells have been shown to participate in the kidney development when they are placed in a rat embryonic niche that allows for continued exposure to a repertoire of nephrogenic signals (78). These cells, however, were found to contribute mainly to

regeneration of damaged glomerular endothelial cells after injury. In addition, the major cell source of kidney regeneration was found to originate from intrarenal cells in an ischemic renal injury model (73, 76). Another potential cell source for kidney regeneration is circulating stem cells, which have been shown to transform into tubular and glomerular epithelial cells, podocytes, mesangial cells, and interstitial cells after renal injury (74, 85–87) (75, 88, 89). These observations suggest that controlling stem and progenitor cell differentiation may lead to successful regeneration of kidney tissues.

Although isolated renal cells are able to retain their phenotypic and functional characteristics in culture, transplantation of these cells in vivo may not result in structural remodeling. In addition, cell or tissue components cannot be implanted in large volumes due to limited diffusion of oxygen and nutrients (90). Thus, a cell-support matrix, preferably one that encourages angiogenesis, is necessary to allow diffusion across the entire implant. A variety of synthetic and naturally derived materials has been examined in order to determine the ideal support structures for the regeneration (70, 72, 91–93). Biodegradable synthetic materials, such as poly-lactic and poly-glycolic acid polymers, have been used to provide structural support for cells. Synthetic materials can be easily fabricated and configured in a controlled manner, which make them attractive options for tissue engineering. However, naturally derived materials, such as collagen, laminin and fibronectin, are much more biocompatible and provide a similar extracellular matrix environment to normal tissue. For this reason, collagen based scaffolds have been used increasingly in many applications (94–97).

Developmental Approaches to Kidney Regeneration

Transplantation of a kidney precursor, such as the metanephros, into a diseased kidney has been proposed as a possible method for functional restoration. In an animal study, human embryonic metanephroi, transplanted into the kidneys of an immune deficient mouse model, has developed into mature kidneys (98). The transplanted metanephroi produced urine-like fluid, however, failed to develop ureters. This study suggests that development of an in vitro system in which metanephroi could be grown may lead to transplant techniques that could produce a small replacement kidney within the host. In another study, the metanephros was divided into mesenchymal tissue and ureteral buds, and each of the tissue segments was cultured in vitro (99). After eight days in culture, each portion of the mesenchymal tissues had grown to the original size. A similar method was used for ureteral buds, which also propagated. These studies indicate that if the mesenchyme and ureteral buds were placed together and cultured in vitro, a metanephros-like structure would develop and suggest that the metanephros could be propagated under optimal conditions.

In another study, transplantation of metanephroi into a non-immunosuppressed rat omentum showed that the implanted metanephroi are able to undergo differentiation and growth that is not confined by a tight organ capsule (100). When the metanephroi with an intact ureteric bud were implanted, the metanephroi are able to enlarge and become kidney-shaped tissue within 3 weeks. The metanephroi transplanted into the omentum were able to develop into kidney tissue structure with a well-defined cortex and medulla. Mature nephrons and collecting system structures are shown to be indistinguishable from those of normal kidneys by light or electron microscopy (101, 102). Moreover, these structures become vascularized via arteries that originate at the superior mesenteric artery of the host (101, 102). It has been demonstrated that the metanephroi transplanted into the omentum survive for up to 32 weeks post-implantation (103). These studies show that developmental approach may be a viable option for regenerating renal tissue for functional restoration.

Tissue Engineering Approaches to Kidney Regeneration

The ability to grow and expand renal cells is one of the essential requirements in engineering tissues. The feasibility of achieving renal cell growth, expansion and in vivo reconstitution using tissue engineering techniques was investigated (91). Donor rabbit kidneys were removed and perfused with a non-oxide solution which promoted iron particle entrapment in the glomeruli. Homogenization of the renal cortex and fractionation in 83 and 210 micron sieves with subsequent magnetic extraction yielded three separate purified suspensions of distal tubules, glomeruli, and proximal tubules. The cells were plated separately in vitro and after expansion, were seeded onto biodegradable polyglycolic acid scaffolds and implanted subcutaneously into host athymic mice. This included implants of proximal tubular cells, glomeruli, distal tubular cells, and a mixture of all three cell types. Animals were sacrificed at one week, two weeks, and one month after implantation and the retrieved implants were analyzed. An acute inflammatory phase and a chronic foreign body

reaction were seen, accompanied by vascular in growth by 7 days after implantation. Histologic examination demonstrated progressive formation and organization of the nephron segments within the polymer fibers with time. Renal cell proliferation in the cell-polymer scaffolds was detected by in vivo labeling of replicating cells with the thymidine analog bromodeoxyuridine (76). BrdU incorporation into renal cell DNA was confirmed using monoclonal anti-BrdU antibodies. These results demonstrated that renal specific cells can be successfully harvested and cultured, and can subsequently attach to artificial biodegradable polymers. The renal cell-polymer scaffolds can be implanted into host animals where the cells replicate and organize into nephron segments, as the polymer, which serves as a cell delivery vehicle, undergoes biodegradation.

Initial experiments showed that implanted cell-polymer scaffolds gave rise to renal tubular structures. However, it was unclear whether the tubular structures reconstituted de novo from dispersed renal elements, or if they merely represented fragments of donor tubules which survived the original dissociation and culture processes intact. Further investigation was conducted in order to examine the process (104). Mouse renal cells were harvested and expanded in culture. Subsequently, single isolated cells were seeded on biodegradable polymers and implanted into immune competent syngeneic hosts. Renal epithelial cells were observed to reconstitute into tubular structures in vivo. Sequential analyses of the retrieved implants over time demonstrated that renal epithelial cells first organized into a cord-like structure with a solid center. Subsequent canalization into a hollow tube could be seen by two weeks. Histologic examination with nephron segment specific lactins showed successful reconstitution of proximal tubules, distal tubules, loop of Henle, collecting tubules and collecting ducts. These results showed that single suspended cells are capable of reconstituting into tubular structures, with homogeneous cell types within each tubule.

Although these studies demonstrated that renal cells seeded on biodegradable polymer scaffolds are able to form some renal structures in vivo, complete renal function could not be achieved in these studies. In a subsequent study we sought to create a functional artificial renal unit which could produce urine (105). Mouse renal cells were harvested, expanded in culture, and seeded onto a tubular device constructed from polycarbonate (97). The tubular device was connected at one end to a silastic catheter which terminated into a reservoir. The device was implanted subcutaneously in athymic mice. The implanted devices were retrieved and examined histologically and immunocytochemically at 1, 2, 3, 4 and 8 weeks after implantation. Fluid was collected from inside the implant, and uric acid and creatinine levels were determined.

Histological examination of the implanted device demonstrated extensive vascularization as well as for mation of glomeruli and highly organized tubule-like structures. Immunocytochemical staining with anti-osteopontin antibody, which is secreted by proximal and distal tubular cells and the cells of the thin ascending loop of Henle, stained the tubular sections. Immunohistochemical staining for alkaline phosphatase stained proximal tubule-like structures. Uniform staining for fibronectin in the extracellular matrix of newly formed tubes was observed. The fluid collected from the reservoir was yellow and contained 66 mg/dl uric acid (as compared to 2 mg/dl in plasma) suggesting that these tubules are capable of unidirectional secretion and concentration of uric acid. The creatinine assay performed on the collected fluid showed an 8.2 fold increase in concentration, as compared to serum. These results demonstrated that single cells form multicellular structures can become organized into functional renal units that are able to excrete high levels of solutes through a urine-like fluid (105).

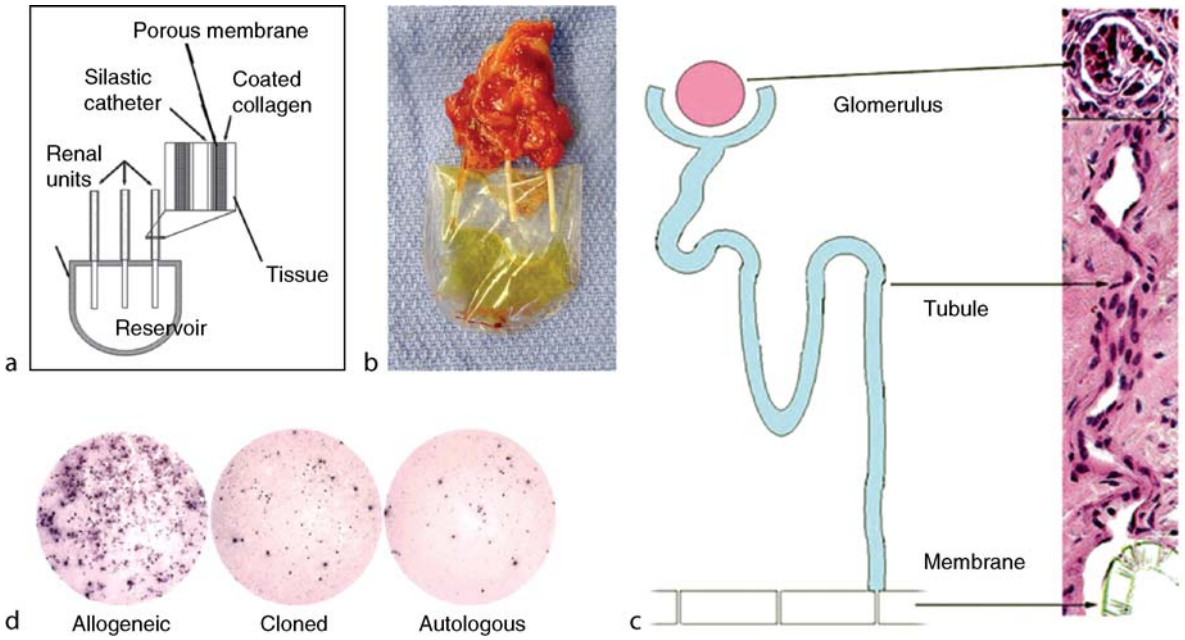
To determine whether renal tissue could be formed using an alternative cell source, nuclear transplantation (therapeutic cloning) was performed to generate histocompatible tissues, and the feasibility of engineering syngeneic renal tissues in vivo using these cloned cells was investigated (84). Nuclear material from bovine dermal fibroblasts was transferred into unfertilized enucleated donor bovine eggs. Renal cells from the cloned embryos were harvested, expanded in vitro, and seeded onto three-dimensional renal devices (*Fig. 19-5a*). The devices were implanted into the back of the same steer from which the cells were cloned, and were retrieved 12 weeks later.

This process produced functioning renal units. Urine production and viability were demonstrated after transplantation back into the nuclear donor animal (*Fig. 19-5b*). Chemical analysis suggested unidirectional secretion and concentration of urea nitrogen and creatinine. Microscopic analysis revealed formation of organized glomeruli and tubular structures (*Fig. 19-5c*). Immunohistochemical and RT-PCR analysis confirmed the expression of renal mRNA and proteins.

Since previous studies have shown that bovine clones harbor the oocyte mitochondrial DNA (106–108) the donor egg's mitochondrial DNA (mtDNA) was thought to be a potential source of immunologic incompatibility. Differences in mtDNA-encoded proteins expressed by cloned cells could stimulate a T-cell response specific for

Figure 19-5

Combining therapeutic cloning and tissue engineering to produce kidney tissue. (a): Illustration of the tissue-engineered renal unit. (b): Renal unit seeded with cloned cells, three months after implantation, showing the accumulation of urine-like fluid. (c): Clear unidirectional continuity between the mature glomeruli, their tubules, and silastic catheter. (d): Elispot analyses of the frequencies of T cells that secrete IFNγ after stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts. Cloned renal cells produce fewer IFNγ spots than the allogeneic cells, indicating that the rejection response to cloned cells is diminished. The presented wells are single representatives of duplicate wells. (See color plate 7)



mtDNA-encoded minor histocompatibility antigens when the cloned cells are implanted back into the original nuclear donor (109). Maternally transmitted minor histocompatibility antigens in mice have been shown to stimulate both skin allograft rejection in vivo and cytotoxic T lymphocytes expansion in vitro (109) that could prevent the use of these cloned constructs in patients with chronic rejection of major histocompatibility matched human renal transplants (110, 111). We tested for a possible T-cell response to the cloned renal devices using delayed-type hypersensitivity testing in vivo and EliSPOT analysis of interferon-γ secreting T-cells in vitro. Both analyses revealed that the cloned renal cells showed no evidence of a T-cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA (*Fig. 19-5d*). This finding may represent a step forward in overcoming the histocompatibility problem of stem cell therapy (111).

These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and transplanted in vivo with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to that of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues in vivo.

However, a naturally derived tissue matrix with existing three-dimensional kidney architecture would be preferable to the artificial matrix used in these experiments, because it would allow for transplantation of a larger number of cells, resulting in greater renal tissue volumes. Thus, we developed an acellular collagen-based kidney matrix, which is identical to the native renal architecture. In a subsequent study we investigated whether these collagen-based matrices could accommodate large volumes of renal cells and form kidney structures in vivo (112).

Acellular collagen matrices, derived from porcine kidneys, were obtained through a multi-step decellularization process. During this process, serial evaluation of the matrix for cellular remnants was performed using histochemistry, scanning electron microscopy (SEM) and RT-PCR. Mouse renal cells were harvested, grown,

and seeded on 80 of the decellularized collagen matrices at a concentration of 30×10^6 cells/ml. Forty cell-matrix constructs grown in vitro were analyzed 3 days, 1, 2, 4 and 6 weeks after seeding. The remaining 40 cell-containing matrices were implanted in the subcutaneous space of 20 athymic mice. The animals were sacrificed 3 days, 1, 2, 4, 8 and 24 weeks after implantation for analyses. Gross, SEM, histochemical, immunocytochemical and biochemical analyses were performed.

Scanning electron microscopy and histologic examination confirmed the acellularity of the processed matrix. RT-PCR performed on the kidney matrices demonstrated the absence of any RNA residues. Renal cells seeded on the matrix adhered to the inner surface and proliferated to confluency 7 days after seeding, as demonstrated by SEM. Histochemical and immunocytochemical analyses performed using H & E, periodic acid schiff, alkaline phosphatase, anti-osteopontin and anti-CD-31 identified stromal, endothelial and tubular epithelial cell phenotypes within the matrix. Renal tubular and glomerulus-like structures were observed 8 weeks after implantation. MTT proliferation and titrated thymidine incorporation assays performed 6 weeks after cell seeding demonstrated a population increase of 116% and 92%, respectively, as compared to the 2 week time points. This study demonstrates that renal cells are able to adhere to and proliferate on the collagen-based kidney matrices. The renal cells reconstitute renal tubular and glomeruli-like structures in the kidney-shaped matrix. The collagen based kidney matrix system seeded with renal cells may be useful in the future for augmenting renal function.

We also investigated the feasibility of creating three-dimensional renal structures for in situ implantation within the native kidney tissue. Primary renal cells from 4 week old mice were grown and expanded in culture. These renal cells were labeled with fluorescent markers and injected into mouse kidneys in a collagen gel for in vivo formation of renal tissues. Collagen injection without cells and sham operated animals served as controls. In vitro reconstituted renal structures and in vivo implanted cells were retrieved and analyzed.

The implanted renal cells formed tubular and glomerular structures within the kidney tissue, as confirmed by the fluorescent markers. There was no evidence of renal tissue formation in the control and the sham operated groups. These results demonstrate that single renal cells are able to reconstitute kidney structures when placed in a collagen-based scaffolding system. The implanted renal cells are able to self assemble into tubular and glomerular structures within the kidney tissue. These findings suggest that this system may be the preferred approach to engineer functional kidney tissues for the treatment of end stage renal disease.

Genital Tissues

Reconstructive surgery is required for a wide variety of pathologic penile conditions, such as penile carcinoma, trauma, severe erectile dysfunction, and congenital conditions such as ambiguous genitalia, hypospadias, and epispadias. One of the major limitations of phallic reconstructive surgery is the scarcity of sufficient autologous tissue.

The major components of the phallus are corporal smooth muscle and endothelial cells. The creation of autologous functional and structural corporal tissue de novo would be beneficial. Autologous cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on acellular collagen matrices and implanted in a rabbit model (113, 114). Histologic examination confirmed the appropriate organization of penile tissue phenotypes, and structural and functional studies, including cavernosography, cavernosometry, and mating studies, demonstrated that it is possible to engineer autologous functional penile tissue. Our laboratory is currently working on increasing the size of the engineered constructs.

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells (115). Autologous rabbit uterine smooth muscle and epithelial cells were harvested, then grown and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval 6 months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue. The feasibility of

engineering vaginal tissue in vivo was investigated (116). Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, while the non-cell-seeded structures were noted to be stenotic (116).

Other Emerging Technologies

Injectable Therapies

Both urinary incontinence and vesicoureteral reflux are common conditions affecting the genitourinary system. Both conditions are usually the result of damage to or malformation of a specific sphincter muscle. Currently, injection of bulking agents around the defective sphincter can be used clinically for these conditions, but biocompatibility of current synthetic bulking agents is a concern. The ideal substance for endoscopic treatment of reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume stable, and safe for human use. Animal studies have shown that chondrocytes (cartilage cells) can be easily harvested and combined with alginate in vitro and the resulting suspension can be easily injected cystoscopically. A similar technique using muscle and muscle precursor cells with the hope of repairing the defective sphincter muscle has been studied. These technologies have been applied in humans for the correction of vesicoureteral reflux in children and for urinary incontinence in adults (117, 118).

Autologous Chondrocytes as Bulking Agents

Injectable bulking agents can be endoscopically used in the treatment of both urinary incontinence and vesicoureteral reflux. The advantages in treating urinary incontinence and vesicoureteral reflux with this minimally invasive approach include the simplicity of this quick outpatient procedure and the low morbidity associated with it. Several investigators are seeking alternative implant materials that would be safe for human use (119).

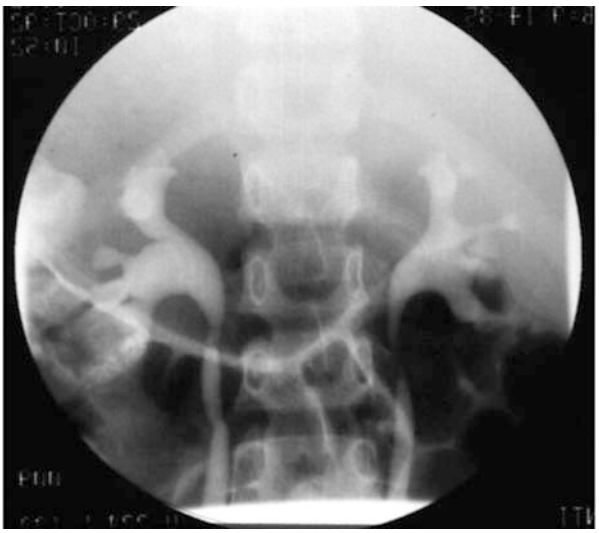
The ideal substance for the endoscopic treatment of reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume stable, and safe for human use. Toward this goal long term studies were conducted to determine the effect of injectable chondrocytes in vivo (120). It was initially determined that alginate, a liquid solution of gluronic and mannuronic acid, embedded with chondrocytes, could serve as a synthetic substrate for the injectable delivery and maintenance of cartilage architecture in vivo. Alginate undergoes hydrolytic biodegradation and its degradation time can be varied depending on the concentration of each of the polysaccharides. The use of autologous cartilage for the treatment of vesicoureteral reflux in humans would satisfy all the requirements for an ideal injectable substance.

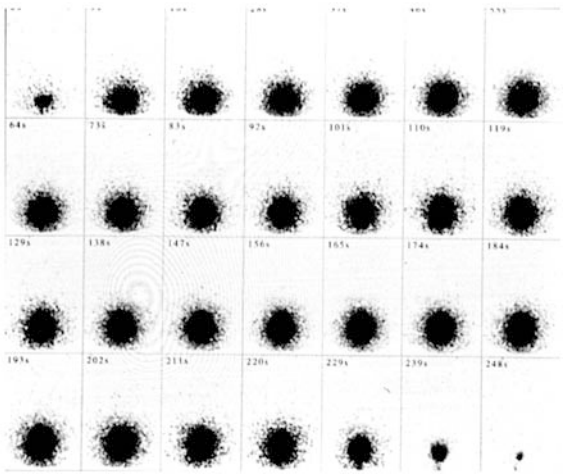
Chondrocytes derived from an ear biopsy can be readily grown and expanded in culture. Neocartilage formation can be achieved in vitro and in vivo using chondrocytes cultured on synthetic biodegradable polymers. In these experiments, the cartilage matrix replaced the alginate as the polysaccharide polymer underwent biodegradation. This system was adapted for the treatment of vesicoureteral reflux in a porcine model (121). These studies showed that chondrocytes can be easily harvested and combined with alginate in vitro, the suspension can be easily injected cystoscopically, and the elastic cartilage tissue formed is able to correct vesicoureteral reflux without any evidence of obstruction.

Two multicenter clinical trials were conducted using this engineered chondrocyte technology. Patients with vesicoureteral reflux were treated at ten centers throughout the US. The patients had a similar success rate as with other injectable substances in terms of cure (*Fig. 19-6*). Chondrocyte formation was not noted in patients who had treatment failure. It is supposed that the patients who were cured have a biocompatible region of engineered autologous tissue present, rather than a foreign material (117). Patients with urinary incontinence were also treated endoscopically with injected chondrocytes at three different medical centers. Phase 1 trials showed an approximate success rate of 80% at follow-up 3 and 12 months postoperatively (118). Several of the clinical trials involving bioengineered products have been placed on hold because of the costs involved with the specific technology. With a bioengineered product, costs are usually high because of the biological nature of the therapies involved. As with any therapy, the cost that the medical health care system can allow for a specific technology is limited. Therefore, the costs of bioengineered products have to be lowered for them to have an impact clinically. This is currently being addressed for multiple tissue-engineered technologies.

Figure 19-6

Autologous chondrocytes for the treatment of vesicoureteral reflux. (a): Preoperative voiding cystourethrogram of a patient with bilateral reflux. A catheter was inserted into the bladder via the urethra, and contrast material was instilled intravesically. Here, contrast material can be seen within both ureters and within the kidneys, indicating reflux is present. (b): Postoperative radionuclide cystogram of the same patient 6 months after injection of autologous chondrocytes. A catheter was inserted into the bladder via the urethra, and a radioactive solution was inserted into the bladder. The bladder was scanned during filling and emptying phases. This panel includes sequential images of the bladder as it was filled and emptied. This shows a normal, round bladder that fills and empties properly. If reflux had been present, the ureters would have been visible in the scan above the round bladder.





As the technologies advance over time, and the volume of the application is considered, costs will naturally decrease.

Injectable Muscle Cells

The potential use of injectable cultured myoblasts for the treatment of stress urinary incontinence has been investigated (122, 123). Myoblasts were labeled with fluorescent latex microspheres (FLM) in order to track them after injection. Labeled myoblasts were directly injected into the proximal urethra and lateral bladder walls of nude mice with a micro-syringe in an open surgical procedure. Tissue harvested up to 35 days post-injection contained the labeled myoblasts, as well as evidence of differentiation of the labeled myoblasts into regenerative myofibers. The authors reported that a significant portion of the injected myoblast population persisted in vivo. Similar techniques of sphincteric derived muscle cells have been used for the treatment of urinary incontinence in a pig model (124). The fact that myoblasts can be labeled and survive after injection and begin the process of myogenic differentiation further supports the feasibility of using cultured cells of muscular origin as an injectable bioimplant.

The use of injectable muscle precursor cells has also been investigated for use in the treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment. Muscle precursor cells are the quiescent satellite cells found in each myofiber that proliferate to form myoblasts and eventually myotubes and new muscle tissue. Intrinsic muscle precursor cells have previously been shown to play an active role in the regeneration of injured striated urethral sphincter (125). In a subsequent study, autologous muscle precursor cells were injected into a rat model of urethral sphincter injury, and both replacement of mature myotubes as well as restoration of functional motor units was noted in the regenerating sphincteric muscle tissue (126). This is the first demonstration of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells. As a result, muscle precursor cells may be a minimally invasive solution for urinary incontinence in patients with irreversible urinary sphincter muscle insufficiency.

Fetal Tissue Engineering

The prenatal diagnosis of fetal abnormalities is now more common and more accurate. Improvements in prenatal diagnosis have led to demand for novel interventions designed to reverse potentially life-threatening processes before birth. Having a ready supply of urologic-associated tissue for immediate surgical reconstruction of congenital malformations at birth may be advantageous. Theoretically, once the diagnosis of the pathologic condition is confirmed prenatally, a small tissue biopsy could then be obtained under ultrasound guidance. These biopsy materials could then be processed expanded in vitro. Using tissue engineering techniques, in vitro-reconstituted structures could then be readily available at the time of birth for reconstruction.

Summary and Conclusions

Regenerative medicine efforts are currently underway experimentally for virtually every type of tissue and organ within the human body. As regenerative medicine incorporates the fields of tissue engineering, cell biology, nuclear transfer, and materials science, personnel who have mastered the techniques of cell harvest, culture, expansion, transplantation, as well as polymer design and biomedical engineering are essential for the successful application of these technologies for patients. Various tissues are at different stages of development, with some already being used clinically, a few in preclinical trials, and some in the discovery stage. Recent progress suggests that engineered tissues may have an expanded clinical applicability in the future and may represent a viable therapeutic option for those who would benefit from the life-extending benefits of tissue replacement or repair.

Presentation of Renal Disease in Children

Introduction

Renal disease in children may present with overt abnormalities clearly associated with the urinary tract, such as the development of macroscopic haematuria or profound oliguria. However, in many instances symptoms may be very non specific or seemingly mild. Children with chronic renal failure present with a wide variety of symptoms including enuresis, failure to thrive, short stature, lethargy and pallor. The onset may be silent and the progress insidious, with symptoms only developing late in its course. Urinary tract infection in infants and small children may, in contrast to older children, present with non-specific manifestations including poor feeding, vomiting, irritability, abdominal pain, failure to thrive, lethargy and restlessness. The possibility of renal disease should therefore be considered in the differential diagnosis of any child presenting to hospital with acute or chronic symptoms.

Antenatal Imaging

Since the first report of renal abnormalities being detected by antenatal ultrasonography in the 1970s (1), there have been major developments in the antenatal assessment of the urinary tract (2–4). In most countries, pregnant women undergo routine ultrasound assessment of the fetus at various stages throughout pregnancy, including a detailed scan performed at around 20 weeks gestation. Ultrasound is particularly informative with regard to renal abnormalities, which account for around 20% of all significant fetal abnormalities detected during gestation (5). Recent developments including 3D ultrasound and magnetic resonance imaging of the fetus will allow these anomalies to be studied in further detail. This has resulted in many significant congenital and inherited abnormalities of the urinary tract being detected antenatally, notably posterior urethral valves, the multicystic dysplastic kidney (MCDK), pelvi-ureteric junction obstruction and polycystic kidney diseases. In the case of posterior urethral valves, this has resulted in the possibility of antenatal therapy, currently the subject of an ongoing randomized controlled trial investigating vesico-amniotic shunting (www.pluto.bham.ac.uk). Large kidneys on antenatal imaging may suggest hydronephrosis, polycystic kidney disease (PKD), MCDK, congenital nephrotic syndrome or rarely a renal tumor whereas small kidneys may point to the presence of renal dysplasia or hypoplasia. PKD, cystic dysplasia and glomerulocystic disease are common causes of echobright kidneys. TCF2 gene mutations are found in almost a third of the children with antenatally diagnosed bilateral echogenic kidneys (6). The presence of renal macrocysts in the antenatal period should alert the physician towards a diagnosis of autosomal dominant PKD, PKD associated with tuberous sclerosis, MCDK or cystic dysplasia.

The sensitivity of ultrasound imaging does, however, result in the detection of many minor abnormalities, particularly unilateral renal pelvic dilatation, which appear to resolve spontaneously in later pregnancy or after birth and are of no long term significance. Their detection may be a source of significant maternal anxiety and multiple invasive investigations where appropriate protocols are not in operation.

Abnormalities of Appearance of Urine

Red or Dark Urine

The presence of blood in the urine causes it to develop a pink to red color. Only a relatively small amount of blood is necessary to produce discoloration. Prolonged contact between blood in the urinary tract and acidic urine causes the haem pigment to become oxidized to a methaem derivative, giving the urine a brown color. In general, the longer the contact and the more acidic the urine, the darker brown the urine becomes.

Contamination with blood from menstruation in older girls needs ruling out. There are a number of causes of false positive haematuria, where alternative substances produce red discoloration (*Table 20-1*). One of the most common of these is the pink discoloration seen in nappies caused by

© Springer-Verlag Berlin Heidelberg 2009

Table 20-1

False positive haematuria; alternative causes of red urine

Foods e.g., beetroot, berries containing anthocyanins and food dyes
Haemoglobinuria e.g., in intravascular haemolysis
Myoglobinuria e.g., in rhabdomyolysis
Urate crystals (a cause of pink discoloration of nappies)
Drugs e.g., rifampicin, phenothiazines, desferroximine, phenindione
Inborn errors of metabolism e.g., porphyria and alkaptonuria

the precipitation of urate crystals. Urine microscopy is therefore mandatory following the detection of red or dark urine. It is important that this is performed on a fresh sample as red cell lysis occurs where samples are allowed to stand for prolonged periods prior to examination.

The passage of fresh red blood in the urine, with or without clots, is most likely to originate from the lower urinary tract, particularly where this is most marked at the beginning or the end of the urinary stream. This highlights the importance of obtaining a comprehensive clinical history in such children. Causes include urethritis, trauma, bladder calculus and schistosomiasis. Urological assessment and cystoscopy in indicated in most of these cases. More uncommon causes of bleeding from the upper tracts include trauma, arteriovenous malformations, tumors and angiomyolipoma associated with tuberous sclerosis.

Fabricated and induced illness by proxy, previously termed Munchausen syndrome by proxy is a very rare disorder, though falsification of urine samples by contamination with maternal or other blood is one of the more common modes of presentation (7). A high index of suspicion needs to be maintained to detect such cases. Absolute confirmation of contamination requires analysis of urinary red cells for differences in blood group type, or if required, DNA profiling.

Dark urine associated with jaundice in the neonate or older child should alert the physician to the presence of conjugated hyperbilirubinaemia, indicative of significant liver or biliary tract disease. Bilirubin and urobilinogen will be detected on dipstick testing the urine in such cases.

Cloudy Urine

The urine may become cloudy secondary to the presence of white blood cells (pyuria) associated with urinary infection, calcium phosphate crystals or a combination of calcium salts, uric acid, oxalate, cystine or struvite. These substances are normally present in the urine, though may be present in excess in various disease states. The precipitation of phosphates and urates is enhanced by refrigeration of the urine sample.

Frothy Urine

The presence of significant quantities of protein in the urine will result in it becoming frothy. Presentation with frothy urine should therefore prompt the physician to perform dipstick analysis followed by formal quantification of protein content.

Offensive or Unusual Smelling Urine

A number of factors may result in an alteration in the smell of urine. Infection with urea splitting organisms including *Ureaplasma urealyticum, Proteus, Staphylococcus, Klebsiella, Providentia* and *Pseudomonas* species may generate an ammonia-like smell, though the positive predictive value of offensive urine for bone fide urinary infection is very low. A number of the inborn errors of metabolism, including maple syrup urine disease, phenylketonuria and isovaleric acidaemia also produce characteristic odors. The change in urine odor following the ingestion of asparagus was first reported in the eighteenth century by a physician to the French royal family (8). This is thought to be due to the presence of S-methylthioacrylate and S-methyl-3-(methylthio)thiopropionate (9), though a combination of methyl mercaptan, dimethyl sulfide, and small amounts of sulfur-oxidized compounds could also be responsible (10).

Passage of Gravel or Stones

The passage of gravel or stones in the urine is an unusual, though recognized mode of presentation of urinary tract calculi. Stones are either metabolic or infective in origin (Chapter 58).

Abnormalities of Volume of Urine

Oliguria

The otherwise healthy neonate is oliguric for the first 2–3 days of life until the onset of the postnatal diuresis.

Ninety-two percent of neonates will pass urine within the first 24 h of life and almost all newborns will do so in the first 48 h (11). Beyond the immediate neonatal period, oliguria is defined a urine output of less than 500 ml/24 h/1.73 m^2; that which is sufficient to maintain homeostasis. The most common cause of oliguria in children is intravascular volume depletion. Where this has been excluded or adequately treated and volume depletion persists, a search for intrinsic or obstructive renal disease should be commenced.

Polyuria and Polydipsia

Of those children presenting to medical practitioners with symptoms of polyuria, only a very small proportion will have a significant renal or other pathology. A strict definition of polyuria does not exist, though a daily urine output exceeding 2 l in school-aged children is unusual. It is important to distinguish polyuria from frequency of micturition where small volumes of urine are passed frequently though the 24 h urine output is within normal limits.

Significant pathologies which result in polyuria are shown in *Table 20-2* and include excessive fluid intake, increased osmotic load, failure to produce or release antidiuretic hormone (ADH) and resistance to the actions of ADH in the kidney. The distinction between primary polydipsia and primary polyuria may be inferred from the relative osmolality of plasma and urine and the response to controlled water deprivation. The distinction between pituitary and renal causes of polyuria may be made by the plasma ADH concentration and the urinary response to D-amino-arginine vasopressine.

Table 20-2
Causes of polyuria in children

Increased fluid intake
Psychogenic/behavioral polydipsia
Hypothalamic polydipsia
Hyperreninaemia including Wilm's tumor
Increased osmotic load
Diabetes mellitus and other causes of hyperglycaemia
Chronic renal failure (urea)
Following mannitol infusion
Failure of ADH production
Cranial diabetes insipidus
Basal skull fracture
Cranial tumors
Post hypophysectomy
Infection; encephalitis, meningitis, tuberculosis
Vascular aneurysm or thrombosis
Failure of renal response to ADH
Nephrogenic diabetes insipidus (X-linked)
Acquired unresponsiveness to ADH
Obstructive uropathy
Hypokalaemia
Hypercalcaemia
Sickle cell disease
Chronic renal failure
Drugs e.g., amphotericin, methoxyflurane, tetracycline

Wetting and Abnormalities of the Passage of Urine

Wetting is the most common urinary tract disorder of childhood, though in most cases there is no organic pathology. The majority of children will achieve daytime bladder control between 3 and 4 years of age (12). The prevalence of nocturnal enuresis is 15–20% at age 5 years and up to 3% in young adults (13). Nocturnal enuresis has a strong genetic predisposition and on its own, is a benign self-limiting condition. Daytime wetting, which can occur as a result of a number of disorders including detrusor overactivity, dysfunctional voiding and, rarely, giggle incontinence which is more common in girls and usually resolves by the age of 9 years. Secondary enuresis, both diurnal and nocturnal raises the possibility of an organic cause (e.g., neuropathic bladder) especially in boys; however it is commonly associated with psychosocial disturbances such as parental separation, the birth of a new child or a death in the family. Diabetes mellitus should always be excluded. A careful voiding and wetting history along with a focused physical examination will help to identify any organic pathology. The presence of dysuria and frequency might suggest a diagnosis of urinary tract infection whereas poor urinary stream and an enlarged bladder would point to a diagnosis of a neuropathic bladder or an obstructive pathology such as posterior urethral valves. Examination of the urine for infection is essential in all children with wetting. In a child with persistent daytime wetting a pre and post-void ultrasound of the renal tract is useful to screen for urinary tract anomalies and to assess bladder emptying. Urodynamic assessment to identify abnormalities of bladder and sphincter function is indicated in children with a neuropathic bladder and in some children with

persistent and troublesome wetting who do not demonstrate a good response to conservative management.

Pollakiuria, a benign, self-limiting condition is characterized by the very frequent (every 5–20 min) passage of urine during the daytime hours. It most commonly presents in pre-school age children and is not associated with wetting.

Edema

Children with renal disease may present with edema, a major clinical manifestation of ECF volume expansion. Edema may occur in the acute nephritic syndrome and other causes of acute renal impairment as a result of failure of salt and water excretion. Here, peripheral edema is accompanied by intravascular volume expansion with hypertension and pulmonary edema. In the nephrotic syndrome, loss of plasma oncotic pressure secondary to hypoproteinaemia and increased vascular permeability result in the loss of fluid from the intravascular into the extravascular space. Here, edema is initially first evident as swelling of the periorbital region, which is often most marked in the morning. With progressive fluid retention, more generalized edema develops in a gravity dependent distribution, the ankle and sacral areas being the most severely affected. This may be associated with abdominal distension secondary to ascites.

Asymptomatic Presentation Following Screening or Routine Assessment

Whilst the universal routine testing of children's urine by dipstick examination is not performed in the large majority of countries, this has been undertaken in Japan, having been introduced by the Ministry of Education in 1973 with the aim of the early detection of asymptomatic renal disease (14). Outside of universal screening programs, children may have their urine tested at the time of attendance at hospital Emergency Departments and out-patient clinics or as part of a routine medical assessment for insurance or immigration purposes. Such testing may detect abnormalities in the urine (commonly microscopic haematuria) which results in referral for further assessment.

Children may have hypertension detected following a routine medical examination performed at school or for participation in particular sporting activities etc. In such instances it is firstly essential to rule out erroneously high blood pressure which has occurred as a result of the use of incorrect measuring equipment or white coat hypertension. Whilst renal disease is widely reported to be the commonest cause of hypertension in children, the rising tide of childhood obesity may soon see this become the predominant cause (15).

The screening of asymptomatic siblings of index cases of renal disease is a difficult area. Clearly where the detection of significant pathology necessitating the commencement of specific therapy is possible e.g., cystinosis, then appropriate testing should be performed. Siblings and close contacts of children presenting with diarrhea associated haemolytic uraemic syndrome are not infrequently found to have evidence of varying degrees of renal impairment and anemia in the absence of any significant symptoms and such detection will allow the commencement of appropriate therapy and follow-up. In contrast, in the asymptomatic siblings of children with autosomal dominant PKD, many authorities would recommend that ultrasound or genetic screening does not take place. Potentially affected individuals should undergo an annual check of blood pressure and urinalysis until they are able to make a fully informed decision about the relative merits of presymptomatic detection, bearing in mind the implications that this may have. There are a number of situations where medical opinion is divided, for instance whether newborn siblings of children with vesicoureteric reflux should undergo radiological assessment; definitive answers to these question are only likely to be obtained through the enrolment of such children in prospective randomized controlled trials.

Urinary Tract Infection

Urinary tract infection is common. Swedish data report a cumulative incidence by 2 years of age of 2.2% in boys and 2.1% in girls (16). In the northern United Kingdom, cumulative referral rates by 7 years of age are as high as 2.8% for boys and 8.2% for girls, rising to 3.6 and 11.3% respectively by 16 years of age (17). Whilst older children may present with classical symptoms of either lower urinary tract infection (dysuria, frequency, wetting) or upper urinary tract infection (systemic upset, fever, loin pain), these features are much less pronounced in the younger child; here nonspecific manifestations may include poor feeding, vomiting, irritability, failure to thrive, lethargy and abdominal pain.

Diagnosis of urinary tract infection is important, as aside from the acute morbidity associated with infection, the development of infection is an important marker of underlying congenital abnormalities of the urinary tract, in particular vesico-ureteric reflux. Furthermore, infection itself is an important cause of renal cortical scarring in those predisposed to this. Therefore a diagnosis of urinary tract infection should always result in

consideration being given to radiological assessment of the urinary tract. Previous guidelines recommended that all children be investigated after a single infection, though more recent guidelines, for instance those produced by the UK National Institute for Health and Clinical Excellence, have recommended radiological investigations are only performed on the very young and those with recurrent or difficult to treat infections (http://www.nice.org.uk/guidance/index.jsp?action=byID&o=11819).

Clinical History

Antenatal History

A record should be made of the results of antenatal imaging studies, particularly the detailed scan performed at around 20 weeks gestation. Abnormalities of liquor volume should be recorded. In the absence of rupture of the amniotic membranes, oligohydramnios or anhydramnios after 16 weeks' gestation represents failure of urine excretion due to obstruction to urine flow or inability of the kidneys to produce urine. Polyuric states including neonatal Bartter's syndrome and congenital nephrotic syndrome are associated with polyhydramnios; it should be remembered, however, that only a small proportion of cases of polyhydramnios are caused by renal disease.

A raised maternal serum alpha-fetoprotein level between 15 and 20 weeks gestation is associated with spinal cord defects and the congenital nephrotic syndromes and is an indication for a detailed antenatal ultrasound scan and amniocentesis.

Close attention should be paid to drug history. Maternal intake of medications such as COX-2 inhibitors, angiotensin converting enzyme inhibitors (ACEi) or angiotensin receptor blockers in the second and third trimester is associated with renal failure in the neonatal period. First trimester exposure to ACEi can lead to major cardiovascular, central nervous system and renal malformations (18).

Other aspects of maternal medical history should be noted. Previous recurrent miscarriages should alert the physician to the possibility of a chromosomal abnormality. There is an increased risk of MCDK among infants of mothers with gestational diabetes. Maternal obesity is associated with increased risk of neural tube defects (19).

Birth History

An enlarged placenta (greater than 25% of the child's birth weight) is a feature of congenital nephrotic syndrome. The presence of hematuria following perinatal asphyxia may be due to renal venous thrombosis. Umbilical arterial catheterization is associated with vascular damage and is the commonest cause of hypertension in the neonatal period (20). The presence of a single umbilical artery in an infant is associated with an increased risk of a variety of renal anomalies including vesicoureteric reflux, MCDK and renal aplasia and dysplasia (21). It is debatable as to whether these infants merit further imaging unless the antenatal scan has demonstrated any abnormality; in such cases an ultrasound scan of the renal tract will provide useful initial information and guide further evaluation.

Family History

A detailed family history forms an essential component of the clinical evaluation and may often provide important clues to the diagnosis. It is considered good practice to document the family tree in the case records. A variety of renal diseases including PKD, familial glomerulonephritis and tubular disorders e.g., Bartter's and Gitelmann's syndromes are inherited. An increasing number of hereditary renal disorders can now be diagnosed by DNA analysis and it is therefore essential that the family is provided with detailed counseling with regard to the potential future implications.

Parental consanguinity is common in a number of societies including the Muslim Middle Eastern countries and the UK Pakistani community, where up to 55% are married to a first cousin (22). This should raise the possibility of conditions which are transmitted in an autosomal recessive manner such as autosomal recessive PKD, juvenile nephronophthisis and cystinosis. End stage renal failure of all causes is also more prevalent in this population (23).

Deafness and renal failure in a male relative may suggest a diagnosis of Alport's syndrome which is most commonly inherited in an X-linked manner. The inheritance of isolated vesicoureteric reflux is felt to be consistent with multifactorial or autosomal dominant with reduced penetrance and has a sibling recurrence rate of 30–50% (24).

General Medical History

Renal disease may be feature of a number of childhood disorders. A Pediatric Nephrologist working in a tertiary centre will often be asked to see children under the care of other specialists and must therefore be familiar with the

renal manifestations of systemic disorders and iatrogenic problems. Renal involvement may be a part of a multisystem disorder such as Henoch Schönlein purpura or systemic lupus erythematosus. Hyponatraemia due to cerebral salt wasting or syndrome of inappropriate ADH secretion is a common problem on the neurosurgical ward. A diagnosis of retinitis pigmentosa should alert to the possibility of juvenile nephronophthisis. Tubulopathy is often seen in children on the pediatric oncology ward following chemotherapy with agents such as adriamycin or ifosfamide. Asymptomatic renal calculi are known to occur after a short course of ceftriaxone and nephrocalcinosis is associated with prolonged use of furosemide.

Urine and Micturition

The clinical history should record information regarding daytime and night-time wetting (see above) and abnormalities of micturition, including the nature of the urinary stream (e.g., hesitancy, staccato micturition, terminal dribbling, the need to stand to void etc). Poor urinary stream should raise the possibility of posterior urethral valves in a male infant, though following the introduction of routine ultrasound scanning, the majority of such cases would be detected in the antenatal period. By 3 years of age most children have some conscious control over micturition and achieve daytime control, but enuresis and daytime accidents can continue to occur. In an older child, the voiding frequency and an estimate of the urinary volume should be documented (25).

Dietary History

The fluid and dietary restrictions in renal disease depend on the type and stage of disease. For instance, while salt and fluid restriction is not necessary in polyuric states such as proximal renal tubular disorders and Bartter's syndrome, anephric children on dialysis will require tight control of their salt and fluid intake. Most children with advanced renal failure will be on a restricted potassium, phosphorus and protein diet. Anorexia associated with renal failure means that these children are often malnourished and input from an experienced pediatric dietician is mandatory.

One of the consequences of the obesity epidemic has been the increasing numbers of overweight children with hypertension, disturbed glucose metabolism and hyperlipidaemia (26). Excessive salt intake may be associated with hypercalciuria.

Psychosocial History

The impact of the disease on the child, for example the amount of school missed, body image, limitations on lifestyle, self-esteem and peer reactions should be assessed. There is a wealth of evidence supporting the view that chronic physical illness and disability are risk factors for mental health problems in children. Social disadvantage, poverty, poor housing, educational failure and family instability are other risk factors. Caring for a chronically ill child is a huge challenge for any family and parents often have to give up employment in order to achieve this. Impact on siblings should be given consideration. A skilled social worker and child psychiatrist or psychologist are therefore essential members of a multiprofessional pediatric nephrology team. The impact of the disease on the child's intellectual, emotional and social progress must be assessed. An awareness of the risk factors will help the physician identify those children who are at particularly high risk of developing mental health problems. Adherence with prescribed medications is a particular problem during adolescence and is the commonest cause of rejection and graft loss in this age group (27).

Clinical Examination

General Assessment (› *Fig. 20-1*)

An initial rapid assessment of the level of consciousness, airway, breathing and circulation should be performed to determine how ill the child is. Any obvious dysmorphic features should be recorded. Pain can be a manifestation of renal disease and is often confused with back pain and other causes of abdominal pain in childhood. The state of the child (clothing and hygiene) should be noted. A record of the mood and demeanor of the child together with the family interaction is informative.

Growth

Growth is an invaluable measure of health during childhood and accurate measurement of height and weight along with the head circumference in younger children is therefore essential. Most growth charts express anthropometric measures in terms of percentiles, however not infrequently children with renal disease are significantly below the lowest percentile lines and therefore expressing height, weight and body mass index in terms of standard deviation score (SDS or Z score) is sometimes more

Figure 20-1

Assessment of the child with renal disease

   Wrist swelling
9. **Urine analysis**
   Microscopy
   Dipstick for blood, protein, nitrite and glucose

informative. Pubertal development (Tanner staging) should also be formally assessed.

Nutrition

Assessment of nutrition in children with renal disease can be a challenge; fluid overload and abnormalities in the distribution of fat and lean body tissue can lead to misinterpretation of the nutritional anthropometric measures (28). The commonly used nutritional markers are dietary assessment, height, estimated dry weight, body mass index, serum albumin and skin fold thickness. Tools for assessing body composition such as dual energy x-ray absorptiometry and bioelectrical impedance analysis can sometimes provide useful information.

Hydration/Volume Status

Assessment of the state of hydration and circulatory status is an important skill for all physicians dealing with children with kidney disease. An understanding of total body water and its distribution between the intravascular (plasma) and extracellular fluid (interstitial) compartments is essential. A child with nephrotic syndrome usually presents with a recent increase in weight and peripheral edema, reflecting an increase in ECF volume, though at the same time may exhibit signs of intravascular volume depletion such as reduced capillary refill time, cold extremities, tachycardia and oliguria. Occasionally, clinical signs may be subtle and measurement of urinary sodium, fractional excretion of sodium (FeNa) and urine osmolality

may provide additional information. In contrast, expansion of the intravascular volume, such as in nephritic states results in hypertension, raised jugular venous pulse, hepatomegaly and the development of pulmonary edema.

Cardiovascular System

Pulse

The rate, rhythm and volume of the pulse should be recorded. Tachycardia with a low volume pulse is a feature of intravascular volume depletion. The presence of a gallop rhythm suggests congestive cardiac failure. The femoral pulses should always be examined; coarctation of the aorta may present with hypertension and cardiac failure. The presence of bruits on auscultation over major arteries such as the carotid or renal arteries suggests extensive vascular disease or renal artery stenosis.

Blood Pressure

Measurement of the blood pressure is an integral part of the assessment of the child with renal disease. It is important to ensure that the right equipment and standards are used to ensure that hypertension is correctly diagnosed; a wrong diagnosis due to incorrect measurement can lead to a battery of unnecessary invasive tests. There is increasing use of ambulatory blood pressure monitoring in children, especially to diagnose essential and white coat hypertension (29). The investigation of hypertension is discussed in Chapter 62.

Precordium

Fluid overload, long standing hypertension and cardiomyopathy will give rise to cardiomegaly. Pericarditis with a rub may be a feature of severe uremia. A heart murmur may suggest a structural anomaly but can also be a feature of infective endocarditis or a hyperdynamic state as occurs in anemia.

Respiratory System

Hyperventilation with Kussmaul respiration suggests the presence of metabolic acidosis. Rachitic deformity of the ribs can be seen in longstanding chronic renal failure. Dullness on percussion over the lung fields might suggest pleural effusion in a child with nephrotic syndrome or a peritino-pleural leak in a patient on peritoneal dialysis. Fine crepitations over the lung bases may indicate the presence of pulmonary edema.

Abdomen

Abdominal Distension

Abdominal distension in renal disease may be due to ascites, bladder enlargement due to urinary retention and mass (see below) and the presence of peritoneal dialysis fluid. In children who have undergone previous abdominal surgery, for example urinary diversion procedures, one should be aware of the possibility of adhesions and obstruction presenting as an acute surgical abdomen. Tenderness with guarding and rigidity is highly suggestive of peritonitis and in these circumstances the opinion of a pediatric surgeon should be sought.

Abdominal Mass

Prior to the onset of routine antenatal imaging, the detection of an abdominal mass was a reasonably frequent mode of presentation of a variety of renal and urological disorders, including the MCDK, pelvi-ureteric junction obstruction and other causes of hydronephrosis. In the neonatal period, 55% of abdominal masses are renal in origin (hydronephrosis 25% and multicystic dysplastic kidney 15%). In later infancy and childhood, the proportion of abdominal masses which are renal in origin increases, largely due to the increased rate of malignant tumors in the age group (30).

Renal causes of an abdominal mass are shown in *Table 20-3*.

Features in the clinical history may help in ascertaining the likely cause of the mass. In the newborn period, the large majority of these lesions will have been identified antenatally, though additional clinical information may inform subsequent investigation and likely diagnosis i.e., the presence of oligohydramnios or polyhydramnios. Beyond the newborn period, a family history of severe hypertension may point to a diagnosis of PKD. Presentation with symptoms and signs of urinary tract infection may point to many of the anomalies associated with urinary obstruction or stasis.

Table 20-3

Causes of an abdominal mass of renal origin

Abnormality	Causes if unilateral	Causes if bilateral
Hydronephrosis (obstructive and non-obstructive)	PUJ obstruction	Causes of bladder outlet obstruction including posterior urethral valves
	VUJ obstruction	Eagle Barrett syndrome
	Primary megaureter	
Cystic mass	Multicystic dysplastic kidney	PKD (dominant and recessive)
	Simple cyst	Cystic disease associated with syndromal diagnosis
	Cystic dysplasia	Cystic dysplasia
Infection	Acute pyelonephritis	
	Xantogranulomatous pyelonephrtis	
	Perinephric abscess	
Vascular	Renal venous thrombosis	
	Arterial thrombosis	
	Acute cortical necrosis	
Tumors	Wilm's tumor	
	Mesoblastic nephroma	
	Leukaemic infiltrate	
Miscellaneous	Compensatory hypertrophy	Beckwith Weidemann syndrome
	Duplex kidney	Acute renal failure
	Fused crossed ectopia	Storage disorders
		Congenital nephrotic syndrome

Hepatosplenomegaly

Liver enlargement in association with renal disease can be seen in a number of conditions including glycogen storage disease type 1, tyrosinaemia and Fanconi-Bickel syndrome. Splenomegaly in a child with haematuria might suggest infective endocarditis. Autosomal recessive PKD may cause hypersplenism as a consequence of hepatic fibrosis. Hepatosplenomegaly in association with renal disease reflects a multi-system disorder which can be inflammatory such as systemic lupus erythematosus or a neoplastic process, for instance lymphoma presenting with acute renal impairment secondary to uric acid nephropathy.

Urinary Bladder

An enlarged urinary bladder can be detected by palpation and percussion and is characteristically associated with suprapubic pain. Gross constipation and local genital inflammation are the common causes of acute urinary retention in children and rarely require urethral catheterization. Lower urinary tract obstruction due to urological causes such as posterior urethral valves, pelvic tumors and the neuropathic bladder should be considered an emergency, immediate decompression of the urinary tract being indicated.

Genitalia

Clinical evaluation of the renal patient is incomplete without examination of the genitalia. The presence of vulvovaginitis, a common gynaecological problem in pre pubertal girls causing dysuria should be noted. In male children the state of the foreskin and the position of the urethral meatus should be recorded. Hypospadias is a common problem with an incidence of up to 1:130 live births; parents should be made aware that circumcision is contraindicated where this is present. Eagle Barratt syndrome is associated with bilateral cryptorchidism. The presence of male pseudohermaphroditism in association with proteinuria and renal impairment in an infant is suggestive of Denys Drash syndrome.

Anus

The presence of an imperforate anus in a neonate should alert the physician towards other associated anomalies such as sacral dysplasia, spinal dysraphism and vesicoureteric reflux.

Nervous System

Whilst a detailed neurological examination is often not required, it is important to record the level of consciousness,

mental status and examination of the cranial nerves, muscle tone, power and reflexes along with the gait and co-ordination. Hypertension can present with papilloedema and is the commonest cause of bilateral Bell's palsy. Seizures are associated with hyponatraemia, uremia, hypocalcaemia, hypertensive encephalopathy, vasculitis and haemolytic uremic syndrome. Blindness can result from rapid lowering of blood pressure in severe hypertension and is also known to occur in association with the use of immunosuppressive agents including methylprednisolone (31) and tacrolimus following renal transplantation (32). In a child with continence issues, careful examination of the peripheral sensory and motor functions together with the assessment of the anal tone is essential.

Skin

SLE can present with the characteristic fixed erythematous malar rash. The presence of a palpable purpura over the extensor surfaces and buttocks suggests Henoch Schönlein purpura. Multiple café au lait spots are seen in neurofibromatosis, which can give rise to hypertension secondary to renal artery stenosis. Tuberous sclerosis is characterized by typical dermatological lesions including facial adenofibromas (adenoma sebaceum), shagreen patches over the lower back and hypopigmented ash leaf macules which may be present anywhere in the body. Icthyosis is a recognized feature of the arthrogryposis, renal Fanconi syndrome and cholestasis (ARC) syndrome. Dystrophic nails should raise the possibility of nail patella syndrome.

Face

Examination of the face can provide valuable clues to the underlying clinical problem. Any obvious dysmorphic features such as Down's or William's syndrome should be noted. Long-term ciclosporin use is associated with hypertrichosis, particularly in the Asian population. Hirsutism is a well recognized feature of steroid toxicity and Cushing's syndrome. Nephrotic syndrome often presents with early morning periorbital swelling and is frequently misdiagnosed as allergic rhinitis. Examination of the oral cavity is important and may reveal gingival overgrowth as a consequence of ciclosporin therapy. Asking the child to smile may reveal a facial expression resembling crying in the child with Ochoa syndrome, which is associated with the presence of a neuropathic bladder.

Eyes

The eyes are affected in a number of renal diseases and therefore input from an experienced pediatric ophthalmologist is invaluable. Coloboma of the eyelid is seen in Goldenhar syndrome. Uncontrolled renal osteodystrophy can lead to scleral calcification. The presence of hypercalcaemia may cause redness of the eyes secondary to the metastatic crystallization of calcium, phosphate and hydroxyapatite in the conjunctiva (33). Slit lamp examination may reveal characteristic crystal deposits in the cornea in cystinosis. In a child with unexplained acute renal failure, examination of the eyes may clinch the diagnosis; for example in tubulointerstitial nephritis and uveitis (TINU) syndrome. Uveitis is also a feature of systemic diseases such as juvenile rheumatoid arthritis. Aniridia is associated with an increased risk of Wilm's tumor. Presence of anterior lenticonus, which is a conical protrusion in the anterior aspect of the lens (seen almost exclusively in males) along with macular changes, is a characteristic feature of Alport's syndrome. Cataracts are seen in Lowe's syndrome and galactosaemia, but can also be a consequence of steroid therapy.

Not infrequently, a child with severe hypertension is referred by an optician with papilloedema and retinal hemorrhages and exudates. Diabetic retinopathy, which parallels nephropathy is rare in childhood and correlates with the duration and control of disease. Nephronophthisis is associated with several characteristic eye lesions; retinitis pigmentosa in Senior Loken syndrome, tapetoretinal degeneration in juvenile nephronophthisis and oculomotor apraxia in children with Cogan syndrome. Retinitis pigmentosa is a feature of Bardet-Biedl syndrome.

Ears

Minor external ear malformations such as preauricular skin tags and pits are found in 0.5–1% of newborns and do not warrant renal evaluation unless accompanied by other systemic malformations (34). Branchial fistulae are a feature of branchio-oto-renal syndrome. Alport's syndrome is characterized by the insidious onset of high tone sensorineural deafness. Sensorineural deafness is also a feature of type 4 Bartter's syndrome which is the most severe phenotype presenting in the neonatal period with life-threatening volume depletion and chronic renal failure. Deafness can be a consequence of aminoglycoside toxicity and is also seen following rapid administration of a large dose of furosemide.

Musculoskeletal System

Muscles

Muscle wasting is a feature of chronic uremia. Myopathy can also be secondary to rickets and renal osteodystrophy which may improve following vitamin D therapy. One of the recognized side-effects of steroid therapy is proximal myopathy, demonstrated by eliciting Gower's maneuver. Up to half of children with mitochondrial disorders will have renal involvement with tubular dysfunction being the commonest pathology.

Skeletal System

Florid skeletal deformities of the weight bearing limbs, such as genu varum or valgum can be seen in infants with rickets. Rachitic rosary and swelling of the wrists and ankles due to epiphyseal swelling are the other well recognized features of rickets. Slipped femoral capital epiphysis is a feature of renal osteodystrophy, and a vascular necrosis of the head of the femur may complicate corticosteroid therapy, particularly following renal transplantation.

Whilst polydactyly is a recognized feature of syndromes such as Bardet Biedl and Meckel Gruber syndrome, isolated polydactyly is usually associated with a favorable outcome. Hemihypertrophy and Beckwith Wiedeman syndrome are associated with an increased risk of Wilm's tumor. Spinal dysraphism should be suspected in infants with a lower midline back lesion such as a subcutaneous mass, dermal vascular malformation, hypertrichosis, a midline dimple or sinus tract, a skin tag or an asymmetric gluteal cleft. Sacral agenesis is seen in infants of insulin dependent diabetic mothers but may also be part of the familial Currarino triad syndrome (presacral mass, sacral agenesis and anorectal malformation) (35).

Joints

Arthropathy is a characteristic feature of Henoch Schönlein purpura and SLE. It is also seen in systemic onset juvenile idiopathic arthritis, which if poorly controlled can lead to renal amyloidosis. Arthralgia and arthritis affect almost half of children with sarcoidosis. Metabolic disorders such as Lowe's syndrome and Lesch-Nyhan syndrome may present with arthropathy. Although hyperuricemia is common in pediatric transplant recipients, gouty arthritis is rare.

Examination of the Urine

Macroscopic Examination

The usual yellow color or urine is due to the presence of a number of pigments, some of which are derived from food (i.e., riboflavine) and others produced endogenously. The intensity of the coloration depends upon the urinary flow rate; where large quantities of urine are produced e.g., following high fluid intake, the urine is paler in color though darker in color at times of reduced urine production.

Where the urine is abnormally red or dark in color, dipstick testing and microscopy examination of the sample should be performed.

Dipstick Examination of Urine

Dipsticks

It is important that urine dipsticks are kept dry in their container with the lid on and that the manufacturer's expiry date is adhered to. A number of automated devices are available. These ensure that the stick is read at the correct time, thus reducing interobserver variability. Most will produce a printout which can be attached to the patient's medical record.

Specific Gravity

Most modern urine dipsticks measure urinary specific gravity, though this information is rarely utilized in clinical practice. Specific gravity is a measure of the mass of individual solutes present per unit volume of urine, as opposed to osmolality, which is the measure of the total particle concentrations, irrespective of the mass of the individual particles. Low values of specific gravity (less than 1.010) are found at times of maximal water excretion and high values (greater than 1.025) at time of maximal urinary concentration.

pH

The pH of healthy urine varies between 4.5 and 8.0. Fasting produces low values and the highest pH measurements are seen following meals. pH values are low where acidaemia is present, except for where this is secondary to renal tubular acidosis.

Blood

Urine dipsticks detect the presence of hemoglobin in the urine through its ability to catalyze a reaction between hydrogen peroxide and o-tolidine. Spotted positivity indicates intact red cells, whereas uniform positivity indicates free hemoglobin (e.g., in intravascular haemolysis or red cell lysis in the urinary tract).

There are a number of causes of false positivity, including the presence of myoglobinuria, oxidizing agents in the urine and heavy bacterial contamination. The presence of reducing agents, such as ascorbic acid in the urine may cause a false negative result. These highlight the importance of confirmation of the presence of red blood cells by microscopy of a fresh sample of urine.

Protein

Urine dipsticks undergo color change from yellow to green following binding with proteins. Albumin is better detected than other urinary proteins including globulins, tubular proteins etc. There are a number of causes of false negative and false positive results (*Table 20-4*). Dipstick analysis is not a good quantitative test because of the effect of urinary concentration; more concentrated urine will show higher protein content, and where proteinuria is detected, formal quantification with a urinary protein/creatinine or albumin/creatinine ratio is indicated.

It is well recognized that urinary protein excretion increases throughout the daytime with prolonged duration in the upright position, and first morning samples should be assessed to rule out any element of orthostatic proteinuria. Transient proteinuria may occur following exertion, fever or acute illness and is of no significance with regard to long term renal outcome.

Table 20-4
Causes of false positive and false negative proteinuria on dipstick testing

False positive proteinuria	False negative proteinuria
Concentrated urine	Dilute urine
Alkaline urine	Acidic urine
Gross haematuria, pyuria, bacteriuria	
Dipstick left in urine too long or delay in reading	
Contamination and drugs	
Antiseptics: chlorhexidine, benzalkonium	

Glucose

Glucose is a small molecule which is freely filtered in the glomerulus. In health, the proximal tubule reabsorbs all of the filtered glucose by an active process., which has an upper rate limit or transport maximum (T_M). Certain normal individuals have a lower T_M for glucose and will have glycosuria at normal or only slightly increased plasma glucose concentrations (so called renal glycosuria). Glycosuria also occurs where overt hyperglycaemia is present, e.g., in diabetes mellitus and in a number of tubular abnormalities, including Fanconi syndrome. The lower limit of detection for glucose in the urine is 0.5 mmol/l.

Leucocytes

A number of routinely available urine testing sticks will detect the presence of leucocyte esterase, indicating the presence of pyuria. Where testing is positive, urine microscopy should be used to confirm this finding.

Nitrites

A number of routinely available urine testing sticks will also detect the presence of nitrites. These are produced by the majority of pathogenic bacteria and their detection provides further screening data to assist in the diagnosis of urinary tract infection. The test has a high specificity but a low sensitivity for the diagnosis of UTI. As such, as a standalone test, it is of limited usefulness. Where UTI is suspected or needs to be excluded, a urine culture is necessary to determine the bacteriological cause and antibiotic sensitivities or to confidently rule out UTI.

Microscopy of Urine

There are many who advocate the routine bedside microscopy of urine in all children who present with suspected renal disease or urinary tract infection. This is not, however, widely performed for a variety of reasons including unfamiliarity with the technique and availability of appropriate microscopes in clinical areas.

Casts

Casts are produced by the aggregation of Tamm-Horsfall protein with cells or cellular debris in the renal tubule. They are best seen in unspun urine as centrifugation may damage casts. Where urine has centrifuged for other reasons, casts are most frequently seen at the edge of the coverslip.

Hyaline casts are present in proteinuric states, though may be found in concentrated specimens of urine from normal individuals. These may appear waxy if lipid droplets are present.

Cellular casts contain cellular material, the source of which may provide some clues regarding the underlying pathology. Red blood cell casts are always pathological and indicate glomerular bleeding. White blood cell casts indicate renal inflammation secondary to pyelonephritis or immunologically mediated disease. Epithelial cell casts (often present with red and white blood cell casts) are produced from shed tubular epithelial cells and may be seen during recovery from acute tubular necrosis.

Red Blood Cells

The excretion of a small number of red cells is a normal phenomenon, which increases with increasing age and following vigorous exercise. Children with febrile illness may develop a transient increase in red cell excretion. However, the persistent presence of greater than 5 red cells/mm^3 in uncentrifuged urine is abnormal. Urine microscopy can distinguish anatomically normal RBCs of lower urinary tract origin from dysmorphic RBCs of glomerular origin which have been distorted during their passage through the filtration barrier. This is best performed using phase contract microscopy, though possible with ordinary light microscopy. In its purest form the distinction is useful, though often a mixture of abnormal and normal cells is present and interpretation is difficult. Acanthocytes are red blood cells with thorn-like projections of varying lengths distributed over the surface due to an increase in membrane cholesterol:lethicin ratio. Where acanthocytes constitute greater than 5% of the urinary red cell population, this may indicate the presence of a glomerulonephritis.

White Blood Cells

The presence of greater than 10 white cells/mm^3 in a midstream sample of urine is considered abnormal. Neutrophils are detected in urinary tract infection, but are also seen in contaminated urine samples, proliferative glomerulonephritis and interstitial nephritis. The presence of osinophils in the urine is a sensitive and specific sign of acute interstitial nephritis.

Bacteria and Other Organisms

Urinary bacteria may be clearly visible without Gram staining. Their detection may be enhanced by the use of phase contrast microscopy. Fungi e.g., *Candida* and *Schistosoma* species (a rare cause of haematuria) may also be detected.

Epithelial Cells

The presence of epithelial cells in the urine may represent desquamation from the urinary tract. Tubular cells may be seen following tubular injury (acute tubular necrosis, acute transplant rejection). Squamous cells are commonly exfoliated from urethra and are a normal finding.

Crystals

Normal urine contains crystals of calcium phosphate and oxalate. Other crystals may be cystine, uric acid or dihydroxyadenine.

21 Laboratory Assessment and Investigation of Renal Function

Aaron Friedman

Introduction

The kidney can be injured by a variety of different mechanisms. Investigating the type of injury and assessing the degree of injury and its progression involves laboratory assessment and often tissue sampling. This chapter will discuss laboratory assessment and investigation with emphasis on the use of blood and urine samples to investigate renal function.

There are a number of terms frequently used in laboratory assessment that are now more precisely defined and help us think about how we use laboratory assessment. In general, laboratory studies are used to help with diagnosis, prognosis, follow up of approach or effect of therapy. Usually the specific laboratory study performed fits the definition of a biomarker – a characteristic that is measured and evaluated objectively as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (1). This chapter will discuss those measurements used primarily in patient care.

Glomerular Function and Injury

Glomerular filtration rate (GFR) is the most widely used indicator of kidney function. The measurement of GFR is based on clearance. Clearance is the removal ("clearance") of a given substance from a fixed volume of plasma in a fixed period of time. This is expressed by the formula: Clearance = $U_x \times V$ where U_x is the urine $\bar{P}_x$ concentration of the substance X, V is volume over time or flow rate and P_x is the plasma concentration of the substance X.

For a clearance measurement to be equal to the GFR, a number of principles must be met. The substance to be measured must be freely filterable through the glomerulus. The substance cannot be reabsorbed or secreted by tubules. Thus, the substance is neither added to urine nor removed from urine during its path through the tubule. The substance must be inert, cannot be toxic to the patient or the kidney, or alter function.

The materials used to measure clearance fall into two basic categories – exogenous and endogenous. Exogenous materials must be infused to provide a constant serum concentration. Endogenous substrate is produced by the body often at a relatively constant rate and in this way usually results in consistent plasma concentration.

Methods of Assessment

1. *Urinary clearance*: In this method plasma and urine are measured. The urine measurement is over a fixed period of time (a few hours to 24 h) with volume and concentration measured. A plasma measurement during or immediately coincident with the urine collections are routinely used. This provides the UV/P. The classic exogenous material used – the gold standard – is inulin. This is true because inulin meets all the criteria listed above for the ideal substance for glomerular filtration rate measurement. The classic endogenous substance is creatinine. When using creatinine the GFR is adjusted to a standard of 1.73 m^2 ($UV/P \times 1/1.73\ m^2$) because the amount of creatinine produced daily does depend on muscle mass. Infants have lower plasma creatinines in part because their endogenous production is relatively low compared with adults (males > females) even if the filtration rate of creatinine is similar (*Table 21-1*). Finally, clearances are by convention expressed as mL/min and in the case of creatinine, mL/min/1.73 m^2.
2. *Constant infusions without urine collection*: This method is based on the simple notion that when an infused substance (which meets the criteria above for a clearance substance) achieves a constant plasma concentration, the rate of infusion (IR) equals the rate of excretion – $C_x = IR_x/P_x$ where x is the substance, C the clearance, IR the infusion rate and P the plasma concentration (2). This methodology is not frequently used. It requires an infusion. GFR may be overestimated if the plasma concentration is measured too early and a constant plasma concentration is not

reached. The methodology also assumes that the substrate infused will reach a constant plasma concentration in a similar period of time. This means that the area of distribution is similar from individual to individual. This assumption is not true for newborns who have a higher than normal extracellular volume (3).

3. *Single injection–plasma disappearance curves* (4): The concept behind this form of measurement is: following an injection, a substance will leave a space (intravascular space) by urinary excretion and further distribution into another space such as the extracellular space. The rate of decline from the intravascular will be rapid early and will slow as distribution progresses. Once fully redistributed, the rate of decline from the intravascular space will reflect the excretion rate. If using a substance that is excreted by filtration alone, the GFR can be measured. This technique requires frequent blood sampling. Some models have been designed that are based on single compartment mathematics (usually waiting to sample after the typical distribution time); this reduces the number of blood samples needed but also reduces accuracy. Also, patients with edema and patients with cardiovascular insufficiency will not fit typical models.
4. *Plasma concentration*: Using an endogenous substrate, the concept of just measuring the plasma concentration is based on the principle that as the GFR goes down, the substrate concentration in plasma must go up. While true, this relationship is not linear. A number of formulas have been used. The most common used in children is $GRF = K \times ht/P_{creat}$ where K is a constant which takes into account age and muscle mass and is different for neonates, boys and girls (see below); ht is height in centimeters, and P_{creat} is plasma concentration of creatinine (3). The two most commonly used endogenous substances are creatinine and cystatin C.

Use of Endogenous and Exogenous Substrates in Clinical Medicine and in Studies for Measure of CFR

Endogenous Substrates

Because creatinine and cystatin C are endogenously produced they are most commonly used for standard clearance methods or plasma concentration methods.

Creatinine

Creatinine is produced from creatine, an intracellular component of skeletal muscle. The circulating concentration of creatinine is dependent on muscle mass and GFR. Creatinine, in fact, is not a perfect substrate for measuring clearance. It is primarily filtered at the glomerulus but is also secreted into urine by tubular epithelial cells (5). Evidence for reabsorption of creatinine has also been reported (6). Because of the combination effects of muscle mass and filtration rate the plasma concentration of creatinine in prematures, neonates, children and adults undergoes change with time. *Tables 21-1* and *21-2* demonstrate plasma concentrations for prematures and newborns *Table 21-2* and children across three age ranges (*Table 21-1*). As the GRF falls, plasma creatinine increasingly overestimates GRF (7,8). This is, in part, because the tubular secretion of creatinine contributes an increasing fraction of total creatinine excreted, leading to a clearance which is increasingly greater than actual GFR.

Creatinine was measured by a "classic" technique using a Jaffe reaction – the production of an orange-red color when creatinine was mixed with alkaline sodium picrate. Recently, modern autoanalyzers are using creatinase and relying on this enzymatic reaction to measure creatinine (3).

The use of creatinine urinary clearances continues. However, the potential errors introduced when obtaining

Table 21-2

Mean values of plasma creatinine during the first weeks of life of term and very low birth weight neonates

Birth weight (g)	Plasma creatinine (μmol/L)[a]

Adapted from García-Nieto V, Santos F. Pruebas funcionales renales. In: Garcia-Nieto V, Santos F, eds. *Nefrología pediátrica*. Madrid: Aula Médica, 2000; and García-Nieto V, Santos F, eds. *Grupo aula medica*. Madrid: Aula Médica, 2000;15–26

a creatinine clearance from plasma plus urine should be understood. First, certain foods can change the plasma creatinine. A cooked meat meal especially in large volumes can influence plasma creatinine by introducing a "nonendongenous" source of creatinine (9). Certain medications and substances can interfere with the tubular secretion of creatinine (cimetidine, trimethoprium, urate) (10). Urine collections are timed. Inaccurate collection times can affect the results. A 24 h collection (1440 min) will report too low a GFR if the collection is actually under 24 h or too high a GFR if the collection is actually >24 h when the time used for calculation is precisely 24 h. Normal values are found in *Table 21-3*.

In aggregate, the use of endogenous substrates are preferred for GFR estimations in clinical situations. The commonly used estimations of GFR are: in children the Schwartz formula (11,12)

$$\text{eGFR} = \frac{\text{KL}}{\text{Scr}}$$

eGFR – estimated GFR in mL/min/1.73 m^2
K – empirically derived constant
L – length in centimeters
Scr – serum creatinine in mg/dL

K is 0.45 in infants, 0.55 in children and adolescent girls and.0.7 in adolescent males.

in adults the Cockraft–Gault equation (13)

$$\text{eGFR} = \frac{[140 - \text{age(y)}][\text{bodyweight(kg)}]}{(72 \times \text{Scr})}$$

eGFR – estimated GFR
140 and 72 are empiric numbers allowing a close correlation between plasma (serum) creatinine and GFR

In adult females the eGFR is corrected by 0.85 because of smaller muscle mass.

More recently, cystatin C has been used as an endogenous marker of renal function and to estimate GFR. Cystatin C is a nonglycosylated protein produced in all cells with relative constancy. Cystatin C is not influenced by age, gender, body habitus or composition (14). Renal handling of cystatin C is filtration with nearly complete catabolism and reabsorption of catabolized products by the proximal tubule. Little or no cystatin C appears in the urine (15,16). Cystatin C circulating level is approximately 1 mg/L in healthy humans.

Is cystatin C a better indicator of GFR than serum creatinine? Because cystatin does not appear in urine it

cannot be used as direct measure of GFR like creatinine or inulin. Studies suggest that serum cystatin C is better correlated with *measured* GFR and that smaller changes in GFR are more readily measured by serum cystatin C than by serum creatinine (14,17). Formulas that have been tested for the use of cystatin C to estimate GFR in children have been reported by Filler (18) and Zappitelli (19).

$$\log_{10}(\mathrm{GF}) = 1.962 + \left[1.123 \times \log_{10}\left(\frac{1}{\mathrm{cys}^{\mathrm{C}}}\right)\right]$$

Estimated GFR using cystatin C($\mathrm{cys}^{\mathrm{C}}$) according to Filler.

There continues to be debate as to whether cystatin C as a measure of estimated GFR is clearly better than serum creatinine (3). *Figure 21-1* shows creatinine and cystatin C levels from prematures to adults.

Exogenous Markers of Clearance

Inulin

This is the classic marker for measuring GFR, since it meets all the criteria for accurate measure of GFR (3). Inulin is a fructose polysaccharide, which is inert. Inulin urinary clearance, constant infusion techniques and even plasma disappearance have provided considerable evidence as to normal GFR for neonates, children and adults (*Figs. 21-2* and *21-3*) (20). Inulin is the gold standard, but because it requires infusion and is most accurate when used as an infusion plus urine collection technique, inulin is rarely used clinically.

Markers using radiolabelled isotopes (radionuclides): In clinical medicine radionuclides are often used to estimate total GFR or to measure difference in clearance between one kidney and the other in the same patient. The fundamentals of this approach rely primarily on single injection, plasma disappearance curves to "measure" GFR. The three commonly used radionuclides for GFR measurements are diethylene triamine penta-acetic acid (DTPA), ethylene diamine tetra-acetic acid (EDTA) and iothalamate. All three require an injection and then measuring the signal from the radiolabelled form to obtain measurement (technetium 99 for DTPA, chromium 51 for EDTA and iodine 125 for iothalamate). Briefly stated, DTPA correlation to 24 h inulin clearance is very good (21), EDTA correlation to inulin clearance is good (21,22), and iothalamate correlation to inulin clearance is only fair (23). In general, DTPA and EDTA do not perform well in neonates. EDTA appears to have an extrarenal source of elimination. The Tc radiolabel may dissociate from DTPA during clearance studies and iothalamate appears to undergo both tubular secretion and reabsorption (20).

Finally, iohexol has been touted as an alternative to inulin. Iohexol is a nonionic, non-radioactive, X-ray contrast medium of low molecular weight which is eliminated from plasma solely by glomerular filtration (24). It is easily measured by HPLC using very small volume increasing the usefulness in children (25). Iohexol GFR measurements correlate well with inulin measurements (26). Iohexol requires an infusion, and the plasma disappearance adheres to a two compartment model (fast peak in 5 min corresponding to peak plasma concentration, slow curve at approximately 90 min corresponding to renal excretion) (27). Iohexol may prove useful as a study tool, but probably not useful as a regular clinical measure of GFR.

Proteinuria

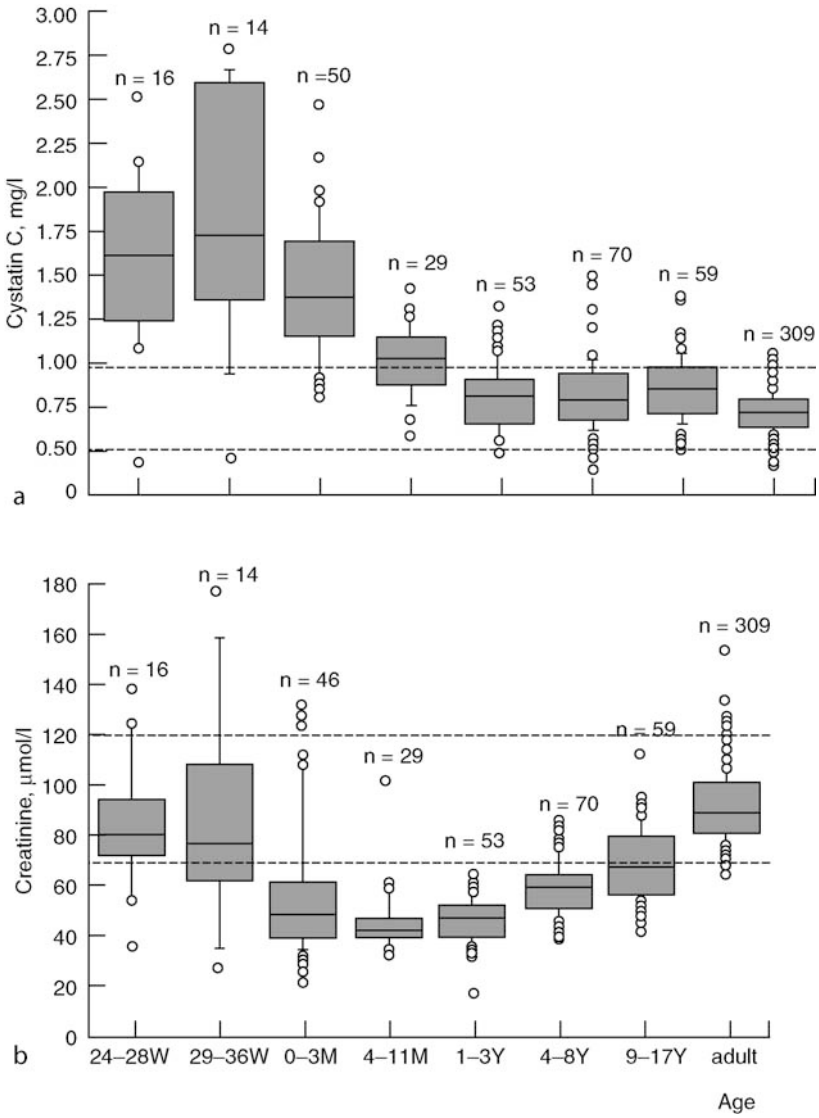
The glomerulus prevents the passage of proteins from plasma to the Bowman's space. This restriction is mediated by charge- repelling primarily negatively charged proteins such as albumin and by size. This combination explains why so little protein appears in Bowman's space as part of ultrafiltrate (Bowman's space albumin concentration is 210 mg/L). Any protein filtered under normal conditions is reabsorbed by the proximal tubule through endocytosis at the luminal membrane. Situations of glomerular injury, where the glomerular basement membrane charge and/or "pore" size is changed, will result in large amounts of protein (including albumin) being filtered. This will readily overwhelm proximal tubule endocytosis and proteinuria will ensue.

Under normal conditions some protein will appear in the final urine. As noted above essentially no albumin will appear in urine, but some *tubular* proteins are routinely measured in normal urine. Most commonly Tamm–Horsfall protein, a glycoprotein secreted by the ascending limb of the loop of Henle can be measured. Generally, the finding of Tamm–Horsfall protein in urine is of no clinical significance.

Proteinuria as a measure of renal injury is used ubiquitously by nephrologists. Protein that appears in urine as a result of the loss of glomerular barrier (termed altered permselectivity) usually results from physical damage to the glomerulus, loss of anionic charge along the glomerular membrane, and hemodynamically mediated protein loss. Loss of anionic charge alone results in increased albumin excretion (selective proteinuria), but as injury worsens and especially if physical injury to the glomerular barrier

Figure 21-1

Box plot distributions showing (a) cystatin C and (b) creatinine values (tenth, twenty-fifth, fiftieth, and ninetieth percentiles) across the age groups. The categories of 24 to 36 and 29 to 36 weeks refer to gestational ages of preterm babies. Dotted lines indicate 95% confidence interval of adult range. Preterm babies born between 24 to 36 weeks' gestation were 1 day old. (Adapted from Finney H, Newman DJ, Thakkar H, et al. Reference ranges for plasma cystatin C and creatinine measurements in premature infants, neonates and older children. *Arch Dis Child* 2000;82:71–75).



results, protein loss becomes non-selective. This degree of selectivity is determined by measuring albumin and another protein usually of higher molecular weight such as immunoglobulin G (IgG) or transferrin. Highly selective proteinuria will have an IgG:albuimin ratio of <0.1.

Proteinuria is used routinely in diagnosis, prognosis, and response to therapy. Often the first clue to renal injury is the finding of proteinuria on a urinalysis. Prognostically, persistent proteinuria or failure of protein excretion to respond to treatment is viewed as a bad prognostic sign. When protein excretion does diminish, apparently in response to therapy, this is viewed not only as a good sign, prognostically, but as a predictor of prolongation of renal function and prolongation of time to severe chronic kidney disease (CKD) or end stage renal disease (ESRD). In this way, the response of

Figure 21-2

Inulin clearance as a function of age X±SD.

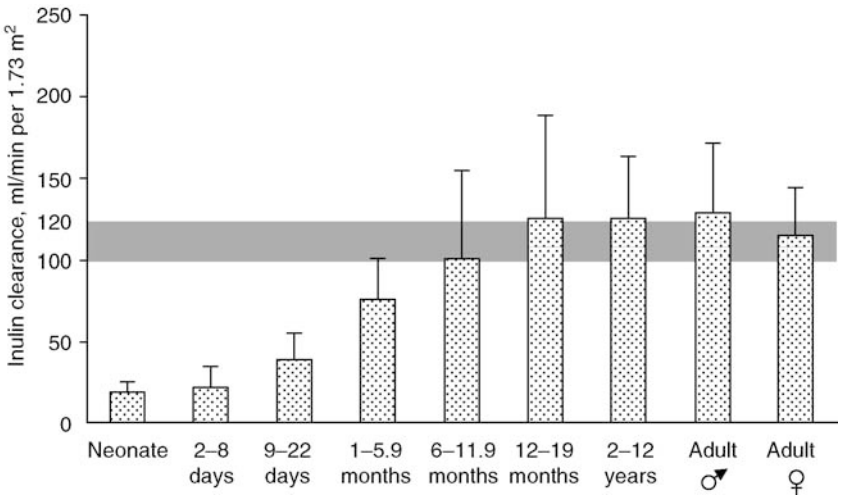


Figure 21-3

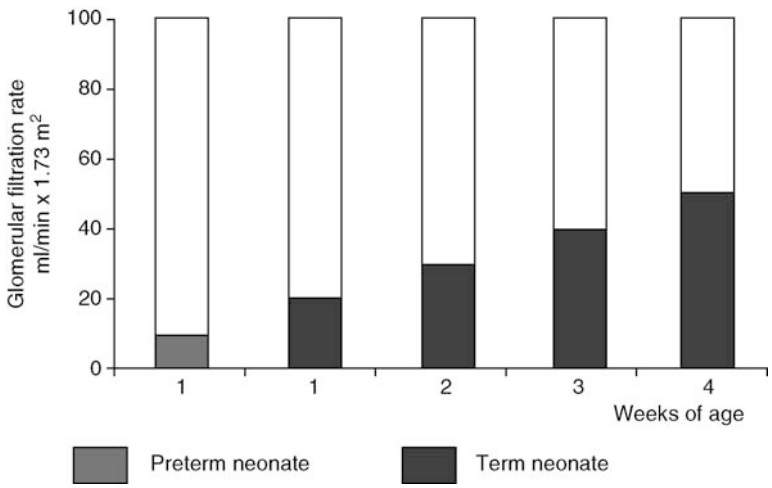
Postnatal increase in glomerular filtration rate in term and preterm infants. Open part in columns represents mature levels of glomerular filtration rates. (Adapted from Guignard JP, Torrado A, Da Cunha O, et al. Glomerular filtration rate in the first three weeks of life. *J Pediatr* 1975;87:268–272.)



protein excretion to treatment is used as a surrogate to predict later changes in glomerular filtration rate. The evidence for proteinuria as a surrogate to predict later change or time to change in renal function is somewhat limited (1).

Another commonly used marker for diagnosis of renal injury is microalbuminuria (preferable terminology – albuminuria). Very small amounts of albumin are excreted in normal individuals when this amount is between 30 mg/g creatinine and 300 mg/g creatinine (or 0.7 mg/m^2/24 h to 7 mg/m^2/24 h). The finding suggests subtle glomerular injury. Albuminuria has been used extensively to diagnose and follow early diabetic nephropathy (28).

Some low molecular weight (LMW) proteins are filtered, but in normal situations these proteins are metabolized and reabsorbed by the proximal tubule. With

impaired proximal tubule function (e.g., Fanconi syndrome, drug injury) these proteins will appear in urine. Commonly measured "tubular" proteins include β_2-microglobulin (more stable but more variable because of higher MW), ∂_1-microglobulin (not protein bound, but unstable in acid urine), retinol-binding protein (strongly bound to plasma proteins).

Other tubular proteins – of tubular origin – have been suggested as markers of tubular injury and especially of tubular necrosis or transplant rejection. Markers of tubular necrosis have included *N*-acetyl glucosaminidase and alanine-aminopeptidase. Both are brush border enzymes released with injury (29). Another promising marker is NGAL (neutrophil gelatinase-associated lipocalin), a tubular protein whose urinary levels increase shortly after tubular injury. Suggestive data from patients' status post cardiac surgery, critically ill patients, contrast induced nephropathy and conditions such as lupus, nephritis and hemolytic uremic syndrome are promising (30). Confirmatory studies are still needed.

Protein Measurement

Dipsticks use a colorimetric measurement of urine protein. It is *not* quantitative, but qualitative, and measures protein: absence or presence in small or large quantities.

A somewhat more quantitative measure is the protein/creatinine ratio measured in a random urine sample. The correlation to 24 h urine protein is reasonably good (31). The sample most frequently used is a first or second morning void sample. First morning void samples should be used when considering orthostatic proteinuria (see below), otherwise, use second morning void samples. *Table 21-4* describes the upper limit of normal for protein/creatinine in the pediatric age range. Nephrotic range protein is >400 mg/mol creatinine or >2 g/g creatinine (in adults a standard definition is >2 g of protein excreted per 24 h).

A 24 h urine collection is the gold standard for defining proteinuria. Such collections are cumbersome, especially in young children, and subject to error (undercollection of fewer than 24 h or overcollection of >24 h).

Table 21-4

Normal values of protein excretion as a function of age

Age (yr)	Proteinuria	
	g/mol creatinine	g/g creatinine
0.1–0.5	80	0.70
0.5–1.0	60	0.55
1–2	45	0.40
2–3	30	0.30
3–5	20	0.20
5–7	19	0.15
7–17	18	0.15

Hematuria

Red blood cells in urine (hematuria) is caused by renal trauma, glomerular injury leading to red cells passing through the glomerular barrier, interstitial or tubular injury, stone disease, cystic disease, malignancy or injury to the urinary tract. Red cells can appear in urine even though they derive from outside the urinary tract. Two examples include menses or excoriation of the epidermis at the urethral meatus. Normal urine has few, if any, intact red cells, generally <2 red blood cells (RBC)/HPF (high powered field) on a urine specimen, which has been centrifuged. This small number will not result in a positive result on urinalysis. At the other extreme, urine will appear red or burgundy with red cells in the urine or with hemoglobin in urine. A urine hematocrit of ≤1 will still turn urine red. Because hematuria is a nonspecific finding, the finding usually indicates some injury but usually does not provide more information. There are two exceptions. First, dysmorphic red cells seen using phase contrast microscopy on microscopic examination of the urine may help determine the site of injury along the urinary tract. If 75% or greater of red cells seen are dysmorphic, the kidney and most likely the glomerulus is the site of injury. If <25% of RBC are dysmorphic (32), the injury site is the urinary tract – renal pelvis or below. Second, if a urinalysis is positive for RBC's but no RBC's are noted, then hemoglobinuria (or myoglobinuria) should be suspected and direct measurement of hemoglobin or myoglobin should be undertaken.

Urinalysis

Likely the most commonly used laboratory test for examining renal function or injury to the kidney or urinary, the urinalysis is easy to perform and is used as a screening test, a diagnostic test and, at times, a follow up examination to test the efficacy of therapy. Its utility is at times overestimated and the risk of either false positives or false negatives should be understood (33).

Urinalysis usually characterized three aspects of urine: (a) physical character: color, clarity, specific gravity and/or osmolality; (b) chemical character: pH, presence of glucose, protein, blood, ketones, bile pigments; (c) microscopic character: red cells (RBC), white cells (WBC), organism casts and crystals. Urine should be clear. Cloudy urine may represent crystals (e.g., calcium phosphate in alkaline urine), cells – WBC, RBC or both. Proteinuria, hematuria and glucose in the urine are often diagnosed first by using urinalysis as the screening test.

The most commonly used method for some physical, chemical and even cellular elements analysis of urine is a dipstick test which employs a colorimetric change to identify abnormalities. These impregnated sticks should be used appropriately. Certain rules pertain:

- Urine tested should be around body or even room temperature. Refrigeration will affect the test results.
- The observations of change should be made after 15 s and up to 1 min after dipping the reagent stick in urine. Too rapid or too late an observation of color change can give a false reading.
- Moisture, sunlight, cold, heat or time (strips have expiration dates) will result in false readings.
- Certain conditions or substances will cause false reading. For example, urinary ascorbic acid will result in false positive proteins and false negative glucose readings. Very alkaline urine will yield a false positive protein reading.

Leukocyte esterase and nitrite measurements are commonly found on urinalysis dipsticks. When WBC, especially neutrophils, are present leukocyte esterase is positive. Nitrite is found in urine as a result of metabolic release by bacteria. Unfortunately, neither is sensitive or specific enough to be able to definitively diagnose urinary tract infections even when used together (34). Routine urinalysis as a screening in the normal population remains controversial (35).

Renal Blood Flow (RBF) (*Table 21-4*)

The measurement of renal blood flow has been of interest to renal physiologists and nephrologists for decades. Normally, blood flow to the kidneys is approximately 1200 mL/min/1.73 m^2. The filtration fraction, that portion of renal blood flow that is filtered through glomeruli, normally is approximately 20% of RBF. The classic measurement method for RBF is the clearance of para-aminohippurate (PAH). To measure RBF, the substance used must be fully extracted from blood after a single pass through the kidney. PAH comes close, as it is both filtered by the glomerulus and secreted by the proximal tubule. It appears that approximately 90% of PAH is extracted in a single pass through the kidney. The classic measurement requires constant infusion and blood and urine measurements to examine clearance. This technique is now used almost exclusively (and not frequently) in the laboratory (20).

Other techniques are used more frequently to measure renal blood flow. These include iodine labeled hippuron (orthoiodo-hippurate), which is handled in a manner similar to PAH, but extraction is less than PAH (36). Another technique is the use of technetium labeled mercaptoacetyl-triglycerine (MAG-3). This technique is not very accurate for the measurement of renal blood flow, but has been used to evaluate urinary tract infection (see chapter on urinary tract infection). Other methods used clinically include contrast enhanced ultrasound (37), color Doppler ultrasound (38), magnetic resonance imaging (39). These may be used to measure renal blood or to compare flow between kidneys; however, renal blood flow measurements are not that accurate, but do provide estimates of blood flow (40).

Tubular Function

The composition of final urine is dependent on the composition of filtrate and then the contribution made by tubular function (reabsorption and/or secretion). The concentration of solute in glomerular filtrate is dependent on diet, water intake, intestinal absorption, non renal losses and age. Thus, normal values for the excretion of solutes are really no more than a typical range for excretion assuming a normal GFR (*Table 21-5*).

Sodium

Under normal conditions, sodium excretion approaches sodium intake. During growth children are in positive balance with respect to most solutes. Day to day, this positive balance amount for sodium or other solutes is small. On a Western diet, sodium excretion in children is approximately 3–4 mmol/kg/24 h (*Table 21-5*). However, body fluid composition, especially extracellular fluid volume, is regulated in part by the regulation of sodium excretion (hormonal influence by aldosterone and atrial natriuretic peptide). The plasma sodium concentration typically does not predict the urinary sodium concentration.

Table 21-5

Urinary solute/creatinine (creat) ratios (fifth and ninety-fifth percentiles) as a function of age

Solute/creat	Age (yr)															
	1/12–1		1–2		2–3		3–5		5–7		7–10		10–14		14–17	
mol/mol	P5	P95	P5	P95	P5	P95	P5	P95	P5	P95	P5	P95	P5	P95	P5	P95

Adapted from Matos V, Melle G van, Boulat O, et al. Urinary phosphate/creatinine, calcium/creatinine, and magnesium/creatinine ratios in a healthy pediatric population. *J Pediatr* 1997;131:252–257; and Matos V, Melle G van, Werner D, et al. Urinary oxalate and urate to creatinine ratios in a healthy pediatric population. *Am J Kidney Dis* 1999;34:1–6

Because sodium reabsorption consumes a substantial amount of energy utilized by the kidney and because sodium reabsorption especially during extracellular volume contraction is essential to restoring normal body physiology, the fractional excretion of (FE) of sodium is often used during episodes of oliguria to differentiate volume contraction from acute renal injury. Fractional excretion is the fraction of solute filtered, which appears in urine.

$$FE = \frac{Us}{Ps} \times \frac{Pcr}{Ucr} \times 100$$

Us – urine solute concentration
Ps – plasma solute concentration
Pcr – plasma creatinine concentration
Ucr – urine creatinine concentration

By concentration FE is reported in percentage, thus multiplication by 100.

If one substitutes sodium in the equation above the FE of sodium can be determined. In other than neonates, during episodes of low urine output a normally functioning kidney will maximally reabsorb sodium and the FE_{NA} will be <1%.

Potassium

On a normal diet potassium excretion in children averages 1–2 mmol/kg/24 h (*Table 21-5*). Potassium excretion in urine under normal circumstances depends on the secretion rate of potassium by the distal tubule. This secretion is regulated by distal tubule sodium delivery and aldosterone. To estimate the regulation by the distal tubule of potassium excretion, the preferred method is the transtubular potassium (concentration) gradient (TTKG). This measure evaluates the gradient between luminal peritubular potassium concentrations and the interstitial potassium concentration in the late distal tubule or collecting duct. The following assumptions make up the foundation of the use of TTKG. The potassium concentration of the distal collecting duct is the same as the systemic potassium concentration. The luminal potassium concentration at the distal tubule is deduced by adjusting the urinary potassium concentration to medullary water reabsorption by the distal tubule and collecting duct. This is done by dividing the final urine potassium concentration by the urine to plasma osmolality ratio. All these also require that there is sufficient sodium in the distal tubule for exchange of sodium and potassium and the urine/plasma osmolality is >1 (41). The calculation is:

$$TTKG = \frac{U_k \times P_{osm}}{Pk \times U_{osm}}$$

TTKG – transtubular potassium gradient
U_k – urine potassium concentration
P_{osm} – plasma osmolality
Pk – plasma potassium concentration
U_{osm} – urine osmolality

In adults a TTKG >5 means aldosterone is active; <3 suggests limited or no mineralocorticoid activity. In children with hyperkalemia a TTKG <4.1 (or 4.9 in infants) suggests decreased mineralocorticoid activity. With hypokalemia a TTKG >2 is indicative of ongoing aldosterone secretion.

Chloride

Urinary chloride excretion is tied to urinary sodium excretion. Urinary chloride depends on diet and extracellular volume status. With extracellular volume contraction, enhanced sodium reabsorption results in enhanced chloride reabsorption. During metabolic alkalosis the urinary chloride concentration can be useful diagnostically. A urinary chloride concentration >10 mmol/L is consistent with diuretic induced renal loss, whereas urine chloride concentration under 10 mmol/L is consistent with gastric loss and volume contraction.

Calcium

Hypercalciuria is defined as calcium excretions >4 mg/kg/24 h or >0.1–0.125 mmol/kg/24 h. A commonly used technique to screen for hypercalciuria is the calcium/creatinine ratio with a value of >0.2 mg/mg (>0.6 mmol/mmol) (42). The value for neonates and infants is higher (*Table 21-5*).

Phosphate

Urinary phosphate excretion is primarily dependent on dietary phosphate intake. Normal urinary phosphate excretion is 10–15 mg/kg/24 h (0.3–0.5 mmol/kg/24 h) in adults and 20–25 mg/kg/24 h (0.6–0.8 mmol/kg/24 h) in children (*Table 21-5*).

Phosphate is handled by reabsorption at the level of proximal tubule. For solutes handled by reabsorption 100-FE represents the tubular reabsorption (percentage of filtered load reabsorbed). For phosphate the TRP (tubular reabsorption of phosphate) represents the percent of phosphate reabsorbed by the proximal tubule. Generally the TRP on a Western diet (high in protein and phosphate) in a child with normal renal function will actually be the maximum that can be absorbed. The TMP (tubular maximum phosphate) reabsorption is reflected in this equation.

$$TMP = GFR \times Sp - Up \times V$$

Sp – serum phosphate concentration
Up – urine phosphate concentration
V – volume

This equation represents the best indicator of renal tubular handling of phosphate (43). With the above assumptions and rearrangement of the equation the commonly used TMP/GFR measurement can be obtained and reflects the serum phosphate concentration at the tubular threshold – the serum phosphate concentration at which phosphate concentration is at its maximum and phosphate begins to appear in urine:

$$\frac{TMP}{GFR} = TRP \times Sp$$

$$\frac{TMP}{GFR} = \left[1 - \left(Up \times \frac{Scr}{Sp \times Ucr}\right)\right] Sp$$

Scr – serum creatinine concentration
Ucr – urine creatinine concentration
TMP/GRF = Sp−(Up × Scr/Ucr) – this is most commonly used

In children >age 2 years, the normal TMP/GFR is 4–6 mg/dL. This falls to 2.8–4.2 mg/dL by age 20 (44).

Glucose

Glucose is filtered and reabsorbed by the proximal tubule. Like phosphate if the filtered load exceeds the maximal capacity of the proximal tubule to reabsorb glucose, the threshold for glucose excretion is reached. The normal plasma threshold for plasma glucose is approximately 180 mg/dL (9.9 mmol/L). Glucose filtration testing where glucose in increasing concentrations is infused (changed every 30 min) until the plasma glucose concentration reaches 350–400 mg/DL. Urine samples are collected at the last 15 min of each 30 min infusion period. This test was used to determine the glucose threshold especially in situations of renal glycosuria. Under normal conditions urinalysis test for glucose will be negative.

Magnesium

Magnesium is filtered and reabsorbed primarily at the proximal tubule and the ascending limb of the loop of Henle. In determining if renal handling of magnesium is normal the FE of magnesium FE_{Mg} is the typical measurement performed. Normally, approximately 5% of filtered magnesium is excreted. With hypomagnesemia the FE_{Mg} can fall to 1%. Under hypomagnesemic conditions the FE_{Mg} of ≥5% suggests renal wasting of magnesium.

Uric Acid, Oxalate, Citrate

Uric acid handling by the kidney is complicated. Uric acid is filtered, reabsorbed and secreted. In children (>age 2 year) and adolescents uric acid excretion is *not* age dependent and is approximately 520 ± 145 mg/1.73 m^2/24 h (3093 ± 875 μmol/1.73 m^2/24 h) (45). A screening test for hyperuricosuria was devised correcting urine uric acid concentration to GFR.

$$\text{Urine uric acid concentration} \times \frac{\text{Plasma creatinine concentration}}{\text{Urine creatinine concentration}}$$

A value >53 mg/dL or 32 μmol/L on first morning void urine in children >2 year of age is considered abnormal (46).

Oxalate forms highly insoluble crystals in urine. Oxalate excretion is in the range of 20–50 mg/1.73 m^2/24 h (0.3–0.55 mmol/1.73 m^2/24 h). In infants the value may be slightly higher (47). Above this range is suspicious for hyperoxaluria.

Citrate excretion in urine is important in reducing the risk of stone formation especially calcium containing stones. Hypocitraturia contributes to stone formation. Citrate excretion below 300 mg/g creatinine (0.176 mol/mol) in girls and 125 mg/g/ creatinine (0.074 mol/mol) in boys suggests hypocitraturia (48).

Acid Base

Anion Gap

The anion gap is a readily available measure to determine if a metabolic acidosis (acidemia) is associated with an endogenous or exogenous unmeasured serum anion leading to an *elevated* anion gap versus the loss of bicarbonate and concomitant increase in chloride leading to a normal serum anion gap. The anion gap represents the fact that routinely measured serum cations, specifically sodium and potassium, outnumber routinely measured anion chloride and bicarbonate. Because electroneutrality must be maintained there must be unmeasured anions that are routinely present in serum. In fact, there are both unmeasured cations and anions. The unmeasured cations add little to the electrical charge – Ca, Mg. Unmeasured anions include: protein such as albumin, phosphate, sulfate and others (e.g., urate). The two most commonly used ways to measure *anion gap* in serum are:

$$\text{Anion Gap (AG)} =$$
$$\text{Na} - (\text{Cl} + \text{HCO}_3) = 10 \pm 2$$
$$(\text{Na} + \text{K}) - (\text{Cl} + \text{HCO}_3) = 12 \pm 4$$

High serum anion gaps reflect endogenously produced anions such as lactate or keto acids, or exogenous anions such as salicylate. A low anion gap can be seen with hypoalbuminuria, or rarely in children, with abnormal cationic proteins.

A related concept is the urinary anion gap. The most easily measured ions in urine are Na, K and Cl. The urinary gap is calculated as:

$$\text{Urinary anion gap} = (\text{Na} + \text{K}) - \text{Cl}$$

Under metabolic acidosis conditions in patients with normal renal function, two important ions are not routinely measured in urine, NH_4 and HCO_3. Ammonium is positively charged, HCO_3 is negatively charged. When urine is acidic especially under a pH of 6 there is little or no HCO_3 in urine. However, with metabolic acidosis NH_4 production is stimulated. NH_4 will be excreted with Cl and therefore, the urinary anion gap will measure more Cl than Na + K. The urinary anion gap will be negative. Therefore, the urinary anion gap is a rough estimate of ammonium excretion. In acidemic patients with impaired NH_4 production (distal renal tubular acidosis, Type IV renal tubular acidosis or chronic kidney disease with impaired NH_4 production) the urinary anion gap remains positive. In patients receiving bicarbonate it is more difficult to use the urinary anion gap especially if the urine pH is high as bicarbonate may make up an important unmeasured anion (49,50). Urinary anion gap has been used in the neonate, but is more difficult to interpret especially in the premature (51).

Another method used to estimate ammonium excretion is the modified urine osmolar gap. Like the urinary anion gap this method recognizes that urinary osmolality is dependent on the concentration of ions in the urine. In particular, this method is useful when the urine pH is high. The equation is (52):

$$\text{Estimated } NH_4 \text{ excretion (mmol/L)} =$$
$$1/2\left[U_{osm} - 2(U_{Na} + U_K) + \frac{U_{urea}}{2.8} + \frac{U_{gluc}}{18}\right]$$

U_{osm} – urine milliosmoles
U_{Na} – urine sodium concentration (mmol/dL)
U_K – urine potassium concentration (mmol/dL)
U_{gluc} – urine glucose concentration (mg/dL)
U_{urea} – urine urea concentration (mg/dL)

Urinary Acidification Test

The assessment of the ability of the kidney to handle an acid load- urinary acidification testing is an exam that may be needed to test for renal tubular acidosis (RTA) and to distinguish type I (distal) RTA from type 2 (proximal) RTA (53–56). Distal RTA fundamentality is an inability to secrete sufficient H+ into the distal tubule lumen to acidify urine. At least three types of studies have been employed: (a) give acid to lower serum pH; (b)furosemide test to deliver large amounts of sodium and chloride to distal tubule and thereby, encourage H+ ion secretion; (c)acetazolamide (or bicarbonate), which delivers large amounts of bicarbonate to the distal tubule. Normal H+ ion secretion will result in HCO_3 and H combining to form water and carbon dioxide. Thus, the pCO_2 of final urine will be considerably higher than blood pCO_2. If a first morning urine pH is <5.5, no additional testing is needed. This is a normal distal acidification.

(a) *Acid test*: Either during spontaneous metabolic acidosis or with the delivery of ammonium chloride (75–100 mmol/m^2 intravenously over 4–6 h, orally with enteric coated capsules over 1 h or orally at 2 mmol/kg/24 h over 3–5 days) such that the blood pH drops to 7.33 or less and the serum bicarbonate falls to below 18 mmol/L. At this point the urine pH should be below 5.5. A concomitant urine measurement of sodium, potassium, chloride and osmolality will assure that insufficient sodium at the distal tubule is not a cause for reduced acidification or that very high ammonia production (urinary anion gap or osmolar gap measurement) has resulted in a urine pH which does not fall below 5.5. Finally, very dilute urine (urine osmolality) will mask good distal H+ secretion. Patients with type II RTA will respond normally once the serum bicarbonate falls below threshold (typically, serum bicarbonate <14 mmol/L).

(b) *Furosemide Test*: 3–4 h following a furosemide dose of 1 mg/kg orally or intravenously, urine pH should fall below 5.5. Patients with type I RTA will fail to reduce urine pH sufficiently; however, patients with type II RTA will respond normally. This test is not predictive of type IV RTA. Measurement of urinary electrolytes (as noted above) will also demonstrate high potassium excretion expected as a result of furosemide.

(c) *Acetazolamide or bicarbonate test*: With this test oral acetazolamide (0.5–1 g/1.73 m^2 or 15–20 mg/kg) or oral bicarbonate (2.5 mmol/kg) should result in bicarbonaturia. A normal response is a urine pCO_2 of >70 mmHg or difference between urine pCO_2 and blood pCO_2 of >20 mmHg (urine – blood pCO_2). This exam requires that urine be collected and stored under oil and in glass to prevent the loss of CO_2 into the air. Patients with type I (distal RTA) will not show the normal pCO_2 response. Patients with type II TA will.

Urinary Concentrating and Diluting (56,57)

Concentrating Ability

Patients may have reduced ability to concentrate urine as a result of a primary or secondary renal defect; as a result of vasopressin deficiency or due to large volumes of water intake (primary polydipsia). Two tests performed separately or sequentially can help delineate causes for failure to concentrate urine. In children or adults urine can be concentrated to 1200 mOsm/kgH_2O). In neonates maximal concentration is rarely above 700 mOsm/kgH_2O.
Tests:

- *Fluid restriction*: A first morning void after 12 h overnight fluid restriction with an osmolality >725 mOsm/kgH_2O, means normal concentrating ability. No further testing is needed. This test cannot be used in children under 2 years of age (see exam below). In children with large volumes of fluid intake for weeks or month (primary polydipsia), the urinary concentrating ability is reduced. Progressive reductions in fluid intake over days or weeks may be necessary in order to perform a thirst test. A thirst test still requires 12–16 h of fluid deprivation or loss of at least 2% of body weight. A loss of 2% of body weight may occur in children with vasopressin deficiency or nephrogenic diabetes insipidus and can occur well short of 12 h of fluid deprivation. When these diagnoses are being considered fluid deprivation should be performed in a controlled setting.
- *Vasopressin administration*: In patients following fluid deprivation where the urine osmolality does not rise above 600 mOsm/kgH_2O or in patients where vasopressin deficiency or nephrogenic diabetes insipidus is suspected and no fluid restriction is performed, vasopressin administration may help make the diagnosis. With a kidney capable of responding to vasopressin, the administration of DDAVP (1-desa-

mino-8-1) arginine vasopressin intranasally at a dose of 10 micrograms for infants and 20 μg in children or adolescents should result in urine osmolality increasing to above 750 mOsm within 6–8 h after administration of vasopressin. This test is best performed under some fluid restriction. In infants a restriction to 50–75% of usual fluid intake is preferred (57,58). In nephrogenic diabetes insipidus, no response to DDAVP will be noted.

Dilution Ability

Rarely is there a need to determine the maximal ability to dilute urine. It can be helpful when trying to determine *excessive* electrolyte loss (sodium, potassium, chloride) in patients with tubular disorders such as Bartter's syndrome. Urine and blood measurements of creatinine, sodium, potassium, chloride, osmolality and urine volume are measured prior to and then after oral water intake of 20 mL/kg over 1–2 h followed by an IV infusion 1–2 L of 2.5% dextrose plus 0.45 saline over 2–3 h. Urine is collected from the start of the study and on hourly intervals. The study results in a determination of the osmolar fractional clearance and the volume of urine produced per 100 mL GFR. The equation that defines the findings is as follows:

$$\mathrm{V} = \text{Volume of urine}/100\text{mlGFR} - \mathrm{Pcr}/\mathrm{Ucr}) \times 100$$

Pcr – plasma creatinine concentration
Ucr – urine creatinine concentration

$$C_{osm} = \text{Osmolar fractional clearance} = \frac{\text{Urine osmolality}}{\text{Plasma osmolality}} \times \mathrm{V}$$

This approach was described by Rodriguez-Soriano and normal values are reported (59). The normal C_{osm} in infants is 4.3 ± 1.3 mL/dL GF and in children the normal is 3.2 ± 0.7 mL/dL GF.

22 Evaluation of Growth and Development

Sandra Amaral · Alicia Neu

Normal Growth

Growth is an invaluable biological indicator of overall health status in children. For this reason, careful assessment of growth should be an integral component in the routine care of any child with kidney disease. To optimize growth and development in children with kidney disease, it is vital to understand both the normal physiology of growth and the impact of kidney disease on growth. It is also imperative to be familiar with current methods of growth assessment and their limitations.

Measurements of Growth

Linear Growth

Pediatric growth charts have been used since the 1970s to assess how a child's growth compares with the growth of age- and gender-matched peers. The most commonly used growth charts were originally developed by the National Center for Health Statistics in 1977 to describe the distribution of height and weight of children in the United States (1). The 1977 growth charts were adopted by the World Health Organization (WHO) for international use. In 2000, the growth charts were updated based on data from the United States National Health and Nutrition Examination Survey (NHANES) from 1971 to 1994. NHANES has collected data on the health and nutrition of Americans since the 1960s (*Figs. 22-1*–*22-4*). In 2006, WHO launched new Child Growth Standards (2). These new standards resulted from a WHO study initiated in 1997 to develop an international standard for assessing physical growth, nutritional status and motor development in children from birth to 5 years of age. The study was a community based, multi-country project conducted in Brazil, Ghana, India, Norway and the United States. Over 8,440 children were included in the study (2). In 2007, WHO constructed growth references for children and adolescents 5 years through 19 years of age to be in accord with the WHO Child Growth Standards for preschool children and the body mass index (BMI) cut-offs for adults (3) (*Figs. 22-5* and *22-6*).

To identify problems with growth, it is necessary to examine growth changes over time. Growth must be assessed accurately and frequently. In the first year of life, linear growth should be assessed at birth, within 1 week after delivery, and then at 1, 2, 4, 6, 9, and 12 months. From 1 to 3 years of age, linear growth should be assessed every 6 months, at 18, 24, 30 and 36 months. Thereafter, linear growth should be measured once yearly.

To ensure accurate assessment of height, both measurement equipment and technique must be precise. Inaccurate height measurements on either an infant measuring board or stadiometer may lead to gross misinterpretation of growth patterns. Length boards and stadiometers should be zeroed on a daily basis and checked with standard length rods at least monthly. *Figure 22-7* demonstrates proper positioning of an infant and older child for height measurement. Special attention should be directed to positioning of the feet and hands. With an infant measuring board, feet must be flat and positioned against the board in line with the back of the head. The toes should point up. The body must be straight. The best way to ensure the head and feet are aligned and against the board is to have one person hold the head and another person hold the feet. In infants, it is often necessary to hold the knees down. Buttocks and shoulders should also touch the back board. The head should be in the Frankfurt plane, with the outer canthus of the eye and the external auditory canal forming a line perpendicular to the back board. For standing measurements, the feet must again be flat. The child should be measured after the removal of socks and shoes so that proper foot positioning can be ensured. Any hair accessories that may impact measurement of the top of the head should be removed if possible. If hair arrangements cannot be removed but may affect the accuracy of the measurement, this should be noted on the growth chart. Have the child stand with his/her back to the height rule. Heels should be slightly apart. The back of the head,

shoulder blades, buttocks, calves and heels should be touching the height rule. The knees should not be bent. Eyes should be forward, arms at sides and shoulders relaxed. The top of the external auditory meatus should be level with the inferior margin of the bony orbit. The head piece of the stadiometer is lowered until it is touching the top of the head and is level. Height is recorded to the resolution of the height rule (i.e., nearest millimeter/half a centimeter). If the participant is taller than the measurer, the measurer should stand on a platform so that he/she can properly read the height rule.

There are several common errors that may occur when obtaining height measurement. A period of increased risk for misinterpretation of height measurement occurs when an infant progresses from sitting to standing. Standard growth charts for infants from 0 to 36 months are based on recumbent length measured on infant measuring boards. Growth charts from 2 to 20 years are based on standing heights only. It is crucial to use the growth chart that correlates with the measurement technique between the ages of 2 and 3 years. Using the incorrect growth chart may lead to gross misinterpretation of a height pattern during the toddler years. Another potential error may occur when plotting the height measurement on the growth chart; height measurement should be recorded on the growth chart as close to the fractional age as possible rather than plotting on the nearest year or half-year. Inaccurate plotting of age may lead to significant discrepancies in height trends.

Most growth charts express height as a percentile for a reference population. The updated 2000 CDC growth charts can be used to obtain both percentiles and z-scores. A z-score is a statistical measure that quantifies the number of standard deviations (SD) a data point is from the mean of the data set. A z-score of zero lies at the mean. The WHO growth standard and reference charts make z-score calculation readily accessible (*Figs. 22-5* and *22-6*). Height percentiles are informative when a child's height measurement lies within them, however z-scores are more helpful for children who are significantly shorter

Figure 22-6

World Health Organization growth reference curves, providing z-scores for height in girls 5–19 years of age (http://www.who.int).

or taller than the standard percentiles. Z-scores (or SDS) are also used for other growth parameters, such as weight and body mass index. Besides the WHO z-score references, z-scores may be calculated using several computer programs that are widely available. Z-scores should be calculated regularly for any child with kidney disease. For children with incident end-stage renal disease (ESRD), height less than 1% for age (z-score < -2.5) at dialysis initiation has been shown to be associated with a more complicated medical course, included increased risk of mortality and prolonged hospitalization (4). For prevalent ESRD pediatric patients, decrease by 1 SDS in height has been shown to be associated with 12% increase in risk of death (5).

Special Considerations in Linear Growth

Several pediatric populations require special consideration when interpreting the standard CDC growth charts. The updated 2000 growth charts represent a more varied pediatric sample than the previous growth charts from the 1970s, however several groups are still underrepresented. Very low birth weight infants ($< 1{,}500$ g) are not included in the standard CDC growth charts. There are separate growth charts available for infants 1,500 g or less and infants 1,501–2,500 g. These charts are based on a large longitudinal cohort of premature infants from the Infant Health and Development Program (IHDP) (6, 7). For both low birth weight and very low birth weight infants, length, weight and head measurements should be recorded under the patient's corrected (or gestation-adjusted) age. The corrected age is calculated by subtracting the number of weeks of prematurity from the infant's chronological age. For most premature infants, length, weight, and head circumference should be plotted under the child's corrected age until the child reaches 2 years. For the extremely low birth weight infant weighing less than 1,000 g at birth, the corrected age is often used until

Figure 22-7

Proper positioning of an infant (a) and child (b) for accurate measurement.

3 years of age. If the child's growth normalizes before 24–36 months of age, chronologic age may be used instead of corrected age.

The standard CDC growth charts also may not adequately represent normal growth patterns for children with special healthcare needs. Several diagnosis-specific growth charts have been developed for conditions in which growth patterns may be impaired, such as Trisomy 21, Turner's syndrome and cerebral palsy (8). Although many of these diagnosis-specific growth charts are based on relatively small sample sizes, they may be useful in understanding expected growth trends in these special populations.

Although the updated CDC growth charts include a more diverse ethnic sampling, racial and ethnic differences in growth remain incompletely understood. Currently, one set of growth charts is promoted for all racial and ethnic groups because studies have suggested that growth differences among racial and ethnic groups are generally the result of environmental rather than genetic influences, and these data are supported by the WHO Growth Reference Study Group (2, 9). There is evidence to suggest that blacks may have an earlier acceleration in growth compared with whites (10). There have also been several studies noting decreased height SDS in Hispanics, especially Mexican Americans(11, 12). Since Hispanics represent up to 30% of pediatric ESRD, it is particularly disconcerting that standard growth charts include a random population comprised of less than 10% Hispanic children (13). Thus, although the racial and ethnic differences in growth trends demonstrated in children with ESRD may not represent genetic influences, it is important to understand that the differences exist and may be in part related to factors other than those associated with kidney failure.

Sitting Height

Measurement of sitting height may be a more useful measure of stature than standing height for children who are wheelchair bound or have impairment of the spine or long bones. There are specific devices for measuring sitting height that are comprised of a stadiometer attached to a base of a known height. The base is a box wide enough for a child to be comfortably seated. The child is placed on the base as erect as possible. Buttocks, shoulders and back of head should be against the back of the height rule. The head should be positioned in the same manner as standard stadiometer measurement. Total height is measured from the floor to the top of the child's head. The length of the sitting base is then subtracted to obtaining the sitting height measurement. The measurement can be plotted on the CDC stature-for-age

chart so that a trend can be ascertained over time. There are references for sitting heights, however the standards are from the early1970s and did not include children with special healthcare needs (14).

Growth Velocity

Growth velocity refers to the rate of change in height over time. Growth velocity is helpful in ascertaining the overall health status of a child as well as the effectiveness of therapy to improve growth. The accuracy and usefulness of measuring height velocity depends on the accuracy of the underlying height measurements and on the time interval over which the measurements are recorded. There is seasonal variation in growth velocity throughout the year in healthy children. Growth velocity charts examine mean change in height in centimeters over 1 year; thus, measurements should be obtained as close to a 1-year interval as possible. The height velocity charts that are most commonly used today are based on large longitudinal studies and are thus more accurate than cross-sectional estimates of rate of change in height (*Figs. 22-8* and *22-9*) (15). Often, in the practice setting, measurements are taken over a shorter time period and extrapolated for 1 year estimates. While this method is more practical clinically, it increases error in calculation and may lead to clinical misinterpretation. Any growth velocity estimates based on data from less than 1 year should be used with caution.

The time period over which the measurements are taken should be marked along the x-axis of the growth chart and the mean growth velocity should then be plotted at the midpoint of the time period. It is also helpful when interpreting the results to record the timing of important clinical events, such as initiation of recombinant human growth hormone (rhGH), on the height velocity chart. This permits assessment of pre- and post-treatment growth response. When calculating height velocity, time periods with and without rhGH treatment should have separate height velocities calculated and should not be averaged together. Averaging will lead to underestimation of the response to rhGH. Height velocity is informative in ascertaining whether a child experiences catch up growth in response to treatment. Catch up growth describes height velocity that exceeds the limits of normal for age for at least 1 year after a period of depressed growth.

Growth velocity patterns are not static. Patterns vary widely with pubertal maturation stages (16, 17). Growth velocity charts provide centile lines that allow a practitioner to assess whether a child is growing within the normal variation for age, regardless of maturation stage. Pubertal growth is characterized by an acceleration in growth followed by a deceleration and then stabilization with closure of the epiphyses. Peak height velocity during puberty is reached earlier in girls than boys. In general, girls reach peak height velocity at 11.5 years whereas boys reach peak height velocity at 13.5 years. Whole-year peak height velocity is on average 8.3 cm per year in girls versus 9.5 cm per year in boys.

Interpretation of height velocity differs significantly from the interpretation of absolute height. Since height velocity is variable, a child may remain at the fifth percentile for absolute height, but the height velocity should change based on the maturational stage. A child needs to maintain a height velocity at the 50th percentile in order to maintain a height at the 50th percentile. If a child maintains height velocity at the 25th percentile throughout maturation, for example, that child will significantly drop percentiles in absolute height. Such a drop would be quite concerning and should prompt evaluation for growth impairment. In a cohort of 1,949 prevalent pediatric patients with ESRD, for each 1 SDS decrease in growth velocity, the risk of death increased by 12% (5). Thus, measurement of height velocity may be a valuable prognostic indicator for overall morbidity in pediatric ESRD.

Head Circumference

It is recommended that occipitofrontal circumference be assessed in all children regularly up to 3 years of age. The measurement of head circumference in infancy and early childhood is particularly important because it reflects the time of most rapid brain growth and neurocognitive development. Head circumference measurements should coincide with the routine clinic assessment schedule after birth. To obtain an accurate head circumference measurement, a flexible but non-stretchable measuring tape should be used. Head circumference or OFC (occipitofrontal circumference) should be measured over the occiput and just above the supraorbital ridges to ensure measurement of the area of greatest circumference.

Just as with height measurements, head measurements should be obtained serially to assess trends in growth and development. A single head measurement may appear normal, but when interpreted in the context of head measurements at other points in time may reveal an abnormal pattern. Rapid growth in head circumference may be concerning for the development of hydrocephalus. Poor growth in head circumference may be indicative of a genetic or metabolic disorder. Head circumference which

Figure 22-8

Height velocity in boys 2 to 19 years of age (From (15) with permission).

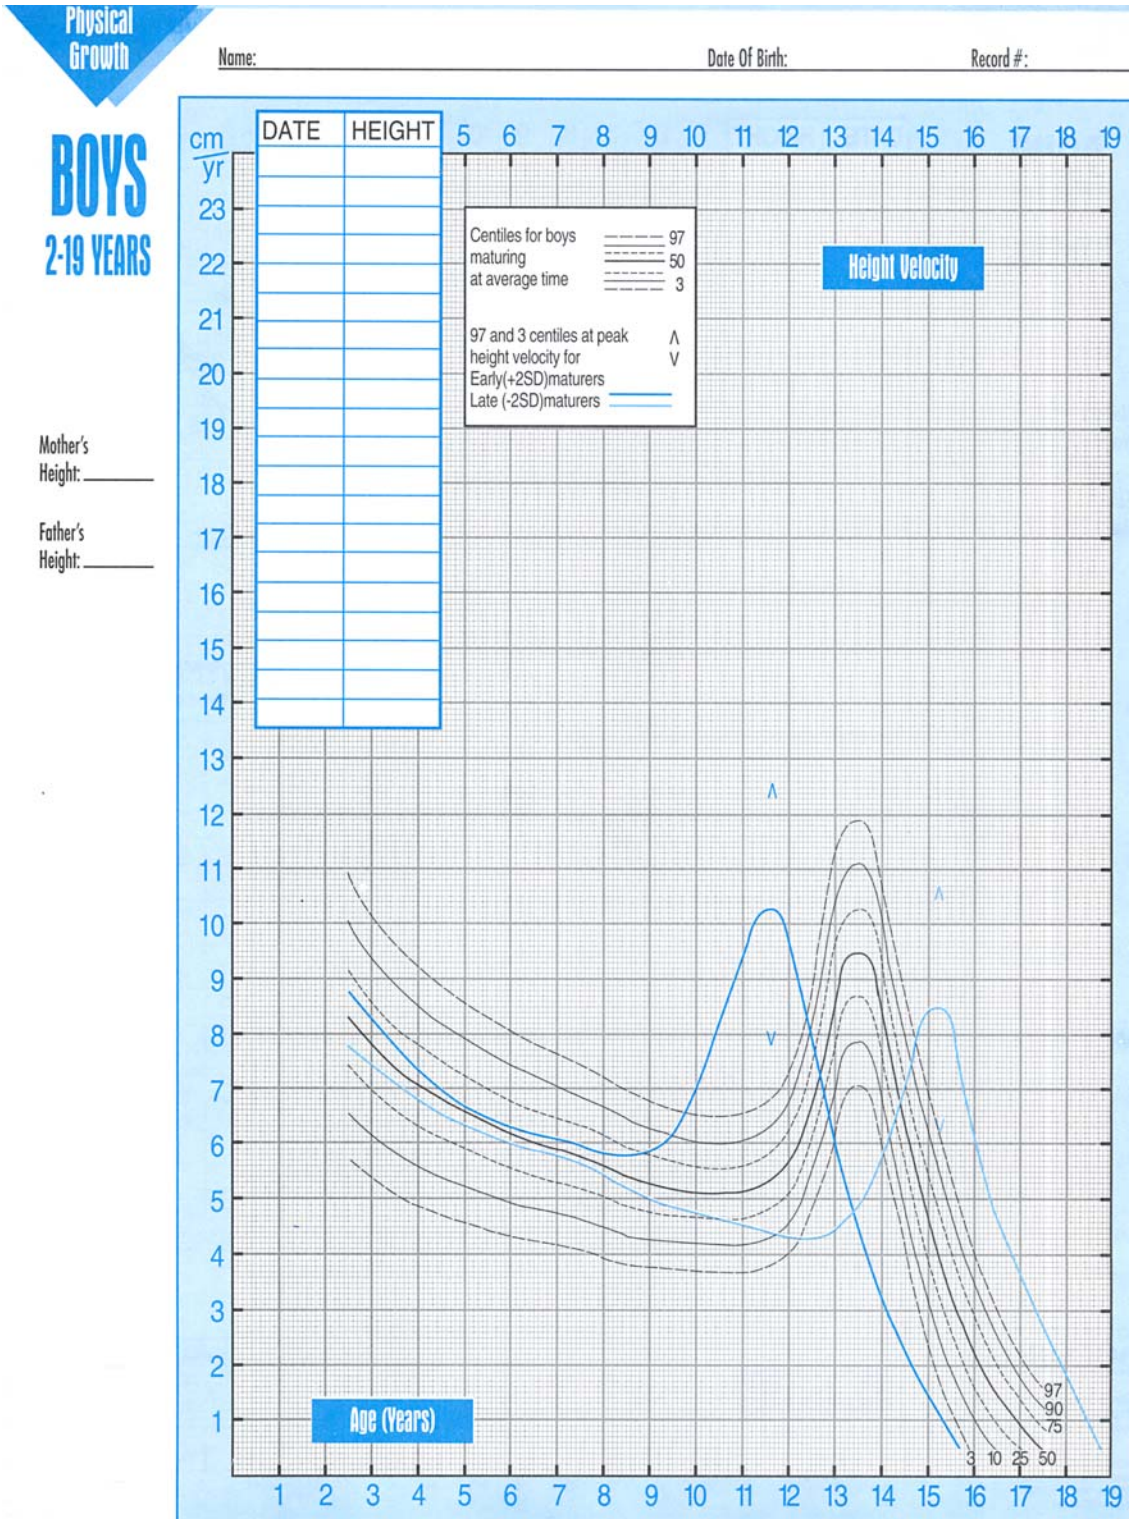

Figure 22-9

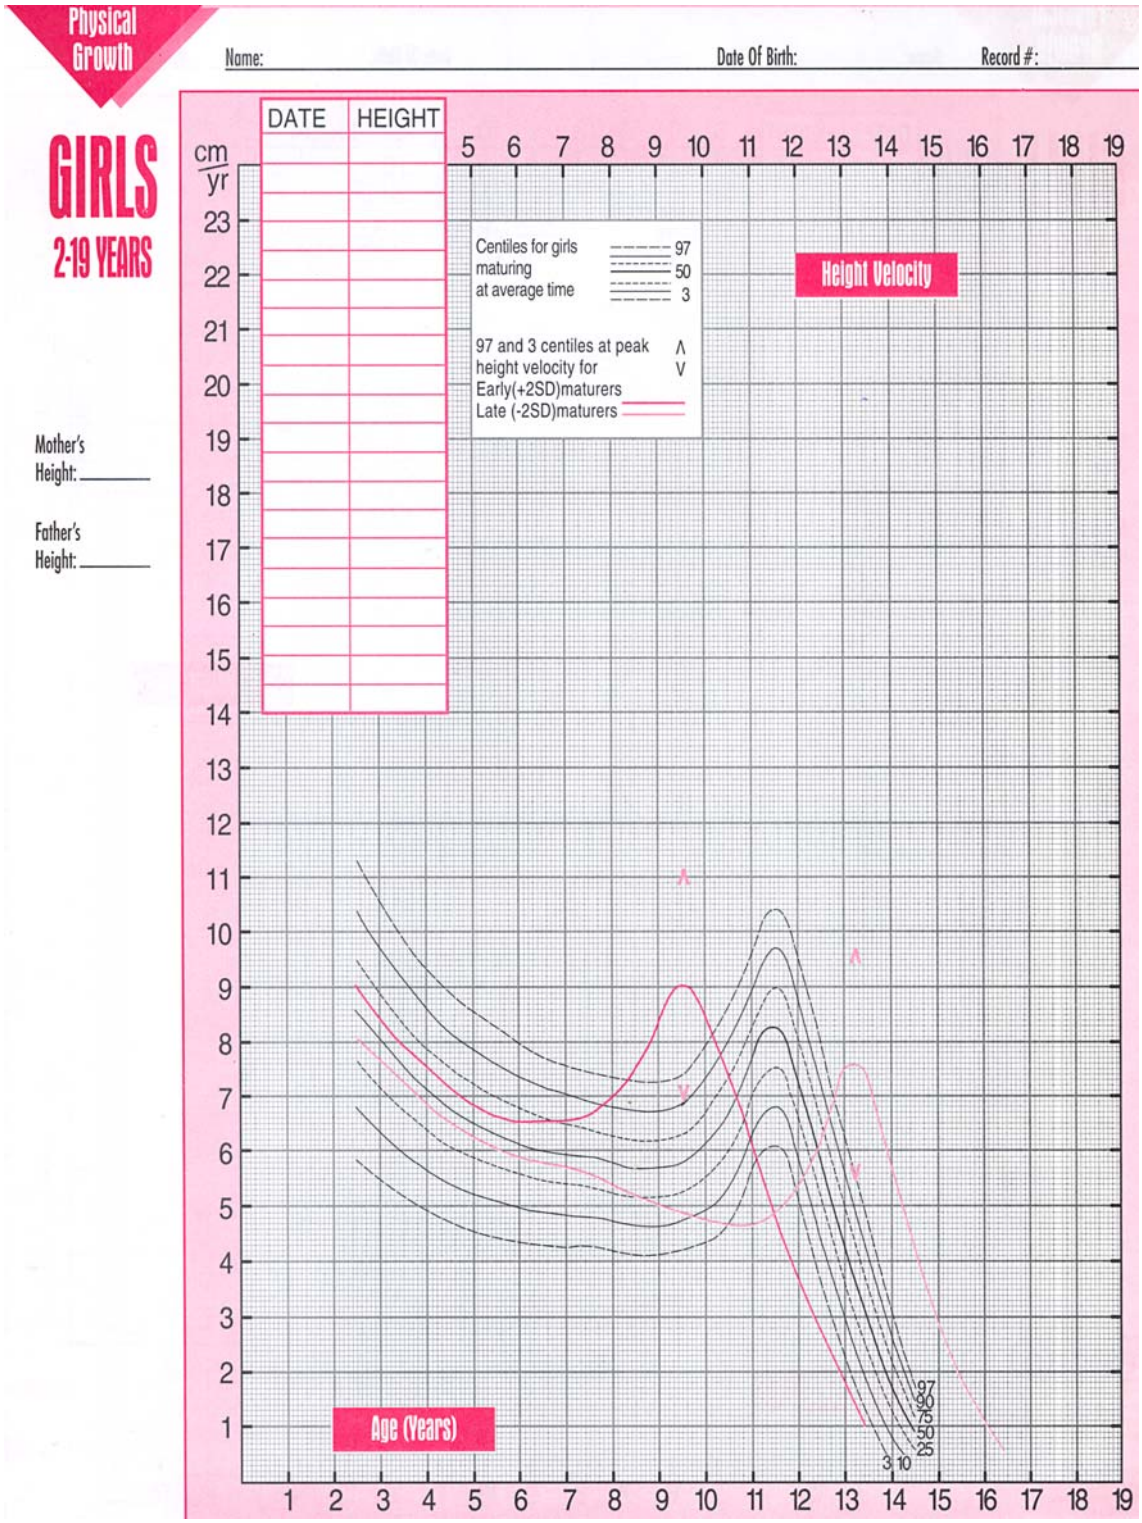
Height velocity in girls 2–19 years of age. (From (15) with permission).



is stable in growth but at the lower or upper percentile margins may be familial. It is often helpful to obtain head circumference measures on the parents.

In most nutritional conditions and chronic diseases, head circumference is not severely affected. Brain growth is generally separate from somatic growth. Thus, head circumference cannot be used to assess presence or progression of chronic kidney disease. When occipitofrontal circumference is altered in the context of kidney disease, this generally suggests that there is a systemic process that has affected the brain as well as the kidneys.

In 1968, Nelhaus reported head circumference means and standard deviations for age and gender in children from birth through 18 years, calculated from published reports in international literature over the preceding 20 years (18). These normative values are still used today and are reflective of a multi-racial and multi-ethnic population of healthy children. No significant racial, ethnic or geographical differences were found in head circumferences and thus the norms have widespread applicability (*Figs. 22-10* and *22-11*).

Body Mass Index

The updated 2000 CDC growth charts include body mass index charts to assess weight correlated with stature (1). Standards are detailed in *Figs. 22-12* and *22-13*. Body mass index is calculated as weight in kilograms divided by height in meters squared. Body mass index provides a better assessment of body mass than absolute weight. According to the body mass index growth charts, overweight is defined as body mass index greater than or equal to the 95th percentile for age and gender. Underweight is defined as body mass index below the fifth percentile. Both too little and too much body mass pose health risks. In prevalent pediatric ESRD patients, an association has been shown between both extremely low and high body mass index measures and increased risk for death (5).

There is increasing prevalence of overweight status in children and adolescents (19). There are significant differences in obesity prevalence by race and ethnicity, with the greatest prevalence being Mexican Americans and non-Hispanic blacks (20, 21). Increases in overweight are notable as young as 2–4 years of age. In a Canadian cohort of over 6,000 children aged 0–19 years who were referred to a tertiary pediatric nephrology center, an increase in body mass index coincided with a significant increase in chronic kidney disease (22).

Body mass index is a practical method of body mass assessment, however, it is not a particularly good measure of overall body composition. To better understand body composition, it is necessary to differentiate between muscle mass and fat mass. There are several other methods for assessing body composition that may be more accurate. Waist to hip ratio has recently been shown to be reliable for assessing cardiovascular and metabolic risk in adults (23). In overweight children, a waist circumference of >90% or a waist to height ratio greater than 0.5 has been associated with increased metabolic and cardiovascular risk (24). Skinfold thickness is also often purported to be a useful anthropometric measure for fat mass, however recent pediatric studies have suggested skinfold thickness to be less informative than body mass index for fat assessment in children (25, 26). Lean body mass may also be assessed using dual-energy X-ray absorptiometry (DEXA) scans. DEXA scans can detect subtle changes in bone mass over time. They also provide data on total fat mass. Use of DEXA scans in children for assessment of body composition may show significant variability across different body sizes and health states and can be particularly problematic in children with chronic kidney disease in whom lean body mass assessment can be confounded by fluid overload (27–29). Bioelectrical impedance measures the conductive resistance of a biological tissue exposed to an electrical current. This method can be used to detect total body water and fat-free mass. Bioelectrical impedance use has been validated in children, including children on dialysis and with kidney transplants (30). Bioelectrical impedance may have utility in assessing dry weight of dialysis patients. It is important to use prediction equations that have been validated in children as the validity of adult commercial software for bioelectrical impedance in children is quite poor (30).

Bone Age

Skeletal development is primarily assessed by radiography. Commonly, left hand radiographs are compared with images of standards in the Greulich and Pyle skeletal age atlas (31). The bone age is reported as the standard that looks most similar to the images in the atlas. There is thus frequent interobserver variability. There are also gaps of an entire year between standards so it is difficult to assess subtle changes in bone maturation. Additionally, the atlas does not account for different bones growing at different rates. There is often a discrepancy between the maturity of bones in the hand versus wrist. Moreover, the Greulich and Pyle atlas was derived from bone standards of white children of upper socioeconomic status living in the United States in the 1930s. Although, the Greulich and

Figure 22-10

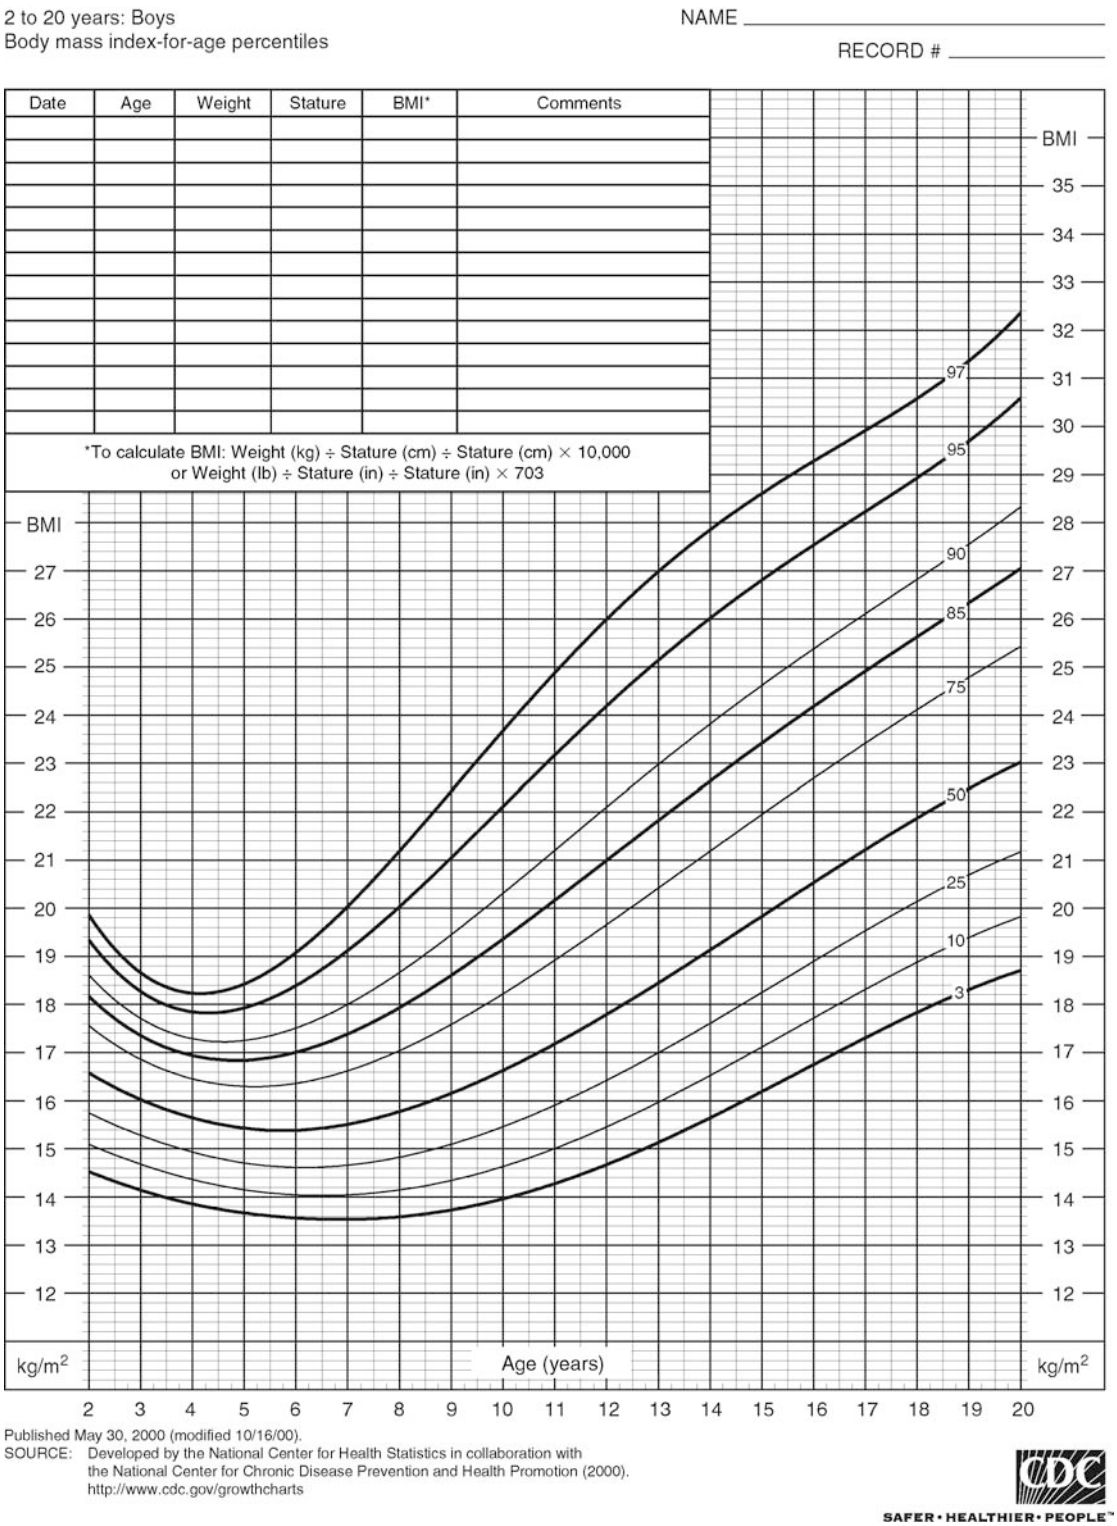

Figure 22-13

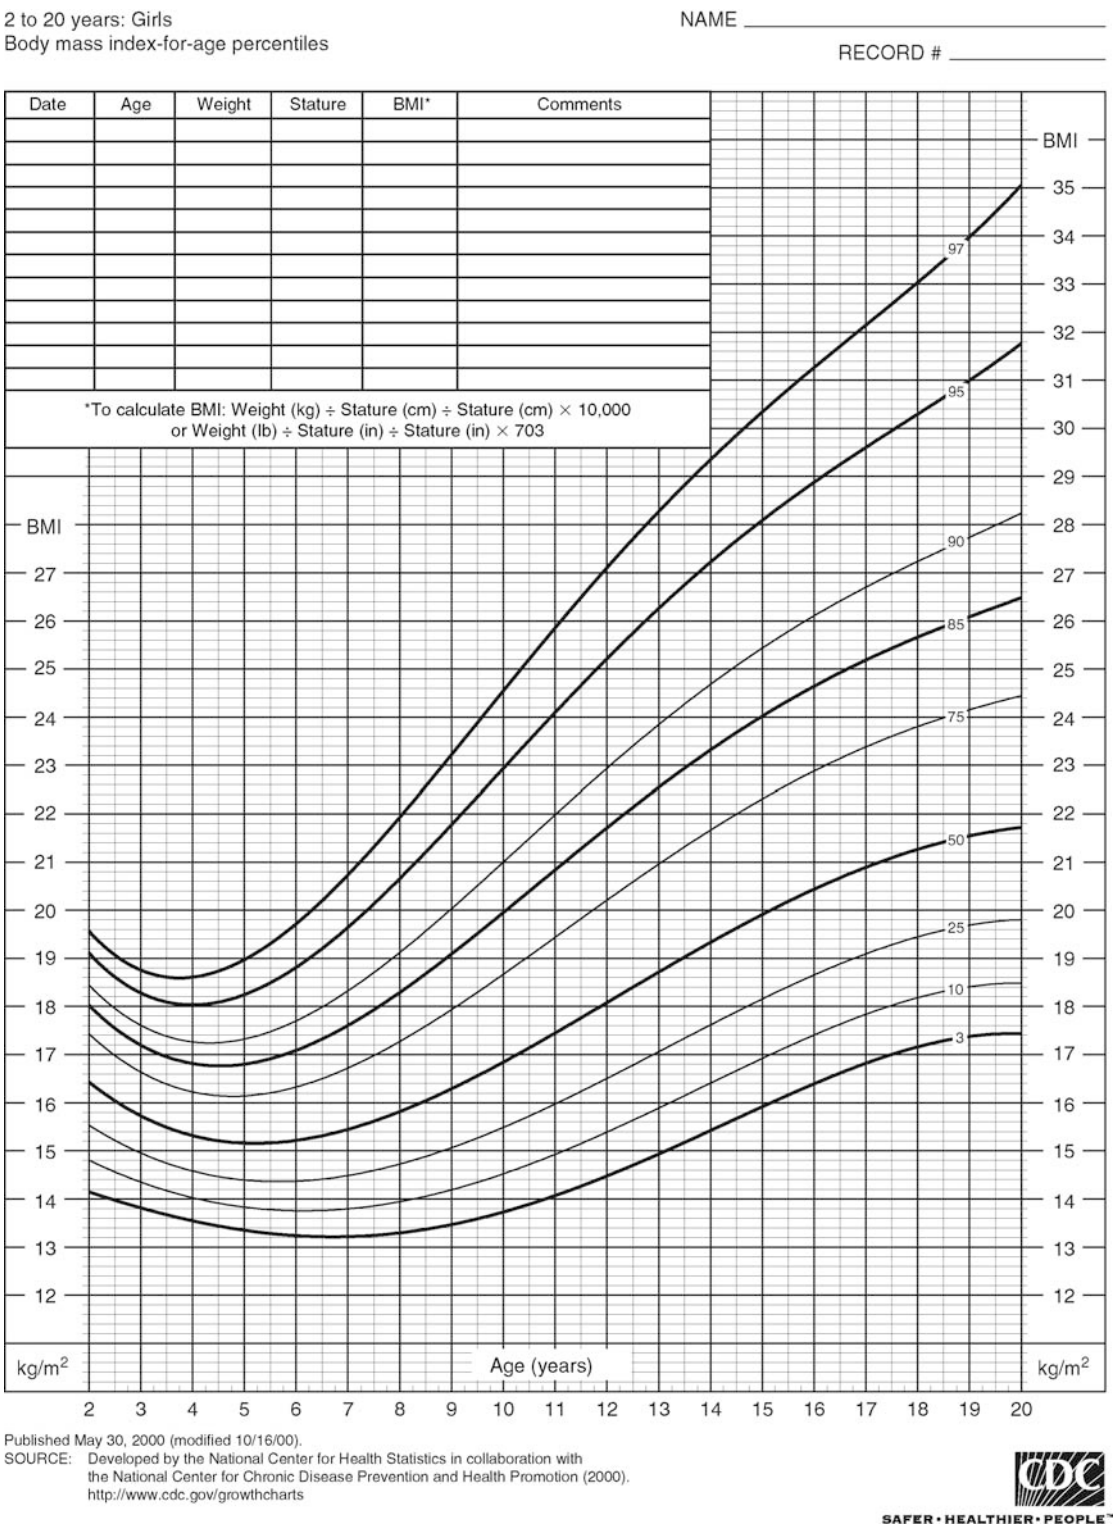
Body mass index (BMI) percentiles for girls 2–20 years of age.



Pyle atlas is a fairly quick and simple assessment, there is debate regarding current applicability of the atlas for diverse pediatric populations. Several studies of children of European and African descent have demonstrated ethnic differences in bone age and variability depending on pubertal status (32–34).

Little is known about the applicability of the Greulich and Pyle atlas for children with chronic kidney disease. One study of 40 children with chronic kidney disease and ESRD in the United Kingdom compared bone age using the Greulich and Pyle atlas with the Tanner and Whitehouse method (35). The Tanner and Whitehouse method showed better repeatability than the Greulich and Pyle atlas. The Tanner and Whitehouse method uses a more detailed examination of each individual bone in the hand (36). In this method, 20 bones of the hand are scored into one of eight categories. The numerical score is translated into a bone age. The advantage of this method is that it accounts for differential maturity of different bones. It also enables assessment of bone age at 0.1 year increments, thus it is more sensitive for detecting less dramatic changes in bone maturation. In most populations, the Greulich and Pyle atlas and the Tanner and Whitehouse method yield comparable results. Thus, since the Tanner and Whitehouse method is significantly more time-consuming, it is much less readily performed by radiologists.

Some newer methods for bone age assessment that involve decreased radiation risk are currently being explored. MRI of the wrist has been proposed as a method of skeletal maturity assessment (37). In MRI, skeletal age interpretation is based on fusion of the left distal radial physis. Studies are also being conducted in ultrasonography of the hand and wrist for children (38, 39). Ultrasonography evaluates the relationship between the velocity of sound passing through the distal radial and ulnar epiphysis and growth, using gender and ethnicity based algorithms. None of these methods is yet validated in a large pediatric population and should be used with caution.

Since bone age has been shown to have significant variability depending on pubertal stage and ethnicity, interpretation of bone age is not completely straightforward. A patient's bone age should not be interpreted dichotomously, as normal or abnormal. Rather bone age should be interpreted within the context of the physical maturity and overall health status of the patient.

Pubertal Stages

Since patterns of height and growth velocity vary widely with stages of pubertal maturity, it is important to accurately assess pubertal stages. Monitoring of pubertal development also provides information regarding general health and potential growth impact of kidney disease. *Figure 22-14* describes the Tanner pubertal staging method which is the universal standard for assessment of pubertal development (39a). For females, there are separate stages for breast development and pubic hair development. These stages may be discordant. For males, there are five stages of genital development. Assessment of male genital development includes accurate assessment of testicular size and penile length in addition to pubic hair development. Testicular size, or volume, should be compared to a standard Prader orchidometer with a gradation of size from 1 to 25 mL. A testicular volume of greater than or equal to 4 mL generally indicates onset of puberty. Both testicles should be measured for accurate assessment (40).

Onset of puberty varies significantly not only between genders but also among individuals of the same gender. There are ethnic differences in pubertal onset as well, with black females experiencing earlier pubertal development than whites. Additionally, both genetic and environmental factors may impact pubertal development. A family history regarding timing of pubertal onset in parents should be obtained if there is any concern of delayed sexual development.

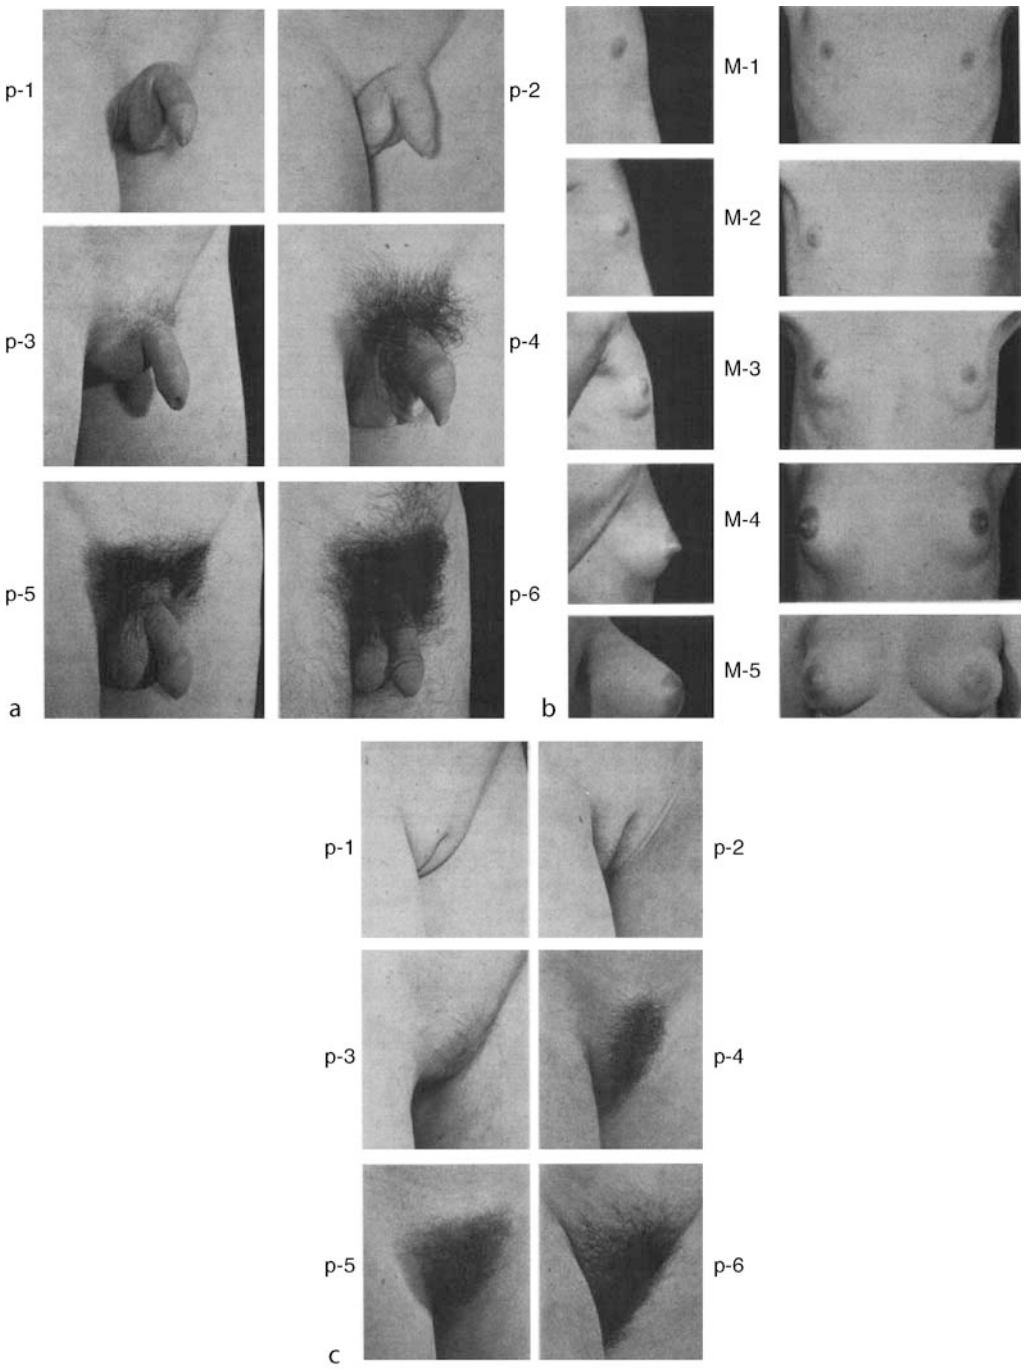
Any child with delayed sexual development should be evaluated by an endocrinologist. For girls, delayed sexual development is diagnosed when there is lack of any breast development by 14 years of age or when there is more than a 5 year delay between breast development and menarche. Girls who fail to reach menarche by 16 years of age should also be evaluated. For boys, delayed sexual development is defined as no testicular enlargement by age 14 or greater than 5 years between the initial and complete maturation of the genitalia (41).

In pediatric patients with kidney disease, accurate assessment of puberty is particularly important. The clinical history, physical exam and growth chart in conjunction with bone age studies can help identify abnormal growth patterns and potential for intervention.

Normal Growth-Phases and Drivers of Growth

There are several phases of growth from infancy through adulthood. The first phase of growth begins in utero. Although chromosomal and genetic abnormalities play a role in intrauterine growth, the primary contributor to adequate fetal growth is appropriate nutrition. Adequate nutrition for the fetus is dependent on both adequate

Figure 22-14 (Continued)



maternal nutrition and adequate delivery of nutrition via a viable placenta. If either of these conditions is not met, intrauterine growth restriction (IUGR) occurs. IUGR has been associated with increased cardiovascular disease, learning difficulties, and insulin resistance in adulthood (42, 43). Approximately 10% of children born with intrauterine growth restriction do not experience catch-up growth (44). It is postulated that there is intrauterine growth programming that occurs in which the in utero environment is permanently altered as an adaptive response. Arterial endothelial dysfunction and arterial stiffness have been demonstrated in term infants, children and young adults born with IUGR (45, 46). The mechanisms for these adaptive changes are poorly understood, however, insulin-like growth factor signaling is believed to play an important role (47, 48).

The second phase of growth occurs post-natally over the first 2 years of life. During this period, there is rapid growth, although the growth velocity gradually declines over time. A newborn generally gains 2 pounds per month in the first 3 months of life. By 1 year of age, this slows to an 8 ounce monthly weight gain. During infancy, there is a shift in growth toward genetic potential and many children will cross percentiles on their growth chart. Mechanisms for infantile growth are not well understood, however, it is evident that nutrition plays a primary role. In a study of interventions for child undernutrition and survival, improved nutrition reduced growth stunting by 36% and mortality by 25% at 36 months of life (49). Nutrition drives insulin and insulin-like growth factors, the primary regulators of growth during this phase of life.

After the second year of life, somatic and brain growth slows, commensurate with declines in appetite and nutritional needs. At this stage, growth is more dependent on growth hormone and is less influenced by nutrition. Between the ages of 2 and 5 years, the average child gains approximately 2 pounds in weight and 7 cm in height annually. Growth velocity essentially stabilizes until the onset of puberty. Growth velocity for any given child may be inconsistent, thus repeated measures during this time period can be invaluable in the assessment of growth disorders.

The last phase of growth constitutes pubertal maturation, driven by sex hormones and increased growth hormone production. Pubertal growth patterns vary by gender. In girls, the growth spurt is greatest in the first 2 years of pubertal onset, followed by an additional 2–3 years of slower growth. For boys, pubertal growth begins slowly. Growth is not spurred immediately by rising levels of testosterone and some boys may experience a decline in growth velocity for 12–18 months before a pubertal growth spurt is noted. As levels of testosterone gradually increase, boys will experience increased growth velocity at mid-puberty. Similarly to females, this increased velocity

Figure 22-14

Stages of pubertal development for boys and girls (a–c). Stages of genital development for boys (a): (1) Preadolescent – testes, scrotum, and penis are of about the same size and proportions as in early childhood. (2) Enlargement of scrotum and of testes – the skin of the scrotum reddens and changes in texture; little or no enlargement of penis at this stage. (3) Enlargement of penis, which occurs at first mainly in length – further growth of testes and scrotum. Increased size of penis with growth in breadth and development of glans; further enlargement of testes and scrotum; increasing darkening of scrotal skin. Stages of breast development for girls (b): (1) Preadolescent – elevation of papilla only. (2) Breast bud stage – elevation of papilla as a small mound; enlargement of areolar diameter. (3) Further enlargement and elevation of breast and areola, with no separation of their contours. (4) Projection of areola and papilla to form a secondary mound; the development of the areolar mound does not occur in all girls. (5) Mature stage – projection of papilla only, caused by recession of the areola to the general contour of the breast. Stages of pubic hair development for boys and girls (a–c): (1) Preadolescent – the vellus over the pubes in not developed further than over the abdominal wall. (2) Sparse growth of long, slightly pigmented downy hair, or only slightly curled, appearing chiefly at the penis or along the labia. (3) Considerably darker, coarser, and more curled; the hair spreads sparsely over the junction of the pubes. (4) Hair now resembles adult in type but the area covered is still considerably smaller than in the adult; no spread to the medial surface of the thighs. (5) Adult in quantity and type with distribution of the horizontal (classically feminine) pattern; spread to the medial surface of thighs but not up linea alba or elsewhere above the base of the inverse triangle. (From (39a) Tanner J. Growth at adolescence. Oxford: Blackwell, 1962, with permission).

lasts about 2 years and is followed by 2–3 additional years of gradual growth. Pubertal development ceases with closure of the epiphyses of the long bones. Epiphyseal fusion is driven by estrogen in both males and females.

Because rates of growth velocity change dramatically from the pre-pubertal stage through puberty, it is vital to assess pubertal development when assessing normalcy of growth. Pubertal parameters tend to correlate better with bone age than chronologic age. Thus, if there is concern of growth delay, bone age is often quite helpful. When an individual shows delayed bone age, this suggests potential for growth. Individuals with constitutional growth delay will generally achieve their genetic potential albeit later than expected. In patients with chronic illness, however, full growth potential may not be achieved, even with therapy.

Determination of Genetic Target Range and Correction of Growth Expectations for Parental Heights

Ultimate, or final, adult height is significantly impacted by genetic potential. Any assessment of absolute height, therefore, must consider the target height range, which is best estimated statistically by parental heights. A height prediction based on the sex-adjusted midparental height can be determined using calculators that are readily available on the internet. For girls, 13 cm is subtracted from the father's height and averaged with the mother's height. For boys, 13 cm is added to the mother's height and averaged with the father's height. For both boys and girls, 8.5 cm on either side of the calculated target height represents the 3rd to 97th percentiles for anticipated adult height (50).

Regulation of the Growth Hormone Axis

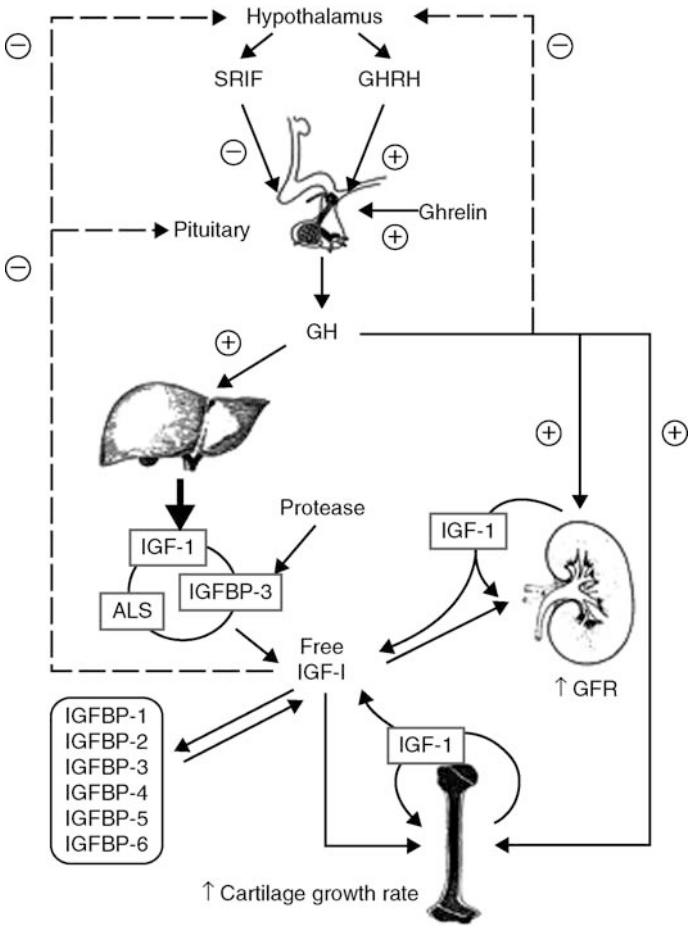
As mentioned above, growth hormone (GH) is the key endocrine influence for postnatal growth. Although a complete discussion of the regulation of the GH/insulin-like growth factor (IGF) axis, shown in *Fig. 22-15*, is beyond the scope of this text, chronic kidney disease is associated with significant alterations in this axis and, therefore, a basic understanding of the regulation of the GH/IGF axis is important when evaluating growth in children with chronic kidney disease (51). Growth hormone is released by the anterior pituitary in a pulsatile fashion under the influence of growth-hormone releasing hormone (GHRH) from the hypothalamus, which stimulates secretion, and somatostatin, which inhibits secretion. GH release is also stimulated by ghrelin, a peptide produced primarily in the stomach whose secretion is dependent on both acute and chronic changes in nutritional status (52, 53). Once released into the blood stream, GH binds to GH receptors to stimulate the production of IGF-I, formerly known as somatomedin C (51). Although GH receptors are located in many organs, the liver produces 75% of IGF-I circulating in plasma (54). Both GH and IGF-I serve in a negative feedback loop to inhibit further GH release (*Fig. 22-15*) (51, 55). The majority of IGF-I in the circulation is bound to IGF binding-protein-3 (IGFBP3) in a complex with an acid-labile subunit, while a smaller fraction is bound to 5 other IGFBP's (IGFBP1, 2, 4, 5, 6) (51). Free IGF-I in the circulation mediates most of the biologic effects of GH, by binding to the IGF-I receptor in many tissues and organs. Binding of IGF-I to IGFPB limits its bioactivity and usually less than 1% of IGF-I in blood remains in the bioactive-free form (51). Serum levels of IGF-1 vary with age, with low levels at birth and peak levels during puberty. Levels of IGF-1 decline with increasing age and may also be low in states of malnutrition, catabolism and chronic disease (56).

Growth Failure and Its Impact in Chronic Kidney Disease

Growth failure has long been recognized as a ramification of CKD (57). The typical growth pattern in a child with congenital kidney failure is shown in *Fig. 22-16*, and demonstrates that while growth during the growth-hormone-dependent growth phase in mid childhood parallels the normal curve, significant loss in terms of linear growth is seen in infancy, the nutrient-dependent growth period, and during the sex-hormone dependent pubertal growth spurt (58, 59). Reports from the North American Pediatric Renal Trials and Cooperative Study (NAPRTCS, previously known as the North American Pediatric Renal Transplant Cooperative Study) reveal that among children with CKD in the registry, 37% of all patients and nearly half of patients under the age of 5 years were less than the third percentile for height at registry enrollment (60, 61). Once end-stage is reached, growth deficits worsen and data from North America, the Netherlands and Australia consistently demonstrate that height standard deviation scores fall further from the mean over time among children who remain on dialysis (62–65). Although the restoration of kidney function with transplantation improves linear growth, data from NAPRTCS

Figure 22-15

The growth hormone (GH) and insulin-like growth factor-I (IGF-I) axis. Pituitary release of GH is controlled by GH-releasing hormone (GHRH) and somatostatin (SRIF), which in turn are regulated by feedback (dashed lines) from circulating GH and IGF-I. Ghrelin, which is produced in the stomach, also stimulates GH release. GH stimulates IGF-I production from the liver and other organs. Most of the IGF-I in the circulation is bound to IGF-binding protein-3 (IGFBP-3) in a complex with acid-labile subunit (ALS); a smaller fraction is bound to the five other IGFBP. Less than 1% of the total IGF-I in blood is in a bioactive-free fraction. Reproduced with permission from (51).

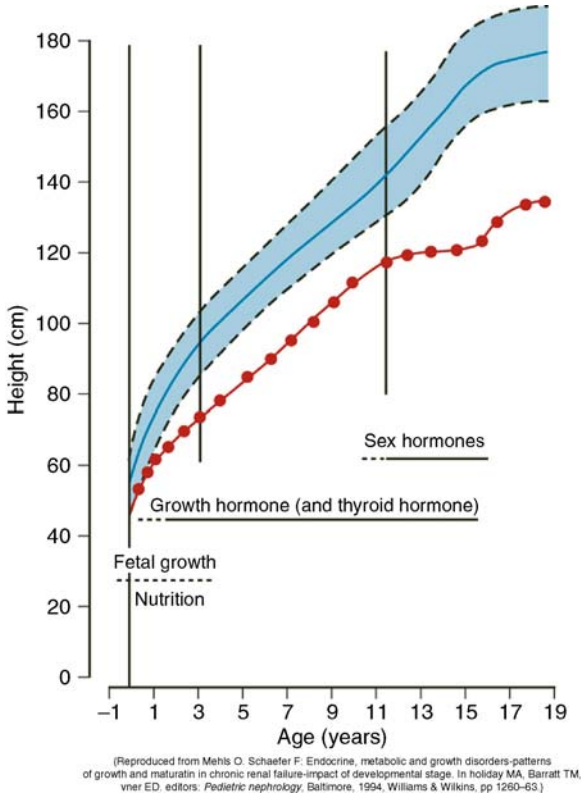


suggest that "catch up" growth is seen only in patients younger than age 6 years, thus transplantation alone does not adequately address growth impairment in children with CKD (66).

The growth failure seen in children with CKD often results in short stature in adulthood. Early data from the NAPRTCS registry revealed that among patients with CKD who were 18–20 years of age, 18.6% were less than the third percentile for height, suggesting that many patients had significant short stature as they approached their final adult height (60). International data have supported this earlier finding, with reduced adult height in 30–50% of patients with childhood CKD (67–71). Recent data, however, suggest that there may be a trend for improvement in the last decade (72, 73). In the NAPRTCS 2007 annual report, transplanted pediatric patients in the 2000–2006 cohort had an average terminal height of −0.98 z-score versus −1.97 in the 1987–1990 cohort. Studies of short stature in adulthood have demonstrated significant negative impact on quality of life (74–76). Broyer and colleagues evaluated long-term social outcomes in 244 adults who had received a kidney transplant in childhood and demonstrated that each 1 cm increase in final adult height was associated with a significantly increased likelihood of being married or living outside of the parent's home (74). In addition, patients in this

Figure 22-16

Typical growth pattern in patients with congenital chronic kidney failure is shown in red. Loss of statural height predominates in infancy and adolescence, with growth parallel to the normal curves in mid-childhood. The shaded area represents the normal range (3–97%). Reproduced with permission from (58).



cohort whose final adult height was more than 2.5 standard deviations below the mean were much less likely to be employed full time (74). Rosenkranz et al. surveyed 39 adult patients with early onset of ESRD regarding perceived quality of life (76). Thirty-six percent of patients reported dissatisfaction with their height compared to 4% of healthy age-matched controls. Positive perception of quality of life was significantly correlated with satisfaction with adult height (76).

The importance of identification and treatment of growth retardation in pediatric patients with CKD goes beyond the need to maximize final adult height, however. In fact, two retrospective cohort studies using large pediatric ESRD registries have demonstrated an association between short stature and increased risk for morbidity and mortality (77, 78). Using data from the Pediatric Growth and Development Study of the United States Renal Data Systems (USRDS), Furth and colleagues categorized pediatric dialysis and transplant patients according to growth velocity over a 1 year period; a height velocity SDS of less than -3 denoted severe growth failure, a height velocity SDS between -3 and -2 was moderate growth failure and height velocity SDS greater than -2 was normal growth (77). Over the 5 year follow up period, after adjusting for age, gender, race, cause and duration of ESRD, and treatment modality (dialysis or transplant), patients with moderate and severe growth failure had higher hospitalization rates than patients with normal growth velocity [relative risk (RR)1.24 (95% Confidence interval (CI) 1.2, 1.3); and RR 1.14 (95% CI 1.1, 1.2), respectively]. In addition, after adjustment, moderate and severe growth failure was associated with a higher risk for death (RR 2.01 (95% CI 1.1, 3.6); RR 2.9 95% (CI 1.6, 5.3), respectively) (77). Similarly, a study of 2,306 pediatric dialysis patients in the NAPRTCS registry demonstrated that short stature patients, defined as patients who were more than 2.5 standard deviations below age and gender norms for height (less than 1%) at the time of dialysis initiation, had significantly more hospital days per month of dialysis follow-up than patients with heights closer to the normal range (78). Height less than 1% was also associated with a twofold higher risk of death, even after controlling for patient age, race, gender, cause of ESRD, whether or not the patient was listed for a kidney transplant, and dialysis modality 78. Although these studies can not prove causality, they both suggest that short stature may be a marker for patients who are at increased risk for morbidity and mortality.

Etiology of Growth Impairment in Chronic Kidney Disease

Although multiple conditions are associated with poor growth in children with CKD, the mechanisms responsible for the influence of many of these factors on growth and whether there is true causality for some factors remains unclear (79–81). CKD can result in impairment in each phase of growth, from in utero to adolescence, and studies suggest that age of onset and duration of CKD are two of the most important predictors of growth failure (82–85). Not surprisingly, congenital/urologic diseases are also a leading predictor of poor growth (83). Among the other chronic kidney conditions, cystinosis and primary hyperoxaluria are associated with the most significant impairment in growth (86, 87). Multiple other factors that have been associated with poor growth in CKD are listed in *Table 22-1* (79–81, 83). A correlation between

degree of renal impairment in terms of glomerular filtration rate (GFR) and short stature has been demonstrated in some studies, but is not a consistent finding (61, 80, 81, 88, 89). This may reflect the inaccuracy of the methods used to measure GFR and/or the fact that other measures of kidney function that might affect growth, including tubular function, are not typically taken into account in these studies. Correction of acidosis and replacement of salt and fluid losses in children with tubular dysfunction has been shown to improve linear growth (90). Protein and calorie malnutrition are commonly seen in children with CKD. The impact of malnutrition on growth is particularly important in infancy, at which time growth is primarily nutrition dependent. Not only can malnutrition contribute to poor growth and development, but it may be associated with increased mortality in children with CKD. Studies using data from USRDS and the Center for Medicare & Medicaid Services' (CMS) Clinical Performance Measures Project have demonstrated an association with low serum albumin and increased risk for hospitalization and death in pediatric dialysis patients (91, 92). It should be recognized, however, that albumin is a relatively poor nutritional indicator, and the low albumin seen in children and adults with ESRD may be related to chronic inflammation, the so-called malnutrition-inflammation complex syndrome (93).

Abnormalities in bone and mineral metabolism can also result in growth impairment. While treatment of hyperparathyroidism with 1,25 dihydroxyvitamin D has been shown to improve growth, some studies suggest that normalizing intact parathyroid hormone levels may result in low bone turnover (i.e., adynamic bone disease) which, in turn, may diminish linear growth (94–96). Finally, although chronic anemia has long been recognized as a contributor to poor growth, many studies of erythropoietin treatment in children with CKD have been unable to demonstrate persistent catch-up growth (97–99). One retrospective cohort study of 47 children who initiated chronic dialysis between 1994 and 2004 demonstrated catch-up growth during predialysis care in 40% of children (100). Catch-up growth was independently associated with both hemoglobin and erythropoietin therapy at first referral. The relationship between anemia and growth requires further exploration in multi-center large studies.

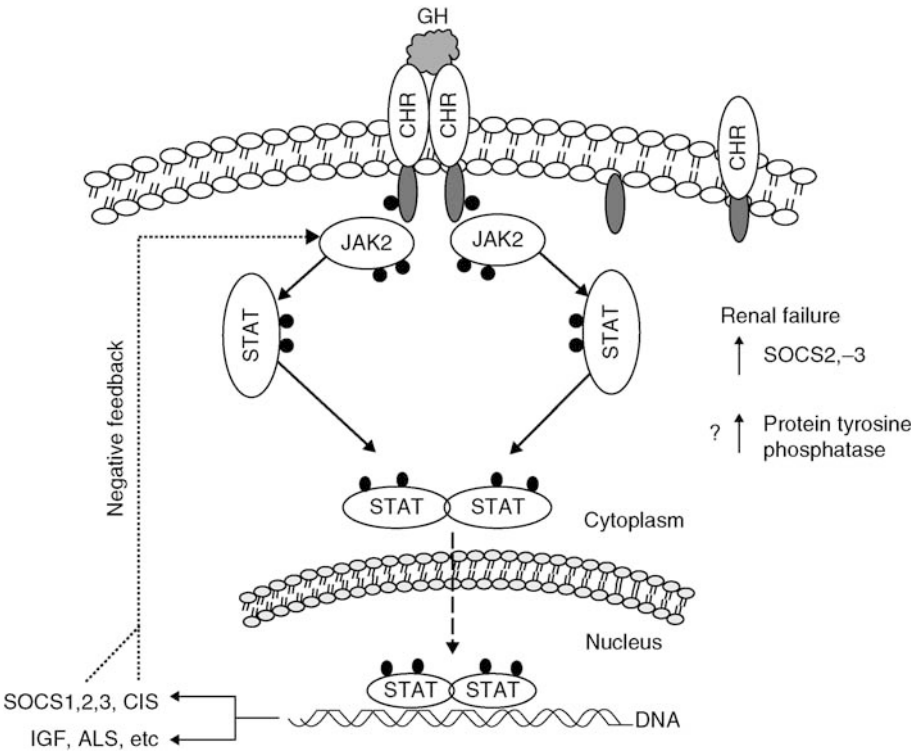
Pertubations of Growth Hormone/ Insulin-Like Growth Factor Axis in Chronic Kidney Disease

Abnormalities of the GH and IGF axis play a major role in growth impairment in CKD (51, 83, 101, 102). Circulating levels of GH are normal or even increased in children with CKD, depending on the degree of renal impairment (103). GH is primarily cleared from the circulation via the liver, reticuloendothelial system and the kidney and the metabolic clearance rate of GH correlates linearly with GFR (104, 105). GH release in children with CKD is variable, with normal or increased release documented in pre-pubertal children, but release is reduced in pubertal children possibly related to decreased stimulation of GH by gonadal hormones (104–107).

The normal to high levels of GH in CKD suggest a state of relative resistance to GH. GH resistance can be due to either reduced density of GH receptors in organs or a postreceptor signaling defect resulting in decreased IGF-I production in response to GH binding. GH receptor binding protein (GHBP) is a product of the proteolytic cleavage of the extracellular domain of the GH receptor. Circulating GHBP levels are reduced in children and adult CKD patients, and GHBP levels correlate with spontaneous growth rate and response to recombinant human growth hormone therapy in children with CKD (108, 109). However, whether GHBP levels are a reliable marker of GH receptor expression is controversial (110). Binding of GH to the GH receptor leads to activation of Janus kinase 2 (JAK2), a receptor-associated tyrosine kinase (*Fig. 22-17*, 111). JAK2, in turn, self-phosphorylates and phosphorylates signaling (signal transducer and activator of transcription or STAT) proteins. Once activated, the STAT proteins move to the nucleus and activate GH-regulated genes. The GH-induced activation of JAK2 and

Figure 22-17

Growth hormone (*GH*)-mediated JAK2/STAT signal transduction. Binding of GH to its receptor (*GHR*) activates Janus kinase2 (*JAK2*), which then self-phosphorylates followed by phosphorylation of the GHR and subsequently STAT 1a, 3, 5a, and 5b. These phosphorylated STATs form dimers that enter the nucleus where they activate target genes including insulin-like growth factor-1 (*IGF-1*) and some suppressors of cytokine signaling (*SOCS*). Phosphorylation of JAK2 and the downstream signaling molecules STAT5, STAT3, and STAT1 and the nuclear levels of phosphorylated STAT proteins are impaired in uremia. Uremia is also associated with upregulation of SOCS. Reproduced with permission from (111).



several of the downstream STAT proteins are reduced in chronically uremic rats (111). In addition, the JAK2/STAT pathway is in part regulated by suppressor of cytokine signaling (SOCS). The term SOCS refers to proteins that are induced by GH and serve as negative feedback by binding to JAK2 and inhibiting STAT phosphorylation (111, 112). SOCS are up regulated in inflammatory states, and it has been suggested that this may be one of the mechanisms involved in the malnutrition-inflammation complex syndrome observed in patients with CKD (113).

In addition to GH resistance, there is evidence that resistance to IGF-I plays an important role in the growth retardation seen in CKD (83, 101). Circulating levels of IGF-I are normal in children with CKD and only mildly decreased in children with ESRD (109). However, IGFBP levels are increased, thereby reducing the amount of bioactive-free IGF-I available (109, 114, 115). The increase in the levels of the IGFBPs is inversely correlated with level of kidney dysfunction, and the molar excess of IGFBPs as compared with IGFs is 200% in children with ESRD and 150% in children with CKD, compared to 25% in healthy children (116). Not only is the level of bioactive-free IGF-I reduced, but there is also evidence that there may be a post-receptor defect of IGF-I signaling which could contribute to the state of IGF-I resistance (83, 117).

Lastly, growth and pubertal development in kidney disease are also impacted by abnormalities in gonadotropin hormones. Normally, leutinizing hormone (LH) is released from the pituitary gland in pulsatile bursts in response to hypothalamic GnRH secretion. Like GH, LH is metabolized by the liver, macrophages and kidney (105). Consequently, in CKD and ESRD, renal clearance of LH is reduced and LH levels may be elevated (118). However, pituitary LH secretion is also altered in kidney disease such that pubertal patients on dialysis produce 70% less immunoreactive LH and 60% less bio-active

LH overnight than their healthy peers (105, 118). The ratio of bioactive LH to immunoreactive LH is also decreased in uremic children (118). Additionally, it has been shown that patients with kidney disease have decreased frequency of plasma LH pulses. This is believed to be secondary to blunted GnRH secretion from the hypothalamus (119). In rat models, uremic serum has been shown to selectively inhibit the hypothalamic GnRH pulse generator (119).

Treatment of Impaired Growth in Chronic Kidney Disease

Although abnormalities of the GH/IGF-I axis are significant contributors to growth retardation in chronic kidney disease, given the multifactorial nature of this problem, correction of any of the possible contributors to growth failure should be attempted. In fact, the National Kidney Foundation (NKF) Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend correction of any nutritional deficiencies or metabolic derangements prior to initiation of recombinant human growth hormone (120). This may include dietary supplementation, including tube feedings in those patients with insufficient intake of protein, energy or other nutrients (120). Delivery of adequate alkali therapy, salt and water to correct deficits should be provided if necessary (120, 90). Finally, abnormalities of bone and mineral metabolism should be treated, although as stated previously, the optimal level of parathyroid hormone control to promote maximum growth is unclear (94–96, 102).

Several studies have demonstrated that treatment with recombinant human growth hormone (rhGH) in children with CKD is safe and efficacious and its use is now considered standard of care (102, 121, 122). A recent Cochrane review included 15 randomized control trials of rhGH treatment in children with CKD, including those on dialysis and status post-kidney transplant, and demonstrated that rhGH treatment resulted in significant improvement in height SDS at 1 year and a significant increase in height velocity at 6 months and 1 year (123). Collectively in these studies, the frequency of reported sides effects were not different between rhGH-treated subjects and the control group (123). However, the impact of rhGH treatment on adult height in pubertal patients has not been clearly delineated, and growth response in pre-pubertal patients in multiple studies has been variable (123–127). In a recent report of the Pfizer International Growth Database (KIGS), Nissel and colleagues evaluated growth and near-final adult height in 240 children with CKD who had received rhGH for at least 1 year and who had reached near-final adult height, defined as height velocity less than 1 cm/year, advanced clinical signs of puberty in boys with an age of at least 16 years and in girls of at least age 14 years (124). The study demonstrated that 40% of patients achieved a final adult height within 2 standard deviations of the norm. Near-final height was positively associated with initial growth deficit and duration of rhGH therapy, but was negatively associated with proportion of time spent on dialysis (vs. conservative therapy or transplant), delayed puberty, female gender and age at initiation of rhGH. The authors commented that the finding that delayed puberty and dialysis therapy are associated with a clear reduction in response to rhGH should prompt care-providers to consider treatment early in the course of CKD and in early childhood. Unfortunately despite these warnings and the well-documented success of rhGH treatment in children with CKD, underutilization of this medication has been repeatedly documented (84, 128). A recent Consensus Committee statement recognized that the lack of clear guidelines for the evaluation and treatment of growth failure in children with CKD are contributing to this underutilization, and provided a proposed algorithm in an effort to address this important need (*Fig. 22-18*, 102).

Future targets for treatment of GH resistance include use of recombinant IGF-I (rhIGF-I), either alone or in combination with rhGH or recombinant IGFBP3, which might mitigate the possible suppression of endogenous GH, IGFBP3 or ALS production by rhIGF-I (101, 129–131). A final potential therapeutic agent is IGFBP3 displacers which could increase free, or bioactive IGF-I levels (132).

Conclusion

In summary, kidney disease has a significant impact on growth. Impaired growth in turn stems from many complex and interacting factors and may lead to increased morbidity and mortality. Thus, proper and frequent assessment of growth in children with kidney impairment is vital. Recognizing growth perturbation in its early stages and treating its causes can have significant influence on the long-term medical and psychosocial outcomes of children with kidney disease. Recombinant growth hormone use should be instituted when appropriate and further research should focus on other potential targets for treatment of GH resistance.

23 Diagnostic Imaging

Stephen F. Simoneaux · Larry A. Greenbaum

Diagnostic Procedures

Imaging is essential for the diagnosis and management of many disorders of the urinary tract (UT). Clinicians should be familiar with the available techniques, including their indications, limitations, and potential complications.

Ultrasound (US) is the most widely used modality because of the information provided, safety, and low cost. Intravenous pyelography (IVP) is currently seldom utilized, but voiding cystourethrography (VCUG) and nuclear medicine studies continue to have important roles. Computed tomography (CT) is readily available and can acquire images rapidly, generally obviating the need for sedation. Magnetic resonance imaging (MRI) generates anatomically precise images without radiation exposure, but at high direct financial cost, and with the need for sedation in young children. Imaging studies should be carefully selected, with consideration of diagnostic utility, cost, and potential complications such as contrast nephropathy and radiation exposure.

Ultrasound

US is the principal imaging modality for visualization of the UT. US provides a rapid assessment of kidney shape and size, and it is especially good at identifying hydronephrosis. Studies are completed without discomfort or need for sedation, and there are no known complications or side effects. In addition, US is relatively inexpensive and readily available. The skill of the examiner can significantly influence the information obtained via US. Lack of patient cooperation and large body habitus may also limit image quality.

Because of its low cost and the absence of side effects, US is the optimal modality for clinical situations requiring repeated evaluations. For example, US can assess hydronephrosis before and after an intervention such as a catheter, stent, or nephrostomy tube placement. US is also ideal as a screening examination for children who need surveillance for kidney stones or malignancy.

Technique

Images are generally obtained with the patient supine, which optimizes visualization of the upper poles, using the spleen and liver as acoustic windows. The contralateral decubitus position may permit better visualization in some patients. In certain situations, placing the patient in the prone position may allow for better visualization of the lower pole if subtle pathology is present. Ideally, the bladder should be visualized while filled with urine. A cooperative child should be asked not to void for a few hours prior to the exam. In a patient who is not toilet trained, the bladder should be visualized first to allow imaging the bladder before the patient voids.

US transducers produce sound waves of varying frequencies. High frequency sound waves do not penetrate tissue as deeply, but provide greater resolution. In most situations, the sonographer should use the highest frequency that penetrates to the desired depth. Hence, high-frequency US permits excellent resolution in infants and small children. Conversely, resolution is decreased in very large or obese individuals.

US evaluation of the UT should include measurement of renal lengths and assessment of renal shape, thickness and echogenicity of the cortex, the presence of corticomedullary differentiation, and evaluation of the renal pelves, ureters, and bladder. The ureters are not usually visible, but may be seen when dilated due to underlying pathology.

There are published standards for US determination of renal length for fetuses, preterm infants, full-term neonates, infants and older children (1–6 ❯ *Table 23-1*). Length measurements should be made with the patient supine or in the contralateral decubitus position; length may be underestimated with the patient prone (7, 8). Gestational age and birth weight correlate with kidney length in newborns (1, 4). In older children, age is a convenient parameter, but length or height is a better predictor of normal kidney length (3, 9, 10). (❯ *Fig. 23-1a* (10)) A multivariable approach allows for improved prediction equations for renal length (11), but such equations are not widely used in clinical practice.

Table 23-1
Renal length

Age	Mean length (cm)	Range (±2 SD in cm)
Term newborn	4.48	3.86–5.10
2 months	5.28	3.96–6.60
6 months	6.15	4.81–7.49
1.5 years	6.65	5.57–7.73
2.5 years	7.36	6.28–8.44
3.5 years	7.36	6.18–8.54
4.5 years	7.87	6.87–8.87
5.5 years	8.09	7.01–9.17
6.5 years	7.83	6.39–9.27
7.5 years	8.33	7.31–9.35
8.5 years	8.90	7.14–10.66
9.5 years	9.20	7.40–11.00
10.5 years	9.17	7.53–10.81
11.5 years	9.60	8.32–10.88
12.5 years	10.42	8.68–12.16
13.5 years	9.79	8.29–11.29
14.5 years	10.05	8.81–11.29
15.5 years	10.93	9.41–12.45
16.5 years	10.04	8.32–11.76
17.5 years	10.53	9.95–11.11
18.5 years	10.81	8.55–13.07

Adapted from Robenbaum et al. (6)

In adults and children, the average left kidney is slightly longer than the average right kidney (3, 4, 9), although this is only observed in slightly more than 50% of measurements of individual patients (the remainder have kidneys of equal length or a longer right kidney) (10). In infants and adults, the median left renal length is about 3 mm longer than the median right renal length (3, 12). In adults and older teenagers, males have longer kidneys, which is explained by their increased height compared to females. Black children have shorter kidneys than white children (11).

Measurement of renal length in children has a fairly high rate of intraobserver and interobserver variation (13); hence, US measurement of renal length lacks the accuracy to allow assessment of renal growth over limited time periods. Measurement of the left kidney length is less accurate, probably because the spleen provides a smaller acoustic window than the liver. Nevertheless, renal length discrepancy in children can be used to predict abnormalities on Technetium 99m-dimercaptosuccinic acid (^{99m}Tc-DMSA) renal scintigraphy (14).

The appearance of the kidneys changes with age. The relative volume of medullary tissue compared to cortical tissue is increased in neonates and infants (*Fig. 23-1b*) (15). Cortical echogenicity is increased in the term newborn kidney, with the majority having the same echogenicity as the liver or spleen (5). Renal cortical echogenicity is further increased in premature infants, with some kidneys having cortical echogenicity greater than the echogenicity of the liver or spleen (16). Cortical echogenicity decreases after birth, and only a small percentage of normal kidneys of term infants have cortical echogenicity equivalent to the liver or spleen by 6 months. Cortical echogenicity is compared to the liver or spleen, but this comparison may not be valid if there is underlying liver disease. Transient increased cortical echogenicity of the kidneys may occur in children with a variety of non-renal illnesses (17).

The kidneys of term newborns have prominent medullary pyramids that are relatively hypoechoic (15). This results in marked corticomedullary differentiation. The echogenicity of the medullary pyramids increases after birth and prominent medullary pyramids are not normally present by 1 year (*Fig. 23-2*). In contrast, the central sinus echo is minimal at birth and gradually increases during the first 10 years of childhood (5).

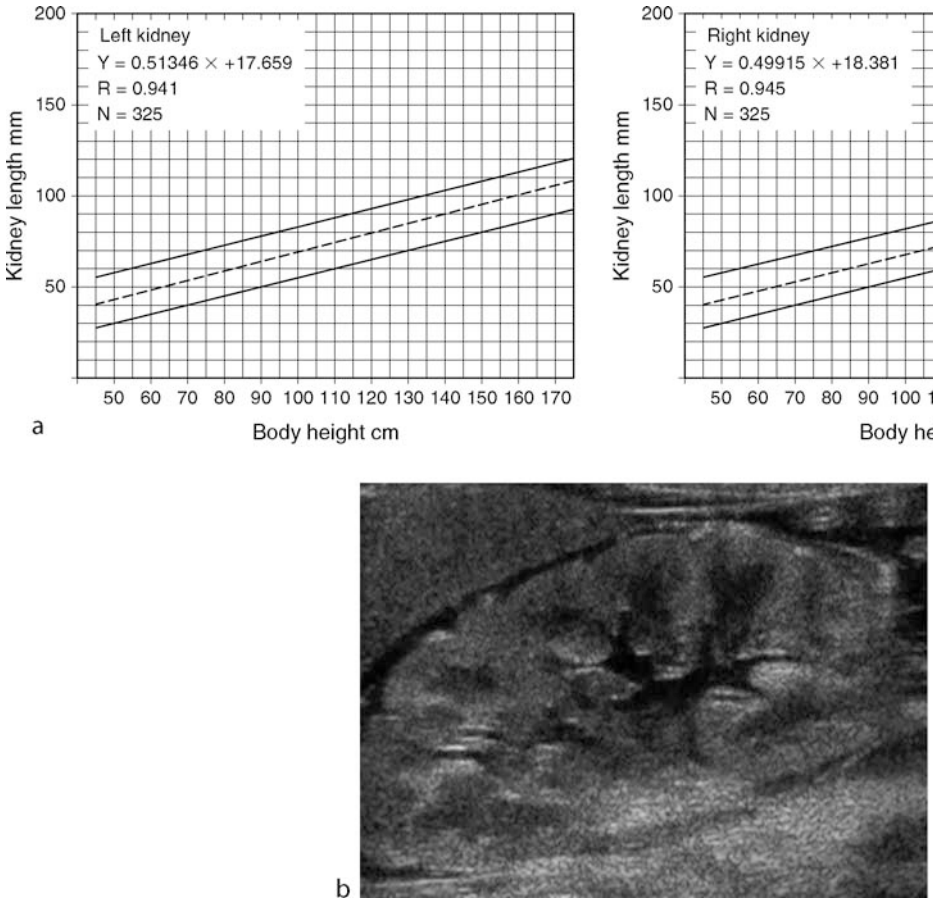
Hydronephrosis may indicate obstruction or vesicoureteral reflux (VUR), or it may be a normal variant, especially when mild. The Society for Fetal Urology developed a grading system for hydronephrosis that is predictive of the presence or absence of obstruction (*Table 23-2*) (18, 19). Mild hydronephrosis is common in newborns, and occurs in a higher percentage of males than females (20).

An increase in bladder wall thickness may be an indication of pathology, especially chronic increased bladder pressure. Measurement of bladder wall thickness is highly dependent on the degree of bladder filling, but does not appear to be dependent on patient age or gender (21), although male neonates may have slightly greater bladder wall thickness than females (20). The upper limit of normal is 5 mm for an empty bladder and 3 mm for a well distended bladder (21).US can be used to accurately estimate bladder volume (22, 23). US measurement of bladder volume after voiding is a useful parameter for assessing bladder function. US may detect ureteroceles or bladder masses.

Doppler US permits evaluation of blood flow, and has been utilized to identify renal artery disease, renal vein thrombosis, tumor thrombosis in the renal vein

Figure 23-1

(a) Length of both kidneys related to body weight. Mean values and the 95% regions of tolerance are determined by routine statistical analysis of 325 children; (b) Normal ultrasound of a neonatal kidney (prone view). Medullary pyramids are hypoechoic with a relatively thin cortex.



and inferior vena cava, and arteriovenous fistulas (24–26). Resistance to blood flow can be quantified by measuring the resistive index (RI), which is calculated from the formula: RI = (peak systolic velocity-end diastolic velocity)/peak systolic velocity. A normal RI is below 0.7 in adults and children who are 6 years of age or older, but higher values are observed in children less than 6 years (27).

Power Doppler mode allows increased sensitivity for blood flow detection, but does not provide information on flow direction or velocity. Power Doppler US is superior to color Doppler US in detecting intrarenal blood flow (28), and in identifying areas of decreased perfusion within the kidney (29). Power Doppler increases the sensitivity of US for detecting acute pyelonephritis (30). Power Doppler is very sensitive to motion artefact and hence requires a very cooperative patient, limiting its utility in young children.

Voiding urosonography (VUS) is an alternative technique for detecting VUR that uses intravesical instillation of an US contrast agent (31, 32). The principal advantage is the elimination of radiation exposure, but bladder catheterization is still necessary. VUS does not provide adequate imaging of the bladder and urethra, and thus should only be used for assessment of VUR. The results with VUS correlate well with conventional VCUG (31, 33–36). It is not yet clear if operator skill or other barriers will limit the widespread use of this technique.

Figure 23-2

Normal ultrasound of the kidney in a 17 year old child (prone view). The renal pyramids are more isoechoic to the pyramids than in a neonatal kidney (*Fig. 23-1b*).

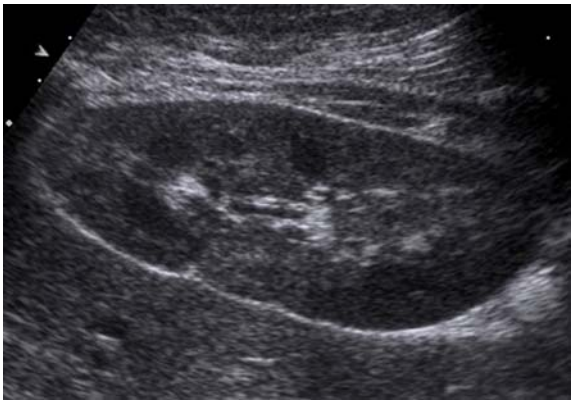


Table 23-2

Society of Fetal Urology grading system for hydronephrosis

Grade	Ultrasound
0	No hydronephrosis
1	Only renal pelvis is seen
2	Renal pelvis and a few calices are seen
3	Virtually all calices are seen
4	Similar to grade 3, but parenchymal thinning present

Application

US is the initial imaging modality in a variety of clinical situations, including evaluation of renal failure, kidney transplant dysfunction, hematuria, screening for renal malignancy, abdominal mass, and follow-up of abnormal prenatal US.

Voiding Cystourethrography

VCUG is the gold standard for the diagnosis of VUR, and most clinical studies of VUR have utilized VCUG. Moreover, VCUG is the only modality that detects VUR and provides detailed information about the bladder and urethra.

Radiation exposure is the most important side effect of VCUG. The radiation dose has been reduced through technological innovations, and a variety of additional approaches are available to further reduce radiation exposure (37, 38). A known allergy to contrast material is a contraindication to the study (39). Because of the need for catheterization, VCUG creates a small risk of iatrogenic infection and trauma to the urethra, although these risks are low (40). In addition, many children and families find catheterization frightening and emotionally traumatic. Sedation with midazolam appears safe and effective (41–43).

Technique

VCUG is done using fluoroscopy. An initial film prior to bladder catheterization detects calcifications or bony abnormalities; an abnormal bowel gas pattern may suggest a mass. The bladder is sterilely catheterized using a feeding tube (5 F in young infants; 8 F in older children) and urine can be obtained for culture. After emptying the bladder of urine, contrast material is infused to fill the bladder based on estimates of bladder capacity, but using gravity to avoid overfilling. The bladder must be filled to capacity to insure an adequate study.

An early film during filling of the bladder is useful for identifying filling defects, such as caused by a ureterocele or bladder tumor. Films are taken before and after voiding, with VUR graded based on the International Reflux Study in Children (44). In young children, who may not allow their bladder to fill to capacity, the sensitivity of VCUG for detecting VUR improves with multiple cycles of bladder filling and voiding (45, 46), but this increases the length and radiation exposure of the procedure. A film during voiding permits visualization of the urethra and is essential in male children (*Figs. 23-3* and *23-4*). At the end of voiding, a final film identifies residual urine and previously unidentified VUR.

Intravenous Pyelography

The availability of US and other imaging modalities has dramatically decreased the use of intravenous pyelography (IVP) (47). The risks of IVP include radiation and contrast exposure; intravenous access is necessary.

Technique

An initial supine film is performed prior to contrast injection. Approximately 5–7 min after contrast, a film

Figure 23-3
Voiding cystourethrogram. Frontal voiding image of normal 8 month old girl.

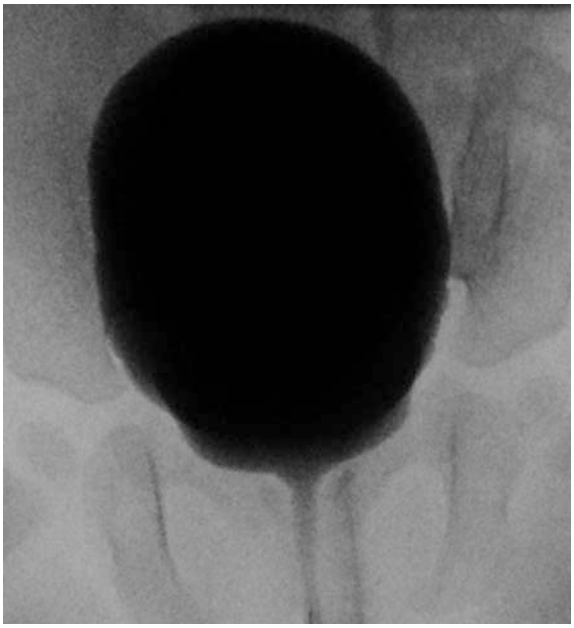

Figure 23-4
Voiding cystourethrogram. Oblique voiding image of a normal 5 month old boy.

centered on the kidneys allows visualization of the nephrogram and the calices. Subsequent films are full length and taken 15 and 30 min after injection. Delayed films are useful in cases of urinary obstruction. Bowel preparation does not improve image quality (48, 49), although a short fasting period is usually recommended. The radiation exposure of IVP can be reduced by adjusting the number of films based on the clinical question and the results of initial films. Nonionic contrast medium improves image quality and decreases the risk of contrast nephropathy.

Application

Poor renal function limits the utility of IVP due to inadequate contrast accumulation in the kidneys. Moreover, poor renal function increases the risk of contrast nephropathy. IVP is currently rarely used in the evaluation of obstructive disease; US and nuclear medicine studies are the preferred imaging modalities. ^{99m}Tc-DMSA has replaced IVP for detection of renal scarring, but IVP provides excellent detail and is certainly an acceptable substitute (50, 51). IVP is useful for evaluation of ectopic ureters, ureteroceles, and fusion anomalies, although alternative imaging (US, MRI, CT) is generally utilized when available.

Computed Tomography

CT provides excellent anatomic resolution of the UT (*Fig. 23-5*), and CT has many applications. Radiation exposure is an important risk of CT, and should limit its use to cases where the detail provided outweighs the risk of the study (52, 53). IV contrast is necessary for optimal studies in most situations. Multiple strategies and innovations have reduced the radiation dose with CT (52, 54), but it remains an important concern (55). Sedation is currently rarely necessary due to rapid image acquisition (56, 57), which also decreases motion artifact (54).

Technique

Thin-section helical imaging, now performed on all CT scanners, allows for multiplanar reformatted images to be obtained quickly and displays the kidneys, ureters, and bladder in three planes. Oral contrast, while often unnecessary for evaluation of the UT, is useful for examinations where differentiating bowel from pathology is necessary. Time constraints (acute trauma) or risk of aspiration may prevent the use of oral contrast. For younger children,

Figure 23-5

CT of a normal 11 year old boy. (a) Axial image through the midpole of both kidneys, (b) coronal image.

excessive movement can be prevented by using blankets or adhesive tape.

Intravenous contrast is usually indicated, with the notable exception of nephrolithiasis evaluation. Low osmolality nonionic contrast is preferred; contrast is dosed based on weight (54, 58). Neonates and infants require a longer delay from contrast injection to imaging.

Application

CT is the preferred modality for initial evaluation of possible symptomatic nephrolithiasis, although US is generally utilized for surveillance to minimize radiation exposure. CT is used for renal tumor staging, and is the optimal modality when trauma of the UT is suspected. CT provides excellent resolution of renal scarring, but ^{99m}Tc-DMSA is more commonly used. CT angiography is useful in assessing for renal artery stenosis (59, 60).

Nuclear Medicine

A variety of radiotracers are utilized for imaging of the UT (61, 62). The radiotracers emit photons, which are detected by a scintillation detector. Nuclear medicine imaging does not provide anatomic detail; it provides functional data that is typically utilized to answer a specific question. Nuclear medicine is often a complementary technique. While there is radiation exposure, it is less than other modalities such as VCUG, IVP, or CT.

Technique

Dynamic Renal Scintigraphy

Technetium 99m-diethylene triamine pentaacetic acid (^{99m}Tc-DTPA) and Technetium 99m-mercaptoacetyltriglycine (^{99m}Tc-MAG$_3$) are the radiotracers currently utilized for dynamic renal scintigraphy. ^{99m}Tc-DTPA is primarily excreted via glomerular filtration; it is not reabsorbed or secreted by the tubules; its clearance is slightly lower than inulin. ^{99m}Tc-MAG$_3$ is predominantly excreted via tubular secretion. For most indications, ^{99m}Tc-MAG$_3$ is superior to ^{99m}Tc-DTPA because ^{99m}Tc-MAG$_3$ is more rapidly excreted and thus provides a superior renal/background ratio.

Patients are encouraged to consume liquids immediately prior to the procedure and should ideally void before injection of isotope. The uncooperative child should be immobilized, but sedation is rarely necessary. Images are obtained with the patient supine; the scintillation detector is below the patient for native kidneys and above the patient for renal transplants. After bolus injection of radiotracer, dynamic images are recorded for 30 min. The initial images assess renal perfusion, and later images evaluate excretion. Differential renal function is calculated using the early images, typically during the second minute, prior to radiotracer appearance in the collecting system.

Diuresis scintigraphy is performed to evaluate a patient for renal obstruction (63, 64); use of a diuretic is only necessary if radiotracer does not rapidly drain from the renal pelvis during initial imaging. A dilated renal pelvis that is not obstructed may have slow drainage of radiotracer due to the increased pelvic volume. Administration

of diuretic allows differentiation of an obstructed kidney from a non-obstructed dilated renal pelvis. Furosemide is given 15–20 min after administration of radiotracer.

Following administration of diuretic, radiotracer drains rapidly from a non-obstructed renal pelvis (*Figs. 23-6* and *23-7*); there is limited washout of radiotracer if obstruction is present. A half-life of radiotracer disappearance greater than 20 min indicates obstruction (65). There is a good correlation between the test results and histological changes (66), and the test is sensitive and specific (65, 67). Diuresis scintigraphy is accurate in newborns, despite their lower glomerular filtration rate (67, 68), although follow-up imaging of normal results is necessary to ensure that obstruction does not subsequently develop (69). Potential causes of false positive results are a massively dilated renal pelvis or a kidney with very poor function (70), but technical modifications may allow for more accurate assessment of a poorly functioning kidney (71–73). False positive results can also be decreased by obtaining images after the patient voids to avoid bladder pressure effects and after placing the child in the erect position to maximize gravitational drainage (74–76).

Cortical Scintigraphy

^{99m}Tc-DMSA is the preferred radiotracer for imaging of the renal cortex (77, 78). ^{99m}Tc-DMSA is taken up by the cells of the proximal tubule, where it binds to sulfhydryl groups (*Fig. 23-8*). The accumulation of ^{99m}Tc-DMSA in the kidney is relatively slow; hence, imaging is typically performed 1.5–3 h after injection. Diagnostic accuracy may improve with an increased delay in imaging if renal function is significantly impaired. Posterior and left and right posterior oblique views should be obtained (77, 78), but there is minimal loss in diagnostic accuracy if only a posterior view is possible in a restless child (79). Anterior imaging is preferred for pelvic or horseshoe kidneys. Additional pinhole images are useful for improving resolution when imaging infants.

A variety of factors may complicate interpretation of ^{99m}Tc-DMSA imaging. Fetal lobulations may give the false impression that there are areas of decreased radiotracer uptake. The splenic impression explains flattening of the superolateral surface of the left kidney (78). The poles of normal kidneys may have relatively decreased uptake of radiotracer. Nevertheless, there is good interobserver agreement in the interpretation of ^{99m}Tc-DMSA scans for scarring and acute pyelonephritis (80, 81).

^{99m}Tc-DMSA is not specific for scars or acute pyelonephritis. Alternative explanations for defects such as cysts, hydronephrosis, infarcts, masses, or a dysplastic half of a duplex kidney can only be identified using alternative imaging strategies (e.g., US). Children with proximal tubulopathies have decreased uptake of ^{99m}Tc-DMSA and increased urinary excretion (82).

Single photon emission computed tomography (SPECT) is an alternative to planar scintigraphy. SPECT

Figure 23-6

Posterior image of a normal ^{99m}Tc-MAG$_3$ renal scan in an 8 year old with hydronephrosis by ultrasound.

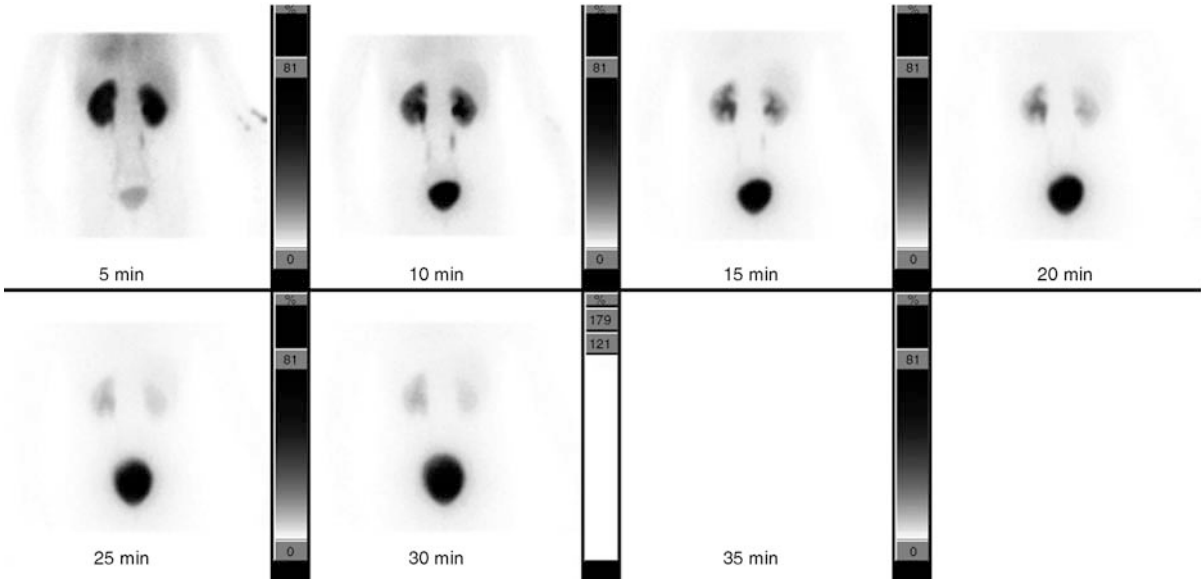

Figure 23-7

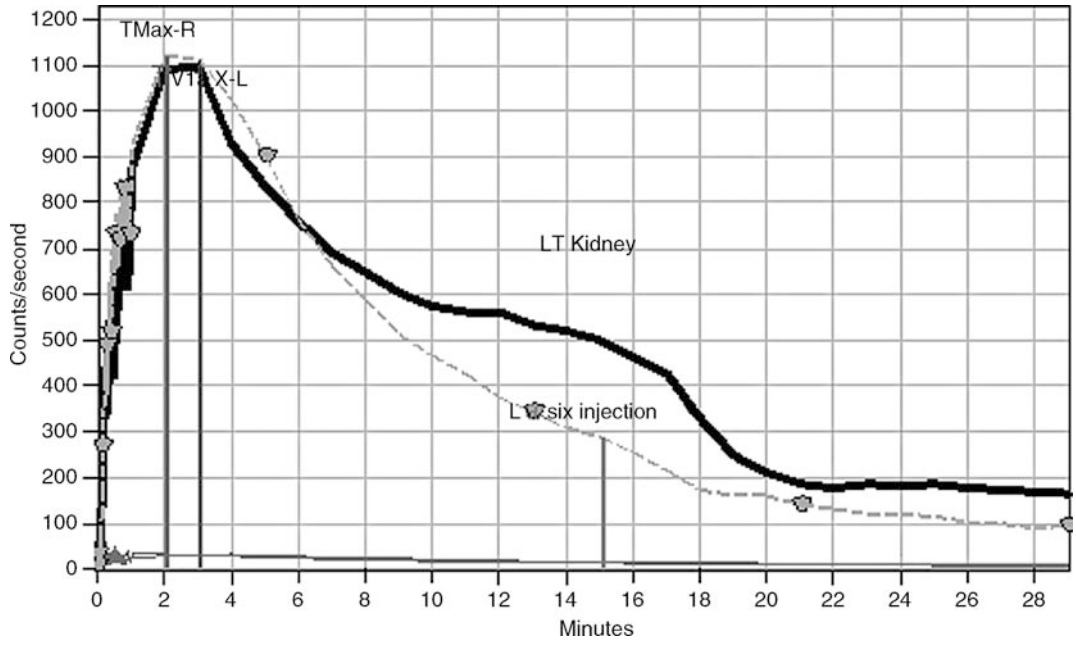
Time-activity curve from ^{99m}Tc-MAG$_3$ renal scan showing symmetric prompt excretion of radiotracer, indicating no obstruction.



appears to offer superior sensitivity for detecting renal scars (83, 84), although with a higher rate of false positive results (85, 86). The clinical relevance of the increased detection of small scars via SPECT is not clear. An intrarenicular septum, a common normal variant, may lead to a photopenic area with SPECT, but can be differentiated from a scar because of preserved cortical uptake (87). The increased imaging time required with SPECT may necessitate sedation in young children.

Split function is determined by outlining the appropriate regions of the kidneys and subtracting the activity of an appropriate background area in the posterior image. Normal split function is 50% +/−6%. Estimates of split function must be corrected for attenuation if there is an anteriorly placed ectopic kidney. Such correction is not accurate with a pelvic kidney due to the effect of the pelvic bone. Imaging may need to be delayed for up to 24 h in an obstructed kidney because isotope accumulation in the renal pelvis may cause an error in estimating split function, with an overestimation of the function of the obstructed kidney if the image is obtained prematurely. A similar approach may be necessary for a nonobstructed, severely dilated renal pelvis, although injection of furosemide, with the subsequent diuresis clearing radiotracer from the dilated pelvis, is an alternative strategy. Estimates of split function are reliable, with good interobserver agreement, except in cases where renal function is significantly impaired (88).

Adrenal Gland Scintigraphy

Meta-iodobenzylguanidine (MIBG), when labeled with either ^{131}I or ^{123}I, is used for the detection of catecholamine-secreting tumors, including pheochromocytomas and neuroblastomas (89–91). MIBG, a guanethidine analog that structurally resembles norepinephrine, is taken up by sympathetic nerve cells. The patient should receive oral nonradioactive iodine before administration of radiolabeled MIBG to compete with free radioactive iodine, minimizing radioactive exposure to the thyroid gland. A variety of medications interfere with MIBG uptake into tissue and should be discontinued prior to MIBG imaging (*Table 23-3*). MIBG radiotracer is injected, with images obtained at various times depending on the isotope. MIBG accumulates in a variety of organs, including the liver, heart and salivary glands; isotope is detected in the kidney and bladder due to renal excretion. Tumors can be identified because of the stronger radiotracer uptake, which is typically focal. ^{123}I has a much lower radiation burden than ^{131}I and results in superior images (92).

Radionuclide Cystography

Radionuclide cystography (RNC) is an alternative to VCUG for the detection of VUR (*Fig. 23-9*) (93–95). In RNC, a catheter is placed into the bladder and a solution containing a radioisotope is infused, with complete filling of the bladder. RNC, because it allows for continuous monitoring, is more sensitive at detecting VUR than VCUG, which cannot utilize continuous monitoring due to radiation concerns. Furthermore, the radiation burden is considerably less than VCUG. However, radionuclide cystography does not permit evaluation of the bladder or the urethra.

Applications

^{99m}Tc-DMSA is the gold standard for the identification of pyelonephritis and renal scars. ^{99m}Tc-DMSA can be utilized to determine split renal function and to identify and characterize renal infarcts or anatomically abnormal kidneys such as horseshoe kidneys, pelvic kidneys and crossed fused ectopia (96, 97).

Dynamic renal imaging with ^{99m}Tc-MAG or ^{99m}Tc-DTPA permits evaluation of renal blood flow, split renal function, kidney location, and urinary drainage. Dynamic renal imaging allows determination of whether hydronephrosis is secondary to renal obstruction or an alternative

etiology such as VUR, high urine flow, or relieved obstruction (98). Dynamic renal imaging can be utilized to determine split renal function and to identify renal artery stenosis when used with captopril (99).

Magnetic Resonance Imaging

MRI, with its ability to image the abdomen in multiple planes and with sequences showing different signal characteristics, provides excellent resolution of the UT without radiation exposure (*Figs. 23-10* and *23-11*) (100). Gadolinium-based contrast at standard doses is significantly less nephrotoxic than iodinated contrast (101, 102), but gadolinium-based contrast is nephrotoxic when used at radiographic doses for angiographic procedures (103–105). Gadolinium-based contrast is the dominant risk factor for the development of nephrogenic systemic fibrosis (NSF) (106), an entity that occurs almost exclusively in patients with end stage renal disease or severe renal impairment. Most cases of NSF have been associated with gadodiamide, although other gadolinium-based contrast agents may lead to NSF (107). Gadolinium-based contrast should be used cautiously in patients with moderate to severe renal impairment (108).

Sedation is typically necessary for infants and young children. MRI is an expensive imaging modality, but it may replace multiple other studies and provide superior resolution in certain clinical situations.

Technique

Magnetic resonance urography (MRU) provides superb anatomic detail combined with functional information (109). In this technique, a gadolinium chelate (Gd-DTPA) is injected and the kidneys are imaged over time. With post-processing of data derived from the study, differential renal function, transit time of the agent through the kidney, and an estimate of glomerular filtration rate can be determined. These techniques are new and depend on meticulous technique, but have great promise for the future of renal imaging.

Application

MRI is valuable in evaluating masses, renal vascular disease, cystic lesions, and congenital abnormalities.

Congenital Kidney and Urological Disorders

Fetal Ultrasound

The widespread use of fetal US has led to a dramatic increase in postnatal imaging of the UT. Most congenital abnormalities of the UT are now detected prenatally, and

Figure 23-10

Renal MRI of a normal 5 year old. (a) Axial T2-weighted image through the mid-pole of the kidneys, (b) coronal T2-weighted image.

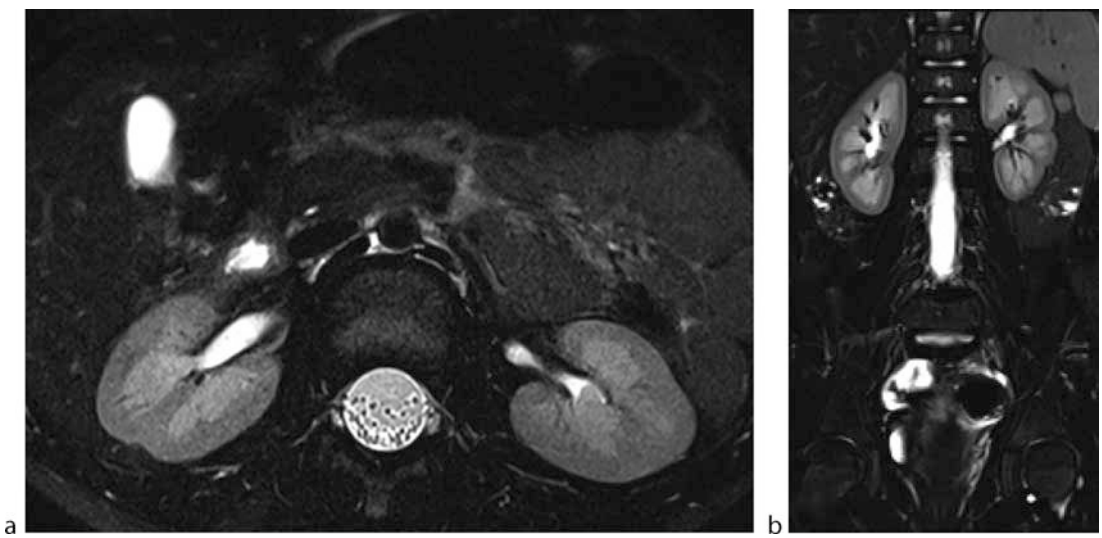

Figure 23-11

Renal MRI. 3-D image of the kidneys and ureters in a normal 12 year old.

this has led to a decrease in the diagnosis of obstructive uropathies as a consequence of urinary tract infection (UTI), potentially diminishing the role of renal US in children with UTI (110, 111).

Fetal kidney length relates to gestational age, and normal values are available (2) (*Table 23-4*). Fetal US is excellent at identifying hydronephrosis, and this may identify infants with UT obstruction or VUR. Oligohydramnios, which may indicate poor urine output due to renal insufficiency, is easily quantified and followed. Persistent oligohydramnios is associated with pulmonary hypoplasia. The fetal bladder, which may be distended with impaired bladder emptying, and the echogenicity of the renal parenchyma are also visualized via fetal US.

Hydronephrosis is the most common renal abnormality on fetal US, and ureteropelvic junction (UPJ) obstruction is the most common pathologic condition, although a high percentage of kidneys are ultimately diagnosed as normal (112). There is a high rate of false negative results when a postnatal US to follow-up on prenatal hydronephrosis is done in the first few days of life, presumably because of low urine output due to physiologic dehydration (113). Hence, the initial postnatal US should either be done at least 4 weeks after birth or the child should have a second US.

Table 23-4

Mean renal lengths for various gestational ages

Gestational age (weeks)	Mean length (cm)	SD	95%CI	n
18	2.2	0.3	1.6–2.8	14
19	2.3	0.4	1.5–3.1	23
20	2.6	0.4	1.8–3.4	22
21	2.7	0.3	2.1–3.2	20
22	2.7	0.3	2.0–3.4	18
23	3.0	0.4	2.2–3.7	13
24	3.1	0.6	1.9–4.4	13
25	3.3	0.4	2.5–4.2	9
26	3.4	0.4	2.4–4.4	9
27	3.5	0.4	2.7–4.4	15
28	3.4	0.4	2.6–4.2	19
29	3.6	0.7	2.3–4.8	12
30	3.8	0.4	2.9–4.6	24
31	3.7	0.5	2.8–4.6	23
32	4.1	0.5	3.1–5.1	23
33	4.0	0.3	3.3–4.7	28
34	4.2	0.4	3.3–5.0	36
35	4.2	0.5	3.2–5.2	17
36	4.2	0.4	3.3–5.0	36
37	4.2	0.4	3.3–5.1	40
38	4.4	0.6	3.2–5.6	32
39	4.2	0.3	3.5–4.8	17
40	4.3	0.5	3.2–5.3	10
41	4.5	0.3	3.9–5.1	4

Gestational age is an average of the gestational ages in weeks determined on the basis of biparietal diameter, femoral length, and abdominal circumference. *SD* standard deviation; 95% *CI* 95% confidence interval; *n* number of fetuses. At distribution was used when $n < 30$ (From Cohen HL et al. (2).)

Deferral of the initial US is inappropriate if the prenatal US suggests the presence of disease that would require immediate intervention (e.g., bilateral hydronephrosis or oligohydramnios). The degree of prenatal hydronephrosis is highly predictive of the likelihood of pathology on postnatal evaluation (114).

Prenatal US can detect children with a variety of other pathologic conditions, including posterior urethral valves, multicystic dysplastic kidney, VUR, megaureter, duplex anomalies with upper-pole hydronephrosis, single kidney, polycystic kidney disease, and Eagle-Barrett syndrome (115).

Megaureter

Megaureter may be primary or secondary to VUR or obstruction. VCUG permits identification of VUR and diuretic scintigraphy establishes the presence of obstruction. MRU provides excellent anatomic detail, often allowing identification of the site of obstruction (116).

Ureterocele

Ureteroceles may be demonstrated by US, VCUG, IVP, or MRU (*Fig. 23-12*). An everting ureterocele may be confused with a bladder diverticulum on VCUG (117). Ureteroceles may obstruct the ureter during voiding.

Ureteropelvic Junction Obstruction

UPJ obstruction is one of the most common congenital kidney disorders, and most cases are now diagnosed by fetal US. Dynamic renal scintigraphy remains the gold standard imaging technique for diagnosing UPJ obstruction (*Fig. 23-13*). MRI is an alternative approach that provides functional information and superior anatomic detail without exposure to radiation, albeit with the need for sedation (*Fig. 23-14*) (118, 119).

A second alternative technique for diagnosing obstruction is the measurement of the resistive index (RI) by Doppler US, with an elevated RI suggesting obstruction. The sensitivity and specificity of this approach is improved by administering normal saline and furosemide prior to US (120). The principal advantage is the elimination of radiation exposure, but this approach is not yet widely utilized.

Abnormal Kidney Number or Location

Unilateral renal agenesis must be distinguished from an ectopic kidney, which can be located anywhere along the course of renal ascent. Such kidneys are often smaller in size. Detection by US is possible, but MRI, IVP or DMSA are often necessary (*Fig. 23-15*). IVP may have limited sensitivity if the ectopic kidney has poor renal function.

Horseshoe Kidney and Crossed Fused Ectopia

Horseshoe kidney, with an incidence of 1 of 400 births, is the most common fusion anomaly. Crossed ectopia

Figure 23-12

Ectopic ureterocele with vesicoureteral reflux. (a) Voiding cystourethrogram shows rounded filling defect in bladder base from ureterocele, (b) voiding cystourethrogram shows reflux into the lower pole moiety of the left duplex system with eversion of the ureterocele (*asteric*). Opacification of the kidney indicates intrarenal reflux.

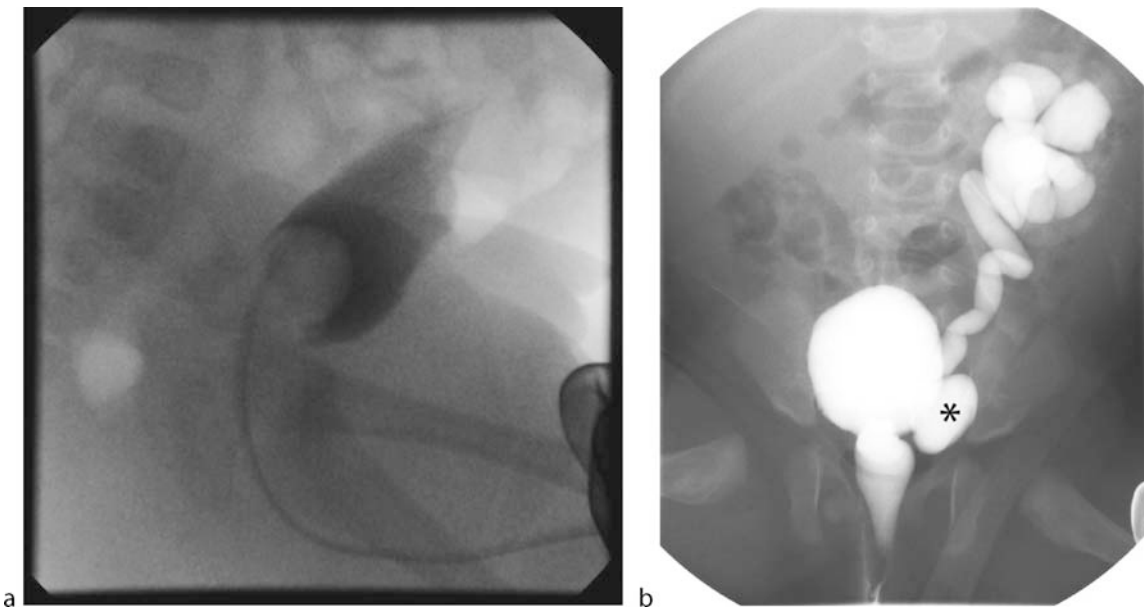

Figure 23-13

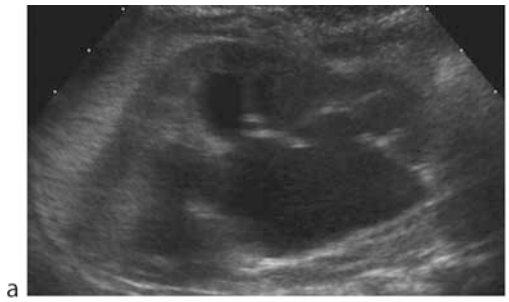
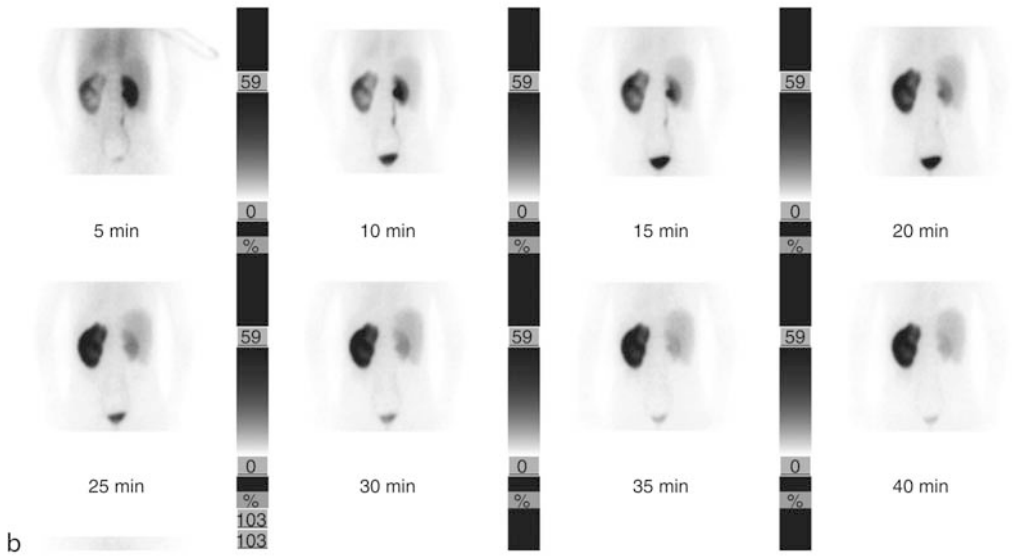
Left ureteropelvic junction obstruction. (a) US image of left kidney shows dilatation of renal pelvis and calices, (b) ^{99m}Tc-MAG$_3$ renal scan shows retention of radiotracer in left kidney, (c) time-activity curve from ^{99m}Tc-MAG$_3$ scan shows a normal right kidney. On the left, little drainage occurs in response to furosemide. T ½ exceeds 20 min.





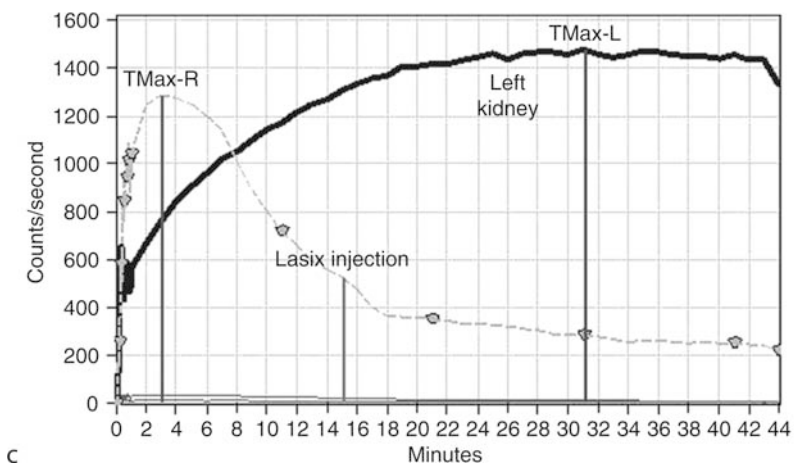


Figure 23-14

Left ureteropelvic junction obstruction. MR Urogram in patient with UPJ obstruction shows dilatation of the left renal pelvis and calices.

Figure 23-15

Crossed-fused ectopia. DMSA renal scan anterior image demonstrates a single fused renal moiety on the right.

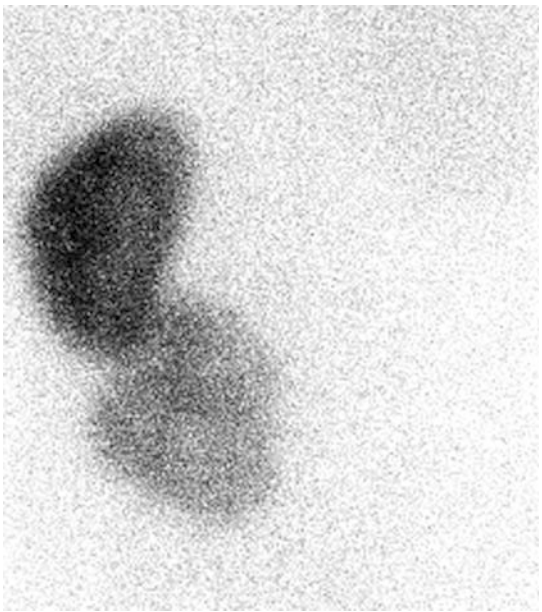

Figure 23-16

Horseshoe kidney. CT scan of abdomen shows a horseshoe kidney with a bridge of renal tissue fused across the midline (*arrowhead*).

occurs in an estimated 1 of 1,000 to 2,000 births. While US can be diagnostic, additional imaging, including IVP, MRI, CT, or DMSA, is often necessary to establish the diagnosis (*Fig. 23-16*).

Renal Dysplasia

Renal dysplasia is a histological diagnosis characterized by primitive ducts and cartilage. US evaluation demonstrates increased echogenicity; most dysplastic kidneys are decreased in size. US may detect cysts, which may vary in size and number.

The incidence of multicystic dysplastic kidney (MCDK) is estimated at 1 in 2,500 newborn (121); it is one of the common prenatally detected fetal anomalies. Postnatal US shows cysts of varying size that do not appear to communicate with each other or the collecting system, and a small amount of abnormal-appearing renal parenchyma. It may be difficult to differentiate MCDK from severe hydronephrosis (122). In MCDK, there is typically no communication between cysts, and the larger cysts are not medial (*Fig. 23-17*). In hydronephrosis, the calyces extend outward from the dilated renal pelvis, and there is functional renal parenchyma surrounding the central cystic structure. If the diagnosis is unclear, a DMSA shows uptake of tracer if hydronephrosis is present, but usually no uptake with MCDK (*Fig. 23-18*). Alternatively, MRI can distinguish these entities.

Figure 23-17
Left multicystic dysplastic kidney. Renal US in an infant shows multiple non-communicating cysts in the left kidney.

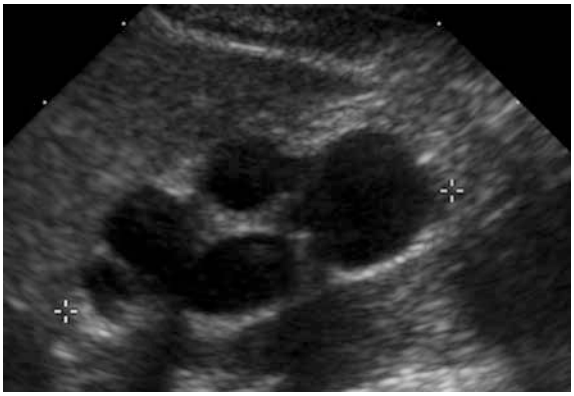

Figure 23-18
Left multicystic dysplastic kidney. DMSA renal scan (*posterior image*) shows no uptake in the left multicystic dysplastic kidney.

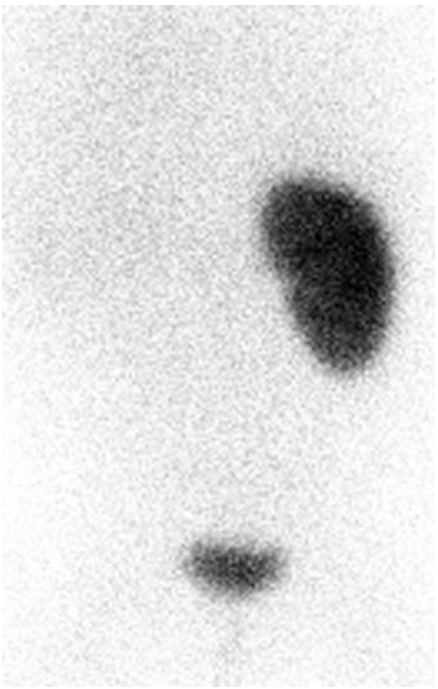

Figure 23-19
Duplex system with ectopic ureterocele. Renal US shows mild hydronephrosis (*arrowheads*) of the upper and lower poles. A band of renal tissue extends across the midpole, indicating a duplex system.

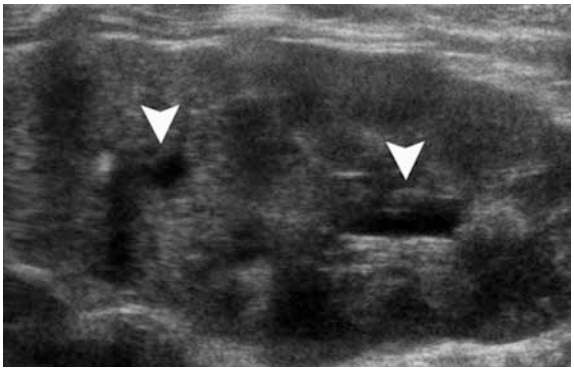

Figure 23-20
Duplex system with ectopic ureterocele. MRU shows hydronephrosis of the right upper pole.

Duplex Collecting System

A duplex collecting system is a common incidental finding and usually of no clinical significance unless hydronephrosis is also present. Associated anomalies include ureterocele, VUR, ectopic ureters, renal dysplasia, and UPJ obstruction (*Figs. 23-19* and *23-20*) (123). The upper pole is more likely to be associated with obstruction at the distal ureter while the lower pole is associated with VUR or UPJ obstruction. US can usually demonstrate

division of the kidney, but is not reliable in distinguishing between bifid ureter and complete ureteral duplication. IVP is being supplanted by MRU for delineating the anatomy of the ureteral duplication when such information is necessary for planning surgery (116). MRU is especially useful for characterization of the distal ureter (124). VCUG may demonstrate VUR or ureterocele.

Ectopic Ureters

Ectopic ureters are three times more common in girls, and approximately 80% are associated with a duplicated collecting system and ectopic insertion of the upper pole ureter. Greater distance from the normal ureter insertion site is associated with more severe ipsilateral renal abnormalities (125). US can demonstrate duplication, hydronephrosis, megaureter, and abnormal renal parenchyma. IVP is useful for delineating the course of the ectopic ureter, although lack of contrast may limit the study if the associated renal unit is poorly functioning. MRU may allow detection of the ectopic ureter if other studies are unsuccessful (124). VCUG is useful for showing reflux, and may indicate the insertion point of the ureter if it is proximal to the external sphincter. DMSA is useful for identifying an ectopic kidney that is the source of an ectopic ureter in a patient with unexplained incontinence (96, 97). By indicating relative renal function, DMSA may also help with surgical planning.

Bladder Abnormalities

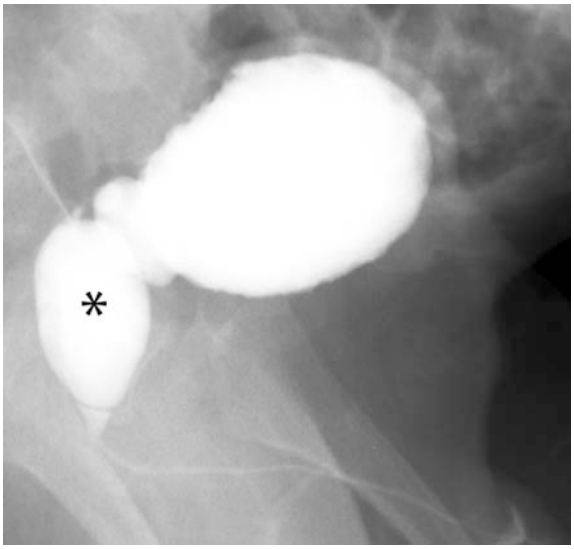
US and VCUG are the standard imaging modalities for patients with a neurogenic bladder (*Fig. 23-21*). VCUG readily identifies bladder diverticula, which are easily missed by US. Bladder wall thickening, consistent with high bladder pressures, can be quantified by US.

Urethral Abnormalities

VCUG is the definitive test for diagnosing posterior urethral valves (*Fig. 23-22*). The prostatic urethra is dilated, the membranous urethra is stenotic, and the distal urethra appears normal. Secondary VUR, hydronephrosis, and bladder abnormalities are often present (*Fig. 23-23*). Other urethral abnormalities (anterior urethral valves, urethral duplication, Cowper's duct cyst, urethral diverticulum, megalourethra) are also best visualized via VCUG.

Figure 23-21
Neurogenic bladder in a 16 year old with a spinal cord injury. Voiding cystourethrogram shows pear-shaped bladder with trabeculations.

Figure 23-22
Voiding cystourethrogram shows dilatation of the posterior urethra (*asteric*) in a boy with posterior urethral valves.



Vesicoureteral Reflux

VCUG is the gold standard for diagnosing VUR, with VUR graded based on the International Reflux Study in Children (*Fig. 23-24*) (44). RNC or VUS, because of decreased or no radiation burden, respectively, are appropriate substitutes for VCUG in clinical situations where the purpose of the study is solely to assess the patient for VUR. Examples include follow-up studies in children with previously diagnosed VUR, screening siblings of children with VUR, and potentially for the initial evaluation of girls with urinary tract infections. Renal US lacks adequate sensitivity and specificity for diagnosing VUR (126–129), although high grade VUR is more likely if hydronephrosis is present (130).

Figure 23-23

Renal US shows dilatation of the right renal pelvis, calices, and ureter in a boy with posterior urethral valves.

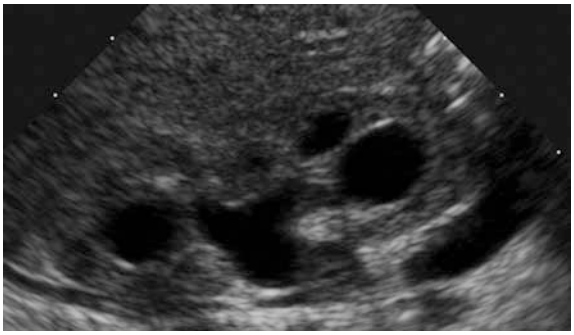


Figure 23-24

Voiding cystourethrogram shows bilateral grade 4 vesicoureteral reflux.

Hereditary Disorders

Cystic Kidney Diseases

In autosomal recessive polycystic kidney disease, intravenous pyelogram (IVP) shows enlarged kidneys with a delayed nephrogram (131). Radial streaks due to contrast in the dilated collecting ducts are usually present in infancy, but may not be visible in older children. Because of concerns regarding intravenous contrast, a renal US is now the usual initial diagnostic test (*Fig. 23-25*). US shows enlarged kidneys with increased echogenicity and poor corticomedullary differentiation; a hypoechoic rim is often visible (132). Older children have increased medullary echogenicity, which may resemble nephrocalcinosis (133). Multiple small cysts may be visible by US (133, 134), but this is quite variable. Macrocysts are sometimes visible in older children (134).

In autosomal dominant polycystic kidney disease, US, CT and MRI are useful for detecting macroscopic cysts (*Figs. 23-26* and *23-27*). The number and size of cysts in children increases with age, and those children with more cysts have increased kidney size (135). In adults, kidney size measured by MRI predicts decline in renal function (136). Increased renal echogenicity may be seen in some children (134). Occasionally, children have marked disease asymmetry, which can create diagnostic confusion (137).

US in nephronophthisis shows hyperechoic kidneys with loss of corticomedullary differentiation; they are of normal or slightly decreased size. Medullary cysts are a hallmark of the disease, but they are not always detected by US. CT is a more sensitive method for identifying medullary cysts and thin-section CT is recommended (138).

The diagnosis of medullary sponge kidney is based on characteristic IVP changes: stagnation of contrast in one or more renal papillae due to dilation of the collecting ducts. The resultant image has been described as a "pyramidal blush." In medullary cystic disease, the kidneys are usually normal or small, and US or CT may show a few medullary cysts (139).

Tuberous Sclerosis

Angiomyolipomas are the most common renal lesion in TS and are readily seen by CT or ultrasound (*Figs. 23-28* and *23-29*). Children with disruption of the contiguous *PKD1* and *TSC2* genes usually have severe cystic disease and are at high risk for hypertension and early kidney failure (140). Renal malignancies, including renal cell carcinoma and malignant angiomyolipomas, are a serious

Figure 23-25

Autosomal recessive polycystic kidney disease in an infant. (a) Longitudinal view shows diffuse enlargement of the right kidney, which is in increased in echogenicity, (b) transverse image through the mid-pole of both kidneys.

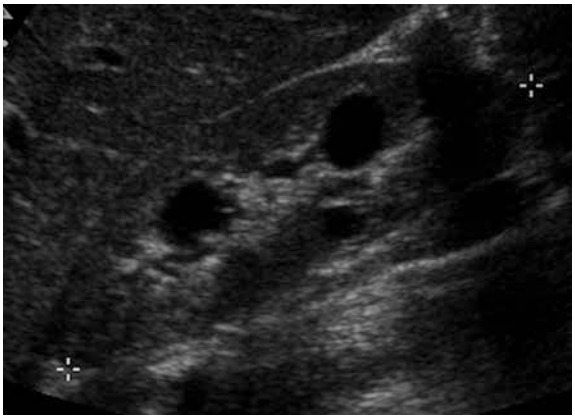
Autosomal dominant polycystic kidney disease. Renal US, longitudinal image, renal cysts of varying sizes in a 15 year old.



concern in TS and both are seen in children, sometimes in early childhood (141, 142). All children with TS should have a renal ultrasound at diagnosis and follow-up renal ultrasounds every 1–3 years, with frequency dictated by the specific clinical situation (143). Patients with extensive or rapidly changing lesions require more frequent follow-up. Those with more severe kidney disease may require CT or MRI to screen for malignant changes. Differentiating angiomyolipomas from malignancy requires careful comparison of sequential images.

Infections of the Urinary Tract

Clinical and laboratory criteria do not reliably differentiate pyelonephritis from cystitis (144–146). DMSA is the gold standard for diagnosing acute pyelonephritis, although MRI and CT provide similar sensitivity (147). US may detect loss of corticomedullary differentiation and renal enlargement, but lacks adequate sensitivity and specificity when compared to DMSA (148–151).

The decreased uptake using DMSA with pyelonephritis may be focal, multifocal or diffuse. Acute pyelonephritis must be differentiated from renal scaring, which is associated with sharper borders and loss of cortical volume. DMSA may allow diagnosis of pyelonephritis in children who have received antibiotics prior to urine culture or who have a negative culture despite clinical and laboratory evidence suggesting pyelonephritis (152).

DMSA is the current standard modality for diagnosing renal scarring (*Fig. 23-30*) (153), with increased sensitivity when compared to US or IVP (154). Scars appear as photopenic areas with volume loss. DMSA should be deferred at least 6 months after an acute infection to differentiate a transient lesion due to infection from a scar (95, 154, 155). MRI has the potential to differentiate acute pyelonephritis from renal scarring, perhaps avoiding the need for radiation exposure and obviating the need for two diagnostic tests (156).

All boys and young girls with a first UTI are conventionally evaluated with a renal US and VCUG (157). The necessity of the this approach has been questioned, especially given the lack of evidence that prophylactic antibiotics are effective in preventing UTIs or renal damage (158). Moreover, because of the widespread use of prenatal US in many countries, the diagnostic yield of US examination in children with UTI is low (159). In girls, the radiation burden of the initial imaging can be reduced by using RNC instead of VCUG. An alternative strategy is to perform DMSA scintigraphy as an initial test in children with UTI, and only perform VCUG or RNC in children with an abnormal DMSA (160).

CT in a 15 year old with autosomal dominant polycystic kidney disease and bilateral cysts of varying sizes. (a) axial image, (b) coronal image.

Figure 23-28

Angiomyolipomas in tuberous sclerosis. Renal US, longitudinal image, demonstrates multiple small echogenic lesions throughout the kidney.

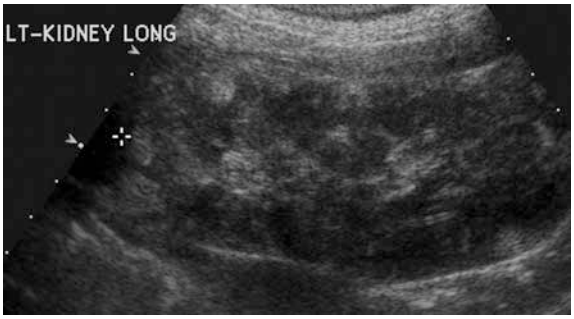

Figure 23-29

Angiomyolipomas in tuberous sclerosis. Renal CT, axial image, with multiple fat-containing lesions in the kidneys.

Renal Failure

US is the initial imaging modality when a patient presents with unexplained renal failure. This generally allows differentiation of chronic renal failure (small, echogenic kidneys with a thin cortex) from acute renal failure. The kidneys may be large if chronic renal failure is secondary to polycystic kidney disease. US readily detects hydronephrosis, which suggests that renal failure is due to an obstructive etiology. Hydronephrosis may also be secondary to VUR, papillary necrosis or high urine output; such hydronephrosis is rarely severe. Renal parenchymal disease is often associated with increased echogenicity (*Fig. 23-31*) (161–163), although a normal US examination does not exclude this possibility. The kidneys generally have a normal appearance in prerenal azotemia. The kidneys may be normal or have increased echogenicity in acute tubular necrosis. Echogenic kidneys, which may be moderately enlarged, are often seen in glomerular disease (162, 164). The kidneys are enlarged and very echogenic in HIV nephropathy(165). The US findings in renal parenchymal disease are rarely specific (163, 164).

Renal Transplant

US is the primary imaging modality for evaluation of the renal transplant (166, 167). US identifies abnormal fluid collections (e.g., lymphoceles, urinomas) and obstruction (*Fig. 23-32*). Doppler US can detect vascular disease after kidney transplant (renal artery thrombosis, renal

Figure 23-30

Renal scarring in a 10 year old with vesicoureteral reflux. DMSA renal scan shows a small right kidney with diffuse renal scarring. Uptake in the right kidney is 20%.

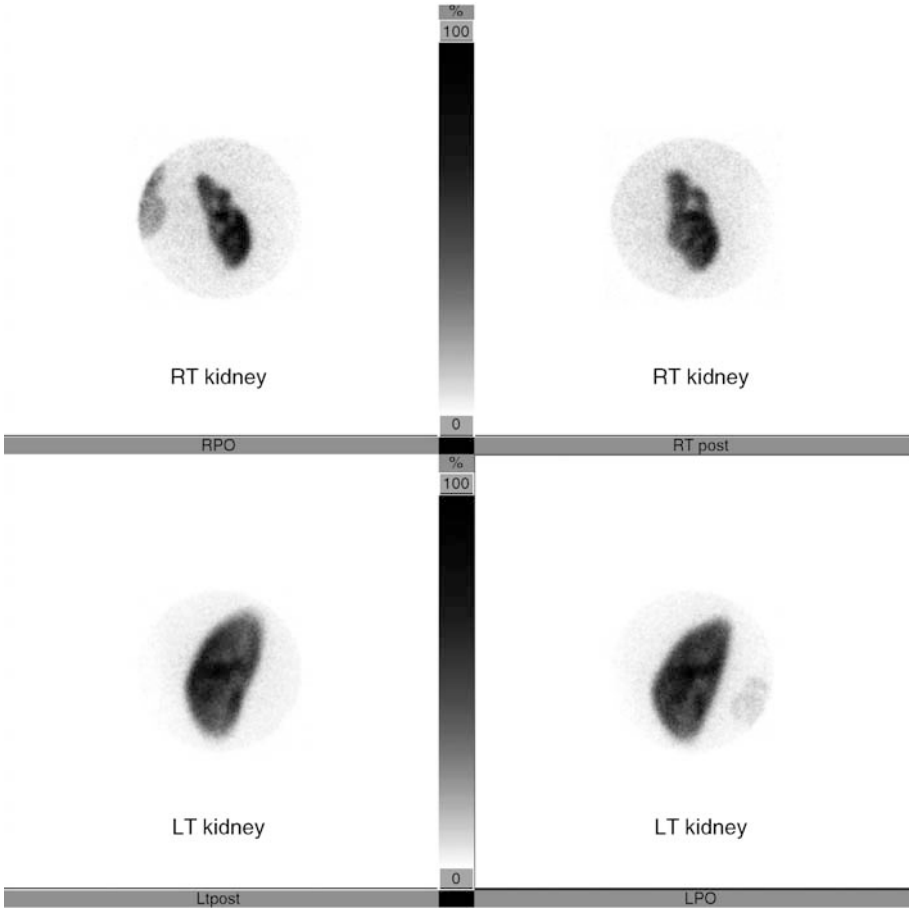

Figure 23-31

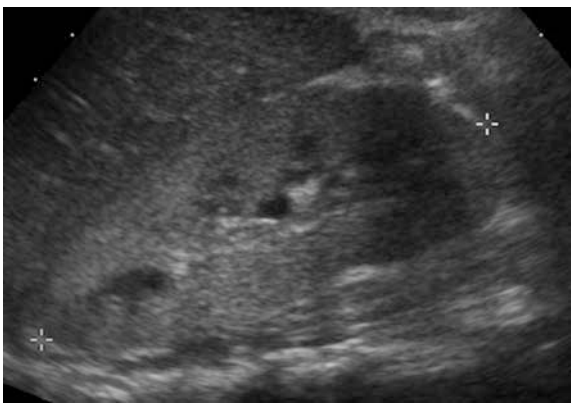
Acute glomerulonephritis in a 3 year old. Renal US shows large echogenic right kidney.



artery stenosis, renal vein thrombosis, arteriovenous fistula) (26, 167–169). There are a number of potential US abnormalities seen in patients with acute graft rejection (increased renal size and echogenicity, decreased or absent central sinus echoes) (170), but US does not have adequate sensitivity or specificity; kidney biopsy remains necessary for the diagnosis of rejection.

Radionuclide imaging (^{99m}Tc-DTPA or ^{99m}Tc-MAG$_3$) is useful when US does not provide an explanation for graft dysfunction. Absence of flow to the kidney occurs with arterial or venous obstruction or with hyperacute rejection. In contrast, a graft with ATN has normal renal perfusion, but delayed or no excretion. Radionuclide imaging is useful for demonstrating urinary obstruction or that a perinephric fluid collection is due to a urine leak (171–173).

Urolithiasis and Nephrocalcinosis

Urolithiasis

US is a sensitive test for detecting calculi in the kidney and the proximal and distal ureter. US does not easily detect stones in the middle portion of the ureter, although hydronephrosis due to obstruction may suggest the diagnosis. Acoustic shadowing is a useful finding, but may not be present with smaller calculi. US is less sensitive than CT in detecting calculi in symptomatic children (*Fig. 23-33*) (174). CT is also superior to US for identification of bladder stones, especially if the bladder is augmented.

Nephrocalcinosis

Nephrocalcinosis is typically detected by US (*Fig. 23-34*), although it may be seen via CT. Plain x-ray only detects nephrocalcinosis in severe cases (175). Causes of cortical nephrocalcinosis include primary hyperoxaluria(176) and cortical necrosis, while there are many entities that may cause medullary nephrocalcinosis (175, 177).

Trauma to the Urinary Tract

CT with contrast is the primary modality for evaluating a patient with suspected trauma to the kidney (*Fig. 23-35*) (178, 179). CT angiography permits detailed evaluation of the renal artery and vein. US is an alternative imaging modality that may identify large lacerations, hematomas, and urinomas; US with Doppler readily identifies significant injuries of the renal artery or vein. US suggests bladder laceration when there is a large amount of fluid in the cul-de-sac. When indicated, VCUG can potentially identify the site of bladder leak and detect urethral injury.

Figure 23-32

Lymphocele in a 15 year old with renal transplant. Renal US shows a complex, loculated fluid mass adjacent (L) to the transplanted kidney (T).

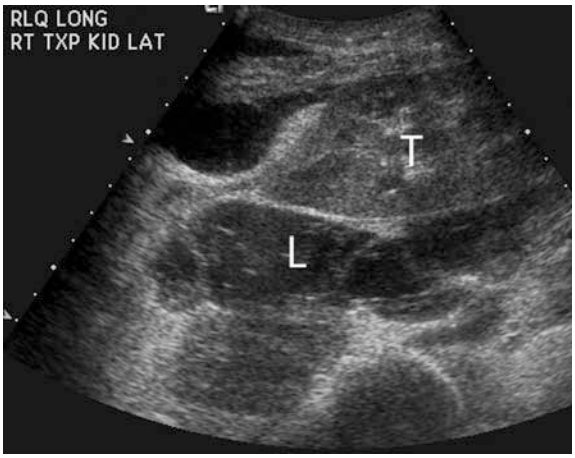


Figure 23-33

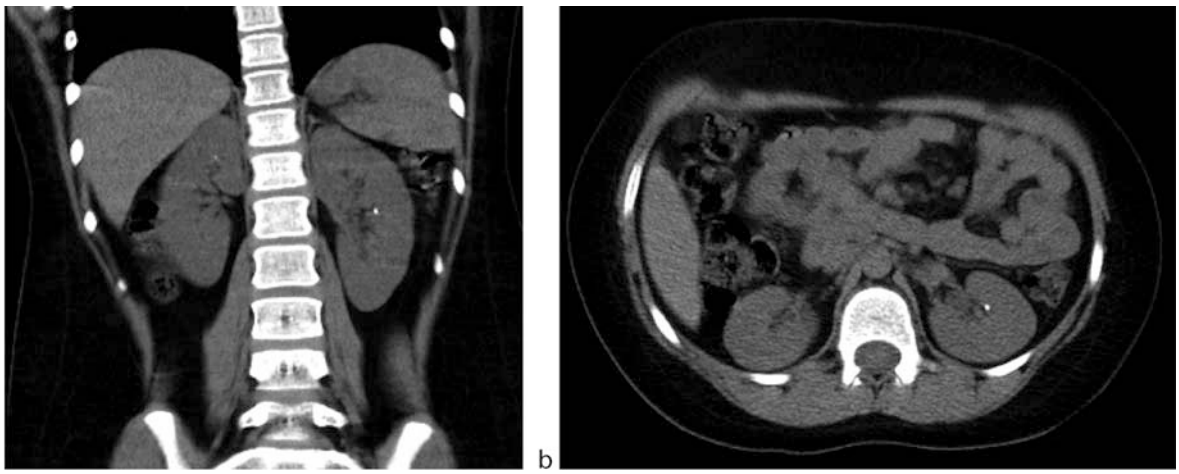
Renal calculus in the mid-pole of the left kidney. (a) Coronal image, (b) axial image.



Renal and Urinary Tract Tumors

Role of Imaging

US is especially suited for initial evaluation, while CT or MRI are necessary for defining tumor extent and the presence of metastases. CT without contrast allows for identification of tumor calcifications; contrast allows for better differentiation of tumor from normal tissue. US is sensitive for the detection of bladder tumors in children (180).

Figure 23-34
Medullary nephrocalcinosis in a 12 year old with renal tubular acidosis. Renal US, longitudinal image, shows echogenic renal pyramids.

Imaging of Specific Renal Tumors

Wilms' Tumor

US and CT are complementary in the evaluation and follow-up of Wilms' tumor (*Figs. 23-36* and *23-37*). US with Doppler may provide superior imaging of tumor in the inferior vena cava in some patients (181). Radiologic staging of Wilms' tumor includes chest x-ray, US of the abdomen and pelvis, and CT of the chest, abdomen, and pelvis. Chest x-ray appears to be an appropriate substitute for chest CT to identify pulmonary metastases (182). MRI is also an effective modality for evaluation of Wilms' tumor (183). US is a sensitive approach for screening patients for tumor recurrence, although CT or MRI is necessary to identify nephrogenic rests (184).

US is the preferred modality for Wilms' tumor screening, which is necessary in children with syndromes that significantly increase the risk of Wilms' tumor (e.g., hemihypertrophy, Denys-Drash syndrome, Beckwith Wiedemann syndrome) (185). Screening should occur every 3–4 months until 8 years of age.

Lymphoma

Children with lymphoma may have renal involvement. By US, renal lymphoma has decreased echogenicity (186).

Figure 23-35
Motor vehicle collision resulting in extensive left renal laceration with a large perinephric hematoma. (a) Axial CT, (b) coronal CT.

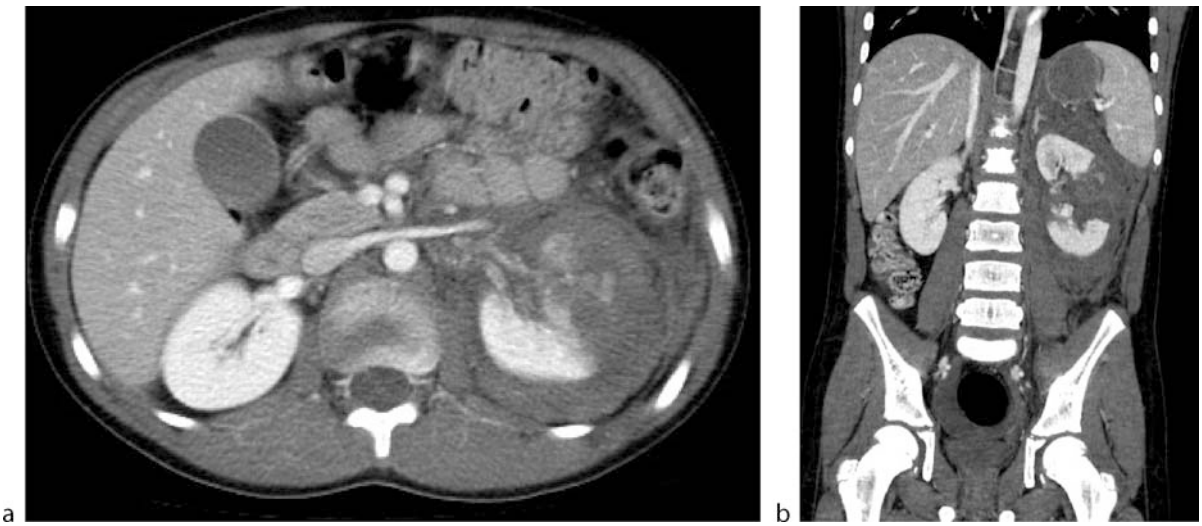


Figure 23-36

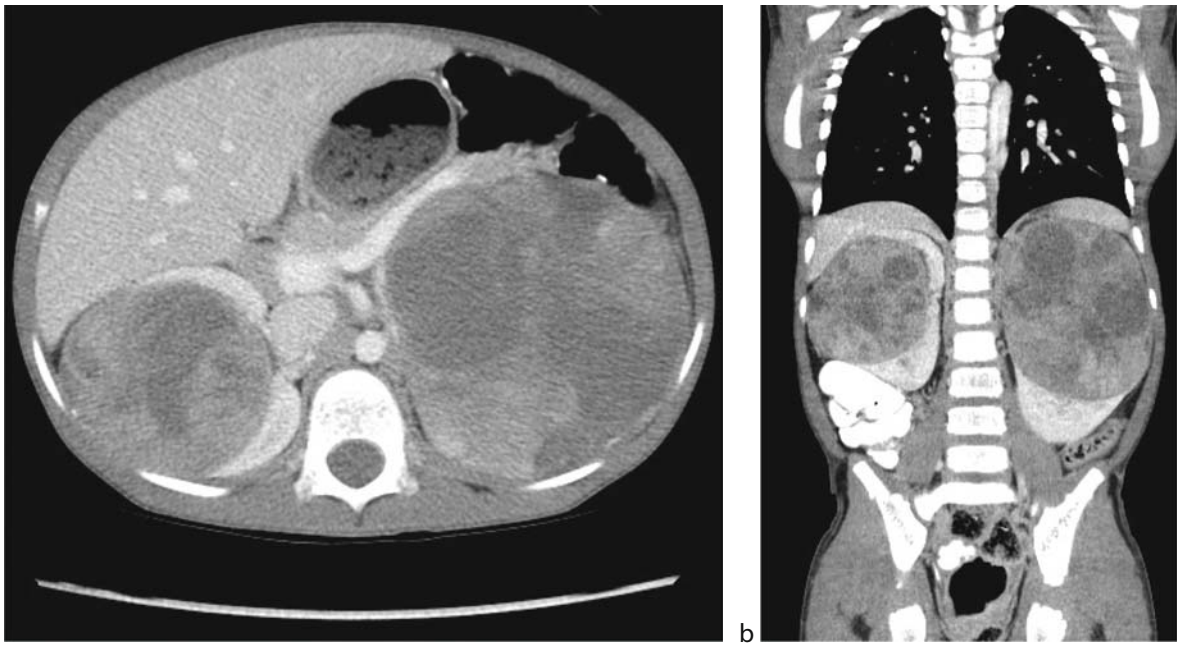
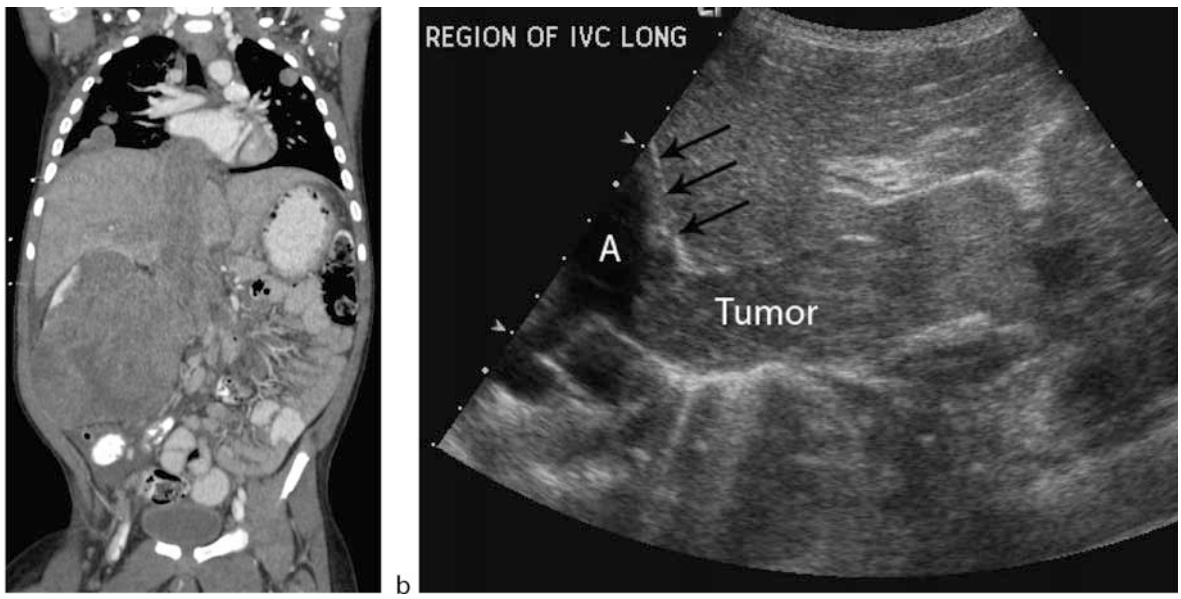
Bilateral Wilms' tumor in a 5 year old with a palpable abdominal mass. (a) Axial CT, (b) coronal CT.



a b

Figure 23-37

Wilms' tumor in a 2 year old. (a) Coronal CT image shows a large right renal mass, pulmonary nodules, and tumor extension into the IVC to the diaphragm, (b) longitudinal US image with tumor filling the dilated IVC extending to the diaphragm (*arrows*) and entering the right atrium (A).



a b

CT may demonstrate "contrast inversion" of the lesions in renal lymphoma: increased density compared to normal parenchyma without contrast and decreased density with contrast (186).

Vascular Disease and Hypertension

Renal Artery Stenosis

Doppler US lacks adequate sensitivity for diagnosing renal artery stenosis in children (187–189), although it may be a useful screening test in adults (190). US may demonstrate a small affected kidney if the stenosis is severe and long-standing; the contralateral kidney may have increased echogenicity (191). Renal scintigraphy before and after captopril has good sensitivity in identifying renovascular disease in children (99). CT and MRI angiography provide excellent visualization of the renal artery (*Fig. 23-38*), but do not visualize distal branch vessel lesions. When clinical suspicion is high, conventional angiography remains necessary to evaluate children with suspected hypertension due to renal artery disease.

Renal Vein Thrombosis

US is utilized to diagnose renal vein thrombosis. The appearance on US varies depending on the timing of imaging. Within the first few days of clot formation, imaging may demonstrate pathognomonic echogenic streaks due to clot in interlobular and interlobar veins (192, 193). Renal enlargement occurs during the first week, and is associated with an echogenic cortex and less echogenic medullary pyramids. Beyond the first week, there is a loss of corticomedullary differentiation and echogenic streaks are no longer visible (192). An additional later finding is calcification of thrombi within renal veins, including large or small veins (194). Long-term imaging outcomes vary from a normal appearing kidney to a small, echogenic kidney with little or no function. In perinatal renal vein thrombosis, renal length is negatively correlated with outcome (195).

US may directly demonstrate clots in the renal vein and inferior vena cava. Doppler US may show absent renal venous flow and pulsatility. The arterial RI is frequently elevated. Clot retraction and formation of collaterals after a few days may create diagnostic confusion due to a return of some venous flow and a decrease in arterial RI. In neonates, adrenal hemorrhage, which is readily seen by US, frequently accompanies renal vein thrombosis and assists in confirming the diagnosis (196, 197). This association is more common on the left due to the common drainage of the renal vein and adrenal vein.

Figure 23-38

Renal artery stenosis in a 13 year old with neurofibromatosis and hypertension. Axial maximal intensity projection CT image shows narrowing of both renal arteries near their origins from the aorta.

Pheochromocytoma

Pheochromocytoma may be strongly suspected based on clinical and laboratory evaluation, but imaging is necessary to confirm the diagnosis and allow for staging and resection, which is usually curative. US may identify a pheochromocytoma in or near the adrenal gland, but US lacks the sensitivity of CT or MRI, especially for small lesions or tumors in other locations (*Fig. 23-39*). Hypertensive crisis may occur if ionic contrast is utilized, but nonionic contrast appears safe at the doses used for CT (198). Chest CT or MRI is indicated if an abdominal lesion is not detected or for staging of malignant disease. Pheochromocytomas enhance on contrast CT, although nonenhancing foci of necrosis and hemorrhage may be present.

MIBG scintigraphy, a complementary imaging modality, may be appropriate as an initial test, to confirm the diagnosis in equivocal cases, or to search for disease when the CT or MRI is negative (*Fig. 23-40*) (199, 200). Positron emission tomography (PET) scan is a potential alternative if all other studies are negative and clinical suspicion remains high (201).

Figure 23-39

Pheochromocytoma in a 14 year old. (a) Axial CT image shows a right pelvic mass (P), (b) sagittal T2-weighted MR image shows a right pelvic mass extending into the adjacent neural foramen (*arrow*).

Figure 23-40

Pheochromocytoma. Posterior ^{123}I-MIBG image shows tumor uptake in the pelvis.

24 Renal Pathology

Agnes B. Fogo

Introduction

This chapter reviews the usual circumstances in which biopsies are obtained, methods of obtaining the biopsy material and analyzing the tissue, and the distinct characteristic morphologic findings in various diseases. Last, experimental techniques that may provide important pathogenic, prognostic, or diagnostic information are discussed.

Renal Biopsy Indications

The indications for renal biopsy vary according to the ethnic and age characteristics of the population studied and the geographic location because these factors influence the incidence of various renal diseases. The indications discussed below present the most common settings in children for which renal biopsy is undertaken.

Hematuria

Isolated hematuria (i.e., without proteinuria and with normal function of the kidney) may be due to hypercalciuria or familial or urologic disease (1–3). Once these disorders are ruled out, a glomerular origin of persistent isolated hematuria should be considered. Red blood cell casts or dysmorphic red blood cells indicate glomerular origin of hematuria. Renal biopsy may define the underlying abnormality in these patients. The most common findings are mesangial proliferative disease or IgA nephropathy (Berger's disease). Less common disorders include hereditary nephritis (Alport syndrome) and thin basement membrane lesion. The latter may be familial (benign familial hematuria) or sporadic. One-quarter to nearly one-half of the patients with isolated hematuria have normal biopsies (1–4). Renal biopsy may, therefore, define the pathology and provide assurance of a benign prognosis in some patients or diagnose a possible hereditary disease, which would initiate screening of other family members. Last, the information obviously can be of importance in avoiding further repeated invasive evaluation in the patient.

Proteinuria

Isolated proteinuria may be postural or due to tubulointerstitial disease. These possibilities should be evaluated completely over time before renal biopsy is considered. Any glomerular disease may cause mild to moderate proteinuria as the only manifestation, and biopsy may yield the diagnosis even at an early stage.

Nephrotic Syndrome

Numerous children with nephrotic syndrome (NS) were studied when renal biopsy first became available. The biopsies showed so-called minimal-change disease (MCD) in the vast majority of cases. The efficacy of corticosteroids in this setting has obviated the need for renal biopsies in most of these cases. Therefore, young children with NS will typically undergo a therapeutic trial of corticosteroids without a biopsy. However, in infants with NS, in older children, or in those with evidence of nephritis (hypertension, hematuria, low C3, or decreased renal function) or failing corticosteroid therapy, renal biopsy is often performed. In these patients, disease other than MCD (e.g., focal segmental glomerulosclerosis [FSGS], membranoproliferative glomerulonephritis [MPGN], IgA nephropathy, membranous glomerulopathy, or more rarely, in infants less than 1 year, Finnish-type nephrotic syndrome or diffuse mesangial sclerosis) is often present (4–9). Children with steroid-resistant NS and FSGS on biopsy may have a podocyte gene mutation, such as podocin, as cause of their disease. Genetic testing is important to identify these children, as 10–30% of children with sporadic steroid-resistant NS and FSGS have such mutations, and do not typically respond to continued immunosuppression (10, 11). These genetically-induced lesions do not show specific renal biopsy morphologic findings.

Acute Nephritis

The child with acute glomerulonephritis may need a biopsy when the course is not typical of acute poststreptococcal disease or if urinary abnormalities persist. Although the primary disease process may be evident in systemic conditions, such as Henoch-Schönlein purpura or systemic lupus erythematosus (SLE), renal biopsy often is indicated to assess severity of injury, to guide therapy and prognosis. Differentiation of specific types of proliferative lesions such as MPGN type I and dense deposit disease (DDD) is made by renal biopsy. This distinction has important implications for eventual treatment because the morphologic lesions of DDD invariably recur in transplants, although the clinical course is less severe than in the native kidney (12, 13).

Acute Renal Failure

The cause of acute renal failure may be clinically obvious, or there may be multiple potential culprits. When prerenal and obstructive causes are not apparent, renal parenchymal disease should be considered. When acute renal failure is associated with nephritis, NS, or evidence of vasculitis or systemic diseases, biopsy is usually performed. Other common causes include acute tubular necrosis or injury, often caused by drug or ischemic injury, vascular disease, and interstitial nephritis. These conditions can often be diagnosed without renal biopsy. However, when the cause remains uncertain after complete evaluation, renal biopsy may be necessary for diagnosis (14).

Rapidly Progressive Glomerulonephritis

Renal biopsy may be considered an urgent procedure in the patient with rapidly progressive glomerulonephritis (RPGN). Various systemic vasculitides that may be distinguished only by specific serologic studies (see below) or renal biopsy must be treated urgently to avoid severe chronic renal damage. Although anti-glomerular basement membrane (GBM) antibody or anti-neutrophil cytoplasmic antibody (ANCA) titers may provide useful information, the ANCA test in particular is not diagnostic of a specific condition, rather it is a screening test for necrotizing vasculitides (15, 16). ANCA positivity, whether in a perinuclear (p-ANCA) or cytoplasmic (c-ANCA) pattern was present in approximately 60% of patients with immune-complex glomerulonephritis with crescents in a study of more than 200 renal biopsies (17). Furthermore, specialized confirmatory ELISA ANCA assays may have a longer turn-around time than the renal biopsy, from which preliminary information from immunofluorescence (IF) and light microscopic studies can be available within hours after biopsy.

Chronic Renal Insufficiency

Patients with chronic renal insufficiency of uncertain etiology are candidates for renal biopsy. Although renal biopsy of the small, shrunken kidney is more risky because of the greater incidence of bleeding complications, the diagnosis of primary disease can be important. This information allows assessment of existing severity of morphologic lesions, determination of risk of recurrence in eventual renal transplant, and suitability of cadaveric vs. living-related donor transplantation. If the disease has a familial basis or recurs frequently with resultant graft loss, cadaveric transplantation may be preferable to living-related donor transplant (13).

Systemic Diseases

The severity of renal involvement in systemic disease, such as hemolytic-uremic syndrome (HUS), Henoch-Schönlein purpura, diabetes mellitus, or SLE, may not be apparent without renal biopsy. The trend is now toward early biopsy in patients with diabetes and renal abnormalities. Severity of lesions and stage of chronicity and activity impart prognostic information and may affect therapeutic decisions (see below). The most extensively studied disease in this regard is SLE. Differentiation of specific class of lupus nephritis by WHO or International Society of Nephrology/Renal Pathology Society (ISN/RPS) class (see below) may be difficult without renal biopsy (18–20). Overall, evidence indicates that renal biopsy findings may be more sensitive than clinical assessment alone in evaluating the severity of renal involvement in SLE (21, 22).

Follow-Up of Disease

With improved therapeutic modalities available for intervention in chronic progressive renal disease, sequential or follow-up biopsies is becoming increasingly necessary to evaluate therapeutic efficacy. On the other hand, additional cytotoxic therapy with its side effects may be withheld if the biopsy shows end-stage histology. Intervention with, for example, low-protein diets or angiotensin-converting enzyme (ACE) inhibitors or angiotensin

type 1 receptor blockers (ARBs) has been shown to alter the course of chronic progressive renal disease (23).

Transplantation

Renal transplant biopsies are useful in assessing episodes of clinically suspected rejection, investigating the cause of decreased renal function or urine output, and detecting the development of de novo or recurrent disease. Occasionally, infection may be diagnosed by renal biopsy. Drug toxicity may be diagnosed by morphologic findings. The absence of lesions in a patient with a rise in creatinine supports calcineurin inhibitor toxicity because this drug commonly causes a decline in the glomerular filtration rate (GFR) by vasoconstriction and not overt structural lesions. The absence of findings of acute rejection in renal biopsy or by needle aspiration (see below) thus can assist in avoiding unnecessary immunosuppressive therapy with its potential for increased morbidity and mortality. Even a diagnosis of chronic allograft nephropathy (CAN) which is not amenable to immunosuppressive therapy, has important therapeutic implications for the patient.

Diseases that recur in the transplant with high frequency include IgA nephropathy, MPGN type I, dense deposit disease (DDD, also known as MPGN type II), FSGS, HUS, and membranous glomerulopathy. The latter two also occur de novo in the transplant. Metabolic diseases such as oxalosis and diabetic nephropathy can also cause recurrent disease in the renal transplant, if liver or pancreas transplantation does not cure the primary abnormality (13). Alport syndrome is caused by mutation in one of the type IV collagen genes, resulting in abnormal GBM assembly and structure. Patients with Alport may develop anti-GBM antibody disease in the transplant because of antibodies against its normal type IV basement membrane collagen (24, 25).

Obtaining Tissue

General Considerations

Percutaneous renal biopsy is the most common method for obtaining tissue for the kidney. In large series, major complications are rare. The technique, first done in 1951 by Iverson and Brun, allows tissue yield in 93–95% of biopsies, with more than 87% of these being adequate (23–25). The biopsy findings altered diagnoses in half of the cases in one series, indicating different therapeutic approaches in approximately one-third of those cases (26). Although some renal diseases show diagnostic features by light microscopy (LM) (*Table 24-1*), special studies add to the sensitivity of the study. For the renal biopsy to be most useful, it must be evaluated appropriately by an experienced renal pathologist. Biopsies must be examined by special LM, IF, and electron microscopy (EM) for the most accurate diagnosis (27). If the nephrologist's hospital does not provide these services, arrangements must be made to send tissue in appropriate fixatives (see below) to a reference laboratory with these capabilities. If such services cannot be provided, it is doubtful whether the institution should be undertaking renal biopsies.

Contraindications

Contraindications to percutaneous biopsy are solitary, ectopic, or horseshoe kidney; bleeding diathesis; abnormal renal vascular supply; and uncontrolled hypertension (26–29). In the era of ultrasound guidance and automated biopsy instruments, solitary kidney may be biopsied safely in selected patients, however (30). Relative contraindications include obesity, uncooperative patients, hydronephrosis, ascites, and small shrunken kidneys, all associated with greater risk for complications. Open biopsy is preferable if the biopsy information is crucial in these conditions. Percutaneous biopsy is contraindicated if the kidney has tumors, large cysts, abscesses, or pyelonephritis because the needle track may facilitate spread of malignant cells or infection. Open biopsy allows selection of specific areas for biopsy in these situations.

Biopsy Technique

The patient may be brought to the hospital on the day of the biopsy. Laboratory evaluation must include a complete blood cell count with normal platelet count, partial thromboplastin and prothrombin times. On rare occasions, infusions of platelets or fresh frozen plasma may be necessary to allow renal biopsy in critical clinical situations in which histopathologic diagnosis is essential. Adequate control of hypertension before the procedure is important as hypertension is a risk for post biopsy bleeding (31). Before biopsy is done, ultrasound examination must confirm that there are two kidneys in normal position. The biopsy optimally is timed so that an experienced technician or pathologist can attend to ensure prompt processing of the biopsy tissue.

Food and drink should have been withheld for at least 6 h before biopsy, and the child should be lightly sedated. The child lies in the prone position with a sandbag or

Table 24-1

Characteristic abnormalities of glomerular diseases

Disease and typical clinical presentation	LM pattern	IF Staining			EM, Other Findings
		Mesangial	Subepithelial	Subendothelial	
Hematuria/nephritis					
Alport's syndrome	Early: normal Late: sclerosis	–	–	–	Thin and thick, split GBM
Mesangial lupus nephritis ISN/RPS II	Mesangial proliferation	+ All Igs, C3, C4	–	–	Immune deposits by EM, reticular aggregates in endothelial cells
Focal lupus nephritis ISN/RPS III	Proliferative, <50% of glomeruli	+	+ (few)	+ (Scattered)	Immune deposits by EM, reticular aggregates in endothelial cells
		–All Igs, C3, C4–			
Diffuse lupus nephritis ISN/RPS IV	Proliferative, >50% of glomeruli wire loops	+	+	+ (wire loop)	Immune deposits by EM, reticular aggregates in endothelial cells
		–All Igs, C3, C4–			
IgA nephropathy	Mesangial proliferation	+ Predominantly IgA	–	–	Immune deposits by EM
Henoch-Schönlein purpura	Mesangial and ± endocapillary proliferation, ± crescents	+ –	+/– Predominantly IgA	+/– –	Immune deposits by EM
Post-infectious GN	Endocapillary proliferation, PMNs	+ Coarsely granular IgG, C3	+ Coarsely granular IgG, C3	–	Irregular, hump-like deposits on top of GBM by EM
Hemolytic-uremic syndrome	Glomerular/arteriolar thrombosis	–	–	–	Increased lamina rara interna by EM, swollen endothelial cells, no deposits
MPGN I	Endocapillary proliferation, lobular double contour GBMs	+ IgG, C3	–	+ IgG, C3	Subendothelial immune deposits by EM, cellular interposition
MPGN II (dense deposit disease)	Mesangial, ± endocapillary proliferation, ribbon-like capillary wall	± C3 globular	– Ribbon-like, C3	Discontinuous	Intramembranous, mesangial non-immune dense deposits by EM
Nephrotic syndrome					
Minimal change disease	Normal	–	–	–	Effacement of podocyte foot processes No deposits
Focal segmental glomerulosclerosis	Segmental glomerulosclerosis, glomerular hypertrophy	+/– IgM, C3	–	–	Effacement of podocyte foot processes, no deposits
Diabetic nephropathy	Increased mesangial matrix, ± nodular, thick GBM, hyalinized arterioles	–	–	–	Thick GBM without deposits

Table 24-1 (Continued)

Disease and typical clinical presentation	LM pattern	IF Staining			EM, Other Findings
		Mesangial	Subepithelial	Subendothelial	
Membranous lupus nephritis ISN/RPS V	Thick GBM, spikes on Jones' stain	Scattered	+	–	Subepithelial, mesangial immune deposits
		+	–All Igs, C3, C4–	–	Reticular aggregates in endothelial cells
Idiopathic membranous GN	Thick GBM, spikes on Jones' stain	–	+	–	Subepithelial immune deposits
		–	IgG, C3–	–	
RPGN					
Anti-GBM disease	Focal segmental necrosis of glomeruli, crescents	–	Linear staining of GBM	–	No deposits by EM
			IgG, C3		
Wegener's granulomatosis	Focal segmental necrosis of glomeruli, crescents	–	–	–	No deposits by EM
Microscopic polyangiitis	Focal segmental necrosis of glomeruli, crescents	–	–	–	No deposits by EM

rolled sheet under the abdomen, and the skin of the flank is "prepped" and draped in sterile fashion. Although the left kidney is usually preferred, either side can be chosen for biopsy. The lower pole of the kidney is marked on the skin with a pen after localization by any of several imaging techniques, such as fluoroscopy, radionuclide scanning, intravenous urography, computed tomography (CT), or ultrasound, the last being the most commonly used method. Local anesthetic is infiltrated first in the skin and then in deeper tissues, taking care not to enter the kidney. In younger children who cannot reliably cooperate in this manner, biopsy is done under anesthesia. Conventional or spring-loaded needles are used for renal biopsies. Most now use the spring-loaded so-called "biopty gun". For conventional needles, the biopsy needle is inserted to the desired position as the patient again holds his or her breath, advancing the cannula over the obturator once the needle is in correct position. The entire needle with the core of tissue is then removed.

The use of an automatic spring-loaded biopsy system has been used widely in the last years because of the simplicity and ease of the technique (32, 33). The kidney is localized with ultrasound guidance, and the depth of the kidney as judged by ultrasound. The biopsy needle is advanced to the kidney capsule under ultrasound observation and guidance. The patient may hold his or her breath for only a few seconds while the spring-loaded needle is activated, causing the obturator to automatically advance into the kidney, and the entire needle is then removed with the tissue core. The speed of automated biopsy needles, however, minimizes the need for the patient to hold respirations, required with conventional needles. It is important to note that the caliber of the needle used with any of these techniques directly impacts the adequacy of the specimen (34). When 18-gauge needles are used with this method, the resulting cores are very small and there is artifact along the edges. The use of a 16-gauge needle thus is more likely to provide an adequate tissue sample without distortion and with fewer passes necessary to obtain adequate tissue.

Usually two cores of tissue are necessary for optimum evaluation, or three cores if 18-gauge needles are used. If tissue cannot be obtained after several passes, the biopsy should be attempted on another day. After biopsy, a dressing is applied, and the child is kept supine in bed for 6 h and monitored with frequent checks of vital signs and urine for hematuria.

Increasingly, percutaneous native and transplant renal biopsies are performed as same day procedures in pediatric patients so that hospital admission is not required. Those with post biopsy perinephric hematomas, post biopsy gross hematuria, or very young children can be observed overnight so that hemostasis is assured (35–37). Open biopsy can be performed under local or general anesthesia. The kidney can be directly visualized even through a small incision. Although a larger sample may be obtained with a wedge biopsy, it is preferable to also perform a needle biopsy to sample deeper cortex and

medulla for assessment of diseases that preferentially involve juxtamedullary glomeruli (see below).

Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy technique is used most often in the transplant setting for analysis of immunologically activated cells. FNA can be useful in evaluating type 1 acute rejection (38). FNA can also obtain material for culture. A modified FNA technique has been described for collection of glomeruli from either native or transplant kidneys to analyze glomerular lesions. This FNA technique has limitations in sample size and is obviously not suitable for study of vascular or fibrotic processes. The less invasive nature of the procedure makes it amenable to serial monitoring of interstitial cellular infiltrates in transplanted kidneys (39).

Complications

Important complications occur in 5–10% of patients (26, 40–48). Major complications, usually bleeding, leading to nephrectomy occurred in 5 patients in a review of 8,081 (48), and 1 patient in a series of 5,120 biopsies. In a series totaling 1,820 biopsies in children, 1 nephrectomy resulted (40–45). Transient microscopic hematuria is universal after biopsy, although macroscopic hematuria is seen in only 5% and requires transfusion in up to 2.3% of patients. Perirenal hematoma is most often asymptomatic and can be seen by CT in up to 85% of biopsies. Symptomatic hematoma is rare, occurring in less than 2%. Arteriovenous fistulae are symptomatic with hematuria, hypertension, or cardiac failure in only 0.5% of biopsies, although bruits may be detected in as many as 75% of patients. Most fistulae heal within a few months. Other complications have been reported, including inadvertent puncture of other viscera or major renal vessels, sepsis, renal infection, and seeding of cancer. Death is rare, less than 0.1% in reviews of large series. Complication rates appear to be slightly higher in less developed countries (40, 42). Complications for the spring-loaded needle biopsy system appear to be similar to conventional needles if the same gauge is used (49). Complications relate in part to the number of passes made to obtain tissue. Therefore, the lower rate of complication with an 18-gauge spring-loaded needle in some studies is offset largely by the need for more passes for adequate samples and the distortion of tissue and edge artifact with use of an 18-gauge needle (see above).

Assessment of the Renal Biopsy

Adequacy of Sample

Cores of fat and connective tissue will float when placed in saline, but a core of renal parenchyma will sink. The biopsy sample should also be visually inspected with a dissecting microscope or hand lens. Glomeruli are visualized as small red dots in the biopsy core. Scarred glomeruli may be difficult to identify since they are not perfused. In diffuse disease, such as membranous glomerulopathy, one glomerulus may be adequate for diagnosis. However, in other diseases, such as crescentic glomerulonephritis, FSGS, or lupus nephritis, disease may be focal. The greater the number of glomeruli sampled, the lower the probability of missing a focally distributed lesion (50). If only 10% of glomeruli in the kidney are involved by the focal process, a biopsy sample of only 10 glomeruli has a 35% probability of missing the lesion, decreasing to 12% if the biopsy contains 20 glomeruli. When one-fourth of glomeruli are involved in the kidney, there is only a 5% chance of missing the abnormal glomeruli in a biopsy of 10 glomeruli. A biopsy of 20–25 glomeruli is sufficient to distinguish between mild disease (less than 20% of glomeruli involved), moderate disease (20–50% of glomeruli involved), or severe disease (more than 50% of glomeruli involved). Unfortunately, the widespread use of small gauge spring-loaded biopsy needles often results in smaller samples, which make the above assessments difficult or impossible. The sample site must also be considered in evaluating the adequacy of tissue. Even a large biopsy, consisting only of superficial glomeruli, cannot exclude the presence of early FSGS, in which the initial involvement is in the juxtamedullary glomeruli. Likewise, although nephronophthisis is most often diagnosed clinically, a juxtamedullary biopsy would be necessary for its morphologic diagnosis.

Allotment of Tissue

Renal tissue should be studied by light microscopic techniques with special stains (hematoxylin and eosin, modified silver stain [periodic acid/methenamine or Jones' stain], periodic acid-Schiff), IF, and EM (51–53). The tissue is divided so that glomeruli are present in each portion of the sample. Optimally, the pathologist or an experienced histotechnologist will attend the biopsy and inspect and allot tissue for each study. If this is impossible, tissue may be placed in saline and brought directly to the laboratory for prompt processing. It is important to handle the tissue gently so that artifacts do not occur.

The fresh tissue must not be picked up with forceps because this will crush and distort the morphology. The core can be handled carefully with a wooden stick or pipette. The core should not be placed on a sponge or gauze pad because this may cause a divotlike artifact as the unfixed tissue molds to the holes of the underlying surface. The biopsy specimen is therefore placed on a clean smooth surface, such as a wax board, for cutting.

It may be difficult to identify the cortical end of the specimen even after inspection with a hand lens or dissecting microscope when scarring or severe injury is present. Therefore, we recommend cutting two 1-mm pieces with a sharp blade from each end of the core for electron microscopic studies. The remaining core is then divided into specimens for IF and LM. Of note, use of an 18-gauge needle yields tissue cores that are too thin to divide lengthwise, leading to a greater chance of problems in allocation of tissue for each method of study. This tissue should be cut across into two pieces for IF and LM. When two cores are obtained, we prefer to duplicate this process, rather than allocating one complete core to one study to maximize chances of adequacy of tissue for each study. When the tissue sample obtained is very small, the nephrologist and the pathologist should consider the differential diagnosis and allocate tissue accordingly. For example, in a case of suspected IgA nephropathy, tissue for IF is most important. Although electron microscopic studies can be done on other portions of tissue (as long as mercury-based fixatives have not been used), IF studies on fixed tissue are not as reliable. When tissue for EM is inadequate, portions of the paraffin-embedded tissue left after light microscopic examination may be cut out from the block and processed for EM. Although the quality is not optimal, diagnostic findings can still be discerned. In special circumstances, when no tissue remains in the paraffin block and a focal lesion in one section must be studied, one may attempt to process the tissue section from a glass slide for EM.

Light Microscopy

Numerous fixatives are used for light microscopic examination, and they vary from institute to institute. Satisfactory results may be obtained with Zenker's, Bouin's, formalin, Carnoy's, or paraformaldehyde. Material for IF studies may be snap frozen immediately at −20°C in solutions of isopentane, dry ice, acetone, or freon and embedded in Tissue-tech, OCT, or other compounds for frozen sections. If tissue cannot immediately be snap frozen, it may be placed in Michel's tissue media, where it may be stored for up to 1 week before freezing. This allows tissue to be sent to reference laboratories for appropriate processing. Tissue for EM may be fixed in glutaraldehyde, formaldehyde, or other appropriate non-mercury fixatives. Tissue placed in glutaraldehyde should be promptly processed, or if stored for future possible processing, should be transferred to an appropriate buffer solution within a week to avoid artifacts. Tissue for LM is routinely processed, embedded in paraffin, and cut into 2- to 3-μ thick sections. Serial sections with multiple levels are then prepared for examination.

If water-soluble compounds are expected, such as urate or uric acid, the tissue should be fixed in ethanol. Lipids are best detected in frozen sections because they are extracted during xylene processing for paraffin sections. Hematoxylin and eosin stains are most useful for overall assessment of the interstitium and crystals. This stain also allows particularly good visualization of infiltrating cells, especially eosinophils. In addition, fibrin may be easily visualized by this stain. Periodic acid-Schiff (PAS) stains glycoproteins and accentuates basement membranes and matrix material and allows definition of the brush border of proximal tubular cells. Areas of hyalinosis and protein precipitation, including cryoglobulin (which usually is dominantly IgM), are also accentuated with PAS. Silver stains, such as Jones' stain, stain basement membrane material but not deposits, thus allowing distinction of these components. Masson's trichrome stain detects areas of collagen deposition by staining bluish. Other special stains, such as immunohistochemistry for specific molecules, may be indicated. Congo red stain detects amyloid. Special stains can detect bacterial or fungal organisms and acid-fast bacilli. Special techniques may also be used on the light microscopic material. These include polarization to detect crystals or foreign bodies and morphometry to assess glomerular size (see below) and severity of interstitial fibrosis quantitatively.

Immunofluorescence

IF studies are most commonly done by direct IF on frozen tissue sections with application of fluorescein-conjugated antibodies directed against IgG, IgA, IgM, and complement component C3. Additional antisera may be used as clinically indicated. These include antisera to kappa or lambda light chain, antisera to hepatitis B antigen, thyroglobulin, fibrinogen, C1q, C4 cyantisera to type IV collagen chains and C4d. Some of these antigens are recognized by antisera even after fixation and can be detected by immunohistochemical techniques (e.g., immunoperoxidase) on the formalin-fixed tissue sections and then studied

with a light microscope. This technique requires enzyme pretreatment of tissue, which must be tailored exactly depending on length and type of fixation, section thickness, and antigen one wishes to study. Direct observation of the digestion process, stopping when all plasma is removed from capillary loops has been used to achieve reliable results (54). These challenges have prevented widespread use of this technique in the USA.

Frozen tissue sections stained by the commonly used method of fluorescein-conjugated antibodies are viewed by IF microscopy, evaluating staining in glomeruli, vessels, tubules, and interstitium. The pattern of glomerular staining is assessed to define granular or linear capillary wall staining or mesangial deposits. Arteriolar staining may be of diagnostic significance. Tubules may show deposits in lupus nephritis, light chain deposition disease or linear staining in the rare anti-TBM antibody disease. Nuclear staining can be seen in lupus or lupuslike diseases as a tissue manifestation of the patient's positive ANA. IF is more sensitive than EM in identifying immune deposits, although EM provides more detailed information on the exact localization of those deposits (52, 53). Lesions of interest should be photographed because fluorescence fades on storage and with light exposure.

Electron Microscopy

Tissue for EM is processed with postfixation in 1% osmium tetroxide, which enhances contrast of the tissue, and then dehydrated and embedded. With new, more rapidly polymerizing embedding media, such as Spurr, tissue may be ready for examination within 1 day. Electron microscopic study was found to add information in 6–11% of renal biopsies in a study from 1983 (27). In a 1997 study, EM was needed to make a diagnosis in 21% of cases, and provided important confirmatory data in approximately 20% of cases (52). EM showed diagnostic pathological abnormalities in 18% of patients with "normal" light microscopic findings. Larger, so-called thick scout sections (1 μ) are stained with toluidine blue to select smaller areas for thin sectioning for the electron microscope. Usually, the glomerulus containing the most representative lesion is chosen, but sclerotic glomeruli are not useful to examine by EM. If there are irregular or focal proliferative lesions, several glomeruli may be sampled, including the proliferative ones. The 60–90 Å thin sections are stained with uranyl acetate and lead citrate before viewing in the EM scope, to enhance contrast.

Immune complex deposits are nonmembrane-bound and denser than basement membrane or matrix materials. In specific diseases, such as cryoglobulinemia, amyloid, immunotactoid or fibrillary glomerulopathies, or lupus nephritis, specific substructure of deposits may be seen. Specific localization of immune complexes is done by EM examination, indicating whether deposits are subendothelial, subepithelial, mesangial, or in all of the above compartments. In some diseases, such as light chain deposition disease or lupus nephritis, deposition may also be seen in vessels and tubules. So-called fingerprint deposits, with substructure reminiscent of fingerprinting, are present in some cases of lupus nephritis. Reticular aggregates (or so-called tubular arrays) of membrane material in endothelial cell cytoplasm throughout the body are characteristically seen in large numbers in patients with SLE or HIV infection, thought to reflect a response to high levels of interferon (53, 55).

EM also delineates specific basement membrane abnormalities. For instance, small subepithelial deposits without surrounding new basement membrane material do not result in spikes, and therefore cannot be visualized by Jones' stain on LM, but can still be detected directly by EM. The lamina densa of the GBM is markedly thickened in diabetic nephropathy. Circumferential cellular interposition is defined by extension of monocytes and mesangial cell cytoplasm into the subendothelial space, with newly formed basement membrane interpositioning between the advancing infiltrating cells and the endothelium with intervening basement membrane material, thus giving rise to the classic double contours seen with silver stain by LM in MPGN. Increased lucent material is present in the expanded lamina rara interna in transplant glomerulopathy, HUS, ecclampsia and other diseases presumed to involve endothelial injury/coagulopathy. In these conditions, deposition of fibrin, fibrinogen and their degradation products may also occur. Fibrin is recognizable by its dense, coarse sheaflike structure by EM, with periodicity observed in favorable sections. Morphometry of the GBM from EM prints is used to diagnose thin basement membranes in hereditary nephritides. EM also allows structural assessment of changes of specific cells (see below). Diagnostic inclusions are seen in various storage/metabolic disease, such as Fabry's disease.

Basic Renal Lesions

Normal

During fetal maturation, the glomerular capillary tufts are initially covered by large, cuboidal, darkly staining epithelial

cells with only small lumina visible (Fig. 24-1). The cells lining Bowman's space undergo similar change from initial tall columnar to cuboidal to flattened epithelial cells, except for those located at the opening of the proximal tubule, where cells remain taller. Immature nephrons may occasionally be seen in the superficial cortex of children up to 1 year of age. Glomerular growth continues until adulthood, with average normal glomerular diameter approximately 95 μ in a group of patients less than 5 years old (average age 2.2 years) and 140–160 μ in adulthood (57, 58).

The normal mature glomerulus consists of a complex branching network of capillaries originating at the afferent arteriole and draining into the efferent arteriole. The glomerulus contains three resident cell types: mesangial, endothelial, and epithelial cells (Fig. 24-2). The visceral epithelial cells (podocytes) cover the urinary surface of the GBM with pseudopodlike extensions called foot processes, with intervening filtration slits. Endothelial cells are opposed to the inner surface of the GBM and are fenestrated. At the stalk of the capillary, the endothelial cell is separated from the mesangial cells by intervening mesangial matrix. The term *endocapillary* is used to describe proliferation filling up the capillary lumen, contributed to by proliferation of mesangial, endothelial and infiltrating inflammatory cells. In contrast, *extracapillary* proliferation refers to proliferation of the parietal epithelial cells that line Bowman's capsule.

The mesangial cell is a contractile cell that also has phagocytic properties. It lies embedded in the mesangial matrix in the stalk region of the capillary loops, attached to anchor sites at the ends of the loop by thin extensions of its cytoplasm. Normally up to three mesangial cell nuclei per lobule are present. The basement membrane consists of three layers distinct by EM, the central broadest lamina densa and the less electron-dense zones of lamina rara externa and interna. Thickening occurs with maturational growth. Most investigators have found thicker basement membranes in boys, with normal range from 220 to 260 nm at 1 year of age, 280 to 327 nm at age 5 years, 329 to 370 nm at age 10 years, and 358 to 399 nm at age 15 years (59, 60). In our laboratory, we found a range of GBM thickness in children with normal kidneys from approximately 110 nm at age 1 year to 222 ± 14 nm at 7 years of age.

The glomerulus is surrounded by Bowman's capsule, which is lined by parietal epithelial cells. These are continuous with the proximal tubule, identifiable by its

Figure 24-1

Schematic illustration of glomerulus, with glomerular capillary attached to a mesangial stalk area. The glomerular endothelium *(E)* is fenestrated and lines the glomerular basement membrane *(GBM),* which covers the mesangium. The outside of the GBM is covered by the epithelial cell and its foot processes *(Ep)*. The mesangial cell *(M)* is embedded within the mesangial matrix *(MM),* with processes connecting to the GBM (Provided courtesy of Professor Wilhelm Kriz with permission from (56).

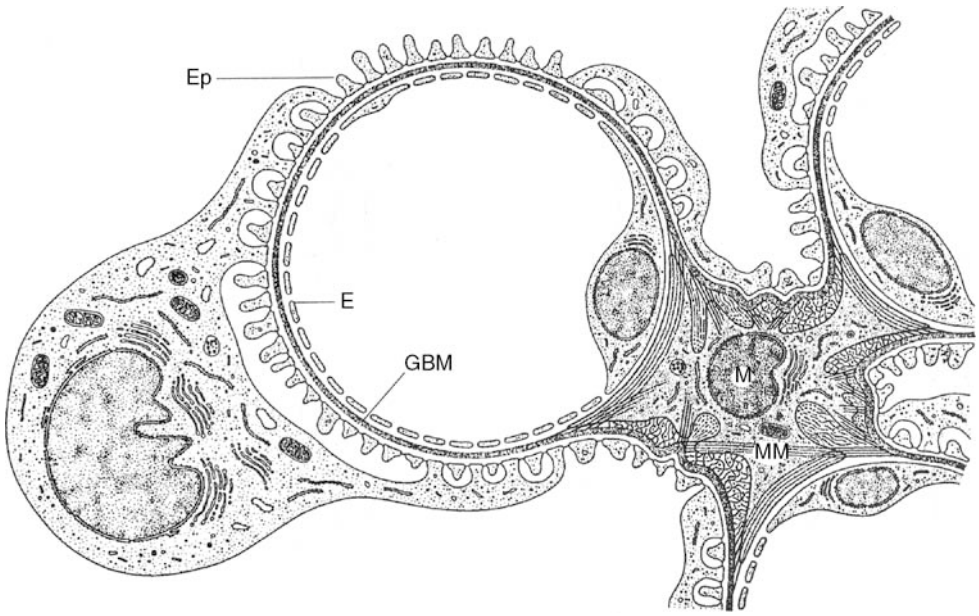

Figure 24-2
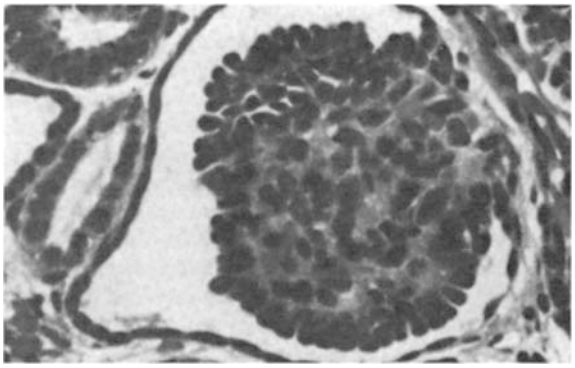
Immature glomerulus with plump, dark epithelial cells from biopsy of a 29-week-gestation baby (PAS, ×670).



PAS-positive brush border. The efferent and afferent arterioles can be distinguished morphologically in favorably oriented sections or by tracing their origins on serial sections. Segmental, interlobular, and arcuate arteries may also be present in the renal biopsy specimen. The cortical biopsy also allows assessment of the tubules and interstitium. Proximal tubules are readily identified by their PAS-positive brush border, lacking in the distal tubules. Collecting ducts show cuboidal, cobblestonelike epithelium. Tubules are normally back-to-back with minimal interstitial cells and the peritubular capillaries intervening. The medulla may also be included in the biopsy.

Overall Pattern

Assessment of the biopsy specimen must include inspection of all sections from different levels because additional glomeruli may be sampled on deeper cuts of the biopsy core and many diseases are characterized by focal lesions. The severity and patterns of lesions are assessed, and normal and affected glomeruli are counted. Lesions are classified as focal if only some (less than half) glomeruli are involved, diffuse if all (or most) glomeruli are involved, segmental if only portions of glomeruli are involved, and global if entire glomerular tufts are involved. Characteristic glomerular disease patterns include lobular proliferation in MPGN, nodular proliferation of mesangial cells and abundant matrix material in characteristic Kimmelstiel-Wilson lesions, focal and segmental sclerosis, intraglomerular/arteriolar fibrin thrombi, necrotizing lesions and crescent formation (*Table 24-1*). The crescent, a lesion due to proliferation of mostly parietal epithelial cells, owes its name to its shape in well-established lesions.

Glomeruli are assessed for alterations in size (see below). It is important to compare with a normal control for a given age group because marked glomerular maturational growth occurs in children. Glomerular hypertrophy may be an important predictor of increased risk of FSGS in children with apparent MCD (see below). Maturational pattern of glomeruli (see above) should be noted. Occasional fetal glomeruli may be found in children beyond infancy and are not of specific diagnostic significance.

Glomeruli are assessed for glomerulosclerosis, that is, the presence of segmental obliteration and scarring of glomerular capillary tufts. Sclerosis may be in a segmental or global pattern (*Table 24-2*). Previous studies suggested that up to 10% of glomeruli may be normally globally sclerosed in people younger than 40 years of age (61). This number may be even smaller in children, with less than 1–3% global sclerosis expected normally up to age 40 or 56, respectively (62, 63). These occasional globally sclerotic glomeruli are thought to represent errors of nephrogenesis. The percentage of global sclerosis increases even with normal aging, up to half the patient's age, minus 10 (63). Globally sclerosed glomeruli in greater percentage indicate the possibility of renal disease (focal global sclerosis) (64).

The pattern of tubulointerstitial fibrosis, whether proportional to glomerular sclerosis or not, whether diffuse or present in a "striped" pattern following the medullary rays, or in broad patchy zones, has diagnostic significance (see below).

Specific Glomerular Cells

Podocytes

The podocytes (glomerular visceral epithelial cells) may show vacuolization in various diseases with severe proteinuria. Although more extensive vacuolization of podocytes has been seen in FSGS compared with patients with MCD (65), these changes are only seen after established sclerotic lesions are identifiable by LM and do not permit distinction of these two disease processes in the early phase in which segmental sclerosis may be undetected. Hypertrophy of podocytes is prominent in MCD and FSGS. Effacement of the foot processes of the podocytes by EM is common to any disease with marked proteinuria, and the podocyte may also show microvillous transformation, with long, attenuated pseudopods. Podocytes are limited in their ability to proliferate. However, the early sclerotic lesion of FSGS is characterized by prominence and apparent increase of the overlying podocytes

Table 24-2

Definitions of common morphological terms

Light microscopy	
Focal	Involving some glomeruli
Diffuse	Involving all glomeruli
Segmental	Involving part of glomerular tuft
Global	Involving total glomerular tuft
Lobular	Simplified, lobular appearance of capillary loop architecture (MPGN)
Nodular	Acellular areas of mesangial matrix (diabetic nephropathy)
Sclerosis	Obliteration and scarring of capillary loop
Crescent	Proliferation of parietal epithelial cells
Spikes	Projections of glomerular basement membrane intervening between subepithelial immune deposits (membranous GN)
Endocapillary proliferation	Increase in mesangial and/or endothelial cells
Hyaline	Descriptive of glassy, smooth appearing material
Hyalinosis	Hyaline-appearing insudation of plasma proteins (focal segmental glomerulosclerosis)
Mesangium	Stalk region of capillary loop with mesangial cells surrounded by matrix
Subepithelial	Between podocyte and glomerular basement membrane
Subendothelial	Between epithelial cell and glomerular basement membrane
Tram-track	Double contour of glomerular basement membrane due to deposits and/or CMIP (see below)
Wire loop	Thick, rigid appearance of capillary loop due to subendothelial deposits
Activity	Score of possible treatment sensitive lesions, based on e.g., extent of crescents, cellular infiltrate, necrosis, proliferation
Chronicity	Score of probable irreversible lesions, based on e.g., extent of tubular atrophy, interstitial fibrosis, fibrous crescents, sclerosis
Immunofluorescence microscopy	
Granular	Discontinuos flecks of staining along capillary loop producing granular pattern
Linear	Smooth continuous staining along capillary loop
Electron microscopy	
Foot process effacement	Flattening of foot processes so that they cover the basement membrane
Microvillous transformatiom	Small extensions of epithelial cells with villus-like appearance
Circumferential mesangial interposition (CMIP)	Extension of cell cytoplasm with interpostion between endothelial cell cytoplasm and basement membrane and underlying new basement membrane formation
Reticular aggregates	Organized arrays of membrane particles within endothelial cells
Immunotactoid GP	Large, organized microtubular deposits, >30 nm diameter
Fibrillary GP	Fibrils 14–20 nm diameter without organization

GP glomerulopathy

("capping" lesion), often associated with endocapillary foam cells. This cellular variant of FSGS may be more common in children than in adults with FSGS (66). The idiopathic collapsing variant of FSGS and HIV-associated nephropathy both show prominent hyperplasia and protein droplets of the podocytes, with overlying segmental collapse of the glomerular capillary tuft. In the situation of recurrent FSGS in the renal transplant, NS and foot process effacement may be seen within weeks after biopsy, with sclerosis becoming apparent at a later date (67). In Fabry's disease, there is accumulation of glycosphingolipid because of deficiency of alpha-galactosidase. Podocytes show marked vacuolization by LM with characteristic whorled, laminated electron-dense myelin bodies by EM. In Fabry's disease, these inclusions may also be present in endothelial cells, tubular epithelial

cells, some interstitial cells, and the vessels in early lesions in children (27, 53, 68).

Mesangial Cells

Hyperplasia of mesangial cells is recognized by LM when more than three mesangial cell nuclei are present per mesangial region. Increased mesangial prominence may be due to increased cellularity, increased matrix, deposits, or a combination. Large mesangial deposits appear on Jones' stain as pinkish areas surrounded by the light silver-staining areas of mesangial matrix. So-called interposition results when the monocyte or mesangial cell cytoplasm extends outward between basement membrane and endothelial cells and new matrix accumulates between the mesangial and endothelial cell bodies.

Endothelial Cells

Extreme proliferation and swelling of endothelial cells can obliterate capillary lumina in conditions characterized by abnormalities of coagulation. Endothelial cells usually contain characteristic reticular aggregates in lupus nephritis and HIV-associated nephropathy (53, 55). Endocapillary cell proliferation is characteristic of for example diffuse proliferative lupus nephritis and MPGN type I.

Crescents

Crescents consist primarily of proliferating parietal epithelial cells with some infiltrating macrophages and are a manifestation of severe glomerular injury. The name reflects the often crescent-shaped sheet of cells filling up part or nearly all of Bowman's space. Crescents result from injuries that break the GBM, leading to exudation of plasma protein and formation of fibrin within Bowman's space, which then induces proliferation of the parietal epithelial cells and infiltration of macrophages. When crescents are a prominent histologic feature, the patient most often presents clinically with a rapidly progressive glomerulonephritis.

Crescents may occur in a variety of diseases. Diseases with crescents as a primary manifestation include antibody-mediated injury (anti-GBM antibody disease), severe immune-complex diseases (e.g., lupus nephritis) and pauciimmune diseases. The latter are often, but not invariably, associated with positive ANCA tests, and may be associated with systemic disease, or be renal limited. The p-ANCA (anti-myeloperoxidase) pattern is most often associated with microscopic polyangiitis, whereas the c-ANCA (anti-proteinase-3) pattern is typical in Wegener's granulomatosis. Of note, positive ANCA tests are not sensitive in distinguishing these categories (15–17). Renal biopsy is therefore critical for accurate diagnosis. Diagnosis and appropriate treatment must occur rapidly in this clinical situation to optimize chances of recovery of renal function. The early lesion of cellular crescents is responsive to cytotoxic therapy. Biopsy indications of irreversible renal damage include breaks of Bowman's capsule and fibrous transformation of the cellular crescents, periglomerular fibrosis, and scarred glomeruli and tubulointerstitium.

Glomerular Basement Membrane

GBM abnormalities are best evaluated by EM. The basement membrane is abnormally thick in diabetic nephropathy (53). Diffuse abnormally thin GBMs, less than 250 nm in adults, are seen in familial hematuria (59, 60). GBM thinning cannot be accurately from EM processed from paraffin tissue, as this back-up technique causes artifactual and variable thinning of GBMs (69). In children, the diagnosis of thin basement membranes is more difficult than in adults because GBM increases in thickness with normal maturation. Glomerular basement membrane thickness should be compared with normal for age and sex (see above; 59, 70, 71). In Alport syndrome, the basement membrane in established lesions is characterized by irregular areas of very thin and very thick, with splitting and splintering of the basement membrane (25, 72). The GBM in nail-patella syndrome is irregular, thickened, and split, with electron-lucent areas containing banded collagen type I fibers (53).

Immune deposits may localize on either side of the GBM. Subepithelial immune deposits are characteristically seen in membranous glomerulopathy. Subendothelial immune deposits are seen for example in proliferative lupus nephritis or MPGN type I.

The basement membrane may appear split by LM in diseases other than MPGN type I or dense deposit disease. In transplant glomerulopathy, the split appearance results from varying degrees of cellular interposition and widening, with increased lucent material in the lamina rara interna. This is also a characteristic finding in preeclampsia, transplant glomerulopathy and chronic HUS or other chronic thrombotic microangiopathies (53).

Tubules

Morphologically evident tubular necrosis correlates poorly with the clinical extent of acute kidney injury (AKI).

The changes vary from nondiagnostic vacuolization to frank necrosis with sloughing of tubular epithelial cells (toxic type) and flattened epithelium characteristic of regeneration (ischemic type). In cortical necrosis, zones of cortex, including glomeruli, are necrotic. In chronic kidney disease, tubules are atrophied with dilation and flattened epithelium, presumably secondary to lesions affecting the glomerulus, although primary tubular and interstitial injury mechanisms may also be involved in these changes. Tubular atrophy is also present in primary tubulointerstitial diseases. Tubulointerstitial fibrosis is an important manifestation of calcineurin inhibitor toxicity. The fibrosis occurs along the medullary rays due to the more severe ischemia occurring in these areas, resulting in a striped, rather than diffuse, pattern of fibrosis, with intervening preserved tubules.

Nonspecific casts of Tamm-Horsfall protein are seen in chronic kidney disease. Other casts may have a diagnostic appearance, such as the giant cells surrounding tubular casts in light chain cast nephropathy (so-called myeloma kidney). Casts of myoglobin with characteristic reddish-brown appearance are seen in rhabdomyolysis, often with associated acute tubular necrosis. Crystals, for example oxalate or cysteine, may be identified by examination under polarized light (73). Tubules contain characteristic inclusions in Fabry's disease (68).

Polymorphonuclear neutrophils (PMNs) within collecting ducts and proximal tubules are diagnostic of acute pyelonephritis. In chronic pyelonephritis, there is tubular atrophy and interstitial fibrosis, characteristically in a patchy, regional distribution (geographic or "jigsaw" pattern). The combination of segmental glomerular sclerosis with ischemic changes of corrugation and thickening of the GBM and periglomerular fibrosis, and patchy, regional interstitial fibrosis and tubular atrophy is also characteristic of reflux nephropathy (74).

Cysts may be demonstrated by biopsy, although the diagnosis of specific cystic diseases is usually made by combination of clinical and ultrasound findings. The segment of the nephron giving rise to the cysts can be identified by histochemical stains (75). Areas of low cuboidal epithelial-lined structures surrounded by a cuff of immature mesenchyme are present in the dysplastic kidney, often with cartilage, fat, or abnormal blood vessels in the interstitium. The deep medullary cystic dilation with thickened, lamellated TBM characteristic of nephronophthisis can be identified with a deep biopsy. Dilation of proximal tubules with microcyst formation in conjunction with extensive foot process effacement by EM is characteristic of congenital nephrotic syndrome of Finnish type. FSGS in a collapsing patten with podocyte hyperplasia, numerous reticular aggregates by EM, and with tubular cystic dilation and interstitial fibrosis out of proportion to the severity of glomerular lesions are highly suggestive of HIV-associated nephropathy (55).

Viral infections, including BK and CMV, result in characteristic nuclear inclusions in tubular epithelia. Specific diagnosis is made by immunostaining for viral proteins. Characteristic viral particles may also be detected by EM (76).

Interstitium

Interstitial edema is a nonspecific change, present, for example, in early acute transplant rejection, renal vein thrombosis, or inflammatory processes. Identification of eosinophils in an infiltrate is suggestive of drug-induced interstitial nephritis, although eosinophils are also present in some cases of idiopathic interstitial nephritis (77). Eosinophils can also be part of acute cellular rejection in the transplant. Nonnecrotizing granulomas, with or without eosinophils, most often reflect drug-induced hypersensitivity reaction. A pleomorphic infiltrate of lymphocytes, plasma cells and PMNs suggests possible BK nephropathy in the transplant, confirmed by finding viral nuclear inclusions and positive immunostaining in tubules (see above) (76). Fibrosis results in increased spacing of tubules because of the accumulation of PAS-positive collagenous material. The collagen also stains specifically blue with Masson's trichrome stain. Fibrosis in a striped pattern suggests calcineurin inhibitor toxicity (78, 79). Occasionally, the interstitium is infiltrated by malignancy. Hematopoietic neoplasms are especially prone to involve the kidney. In cystinosis, characteristic rectangular or trapezoid crystals are present mostly in monocyte/macrophages, and can be recognized by EM or when polarized on frozen sections (73).

Vessels

Arterioles and larger segmental and interlobular arteries are evaluated for changes in the intima and media; the presence of deposits, fibrin, hyalin, amyloid, or other material; or the presence of vasculitis. Arterioles show inclusions early in children with Fabry's (68). Larger vessels typically are not sampled by a biopsy, and diseases such as classic polyarteritis nodosa that affect these large vessels are therefore best evaluated by other methods (e.g., arteriography). Intimal fibrosis and medial thickening with hyperplasia and hypertrophy of media are characteristic of hypertensive injury. Concentric medial necrosis

with nodular protein deposition suggest acute calcineurin inhibitor nephrotoxicity (79). Fibrin thrombi, when present in glomeruli and/or arterioles, are the essential lesion of the thrombotic microangiopathies caused by e.g. HUS (53). Fibrin localizes predominantly within glomerular lumina in disseminated intravascular coagulation and hyperacute rejection.

Clinical Pathological Correlations

After evaluation of the structural changes of the renal biopsy in conjunction with the clinical history, a diagnosis may be obvious. In some cases, the biopsy specimen may show overlap features, or there may be elements that do not correlate clearly with the clinical setting. Close collaboration by nephrologists and pathologists is essential in arriving at the diagnosis. The pathologist must be familiar with clinical manifestations of renal disease, and the nephrologist should be familiar with the terminology used by the pathologist to describe the biopsy findings (*Table 24-2*).

When lesions are evaluated, the balance of all elements must be considered. When a typical disease pattern is not present, one must consider whether more than one process is taking place. For instance, drug-induced interstitial nephritis may be superimposed on other glomerular disease. This is especially true in the transplant setting, where multiple disease processes may occur at one time. In some instances, the biopsy findings do not correlate with the patient's renal function. When such apparent discrepancies are found, one possibility is that the biopsy specimen is not representative of all the nephrons of the kidney. The number of glomeruli necessary to estimate the severity of diseases that show focal distribution has been discussed above. However, the extent of glomerulosclerosis may in and of itself not correlate with renal function. Tubular atrophy and interstitial fibrosis may be more closely correlated with extent of renal damage and renal function (80–82). One must also consider the elements other than structure that influence the patient's renal function (i.e., blood pressure, filtration properties of the GBM, and the glomerular filtering surface area). Patients with enlarged glomeruli, either caused by compensatory hypertrophy or by a primary pathological process, may show less deterioration of renal function than expected based on the extent of glomerular scarring. Similarly, treatment of the patient with antihypertensive agents that affect glomerular filtration rate (e.g., ACE inhibitors, which preferentially dilate efferent arterioles) may actually increase serum creatinine levels in the short run. Compensation by remaining nephrons may mask ongoing severe disease processes such that creatinine levels may remain near normal until late in the course of disease when therapy is less likely to have an impact on chronic progressive injury.

Diagnostic Findings in Selected Renal Diseases

Minimal Change Disease/Focal Segmental Glomerulosclerosis

MCD is diagnosed only after the exclusion of abnormal findings at the light microscopic level, with diffuse foot process effacement as the only abnormality by EM. The disease is characteristically sensitive to glucocorticoid therapy. However, repeated renal biopsies in patients with apparent MCD initially have shown progression to FSGS, which has a high incidence of progression to end-stage renal disease (ESRD) (83, 84). As discussed above, a small sample may not include the segmentally sclerotic glomerulus, diagnostic of FSGS. In FSGS, there is often also hyalinosis, an exudation of plasma proteins and lipids with a glassy, smooth (hyaline) appearance on LM. There are no immune deposits, and foot process effacement is present in all glomeruli by EM (*Fig. 24-3*). Mesangial expansion in the native kidney FSGS biopsy may be associated with increased risk for recurrence in the transplant (85).

The presence of IgM by IF without deposits by EM in a biopsy that otherwise appears to be MCD (so-called IgM nephropathy) does not have prognostic value (86). Some variants of FSGS may have prognostic value (87). A recently proposed working classification of FSGS aims to examine whether morphological patterns of FSGS have prognostic implications (*Table 24-3*) (88). The usual type is diagnosed when no special features are present. The collapsing type of FSGS, characterized by collapse of the glomerular tuft, either segmental or global with associated podocyte hypertrophy/hyperplasia, shows a rapid progression to end-stage disease (89). The cellular lesion, with endocapillary proliferation with frequent foam cells and often with podocyte hyperplasia, may represent an early stage of FSGS, and appears to occur more often in children with FSGS than adults (66, 90). The tip lesion, that is adhesion, sclerosis or endocapillary foam cell lesion localized to the proximal tubular pole, appears to have better prognosis (91–93). The perihilar variant, with sclerosis and hyalinosis localized to the vascular pole, likely more often represents a secondary sclerosing process (88).

Figure 24-3

Minimal change disease. The foot processes are effaced (×11,000).

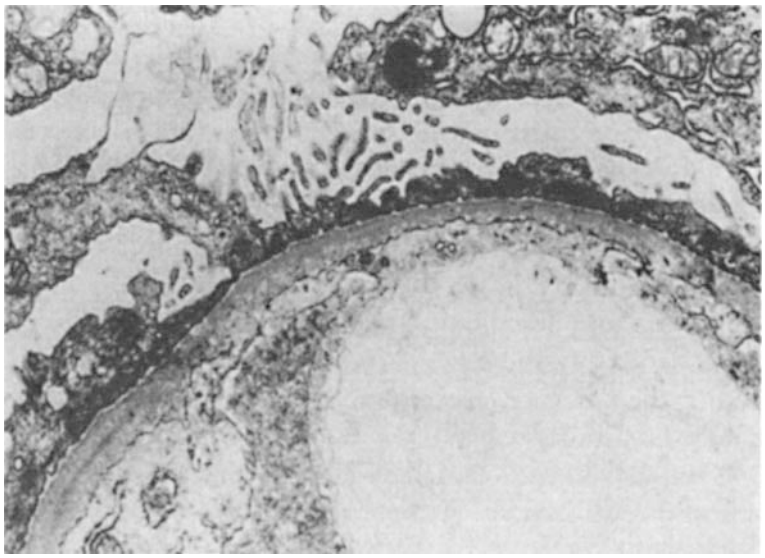


Table 24-3

Working classification of FSGS

Type	Key histologic feature	Possible prognostic implication
FSGS, nos	Segmental sclerosis	Typical course
Collapsing FSGS	Collapse of tuft, GVEC hyperplasia	Poor prognosis
Cellular FSGS	Endocapillary proliferation, often GVEC hyperplasia	?Early stage lesion
Tip lesion	Sclerosis of tuft at proximal tubule pole	?Better prognosis
Perihilar variant	Sclerosis and hyalinosis at vascular pole	?May reflect a secondary type of FSGS

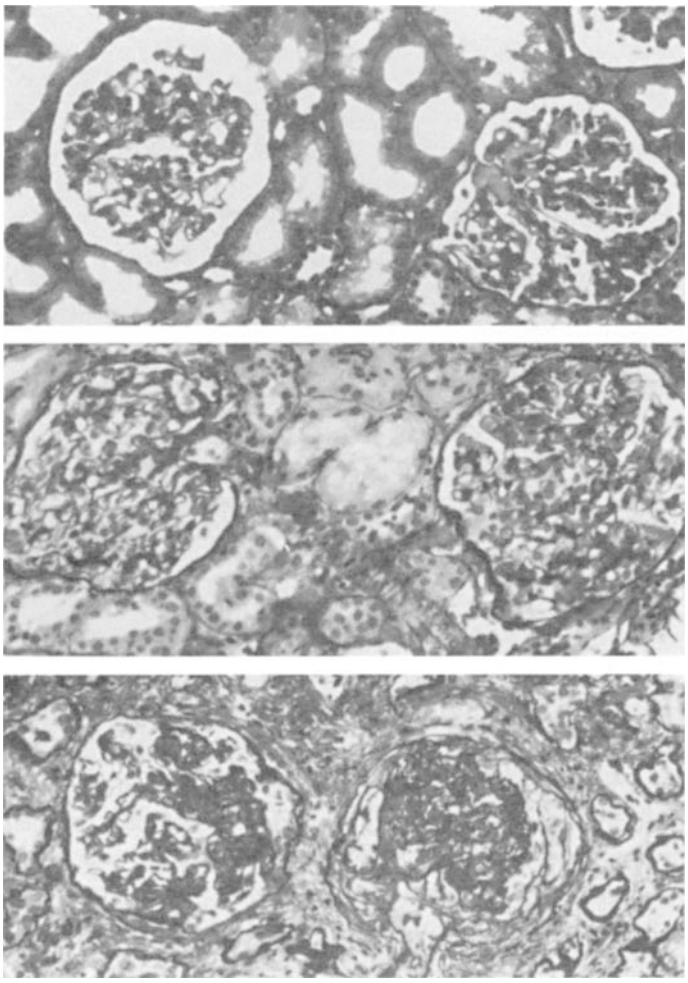
nos not otherwise specified; *GVEC* glomerular visceral epithelial cell

C1q nephropathy is characterized by either no sclerosis or segmental glomerulosclerosis by LM, with mesangial C1q deposits and lesser immunoglobulin components without dominant or codominant IgA (94). EM shows mesangial and paramesangial dense deposits but a lack of reticular aggregates. Patients typically are adolescents and have steroid-resistant NS and do not have clinical evidence of SLE. Although these findings suggest a distinct clinicopathologic entity, the prognostic significance of these lesions has not yet been established. Progression to ESRD has occurred in some patients with sclerosis at biopsy, but long-term outcome of those without sclerosis at presentation has not yet been established.

Because therapy and prognosis are different for MCD vs. FSGS, early distinction of these two entities is of primary interest. We studied pediatric patients with steroid-resistant nephrotic syndrome and MCD on renal biopsies and compared to patients with apparent MCD on biopsy who subsequently progressed to overt FSGS (57). Morphometric analysis of initial biopsies showed that glomerular size at the onset of disease, before sclerosis was apparent, was remarkably larger in patients who subsequently progressed to FSGS (*Fig. 24-4*) (95, 96). There was a higher risk for development of FSGS in patients <5 years old with glomerular area greater than 1.5 times that of normal age-matched controls. On the other hand, glomerular size equal to or less than normal controls in this group of patients indicated a good prognosis. Calculated glomerular diameter for increased risk of FSGS in these patients less than 5 years old was more than 118 μ vs. 95 μ glomerular diameter in age-matched controls. Depending on processing and fixation,

Figure 24-4

Apparent minimal change disease (MCD) with subsequent progression to focal segmental glomerulosclerosis (FSGS). The first biopsy from this 5-year-old girl, *middle panel,* was indistinguishable from MCD, except for marked glomerular hypertrophy vs. age-matched typical MCD with subsequent benign clinical course *(top panel).* The patient's later biopsy, *bottom panel,* 50 months later, showed segmental sclerosis, diagnostic of FSGS (Jones' stain, ×160).



these values may vary (our values are based on paraffin-embedded tissue fixation in formalin or Zenker's fixative). Normal ranges should be established in each laboratory assessing glomerular size.

From these studies, abnormal glomerular enlargement suggests a high probability of development of FSGS in pediatric patients with apparent MCD. Causes of abnormal glomerular enlargement other than idiopathic FSGS, such as diabetes mellitus, cyanotic cardiovascular disease, and massive obesity, must be excluded before such inferences can be made. Interestingly, the incidence of FSGS may be increased in these diseases. The association of abnormal glomerular growth with development of glomerulosclerosis may reflect a pathogenic linkage, in that processes leading to excess matrix and sclerosis may be manifested as glomerular growth. This view is supported by the coexistence of these two processes in many other diseases, including sickle cell diseases, HIV infection, and reflux nephropathy (97).

Alterations of dystroglycans, specific proteins that are expressed along the GBM, may be of use in differentiating MCD in FSGS. α- and β-dystroglycans were decreased in MCD, but preserved in the nonsclerotic areas of FSGS in a small study (98). Recently, molecular studies also indicate distinct gene expression profiles in MCD vs FSGS, with much higher ratio of podocin to synaptopodin in mRNA in the former (99).

Recently, specific gene mutations of podocyte-specific genes have been identified in some forms of familial FSGS. The slit diaphragms are crucial for regulation of permselectivity, and are decreased in density in proteinuric conditions. Mutations of several slit diaphragm genes cause proteinuria and FSGS. The gene for autosomal dominant FSGS has now been localized to ACTN4, at chromosome 19q13. ACTN4 encodes alpha-actinin-4, and a gain-of-function mutation with possible altered actin cytoskeleton interactions has been proposed. The prognosis of this form of familial FSGS has been poor, with progression to renal disease in 50% of patients by age 30. Recurrence of NS in the transplant has been very rare, presumably related to immune events, as the transplant does not carry the mutated gene (100). Autosomal recessive FSGS with early onset and rapid progression to end stage is caused by mutations in NPHS2, which encodes podocin (101). Podocin is expressed only in podocytes and is an integral stomatin protein family member. Its function is not determined. Mutations in NPHS2 have been described in sporadic steroid resistant FSGS (11). TRPC6, a receptor, is mutated in other kindreds with FSGS, with variable penetrance and adult onset (102). Phospholipase C epsilon mutation (NPHS3) recently was found to underly many cases of DMS or rare cases of FSGS, with rare steroid response (103–105). These familial forms do not have specific morphological features of the segmental sclerosis.

Congenital nephrotic syndrome (CNS) of Finnish type shows mesangial hypercellularity or no glomerular lesions and dilated proximal tubules by light microscopy. The gene mutated is nephrin and is also in the 19q13 region (106). Nephrin localizes to the slit diaphragm of the podocyte, and is tightly associated with CD2 associated protein (CD2AP). Nephrin is thought to function as a zona occludens type junction protein. CD2AP plays a crucial role in receptor patterning and cytoskeletal polarity, and its absence resulted in sclerosis and foot process effacement in mice, supporting a role for CD2AP in the function of the slit diaphragm. Rare case reports of CD2AP mutation in human FSGS exist (107). Laminin-β2 (LAMB2) is mutated in Pierson syndrome, often with microcoria and CNS abnormalities, with mesangial sclerosis (108, 109).

FSGS associated with mitochondrial cytopathy, due to a mutation of mitochondrial DNA in tRNAleu(UUR), may show multinucleated podocytes and have abnormal mitochondria by electron microscopic examination. Patients also have unusual hyaline lesions in the arterioles. Some patients with FSGS without full-blown features of mitochondrial cytopathy (i.e., myopathy, stroke, encephalopathy, occasionally diabetes mellitus, hearing problems, cardiomyopathy) have also been reported to have this mitochondrial mutation (110). For further discussion of MCD and FSGS, see Chapters 45 and 46.

Hemolytic-Uremic Syndrome

HUS is the most common disease in children that is manifested by injury to the microvasculature and is typically due to E. coli 0:157 verotoxin and associated with diarrhea. In adults, thrombotic thrombocytopenic purpura, related to ADAMTS13 deficiency, and postpartum renal failure may produce similar morphologic changes. The characteristic lesion of these conditions is thrombotic microangiopathy (TMA). By LM, thrombi in glomeruli and arterioles are present (*Fig. 24-5*). The renal biopsy findings, rather than clinical parameters, have recently been found to best predict long-term prognosis (111). Patients with cortical necrosis have a particularly ominous prognosis. The extent of glomerular vs. arteriolar involvement is also of prognostic significance. Generally, both the long-term prognosis and the clinical presentation are more severe if larger vessels are involved. Arterial involvement was not seen in biopsies performed during the first 2 weeks of hospitalization (112). The glomerular endothelium is markedly swollen, nearly occluding capillary lumina. Fibrin thrombi are visualized easily. With chronicity, these areas may progress to segmental ischemic collapse with sclerosis, especially when arterioles are involved. The arterioles can become completely occluded by thrombi, with necrosis of vessel walls. IF shows occasional nonspecific entrapment of C3 and IgM in injured areas with fibrin and fibrinogen. EM shows extreme swelling of the glomerular endothelium with increased lucent material in the lamina rara interna of the basement membrane with entrapped platelets, fibrin, and red cell fragments, without immune deposits (*Fig. 24-6*). De novo thrombotic microangiopathy in the renal transplant is indistinguishable morphologically from HUS in the native kidney. Cyclosporine and FK506 have both been implicated in its pathogenesis (113, 114). Mutations of complement regulatory genes are implicated in familial and some diarrhea-negative sporadic cases. The morphologic characteristics of the TMA lesion are largely the same regardless of etiology. For further discussion of HUS, see Chapter 48.

Henoch-Schönlein Purpura/IgA Nephropathy

Henoch-Schönlein purpura is often viewed as the systemic variant of IgA nephropathy (Berger's disease) (4, 115).

Figure 24-5

Arteriolar fibrin thrombi with minor areas of thrombi in capillary loops in hemolytic uremic syndrome (Jones' stain, × 270).

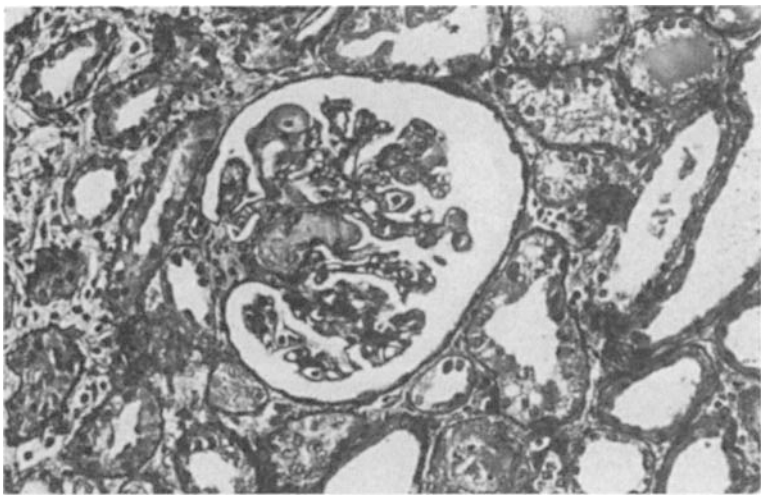


Figure 24-6

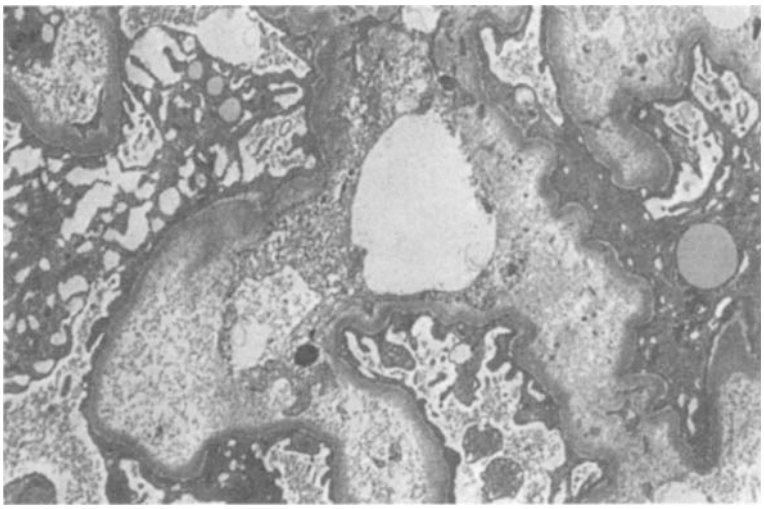
Hemolytic uremic syndrome. The lamina rara interna (endothelial side of the glomerular basement membrane) is widened with increased lucent material. No immune deposits are present (× 3,300).



The glomerular manifestations are similar, and vary in both, likely depending on extent and location of deposits. In some cases, there is only focal or even diffuse mild to moderate mesangial proliferation (*Fig. 24-7*) (116). In more severe cases, there is focal or even diffuse endocapillary proliferation. In severe cases, there may also be necrosis of glomerular tufts with crescents in Bowman's space. IF by definition shows predominance or codominance of mesangial IgA, with capillary loop deposits in more severe cases. IgG, IgM, and C3 deposits may also be detected. The immunoglobulin deposits are present diffusely, even in glomeruli that appear normal by LM. By EM, electron-dense mesangial deposits are present, with occasional "spill-over" of deposits to subendothelial regions in the regions adjacent to the mesangium, particularly in cases with endocapillary proliferative lesions (*Fig. 24-8*). Deposits are decreased when clinical remission occurs (117). In Henoch-Schönlein purpura, deposits are often present in subendothelial as well as mesangial areas, associated with more severe glomerular lesions, including crescents, and worse outcome (116). Classification schemas analogous to those for lupus nephritis have

Figure 24-7

been proposed, but have not had widespread use (118, 119). Therefore, a recent International Study Group of IgA Nephropathy composed of nephrologists and pathologists reviewed a large number of cases to determine which biopsy lesions have prognostic implications (120). Mesangial hypercellularity, i.e., more than half the glomeruli with more than 3 nuclei in a mesangial area, proliferation (either endo- or extracapillary), segmental sclerosis and increasing interstitial fibrosis were each associated with worse long-term outcome. For further discussion of Henoch-Schönlein purpura/IgA nephropathy, see Chapter 42.

Membranoproliferative Glomerulonephritis Type I

Type I MPGN is characterized by a tram-track appearance of the GBM on silver stain, because of duplication around intramembranous/subendothelial deposits and interposition of mesangial cells and macrophages (*Fig. 24-9*). The glomeruli are enlarged and hypercellular with a lobular appearance by LM (*Fig. 24-10*). There is marked mesangial and endocapillary hypercellularity and occasional PMNs and mononuclear cells may be present. By IF, C3 predominates in a coarse granular pattern along basement membranes, with moderate amounts of IgG and usually lesser IgM. Subendothelial and mesangial immune deposits are seen by EM (4, 53). MPGN may be idiopathic or secondary to any of numerous chronic infections. Hepatitis C positivity, often with associated cryoglobulins, was present in about one fourth of adult cases of MPGN type I in adults in Japan and the United States (121, 122). This association has not been demonstrated in children with apparent idiopathic MPGN (123). MPGN type I recurs in 20–30% of grafts, and may lead to graft loss (13). Secondary MPGN, more common in adults, more often demonstrates a focal

Figure 24-9

segmental pattern of proliferation, contrasting the more diffuse involvement seen in idiopathic MPGN, more common in children.

Dense Deposit Disease

In dense deposit disease (DDD), the glomeruli may appear similar by LM to those of type I MPGN, and this disease has therefore also been called type II MPGN. However, the pathogenesis is entirely different. These patients often show circulating IgG autoantibodies, also known as C3 nephritic factor (12, 124, 125). The basement membranes are deeply eosinophilic, often with a ribbon garland or sausage-shaped contour. By IF, discontinuous smooth linear deposits of C3 along the GBM and round globular mesangial deposits are found, typically without immunoglobulin staining. The disease is named dense deposit disease because of the characteristic appearance by EM with strongly electron-dense deposits within the basement membrane. Studies of the dense deposits indicate that these are likely an alteration of basement membrane material and not deposition of circulating immune complexes. Although less specific than

electron microscopic diagnosis, deposits can also be identified by their staining with the fluorescent dye thioflavin T in cases where electron microscopic examination cannot be performed (125). A recent large international study of 69 cases of DDD by the Renal Pathology Society showed mesangial proliferation was most common, followed in order by membranoproliferative appearance with endocapillary proliferation, crescentic or acute proliferative patterns (126, 127). Renal survival may be worse in DDD than in type I MPGN (median survival 8.7 vs. 15.3 years) (128). The distinction between these two diseases is also important since dense deposit disease invariably recurs in renal transplantation, although loss of graft is not always the outcome (12).

Lupus Nephritis

Lupus nephritis is not a single disease but rather there is a spectrum of severity of involvement of the kidney by the immune complexes characteristic of SLE. Most patients with SLE will have morphologic manifestation of renal immune deposition. However, patients who undergo renal biopsy most often have clinical renal manifestations and will have more pronounced changes. Lupus nephritis is characterized by deposits in all anatomic compartments of the glomerulus (i.e., mesangial, subepithelial, and subendothelial regions) (19–21) (*Figs. 24-11* and *24-12*). All immunoglobulin classes with dominant IgG, C3, and smaller amounts of C4/C1q are usually found in lupus nephritis deposits (*Fig. 24-13*), and immune complex deposits are seen by EM. Reticular aggregates (see above) are typically seen in endothelial cells in any class of lupus nephritis (4, 53) (*Fig. 24-14*).

The WHO classifications, either the original or modified, were previously most commonly used (18, 19). However, the International Society of Nephrology (ISN) and the Renal Pathology Society (RPS) put forth a revised lupus nephritis classification to clarify some areas of difficulty in the previous versions (20, 129, 130). Greater interobserver reproducibility occurs with the ISN/RPS classification (129). In this new ISN/RPS classification, Class I has minimal mesangial deposits with normal LM. Class II is characterized by mesangial expansion visible by LM and mesangial deposits, with only scattered peripheral loop deposits. In class III, focal lupus nephritis, deposits are present in mesangial areas and there are lesions of either active endocapillary proliferation, necrosis, cellular crescents, sclerosis, fibrocellular or fibrous crescents. These focal lesions, by definition, involve less than 50% of glomeruli. The subendothelial deposits can result in thick, rigid-appearing capillary basement membranes by LM, the so-called wire-loop lesions. "Hyaline" thrombi (aggregates of immune complexes) may fill capillary lumina. When these lesions affect more than 50% of glomeruli, lupus nephritis is characterized as class IV diffuse lupus nephritis. The proliferative lesions of both class III and IV are typically associated with subendothelial deposits in addition to mesangial deposits, with only rare or scattered subepithelial deposits. IF demonstrates

Figure 24-11

Diffuse lupus nephritis (ISN/RPS Class IV) with massive dense mesangial and subendothelial deposits, and fewer deposits in subepithelial areas (× 5,600).

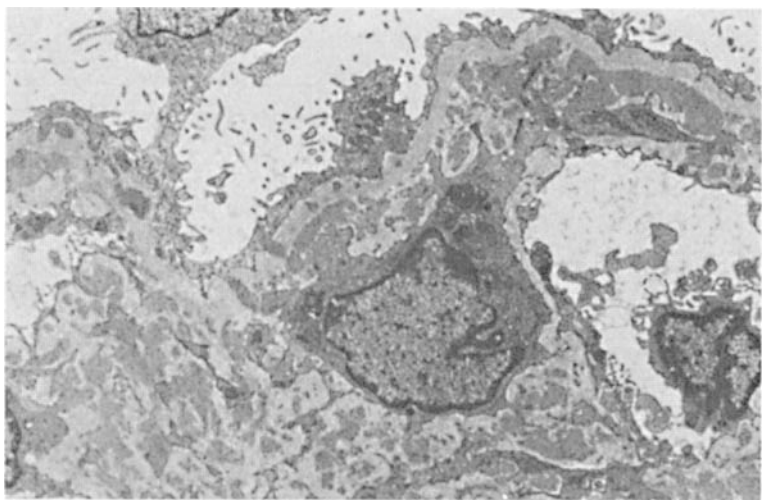

Figure 24-12
Membranous glomerulopathy with subepithelial deposits and intervening lamina densa (seen as spikes by silver stain on LM) (× 15,580).

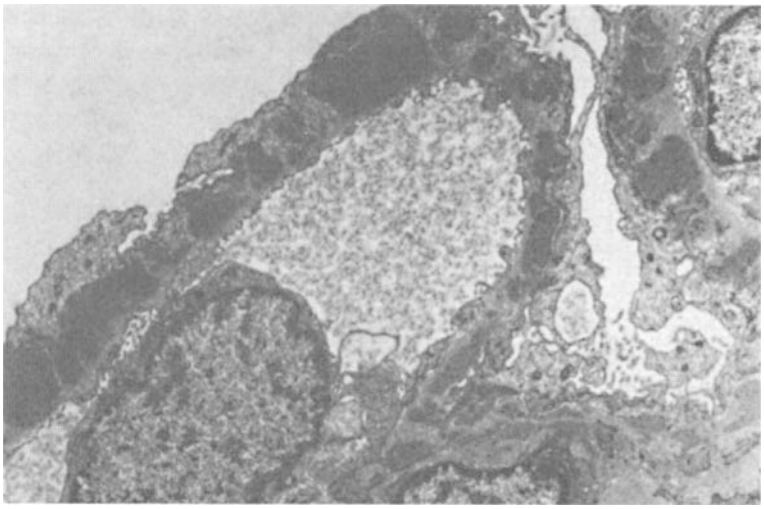

Figure 24-13

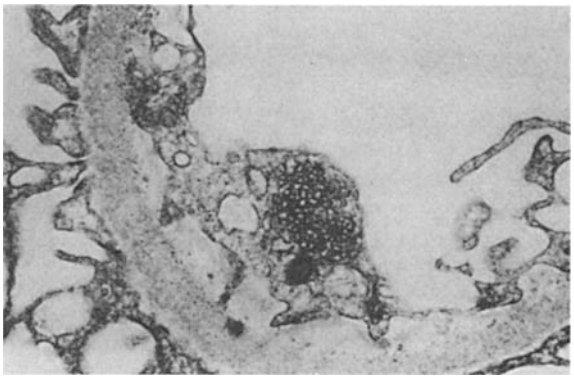
widespread distribution of immune complexes. EM confirms the massive and extensive immune complex deposition (*Fig. 24-11*). For class III and IV, the extent of active vs chronic lesions is specified. The segmental necrotizing lesions in class IV lupus nephritis may have worse prognosis, and thus the presence of these lesions vs global endocapillary proliferation is noted (20, 130).

Figure 24-14
Endothelial cell containing tubular-shaped reticular aggregates in lupus nephritis (× 20,000).



Class V membranous lupus nephritis is characterized by predominance of subepithelial deposits in a pattern similar to that of idiopathic membranous glomerulopathy, with added mesangial deposits (*Fig. 24-12*). Subendothelial deposits are minor components in class V. When there are superimposed focal or diffuse proliferative lesions in addition to membranous changes, both processes are diagnosed, e.g., combined focal or diffuse lupus nephritis and membranous lupus nephritis, ISN/RPS Class III + V or Class IV + V, respectively. Widespread chronic sclerosing lesions in a nonspecific pattern in a case of lupus nephritis are defined as Class VI. Tubular basement membrane deposits can occur in any class of lupus nephritis and

may account in part for the tubulointerstitial injury. Vascular lesions include immune deposits, or thrombotic microangiopathy, often related to anti-phospholipid antibodies. Vasculitis occurs rarely. For further discussion of lupus nephritis, see Chapter 47.

Anti-Glomerular Basement Membrane Antibody Disease

Light microscopic examination shows crescentic glomerulonephritis with focal necrotizing lesions. Patients may not always show detectable serum levels of anti-GBM antibodies, especially after the acute phase of illness. Serology is positive in 95% of patients in the first 6 months after onset. However, in all patients, even those with negative serology, linear IgG staining by IF of glomerular basement membranes is present (*Fig. 24-15*). Standard EM does not visualize the immune deposits, perhaps because of the diffuse distribution of the antigen (α3 type IV collagen NC-domain). Patients with more than 50% crescents have a worse prognosis (131). For further discussion of anti-GBM antibody disease, see Chapter 29.

Wegener's Granulomatosis

By LM, the appearance of Wegener's granulomatosis is the same as for other non-immune complex crescentic necrotizing glomerulonephritides, such as microscopic polyangiitis or anti-GBM antibody disease (*Fig. 24-16*). The lesions are focal and segmental. Granulomas are rare in the kidney, and arteritis is rarely found in the small sample inherent to the renal needle biopsy. IF studies allow differentiation of the lesion from anti-GBM antibody disease. It shows fibrin and fibrinogen in areas of necrosis, and nonspecific trapping of immunoglobulin, especially IgM. By EM, immune deposits are not identified. Distinction from microscopic polyangiitis cannot usually be made by renal biopsy findings. Clinical manifestations must be used to distinguish between these two disorders. For further discussion of Wegener's granulomatosis, see Chapter 45.

Postinfectious Glomerulonephritis

Patients with typical postinfectious glomerulonephritis due to streptococcal infection do not usually undergo renal biopsy. Infectious agents other than streptococci can also cause postinfectious glomerulonephritis. When the diagnosis remains in question, when abnormalities persist, or when the initial disease is severe, renal biopsy may be done. Glomeruli are enlarged and hypercellular with prominent endocapillary proliferation and infiltration by neutrophils and mononuclear cells (*Fig. 24-17*) (132). In severe disease, crescents are present. Occasionally,

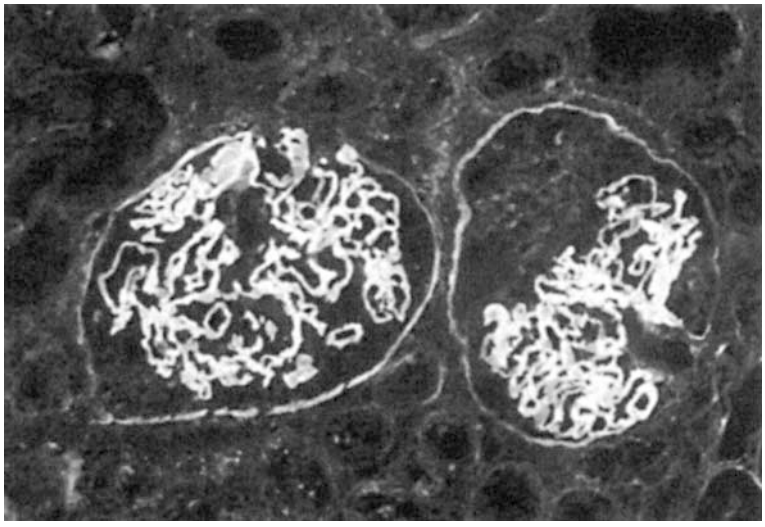

Figure 24-16

Segmental necrosis and crescent in Wegener's granulomatosis. Immunofluorescence was negative (Jones' stain, × 430).

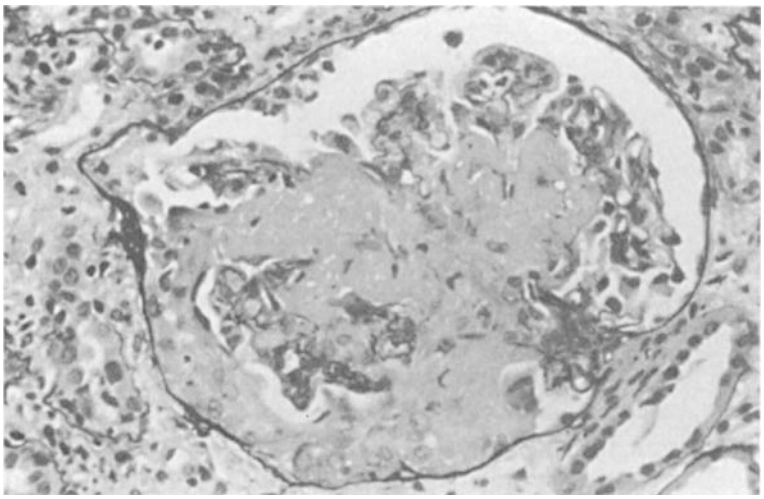

Figure 24-17

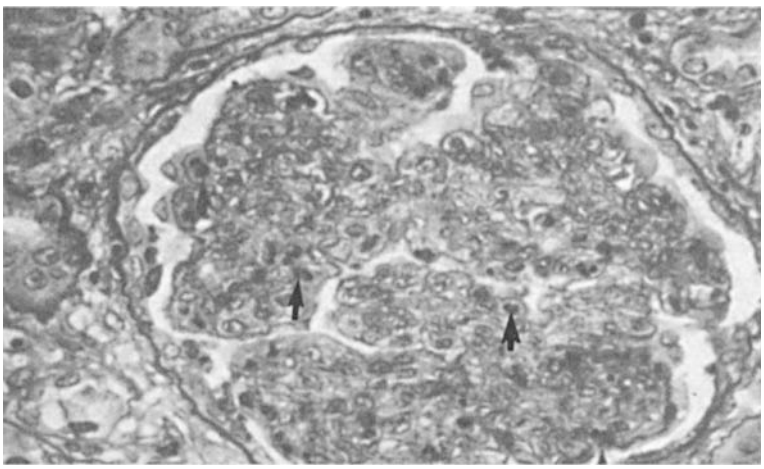
Postinfectious glomerulonephritis with endocapillary proliferation and PMN infiltration (*arrows*) (PAS, × 430).



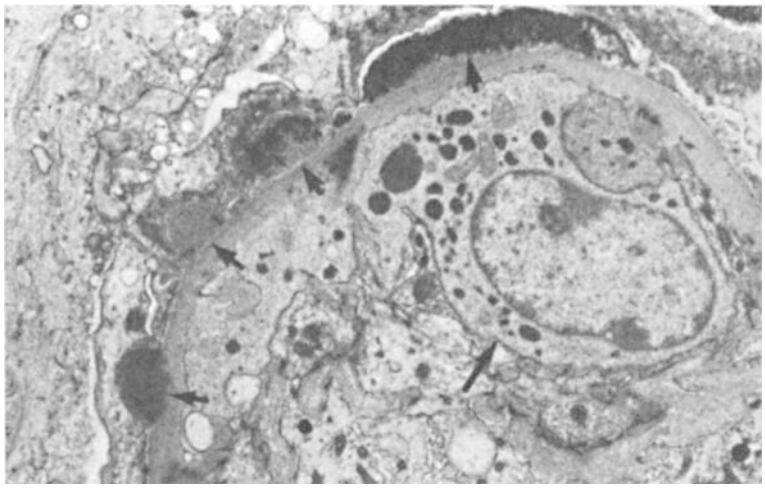
large subepithelial deposits can be visualized by LM. These differ from those typical of membranous glomerulopathy in being more unevenly distributed along the capillary basement membrane and larger in size. The deposits lie on top of the basement membrane, rather than being embedded within it (as in membranous glomerulopathy), and therefore spikes are not usually present. By IF, there are coarsely granular, discontinuous areas of IgG and prominent C3 along the capillary wall and in the mesangium. Postinfectious glomerulonephritis due to staphylococcal infection may have dominant IgA rather than IgG, and can be distinguished from IgA nephropathy by EM appearance of deposits (133). Electron-dense subepithelial deposits are large, variegated, hump- or dome-shaped and irregularly spaced (*Fig. 24-18*). Occasional mesangial deposits are present in many biopsies. For further discussion of postinfectious glomerulonephritis, see Chapter 30.

Diabetic Nephropathy

Diabetic nephropathy affects 30–40% of patients with diabetes mellitus, either type 1 or type 2, with overt clinical nephropathy manifest 15–20 years after onset of diabetes. Therefore, diabetic nephropathy has been

Figure 24-18

Electron micrograph of subepithelial large, irregularly spaced, hump-shaped subepithelial deposits in postinfectious glomerulonephritis. The deposits are variegated and lie on top of the GBM (*small arrows*). There is endocapillary proliferation with PMN (*long arrow*) infiltration (×7,000).



considered a disease of adults. However, adolescents may have diabetic renal lesions even after short duration of disease (134). In addition, obesity and type 2 diabetes mellitus are increasing in children. The structural changes in these diabetic children include GBM thickening and mesangial expansion and were associated with proteinuria, hypertension, and decline in GFR. Overt diabetic nephropathy with nodular glomerulosclerosis and afferent and efferent arteriolar hyalinization was present in several of these young patients. For further discussion of diabetic nephropathy, see Chapter 50.

Alport Syndrome/Thin Basement Membrane Lesion

Early in life in males with classic Alport syndrome, and in female carriers, the renal biopsy may show no significant light microscopic abnormalities. At later stages, glomerulosclerosis, interstitial fibrosis and prominent interstitial foam cells are typical. These foam cells are not specific for this disease, and are found in numerous proteinuric states. Glomeruli can show segmental sclerosis. Immunofluorescence may show non-specific trapping of IgM. By electron microscopy, the diagnostic lesion consists of irregular thinned and thickened areas of the glomerular basement membranes with splitting and irregular multilaminated appearance of the lamina densa, so-called "basket weaving". In between these lamina, granular, mottled material is present. Similar GBM changes by EM, but with normal collagen chain staining (see below) have been reported in Frasier syndrome. This entity is due to WT-1 mutation, and manifests as NS with FSGS by LM, no deposits, pseudohermaphroditism and increased risk of gonadoblastoma (135). At early stages of Alport, i.e., in children or carrier women, the glomerular basement membrane may show only thinning. Some males with classic Alport syndrome only have glomerular basement membrane thinning even at advanced clinical stages (25, 136). Rarely, Alport patients may have proliferative lesions with IF and EM deposits within lamellated GBM areas, suggesting trapping of immunoglobulins rather than a superimposed immune complex disease (137).

Immunostaining for type IV collagen chains can aid in the interpretation of thin basement membranes (136). Heterotrimers of α3, α4 and α5 type IV collagen are a key normal component of the GBM. Mutation of α5 type IV collagen in X-linked Alport syndrome, or of α3 or α4 subchains in autosomal forms, prevents incorporation of the other chains into this heterotrimer of the GBM. Thus, in kidney biopsies, about 70–80% of males with X-linked Alport syndrome lack staining of GBM, distal tubular basement membrane and Bowman's capsule for α3, α4 and α5 (IV) chains. In autosomal recessive Alport syndrome, due to mutations of either α3 or α4, the GBMs also usually show no expression of α3, α4 or α5 type IV collagen. In contrast to X-linked cases, there is normal expression of α5 type IV collagen in Bowman's capsule, distal tubular basement membrane and skin, where the α5 collagen chain are part of other heterotrimers. Female

heterozygotes for X-linked Alport syndrome show mosaic staining of GBM and distal TBM for α3, α4 and α5 type IV collagen chains, and skin mosaic staining for α5 type IV collagen due to the Lyonization effect. Patients with autosomal dominant Alport syndrome have not been studied immunohistochemically. Of note, occasional cases with Alport syndrome clinically and by renal biopsy showed apparent normal α5 type IV pattern of skin IF staining, and about 20% of male X-linked Alport patients show faint or even normal staining of the GBM for α3 and α5, likely because the antigenic site recognized by the antibody has not been altered by the mutation (136).

Thinning of the GBM is also the characteristic finding in benign familial hematuria (70, 71). The diagnosis of thin basement membranes is based on morphometric measurements from electron microscopic prints, and was present in 1.9% of a large native kidney biopsy series (138). LM and standard IF are normal. The GBM thickness normally increases with age. Normal thickness in adults in one series was 373 ± 42 nm in men vs. 326 ± 45 nm in women. GBM thickness < 250 nm has been used as a cutoff in many series (139). In another series, average was 330 ± 50 nm in males and 305 ± 45 nm in women (138). In children, the diagnosis of thin basement membranes must be made with caution, establishing normal age-matched controls within each laboratory. In our laboratory, we found a range of GBM thickness in normal children, from approximately 110 nm at age 1 year to 222 ± 14 nm in seven year olds. As mentioned above, thin GBM (without lamellation) is also the early, or may be the only, manifestation in some kindreds with Alport syndrome and in female carriers of X-linked Alport. Thus, the presence of thin GBM cannot per se be taken to categorically indicate a benign prognosis. Some patients with a clinical diagnosis of benign familial hematuria and α4 or α3 type IV collagen, suggesting that they may represent a carrier state of autosomal recessive Alport (140).

Prognostic Implications of Biopsy Findings

When the biopsy sample is adequate, extensive, severe, and irreversible lesions signify a dismal prognosis for the patient. Globally sclerotic glomeruli are not amenable to treatment, although evidence from human diabetic nephropathy and animal studies indicates that the earlier stages of sclerosis may be affected by some therapeutic interventions, and may even be reversible (141–143). Similarly, active lesions with ongoing cellular crescents, necrosis, and inflammatory infiltrate are potentially dramatically modulated by therapy, allowing subsequent healing. There may be minimal irreversible damage to glomerular structures when intervention occurs early.

Although the renal biopsy may yield a diagnosis, there is less information of prognostic indicators in diseases that have a variable course. Extensive analysis aimed at determining histologic features associated with poor prognosis has been done in some diseases discussed below.

Classification schemes, especially for lupus nephritis and membranous glomerulopathy, imply progression from one stage of disease to the next. Although sequential biopsies have illustrated progression from focal to diffuse proliferative glomerulonephritis in lupus nephritis, there is not clear-cut evidence that progression occurs among all ISN/RPS classes (18, 19, 21, 130). In lupus nephritis, patients with less severe proliferative disease, especially segmental necrotizing lesions, appear to have better prognoses.

Although the presence of cellular crescents is associated with activity of disease clinically, the renal biopsy offers additional prognostic information beyond that gleaned from the clinical presentation (144). Focal and diffuse proliferative lesions (ISN/RPS III and IV) may present very similarly clinically, but only the latter appears to require intense, long-term immunosuppression. Lesions of activity in lupus nephritis include endocapillary proliferation, necrosis, cellular crescents, and interstitial inflammatory cells. Lesions that indicate chronicity include tubular atrophy, interstitial fibrosis, glomerular sclerosis, and fibrous crescents.

Although assessment of activity and chronicity indices is useful for population groups, these appear to have less absolute information to guide assessment in individual patients. Nonetheless, in large series, assessment of indices of activity and severity in patients with lupus nephritis or other diseases has shown some correlation with prognosis and response to therapy. Diffuse proliferative lesions, extensive crescents, segmental necrosis and tubulointerstitial fibrosis are associated with progression to ESRD (144, 145). The best prognostic indicator in a recent study was the proportion remaining of intact glomeruli in follow-up biopsies (146).

IgA nephropathy was previously thought to have a benign prognosis. In a large series of adult patients with IgA nephropathy, poor prognosis was indicated by segmental glomerulosclerosis, adhesions or crescents, and tubulointerstitial fibrosis (147). Progression occurs in 11–15% of pediatric patients (4, 97, 116, 148). Scoring of activity and chronicity of lesions has been correlated with clinical course. Activity is assessed by degrees of

crescent formation, mesangial proliferation, and interstitial infiltrate. Chronicity is scored by degrees of fibrous crescents, segmental and global sclerosis, tubular atrophy, and interstitial fibrosis (149). High indices of chronic injury and focal segmental glomerular changes were associated with a worse prognosis (150, 151). Histologic features that predicted progression in a recent multicenter study in children were crescents, tubulointerstitial fibrosis, and glomerulosclerosis in 20% or more of glomeruli (141). Predominance of matrix expansion appears to be a later stage of injury, associated with a higher percentage of sclerosis and persistent proteinuria (118). Extension of deposits to glomerular basement areas has also been reported as a poor prognostic indicator (149). A recent International Study Group of IgA nephropathy identified four lesions associated with worse long-term outcome, namely mesangial hypercellularity, i.e., more than half the glomeruli with more than 3 nuclei in a mesangial area, proliferation (either endo- or extracapillary), segmental sclerosis and increasing interstitial fibrosis (120).

Focal glomerulosclerosis superimposed on membranous glomerulopathy has been associated with more severe tubulointerstitial nephritis and a worse outcome. This lesion was present in 20% of children with hepatitis B-associated membranous glomerulopathy (152).

Renal Transplant Biopsy

The primary use of biopsy in the renal transplantation is to uncover the reason for altered renal function. Causes of renal dysfunction in the transplant can be broadly divided into those related to rejection, drug toxicity, recurrent or de novo disease, and those related to the procedure itself, such as acute tubular necrosis.

Rejection

Acute rejection is diagnosed by the presence of either interstitial inflammation with lymphocytes and plasma cells infiltrating tubules (tubulitis, the hallmark of acute interstitial type rejection, *Fig. 24-19*), or when more severe, by extension of this process to vessels, with subendothelial arterial or arteriolar infiltration by lymphocytes (endothelialitis, the hallmark of acute vascular rejection, *Fig. 24-20*). The interstitial changes of acute rejection are not pathognomonic. In contrast, the finding of endothelialitis is highly specific for acute vascular rejection. Appropriate stains, such as PAS, must be used to allow visualization of the tubular basement membrane and identification of tubulitis. An adequate specimen for evaluation of possible rejection should contain at least two cores, with at least seven glomeruli and two arteries (153).

Several schemes have been used to diagnose and classify rejection: The Banff scoring system, based on detailed scoring of various components of injury; and the Cooperative Clinical Trials in Transplantation (CCTT) criteria (153, 154). In both classification schemes, acute rejection is based on the presence of tubulitis or endothelialitis, i.e., lymphocytes in the tubule under the tubular basement membrane or underneath the endothelium of arteries. Other inflammatory cells (e.g., eosinophils, neutrophils, and plasma cells), although much fewer in number than T lymphocytes, may also contribute to the infiltrate in acute rejection. Type I rejection in both schemas is diagnosed when interstitial lymphocytic infiltrate and tubulitis are present (>25% of parenchyma infiltrated in Banff, >5% in CCTT) (*Fig. 24-20*). Infiltrate and tubulitis less than specified for type I is called "borderline" by Banff criteria (154). Type II acute vascular rejection is diagnosed in both schemas when there is mild or moderate endothelialitis (arteritis). Severe acute vascular rejection, type III, is diagnosed when there is transmural vascular inflammation and/or fibrinoid necrosis. These types are differentiated not only based on histologic pattern, but also on differences in underlying mechanisms and response to therapies: type I and II are likely T-cell dependent processes and are separated based on the likely greater clinical severity of any rejection when endothelialitis is present, whereas antibody-mediated mechanisms contribute to type III changes.

Identification of acute rejection at earlier stages and thus initiation of treatment at milder levels of injury appear to be clinically important. Thus, mild tubulitis that is borderline by Banff criteria, even in normally functioning grafts, was found to be predictive of higher serum creatinine at follow-up. In contrast, treatment of such subclinical rejection in the early time period after transplantation resulted in better preserved renal function at 24 months (155).

There are no specific IF or electron microscopic immune complexes associated with acute rejection. The recent surge of exciting molecular studies indicates the possibility of earlier, more sensitive, and specific diagnosis of acute rejection using these techniques (see below) (156). In particular, presence of C4d, a complement breakdown product which binds covalently to tissue, in peritubular capillaries, is highly associated with anti-donor antibodies (humoral rejection) (157). Diagnosis of humoral, antibody-mediated rejection has important

Figure 24-19

Acute rejection, classified as type I by Cooperative Clinical Trials in Transplantation criteria. There is interstitial lymphocytic infiltrate with tubulitis, activated lymphocytes, tubular cell injury, and interstitial edema (Jones' stain, × 220).

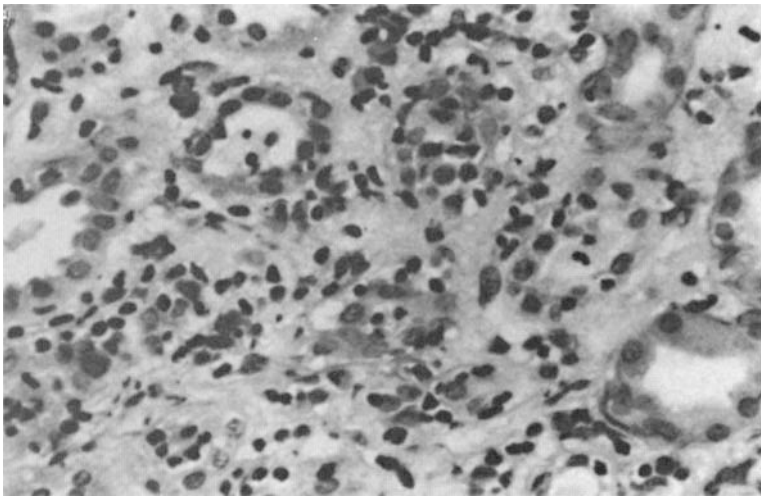


Figure 24-20

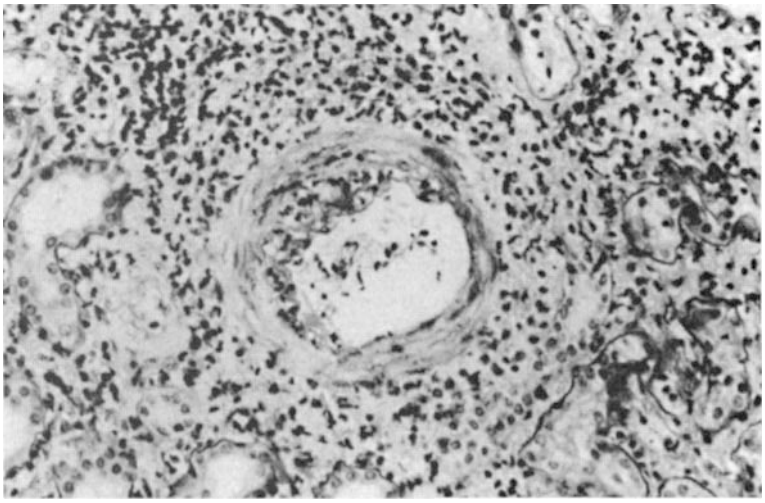
Acute vascular rejection, classified as type II by Cooperative Clinical Trials in Transplantation criteria. There is subendothelial infiltration by lymphocytes in this artery, so-called endothelialitis (Jones' stain, × 220).



therapeutic and prognostic implications. C4d staining can be done on frozen or fixed paraffin-processed tissue, although the latter is less sensitive (158).

The changes of chronic rejection include intimal fibrosis of arteries, interstitial fibrosis, and transplant glomerulopathy (154, 159). A previous or baseline biopsy is necessary to prove that intimal fibrosis is de novo and potentially represents chronic rejection, rather than a preexisting, nonspecific change in the graft. Interstitial fibrosis is also a nonspecific finding and may result from various injuries. Transplant glomerulopathy is a more specific lesion indicative of chronic rejection, i.e., scarring injury related to previous immune injury. By LM, the glomeruli show basement membrane splitting and corrugation, and even segmental sclerosis with hyalinosis. The latter lesion likely resulted in erroneous reports of de novo "idiopathic FSGS" in the transplant. However, in transplant glomerulopathy, there is widening of the

lamina rara interna of the GBM with cellular interposition and new basement membrane formation by EM. Reduplication of basal lamina of peritubular capillaries is suggested to be more specific of transplant glomerulopathy but may also occur in some other glomerular diseases and HUS (160).

Calcineurin Inhibitor Toxicity

Calcineurin inhibitor toxicity may manifest in various ways. Tacrolimus (FK506) has much the same spectrum of toxicity as cyclosporine (159, 161). The most common morphologic lesion in patients with a clinical diagnosis of cyclosporine toxicity, as verified by clinical follow-up, is that of a normal kidney biopsy morphologically. In these patients, renal dysfunction is due to reversible, calcineurin inhibitor-induced vasoconstriction and hypofiltration. Morphologic changes of calcineurin inhibitor toxicity include arteriolopathy with injury to the endothelium and vascular smooth muscle cells. In its classic form, this injury results in nodular IgM IF positivity along the apical side of the arteriole, with necrosis and smooth muscle cell injury demonstrated by EM (159, 161). By LM, concentric hyalinosis is present, whereas typically eccentric, more segmental hyalinosis is associated with hypertension. Isometric tubular vacuolization in a patchy distribution, although not specific, is also indicative of cyclosporine toxicity. Chronic calcineurin inhibitor toxicity results in a striped distribution of interstitial fibrosis caused by injury along the medullary rays (159). This pattern often cannot be gleaned in small needle biopsies. FSGS with ischemic, corrugated GBMs in remaining glomeruli may also result from calcineurin inhibitor toxicity and can be associated with significant proteinuria (161).

Calcineurin inhibitors have also been associated with thrombotic microangiopathy lesions (see above) (159, 161). Of note, thrombotic microangiopathy can occur in patients who are recipients of transplants of kidneys or other organs and following radiation, with or without calcineurin inhibitor treatment. In some patients, collapsing type glomerulosclerosis may be associated with cyclosporine toxicity, likely representing a response to severe vascular injury and ischemia (162).

Recurrent and De Novo Disease

Recurrent and de novo disease are important causes of renal allograft injury, affecting approximately 10% of renal allografts (159). Of all graft loss, 2–4% is due to recurrence of disease. IF microscopy should be performed in all transplant biopsies to rule out this possibility. When IF or LM findings in conjunction with the clinical setting indicate an undetermined lesion, electron microscopic study should also be performed.

In children the most common recurrent diseases include IgA nephropathy and Henoch-Schönlein purpura, MPGN, dense deposit disease, and FSGS (163). Although SLE has been reported to recur only rarely, our experience indicates a recurrence rate of approximately 30% (164). However, morphologic recurrence of disease does not necessarily lead to graft loss (159, 163). Dense deposit disease recurs morphologically in nearly all patients, but with only 10 to 20% resultant graft loss. In contrast, HUS has a recurrence rate of 15–25% and 40–50% of these experience graft loss. Although IgA nephropathy recurs in approximately 50% of patients, only 10% of grafts with recurrent disease are lost. MPGN type I recurs in 20–30%, with 10–40% graft loss. FSGS recurs in 20–30% of cases, resulting in graft loss in 30–50% of these. Of note, in recurrent FSGS, the only morphologic change found in the first weeks after recurrence of proteinuria is foot process effacement, with early segmental sclerosis detectable at 6–8 weeks after recurrent NS.

De novo disease may also affect the transplant. Membranous glomerulopathy is the most common de novo glomerulonephritis in the transplant. The etiology remains unknown (159). Glomerulonephritis related to infections, such as hepatitis C-related MPGN, also can occur in the transplant. Early changes of diabetic nephropathy develop much more rapidly in the transplant than in the native kidney and may occur within a few years, whether diabetes preexisted or is corticosteroid-induced (165). Thrombotic microangiopathy may be related to drug toxicity (see above) or be idiopathic in the transplant.

Posttransplant lymphoproliferative disease (PTLD) is due to the unrestrained proliferation of B lymphocytes, most often because of transformation by Epstein-Barr virus, and is an aggressive process, which if untreated, disseminates and may cause death (166). PTLD may respond to decreased immunosuppression. An expansile lymphoid infiltrate with atypical, transformed lymphocytes and serpiginous necrosis are features suggestive of PTLD (166). Immunohistochemical studies can be used to detect Epstein-Barr virus to further support this diagnosis. Typing studies of the lymphocytic infiltrate are not often helpful because most PTLD is polytypic, rather than clonal. Of note, acute rejection and PTLD may be present concurrently.

Polyoma virus nephropathy (PVN), most often due to the BK virus, has increased in the last years in the transplant, perhaps related to increased immunosuppression (76). PVN occurs in both adult and pediatric transplant recipients (167). The biopsy shows a pleomorphic infiltrate with lymphocytes, plasma cells, PMNs and occasional eosinophils, with enlarged tubular cells with smudgy nuclei. Early lesions (stage A) with minimal inflammation, fibrosis or injury have better prognosis than stage B with marked viral changes and inflammation and moderate fibrosis, or stage C, with extensive fibrosis (76). BK infection is confirmed by immunostaining. In some BK nephropathy cases, there may be associated tubular basement membrane deposits staining with IgG and C3 and visualized by EM (168). There may be some response to decreased immunosuppression and antiviral therapy.

New Methods for the Future

With the recent surge of application of molecular biology techniques to the study of renal disease, candidate factors involved in pathogenesis and progression of disease are being studied in animal models. Studies in human beings have also commenced. With further development of such studies, we may identify specific abnormal processes and thus target therapy more specifically. Research techniques that have been advantageously applied to elucidate pathogenesis of disease include immunostaining; identifying specific antigen in deposits of membranous glomerulopathy in some patients (thyroglobulin with Hashimoto's disease, hepatitis B, C antigen); light chains or paraproteins in plasma cell dyscrasia-associated diseases; identification of specific type IV collagen abnormality in Alport syndrome; C4d as a marker of humoral rejection and elucidation of pathogenesis of specific *E. coli*-associated toxins in some forms of HUS.

Current studies are aimed at understanding disease etiologies and mechanisms at a molecular and proteomic level, studying renal biopsies by laser capture microdissection (LCM), with real time reverse transcription polymerase chain reaction (RT-PCR), and in situ hybridization techniques (99, 169–171). Recent efforts have expanded use of these techniques to study mechanisms of injury and progression. Competitive and real time RT-PCR have been used successfully on small cores and even single isolated glomeruli from human biopsies (99, 169). Modulation of growth factors, collagens, cytokines, chemokines and their receptors has been investigated molecularly in renal biopsies. Cytokines and chemokines and their receptors were upregulated in diseases with macrophage influx and mesangial cell proliferation, supporting an important role in initiating and perpetuating injury. Such approaches can offer exciting new mechanistic insights into renal diseases.

In parallel, genetic studies are targeted both at diagnosis and identifying patients at risk for progression in diseases with a variable course, such as diabetes and IgA nephropathy. Genetic screening for podocin mutations is often done in children with FSGS. Polymorphisms of the renin-angiotensin system genes have been implicated as risk factors for progression and also as indices for response to therapies that target this system (172, 173). Noninvasive urinary proteomic studies are also explored to identify particular signature patterns indicative or predictive of specific lesions or risks (174, 175).

Diagnostic use of RT-PCR and in situ hybridization has focused on detection of viruses, including hepatitis B and C, cytomegalovirus, polyoma virus and Epstein-Barr virus. Increased expression of various immune-activated genes, such as perforin, granzyme and fas ligand, quantified by competitive RT-PCR showed initial high predictive value for acute rejection, but subsequent studies have not been as clear-cut (149).

Together these approaches promise to map risks and mechanisms of disease initiation and progression and point to targets to achieve resolution of injury. Sequential biopsies with evaluation of changes in structure and patterns of abnormal factors and modulation by therapy may be necessary to fully understand pathogenesis. Instead of diagnoses of morphologic patterns recognized by current techniques in the renal biopsy specimen, molecular techniques may allow more precise diagnosis of the specific diseases and identification of injury mechanisms.

Acknowledgments

The author wishes to thank Drs. Tina Kon, Aida Yared and Tray Hunley for their suggestions.

Glomerular Disease

25 Congenital Nephrotic Syndrome

Hannu Jalanko · Christer Holmberg

Renal diseases associated with nephrotic syndrome (NS) in the first year of life are uncommon and make up a heterogeneous group of disorders (1). Congenital nephrotic syndrome (CNS) is defined as proteinuria manifesting in the first 3 months of life. NS appearing later during the first year (4–12 months) is defined infantile, and NS manifesting thereafter is called childhood NS. While this classification is used to help the clinical diagnosis, it is arbitrary in the sense that NS caused by a specific gene mutation can manifest soon after birth or later in childhood. However, since the management of CNS is often different from the more common forms of childhood NS, the terminology still seems warranted (*Table 25-1*).

Primary CNS is typically caused by mutations in genes encoding for components of the glomerular filtration barrier (2–4). The classical form is the Finnish type of CNS (CNF), which is caused by mutations in the nephrin gene (*NPHS1*) leading to massive proteinuria, hypoproteinemia and edema in the newborn period. Other known genes causing CNS are podocin gene (*NPHS2*), Wilms' tumor factor 1 gene (*WT1*), laminin β2-gene (*LAMB2*), and PLCe1 gene (*PLCe1*). These disorders have a more widespread age of onset and also more variable clinical manifestations. CNS can also be part of more generalized syndromes, or be caused by neonatal infections, especially in Africa and Asia. Thus, the diagnosis of a patient with early manifestations of NS must be based on several criteria including clinical presentation, family history, laboratory findings, renal histology and genetic testing.

Glomerular Filtration Barrier

Glomerular Capillary Wall and Podocytes

The main feature of primary CNS is the extensive leakage of plasma proteins into urine through the kidney filtration barrier (5, 6). This barrier is located in the glomerular capillary wall and comprises three layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell (podocyte) layer with distal foot processes and interposed slit diaphragms (SDs) (*Fig. 25-1*). The filter is a highly sophisticated size- and charge-selective molecular sieve, and normally only water and small plasma solutes pass into Bowman space (7, 8). As 100–200 l of protein free filtrate (primary urine) is formed daily, one can calculate that 3–6 kg of albumin has to be prevented from crossing the glomerular filtration barrier each day.

The flow of glomerular filtrate follows the extracellular route, passing across the GBM and SD, which bridge adjacent foot processes just above the GBM. The GBM is a protein network formed by type IV collagen, laminin, nidogen and negatively charged proteoglycans. The role of GBM in glomerular permselectivity has been debated, but it is now known that a primary defect in a GBM component results in heavy proteinuria (9). Podocytes and SD are, however, even more important in preventing proteinuria than the GBM (4, 10, 11). Podocytes are specialized cells that consist of the cell body and primary, secondary and tertiary processes. The cytoskeleton of the cell body and major processes consist of primary of microtubules and intermediate filaments, whereas actin is the major cytoskeletel component of foot processes. Actin network and the interacting proteins, such as α-actinin-4, maintain the architecture of the foot processes and responds to signals from the outside (e.g., SD and GBM) modifying the cellular functions accordingly (12–14).

Slit Diaphragm Components

The precise molecular structure of SD is still unresolved (*Fig. 25-2*). The first SD component identified was nephrin, which is a 1,241-residue cell adhesion protein of the immunoglobulin family (15–18). The extracellular part of nephrin contains eight immunoglobulin like modules and one type III fibronectin domain (*Fig. 25-3*). The intracellular domain contains nine tyrosine residues, which may become phosphorylated by protein kinases. This phosphorylation modulates the interaction of nephrin with other proteins, such as adaptor protein Nck and phophoinositide 3-kinase (PI3K) (19–21). These proteins link nephrin to actin cytoskeleton, suggesting an important role for nephrin in the regulation of the actin cytoskeleton and podocyte morphology. Nephrin takes part also in other cell signaling processes involved in the podocyte cell survival (22, 23).

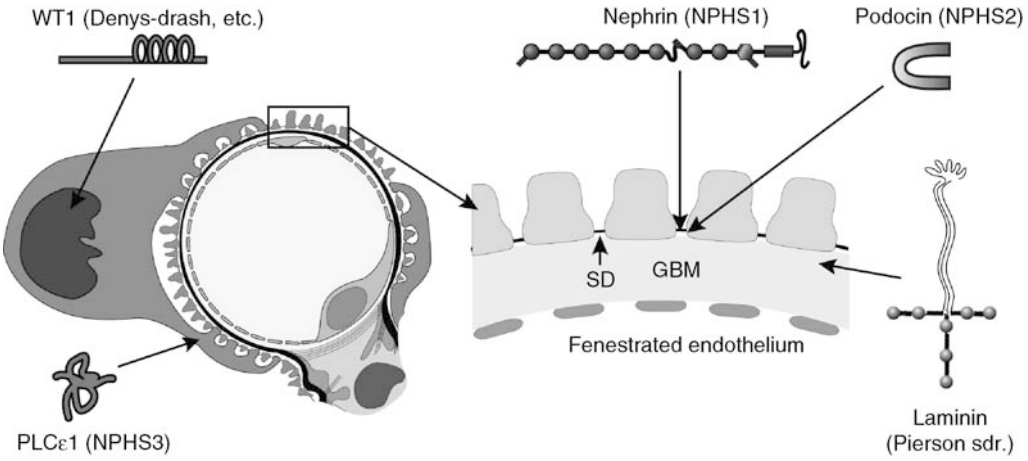
Table 25-1

Classification of Congenital Nephrotic Synrome (CNS)

Primary CNS
Nephrin (*NPHS1*) gene mutations (CNF, NPHS1)
Podocin (*NPHS2*) gene mutations
Phospholipase C epsilon 1 (*PLCE1*) gene mutations (NPHS3)
Wilms tumor suppressor 1 (*WT1*) gene mutations (Denys-Drash, isolated NS)
Laminin β2 (*LAMB2*) gene mutations (Pierson syndrome, isolated NS)
Laminin β3 (*LAMB3*) gene mutations (Herlitz junctional epidermolysis bullosa)
Lim homebox transcription factor 1β (*LMXB1*) mutations (Nail-patella syndrome)
Mitochondrial disorders
Syndromic CNS with brain malformations (Galloway-Mowat; gene defects not yet known)
Syndromic CNS without brain involvement (gene defects not yet known)
Secondary CNS
Congenital syphilis
Toxoplasmosis, malaria
Cytomegalovirus, rubella, hepatitis B, HIV
Maternal systemic lupus erythematosus (SLE)
Neonatal antibodies against neutral endopeptidase
Maternal steroid-chlorpheniramine treatment

Figure 25-1

A cross-sectional image of one glomerular capillary (*left*) and glomerular capillary wall (*right*), which comprises three layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell layer with podocyte foot processes an interposing slit diaphragms (SD). The figure also depicts the five important molecules in the pathogenesis of CNS. WT1 is a transcription factor important for podocyte functions. PLCε1 is a cytoplasmic enzyme involved in cell signaling. Nephrin is a major component of SD and podocin is an adapter and scaffold protein for the SD components. Laminin is an important component of GBM.



In addition to nephrin, several other new podocyte proteins have been identified in the SD, such as Neph1, Neph2, Neph3, FAT 1 and FAT 2 (24, 25). According to the present understanding, nephrin associates with the Neph-proteins extracellularly and form the backbone of SD (26–28). Neph-proteins are structurally related to nephrin and they are also involved in the cell signaling (28). Mice with genetic defects in Neph1 develop heavy

Figure 25-2

A hypothetical model of the major components of the slit diaphragm and the basal membrane of the podocyte foot process anchoring it to glomerular basement membrane (GBM). See the text. The backbone of the SD is formed by nephrin, Neph- and FAT-proteins. The adapter proteins, such as podocin, Nck and C2AP, link SD to actin cytoskeleton as well as take part in the cell signaling.

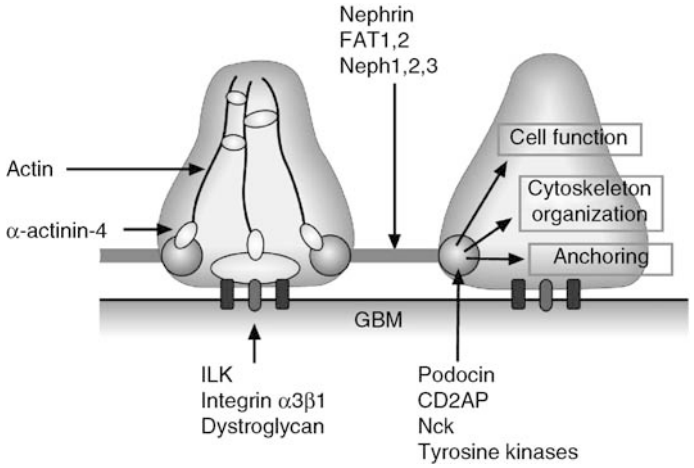


Figure 25-3

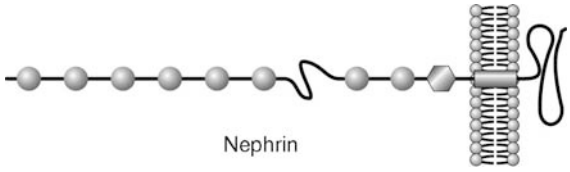
The nephrin molecule is a transmembrane cell adhesion protein with small intracellular and transmembrane domains and a larger extracellular domain. The extracellular domain contains eight Ig-like modules and one fibronectin type module adjacent. The extracellular part contains three cysteine residues taking part in molecular interactions. The intracellular part contains several tyrosine residues phosphorylated by protein kinases, which is important for cellular signaling.



proteinuria, but no humans with mutations in Neph1 have so far been identified (24).

Nephrin and Neph-proteins interact with the adapter proteins podocin, CD2AP and ZO-1, that are located in the cytosolic part of the podocyte foot process (29–34). Podocin is encoded by the *NPHS2* gene and it is a small hairpin-like protein belonging to a raft-associated stomatin family. It is a scaffolding protein and serves in the structural organization of the SD as well as in the signal transduction from the SD into podocytes (13, 19, 33, 35). Genetic mutations in podocin result in CNS as well as NS manifesting later in life.

Primary Nephrotic Syndrome

Nephrin Gene Mutations

CNF originally denoted to a severe form congenital nephrotic syndrome typically seen in the Finnish newborns (36, 37). The disease (also called as NPHS1) is highly enriched in Finland, the incidence being 1:8,200 live births (38). However, patients are reported all over the world among various ethnic groups (39–43). A very high incidence (1/500 live births) of CNF has been reported among the Old Order Mennonites in Lancaster County, Pennsylvania (41).

Genetics (42)

CNF is inherited as an autosomal-recessive trait (16). The *NPHS1* gene is located to chromosome 19q13.1 and exon sequencing analyses has revealed two important mutations in over 90% of the Finnish patients (Fin-major and Fin-minor) (16). Both mutations result in a stop codon and a truncated nephrin protein not expressed in SD. Several reports on *NPHS1* mutations in non-Finnish patients have been published (39–46). The patients come from Europe, North America, North Africa, Middle East and Asia. Most non-Finns have individual mutations including deletions, insertions, nonsense, missense, and splicing mutations spanning over the whole gene. Missense mutations are all located within the extracellular part, and clustering to

exons coding for the Ig-like motifs two, four and seven have been reported.

The Fin-major and Fin-minor mutations are rare outside Finland, but enrichment of other mutations has been reported also in non-Finns. In Mennonites, 1481delC mutation is common and leads to a truncated protein of 547 residues (41). On the other hand, a homozygous nonsense mutation R1160X in exon 27 has been found in all Maltese cases (42). Importantly, six of the 16 cases with this mutation had an atypically mild disease. The same mutation has been reported in six French patients and two of them had a mild disease.

Pathogenesis

Mutations in the *NPHS1* gene result in defective nephrin molecule and disturbed structure and function of the glomerular filtration barrier. The Fin-major and Fin-minor mutations cause a complete absence of nephrin in SD, and these kidneys lack the filamentous image of SD in electron microscopy (*Figs. 25-4* and *25-5*). Similarly, nephrin knock-out mice lack the slit diaphragm filaments in electron microscopy and die of severe proteinuria soon after birth (47). The findings suggest that the absence of nephrin leads to leakage of plasma proteins into urine through the "empty" podocyte pores. Liu et al. have shown that many missense mutations cause misfolding of nephrin protein and defective intracellular nephrin transport with absence of nephrin in SD as well (48). This most probably explains why even "mild" mutations cause heavy proteinuria and a severe form of CNS.

The expression of nephrin was first reported to be restricted to glomerular podocytes and this was later confirmed (16, 49). The data obtained especially from

Figure 25-4

Electron microscopy of the glomerular capillary wall. (a) Normal kidney showing the podocyte foot processes, the glomerular basement membrane, and the fenestrate endothelium. (b) CNF kidney with irregular podocyte foot processes (effacement) typical for all proteinuric kidney diseases. (c) Immunoelectron microcopy of a podocyte pore in a normal kidney. The filamentous image of the slit diaphragm (S) is seen (*arrow*). Antibodies against the intracellular part of nephrin show the localization of nephrin in the SD (gold particles). (d) Immunoelectron microscopy of the podocyte slit pore in a CNF kidney. No SD or nephrin is seen.

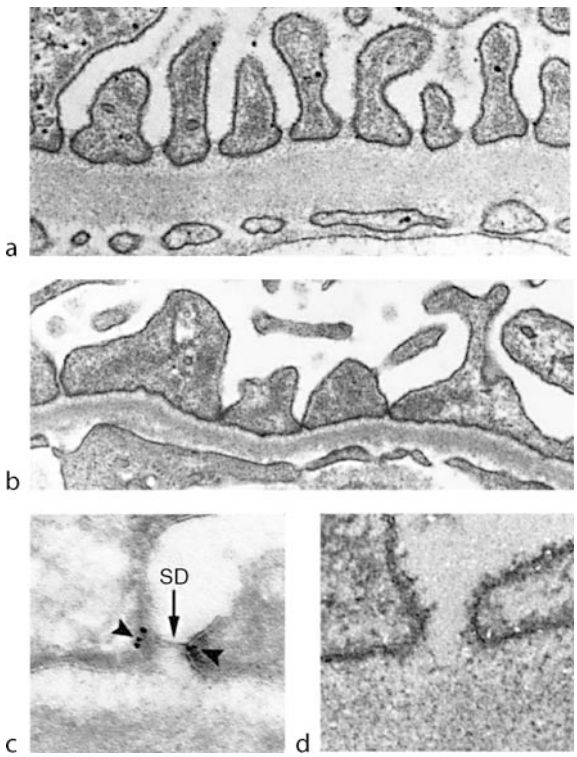


Figure 25-5

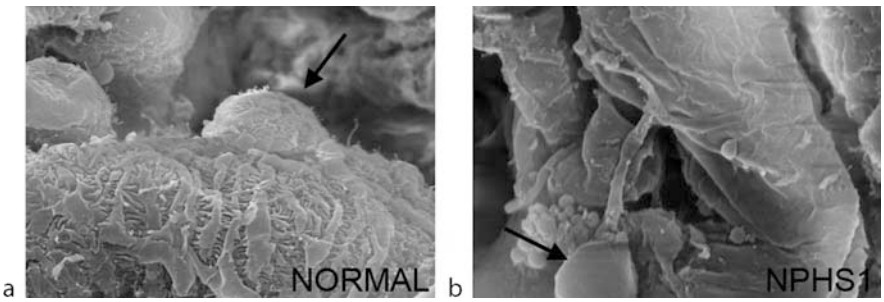
Scanning electron microscopy of a capillary wall in a normal and a CNF(NPHS1) kidney. (a) The podocyte cell body (*arrow*) and the primary, secondary and tertiary processes are clearly seen. (b) In the NPHS1 kidney, the podocyte structure is distorted. The cell body (*arrow*) "hang" in a primary process and the ramification of secondary processes is absent.



mice, however, suggest that nephrin may also be expressed in some areas of the central nervous system, pancreatic β-cells, and testis (47). No constant extrarenal manifestations, however, are observed in CNF patients speaking against a significant role of nephrin in other organs than kidney (50).

Renal Pathology

The CNF kidneys develop quite normally in the fetal period (51, 52). At the 16–22 gestational weeks, the glomeruli show little changes in light microscopy, but occasional dilated tubules may be seen (51, 53). On electron microscopy the mature glomeruli show effacement of podocyte foot processes and the SD image may be completely missing in cases with severe *NPHS1* mutations (46). It is remarkable that also carriers of *NPHS1* mutations can have these "proteinuric" changes making the pathological diagnosis difficult (54).

After birth, the CNF kidneys are large with the mean kidney weight of almost twice that of age-matched control children (51). The glomeruli show a slight to moderate increase of mesangial matrix and mesangial hypercellularity (*Fig. 25-6*). Degenerative changes such as shrinking of the glomerular tuft, fibrotic thickening of the Bowman's capsule, and glomerular sclerosis become evident with time (55). Electron microscopy shows effacement of foot processes, irregulariry in the GBM, and some swelling of the endothelial cells (peliosis) (56). Dilated proximal tubules are few at first, but radial dilations of the tubules become obvious with time (*Fig. 25-7*). Also, interstitial fibrosis and lymphocyte collections especially around sclerotic glomeruli increase substantially within the first 1–2 years (57).

Clinical Features

The basic problem in CNF is severe renal loss of plasma protein, which may begin already in utero (38). The early signs and symptoms are secondary to this protein deficiency (36, 38, 46). In a recent survey, over 80% of the children were found to be born prematurely (<38th week), with a mean birth weight of 2,600 g (1,500–3,500). However, only two of the 46 newborns were small for gestational age (46). Most neonates do not have major pulmonary problems, although amniotic fluid is often meconium stained. The placenta is larger than normal and almost invariably weighs more than 25% of the baby's birth weight. The mean ratio of placental to infant weight (ISP) is 0.38 in babies with CNF, compared with 0.18 in normal babies. The reason for this is not known.

In typical CNF, edema and abdominal distension become evident soon after birth. NS was diagnosed within the first week in 82% of the Finnish patients and within 2 months in rest of the cases (46). In a recent survey of European and Turkish patients, CNF manifested within the first 90 days in all 18 cases (2). Protein losses lead to severe hypoalbuminemia (<10 g/l) before protein substitution is started (58). Without albumin substitution and nutritional support, the classical features of CNF, such as generalized edema, abdominal distension, ascites, and widened cranial sutures and fontanelles, may develop during the first weeks or months of life (36).

Infants with CNF do not have extrarenal malformations. Minor functional disorders in central nervous system and heart, however, are quite common. Most children have muscular hypotonia, and mild atrophic changes in the brain were observed by computer tomography (CT) or magnetic resonance imaging (MRI) in a third of the Finnish infants (46). In 8% of the Finnish

Figure 25-6

Light microscopy of two glomeruli in a kidney with CNF. The histological structure is normal with only slight increase of mesangial matrix and mesangial cell proliferation (×400).

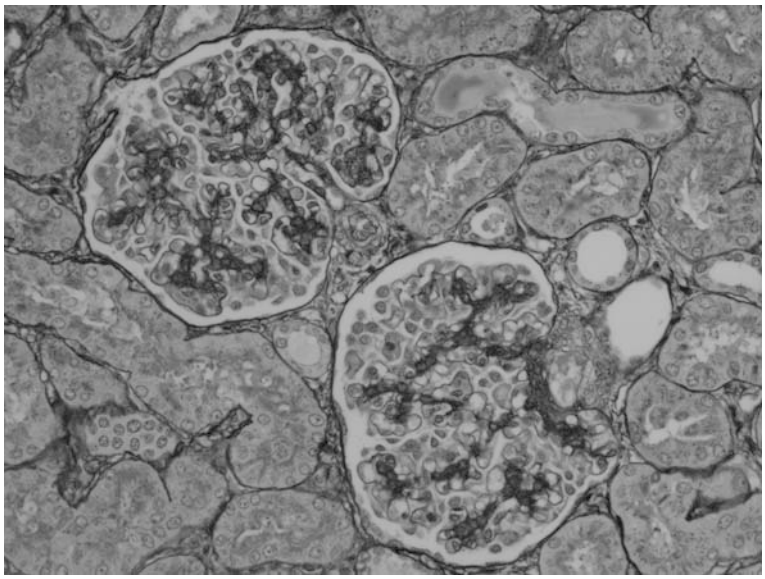


Figure 25-7

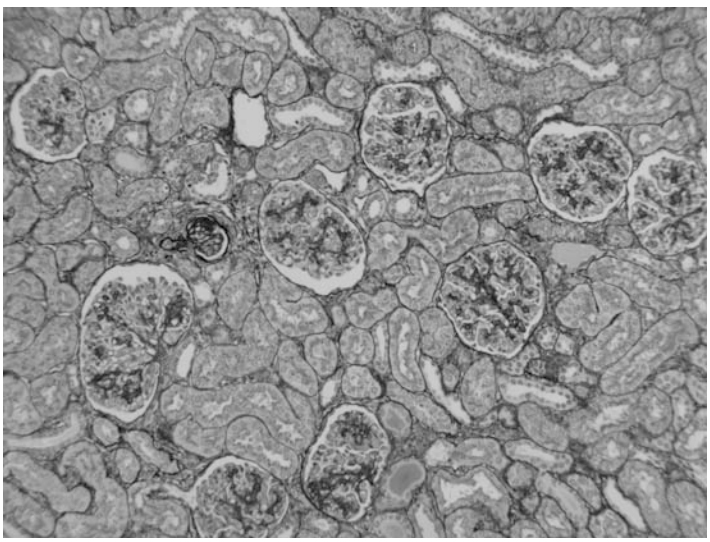
Histological picture of a CNF kidney at 7 months of age. The general structure is almost normal and the tubules are focally dilated. Arteriolar wall thickening is also evident (×100).



patients dystonic cerebral palsy has been diagnosed; the etiology of this is not known. Minor cardiac findings such as hypertrophy and mild pulmonary stenosis has been reported in one fourth of the Finnish patients (46). In a report form Malta, pulmonary valve stenosis was found in three cases and a subaortic stenosis in one patient (59).

Laboratory Findings

The magnitude of proteinuria depends on the "severity" of the *NPHS1* mutations. Typically, the first urine analysis already shows proteinuria, microscopic hematuria, and some leukocyturia. If the serum albumin concentration is

not low (<15 g/l), the urinary protein concentration usually exceeds 20 g/l (58). In addition to albumin, many other proteins are lost in the urine: immunoglobulin G (IgG), transferrin, apoproteins, lipoprotein lipase (LPL), antithrombin III (ATIII), ceruloplasmin, vitamin D binding protein, and thyroid binding globulin (60). The serum levels of these and their ligands (e.g., thyroxin) are low in serum, leading to secondary metabolic disturbances. The low thyroxin concentration leads to an increase in thyroid-stimulating hormone (TSH) (61).

Low serum albumin and postheparin plasma LPL activities and high free fatty acid concentrations lead to hypertriglyceridemia. Total and low-density lipoprotein (LDL) cholesterol levels are high but high-density lipoprotein (HDL) levels are low and the LDL and HDL particles are enriched with triglycerides (62). These lipid abnormalities and arteriolar changes seen already during the first year of life may lead to an increased risk of arteriosclerosis. In a recent analysis, deficiency in polyunsaturated fatty acids was especially prominent in infants with CNS, and this was regarded as a possible risk factor for the developing brains (63).

Podocin Gene Mutations

Genetics

Mutations in the *NPHS2* gene, encoding for a podocyte protein podocin, are a common cause of a steroid resistant NS (SRNS) in children and adults, accounting for up to 28% of sporadic and over 40% of familial cases of SRNS manifesting at various ages (29, 64–70). The podocin gene mutations, however, are also an important cause of CNS. In a recent report, recessive *NPHS2* mutations accounted for half of the CNS cases in 80 European families, while *NPHS1* mutations were responsible for only one third of the cases (2). The *NPHS2* mutations have also been found in CNS patients from Japan and elsewhere.

Hinkes et al. recently found *NPHS2* mutations in 18% of over 400 patients from a worldwide cohort of SRNS cases with the disease onset ranging from birth to 21 years (71) They found that severe, truncating mutations (nonsense or frameshift) resulted in early onset of NS (from birth to 9.1 years of age; mean 1.75 years). This was also true for homozygous R138Q mutation (from birth to 5.4 years; mean 1.77 years), which is common in European patients. The fact that identical mutations may result in onset of SRNS over spectrum of several years suggests that additional modifying factors are involved. Since podocin is a podocyte adapter protein required for the proper targeting of nephrin into SD, also nephrin expression may be distorted in CNS caused by *NPHS2* mutations (42, 72). Co-existence of *NPHS1* and *NPHS2* mutations with two homozygous mutations in one gene and one heterozygous mutation in the other gene resulting in a triallelic hit has been reported in CNS patients (42, 73).

Clinical Features

No systematic analysis of the clinical findings in CNS patients with *NPHS2* mutations has been published. The severity of proteinuria and the clinical findings are more variable than in CNF patients. According to the report by Hinkes et al., the patients develop end stage renal disease (ESRD) on average 6.6 years after diagnosis (2). As podocin is only expressed in kidney glomerulus, extra-renal manifestations are unlikely. The founder mutation R138X was, however, recently associated with cardiac anomalies in six consanguineous Arabs (74). In another cohort of 12 patients, 10 had a normal heart condition and two presented mild anomalies with mitral insufficiency and left ventricular hypertrophy (75).

In general, most patients with *NPHS2* mutations show histology of focal segmental glomerulosclerosis (FSGS). However, in the recent report, the CNS patients with *NPHS2* mutations often had minimal histological changes (MCNS) or NPHS1-type histology, and FSGS was present in only a third of the patients. Thus, it is clear that CNS caused by *NPHS1* or *NPHS2* mutations cannot be differentiated by the renal histology (71).

CNS patients with *NPHS2* mutations do not respond to steroid therapy and kidney transplantation is the only curative treatment option. Importantly, patients with *NPHS2* mutations have a reduced risk of recurrence of the nephrotic syndrome after kidney transplantation (64).

WT1 Gene Mutations

Genetics

Wilms' tumor suppressor gene (*WT1*) is located on chromosome 11p13 (76). It encodes for a nuclear WT1 protein, which is a transcription factor of the zinc finger family presumed to regulate the expression of numerous target genes through DNA binding (77). WT1 plays a crucial role in the embryonic development of the kidney and genitalia. In mature kidney, WT1 is abundantly expressed in podocytes and it is believed to control the expression the SD proteins, such as nephrin (78). The *WT1* gene

contains ten exons, the first six of which encode a proline/glutamine-rich transcriptional regulatory region. Exons 7–10 encode the four zinc fingers of the DNA-binding domain. Up to 24 different isoforms of WT1 may result from the combination of alternative translations sites, alternative RNA splicing, and RNA editing. The biological role of all these isoforms is not known.

A variety of *WT1* mutations, which either affect development or induce tumor formation, have been identified. Developmental defects include the Denys-Drash syndrome (DDS), Frasier syndrome (FS), and WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation) (79). Missense mutations mostly cause DDS, donor splice site mutations in intron 9 are associated with FS, and constitutional deletion of one whole copy of *WTI* is associated with WAGR. FS is characterized by the association of male pseudo-hermaphroditism and glomerulopathy (80, 81). There is complete male to female gender reversal in 46,XY patients. FS is associated with gonadoblastomas but not with Wilms' tumor. Proteinuria is detected in childhood, usually between 2 and 6 years of age, and kidney biopsy reveals FSGS. The renal disease does not respond to medical therapy but it has a slower progressive course to renal failure than DDS.

Denys-Drash Syndrome

DDS is caused by heterozygous mutations in *WT1* (82, 83). More than 60 germline mutations (both familial and de novo) have been described in DDS patients. Most are missense mutations within exon 8 and 9, coding for zinc finger domains 2 and 3, which leads to alteration in the DNA-binding capacity of WT1 (84). Also deletions, insertions and nonsense mutations have been described in DDS patients leading to a truncated protein (85). The most prevalent mutation is R394W located at the zinc finger 3. The mutant protein probably suppresses the normal allele, which explains the more severe phenotype seen in DDS compared with children with complete deletion of one WT1 allele. In most patients the nuclear expression of WTI is absent or reduced in podocytes. The podocyte function is affected and, at the molecular level, up-regulation of PAX2 and down-regulation of nephrin have been reported (86, 87). Also, the expression of growth factors that regulate glomerular capillary development is affected in DDS (88).

DDS is a combination of NS with DMS, male pseudohermaphroditism and Wilms' tumor (89, 90). DDS can be divided in three clinical categories: (1) genotypic males with all three abnormalities, (2) genotypic males with nephropathy and ambiguous external and/or internal genitalia only, and (3) genotypic females with nephropathy and Wilms tumor only (85). While male pseudohermaphroditism is an important diagnostic sign, the diagnosis in females may be difficult and delayed. The renal tumor and nephropathy may be clinically simultaneous, but in some cases, the nephropathy either precedes the tumor or remains the only abnormality of the disease (91, 92).

The nephropathy begins with proteinuria and NS. It is usually discovered at the age of a few months, sometimes at birth. Renal failure is often noted concomitantly with NS and progression to ESRD before the age of 4 years is the rule. The characteristic glomerular lesion is DMS (93). No correlation between the genotype and the severity of renal disease has been observed. Because the renal disease in DDS is resistant to drug treatment, kidney transplantation remains the only therapeutic alternative, and favorable results without recurrence of DMS have been reported. In order to avoid the development of Wilms' tumor, bilateral nephrectomy at the onset of terminal renal failure is recommended. Based on a recent report by Hu et al., removal of native kidneys should be performed to all patients with nephropathy caused by *WT1* mutations (94).

Isolated NS with DMS

Mutations in *WT1* can also cause an isolated kidney disease with NS appearing at a various age. In many cases, the kidney biopsy reveals DMS histology. Three studies reported *WT1* mutations in eight of 21 patients with isolated DMS (95–99). These mutations were localized on exons 7, 8, 9 and on intron 9 in the *WT1* gene.

The connection between CNS and DMS was described already in 1970s (1, 100). As the clinical picture appeared to be distinct, DMS was thought to represent a specific entity. In the published reports, proteinuria was often moderate and NS was detected soon after birth or later in infancy, often in the second and third years. The disorder did does not respond to medical therapy and terminal renal failure often develop within a few months or years.

It is clear now that isolated DMS is not a single entity but probably caused by several gene defects. Besides *WT1*, mutations in the *PLCE1* gene may result in DMS, as discussed later.

Laminin β2 Gene Mutations (Pierson Syndrome)

Pierson syndrome is a recently identified form of primary CNS caused by loss-of-function mutations in the *LAMB2* gene (101–104). This gene encodes for the

laminin β2-chain, that is specifically expressed in the GBM, ocular structures, and neuromuscular synapses. Laminins are extracellular matrix proteins with important roles in cell adhesion, differentiation and proliferation. The deficiency of laminin β2-chain results in the GBM alterations and impairment of the function of the glomerular filtration barrier. In an animal model, lack of laminin β2-chain resulted in ectopic deposition of laminin and mislocalization of anionic sites in the GBM (9). These changes and proteinuria preceded the lesions in podocytes indicating that the GBM lesions were responsible for protein leakage.

Pierson syndrome comprises CNS with the histological lesions of DMS, associated with complex ocular maldevelopment. The renal disease may start prenatally resulting in terminal renal failure during the first few weeks or months of life (103, 104). The most characteristic ocular feature in Pierson syndrome is microcoria, a fixed narrowing of the pupils due to a defect of the dilatator muscle. Ocular manifestations also include abnormalities of the lens, cornea and retina, often leading to blindness. Patients who survive the newborn period due to renal replacement therapy develop neurological deficits, consistent with the known expression of laminin β2 in the nervous system. These include severe muscular hypotonia and psychomotor retardation (105).

Pierson syndrome is typically caused by biallelic truncating mutations in the *LAMB2* gene. Recently, several reports have revealed new *LAMB2* mutations causing variants of Pierson syndrome. Hasselbacher et al. described children with CNS and early development of ESRD, but without eye anomalies or with minor ocular changes different from those observed in Pierson syndrome (106). Kagan et al. described a patient with CNS, high-grade myopia, and minor structural eye anomalies, but no microcoria (107). The patient had normal renal function at the age of 16 months. Choi et al. presented a girl with congenital microcoria and infantile NS, with normal renal function still at the age of 6 years and another female patient with isolated CNS without ocular involvement. Her renal function deteriorated progressively over several months, and retinal detachment developed at the age of 10 months (108).

Since missense mutations in the *LAMB2* gene present with a spectrum of symptoms, genetic analysis of *LAMB2* gene is indicated in CNS patients with no mutations in the *NPHS1* and *NPHS2* genes. *LAMB2* gene mutations, however, are much less frequent as indicated by the recent European report on early-onset NS revealing missense *LAMB2* mutations in 2 out of 46 patients (4.4%) with CNS (2).

PLCε1 Gene Mutations

Mutations in the phospholipase C epsilon 1 (*PLCE1 or NPHS3*) gene were recently identified as a new cause of autosomal recessive form of early-onset NS (109). PLCe1 is a phospholipase enzyme and a signaling protein for many G protein-coupled receptors, including angiotensin II. PLCe1 promotes the downstream activation of protein kinase C enhancing calcium signaling events. PLCe1 is abundant in kidney glomerulus and localizes to the cytoplasm of the podocyte cell body and major and secondary processes. It interacts with IQ motif-containing GTPase-activating protein 1 (IQGAP1), which also interacts with nephrin (110). This suggests that PLCe1 may be involved in the SD signaling and the function of the glomerular filter (111). PLCe1 is highly expressed in the developing glomerulus and the absence of PLCe1 may halt kidney development leading to DMS-type glomerular lesions. Of note, this is associated with a major reduction in the expression of nephrin and podocin (112).

Mutations in *PLCE1* were originally reported in 14 patients from seven families (109). Most patients were Turkish and the age at the onset of the disease ranged from 2 months to 9 years. The patients had no extrarenal manifestations. Twelve patients had homozygous truncating mutation, and all developed proteinuria with DMS. Nine of these 12 patients progressed to ESRF by the age of 5 years. Interestingly, two patients responded to cyclosporine A or prednisone and have remained in remission for several years. Two siblings had nontruncating missense mutations and both had FSGS on the renal biopsy.

Gbadegesin et al. recently analyzed the relative frequency of *PLCE1* mutations in a worldwide cohort of children with "idiopathic" DMS and found truncating PLCe1 mutations in 10 of the 35 families (29%) (113). The age of patients at the onset of the disease varied between 1 and 36 months and most patients progressed rapidly to ESRD, with an age range of 8–60 months. Importantly, three of the 35 families had mutations in the *WT1* gene and none had *LAMB2* mutations. Thus, *PLCE1* mutations were the most common cause of isolated DMS in this cohort.

Other Forms of Primary CNS

Galloway-Mowat Syndrome

In 1968, Galloway and Mowat described two siblings showing congenital microcephaly, NS, and hiatus hernia (114). Several subsequent reports showing various brain malformations and congenital or early-onset NS have been

called Galloway-Mowat syndrome. The classic Galloway-Mowat syndrome is an autosomal recessive disorder, but the gene has not been identified (115). Since podocytes an neuronal cells share common morphology and biology with many proteins expressed in both types of cells, the association of CNS and brain anomalies is not unexpected.

Some patients with CNS and brain malformation show DMS (116, 117). Pathological changes other than DMS have also been reported (116, 117). A wide variety of additional anomalies have also been reported in patients with this association, including dysmorphic facial features (118–121). Other defects include ocular, limb, cardiac, and diaphragmatic anomalies (122, 123).

Other Genetic Forms

Nail-Patella Syndrome is caused by mutations in the gene coding for Lim homebox transcription factor 1β (LMXB1) (124, 125). This protein is expressed in podocytes and regulates the synthesis of α-chains of type IV collagen, podocin and CD2AP. Renal symptoms are found in a third of these patients and a single case with CNS has been described (126). NS has also been described in single patients with Lowe syndrome (127), Herlitz junctional epidermolysis bullosa (128), sialic acid storage disease (129), and mitochondrial disorders (130–133).

Secondary Nephrotic Syndromes

NS has been described secondary to some congenital and infantile disorders. Syphilis, toxoplasmosis, some viral infections, and the infantile form of SLE are currently the most important secondary causes of congenital and infantile NS.

Infections

Congenital syphilis has long been known to cause CNS. It may cause a nephritic or nephrotic syndrome in the newborn (134, 135). Proteinuria and hematuria are present, but severe NS is less common. NS may manifest in the newborn but is more often seen between 1 and 4 months of age. Membranous nephropathy is a common finding in kidney biopsy. Antimicrobial therapy, usually penicillin, is curative, provided that irreversible renal lesions have not developed (136).

An association of neonatal cytomegalovirus (CMV) infection and CNS has also been reported (137, 138). In these cases, DMS type histology is often found and the disease clearly responds to ganciclovir therapy. In these infections, manifestations other than NS lead to the correct diagnosis. Toxoplasmosis has been associated with CNS in a few cases (139). Congenital rubella has been reported to cause CNS with membranous glomerulonephritis (140). The acquired immunodeficiency syndrome caused by the human immunodeficiency virus is associated with nephropathy, including NS. This disease usually affects children older than 1 year, but some infants with nephropathy have been reported (141). Hepatitis B virus may cause membranous glomerulonephritis, and infants with nephrosis associated with hepatitis B infection have been described (142).

Autoimmune Disorders

Although SLE is rarely diagnosed before 5 years of age, an infantile form of SLE has been reported. NS was the major clinical finding in five infants aged 6 weeks to 6 months with SLE (143). These patients had elevated antinuclear antibody titers, hypocomplementemia, and diffuse proliferative glomerulonephritis. Response to the immunosuppressive therapy was poor in many cases. Neonatal membranous nephropathy secondary to feto-maternal alloimmunization with antibodies against neutral endopeptidase present on podocytes have been reported in a few cases CNS (144, 145).

Diagnosis of CNS

Clinical Findings

In severe forms of CNS, generalized edema, urinary protein >20 g/l, and serum albumin level <10 g/l can be detected in the newborn period. The amount of proteinuria, however, varies in different entities and the clinical signs may not be evident during the first weeks or months of life. Also, the true magnitude proteinuria may be detectable only after partial correction of hypoproteinemia by albumin infusions. Small amounts of red blood cells and leucocytes are often present in urine. Serum creatinine and urea levels are variable. Renal function remains normal for the first months in CNF, but in other forms of CNS kidney failure may develop faster. Blood pressure values can be low due to hypoproteinemia and low oncotic pressure, or elevated if renal failure is already present.

In newborns, the placental weight >25% of birthweight is present in CNF, but may be seen in other forms of CNS (46). The kidneys may be of normal size

or larger than normal by ultrasound examination, and the renal cortex is often hyperechogenic. Search for possible non-renal malformations is important, especially since they may give clue to the etiologic diagnosis. These include genital abnormalities (WT1), eye defects (LAMB2), and neurological disorders (Mowat–Galloway). CNS caused by nephrin, podocin or PLCe1 mutations is not associated with extrarenal malformations. Cardiac evaluation, however, often reveals ventricular hypertrophy but structural defects are rare. If infectious etiology is regarded possible, search for specific antibodies (e.g., syphilis, toxoplasma) or DNA/RNA (e.g., CMV, hepatitis B, HIV) in blood samples is indicated.

Kidney Biopsy

Renal biopsy often does not allow the diagnosis but may guide genetic testing. Indeed, a specific gene defect may cause several types of glomerular lesions, such as mesangial expansion, FSGS, MCNS and DMS. Moreover, the same histological glomerular lesion may be due to different genetic defects. Tubular dilatations and interstitial fibrosis and inflammation, can be seen in all forms of proteinuric diseases. Thus, the indications for renal biopsy are not clear. The knowledge of the severity of glomerular sclerosis and interstitial fibrosis may help in the treatment strategies. On the other hand, the lesions are focal and the biopsy findings may be misleading. If immunohistochemistry for nephrin and podocin is available, analysis of their expression in biopsy sample is useful. Total lack of either protein speaks for a severe disorder not responding to antiproteinuric therapy. Immunofluorescence microscopy may reveal the presence of IgG deposits in patients with membranous nephropathy.

Gene Testing

Genetic analysis is the method of choice for the precise diagnosis of CNS. The knowledge of etiology helps in assessing the management and prognosis, in follow up for possible associated symptoms, and in genetic counseling. Analysis of the *NPHS1* and *NPHS2* mutations is warranted in all CNS patients. These analyses are commercially available in Athena Diagnostics. If no mutation is detected in these genes or if clinical findings speak for mutations in *WT1*, *LAMB2,* or *PLCe1* gene, analysis of these genes may be obtained in research laboratories.

Prenatal diagnosis in families with a known risk for CNS should be based on genetic testing whenever possible. The results can be obtained fast if the mutations are already known. In case of no family history or if the mutations in the affected child have not been identified, prenatal genetic testing is a challenge, since sequencing of the *NPHS1* (29 exons) and *NPHS2* (eight exons) genes is time consuming and usually not possible within the short time frame available. Especially CNF can still be suspected prenatally based on an elevated alpha-fetoprotein (AFP) levels in maternal serum and amniotic fluid (146). If the AFP concentration in amniotic fluid is very high and the ultrasound examination does not reveal fetal anencephaly or other malformations, CNF is a likely diagnosis. However, heterozygous fetal carriers of *NPHS1* gene mutations may have temporarily elevated AFP levels in amniotic fluid and maternal serum and repeated measurement of amniotic fluid AFP before the 20th week of pregnancy is recommended in cases with high AFP levels (54).

Management of CNS

In contrast to most cases of childhood NS, immunosuppressive drugs are ineffective in primary CNS (147). This was the case in a recent report, in which only one of the 45 patients with primary CNS achieved a persistent remission following steroid treatment (2). The genetic defect in this child was not identified. Two patients with *PLCE1* gene mutations have also shown improvement after immunosuppressive therapy, but the mechanism behind this is not known (109). In general, CNS children with known disease-causing mutations should be spared unwarranted steroid treatment. In secondary CNS, specific therapy against the infectious agent, of course, is warranted and often effective.

In most patients, the goals during the first months are to control proteinuria and edema, provide good nutrition, and prevent thrombosis and infections, allowing the child to reach a weight and body size consistent with successful kidney transplantation (131, 148, 149). With an optimal therapy growth and development are satisfactory and the patients can spend most of the time at home. In most cases, ESRD is to be expected within the first years of life.

Albumin Substitution

The magnitude of the protein losses into urine is crucial for the therapeutic decisions (*Table 25-2*). If proteinuria is modest, only occasional albumin infusions may be needed. On the other hand, heavy proteinuria (10–100 g/l) inevitably leads to life-threatening edema, protein malnutrition, reduced growth, and secondary complications. In

Table 25-2

Management of Infants with primary CNS

Protein substitution parentally
– 20 % albumin infusions as required
– dosing 3-4 g/kg/day when severe NS
– divided in 1-3 infusions (day or night)
– furosemide (0.5mg/kg) together with albumin
– deep vein catheter needed
Nutrition
– hypercaloric diet (130 kcal/kg/day)
– protein supplementation (4 g/kg/day)
– lipid supplementation (rapeseed/sun flowr oil)
– A,D,E and water soluble vitamins
– calcium, magnesium (potassium) supplementation
– nasogastric tube or gastrostomy often required for proper feeding
Medication
– anticoagulation (warfarin, AT III infusions)
– thyroxin substitution
– parenteral antibiotics when bacterial infection suspected
– antiproteinuric drugs (ACE-inhibitor, AT II R blocker, indomethacin)
Dialysis
– terminal renal failure
– after nephrectomies
Transplantation
– after dialysis/pre-emptive
– extraperitoneal grafting when > 9 kg

these cases, protein substitution by parenteral albumin infusions is mandatory. Our practice in treating CNF patients is to infuse 20% albumin solution together with a bolus of intravenous furosemide (0.5 mg/kg), using deep-vein catheters after 3 weeks of age. The substitution is first divided into three 2-h infusions (starting dose of 1–5 ml/kg/infusion), and after a few weeks albumin is given as one 6-h infusion during the night (up to 15–20 ml/kg/night; which is 3–4 g/kg of albumin). This substitution corrects hypoproteinemia only temporarily, but the patients do not have substantial edema.

Antiproteinuric Medication

A reduction in the protein excretion using an ACE-inhibitor and indomethacin has been reported in infants with primary CNS (150–152). Blockade of renin-angiotensin axis not only reduces glomerular perfusion pressure, but also exerts protective measures on podocytes (153). In a few patients with CNS, adding of angiotensin II receptor (AT II) blocker to ACE-inhibitor medication, has further reduced proteinuria (154). Thus, treatment with these drugs (and indomethacin) is worth trying in many cases of CNS. In our experience, CNF patients with the severe (truncating) Fin-major and Fin-minor mutations do not respond to captopril or indomethacin, but if a mutation leads to a single amino acid change and quite normal nephrin expression, a reduction in the protein excretion may be observed (46).

Nutrition

Infants with severe CNS have traditionally been treated with a high-energy (130 kcal/kg/day) and a high-protein (3–4 g/kg/day) diet (58, 153). Breast milk and milk formulas are first used and the excess protein is given as a

casein-based protein product. Glucose polymers are given to increase energy intake and a mixture of rapeseed and sunflower oil to balance the lipid levels. The children also receive vitamin D_2 (400 IU/day) which can be changed to alpha-calcidiol when an increase of parathyroid hormone level is noticed. Multivitamin preparations are given according to the recommended dietary allowances for healthy children of the same age. Supplementary magnesium (50 mg/day) and calcium (500 –1,000 mg/day) are also given to keep the serum levels within the normal range. The daily water intake is 100–130 ml/kg. Most patients need a nasogastric tube to guarantee their energy intake. Modifications to this treatment are, of course, necessary with deteriorating renal function.

Additional Medication

Patients with NS often have low levels of serum thyroid-binding globulin and thyroxin (155, 156). McLean et al. reported an increase in TSH in four of five patients with CNS and a positive response to thyroxin substitution (61). We have a similar experience. Although serum thyroxin concentration is always low, TSH may be normal in the beginning but increases in most patients during the first months. Thus, we have adopted a policy of routinely giving thyroxin from birth, adjusting the dosage according to TSH.

Increased levels of macroglobulins, fibrinogen, thromboplastin, and factors II, V, VII, X, and XII, contribute to hypercoagulopathy (157). Thromboses and severe coagulation problems have been reported in children with CNS (158) and the use low-dose aspirin and dipyridamole therapy has been recommended. All Finnish CNF patients are treated with sodium warfarin from 3 to 4 weeks of age, and no severe thrombotic complications have occurred since this therapy was commenced. Before surgical or vascular procedures, warfarin is stopped and ATIII (50 IU/kg) is given to temporarily correct the ATIII deficiency.

Bacterial infections may be a major problem in infants with NS. Because of urinary losses of gamma globulin and complement factors B and D (159), nephrotic children are especially prone to infections caused by capsular bacteria such as pneumococci, and prophylactic use of penicillin has been recommended. Ljungberg et al. retrospectively analyzed the incidence and type of infection in 21 infants with CNF during the first year of life (160). The infants suffered from 63 verified and 62 suspected episodes of sepsis. The use of central venous lines had no effect on the incidence, and the prophylactic use of antibiotics or immunoglobulins did not reduce the incidence. Thus, we do not recommend prophylactic medication, but a high degree of suspicion for septic infections is warranted. The symptoms are often vague and masked by signs of focal infections occurring at the same time. Antibiotic therapy should be started promptly on suspicion and should cover the major hospital strains of bacteria. Response to treatment is usually excellent. Because of the urinary loss of IgG, vaccinations are normally given after nephrectomies.

Unilateral Nephrectomy

Some centers have proposed unilateral nephrectomy to reduce protein losses (161, 162). This decreases the need and frequency of the albumin infusions and may help in the every day management so that the start of dialysis and renal transplantation can be postponed to an older age. In children with severe CNF, we perform bilateral nephrectomy and peritoneal dialysis at an early age to avoid the many problems encountered during the nephrotic stage. Prolonged NS is also accompanied by pathological lipid status which leads to vascular changes already during infancy.

Dialysis

Although normal growth can be achieved with optimal therapy during the nephrotic stage, the patients with severe CNS are still malnourished and hypoproteinemic (163). To optimize treatment we perform bilateral nephrectomy and commence peritoneal dialysis (CCPD) when the infant weighs about 7 kg. The aim is to improve the child's nutritional state before the kidney transplantation (58). The general condition improves, muscle mass increases, and catch-up growth can be documented while receiving CCPD (164–166). However, in contrast to our practice, transplantation can be performed also preemptively and the results are satisfactory.

Kidney Transplantation

Renal transplantation has become an established mode of therapy for most children with CNS. The fact, that CNS children are often transplanted at 1–3 years of age using adult-size kidneys, may sometimes be surgically demanding and increase the risk for thrombotic and ureteral complications, as compared to older recipients. A healthy parent with a single mutation in nephrin or podocin gene

can be used as a donor in the transplantation. Postoperatively abundant hydration of the recipient (2,500 ml/m^2) is necessary to maintain optimum aortic and renal artery blood flow and avoid low-flow states that could damage the graft (167).

The use of immunosuppressive medication should be balanced in order to prevent rejection episodes which may be clinically subtle and, on the other hand, avoid the many side-effects associated with these drugs. Recurrence of NS in the graft has occurred in some CNF children who have developed anti-nephrin antibodies after transplantation. Treatment of the recurrence with cyclophosphamide and plasma exchanges (and more recently with anti-CD20 antibodies) normally leads to remission (168). Recurrent NS has also been reported in patients with *NPHS2* mutations, but in these cases no anti-podocin antibodies were detected (169).

Overall, the results of kidney transplantation in CNS are quite good and similar to those obtained in other etiologies. Patient survival at 5 years is over 90% and graft survival over 80% in registry databases and in single centers (170). Also, the quality of life is good in most patients. A great majority (72%) of those who have reached the school attend a normal class. The early CNF patients who suffered from thrombotic complications have neurologic handicaps (171–174). Chronic allograft nephropathy is a major problem in these patients and a second transplantation is inevitable when the patients become young adults.

Concluding Remarks

During the past few years our knowledge on the genetic and molecular basis of CNS has greatly increased. Podocyte proteins play an important role in the glomerular sieving and mutations in the nephrin, podocin, WT1, PLCε1, and lamininB2 account for most cases of CNS. It is to be expected that more genetic defects will be found in CNS patients in the near future. The management of these infants has improved.

26 Inherited Glomerular Diseases

Clifford E. Kashtan · Marie-Claire Gubler

In recent years the determined efforts of numerous investigators and the dedicated participation of patients, families and clinicians have led to the mapping and identification of numerous genetic loci involved in inherited glomerular disease and the functional characterization of their protein products. This information has generated important insights into the cell–cell and cell–matrix interactions required for normal glomerular structure and function, and the mechanisms by which genetically programmed disruptions in these interactions produce disease phenotypes. Additionally, our ability to predict prognosis and provide accurate genetic counseling has been greatly enhanced by this expansion of our knowledge base.

Inherited glomerular diseases can be roughly divided into two categories based on clinical presentation. Hematuria is typically the initial symptom of inherited diseases of glomerular basement membranes, with the exception of Pierson syndrome. In patients with inherited podocyte diseases the predominant clinical abnormality at presentation is proteinuria. This chapter will focus on inherited diseases of glomerular basement membranes, particularly Alport syndrome and thin basement membrane nephropathy, which together account for 30–50% of children with isolated glomerular hematuria referred to pediatric nephrology clinics for consultation (1–4).

The Glomerular Basement Membrane

The structural and functional characteristics of the normal glomerular capillary wall are discussed in detail elsewhere in this text. For the purposes of this chapter, this discussion will focus on the major protein components of glomerular basement membrane (GBM), type IV collagen and laminin, which form networks bridged by entactin/nidogen and heparan sulfate proteoglycans (agrin).

Type IV collagen. The type IV collagen protein family comprises six α chains that share several basic structural features: a collagenous domain of ~1,400 residues containing the repetitive triplet sequence glycine-X-Y (Gly-X-Y, with X and Y representing other amino acids); a carboxyterminal noncollagenous (NC1) domain of ~230 residues, including 12 completely conserved cysteine residues; and an aminoterminal noncollagenous sequence of 15–20 residues. The collagenous triplet sequence in each chain contains ~20 interruptions. The secreted form of type IV collagen is a heterotrimer composed of three α chains, resulting from self-association of NC1 domains and folding of the collagenous domains into triple helical structures. Amino acid sequences within the NC1 domains determine the specificity of chain association, resulting in three major trimeric species: α1α1α2, α3α4α5 and α5α5α6 (5). While the interstitial collagens, such as type I collagen, lose their NC1 domains after chain association and form fibrillar networks, type IV collagen trimers form open, nonfibrillar networks through NC1–NC1 interactions between two trimers and aminoterminal interactions of four trimers.

α1α1α2(IV) trimers are present in all basement membranes. α3α4α5(IV) and α5α5α6(IV) trimers are more restricted in their distributions in basement membranes (*Fig. 26-1*). In normal, mature human kidneys, α3α4α5(IV) trimers are found in GBM, Bowman's capsules and the basement membranes of distal tubules. α5α5α6(IV) trimers are present in Bowman's capsules and the basement membranes of distal tubules and collecting ducts of normal kidneys but are not found in GBM (6, 7). α5α5α6(IV) trimers are also found in normal epidermal basement membranes, but α3α4α5(IV) trimers are not. α3α4α5(IV) trimers are also found in several ocular and cochlear basement membranes, as discussed in the section on Alport syndrome below.

Each type IV collagen a chain is encoded by one of six distinct genes, COL4A1 – COL4A6, which are arranged in pairs on three chromosomes (*Fig. 26-2*). COL4A1 and COL4A2 encode the α1(IV) and α2(IV) chains, respectively, and are located on chromosome 1. The α3(IV) and α4(IV) chains are respectively encoded by the COL4A3 and COL4A4 genes on chromosome 2, while the α5(IV) and α6(IV) genes are encoded by the COL4A5 and COL4A6 genes on the X chromosome. The paired genes are arranged in a 5′-5′ orientation, with intervening sequences of varying length that contain regulatory elements.

Laminin. Laminin also forms networks based on heterotrimeric subunits. Each subunit consists of an α, β and

γ chain. There are 11 known laminin chains (α1–5, β1–3, and γ1–3), each encoded by a distinct gene, that form 15 heterotrimeric isomers. Laminin-521 (previously known as laminin 11) has the composition α5β2γ1 and is the laminin form found in GBM (8).

Glomerular Basement Membrane Disorders

To date, mutations affecting two of the major proteins of GBM, type IV collagen and laminin, have been identified as causes of inherited glomerular disease. Mutations in type IV collagen cause Alport syndrome, some cases of thin basement membrane nephropathy, and HANAC syndrome, comprising hereditary angiopathy, nephropathy, aneurysms and muscle cramps (*Table 26-1*). Mutations in laminin have been implicated in Pierson syndrome.

Type IV Collagen Disorders

Alport Syndrome

Dominantly-transmitted hematuria was first described as a clinical entity in the early 1900s (9). Over the next 20 years, studies of this condition in successive generations of a single family described development of proteinuria and renal insufficiency in affected individuals, particularly males, and in 1927 Alport reported the association of nephritis with neural deafness in this family (10, 11). Numerous descriptions of families with hereditary nephritis were published in the 1950s and 1960s, leading ultimately to the observations that established Alport syndrome as a heritable disorder of type IV collagen. These signal events included the identification of unique ultrastructural alterations in Alport glomerular basement membranes (GBM) (12–14), the observation that Alport

Table 26-1
Type IV collagen disorders

Disorder	Inheritance	Locus	Gene product
Alport syndrome	X-linked	COL4A5	α5(IV)
	Autosomal recessive	COL4A3 or COL4A4	α3(IV) or α4(IV)
	Autosomal dominant	COL4A3 or COL4A4	α3(IV) or α4(IV)
Thin basement membrane nephropathy	Autosomal dominant	COL4A3 or COL4A4	α3(IV) or α4(IV)
HANAC syndrome	Autosomal dominant	COL4A1	α1(IV)

GBM exhibited abnormal reactivity with anti-GBM sera directed against antigens associated with type IV collagen (15–17), the mapping of the major Alport locus to the X chromosome (18), the discovery of a type IV collagen gene (COL4A5) on the X chromosome (19), and finally the description of COL4A5 mutations in families with X-linked Alport syndrome (20).

Genetics

There are three genetic forms of Alport syndrome. X-linked Alport syndrome (XLAS) is caused by mutations in the COL4A5 gene and is the predominant form of the disease, accounting for ~80% of patients. Affected males are hemizygotes carrying a single mutant COL4A5 allele. Affected females carry a normal COL4A5 allele as well as a mutant allele and are therefore heterozygotes. About 15% of patients with Alport syndrome have the recessive form of the disease (ARAS), due to mutations in both alleles of the COL4A3 or COL4A4 gene. These patients are either homozygotes who have the identical mutation in both alleles of the affected gene (and who may have consanguineous parents) or compound heterozygotes who have inherited different mutations in the affected gene from their parents. About 5% of patients have autosomal dominant Alport syndrome (ADAS) caused by heterozygous mutations in COL4A3 or COL4A4. Most individuals with heterozygous COL4A3 or COL4A4 mutations are asymptomatic or exhibit isolated, nonprogressive microscopic hematuria associated with thin glomerular basement membranes (thin basement membrane nephropathy, or TBMN). For reasons that are as yet uncertain, some people with heterozygous mutations in COL4A3 or COL4A4 have a progressive course leading to chronic renal failure or end-stage renal disease, and are thus considered to have ADAS.

Several hundred different mutations in the COL4A5 gene have been identified in patients and families with XLAS (21–23). While the great majority of these mutations are unique, a small group of missense mutations accounts for a large portion of XLAS patients in the U.S. (24). Reported mutations include large rearrangements (~20%), small deletions and insertions (~20%), missense mutations that alter a glycine residue in the collagenous domain of the α 5(IV) chains (~30%), other missense mutations (~8%), nonsense mutations (~5%) and splice-site mutations (~15%) (21–23). The COL4A5 genotype has a powerful effect on the course of XLAS in affected males (22, 23). Large deletions, nonsense mutations and small mutations that alter the translational reading frame are associated with a 90% probability of progression to ESRD by age 30 (22, 23). This risk is 70% in patients with a splice-site mutation and 50% in those with a missense mutation (22, 23). The position of a glycine substitution may also affect the XLAS phenotype (23). These genotype-phenotype correlations are not apparent in females with XLAS, perhaps as a result of the overwhelming influence of random X-chromosome inactivation on disease course in XLAS females (25).

A similar variety of mutation types has been described in patients and families with ARAS (21, 26–30). Because of small patient numbers, genotype-phenotype correlations in ARAS have not been described.

Clinical Features

Gender and genotype are the major determinants of the severity of renal, cochlear and ocular disease in Alport syndrome. Males with XLAS, and patients of either gender with ARAS, inevitably progress to end-stage renal disease (ESRD) and the majority develop sensorineural deafness. The pacing of these events is influenced by the nature of the underlying disease mutation. While the majority of women with XLAS have mild disease manifestations, ESRD and severe deafness develop in a significant minority. Patients with ADAS exhibit relatively slow progression of renal and cochlear dysfunction, and ocular findings are much less common than in XLAS and ARAS (31, 32).

Renal. Persistent microscopic hematuria is the cardinal clinical feature of Alport syndrome, occurring in 100% of males with XLAS, 95% of females with XLAS

and in all patients with ARAS (22, 25). Hematuria is likely present from infancy in XLAS males and in patients with ARAS. Episodic gross hematuria is not unusual, especially during childhood (33). Some children with Alport syndrome have virtually constant gross hematuria.

Overt proteinuria typically appears during later childhood or adolescence in XLAS males and in ARAS patients and increases progressively, often into the nephrotic range (33–35). About 75% of XLAS females ultimately develop proteinuria of some degree (25). Most children with Alport syndrome have normal blood pressures, but hypertension is common in adolescent males with XLAS and teen-aged ARAS patients.

In XLAS males, the probability of ESRD is 50% by age 25, 80% by age 40 and 100% by age 60 (22). COL4A5 genotype has a powerful effect on rate of progression to ESRD in XLAS males. Large deletions and nonsense mutations confer a 90% probability of ESRD before age 30, compared to a 70% risk with splice site mutations and a 50% risk with missense mutations (22).

Women with XLAS exhibit a lower but substantial risk of progression to ESRD than XLAS males. According to one study of a large cohort of XLAS females, the risk of ESRD is 12% by age 45, 30% by age 60 and 40% by age 80 (25). Proteinuria and sensorineural deafness are risk factors for ESRD in XLAS females (36). COL4A5 genotype does not have measurable effects on the rate of progression to ESRD in XLAS females, perhaps due to the overwhelming influence of X-inactivation balance (25). The epidemiology of ESRD in ARAS is probably similar to XLAS males, although comparable data is lacking. It takes ~50 years for 50% of ADAS patients to develop ESRD, twice as long as XLAS males (31).

Cochlear. Hearing is normal at birth and during early childhood. Symmetrical deficits in sensitivity for high frequency sounds often become detectable by audiometry in late childhood. In XLAS males the probability of hearing loss is 50% by age 15, 75% by age 25 and 90% by age 40 (22). COL4A5 genotype influences the probability of hearing loss, with 90% of those with deletions, nonsense mutations and splice site mutations exhibiting deafness before age 30, compared to 60% of those with missense mutations (22). In XLAS females the probability of hearing loss is 10% by age 40 and 20% by age 60 (25). The majority of patients with ARAS develop deafness, although precise data on timing is not available.

Over time, the hearing deficit progresses into the frequency range of conversational speech. Because the deficit typically does not exceed 60–70 dB and speech discrimination is preserved, hearing aids are effective in most affected individuals.

Ocular. Anomalies of the lens, retina and cornea are common in Alport syndrome, especially among males with XLAS and patients with ARAS, often becoming apparent during adolescence and young adulthood (37). About 15% of XLAS males exhibit anterior lenticonus, in which the central portion of the lens protrudes into the anterior chamber (22). While this lesion is often asymptomatic, it may be associated with reduced visual acuity, and cataracts and even rupture of the lens may occur. Alteration of retinal pigmentation, consisting of whitish-yellowish perimacular flecks, occurs in about 15% of XLAS males (22), often in association with lenticonus. Corneal abnormalities include recurrent corneal erosions (38, 39) and posterior polymorphous dystrophy (40).

Other. The association of XLAS with smooth muscle tumors (leiomyomas) of the esophagus, tracheobronchial tree and, in women, the external genitalia, has been described in several dozen families (41–43). Symptoms such as dysphagia, postprandial vomiting, epigastric or retrosternal pain, recurrent bronchitis, dyspnea, cough, and stridor often appear in late childhood. The Alport syndrome-diffuse leiomyomatosis complex arises from X-chromosomal deletions involving COL4A5 and the proximal portion of the adjacent COL4A6 gene (44).

Mental retardation, midface hypoplasia, and elliptocytosis have been described in a small number of XLAS males who carry deletions that extend downstream of the 3′ end of the COL4A5 gene (45).

Pathology

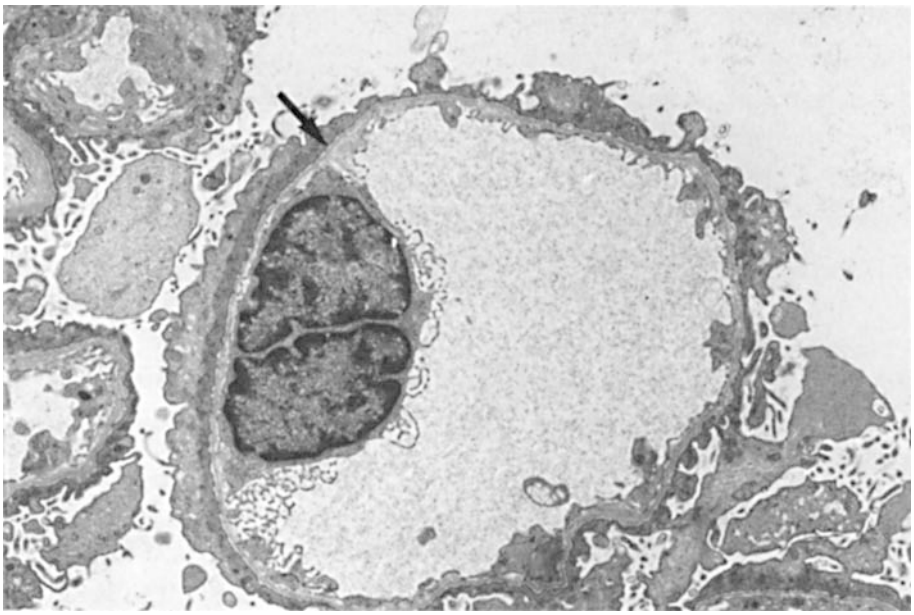
The clinical features of Alport syndrome originate in changes in basement membrane structure and function initiated by absence or abnormalities of α3α4α5(IV) and α5α5α6(IV) networks.

Renal. Light microscopic abnormalities are unusual in children with Alport syndrome who are less than 5 years of age. Mesangial hypercellularity and matrix expansion, and eventually focal segmental glomerulosclerosis, are common in older children and adolescents, especially boys. Tubular atrophy and interstitial fibrosis develop progressively after age 10 in boys with Alport syndrome (46).

Electron microscopy may reveal pathognomonic changes, depending on the patient's age and gender. The earliest abnormality is diffuse attenuation of the GBM; consequently, differentiation of Alport syndrome from thin basement membrane nephropathy by routine renal biopsy processing may be difficult in children (*Fig. 26-3*). To further complicate matters, some families with Alport syndrome due to COL4A5 mutations, GBM attenuation is the only ultrastructural abnormality. However, the great majority of boys with XLAS and both boys and girls with

Figure 26-3

Electron micrograph. Lead citrate and uranyl acetate stain (×4,800). Alport syndrome. Thin and regular GBM (*arrow*) with attenuated lamina densa. Epithelial foot processes are extensively fused.



ARAS develop the classic Alport GBM lesion, consisting of diffuse thickening accompanied by "basket-weave" transformation of the lamina densa, intramembranous vesicles and densities, scalloping of the epithelial surface of the GBM and foot process effacement (*Fig. 26-4*). The percentage of GBM displaying this lesion increases progressively with age in boys with XLAS (34). Females with XLAS display a range of GBM alteration, from focal GBM attenuation to diffuse thickening and basket-weaving, and there is no consistent correlation of GBM findings and age (34).

Routine immunofluorescence is normal or shows nonspecific immunoprotein deposition. Because disease-causing mutations result in abnormal expression of α3α4α5(IV) and α5α5α6(IV) networks in basement membranes in most Alport patients, specific immunostaining for type IV collagen α chains is useful for both diagnosis and differentiation of XLAS and ARAS (47) (*Figs. 26-5* and *26-6*). Expression of the α3(IV), α4 (IV) and α5(IV) chains is completely absent in ~80% of XLAS males, and 60–70% of females with XLAS exhibit mosaic expression of these chains (*Fig. 26-5*). In most patient with ARAS, GBM is nonreactive with antibodies to the α3(IV), α4(IV) and α5(IV) chains, and Bowman's capsules and tubular basement membranes are also negative for the α3(IV) and α4(IV) chains (48) (*Fig. 26-6*). However, immunostaining for α5(IV) chains in Bowman's capsules and tubular basement membranes is positive, because in these basement membranes expression of α5α5α6(IV) networks is preserved. It is important to note that altered immunostaining for the α3(IV)-α6(IV) chains in patients with XLAS and ARAS is not age-dependent. Therefore, this method can provide diagnostic information even in patients who are too young to display characteristic abnormalities in GBM ultrastructure.

Normal epidermal basement membranes (EBM) express the α5α5α6(IV) network but not the α3α4α5(IV) network. Epidermal basement membranes show negative staining for α5(IV) chains in about 80% of XLAS males, and mosaic expression of α5(IV) is observed in 60–70% of XLAS females, allowing diagnosis of XLAS by skin biopsy (49, 50) (*Fig. 26-5*). Skin biopsy is not useful for diagnosis of ARAS, since expression of α5(IV) in epidermal basement membranes is normal (48) (*Fig. 26-6*).

Cochlear. The hearing loss of Alport syndrome arises from cochlear dysfunction (51). Normal cochleae in mice, dogs and humans express type IV collagen α3, α4, and α5 chains in the spiral limbus, spiral ligament and in the basement membrane interposed between the organ of Corti and the basilar membrane (52–55). However, expression of these chains is absent in cochleae of ARAS mice (52), XLAS dogs (53) and men with XLAS (55). Careful examination of well-preserved cochleae from men with XLAS and deafness revealed a zone of separation

Figure 26-4

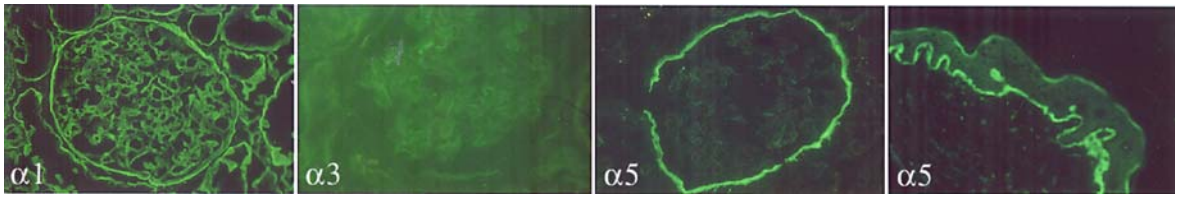
between the organ of Corti and the underlying basilar membrane, and cellular infiltration of the tunnel of Corti and the spaces of Nuel (56). These changes are not observed in similarly well-preserved cochleae obtained from normal individuals or patients with other causes of deafness. The structural changes observed in Alport cochleae may be associated with defective attuning of basilar membrane motion and hair cell stimulation, resulting in reduced

Figure 26-6

Immunofluorescene microscopy. Distribution of the α(IV) chains in renal and epidermal basement membranes of patients affected with autosomal recessive Alport syndrome. (See color plate 10)



acuity of hearing. Similar changes have not been observed in cochleae from mice or dogs with Alport syndrome, although deafness in these models is minimal or absent.

Ocular. The α3, α4, and α5(IV) chains are normal components of several basement membranes in the eye, including the corneal basement membrane, Descemet's membrane, lens capsule, the internal limiting membrane of the retina, and the retinal pigment epithelium basement membrane (54, 57–59). The ocular manifestations of Alport syndrome likely arise from absence or abnormality of α3α4α5(IV) networks in these basement membranes. The lens capsules of Alport patients with anterior lenticonus exhibit marked attenuation and focal areas of dehiscence, suggesting that the lens capsule lacks the mechanical strength to maintain normal lens shape (58, 60, 61).

Diagnostic Considerations

Accurate diagnosis of Alport syndrome and differentiation of this condition from other causes of familial and sporadic glomerular hematuria are based upon careful clinical evaluation, reliable pedigree data and thoughtful consideration of the relative merits of skin biopsy, kidney biopsy and molecular analysis.

In a child with isolated hematuria, a positive family history of hematuria in the absence of a history of ESRD suggests a diagnosis of thin basement membrane nephropathy (TBMN). Two rare causes of familial hematuria associated with macrothrombocytopenia, Epstein and Fechtner syndromes, can be excluded if the platelet count is normal. Familial IgA nephropathy (62) and membranoproliferative glomerulonephritis (63) are uncommon causes of familial hematuria.

In the absence of a family history of hematuria, the differential diagnosis of glomerular hematuria includes Alport syndrome, TBMN, IgA nephropathy, membranoproliferative glomerulonephritis, membranous nephropathy, lupus nephritis, postinfectious glomerulonephritis and Henoch-Schonlein nephritis. Associated clinical findings (e.g., rash, arthritis) or laboratory findings (e.g., hypocomplementemia) will suggest diagnoses other than Alport syndrome in many of these patients.

While results of hearing evaluation are likely to be normal in young children with Alport syndrome, audiometry may be very useful in children over 6–8 years of age. Ophthalmologic assessment may also provide valuable information, although ocular lesions are more prevalent in Alport patients with advanced disease, and less likely to be present in the population of young patients in whom differential diagnosis of hematuria may be more difficult.

Tissue studies can complement clinical and pedigree information that is insufficient to clearly differentiate Alport syndrome from other diagnoses. Skin biopsy with immunostaining for the α5(IV) chain, as described above, may be diagnostic, especially when clinical and pedigree data strongly suggest a diagnosis of XLAS. Normal expression of the α5(IV) chain in epidermal basement membrane can be explained in several ways: (1) the patient has XLAS, but his or her COL4A5 mutation does not abolish α5(IV) expression; (2) the patient has a form of Alport syndrome (ARAS or ADAS) in which expression of α5(IV) in epidermal basement membranes is not affected; or (3) the patient does not have Alport syndrome. Whereas skin biopsy is useful only if it provides definitive confirmation of a diagnosis of XLAS, renal biopsy carries the advantage of enabling the diagnosis of XLAS, ARAS and non-Alport kidney disease, particularly if type IV collagen immunostaining is applied.

Mutation detection rates of 80–90% are attainable in males with XLAS using direct sequencing of COL4A5 (64). Comparable data for detection of COL4A3 and COL4A4 mutations in patients with ARAS are lacking. COL4A5 mutation analysis has been commercially available in Europe for some time, and has recently become available in the United States. Laboratories providing type IV collagen gene sequencing can be found through the GeneReviews website (www.genereviews.org) and through the website of the Alport Syndrome Foundation (www.alportsyndrome.org).

Treatment

There have been no controlled therapeutic trials in human Alport syndrome. Consequently, treatment recommendations must be derived from animal studies and anecdotal reports. In murine ARAS several interventions have proven efficacious, including angiotensin antagonism (65–67), TGFb-1 inhibition (68), chemokine receptor 1 suppression (69), administration of bone morphogenic protein-7 (70), blockade of matrix metalloproteinases (71) and bone marrow transplantation (72, 73). Inhibition of angiotensin converting enzyme (ACE) treatment resulted in prolongation of survival in dogs with XLAS (74). In uncontrolled studies of human Alport subjects ACE inhibition reduced proteinuria, at least transiently (75, 76).

Cyclosporine treatment also resulted in prolongation of survival in male XLAS dogs (77). Cyclosporine treatment diminished proteinuria and appeared to stabilize renal function in a small, uncontrolled study of Alport males (78). However, apparent acceleration of renal fibrosis was suggested by the results of another study of cyclosporine treatment in Alport patients (79).

At the present time, angiotensin antagonism aimed at suppression of proteinuria appears to be the least risky of available treatment options. There is as yet no evidence that initiation of angiotensin blockade can delay the onset of overt proteinuria in Alport patients who have isolated hematuria. With advancing disease, management of hypertension and other complications of nephrotic syndrome and renal insufficiency is required.

Renal Replacement Therapy

Patients with Alport syndrome typically have excellent outcomes following renal transplantation (80). Two issues require the special attention of transplant physicians involved in the care of Alport patients. First, evaluation of potential related donors must identify affected individuals who may be at risk for development of significant renal insufficiency. Second, posttransplant monitoring must allow early diagnosis of posttransplant anti-GBM nephritis, a complication of transplantation that is unique to Alport syndrome.

Familiarity with the genetics of Alport syndrome and the signs and symptoms of the disease is required for informed donor evaluation. Since 100% of males with XLAS have hematuria (22), the absence of hematuria excludes Alport syndrome in male relatives of XLAS patients. About 95% of females with XLAS have hematuria (25), so there is only a 5% chance that a female without hematuria is affected. Given that by age 60 there is an estimated risk of ESRD of 30% in women with XLAS (25), female members of XLAS families who have hematuria should generally be discouraged from kidney donation.

Anti-GBM nephritis occurs in ~3% of transplanted Alport males (80). The onset of anti-GBM nephritis typically occurs during the first year after transplantation, and usually results in irreversible graft failure within weeks to months of diagnosis. There is a high rate of recurrence in subsequent allografts. In XLAS males the primary target of anti-GBM antibodies is the α5(IV) chain (81, 82). Females with XLAS who require transplantation are at little or no risk of developing anti-GBM nephritis. However, both males and females with ARAS can develop anti-GBM nephritis after transplantation. The α3(IV) chain is the primary target of anti-GBM antibodies in ARAS patients (81, 83). Goodpasture auto-antibodies and anti-GBM antibodies from transplanted Alport patients target distinct epitopes on the carboxyterminal noncollagenous (NC1) domain of the α3(IV) chain (84).

Renal allograft biopsy with routine immunofluorescence should be performed early in the evaluation of Alport patients who develop hematuria or increased creatinine after transplantation, or if circulating anti-GBM antibodies are detected. Anti-GBM nephritis after renal transplantation should be treated with cytotoxic therapy and plasmapheresis, although such therapy has been unsuccessful in the majority of reported patients.

Thin Basement Membrane Nephropathy

Historically, families displaying autosomal dominant transmission of isolated, nonprogressive hematuria were classified as having "benign familial hematuria" (85–87). Affected patients typically exhibited no renal parenchymal abnormalities apart from thinning of glomerular basement membranes (GBM) observed by electron microscopy (88–93). The more inclusive term "thin basement membrane nephropathy" (TBMN) has gradually displaced benign familial hematuria as the preferred designation for hematuria associated with thin GBM, because it encompasses sporadic cases of hematuria associated with thin GBM; familial or sporadic cases of thin GBM in which hematuria is accompanied by proteinuria, hypertension and/or renal insufficiency; and benign familial hematuria.

Thinning of GBM is a pathological description rather than a distinct entity. Depending on the timing of renal biopsy, GBM attenuation may be observed in patients with hemizygous or heterozygous mutations in COL4A5

(X-linked Alport syndrome, or XLAS), biallelic mutations in COL4A3 or COL4A4 (autosomal recessive Alport syndrome, or ARAS), heterozygous mutations in COL4A3 or COL4A4 (the carrier state of ARAS) and mutations at nontype IV collagen loci (94). The natural history of hematuria associated with thin GBM is determined by the underlying mutation, perhaps in combination with remote modifier genes. Hemizygous mutations in COL4A5 and biallelic mutations in COL4A3 and COL4A4 result in progressive GBM thickening, proteinuria and renal failure. Heterozygous mutations in COL4A3 or COL4A4 are usually associated with persistent GBM attenuation, isolated hematuria and benign outcomes. Heterozygous mutations in COL4A5, in women with XLAS, are associated with a wide range of prognostic outcomes, as described in the section on Alport syndrome. Perhaps this spectrum of outcomes reflects differences in the cellular responses provoked by complete absence of α3α4α5(IV) networks from GBM (hemizygous XLAS and ARAS), mixed α3α4α5(IV)-positive and α3α4α5(IV)-negative GBM (heterozygous XLAS) and homogeneous reduction in GBM content of α3α4α5(IV) networks (heterozygous COL4A3 or COL4A4 mutations).

Clinical Features

Persistent microscopic hematuria, associated with normal blood pressure, renal function and urine protein excretion, is the characteristic feature of TBMN in childhood (2, 3). TBMN is not specifically associated with hearing loss, ocular defects or other extrarenal abnormalities.

Proteinuria has been reported in up to 30% of adults with thin GBM (92, 95–99). About 5–7% of adult patients with TBMN have elevated serum creatinine levels (95, 98, 99).

Pathology

Diffuse attenuation of the lamina densa and GBM, with preservation of normal podocyte anatomy, is the characteristic histological abnormality in TBMN. Glomerular obsolescence or sclerosis may be observed in adult patients with TBMN, including some with heterozygous COL4A3 or COL4A4 mutations (98, 100).

GBM width is dependent on age and gender. The lamina densa and GBM increase rapidly in width between birth and 2 years of age, followed by a more gradual increase during childhood and adolescence (101). Adult men exhibit greater GBM widths than adult women (102).

Because different investigators have used different techniques to measure GBM width, a standard definition of "thin" GBM does not exist. In children the threshold is 200–250 nm (1, 3, 103), while the adult threshold ranges from 250 to 330 nm (92, 104).

Routine immunofluorescence studies of renal biopsy material from patients with TBMN are typically unremarkable. Immunostaining using specific antibodies against α3(IV), α4(IV), and α5(IV) chains yields normal results in patients with TBMN (88, 89, 105).

Diagnostic Considerations

IgA nephropathy, TBMN and Alport syndrome together account for the majority of children with glomerular hematuria seen in pediatric nephrology clinics (1–4). Thorough clinical evaluation, including detailed pedigree analysis, can assist in determining which children need tissue studies and which can be followed prospectively without biopsy. Obtaining urinalyses on first-degree family members may provide valuable information, since adults with familial hematuria may be unaware that they are affected (106).

When a child has isolated microscopic hematuria, a family history of dominantly transmitted hematuria and a negative family history for renal failure, a clinical diagnosis of TBMN is reasonable, and renal biopsy is unnecessary. These children should be followed prospectively every 1–2 years. If proteinuria or hypertension develops, renal biopsy should be considered.

In children who have persistent microscopic hematuria but do not have affected relatives, renal biopsy is often informative. In those children whose renal biopsy findings are limited to GBM attenuation, the clinician's challenge is to differentiate TBMN and Alport syndrome. Audiometry and ophthalmologic examination may be helpful in older children but these studies will usually be normal in young children with Alport syndrome. Abnormal results of immunostaining for the α3(IV), α4(IV) and α5(IV) chains suggests a diagnosis of Alport syndrome. While normal immunostaining results cannot entirely exclude Alport syndrome, they can help support a suspected diagnosis of TBMN.

The role of molecular analysis of the COL4A3, COL4A4 and COL4A5 genes in patients with suspected TBMN remains to be determined. Since the finding of a heterozygous mutation in COL4A3 or COL4A4 cannot guarantee a benign prognosis (100, 107–109), the need for follow-up examination of such patients would not be precluded.

Treatment

Since TBMN usually has a benign outcome, treatment is rarely indicated. Patients with TBMN who have proteinuria are theoretically candidates for angiotensin blockade.

Hereditary Angiopathy with Nephropathy, Aneurysms and Cramps (HANAC Syndrome)

Mutations in the COL4A1 and COL4A2 genes have not been found in patients with Alport syndrome or TBMN (110). Recently, missense mutations in the COL4A1 gene were described in three families displaying an autosomal dominant hereditary angiopathy associated with nephropathy, aneurysms and muscle cramps (HANAC syndrome) (111). The mutations affect three highly conserved glycine residues in the collagenous domain of the α1(IV) chain. Retinal arteriolar tortuosity and retinal hemorrhages were common to affected individuals in all three families, as were intracranial aneurysms, leukoencephalopathy and elevated creatine kinase levels. In two families, affected individuals had muscle cramps. Renal findings in affected individuals included microscopic and gross hematuria in one family, mild renal insufficiency in two families and renal cysts in all three families.

Renal biopsy in affected individuals with hematuria showed no abnormalities of GBM structure or type IV collagen expression. However, basement membranes of Bowman's capsules, tubules and interstitial capillaries exhibited irregular thickening, splitting into multiple layers and focal interruptions.

Laminin Disorders

Pierson Syndrome

The association of congenital nephrotic syndrome with eye abnormalities in siblings was first described by Pierson in 1963 (112). Affected infants died within the first year of life with ESRD. Subsequent reports of additional patients described variable abnormalities on fetal ultrasound, including kidney enlargement and hyperechogenicity, oligohydramnios, placental enlargement and/or pulmonary hypoplasia (113, 114). Infants surviving to term exhibited congenital nephrotic syndrome, with renal biopsy findings of mesangial sclerosis and diffuse GBM abnormalities, accompanied by ocular globe enlargement (buphthalmos) with reduction in the size and reactivity of pupils (microcoria). Additional ocular findings in some patients included cataract, posterior rupture of the lens capsule and retinal abnormalities. Some affected children were also found to have muscular hypotonia, central nervous system hemangioma and genital abnormalities (115, 116).

The gene for Pierson syndrome was mapped to chromosome 3p14-p22 and identified as LAMB2, the gene encoding the laminin β2 chain, by Zenker and colleagues in 2004 (113). Subsequent reports indicate that LAMB2 mutations may be associated with isolated congenital nephrotic syndrome and with mild variants of Pierson syndrome (117–121). The absence of the laminin β2 chain in transgenic mice results in massive proteinuria along with retinal and neuromuscular abnormalities (122). In these mice, proteinuria precedes the appearance of podocyte abnormalities, suggesting that the GBM contributes to the barrier function of the glomerular capillary wall.

Type III Collagen Nephropathies

Nail-Patella Syndrome (Hereditary Osteo-Onychodysplasia)

Nail-patella syndrome (NPS) is a rare autosomal dominant disorder characterized by dystrophic nails, hypoplasia or absence of the patellae, dysplasia of the elbows and iliac horns, and renal disease (123, 124). Affected individuals may also exhibit glaucoma and sensorineural deafness (125, 126). The disorder affects about 1 in 50,000 individuals. The severity of renal involvement, which occurs in 30–40% of patients, determines prognosis.

Genetics

Targeted disruption of the LIM homeodomain transcription factor gene Lmx1b in mice resulted in hypoplastic nails and absent patellae as well as renal disease, suggesting a possible locus for human NPS (127). LMX1B, the human homologue of Lmx1b, and the NPS locus were found to map to chromosome 9q34, and heterozygous mutations in LMX1B were identified in NPS patients (128, 129). A variety of LMX1B gene defects have been identified in NPS patients, including missense, splicing, insertion/deletion and nonsense mutations (128–134). The results of *in vitro* experiments in which the transcriptional effects of mixing wild-type and mutant LMX1B protein are measured, along with the variety of observed mutation types, suggest that the NPS phenotype results from haploinsufficiency rather than a dominant-negative mechanism (130, 135). Mutations in the homeodomain of LMX1B protein and female gender may confer an increased risk of renal involvement (126).

LMX1B protein is specifically expressed in glomerular podocytes, beginning at the S-shaped body stage of glomerular development (127). Lmx1b-null mice exhibit marked reduction in GBM expression of the α3 and α4

chains of type IV collagen, and the slit diaphragm proteins podocin and CD2AP (136–138). However, changes in expression of these putative targets of LMX1B were not observed in kidneys of patients with NPS nephropathy (139), perhaps because patients with NPS are heterozygous for LMX1B mutations, leaving the mechanisms for the renal effects of LMX1B mutations uncertain.

Clinical Features

Renal. Less than half of NPS patients have clinical renal disease (140, 141). Symptoms include microscopic hematuria and mild proteinuria, and typically appear in adolescence or young adulthood. Occasional patients develop nephrotic syndrome and hypertension. The nephropathy is typically mild, with about a 10% risk of progression to ESRD. Marked differences in the severity of the nephropathy can be observed in related patients, suggesting the influence of superimposed factors.

Nails. Nail abnormalities occur in over 90% of patients and are usually apparent from birth (142). Fingernails, especially on the thumb and index finger, are more severely affected than toenails. The nails may be absent or dystrophic with discoloration, koilonychias, longitudinal ridges or triangular lunulae.

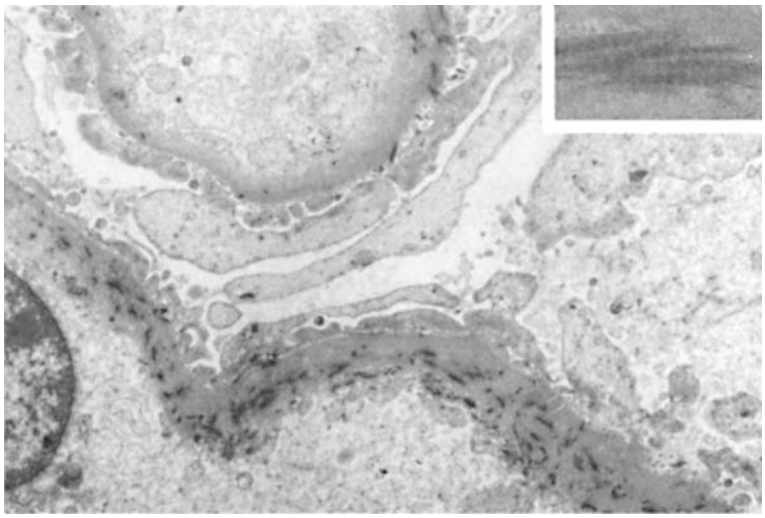
Skeletal defects. Over 90% of NPS patients exhibit aplasia or hypoplasia of the patellae (142). Associated symptoms may include knee pain, effusions, dislocations and osteoarthritis. Dysplasia of the elbows occurs in over 90% of patients (142). Anomalies such as hypoplasia of the radial head with dislocation, posterior processes at the distal ends of the humeri, hypoplasia of the olecranon and elongation of the neck of the radius may be associated with mild to severe limitation in extension, pronation and supination of the forearm. About 80% of patients display osseous processes projecting posteriorly from the iliac wings, known as iliac horns, which are pathognomonic for NPS (142).

Pathology

The nephropathy of NPS has no specific features by light microscopy or routine immunofluorescence. Focal segmental glomerulosclerosis and deposits of IgM and C3 may be observed, depending on the severity of renal involvement. Characteristic lesions are observed by electron microscopy (143, 144). With standard staining techniques the GBM and mesangium exhibit multiple lucencies, imparting a "moth-eaten" appearance. Staining with phosphotungstic acid reveals clusters of cross-banded collagen fibrils within these lucent areas (*Fig. 26-7*). These collagen fibrils have been observed in NPS patients with no clinically evident renal disease, and there is no correlation between the extent of GBM changes and patient age, severity of proteinuria or degree of renal functional impairment (130, 131). Staining of NPS kidneys with antibodies against type III collagen produced irregular, discontinuous labeling of GBM in normal-appearing glomeruli and focally intense staining of sclerotic glomeruli (139).

Figure 26-7

Electron microscopy. Phosphotungstic acidstain (×10,500). Nail patella syndrome. Irregular distribution of fibrillar collagen within the GBM. Inset shows the typical periodicity of interstitial collagen (×48,000).



Treatment

There is no specific therapy for NPS renal disease. Kidney transplantation has been carried out successfully, and recurrence of disease apparently did not recur. Selection of living donors must be performed with care, since NPS is an autosomal dominant disorder.

Collagen Type III Glomerulopathy

Renal disease associated with glomerular deposits of type III collagen has been described in patients who have no extrarenal abnormalities (145–148). In comparison to NPS patients, subjects with collagen type III glomerulopathy have relatively severe renal findings, more extensive histological changes and greater glomerular type III collagen accumulation.

Clinical Features

Patients with collagen type III glomerulopathy can present in childhood or in adulthood. Early presentation is associated with a more severe disease course. Proteinuria is common to the juvenile and adult forms of the disease. In children, proteinuria progresses to nephrotic syndrome and is accompanied by hypertension and the development of renal failure (145, 148). Microangiopathic hemolytic anemia has been described in some patients. Patients presenting in adulthood exhibit more gradual increase in proteinuria and loss of renal function (147).

Pathology

Light microscopy shows enlarged glomeruli with mesangial expansion and glomerular capillary wall thickening due to subendothelial accumulation of poorly staining material. Routine immunofluorescence studies are unremarkable or show nonspecific immunoprotein deposits. Electron microscopy shows deposits of electron-lucent material in mesangial matrix and GBM. Staining with phosphotungstic acid demonstrates fibrillar collagen in these deposits which is identified as type III collagen by specific immunostaining.

Hereditary Nephritis with Thrombocytopenia and Giant Platelets: Epstein and Fechtner Syndromes

Epstein and Fechtner syndromes are allelic, autosomal dominant disorders that have some features in common with Alport syndrome, such as hematuria, progressive nephropathy and sensorineural deafness (149, 150). However, these conditions are distinguished clinically from Alport syndrome by the invariable presence of thrombocytopenia and giant platelets. In addition, granulocytes of patients with Fechtner syndrome display cytoplasmic inclusions known as Dohle-like bodies, and these patients may develop cataracts. In some patients ultrastructural changes in GBM resemble those of Alport syndrome (151, 152). However, glomerular expression of type IV collagen α3, α4 and α5 chains is normal in these patients (152).

Despite the similarities with Alport syndrome, Epstein and Fechtner syndromes are genetically distinct disorders. Following the mapping of the Epstein and Fechtner loci to chromosome 2q11–13 (153, 154), heterozygous mutations in MYH9, the gene that encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA), were identified in patients with these disorders, as well as in patients with two other conditions featuring giant platelets, Sebastian syndrome and May-Hegglin anomaly, and in nonsyndromic hereditary deafness (DFNA17) (155–158). NMMHC-IIA is expressed in podocytes (159), but the mechanism by which mutations in this protein might adversely affect podocyte function is unknown.

Hereditary Metabolic Disorders with Primary Glomerular Involvement

Fabry Disease

Anderson-Fabry disease is a rare X-linked disorder of glycosphingolipid metabolism resulting from deficiency of the lysosomal hydrolase a-galactosidase A. Clinical aspects of this disease are discussed in Chapter 51.

Renal tissue from all hemizygous patients demonstrates characteristic glycolipid accumulation within every glomerular, vascular and interstitial cell and within distal tubular cells, regardless of age at biopsy. Two intermingled cell populations, normal cells and cells exhibiting glycolipid accumulation, are observed in heterozygous females. Degenerative renal changes develop with age. They initially affect vessels and consist of round fibrinoid deposits resulting from smooth muscle cell necrosis. These changes are followed by nonspecific vascular, glomerular and tubulointerstitial lesions (160). Enzyme replacement appears to result in decreased glycolipid storage in renal cells and stabilization of renal function (161, 162).

Other Glomerular Lipidoses

Nephrosialidosis is a rare autosomal recessive condition caused by neuraminidase deficiency. Clinical and radiologic features include dysmorphic facies, visceromegaly, mental retardation, skeletal anomalies, marrow foam cells and cherry-red spot on fundoscopy. Renal involvement consists of proteinuria and progression to ESRD early in life (163). Renal biopsy findings include podocyte and proximal tubular cell vacuolization. By electron microscopy many of these vesicles appear empty, but others contain flocculent or membrane-like electron-dense material. Wheat germ agglutinin binds to cytoplasmic material in podocytes and tubular cells, indicating the presence of compounds with terminal sialic (neuraminic) acid moieties (164).

Silent accumulation of glycolipids or mucopolysaccharides has been described in patients with Gaucher disease, Niemann-Pick disease, I-cell disease and GM1 gangliosidosis (165). Clinical renal disease during childhood is unusual in patients with these disorders.

Hereditary Metabolic Disorders with Secondary Glomerular Involvement

Familial Amyloidosis

Hereditary amyloidosis encompasses a group of autosomal dominant disorders characterized by extracellular accumulation of protein fibrils arranged in an antiparallel β-pleated sheet configuration. These disorders are classified according to the protein composing amyloid fibrils and/or the type of mutation in the corresponding gene. Transthyretin variants have been found in most affected families, but variants of cystatin C, gelsolin, apoliprotein A1, fibrinogen and lysozyme have described in other kindreds (166). Symptomatic renal involvement is unusual during childhood.

Familial Mediterranean fever is an autosomal recessive disorder described primarily, but not exclusively, in several ethnic groups originating in the Mediterranean region. The disease is characterized by recurrent episodes of fever, abdominal pain, joint pain, pleuritis and pericarditis. Renal amyloidosis of the AA type may result in proteinuria and eventual renal failure. Renal amyloidosis of the AA type may be associated with the autosomal dominant disorders *Muckle-Well syndrome* and *tumor necrosis factor receptor-1 associated periodic syndrome (TRAPS)* (167).

Alpha-1 Antitrypsin Deficiency

Chronic liver disease due to deficiency of alpha-1-antitrypsin (α1AT) may be associated with glomerulonephritis in children (168–170). Renal biopsy reveals diffuse or focal segmental membranoproliferative glomerulonephritis, type I in most cases, associated with subendothelial deposits composed of immunoglobulin and complement. Renal manifestations include proteinuria, hypertension and renal failure. Regression of nephrotic syndrome and glomerular lesions after liver transplantation has been observed (171).

Alagille Syndrome

Alagille syndrome is an autosomal dominant disorder with variable penetrance that causes cholestasis in childhood, associated with characteristic facies, cardiac malformations, vertebral abnormalities, posterior embryotoxon, hypogonadism, growth retardation and high-pitched voice. The disease results from mutations in *Jagged1*, which encodes a ligand for the Notch1 receptor (172). Accumulation of lipid vacuoles in mesangial matrix, mesangial cells and GBM has been observed in some patients (173) (› *Fig. 26-8*). The extent of mesangiolipidosis correlates with the severity of cholestasis. Although the glomerular lesions are present early in life, renal symptoms in childhood are unusual. Progression to ESRD may occur in affected adults.

Hereditary Lecithin-Cholesterol Acyltransferase (LCAT) Deficiency

LCAT deficiency is a rare autosomal recessive disorder characterized by the inability to esterify plasma cholesterol, leading to deposition of unesterified cholesterol in tissues, including the kidney (174). Progression to ESRD usually occurs in the fourth or fifth decade. Glomerular lesions include accumulation of foam cells of endothelial and mesangial origin and massive accumulation of lipids within the mesangial matrix and subendothelial GBM (174).

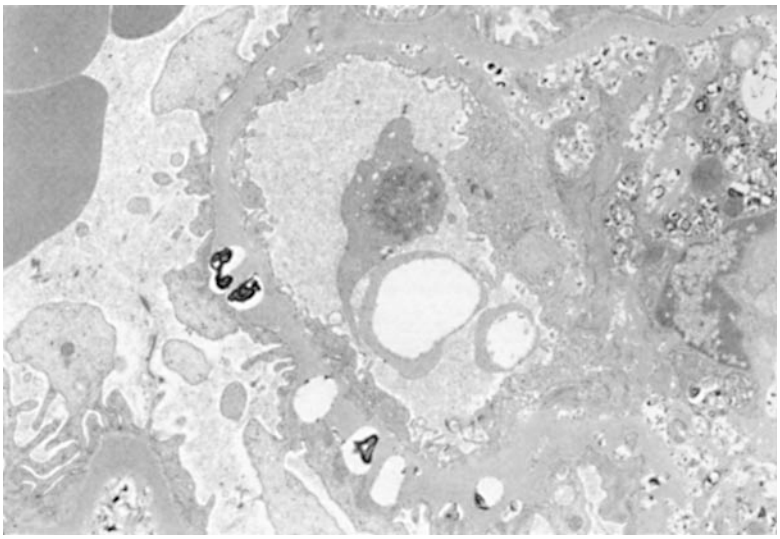
Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy is characterized by intraglomerular lipoprotein thrombosis and high plasma concentrations of apolipoprotein E (175). The disease is usually detected in adults, but onset of symptoms during childhood has been described (176). Renal symptoms range from proteinuria to nephrotic syndrome, and progression to ESRD occurs in some patients. Recurrence of glomerular lesions after renal transplantation has been observed (177). Mutations in apolipoprotein E have been found in patients with this disorder (178).

Glomerular lipidosis has also been reported in patients with *familial hypercholesterolemia* resulting from defects in the LDL receptor, in *type III hyperlipoproteinemia*, and in patients with *cholesterolic polycoria*. Renal symptoms usually appear in adulthood in patients with these disorders.

Figure 26-8

Electron microscopy. Lead citrate and uranyl acetate stain (×8,600). Alagille syndrome. Massive accumulation of lipid vacuoles within mesangial cells and matrix. Irregular distribution of lipid vacuoles within the GBM.



Familial Juvenile Megaloblastic Anemia

Familial juvenile megaloblastic anemia (Imerslund-Grasbeck syndrome) is a rare autosomal recessive disorder caused by selective vitamin B12 malabsorption. Anemia is detected in infancy or early childhood and is associated with mild, nonprogressive proteinuria. Most cases arise from mutation in the gene for either cubilin (chromosome 10) or amnionless (chromosome 14), which are components of the intestinal receptor for the vitamin B12-intrinsic factor complex as well as the receptor that mediates proximal tubular reabsorption of filtered protein (179).

Other Hereditary Diseases with Glomerular Involvement

Charcot-Marie-Tooth (CMT) Disease

CMT disease is a genetically heterogeneous, familial peripheral neuropathy resulting in progressive symmetric atrophy and weakness of distal muscles and sensory deficits. Autosomal dominant and X-linked forms have been described, due to mutations in the myelin protein zero gene on chromosome 1, peripheral myelin protein 22 gene on chromosome 17, and the connexin 32 gene on the X chromosome (180). Proteinuria and progression to ESRD associated with focal glomerulosclerosis occur in some patients (181). Since some of these patients are also deaf, CMT disease could potentially be misdiagnosed as Alport syndrome. No specific ultrastructural changes in GBM have been described in patients with CMT disease.

Cockayne Syndrome

Cockayne syndrome is an autosomal recessive disorder characterized by growth retardation, neurologic abnormalities, premature aging, senile facies, sensorineural deafness, cataracts, retinopathy, sun sensitivity and dental caries (182). The disorder arises from mutations in genes involved in DNA nucleotide excision repair (183). Renal symptoms including hypertension, proteinuria and renal insufficiency occur in about 10% of patients, associated with diffuse, homogeneous GBM thickening (184).

Hereditary Acro-Osteolysis with Nephropathy

Hereditary acro-osteolysis is a rare disorder characterized by arthritic episodes and progressive resorption of carpal and tarsal bones. Familial (dominant or recessive) and sporadic cases have been reported. Hypertension, proteinuria and progressive renal failure occur in some patients (185). Renal biopsy findings include arteriolar thickening and sclerosis and focal glomerulosclerosis.

Other Syndromes with Renal Involvement

Renal abnormalities, typically cystic renal dysplasia and/or tubulointerstitial lesions, are found in most patients with *Bardet-Biedl syndrome (BBS)*, a genetically heterogeneous, autosomal recessive disorder whose cardinal features included obesity, polydactyly, mental retardation, retinal dystrophy and hypogonadism (186). Glomerular symptoms such as proteinuria and questionable glomerular changes have been described in a few patients (187). Mutations in several genes involved in the functioning of primary cilia have been linked to BBS (188).

Alstrom syndrome is an autosomal recessive disorder characterized by cone-rod dystrophy, obesity, progressive sensorineural deafness, dilated cardiomyopathy, insulin resistance syndrome and developmental delay. Renal tubular dysfunction and tubulointerstitial lesions have been observed in some patients (189). Renal disease due to vascular lesions and secondary glomerulosclerosis occurs in some patients with *familial dysautonomia.*

Hereditary Glomerulopathies Without Extrarenal Symptoms

Fibroncectin Glomerulopathy

Fibronectin glomerulopathy is associated with massive accumulation of fibronectin derived mainly from the soluble plasma isoform, transmitted as an autosomal dominant trait (190–192). A substantial fraction of cases arises from mutations in the gene FN1 (193), which is located on chromosome 2 and encodes fibronectin, but another locus appears to exist at chromosome 1q32 (194). Clinically, the disease is characterized by proteinuria of variable magnitude, typically first observed in early adulthood. Subsequently, patients develop hypertension and renal insufficiency, with gradual progression to ESRD.

Other Familial Glomerulopathies

Persistent proteinuria with the abrupt development of rapidly progressive renal failure, malignant hypertension and microangiopathic hemolytic anemia during the third or fourth decade of life, transmitted as an autosomal dominant trait, has been described in several families (195). Renal biopsy findings included diffuse vascular injury, ischemic glomerular changes, and glomerular deposits of IgM and C3. The cause(s) of this disorder is apparently unknown.

Mitochondrial Cytopathies

Mitochondrial cytopathies are a heterogeneous group of disorders resulting from genetic defects in enzymatic complexes of the respiratory chain, leading to impaired oxidative phosphorylation and energy production. The most common renal defect is the de Toni-Debre-Fanconi syndrome, associated with nonspecific abnormalities in tubules and intersititium on renal biopsy, but glomerular lesions such as focal segmental glomerulosclerosis, collapsing glomerulopathy and crescentic glomerulonephritis may also occur (196). Proteinuria has been found in patients with maternally inherited diabetes and/or deafness and in patients with complete or incomplete MELAS syndrome (*m*itochondrial *e*ncephalopathy with *l*actic *a*cidosis and *s*troke-like episodes).

27 Idiopathic Nephrotic Syndrome: Genetic Aspects

Eduardo Machuca · Ernie L. Esquivel · Corinne Antignac

Introduction

Hereditary forms of nephrotic syndrome (NS) have been considered as infrequent disorders; however, 3–6% of the cases with NS have an affected sibling (1–3). Over the last decade, screening of large cohorts of pediatric patients presenting with steroid-resistant nephrotic syndrome (SRNS) for gene mutations has revealed the importance of genetic disorders in the pathogenesis of proteinuric glomerulopathies. At least 66% of the cases presenting with SRNS during the first year of life have an underlying genetic disease (4). In cases with infantile and juvenile SRNS, the overall proportion of genetic forms appears significantly lower, although the precise frequency remains unknown. Because autosomal recessive diseases may present as sporadic cases, the incidence of hereditary forms of NS is certainly underestimated. From a clinical perspective, most patients with hereditary SRNS will be resistant to immunosuppressive agents and do not experience relapse after transplantation (5–7).

Gene discovery efforts aimed at unraveling the causes of Mendelian forms of nephrotic syndrome have resulted in the identification of mutations in novel genes that encode proteins crucial for the establishment and maintenance of the glomerular filtration barrier. These discoveries have helped decipher the pathophysiologic mechanisms of the glomerular filtration process. Mutations in six genes have been implicated in different forms of non-syndromic SRNS (*Table 27-1*, *Fig. 27-1*). Mutations in *NPHS1*, encoding nephrin, are responsible for most of the cases with congenital nephrotic syndrome (CNS) and might be found in infantile forms of SRNS (8, 9). Mutations in the *NPHS2* gene, encoding podocin, are the most frequent cause of early-onset autosomal recessive SRNS (10), and account for 37.5% of the cases with NS presenting in the first year of life among European populations (4). Some dominant forms of juvenile and adult onset SRNS are due to mutations in *ACTN4* and *TRPC6* (11, 12), encoding the cytoskeletal protein α-actinin-4 and the transient receptor potential ion channel (TRPC) 6, respectively. More recently, mutations in *PLCE1*, which encodes for phospholipase C-epsilon-1, were found in patients with early-onset SRNS and diffuse mesangial sclerosis (DMS) (13).

Syndromic forms of SRNS are less common (*Table 27-1*, *Fig. 27-2*) and may be due to mutations in several genes with varied functions including transcription factors, mitochondrial and lysosomal proteins or constituents of the glomerular basement membrane (GBM). Frasier syndrome (14–16), Denys-Drash syndrome (17–20) and WAGR syndrome (21) are caused by mutations in *WT1*, which encodes for a transcription factor, the Wilms' tumor protein. Furthermore, isolated forms of SRNS may be due to mutations in *WT1* (22). Most cases with Pierson syndrome carry mutations in the *LAMB2* gene, encoding laminin β2, a main component of the GBM (23). Mutations in *LMXB1*, encoding the LIM homeobox transcription factor 1β, are associated with nail-patella syndrome (24). In addition, mutations in the *ITGB4* (epidermolysis bullosa) (25), *SMARCAL1* (Schimke syndrome) (26), *MTTL1* (MELAS syndrome) (27, 28) and *SCARB2* (action myoclonus-renal failure syndrome) genes (29) have been found in patients with diverse extrarenal manifestations associated with SRNS. Patients with primary coenzyme Q10 deficiency due to mutations in *COQ2* and *PDSS2* may develop nephrotic syndrome in addition to neuromuscular symptoms (30–32), although patients with isolated SRNS have been described as well.

This chapter will review the available epidemiologic data, genotype-phenotype correlations and the mechanisms by which mutations in genes implicated in hereditary forms of isolated SRNS lead to proteinuric glomerular disease. A genetic overview on recently discovered genes responsible for rarer cases of hereditary syndromic SRNS and advances in the study of familial Steroid Sensitive Nephrotic Syndrome (SSNS) are presented, as well.

Table 27-1

Hereditary forms of steroid-resistant nephrotic syndrome

Gene	Locus	Inheritance	Protein	Disease
Non-syndromic forms of nephrotic syndrome				
NPHS1	19q13.1	AR	Nephrin	Congenital nephrotic syndrome of the Finnish type. Early-onset SRNS
NPHS2	1q25-31	AR	Podocin	Early and late onset autosomal recessive steroid-resistant nephrotic syndrome. Congenital nephrotic syndrome
PLCE1	10q23	AR	Phospholipase C epsilon 1	Early-onset SRNS with diffuse mesangial sclerosis and FSGS
CD2AP	6p12.3	AR	CD2 associated protein	Early-onset SRNS and FSGS
ACTN4	19q13	AD	α-actinin-4	Late-onset SRNS with incomplete penetrance and slow progression to ESRD
TRPC6	11q21-22	AD	Transient receptor potential ion channel 6	Adult-onset SRNS with FSGS
Unknown	2p12-13.2	AR	Unknown	Steroid-sensitive nephrotic syndrome
Syndromic forms of nephrotic syndrome				
WT1	11p13	AD	Wilms' tumor 1	Denys-Drash syndrome, Frasier syndrome, WAGR syndrome, isolated FSGS and DMS
LAMB2	3p21	AR	Laminin-β2	Pierson syndrome
SMARCAL1	2q35	AR	SW1/SNF2-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a-like 1	Schimke immuno-osseus dysplasia
SCARB2	4q13-21	AR	Scavenger receptor 2 (LIMP-2)	Action myoclonus renal failure
LMX1B	9q34.1	AD	LIM-homeodomain transcription factor 1, beta	Nail-patella syndrome
COQ2	4q21-q22	AR	Parahydroxygenzoate-polyprenyltransferase enzyme	COQ10 deficiency, early-onset SRNS, with or without encephalomyopathy
PDSS2	6q21	AR	Decaprenyl diphosphate synthase-2	COQ10 deficiency, Leigh syndrome and SRNS
MTTL1	Mitochondrial		Mitochondrial tRNA for leucine (UUR)	MELAS syndrome. Mitochondrial diabetes, deafness and FSGS, with or without nephrotic syndrome
ITGB4	17q25.1	AR	Integrin-β4	Epidermolysis bullosa and FSGS
Unknown	14q24.2	AR	Unknown	SRNS and deafness
Unknown	11q24	AD	Unknown	SRNS and deafness
Unknown	Unknown	AR	Unknown	Galloway Mowat syndrome

AR autosomal recessive, *AD* autosomal dominant. In certain cases, mutations in *WT1*, *LAMB2*, *COQ2* and *PDSS2* can be associated with isolated SRNS

Isolated Steroid-Resistant Nephrotic Syndrome

Mutations in the *NPHS2* Gene Encoding Podocin

Gene Identification and Protein Characterization

In 1995, Fuchshuber et al. mapped a genetic locus on chromosome 1q25-31 (SRN1, MIM #600995) in a group of patients from Europe and Northern Africa who presented with childhood onset SRNS, autosomal recessive inheritance, renal histologic findings of Focal Segmental Glomerular Sclerosis (FSGS) and absence of extra-renal disorders (33). These patients rapidly progressed to end-stage renal disease but no recurrence occurred after renal transplantation. Boute et al. used a positional cloning approach thereafter and identified mutations in the *NPHS2* gene, encoding a novel protein podocin (10). Subsequent studies further defined the phenotype associated with mutations in the *NPHS2* gene, revealing that patients usually develop NS from birth to 6 years of age, do not respond to immunosuppressive agents and reach ESRD before the end of the first decade of life (4–6, 34). Histologic findings range from minimal glomerular changes, in patients biopsied early, to FSGS at later stages (10).

Mutations in the *NPHS2* gene are responsible for 39 to 48% of familial and for 10 to 28% of sporadic cases of SRNS (5, 6, 35–37). Interestingly, *NPHS2* mutations have also been identified in patients presenting with congenital onset of NS (4–6, 38). Hinkes et al. demonstrated that among central European patients with NS presenting in the first 3 months of life, podocin mutations comprise 51.4% of all mutations identified (4). In addition, linkage to the chr 1q25-31 locus and mutations in the *NPHS2* gene have been described in patients with late-onset FSGS; therein further broadening the spectrum of phenotypes attributable to podocin mutations (39, 40).

The *NPHS2* gene spans a 25 kb region, consists of eight exons, and encodes podocin, a predicted 42-kDa protein with 383 amino acid residues. Podocin is a lipid raft-associated protein bearing strong homology with stomatin, an integral membrane protein of human erythrocytes which regulates monovalent cation transport and acts as a cytoskeletal anchor (41). Stomatin is also expressed in vertebrate sensory neurons where it plays a role in mechanotransduction (42–44). Moreover, the podocin orthologue in *C. elegans* is the protein MEC-2 (10), which links a neuronal mechanosensory channel involved in touch with the microtubular and cytoskeletal framework and leads to the opening of ion channels (45). Podocin is predicted to be an integral membrane protein with a single transmembrane domain and intracellular NH2- and COOH-terminal ends; thus, forming a hairpin-like structure (10). Immunolocalization studies have localized podocin exclusively in kidney at the slit diaphragm of podocytes (46, 47).

Podocin Expression and Interactions

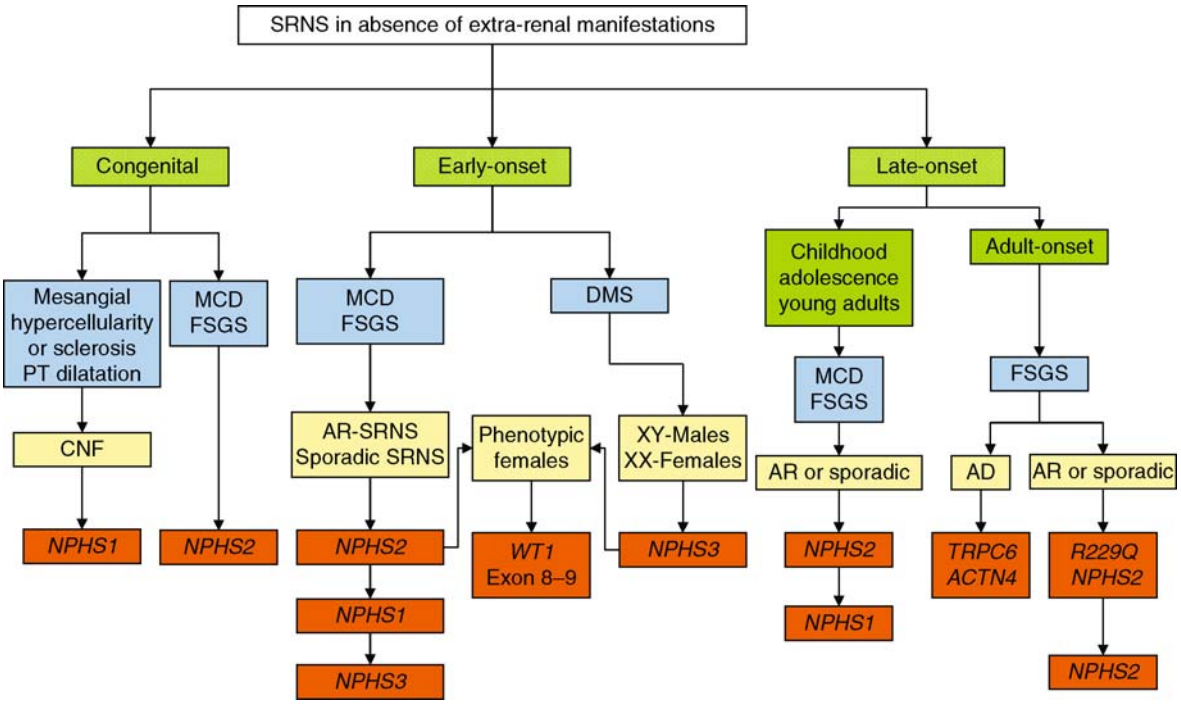
At the mRNA level, podocin is expressed as early as the S-shaped stage, concomitant with vascularization of the interior cleft of the developing nephron (10); whereas protein expression has been documented beginning at the later capillary stage (47). Podocin was demonstrated to accumulate in an oligomeric form in lipid rafts of the slit diaphragm, in complex with nephrin and CD2AP (46), suggesting a potential role of podocin as a scaffolding protein. Nephrin-induced signaling is greatly enhanced by podocin, which binds to the C-terminus of nephrin (48). Interactions of podocin with nephrin, NEPH1, CD2AP and TRPC6 are crucial for structural organization and regulation of filtration function of the slit diaphragm, mechanosensory signaling, podocyte survival, cell polarity and cytoskeletal organization (46, 49–53). In addition, podocin binds cholesterol and creates large protein-cholesterol supercomplexes in the slit diaphragm, thereby regulating the activity of associated TRPC ion channels (51, 52).

Allelic Variants and Genotype/Phenotype Correlations

Mutations in the *NPHS2* gene include a full spectrum of protein-truncating nonsense and frameshift mutations, splice-site variants and missense changes and involve all eight coding exons (6, 10, 35). To date, more than 90 pathogenic mutations and 25 variants of unknown significance have been reported. Mutations are frequently found in pediatric patients with SRNS originating from central Europe and North America, Turkey, Middle East, North Africa and South America (4, 6, 10, 35, 37, 38, 40, 54–61). However, *NPHS2* mutations are rarely detected in cases from Japan (62–65), China (66, 67), Korea and sub-Saharan Africa (68, 69). Several founder mutations have been identified, including p.R138Q in Europe (10, 35), p.R138X in Israeli-Arab population (55), p.V260E in the Comoros island and p.A284V in South America

Figure 27-1

Clinical and genetic approach in patients with non-syndromic SRNS. An exhaustive investigation of extra-renal manifestations must be performed during the first clinical evaluation and subsequent follow-up. In cases in which mutations in *NPHS1*, *NPHS2*, *NPHS3* and *WT1* have been excluded, mutational screening of *LAMB2*, *COQ2* and *PDSS2* might be performed. A first approach genetic screening is proposed according to the phenotype; a negative result implies additional genetic testing if applicable MCD: minimal change disease, FSGS: focal segmental glomerulosclerosis, DMS: diffuse mesangial sclerosis, PT: proximal tubular, AR: autosomal recessive and AD: autosomal dominant.



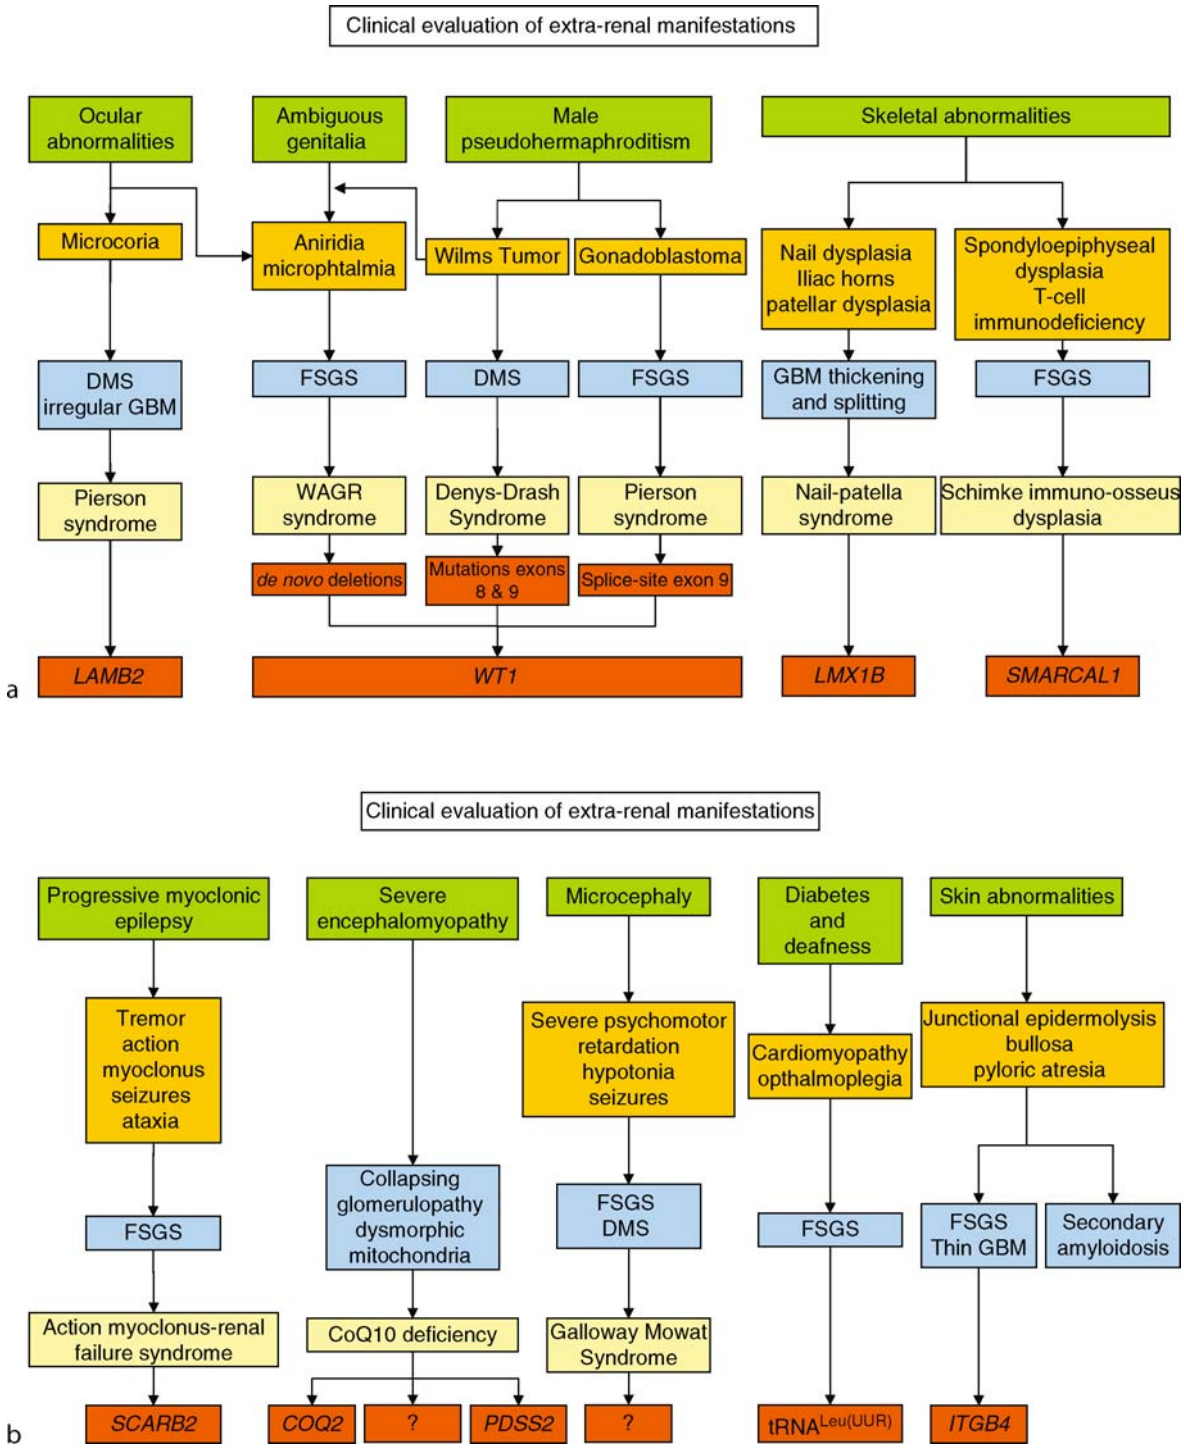
(Antignac, unpublished data). Considering the two largest cohorts comprising pediatric patients with SRNS (5, 37), the most common mutation is p.R138Q, which represents up to 32% of mutant alleles (5).

Individuals bearing pathogenic *NPHS2* mutations in the homozygous or compound heterozygous state manifested earlier than those in whom pathogenic mutations were not identified, for both familial and sporadic cases (5, 37). The mean age at onset of NS in patients carrying two pathogenic mutations ranges between 2.6 and 3.4 years of age (5, 37). Weber et al. also found that patients with frameshift or nonsense mutations in the homozygous or compound heterozygous states led to an earlier onset of nephrotic syndrome than those carrying missense mutations (5). In addition, individuals homozygous for the p.R138Q mutation present with early-onset disease (5, 37). At least two mutations, p.V180M and p.R238S, are associated with a milder phenotype, including later age at onset of NS and age at ESRD (5). The p.R138X mutation has been associated with a high incidence of cardiac abnormalities in children (70), although this finding has not been confirmed in patients carrying other mutations (71).

The p.R229Q variant is the most frequently reported non-synonymous *NPHS2* variant in Caucasians (72), particularly among Europeans, in whom the observed frequency of heterozygotes ranges from 0.03 to 0.13 (5, 6, 40, 72–74). In African-Americans and sub-Saharan populations the p.R229Q allele is infrequent (72). In vitro studies demonstrated decreased binding of the p.R229Q mutant protein to nephrin, suggesting that this variant may be pathogenic (40). Indeed, the p.R229Q variant has been associated with microalbuminuria in a cohort of Brazilian individuals of mixed European and African ancestries (73). Furthermore, the frequency of the p.R229Q allele is significantly higher among individuals of European descent with FSGS compared with controls of similar origin (Machuca et al, in press) (40, 72). This observation has not been confirmed in cohorts with a high proportion of individuals of African-American origin or in patient

Figure 27-2

Clinical and genetic approach in patients with syndromic nephrotic syndrome. Proposed algorithm to decide for directed mutational screening according with the main extra renal manifestations and histological findings in the kidney biopsy.



cohorts with a presumed immune form of nephrotic syndrome (75, 76). In SRNS patients, the p.R229Q polymorphism is frequently found in a compound heterozygous state with a pathogenic *NPHS2* mutation, whereas this association has never been detected among controls (5, 40). These patients present with nephrotic syndrome and ESRD in the second and third decades of life, respectively, markedly contrasting them from patients bearing two pathogenic *NPHS2* mutations (Machuca et al, in press). By contrast, R229Q in the homozygous state has been reported in patients with NS as well as in controls (5, 37, 59), and more likely has a modulatory effect on the risk of developing renal disease. These observations support a pathogenic role of the p.R229Q variant.

Finally, tri-allelic inheritance of *NPHS1* and *NPHS2* mutations has been occasionally reported (36, 54, 77), but additional studies are needed to better understand the complex genetics of renal disease progression in the setting of nephrotic syndrome.

The identification of *NPHS2* mutations in children presenting with nephrotic syndrome may have important clinical implications. Screening of *NPHS2* mutations in patients with SSNS (6), late steroid resistance (78), steroid-dependence or frequent relapses and those with sensitivity to cyclophosphamide have failed to identify pathogenic mutations (6, 36, 79). Patients with mutations in the *NPHS2* gene do not respond to steroid or immunosuppressive therapy; although in a small number of cases a partial reduction of proteinuria has been reported with cyclosporine A (4, 6). Avoidance or withdrawal of immunosuppressive therapies in these patients would spare them from the potential risks and side-effects associated with these drugs.

NPHS2 mutations are rare in patients presenting with FSGS and relapse after transplantation (5). Indeed, patients with two pathogenic *NPHS2* mutations have a significantly lower risk of relapse after transplantation than cases in whom mutations were not identified (8% vs. 30%) (5, 6, 80, 81). Patients bearing mutations in the heterozygous state have a risk comparable to those without mutations (82). In the few patients reported with two *NPHS2* mutations who developed proteinuria post-transplant (5, 6, 83–86), the clinical evolution and renal histology did not correspond to the classic picture of NS relapse after transplantation (5, 83, 85). This potentially suggests de novo glomerulopathy or drug toxicity. In contrast with the mechanism of relapse in cases with *NPHS1* mutations, there is no evidence to support a role for anti-podocin antibodies (5, 83, 87). To-date, the pathophysiologic mechanisms of recurrence of proteinuria in these patients are unclear.

Functional Studies

Functional studies have elucidated some of the mechanism by which missense podocin mutations lead to disease. In vitro studies have shown that podocin missense mutations may either maintain proper intracellular targeting to the plasma membrane or be retained in the endoplasmic reticulum (ER) (88). Interestingly, patients with missense mutations retained in the ER had an earlier onset of disease than patients with mutations that traffic to the membrane (20.8 ± 4 vs. 128.7 ± 9 months) (88). Plasma membrane localization of p.V180M and p.R238S mutations suggests that their deleterious effect could affect the function of the protein by directly modifying its signaling properties and/or altering its interaction with other proteins at the slit diaphragm (88). Moreover, the p.R138X podocin mutant is able to traffic to the plasma membrane (88); however, nephrin is not recruited to lipid rafts, from which downstream signaling events are generated (50). In cells expressing ER-retained podocin mutants, nephrin is similarly retained in the endoplasmic ER (89).

A potential therapeutic strategy that might delay the onset and ameliorate the severity of glomerular disease in patients with missense mutations in genes encoding proteins located in the plasma membrane (i.e., slit-diaphragm) relies on chemical chaperones. Several of these molecules have been used in in vitro systems, allowing for targeting of the mutant protein to the plasma membrane (90).

Animal Models

Podocin-null mice ($Nphs2^{-/-}$) mice are massively proteinuric at birth, NS progresses rapidly, and animals die in the first 5 weeks of life with end-stage renal failure (91). Interestingly, disease progression rate is strongly determined by genetic background and appear to be subject not only to genetic modification, but also to the effects of the maternal environment in which mice are nourished prior to weaning (92). Nephrogenesis appears to be normal in podocin null mice and kidney size at birth is similar to that in wild-type littermates. Unexpectedly, $Nphs2^{-/-}$ mice do not show FSGS lesions, but display typical features of diffuse mesangial sclerosis (DMS). In addition, severe arteriolar lesions characterized by marked thickening of the arteriolar wall, endothelial cell hypertrophy, diffuse dilatation of peritubular capillaries, and multiple foci of interstitial hemorrhages predominating in the superficial cortex are observed. By electron microscopy, podocyte foot processes are only occasionally seen, are abnormal and lack slit diaphragms (91). Resembling the

phenotype of a *Nphs2* null mouse, a mouse model in which the p.R138Q mutant is expressed, leading to mislocalization of the mutant podocin in the ER, develops early-onset severe nephrotic syndrome, display features of DMS, progress rapidly to ESRD and dies at 5 weeks after birth (93). Similarly, mice deficient for CD2AP or NEPH1 develop progressive DMS as the one observed in mice lacking podocin (94, 95).

In addition to mouse models, the zebrafish pronephros has been used as a model of glomerular maturation and development of the filtration barrier. Zebrafish podocin shares 46% identity with the human protein, is specifically expressed in pronephric podocytes, and is required for the development of pronephric podocyte cell structure. Knockdown of podocin expression using antisense morpholino-oligonucleotides results in a loss of slit diaphragms, failure to form normal podocyte foot processes and loss of podocyte barrier function in the mature pronephros (96, 97).

Mutations in the *NPHS1* Gene Encoding Nephrin

NPHS1 has been identified as the major gene involved in congenital nephrotic syndrome of the Finnish type (CNF) (8). However, recent findings have broadened the spectrum of renal disease related to nephrin mutations since patients with childhood-onset SRNS may have *NPHS1* mutations (9, 98). The clinical aspects of CNF, the identification of the *NPHS1* gene and characterization of nephrin are extensively described in chapter 25.

Epidemiologic Overview of NPHS1 Mutations

In the Finnish population, 94% of patients with CNF bear either of two protein-truncating mutations in the *NPHS1* gene (8). The Fin-major mutation (c.121delCT; p.L41fsX91) leads to a frameshift deletion of two base pairs in exon two, resulting in a premature stop codon. The Fin-minor mutation (c.3325C>T; p.R1109X) generates a premature truncation of the terminal 132 amino acids of the protein. The Fin-major and Fin-minor mutations account for 78% and 16% of the mutated alleles in Finnish CNF patients, respectively (8); but are rare in other ethnic groups, therein suggesting founder effects (54). Other founder mutations have been sequenced among Old Order Mennonite patients from Lancaster, Pennsylvania (c.1481delC; p.S494fsX548) and patients from Malta (c.3478C > T; p.R1160X) (54, 99).

More than 100 *NPHS1* mutations have been reported worldwide in patients with CNF, most of which are private mutations found in non-Finnish patients (4, 38, 54, 64, 100–106). In Europe, North Africa and North America, the *NPHS1* mutation detection rate is estimated to be 66% (107). Among central European and Turkish patients presenting with NS in the first 3 months of life, *NPHS1* mutations were found in 34.3% and 54.5% of cases, respectively (4). However, *NPHS1* mutations were identified in only 2/13 patients in Japan (64). The lower frequency of congenital cases attributable to *NPHS1* mutations in these ethnic groups compared to Finnish population points to the genetic heterogeneity of congenital nephrotic syndrome.

Milder and Unusual Phenotypes Associated with *NPHS1* Mutations

The spectrum of *NPHS1* mutations includes protein-truncating nonsense and frameshift insertion/deletion mutations, splice-site changes and missense variants. Most of these mutants are retained in the endoplasmic reticulum (ER), although Liu et al. have demonstrated that in vitro treatment with a chemical chaperone may allow for trafficking to the plasma membrane (108, 109). These mutations lead to a severe CNF phenotype, although some *NPHS1* mutations have been reported in milder cases.

The p.R1160X mutation results in an unexpectedly milder phenotype in about 50% of cases, most of whom were females, suggesting a gender effect (54). This mutation is predicted to form a truncated protein lacking the C-terminal 82 amino acids implicated in the interaction with podocin. Surprisingly, all affected cases were homozygous for this mutation and, among those in which renal biopsy was performed, histologic findings were consistent with CNF. Nevertheless, these patients either had mild proteinuria or were in remission between the ages of 5 and 19 years.

Recently, *NPHS1* mutations were identified in a cohort of 160 patients presenting with SRNS after 3 months of age (9). Mutations in the *NPHS2* gene were excluded, as were mutations in exons 8 and 9 of the *WT1* gene in phenotypically female patients (9). The mean age of onset of NS was 3 years (range 6 months to 8 years). Six patients had preserved renal function after 6 years of age, based on a normal serum creatinine. Renal biopsy performed at the time of presentation revealed that most cases had

MCD or FSGS. All patients were resistant to corticosteroids, as well as other immunosuppressive agents when tried. Nine patients out of 98 with sporadic SRNS, and 1 family with 2 affected siblings among 44 families with familial SRNS, carried pathogenic *NPHS1* mutations. Affected cases were compound heterozygotes for at least one "mild" missense mutation, which exhibited normal trafficking to the plasma membrane and maintained the abilities to form nephrin homodimers and to heterodimerize with NEPH1. These findings may explain the lesser severity of disease observed in these cases.

Finally, Kitamura et al. described the clinical course of two siblings bearing compound heterozygous *NPHS1* missense mutations (98). The severe c.793T>C (p.C265R) mutation leads to ER retention, whereas the mild c.2464G>A (p.V822M) mutation encodes a protein that partially retains plasma membrane targeting. Both patients presented with mild to moderate persistent proteinuria detected from birth to 10 months of age, with several self-limited episodes of nephrotic syndrome triggered by upper airway infections. Kidney histology in both cases revealed minimal changes.

These recent studies highlight the importance of *NPHS1* mutation screening in cases of childhood onset NS, particularly in those in whom mutations in podocin were not found. Studies of large patient cohorts with a broader range of disease onset and ethnic backgrounds are needed to better define the frequency and phenotypic spectrum of nephrin mutations.

Animal Models

Mouse models in which the *Nphs1* gene has been inactivated revealed lesions reminiscent of histological changes observed in CNF patients and absence of slit diaphragms, corroborating the crucial role of nephrin in the establishment and maintenance of the glomerular filtration barrier. *Nphs1* inactivation resulted in massive nonselective proteinuria, edema immediately after birth and death within 24 h (110–112). Histological characterization revealed slightly enlarged kidneys, dilated proximal and distal tubules, and microcysts in the cortex and medulla (110). No prominent changes in the branching morphogenesis of the developing collecting ducts could be found (112). Bowman spaces were enlarged and glomeruli were sclerotic and showed hypercellularity and excessive extracellular matrix deposition (112). Electron microscopy revealed effacement of podocyte foot processes and absence of slit diaphragms (110). The glomerular basement membrane appeared normal, and the expression of several basement membrane proteins including type IV collagen, laminin, nidogen, and perlecan, as well as podocyte-specific proteins such as podocin, CD2AP, α-actinin-4, synaptopodin, integrin α3, and α3, α4 and α5 chains of type IV collagen were normal (111).

The nephrin homologue in zebrafish shares only 36% identity with human nephrin; however, both have a similar predicted secondary structure. Nephrin is expressed in the zebrafish pronephros, specifically in the slit diaphragms of podocyte foot processes (96). Nephrin targeting with morpholino antisense oligonucleotides resulted in pericardial edema progressing to generalized edema (96). Nephrin morphant embryos demonstrated podocyte foot process effacement, lacked slit diaphragms and showed filtration barrier dysfunction in the mature pronephros (96). These findings resemble those found in podocin and CD2AP morphant embryos (96, 97).

Mutations in *PLCE1* Encoding Phospholipase C Epsilon 1

The *NPHS3* gene locus was identified on chromosome 10q23.32-q24.1 in seven consanguineous SRNS families (13). A positional cloning approach coupled to gene expression profiling in rat glomeruli identified the *PLCE1* gene, encoding phospholipase C epsilon 1, as a good candidate. Mutational analysis subsequently revealed truncating and missense mutations in several of its 34 exons (13). In the 12 affected individuals carrying truncating mutations, proteinuria and edema, manifested at a median age of 0.8 years (range 0.2–4.0 yrs) and progressed to ESRD by 5 years of age (13). Furthermore, individuals bearing truncating mutations demonstrated lesions of DMS on renal biopsy, whereas FSGS was found in the affected cases homozygous for missense mutations. In the affected individuals presenting with DMS, immunofluorescence studies revealed that *PLCE1* mutations may lead to an arrest of glomerular development at the S-shaped stage, suggesting a potential role not only in cell junction and signaling events, but in development, as well (13). Interestingly, two patients bearing truncating mutations achieved complete remission when treated early and remain free of proteinuria after several years of follow-up; hence potentially opening a window of opportunity for therapy of some forms of hereditary NS (13, 113). Subsequently these investigators have shown that mutations in the *PLCE1* gene account for 28.6% of cases of isolated DMS in a cohort of 40 patients from 35 families mostly of Turkish origin (114). An additional report has described 4 patients with early-onset SRNS, DMS and

PLCE1 mutations (38). In our cohort of patients with SRNS, we have identified several cases carrying truncating *PLCE1* mutations presenting with early-onset SRNS and exhibiting FSGS on renal biopsy (Antignac, personal observation).

PLCε1 is a phospholipase enzyme that catalyzes the hydrolysis of phosphatidylinositol-4,5-biphosphate and generates two second messengers: inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG) (115). IP3 releases Ca^{2+} from intracellular stores, and DAG stimulates protein kinase C. These products initiate a cascade of intracellular responses that result in cell growth and differentiation. Based on the observation that nephrin levels were diminished in the glomeruli of patients bearing mutations in *PLCE1*, it has been shown that PLCε1 interacts with the C-terminal half of IQGAP-1 (13), a cell junction-associated protein and binding partner of nephrin involved in cell morphology and adhesion (116).

The PLCε1 zebrafish orthologue shares 65% identity with the human protein sequence, suggesting conserved function among evolutionarily distant organisms. *Plce1* targeting using antisense morpholino oligonucelotides induced edema and glomerular filtration barrier dysfunction, similar to zebrafish nephrin and podocin loss-of-function morphants (96). Surprisingly, PLCε1 null mice have no obvious developmental defects or evidence of glomerular filtration barrier abnormalities (13, 117).

Mutations in *CD2AP*

CD2AP is a 70-kilodalton adaptor protein that was originally cloned as an interaction partner of CD2, a signaling protein expressed on the surface of T lymphocytes (118). It has been shown that CD2AP is involved several processes including the regulation of the actin cytoskeleton (119–121), endocytosis (122, 123), in the phosphatidylinositol 3-kinase/AKT survival pathway and in the repression of TGF-β induced apoptosis (50, 124).

In the kidney, CD2AP is expressed in podocytes, proximal tubules and collecting ducts. *Cd2ap* null mice developed proteinuria 2 weeks after birth and die by 6 to 7 weeks of age due to advanced renal insufficiency (94). Renal histology showed increased glomerular size and cellularity, foot-process effacement at 1 week, and subsequent abnormal mesangial matrix deposition and glomerular sclerosis 4 weeks after birth (94). *Cd2ap*$^{+/-}$ mice did not develop proteinuria when followed up to 1 year; however, exhibited variable degrees of increased mesangial expansion and hypercellularity at 9 months of age. Two out of 30 patients with idiopathic FSGS were found to carry a heterozygous truncating mutation in the *CD2AP* gene (125), which lead to a reduce expression at the mRNA and protein level. These results suggested that CD2AP could act as a determinant of human susceptibility to glomerular disease.

Recently, Löwik et al. described a patient presenting at 10 months of age with failure to thrive, anemia, hypoalbuminemia and massive proteinuria (126). Renal biopsy showed global glomerular sclerosis and was suggestive of collapsing FSGS. Mutation analysis of the *CD2AP* gene revealed a novel truncating mutation in the homozygous state, which displayed significantly decreased F-actin binding efficiency *in vitro*. The mutant allele was not expressed in the patient's lymphocytes. At the age of 5 years the patient was transplanted, without relapse of proteinuria (126). Both parents were heterozygous for the mutation and had normal glomerular filtration rate and no proteinuria. An additional patient bearing a heterozygous missense mutation in *CD2AP* in association with a missense mutation in *NPHS2* was recently reported (127). This patient presented with SRNS and relapse after transplantation. Both parents had normal serum creatinine and no proteinuria (127). Mutational screening of large cohorts of SRNS patients will be crucial to elucidate the frequency of *CD2AP* mutations and the spectrum of phenotypes.

Autosomal Dominant Forms of SRNS

Autosomal dominant (AD) forms of FSGS are infrequent and generally observed in adults. Variable degree of proteinuria is detected between the third and fourth decades of life and slowly progresses to ESRD (128, 129). So far, two loci have been mapped in cases with non-syndromic AD FSGS; nevertheless, genetic heterogeneity is likely, since no linkage to those loci has been found in several families with similar phenotype (129).

Mutations in *ACTN4* Encoding α-actinin-4

A genome-wide scan performed in a 100-member kindred allowed Mathis et al. to map the first locus of AD FSGS on chromosome 19q13 (130, 131). Linkage analysis including additional families helped to reduce the size of the region and led to the identification of 3 nonconservative missense mutations in the *ACTN4* gene. *ACTN4* encodes for the actin-binding protein α-actinin-4, which is highly expressed in podocytes (11). Affected cases presented with proteinuria starting in the teenage years

or later, slowly progressed to renal insufficiency and developed ESRD in the fifth decade of life (11, 132). Disease was incompletely penetrant, since several individuals from 2 out of 3 families carried a disease allele without clinical symptoms. In affected cases, kidney histology revealed lesions consistent with FSGS and no evidence of a primary basement membrane defect or of immune complex deposition.

Further mutation screening of the *ACTN4* gene in cases with familial and sporadic forms of FSGS allowed the identification of several additional patients carrying mutations (133, 134). In one affected case, proteinuria was diagnosed at 5 years of age and rapidly progressed to ESRD. Unexpectedly, this patient presented recurrence of proteinuria after transplantation. A superimposed immune form of SRNS or a *de novo* glomerulopathy may better explain the outcomes in this patient. Additional screening of small cohorts of patients with sporadic adult-onset FSGS and congenital SRNS have failed to identify *ACTN4* mutations (62, 64, 135). Overall, *ACTN4* mutations seem to account for approximately 4% of familial FSGS (134), although the precise proportion of AD forms in which this gene is mutated is unknown.

The mechanisms by which α-actinin-4 mutations cause disease in humans have been partially elucidated through functional studies and the characterization of mouse models. These studies suggest that the phenotypes in mice and humans involve both gain-of-function and loss-of-function mechanisms (11, 134, 136, 137). Alpha-actinin-4 has a key role in the maintenance of podocyte architecture cross-linking and bundling of actin filaments (138). Disease-associated mutations occur in the actin-binding domain, increasing actin-binding activity *in vitro* and diverting its normal localization from actin stress fibers and focal adhesions *in vivo* (11, 134, 137). Moreover, over-expression of GFP-fusion mutant proteins in cultured podocytes led to the formation of aggregates adjacent to the nucleus, confirming the subcellular mislocalization of mutants (134). Further supporting the hypothesis of loss-of-function, Yao et al. showed increased degradation of α-actinin-4 in cells from knock-in mice carrying an *Actn4* point missense mutation homologue, in comparison to that found in humans with FSGS (136). Finally, a β1-integrin-dependent, α-actinin-4 mediated adhesion is necessary to maintain podocyte attachment to the-glomerular basement membrane (139, 140). Consequently, podocytes from α-actinin-4 deficient mice showed reduced adherence to GBM components type IV collagen and laminin-10 and -11 (140).

The phenotype seen in $Actn4^{-/-}$ mice is more aggressive than the human disease. *Actn4* null mice exhibited abnormalities only in the kidneys. At 5 weeks of age, mice had only focal areas of podocyte foot process effacement, whereas FSGS was evident by 10 weeks. Proteinuria was observed with increasing age in most, but not all mice. Progressive renal insufficiency led to death at 12 weeks after birth. Mice heterozygous for the targeted allele ($Actn4^{+/-}$) showed no obvious phenotype up to 6 months of age (141).

Resembling human disease, a transgenic mouse developed by Michaud et al. (142), which expressed both endogenous wild-type and a K256E-mutant α-actinin-4 transgene, developed proteinuria at 10 weeks, elevated blood pressure and histological features consistent with FSGS. Interestingly, not all *ACTN4* mutant mice were proteinuric, and only a few among those with proteinuria had reduced renal function. Detailed histological analysis revealed segmental sclerosis and tuft adhesion of some glomeruli, tubular dilatation, mesangial matrix expansion, podocyte vacuolization and foot process fusion (142).

A mouse model in which one *Actn4* allele was replaced with a copy bearing a disease-associated mutation in humans (K256E) was developed by Yao et al. (136). Although this model is genetically closer to the human disease, homozygous mutant mice had no glomerular defects evident using light microscopy, although focal areas of foot process effacement and abnormal electron-dense structures in the podocyte cell bodies were observed at the electron microscopic level. Careful assessment of *Actn4* heterozygous mutant mice confirmed that they do not develop evident FSGS, but exhibit focal glomerular hypertrophy and mild glomerular ultrastructural changes (143). The mechanisms underlying the differences between the human and mouse phenotypes remain unknown. Additional modulating factors appear to play a role in the development of *ACTN4*-mediated human disease.

Mutations in *TRPC6* Encoding the Transient Receptor Potential Cation Channel 6

Winn et al. identified a second locus for autosomal dominant FSGS on chr 11q21-22 in a large family from New Zealand (144). Affected cases presented with nephrotic range proteinuria in their third or fourth decade and developed progressive renal insufficiency within 10 years after NS presentation. Using fine-mapping and candidate gene screening, the same group of investigators subsequently detected a missense mutation in the *TRPC6* gene, encoding the transient receptor potential cation channel, subfamily C, member 6 (12). TRP channels are involved in mechanosensation (145), ion homeostasis,

cell growth and PLC dependent calcium entry into cells (146). The proline to glutamine substitution at position 112 (p.P112Q) found in the index family, was shown to enhance TRPC6-mediated calcium signals in response to angiotensin II, suggesting that mutations in this gene disrupt glomerular cell function by amplifying injurious signals triggered by ligands, such as angiotensin II (12).

Subsequently, Reiser et al. identified *TRPC6* mutations in five other unrelated families of diverse ethnic origin (53). Only two of the five mutations were associated with an increase in calcium influx, suggesting that diverse mechanisms may result in dysregulation of the ion channel or may affect the interaction with other slit diaphragm proteins (53). In addition, they demonstrated that *TRPC6* is expressed in podocytes, specifically at the slit diaphragm where it interacts with podocin and nephrin (53).

In our cohort, we have found one patient bearing a *de novo* missense mutation in exon 13 of *TRPC6*, comprising a highly conserved region in the cytoplasmic tail of the protein (Antignac, unpublished data). This patient presented with NS at 6.5 years of age and reached ESRD a few months after diagnosis. Renal histology revealed advanced FSGS. No relapse was observed after transplantation. Mutation screening of large cohorts of patients is needed to evaluate the epidemiologic relevance of *TRPC6* mutations and the phenotypic spectrum of renal disease attributable to the *TRPC6* gene.

The contribution of animal models to understand the mechanisms underlying mutations in *TRPC6* has been limited. Targeted deletion of *Trpc6* in mice was not associated with a renal phenotype; although, mice exhibited an elevated blood pressure and enhanced agonist-induced contractility of isolated aortic rings, as well as cerebral arteries (147). An animal model carrying a missense point mutation in the *Trpc6* gene, homologous to those found in humans, will be required to confirm a gain-of-function mechanism as the triggering event leading to glomerular disease. An evaluation of the role of TRPC6 in kidney disease using zebrafish has not been possible since *TRPC6* was not detected at RNA level in developing and adult zebrafish podocytes (148).

Syndromic Steroid-Resistant Nephrotic Syndrome

Pierson Syndrome: Mutations in *LAMB2* Encoding Laminin β2

In 1963, Pierson et al. described two patients with congenital nephrotic syndrome, unique ocular abnormalities and histopathological features of DMS (149). Subsequently, several isolated case reports appeared in the literature (150–154). Zenker et al. designated this disorder Pierson syndrome, refining the phenotype based on the description of eleven affected cases from two large consanguineous families and after reviewing previous case reports (155). Clinical findings include nephrotic syndrome and oliguria presenting at birth or within the first days of life, enlarged or large appearing cornea in some cases suggesting buphthalmos, extremely narrow, nonreactive pupils (microcoria) and DMS with an irregular basement membrane (155).

In two consanguineous families, a genome-wide scan and homozygosity mapping allowed the identification of a potential locus in chromosome 3p (23). Subsequent positional cloning was greatly facilitated by the previous description of the development of congenital nephrotic syndrome in *Lamb2* null mice (156). Affected cases from five families had truncating or missense mutations of the *LAMB2* gene, either in the homozygous or compound heterozygous states, leading to absent or reduced expression, respectively, of laminin β2 in the kidneys (23). Interestingly, mutation screening in additional families revealed patients bearing missense mutations in *LAMB2* who presented with congenital nephrotic syndrome, minor or no ocular defects (transient fundus hypopigmentation, nistagmus and myopia) and normal psychomotor development (157–159). Childhood onset of Pierson syndrome has likewise been reported in a non-consanguineous family with seven affected individuals, with nephrotic syndrome and ESRD presenting between 5 and 10 years of age (160). Ocular problems paralleled or even preceded the renal symptoms. Visual impairment was progressive since affected individuals had no signs of impaired vision in early infancy, and they all developed blindness around 2 years of age (160).

Laminins are heterotrimeric extracellular matrix proteins that provide the basic scaffold for assembly of the other components of the glomerular basement membrane, including type IV collagen, nidogen/entactin and sulfated proteoglycans (161). The glomerular basement membrane is composed exclusively of laminin-521 (α5β2γ1) (162). The α5 chain is required for GBM integrity and glomerular vascularization (163), whereas the β2 chain is dispensable for glomerulogenesis; concordantly, *Lamb2* null mice displayed no glomerular developmental abnormalities at birth (164).

The clinical features observed in patients with Pierson syndrome are consistent with the phenotype of *Lamb2* null mice, which present with failure to thrive, heavy proteinuria within the first weeks of life (156), and revealed

foot-process effacement and increased GBM permeability (164). In addition, mice show aberrantly formed and functionally impaired neuromuscular junctions (165, 166), and both structural and functional abnormalities in the retina (167, 168). Indeed, these findings reflect the fact that laminin β2 is highly expressed in the glomerulus, the skeletal neuromuscular junction and the retina (167–169).

Denys-Drash, Frasier and WAGR Syndromes: Mutations in *WT1* Encoding the Wilms' Tumor Protein

Through a positional cloning approach, the *WT1* gene was found to be inactivated in Wilms' tumor (170–172). The *WT1* gene is located on chromosome 11p13 and encodes a zinc finger transcription factor that functions both as a tumor suppressor and as a critical regulator of kidney and gonadal development (173–175). The key role of *WT1* in kidney development has been highlighted by the development of animal and *in vitro* models showing the failure of, arrest in or delayed development of nephrogenesis in the absence of *WT1* expression (174, 176, 177). Mutations in the *WT1* gene are associated with varied syndromic forms of glomerular disease and genitourinary abnormalities, as well as isolated cases of SRNS.

Denys-Drash syndrome (DDS, MIM 194080) is a rare urogenital disorder comprising nephropathy due to DMS, associated with male pseudohermaphroditism and Wilms' tumors (17, 18). Nephrotic syndrome presents in the first months of life, may be preceded by isolated proteinuria and is always resistant to steroid therapy. Progression to ESRD occurs before 4 years of age and no recurrence is observed after renal transplantation (178–180). Wilms' tumor may be the first presentation of the disease or may be discovered later during the course of nephropathy by systematic ultrasound screening. Patients with Denys-Drash syndrome bear heterozygous mutations, mostly *de novo*, in exons 8 and 9 of the gene, encoding the second and third zinc finger domains (19, 20). *In vitro* studies have confirmed that missense mutations in the *WT1* gene lead to a change in the structural organization of the zinc finger domains, leading to loss or alteration of their DNA-binding abilities (181). Isolated cases of DMS have also been attributed to mutations in *WT1* (182–184).

Frasier syndrome (FS, MIM 136680) is characterized by male pseudohermaphroditism with normal female external genitalia, streak gonads and 46,XY karyotype. Patients have an increased susceptibility to gonadoblastomas, but do not develop Wilms' tumors. FS is associated with childhood-onset proteinuria, usually between 2 and 6 years of age, slowly progressing to ESRD towards the adolescence or early adulthood, exhibiting histological finding of FSGS on renal biopsy (15, 16). As in Denys-Drash syndrome, inheritance is autosomal dominant, although most cases are sporadic due to *de novo* mutations. The *WT1* gene encodes up to 36 different isoforms, which are products of alternative translation start sites, alternative splicing and RNA editing (185).

Of particular interest are WT1(+KTS) and WT1 (-KTS) variants, which differ by the presence of the three amino acids KTS between zinc fingers 3 and 4. The presence of this insert influences the molecular and biochemical properties of the resulting protein. While WT1 (−KTS) binds DNA efficiently and acts as a transcriptional activator, WT1(+KTS) seems to have higher affinity to RNA (186). Mutations in the donor splice site in intron 9 of the *WT1* gene are causative of Frasier syndrome, and leads to alternative splicing and loss of the +KTS isoform of the protein (14). This results in an alteration of the normal ratio of +KTS/-KTS isoforms in the cell (187).

De novo deletion of the 11p13 locus leads to WAGR syndrome (MIM 194072), characterized by Wilms' tumors, aniridia, genitourinary abnormalities and mental retardation (21). Aniridia is due to the deletion of the *PAX6* gene, which resides in the same locus than *WT1*.

Mutations in *WT1* have also been associated with the development of isolated SRNS with kidney histology consistent with FSGS in some phenotypic females (XX or XY karyotype). Disease onset varies between few months of age to the end of the first decade of life, with rapid progression to ESRD (22, 188–190). Most of the cases carry missense or splice-site mutations in exons 8 and 9 of the *WT1* gene. In these patients, genetic counseling is essential, since a male child from an affected XX female, would either have Denys-Drash syndrome or Frasier syndrome, respectively (188, 189).

Nail-Patella Syndrome: Mutations in *LMX1B* Encoding the LIM Homeobox Transcription Factor 1 β

Nail-patella syndrome (NPS; MIM 161200) is an autosomal dominant disorder with complete penetrance and variable phenotypic expression, characterized by pleiotropic developmental defects of dorsal limb structures. The most characteristic finding is nail involvement. Nails may be absent, hypoplastic or dystrophic. Defects are often bilateral, symmetrical and may be observed at birth. An additional pathognomonic feature of NPS are iliac horns, which are bony processes that project posteriorly and

laterally from the central part of the iliac bones of the pelvis (191). Frequently, patellae may be hypoplastic or absent; involvement of shoulders, elbows and ankles is less common, and may be asymmetrical (192). Nephropathy may occur in 25–50% of the cases (193–197), being more frequent in women (197). This manifests as microalbuminuria progressing to proteinuria, usually associated with hematuria. Proteinuria, which may be intermittent, may present at any age, diagnosed in most of the cases after the second decade of life. Overt nephrotic syndrome is not a common feature and progression to ESRD occurs in 5–14% of the cases, usually many years after proteinuria onset (197, 198). To-date, no recurrence of proteinuria after transplantation has been reported (193, 199). Light microscopy of renal tissue usually reveals no specific changes (200), while glomerular basement membrane exhibits ultrastructural abnormalities that are the most specific histological hallmark of NPS (193, 201–203). Typically, there is irregular thickening and splitting of the GBM glomerular basement membrane, with electron lucent areas, and the presence of clusters of fibrillar type III collagen within the GBM and the mesangial matrix. Finally, primary open angle glaucoma and sensorineural hearing impairment have been recognized as less frequent features of the disease (197, 204).

Chen et al. demonstrated that targeted disruption of the *Lmx1b* gene (LIM homeobox transcription factor 1 β) in mice resulted in distinctive skeletal defects including hypoplastic nails, absence of patellae, joint abnormalities and glomerular basement membrane defects, recapitulating the phenotype of NPS (205). The disease phenotype was observed only in homozygous mutant mice, whereas heterozygous littermates did not exhibit any evident abnormalities. Nevertheless, these results led to the identification of de novo heterozygous mutations in the *LMX1B* gene in patients with NPS (24).

Approximately 85% of families with NPS present mutations in *LMX1B*, which consistently segregate with disease in an autosomal dominant pattern with complete penetrance. The majority of mutations, including nonsense mutations, small intragenic insertions/deletions or splice-site mutations, results in protein truncation. Missense mutations generally involve substitutions in the homeodomain region critical for DNA binding (195–197, 206, 207). Recently, entire-gene deletions were reported by Bongers et al., confirming that haploinsufficiency of the LMX1B transcription factor underlies this disease (208).

The precise role of LMX1B in the kidney remains partially elucidated. Immunohistochemical studies in several patients bearing heterozygous mutations in the *LMX1B* gene revealed that the expression of the α3 and α4 chains of type IV collagen, as well as podocin and CD2AP are no different than normal controls (209). In mouse, *Lmx1b* is expressed exclusively in glomeruli. Podocyte-specific *Lmx1b* inactivation invariably leads to proteinuria, renal insufficiency and death at 2 weeks after birth (210). In addition, LMX1B may be critical for glomerular development, since mice with podocyte-specific inactivation of *Lmx1b* showed severely impaired glomerular development and podocyte differentiation (211). Potential targets of *Lmx1b* in the kidney have been demonstrated in the shared 5′ regulatory regions of *Col4a3* and *Col4a4* genes (212), and in the promoter regions of the *Nphs2* and *Cd2ap* genes (211, 213). In *Lmx1b*-deficient mice, the abundance of α(3)IV and α(4)IV chains of collagen were markedly diminished (212), as were the levels of podocin (211, 213), CD2AP (213), synaptopodin and VEGF (211). Nevertheless, no downregulation in the expression of the α3 and α4 chains of type IV collagen, podocin and CD2AP, were observed in mice in which *Lmx1b* had been inactivated specifically in podocytes (210). Interestingly, immunohistochemical studies in two patients bearing heterozygous mutations in the *LMX1B* gene revealed no downregulation in the expression of the α3 and α4 chains of type IV collagen, and in podocin and CD2AP (209). The latter findings may be explained by the fact that these patients carry one functional and one mutated alleles, whereas mice have two mutant alleles.

Schimke Immuno-Osseus Dysplasia: Mutations in *SMARCAL1*, Encoding the swi/snf-Related Matrix-Associated Actin-Dependent Regulator of Chromatin, Subfamily-A-Like-1

Schimke immuno-osseus dysplasia (SIOD, OMIM 242900) is a rare autosomal recessive disorder characterized by spondyloepiphyseal dysplasia, progressive renal dysfunction due to focal segmental glomerulosclerosis and T-cell immunodeficiency (214). Other additional, although inconstant features include cerebral ischemia, migraine-like headaches, deficiency of other blood cell lineages, hyperpigmented macules, corneal opacities, microdontia, intellectual delay, recurrent infections, premature atherosclerosis, hypothyroidism, cerebellar atrophy and testicular hypoplasia with atrophy and azospermia (215–218). Kidney disease in patients with SIOD manifests typically with proteinuria evolving to overt nephrotic syndrome, which is diagnosed between the first year of life and 14 years of age (215, 216). No response to steroids has been documented in patients who have been

treated; nevertheless, transient reductions in proteinuria using ACE inhibitors, NSAID or even cyclosporin A have been observed (216). Patients who survive infectious complications progress to ESRD between 5 and 15 years of age. Numerous cases have been transplanted without evidence of relapse in the allograft (216); however, the evolution of cerebrovascular and infectious complications do not seem to improve after transplantation.

A genome-wide scan, performed in four families, detected significant linkage at chromosome 2q35, and mutations were identified in the *SMARCAL1* gene (26). This gene encodes a member of an SNF2 subfamily of proteins that mediate DNA-nucleosome restructuring during gene regulation and DNA replication, recombination, methylation and gene repair (swi/snf-related matrix-associated actin-dependent regulator of chromatin, subfamily-a-like-1 gene). The gene consists of 18 exons and encodes a 106-kDa protein with 954 amino acid residues. The majority of mutations identified involve nonsense and frameshifting mutations, likely leading to loss-of function (26). Recently, Clewing et al. showed that *SMARCAL1* biallelic mutations accounted for the phenotype in 38 of 72 independent cases with SIOD (219), revealing the genetic heterogeneity of this syndrome. Patients with two missense mutations tended to have a milder course of disease, surviving beyond 15 years of age. The functional targets of SMARCAL1 remain unidentified.

Action Myoclonus-Renal Failure Syndrome: Mutations in *SCARB2* Encoding the Lysosome Membrane Protein 2

Action myoclonus-renal failure syndrome (AMRF, MIM 254900) is a rare autosomal recessive disease characterized by progressive myoclonic epilepsy associated with renal failure. It typically presents at 15–25 years of age with neurological symptoms including tremor, action myoclonus, seizures and later ataxia, while cognitive function is preserved. Proteinuria is usually diagnosed concomitantly with the onset of neurologic symptoms at a median age of 19 years (220), although proteinuria may also be the first symptom. Progression of renal impairment to ESRD occurs generally within 5 years after onset of proteinuria (220, 221). The renal pathology is characterized by focal glomerulosclerosis, sometimes with features of glomerular collapse (220). In three unrelated families, Berkovic et al. identified a region on chromosome 4q13-21 linked to AMRF. Subsequently, using gene expression profiling to prioritize gene sequencing within the region, they identified homozygous truncating mutations in the *SCARB2* gene (encoding LIMP-2). These mutations led to a downregulation of SCARB2 mRNA and undetectable protein levels in western blots of cell lysates from lymphoblastoid B cell lines from the two affected subjects (29).

LIMP-2 is a transmembrane protein of the CD36 superfamily, which is ubiquitously expressed and is mainly found in lysosomes and late endosomes, where it is required for their biogenesis and maintenance (222–224). It has been shown that LIMP-2 acts as a trafficking receptor for β-glucocerebrosidase (β-GCase) (225), a lysosomal enzyme deficient in most cases of Gaucher disease. Interestingly, a nonsense mutation involving the interaction domain of LIMP-2/β-GCase was recently identified in two patients with ARMF in which a severe β-GCase deficiency was detected in cultured skin fibroblast (221). The pathophysiologic events leading to NS and FSGS in patients with *SCARB2* mutations remain to be elucidated.

In mouse, the *Limp2* gene is expressed in a range of tissues including brain and kidney. Interestingly, a *Limp2*-deficient mouse model presents with hearing impairment, demyelinating neuropathy, cerebral and cerebellar cytoplasmic inclusions, hydronephrosis caused by ureteropelvic junction obstruction, mesangial proliferation and foot-process effacement, but does not recapitulate the glomerular lesions seen in humans (29, 223). Proteinuria is present, but occurs only with aged mice (29).

Mitochondropathies Manifesting with Nephrotic Syndrome

The mitochondropathies are a diverse group of disorders due to structural, biochemical, or genetic derangements of mitochondria (226). Renal dysfunction is a rare event, and may result from mutations in the mitochondrial or nuclear genomes. The mitochondrial genome encodes for 13 essential subunits of the mitochondrial respiratory chain, as well as the 22 transfer RNA (tRNA) and 2 ribosomal RNA (rRNA) genes (227). The c.3243A>G point mutation in the $tRNA^{Leu(UUR)}$ gene is associated with MELAS syndrome (myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) (27). Some patients carrying $tRNA^{Leu(UUR)}$ gene mutations may present with diabetes and deafness (228, 229), cardiomyopathy (230), progressive external ophthalmoplegia and FSGS (231–236), with or without the nephrotic syndrome (234–240). Although most of the affected cases are diagnosed in adulthood and have glomerular disease associated with other manifestations of mitochondrial disease, some patients present with isolated nephropathy or may have an earlier onset during the adolescence (235, 238, 240, 241).

Nephrotic syndrome has, likewise, been described in coenzyme Q_{10} (CoQ_{10}) deficiency (MIM 607426), in association with encephalomyopathy and multisystemic involvement (30, 242, 243). The *COQ2* gene is part of the coenzyme Q_{10} pathway, a component of the mitochondrial respiratory chain vital for the transport of electrons from complexes I and II to complex III. Mutations in the *COQ2* gene were identified in several patients presenting with early-onset nephrotic syndrome, with or without neuromuscular symptoms (244). The clinical presentation varied from severe oliguric renal failure due to crescentic GN on the fifth day of life to development of SRNS at 18 months in association with collapsing glomerulopathy (244). In all renal biopsies dysmorphic mitochondria were characteristic (244).

Lopez et al. recently described an infant with fatal Leigh syndrome, CoQ10 deficiency in muscle and fibroblasts, nephrotic syndrome, and compound heterozygous mutations in the *PDSS2* gene (245). The *PDSS2* gene encodes a subunit of decaprenyl diphosphate synthase, the first enzyme of the CoQ10 biosynthetic pathway (245). Similarly, the *kd/kd* mouse, which develops collapsing glomerulopathy, carries mutations in the murine orthologue of the human *PDSS2* gene (246). Moreover, mice in which the *Pdss2* gene has been conditionally inactivated in podocytes exhibit proteinuria and foot process effacement (247). Recently, Saiki et al. showed that coenzyme Q10 supplementation rescues renal disease in *Pdss2 kd/kd* mice (248).

It is likely that mutations in other genes involved in the CoQ10 biosynthetic pathway are responsible for cases of NS with or without neuromuscular manifestations. In cases with CoQ10 deficiency, early ubiquinone supplementation may be crucial for the resolution of renal symptoms and for preventing neurologic damage, as demonstrated in patients and animal models (248, 249).

Finally, a deletion in the mitochondrial DNA has been associated with FSGS in a cohort of Japanese patients and in a Turkish patient (239, 250).

Hereditary Multisystemic Disorders of Unknown Cause Associated with Steroid-Resistant Nephrotic Syndrome

Galloway-Mowat syndrome

Galloway-Mowat syndrome is a rare disorder, of autosomal recessive inheritance, characterized by SRNS, microcephaly and severe neurological impairment (251). Disease frequency is unknown; however more than 70 cases have been reported since the original description in 1968 (251). Inconstant morphological defects include hiatus hernia, micrognathia, arachnodactyly and floppy ears. Proteinuria is usually discovered within the first year of life; although congenital onset is not unusual as are cases in which the onset of NS is close to the third year of life (251–259). Kidney histology may reveal either FSGS or DMS, the later more frequent in early onset forms (254, 260–263). In addition, a single patient with collapsing FSGS has been recently reported (264). The great majority of patients reach ESRD between 36 and 72 months after birth, although there are rarer cases with preserved renal function after this age (259, 263).

The distinctive neurological feature is marked microcephaly, which might be congenital (primary) or may develop after birth (secondary). Structural brain abnormalities include cortical and cerebellar atrophy, severe myelination deficiency and gyral defects (257, 263, 265–268). Profound mental retardation, hypotonia and seizures are the most recurrent neurological symptoms. In addition, choreoathetosis may develop later in the course of the disease (Antignac, personal observation). Sensorineural blindness and deafness have also been described. Patients may occasionally be able to walk, interact with their families and eventually develop a rudimentary monosyllabic language (Antignac, personal observation). The association with microphthalmia and corneal defects has been occasionally reported (252, 260, 261, 269–271). Undeniably, ocular malformations are a common feature of Pierson syndrome, in which microcephaly might be occasionally observed (272). Due to the overlapping phenotype with GMS, screening of mutations in laminin-β2 and several related proteins was performed by Dietrich et al. in 18 unrelated patients with GMS (273). Unfortunately they failed to find pathogenic mutations. Indeed, GMS represents a heterogeneous group of diseases and so far, the underlying genetic abnormalities have not been identified.

SRNS and Deafness

The association of SRNS and deafness has been described in patients with familial forms of SRNS with both autosomal dominant and recessive inheritance, revealing the genetic heterogeneity of this clinical association. Excluding patients carrying mutations in genes involved in the mitochondrial respiratory chain, in which deafness and nephrotic syndrome may be present in addition to neuromuscular symptoms, two loci have been identified to-date (274, 275).

Ruf et al. mapped the first locus on chr 14q24.2 in a consanguineous Palestinian family (275). Congenital

sensorineural deafness was diagnosed in the four affected cases. The onset of NS ranged from 0.3 to 6.4 years and all the patients progressed to ESRD before 10 years of age. Kidney histology was compatible with FSGS. Three cases were transplanted, with no relapse of proteinuria. Prakash et al. described a 39-member kindred from India, consisting of 7 affected members, showing male-to-male transmission with an AD pattern of inheritance (274). Age at presentation varied between 8 and 44 years of age. Five of the affected cases also had sensorineural deafness. Renal biopsies revealed FSGS with irregular GBM. A genome-wide scan identified a novel locus on chr 11q24, after exclusion of linkage to currently known loci for Alport syndrome.

Epidermolysis Bullosa and FSGS

Nephrotic syndrome and renal failure may occur in some patients with epidermolysis bullosa (276). The most common histological finding is secondary amyloidosis (277–283). The association of FSGS and epidermolysis bullosa has been reported in a male infant with pyloric atresia, junctional epidermolysis bullosa and nephrotic range proteinuria diagnosed 6 weeks after birth (25). Renal biopsy revealed immature glomeruli, segmental sclerosis in the absence of microcystic tubular dilatation, atrophy and interstitial fibrosis. Ultrastructural changes included a thin glomerular basement membrane, extensive foot process effacement and microvillous transformation of podocytes. Mutation analysis of the β_4- and α_6-integrin genes *ITGB4* and *ITGA6* revealed a homozygous missense mutation in exon 31 of the *ITGB4* gene, resulting in a substitution of tryptophan for arginine at codon 1281. This mutation affects the second fibronectin type III domain which is involved in the interaction with bullous pemphigoid antigen 1 (BPAG1) and plectin. Moreover, in one patient with pyloric atresia, epidermolysis bullosa and nephrotic proteinuria diagnosed at 5 months of age, mutation screening of the *ITGB4* gene revealed a c.4851delCA truncating mutation (Dr. Françoise Broux, Rouen, France; personal communication). The mechanisms by which mutations in the *ITGB4* gene induce glomerular disease remain unknown.

Familial Forms of Steroid-Sensitive Nephrotic Syndrome

The incidence of SSNS in pediatric population ranges between 2 and 7/100,000. Although most of the cases are sporadic, several reports have confirmed the existence of hereditary forms of this disease (1, 284–289). The exact incidence of familial forms of SSNS is unknown, but according to a single survey, it may represent up to 3% of the cases (1). Based on six cases reports describing 58 patients from 21 families, the most common pattern of inheritance was autosomal recessive. There was a male-to-female preponderance of 3 to 1 and the average age of onset was 4 years. Kidney histology revealed minimal change disease. Most of the cases presented with multiple episodes of relapse and achieved complete remission at the end of adolescence (284–289). Analysis of our own cohort consisting of 46 affected cases from 23 families, revealed similar results (Antignac, unpublished data).

At least two attempts to identify a putative disease locus have been performed (288, 289). Ruf et al. performed a genome-wide scan in a consanguineous SSNS kindred allowing the identification of a locus on chr 2p12-p13.2 between markers *D2S292* and *D2S289* (288). More recently, Landau et al. studied an extended SSNS Bedouin family with a high rate of consanguinity (289). A whole genome scan was performed, using 382 microsatellite markers; however, the index family was not linked to any of the presently known loci associated with nephrotic syndrome. It remains unanswered whether the primary defect in hereditary SSNS lies in a gene that plays a central role in the function of the immune system, or in a gene expressed in podocytes.

Conclusion

Hereditary forms of NS are far more common than previously thought 10 years ago, since the discovery of mutations in causative genes in cases with Mendelian inheritance, as well as in patients with sporadic disease. Most of the cases with hereditary forms of NS have a disease onset within early childhood, are resistant to immunosuppressive therapy, and do not relapse after kidney transplantation. The highest rates of mutation detection are in patients presenting with proteinuria in the first year of life and subsequently decrease among older patients.

It is plausible that more complex patterns of inheritance, as has been described in patients bearing bi- or triallelic variants, may be associated with an increased risk of developing NS. Indeed, disease predisposing mutations may lead to variable disease expression and penetrance depending upon unidentified environmental and genetic factors. Moreover, common variants in genes expressed in podocytes may account for an increased risk of FSGS and

ESRD observed in selected ethnic groups, as has been described recently with the *MYH9* gene, in which several haplotypes conferred a major-risk effect for FSGS in individuals of African ancestry (290–292).

The accessibility to custom genotyping chips and deep-sequencing techniques will facilitate the screening of mutations in a broader approach, including clusters of podocyte-specific genes. To-date, several fascinating disorders, such as Galloway-Mowat syndrome, involving brain and kidney development, and familial forms of SSNS, connecting podocyte physiology and the immune system, remain unsolved.

Non-syndromic forms of NS are frequently restricted to mutation in genes exclusively expressed in podocytes at the slit-diaphragm, while the association with extrarenal manifestations is observed in cases carrying mutations in ubiquitously expressed genes, mostly transcription factors or components of the mitochondrial respiratory chain. Nevertheless, individuals with mutations in genes associated with syndromic SRNS may present with a milder phenotype and only with SRNS; thus, making directed mutation screening a difficult task.

A promising therapy, still explored at a basic level, include protein chaperones. These drugs redirect the trafficking of missense mutant proteins to the plasma membrane when abnormally retained in subcellular organelles. Additional encouraging results have been obtained with drugs, which stabilize the podocyte actin cytoskeleton.

It is now clear that genetic diagnosis of cases with SRNS or familial NS is necessary to avoid ineffective therapies, to allow for accurate genetic counseling and, in the future, to offer specific mutation-based therapies.

28 Idiopathic Nephrotic Syndrome in Children: Clinical Aspects

Patrick Niaudet · Olivia Boyer

In children, the most common cause of nephrotic syndrome is idiopathic nephrotic syndrome (INS), also called nephrosis (1). INS is defined by the combination of a nephrotic syndrome (proteinuria, hypoalbuminemia, hyperlipidemia, and edema) and non-specific histological abnormalities of the kidney including minimal changes, focal and segmental glomerular sclerosis (FSGS), and diffuse mesangial proliferation. Glomeruli show a fusion of epithelial cell foot processes on electron microscopy and no significant deposits of immunoglobulins or complement on immunofluorescence.

Many authors consider minimal change disease, diffuse mesangial proliferation and FSGS as separate diseases because of differences in response to corticosteroids and subsequent clinical course. Indeed, these various pathologic features carry prognostic significance. Patients with FSGS and those with diffuse mesangial proliferation have more frequently hematuria, are often resistant to corticosteroid treatment, progress more often to renal failure and may have a recurrence of the nephrotic syndrome soon after renal transplantation. Recent data have comforted the belief that minimal change disease and FSGS are different entities. FSGS appears to be a podocyte disease (2). The notion of "podocyte dysregulation" (3, 4), the different expression of cyclin-dependent kinase inhibitors in minimal change disease and in FSGS, the role of these cell cycle disturbances leading to podocyte proliferation and maturation (5) and the identification of parvovirus B 19 in glomeruli of patients with FSGS (6, 7) are in favor of distinct entities. Moreover, Streulau et al. found TGF-β1 gene expression in 18 of 20 patients with steroid resistant FSGS and in only 3 of 14 steroid-sensitive patients (8). These data support a sequence of immunologically mediated events that contribute to progressive renal damage in children with FSGS.

In the early stages, FSGS and minimal change disease are indistinguishable (9). A significant number of patients with FSGS respond to corticosteroids, whereas some steroid resistant patients have no sclerotic changes on biopsy specimens containing adequate tissue (10, 11). Therefore, some authors believe that, although histological variants of the INS carry prognostic significance, they cannot at present be considered as separate entities (12).

The term minimal change disease has become synonymous with steroid sensitive INS although renal biopsy is usually not performed in patients who respond to steroid therapy. Indeed, in many centers, renal biopsy is recommended only for those patients who fail to respond to steroids. Consequently, renal biopsy findings in recent published series are not representative of the true incidence of various histopathological categories seen in INS. It is therefore more appropriate to classify the patients according to their response to steroid therapy. Response to steroid therapy carries a greater prognostic weight than the histological features seen on initial renal biopsy. Thus, two types of INS can be defined: steroid-responsive nephrotic syndrome, in which the proteinuria rapidly resolves and steroid-resistant nephrotic syndrome, in which steroids do not induce remission.

Epidemiology

The incidence of INS varies with age, race, and geography. The annual incidence in children in the USA and in Europe has been estimated to 1–3 per 100,000 children below age of 16 (13–15), with a cumulative prevalence of 16 per 100,000 children. Similar figures were recently reported from New Zealand (16). Geographical and/or ethnic differences are well known. In the United Kingdom for example, the incidence of INS is sixfold greater in Asian than in European children (17); this is also true for Indians (18), for Japanese and SouthWest Asians. INS is less frequent in Africa (19–21). Such differences underline the role of genetic as well as environmental factors in the pathogenesis of the disease.

Whereas INS accounts for only 25% of adult cases (22), it is by far the most common cause of nephrotic syndrome in children. Almost all nephrotic children between 1 and 6 years of age in Western countries suffer from INS. The International Study of Kidney Disease in Children found minimal change disease in 76.6% of children with primary nephrotic syndrome (13).

© Springer-Verlag Berlin Heidelberg 2009

There is a male preponderance in children, with a male:female ratio of 2:1 (13, 23), but both sexes are similarly affected in adolescents.

The familial occurrence of INS is well known (see chapter "Genetic").

Associated Disorders

INS is, by definition, a primary disease. Nevertheless, in a number of cases, an upper respiratory tract infection, an allergic reaction, or another factor may immediately precede the development or relapse of the disease.

Many agents or conditions have been reported to be associated with INS such as infectious diseases, drugs, allergy, vaccinations, and malignancies (*Table 28-1*). The question remains whether these factors are real causes, a simple coincidences, or precipitating agents.

Table 28-1

Conditions associated with idiopathic nephrotic syndrome

Allergy
Pollen
Fungi
Cow's milk
House dust
Bee stings
Cat fur
Poison ivy
Drugs
Nonsteroidal antiinflammatory drugs
Ampicillin
Gold
Lithium
Mercury
Trimethadione
Malignancies
Hodgkin disease
Non-Hodgkin lymphoma
Colon carcinoma
Bronchogenic carcinoma
Others
Viral infection
Kimura's disease
Diabetes mellitus
Myathenia gravis
Immunization

Allergy is associated with up to 30% of cases (24–26). Among a list of anecdotal cases, the allergens reported include fungi, poison ivy, ragweed pollen, house dust, jellyfish stings, bee stings and cat fur. A food allergen may be responsible for relapses of steroid-sensitive nephrotic syndrome, such as cow's milk and egg. Laurent et al. evaluated the effect of an oligoantigenic diet given for 10–15 days to 13 patients. This diet coincided with improvement of proteinuria in nine, including complete remission in five (27).

The association between minimal change disease and malignancies mainly concerns lymphomatous disorders: Hodgkin's disease and non-Hodgkin's lymphomas (28, 29). The nephrotic syndrome may be the presenting feature of the disease. It usually disappears after successful treatment of the malignancy. Other types of neoplasia may also be associated with INS as colon carcinoma, bronchogenic, small-cell carcinoma (30).

Eosinophilic lymphoid granuloma in orientals (Kimura's disease) has also been reported in association with INS (31–33).

Several cases of minimal change disease have been reported in association with the onset of insulin-dependent diabetes mellitus. The disease is usually responsive to corticosteroids and follows a relapsing course.

Clinical and Biological Features

The disease may occur during the first year of life, but it usually starts between the ages of 2 and 7 years, with a male to female ratio of 2/1. The onset is often preceded by an upper respiratory tract infection. The disease is characterized by a sudden onset, edema being the major presenting symptom. It becomes clinically detectable when fluid retention exceeds 3–5% of body weight. Periorbital edema frequently misdiagnosed as allergy, is often the initial symptom. Edema is gravity dependent, localized to the lower extremities in the upright position, and to the dorsal part of the body in reclining position. This edema is white, soft, and pitting, keeping the marks of clothes or finger pressure. Anasarca may develop with ascites, and pleural and pericardial effusions. Although there may also be abdominal distension, dyspnoea is rare. Periorbital edema may limit eye opening and edema of the scrotum and penis, or labiae, may be seen. A rapid formation of ascites is often associated with abdominal pain and malaise: these symptoms may also be related to concomitant hypovolemia. Abdominal pain is occasionally due to a complication such as peritonitis, thrombosis or, rarely, pancreatitis. Cardiovascular shock is not unusual,

secondary to the sudden fall of plasma albumin, with abdominal pain and symptoms of peripheral circulatory failure with cold extremities and hypotension. Emergency symptomatic treatment is needed. Blood pressure is usually normal but sometimes elevated (13, 34).

The nephrotic syndrome is occasionally discovered during a routine urine analysis. Macroscopic hematuria is observed in a few cases (34). The disease may also be revealed by a complication. Peritonitis due to *Streptococcus pneumoniae* is a classical mode of onset (35). Deep-vein or arterial thromboses and pulmonary embolism may also occur during the first attack or during a relapse.

Urinalysis

Proteinuria is detected by dipstick testing 3 or 4+. Quantitative evaluation gives figures ranging from less than 1 g to more than 10 g/day. The nephrotic range proteinuria is defined as >50 mg/kg/day or 40 mg/h/m^2 but the mean value during the first days may be higher as the urinary concentration of proteins also depends on the plasma albumin concentration. In young children it may be difficult to perform 24-h urine collection and urinary protein/creatinine ratio or U albumin/U creatinine ratio in untimed urine specimens are useful. For these two indices the nephrotic range is 200–400 mg/mmol (36).

In most cases, proteinuria is highly selective, consisting of albumin and lower molecular weight proteins. The selectivity of proteinuria may be appreciated by polyacrilamide gel electrophoresis or by the evaluation of the Cameron index which is the ratio of IgG (MW 150 kDa) to transferrin (80 kDa) clearances. A favorable index would be below 0.10, or better below 0.05; a poor index is above 0.15 or 0.20. Such poor index is more often associated with FSGS. However, there is a considerable overlap in results and the test has limited value. The amount of protein excreted in the urine does not reflect the quantity of protein crossing the glomerular basement membrane since a significant amount is reabsorbed in the proximal tubule. Some children with severe steroid resistant nephrotic syndrome and tubulo-interstitial lesions have both glomerular and tubular proteinuria with an increased excretion of β-2 microglobulin, retinol binding protein and lysozyme due to an impaired protein reabsorption in the proximal tubule.

The urine sediment of patients with INS often contains fat bodies. Hyaline casts are also usually found in patients with massive proteinuria, but granular casts are not present unless there is associated acute renal failure and acute tubular necrosis. Macroscopic hematuria is rare, occurring in 3% of patients. Microscopic hematuria is present in 20% of cases and has no influence on the response to steroid therapy.

Urinary sodium excretion is low (<5 mmol/24 h), associated with sodium retention and edema. Kaliuresis is usually higher than natriuresis, but it may be reduced in oliguric patients.

Blood Chemistry

Serum proteins are markedly reduced and serum lipid usually increased. Proteinemia is below 50 g/l in 80% of patients, and below 40 g/l in 40%. Albumin concentration usually falls below 20 g/l and may be less than 10 g/l. Electrophoresis shows not only low albumin levels but also increased α-2 globulins and, to a lesser extent, β-globulins, while γ-globulins are decreased. IgG is markedly decreased, IgA slightly reduced, IgM is increased, while IgE is normal or increased. Among other proteins, fibrinogen and β-lipoproteins are increased and antithrombin III is decreased.

Hyperlipidemia is a consequence of (I) an increased hepatic synthesis of cholesterol, triglycerides and lipoproteins, (II) a decreased catabolism of lipoproteins due to a decreased activity of lipoprotein lipase which normally transforms VLDL to LDL via IDL and (III) a decreased LDL receptor activity and an increased urinary loss of HDL (37, 38). Total cholesterol and LDL cholesterol are elevated while HDL cholesterol remains unchanged or low, particularly HDL2, leading to an increased LDL/HDL cholesterol ratio (39). Patients with severe hypoalbuminemia have increased triglycerides and VLDL. Apoproteins, apo B, apo CII, apo CIII are also elevated. The levels of lipoprotein Lp(a) are elevated in nephrotic patients which further contribute to an increased risk of cardiovascular and thrombotic complications.

Serum electrolytes are usually within the normal range. A low sodium level may be related to dilution from inappropriate renal retention of water due to hypovolemia and inappropriate antidiuretic hormone secretion. The mild reduction of plasma sodium concentration is often an artifact related to hyperlipidemia. Serum potassium may be high in oliguric patients. Serum calcium is consistently low as a result of hypoproteinemia. Ionized calcium is usually normal but may be decreased due to urinary loss of 25-hydroxyvitamin D3 (40) and normal but inappropriate levels of calcitriol (41). Blood urea nitrogen and creatinine concentrations are usually within the normal range, or slightly increased in relation to a modest reduction in the glomerular filtration rate (GFR).

A few patients with FSGS and a poor subsequent outcome present with a Fanconi syndrome: glycosuria, aminoaciduria, urinary bicarbonate loss, and hypokalemia (42). A defect in urinary acidification has also been reported (43).

Hematology

Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Anemia with microcytosis may be observed, probably related to urinary loss of siderophilin. The urinary loss of erythropoietin may also contribute to anemia (44). Thrombocytosis is common and may reach 5.10^8 or 10^9/l.

Complications

Hypovolemia

A few children are severely hypovolemic and this complication is observed typically early during a relapse (*Table 28-2*). Sepsis, diarrhea or diuretics may precipitate hypovolemia. These children often complain from abdominal pain, have low blood pressure and cold extremities. Hemoconcentration with a raised hematocrit accompanies hypovolemia.

Acute Renal Failure

Renal function is usually within normal limits at presentation. A reduction of the GFR, secondary to hypovolemia, infection or thrombosis is frequent (45, 46). A reduced GFR may be found in patients with normal effective plasma flow. Bohman et al. showed a close relationship between the degree of foot process fusion and both GFR and filtration fraction, suggesting that fusion of foot processes could lead to a reduction of glomerular filtering area and/or of permeability to water and small solutes (47). This reduction is transitory, with a rapid return to normal after remission. Van de Walle et al. found that changes in glomerular permeability may have a major role in acute renal failure (46).

Marked oliguria may occur in children (48). Oliguric renal failure may be the presenting symptom. Renal failure may be secondary to bilateral renal vein thrombosis, which is recognized by sonography or to interstitial nephritis which has been reported, especially with furosemide. Skin rash and eosinophilia are suggestive of this diagnosis.

Acute renal failure is usually reversible, often with high dose furosemide induced diuresis, especially with intravenous infusion of albumin (49). In some cases, where glomerular structure is normal on initial histology, renal failure may last for as long as a year (50) and sometimes be irreversible (51).

Table 28-2
Nephrotic hypovolemia

Clinical features	Precipitating factors
Abdominal pain	Severe relapse
Hypotension	Infection
Sluggish circulation	Diuretics
Relative polycythemia	Paracenthesis
Acute tubular necrosis	Diarrhea
Thrombosis	

Chronic Renal Failure

The main difference between responders and nonresponders is the tendency of the latter to develop end-stage renal failure, which is seen in less than 3% of responders, even in the highly-selected series. This complication occurs in 50% or more of the steroid resistant patients after a follow-up of 10 years. The only "benefit" of the decrease of GFR is the improvement of the nephrotic syndrome due to a decrease of proteinuria.

We have retrospectively analyzed in the Enfants Malades series the outcome of 181 children with steroid resistant INS who have been followed for at least 5 years. Eighty-five percent were primary nonresponders and 15% late nonresponders. Initial renal biopsy had shown minimal changes in 62 cases and FSGS in 119 cases. Renal survival rates were 65% at 5 years, 50% at 10 years and 34% at 15 years. Interestingly, the rate of progression to end stage renal failure was similar in patients with minimal changes or FSGS on initial biopsy.

The data reported in other series are difficult to compare as most of them deal with patients with FSGS. The Southwest Pediatric Nephrology Study group reported 75 children with FSGS followed for periods of 7–217 months (52). Twenty-one percent had progressed to end stage renal failure, 23% had decreased glomerular filtration rate, 37% had a persistent nephrotic syndrome and 11% were in remission. Paik et al. retrospectively analyzed 92 children with steroid resistant FSGS and found renal

survival rates at 5, 10 and 15 years of 84, 64 and 53% respectively (53). Poor pronostic factors of chronic renal failure were asymptomatic proteinuria at presentation, initial renal failure and higher proportion of glomeruli with segmental sclerosis.

Progression to end stage renal failure has been reported to be more rapid in patients of African or Hispanic descent when compared with Caucasians. Ingulli and Tejani found that among 57 African American and Hispanic children, 50% of them had reached end stage renal failure within 3 years and 95% had reached this stage after 6 years (54). In addition, among the children with INS, the proportion of those with steroid resistant FSGS tends to be more important in African American and Hispanic children.

Growth

Growth may be severely affected in children with persistent nephrotic syndrome. Depletion of hormones due to urinary losses is a possible cause of stunting. Hypothyroidism related to urinary loss of iodinated proteins has been observed and may be corrected (55). A low plasma IgF1 and IgF2 level associated with a urinary loss of the carrier proteins has also been reported (56).

Infections

Bacterial infections are frequent in nephrotic children (*Table 28-3*). Sepsis may occur at the onset of the disease. The most common infection is peritonitis, often with *Streptococcus pneumoniae* (57). Other organisms may be responsible: *E. coli*, streptococcus B, *Haemophilus influenzae* and other gram negative organisms. Apart from peritonitis, children may develop meningitis, pneumonitis and cellulitis. Several factors may explain the propensity of nephrotic children to develop bacterial infections: low IgG levels due to an impaired synthesis, urinary loss of factor B and impaired T lymphocyte function. Factor B is a cofactor of C3b of the alternative pathway of complement which has an important role in opsonization of bacteria such as *Streptococcus pneumoniae*.

Viral infections may be observed in patients receiving corticosteroids or immunosuppressive agents. Chickenpox is often observed in these young children and may be life-threatening if acyclovir is not started rapidly. Interestingly, measles infection may induce long-lasting remissions.

Thrombosis

Nephrotic patients are at risk of developing thromboembolic complications. Arterial thrombosis is less frequent (19–27%) compared to venous thrombosis (73–81%) (58, 59). Several factors contribute the increased risk of thrombosis, including hypercoagulability state, hypovolemia, immobilization and infection (*Table 28-4*). A number of hemostatic abnormalities have been described in nephrotic patients: increase in platelet aggregability, increase in fibrinogen, factors V, VII, VIII, X and XIII while the levels of anti-thrombin III, heparin cofactor, protein C, protein S, factors XI and XII are decreased, increase in the fibrinolytic system components such as tPA, PAI-1 (58). The incidence of thromboembolic complications in nephrotic children is close to 3%. However this percentage may be underestimated as shown by systematic ventilation-perfusion scans showing defects consistent with pulmonary embolism in 28% of patients with steroid dependent INS (60). Pulmonary embolism should be suspected in cases of pulmonary or cardiovascular symptoms; this may be confirmed by angiography or angioscintigraphy. Renal vein thrombosis should be suspected in cases with sudden macroscopic hematuria or acute renal failure. Doppler ultrasonography shows an increase in kidney size and the absence of blood flow in

Table 28-3

Infections in nephrotic syndrome

Clinical syndrome	Risk factors
Pneumococcal peritonitis	Low IgG
Haemophilus infection	Low factor B
Gram negative sepsis	Edematous tissue
Staphylococcus cellulitis	Impaired lymphocyte function
	Corticosteroids
	Immunosuppressive drugs

Table 28-4

Thrombosis in nephrotic syndrome

Clinical syndrome	Risk factor
Pulmonary emboli	Hypovolemia
Pulmonary artery thrombosis	Hyperviscosity
Cerebral venous thrombosis	Low anti-thrombin III
Renal vein thrombosis	High fibrinogen
Peripheral venous	Platelet hyperaggregability
Artery thrombosis	Hyperlipemia

the renal vein. Thrombosis may affect the arteries such as pulmonary arteries or other deep veins.

Renal Biopsy

Renal biopsy is usually not indicated before starting corticosteroid therapy. It is only indicated in children less than 1 year of age, when the child has macroscopic hematuria or hypertension or low C3 levels or persistent renal failure and when the child fails to respond to corticosteroid therapy. A renal biopsy may be indicated in patients who relapse before considering alternative therapy, namely anticalcineurin agents.

Light microscopy shows three morphological patterns: minimal changes, diffuse mesangial proliferation, and FSGS.

Minimal Change Nephropathy

On light microscopy, glomeruli may be normal with normal capillary walls and normal cellularity (*Fig. 28-1*). Swelling and vacuolation of epithelial cells and a slight increase in mesangial matrix are often observed. A mild mesangial hypercellularity may be noted (61) as well as scattered foci of tubular lesions and interstitial fibrosis.

Ultrastructural changes are always present, involving podocytes and mesangial stalks. Podocyte foot process fusion is generalized and constant (*Figs. 28-2* and *28-3*); its extent is closely related to the degree of proteinuria (62). Other epithelial changes consist of microvillus formation and the presence of numerous protein reabsorption droplets. The glomerular basement membranes are normal with no parietal deposits.

Figure 28-1

Minimal change disease. Glomeruli appear normal by light microscopy with no tubulointerstitial lesions.

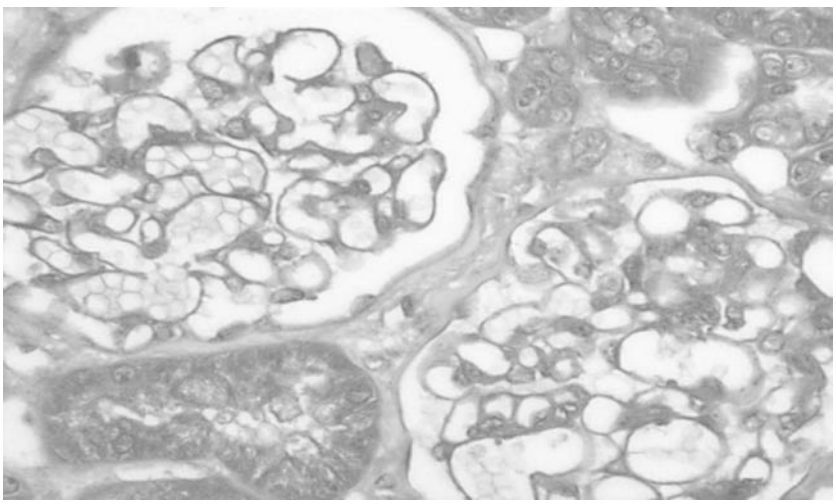

Figure 28-2

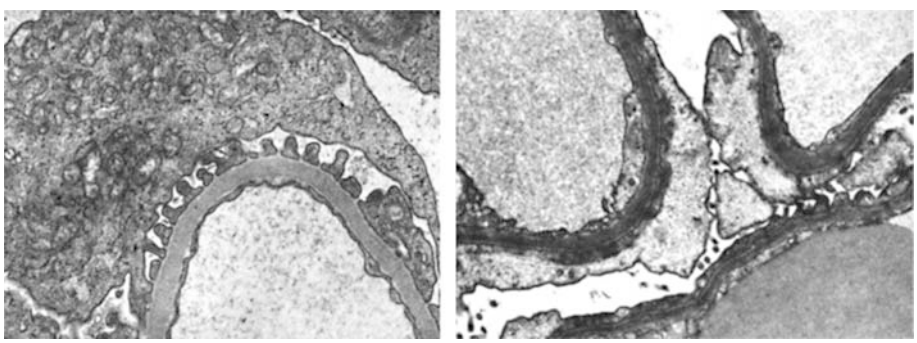
Electron microscopy. On the *left*, normal aspect with the podocyte foot processes attached to the glomerular basement membrane. On the *right*, minimal change disease with effacement of foot processes.



The endothelial cells are often swollen (63). Mesangial alterations include mesangial cell hyperactivity, increased mesangial matrix, and occasionally finely granular, osmiophilic deposits located along the internal side of the basement membrane. These ultrastructural alterations are nonspecific and are probably related to massive proteinuria.

Diffuse Mesangial Proliferation

Some patients with steroid resistant INS show a marked increase in mesangial matrix associated with hypercellularity (*Fig. 28-4*) (61, 64, 65). However, peripheral capillary walls are normal, and immunofluorescence microscopy is negative. Electron microscopy shows foot process fusion similar to the changes observed in minimal change disease. The presence of mesangial hypercellularity has been found to have prognostic significance with a higher rate of progression to renal failure (64) but these findings were not confirmed by other authors (52, 66).

Focal and Segmental Glomerular Sclerosis

The glomerular lesions affect a variable proportion of glomeruli (10, 61). The focal changes are limited to a part of the tuft, the other capillary loops showing no modification. The lesions always predominate at the corticomedullary junction (67). The segmental lesion affects a few capillary loops which stick together either at the

Figure 28-3

Scanning electron microscopy showing the normal aspect of podocytes with their foot processes on the *left* and their effacement in minimal change disease on the *right*.

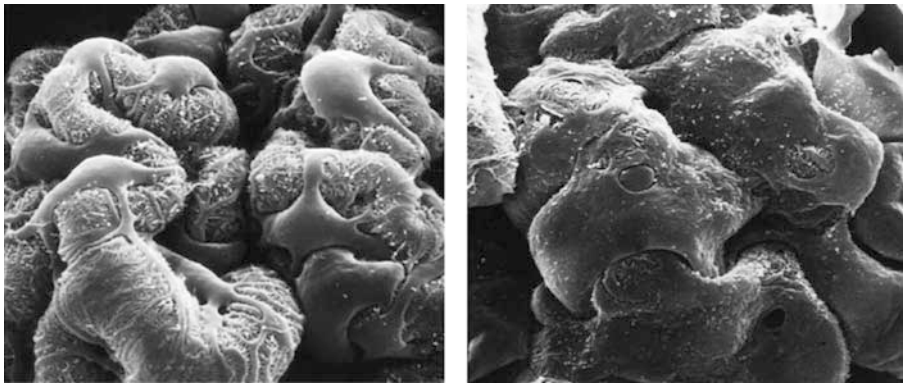


Figure 28-4

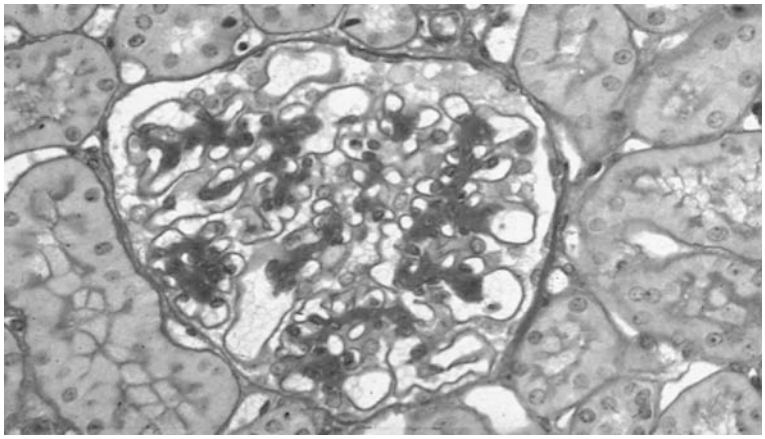
Diffuse mesangial proliferation with an increased number of mesangial cells and mesangial matrix.



hilum or at the periphery of the tuft, or at both (Fig. 28-5) (68, 69). The clinical course has been found to be more benign when the location of these sclerotic lesions is peripheral (the tip-lesion), although such findings have not been confirmed by other authors (67, 70–72). Hyaline material is often present within the sclerotic lesions. A clear "halo" zone is observed at the periphery of the sclerotic segments (Fig. 28-6). The segmental lesion has a different aspect depending on whether it affects a group of capillary loops free in Bowman's space or is adherent to Bowman's capsule. The "free" sclerotic segments are always surrounded by a "crown" of flat or hypertrophied podocytes. The podocytes form a continuous layer overlying the damaged areas of the tuft and in close apposition to the clear "halo." When the sclerotic lesion is adherent to Bowman's capsule, there is a direct synechia between the collapsed capillary loops and Bowman's basement membrane. The rest of the tuft and the nonsclerotic glomeruli show either "minimal changes" or "diffuse mesangial proliferation"

Figure 28-5

FSGS. In early stage, there is a segmental collapse of glomerular capillaries surrounded by hypertrophic podocytes containing intra-cytoplasmic vacuoles.

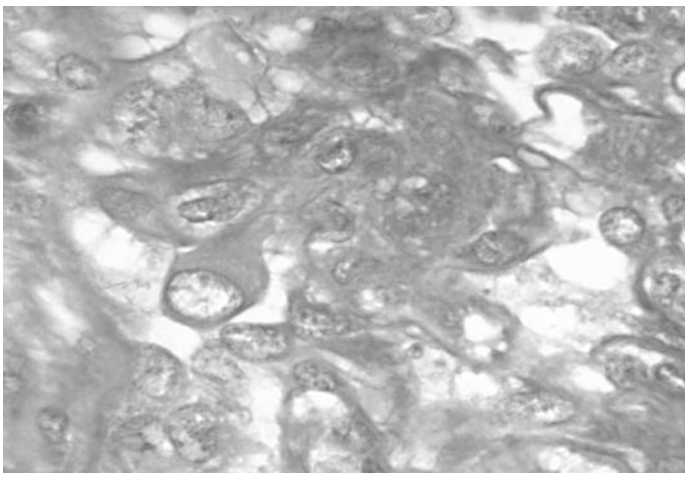


Figure 28-6

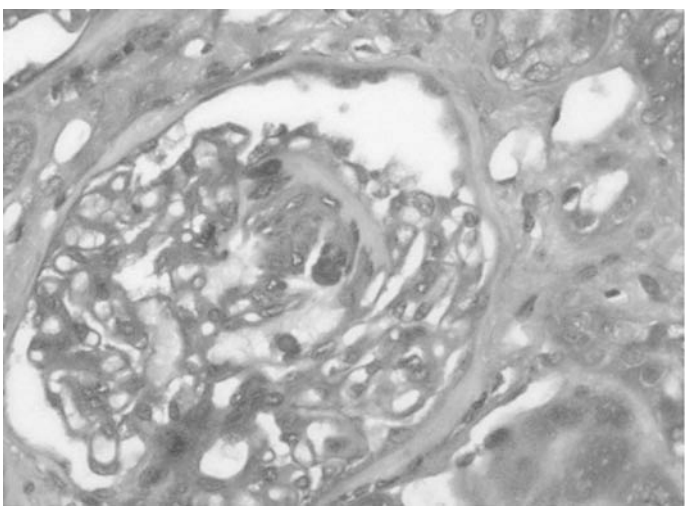
FSGS. Segmental lesion of the tuft characterized by the deposition of hyaline material at the inner side of the glomerular basement membrane with a ring of podocytes separated from the glomerular basement membrane by a clear ''halo.''



both with foot process fusion. Glomerular hypertrophy is common in FSGS, and when such hypertrophy is found in minimal change disease, it is somewhat predictive of further development to FSGS (73, 74).

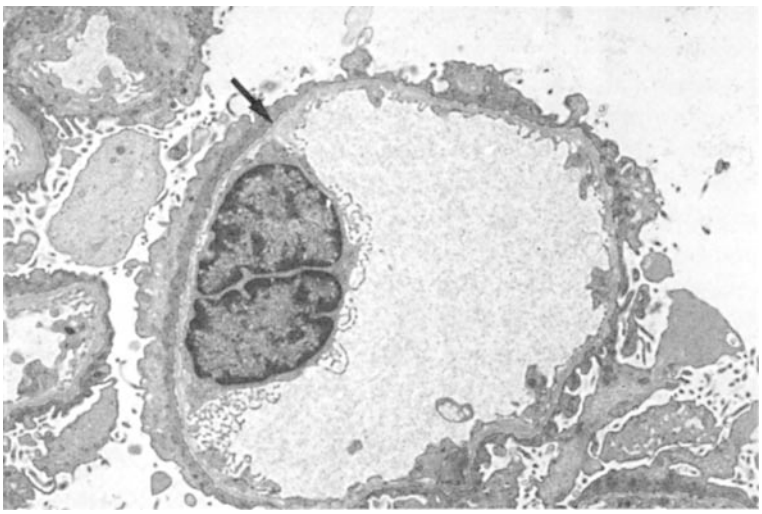
Tubular atrophy and interstitial fibrosis are often present and apparently proportional to the glomerular damage (10, 75). Focal glomerular lesions should therefore be suspected when focal tubular and interstitial changes are found associated with minimal glomerular changes. Erkan et al. found apoptosis in proximal and distal tubular cells of children with idiopathic FSGS (76). There was a correlation between the degree of proteinuria and the number of apoptotic cells. An elevated tubule cell apoptosis rate at the time of initial biopsy was found to be an independent predictor of progression to end stage renal disease.

On electron microscopy, the lesion is characterized by the presence of paramesangial and subendothelial, finely granular, osmiophilic deposits (75, 77, 78) with either disappearance or swelling of endothelial cells, and an increase in mesangial matrix material (*Fig. 28-3*). Fatty vacuoles may be seen, either in the middle of the abnormal deposit or in the cytoplasm of endothelial and mesangial cells. The peripheral synechia, located between podocytes and basement membrane, is formed by the apposition of acellular material in which thin and irregular layers of newly formed basement membranes are visible. Modifications of the podocytes consist of focal cytoplasmic degeneration, breakdown of cell membranes, and detachment of epithelial cells from basement membranes, with filling of the resulting space by cell debris and new membranes (79).

A pathologic classification of FSGS has been proposed with five histologic variants: FSGS not otherwise specified (NOS), perihilar variant, cellular variant, tip variant, and collapsing variant (80). All variants share podocyte alterations. This classification may have clinical implications in terms of response to therapy and risk of progression to renal failure. For example, glomerular tip lesions have been associated with better outcomes and collapsing variant with worse outcomes (71, 72). The glomerular tip lesion was found to be a predictor of a favorable response to therapy in a pediatric series (81). At present, this classification has no implication for treatment options.

A subgroup of patients have collapsing focal segmental glomerular sclerosis characterized by a global collapse of the glomerular capillaries with marked hypertrophy of epithelial cells (*Fig. 28-7*) (82). These patients have a severe nephrotic syndrome and rapidly progress to renal failure. The rate of response to steroids is poor. The incidence of collapsing glomerulopathy seems to have increased in the recent years. The main cause of secondary collapsing glomerulopathy is HIV associated nephropathy (83). Many authors consider that "collapsing glomerulopathy" is a distinct form of FSGS which may be "idiopathic," also observed in patients with recurrent nephrotic syndrome after renal transplantation, associated with HIV, parvovirus B19 infection or CMV infection (84, 85). Idiopathic

Figure 28-7
Collapsing glomerulopathy.



collapsing glomerulopathy predominates in blacks and has a poor prognosis (86).

FSGS is characterized by important changes in the podocytes, with major cell cycle derangement (3, 4). The normal mature podocyte does not divide and does not express proliferative markers such as PCNA and Ki-67. The podocyte express several cell surface proteins such as WT-1, C3b receptor, glomerular epithelial protein-1 (GLEPP-1), podocalyxin, synaptopodin and vimentin. The first stages of FSGS are characterized by the loss of the cell surface proteins (de-differentiation) and the expression of macrophage markers and cytokeratin (trans-differentiation). Proliferations markers (PCNA and Ki-67) are expressed, indicating a mitotic activity. This "podocyte dysregulation" is accompanied by podocyte detachment from the glomerular basement membrane.

FSGS is an irreversible scarring process in the glomeruli, as shown by the analysis of repeat biopsies (77, 78, 87). Studies in experimental animals (88) as well as in nephrotic patients have shown that proteinuria precedes the development of focal sclerotic lesions. The same sequence was reported in patients with recurrence of the disease after transplantation. Within weeks following recurrence of proteinuria podocytes observed by electron microscopy appear swollen and vacuolated. The podocytes exhibit strong mitotic activity, with multinucleation and expression of the PCNA and Ki-67 proliferation markers.

FSGS is not a specific histopathological lesion: similar alterations may be seen in persistent idiopathic proteinuria, heroin-associated nephropathy and, independently, in association with HIV infection, Alport's syndrome, hypertension, pyelonephritis, and obesity. It has also been reported in renal hypoplasia with oligomeganephronia, after partial nephrectomy and in other conditions with a reduction in nephron number, including reflux nephropathy or obstructive uropathy.

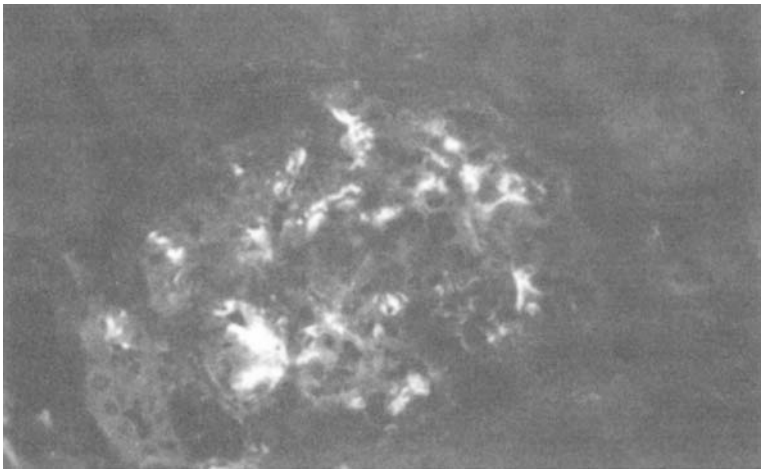
IgM Associated Nephropathy

Immunofluorescence microscopy is usually negative (89, 90). However, mesangial deposits of IgM, IgG, C3 and more rarely IgA have been reported. The most commonly found is IgM (*Fig. 28-8*) and Cohen et al. found that patients with IgM deposits in the mesangium had a poor response to corticosteroids (91). Other studies did not confirm these findings. Habib et al. reported on immunofluorescence studies in a series of 222 children with INS (92). Although IgM was the immunoglobulin most frequently present in the glomeruli (54 of 222), there was no correlation between IgM deposits, the initial response to steroid therapy or the final outcome. IgM deposits have also been described in association with diffuse mesangial proliferation and with FSGS.

A number of patients with INS display mesangial deposits of IgA. They are classified by some as IgA nephropathy. Others consider that mesangial IgA in patients with nephrotic syndrome and minimal changes, that is, without cellular proliferation is coincidental (92–94). This applies to INS associated with mesangial IgA deposits and explains a rapid response to steroids, which would not be the case in true IgA nephropathy.

Figure 28-8

INS with minimal changes. Diffuse mesangial deposits of immunoglobulin M.



Relationship Between the Different Histological Patterns

Repeat renal biopsies in patients with INS have shown morphological transition between the three main histological patterns. Some patients with clear evidence of minimal changes on initial biopsy have FSGS on a second biopsy. A high proportion of these patients are steroid-resistant. Tejani found that FSGS lesions had developed in 60% of 48 patients with steroid resistant minimal change disease, in association with aggravation of symptoms (95). The progression to sclerosis may occur from minimal change or from mesangial proliferation (64, 96). Conversely, some patients who show diffuse mesangial proliferation, whether or not associated with focal sclerosis on initial biopsy, may loose hypercellularity with time and show minimal change or FSGS on repeat biopsy (52).

In conclusion it may be considered that, at least in children, minimal change disease, FSGS, and diffuse mesangial proliferation represent histological variations of INS which may be found alone or in any combination on sequential biopsies in the same patient.

Clinicopathologic Correlations

The relative frequencies of the three histologic patterns differ in steroid sensitive and steroid resistant patients. A report of the International Study of Kidney Disease in Children showed that among 354 patients with INS who had an initial response to prednisone, 95.5% had minimal change disease, 3% had FSGS and 1.5% had diffuse mesangial proliferation (97). Conversely, among 55 patients who had failed to respond to prednisone, 45.5% had minimal change disease, 47.5% had FSGS and 7% had diffuse mesangial proliferation. This study also analyzed the numbers of responders and nonresponders within each histologic category. Among the 363 patients with minimal changes, 91.8% were responders and 6.9% nonresponders whereas among the 37 patients with FSGS, 29.7% responded to prednisone and 70.3% did not. Waldherr et al. found that only 2 out of 36 patients with diffuse mesangial proliferation responded to corticosteroids (64). An increase in steroid resistance has recently been reported in patients with FSGS (98).

Pathophysiology

Mechanisms of Proteinuria

In normal individuals, the clearance of albumin is about 1% of that of neutral proteins with similar molecular weight, such as polyvinylpyrrolidone or dextran. Similarly, the clearance of neutral dextran is higher than that of anionic sulfate dextran of similar molecular weight. These data indicate that the permeability of the glomerular basement membrane (GBM) is determined not only by the size but also by the charge of the protein. It is believed that the anionic charge of the glomerular basement membrane is responsible for the charge selectivity of filtration. The anionic (negative) charges of the glomerular basement membrane repulse the negatively charged albumin molecules, whose isoelectric point is 4.6.

The mechanism of proteinuria in the absence of histological alterations on light microscopy has suggested an electrochemical disorder of the GBM. Indeed it was shown that the glomerular K_f is diminished despite increased permeability to serum albumin. Using polyvinylpyrrolidone (99) or dextrans (100) with Einstein–Stokes radii between 2.0 and 4.8 nm as test macromolecules, the pore-size of the GBM was shown to be reduced contrasting with massive albuminuria. This suggested a loss of glomerular negative charges. Kitano et al., using polyethylamine as a cationic probe, reported a decrease in the anionic charges of the GBM in minimal change disease (101). Carrie et al. studied renal biopsy sections stained by colloidal iron and showed that its glomerular uptake was markedly reduced (100). A reduced sialic acid content in the GBM, as sialic acid residues may be responsible for glomerular negative charges (102).

Van den Born et al. produced a mouse monoclonal antibody to partially purified heparan sulfate proteoglycan isolated from rat glomeruli (103). By indirect immunofluorescence, the monoclonal antibody bound to the GBM on rat kidney sections. By electron microscopy a diffuse staining of the GBM was observed. After intravenous injection, the monoclonal antibody was localized along the GBM with a granular staining, and 1 day later in the mesangium with a concomitant decrease in staining along the GBM. By electron microscopy, 1 h after injection, the antibody was bound mainly to the inner side of the GBM. Intravenous injection of this antibody in rats resulted in selective proteinuria. This model shows that neutralization of heparan sulfate anionic charges may contribute to albuminuria.

Levin et al. and Boulton-Jones et al. presented data indicating that loss of negative charges was not restricted to the glomeruli but was also found on erythrocyte and platelet membranes, as shown by reduced binding of Alcian blue, a cathionic dye (104, 105). A cathionic protein is found in the plasma and the urine of patients in relapse.

The Immune System in Steroid-Responsive INS

In 1974, Shalhoub postulated that INS might be secondary to a disorder of T-lymphocyte function (106). He hypothesized that the expansion of a T-lymphocyte clone might results in the production of a lymphokine, which increases the permeability of the glomerular filtration barrier to proteins. The arguments supporting this hypothesis were the response of the disease to corticosteroids and to alkylating agents, the remission occurring in association with measles, which depresses cell-mediated immunity, the susceptibility of patients to pneumococcal infections and the occurrence of minimal change nephrotic syndrome in patients with Hodgkin's disease. There are other arguments for the role of a circulating permeability factor produced by mononuclear cells in the pathogenesis of the disease (107–109). The immediate recurrence of proteinuria after renal transplantation in some patients (110), the disappearance within few weeks of proteinuria when a kidney from a patient with MCD has been transplanted in a patient without nephrotic syndrome (111), the development of transient neonatal proteinuria and hypoalbuminemia in two children born to a woman with steroid resistant FSGS that disappeared within 2 and 3 weeks respectively (112), the onset of proteinuria in rats following the injection of serum taken from patients with recurrence after renal transplantation (113). The Buffalo/Mna strain of rats spontaneously develops proteinuria with FSGS at 2 months of age. Le Berre et al. found that the nephrotic syndrome recurs when Buffalo/Mna rats receive a kidney from a healthy LEW.1W rat (114). Conversely, proteinuria and renal lesions regress when kidneys from a Buffalo/Mna rat are transplanted into normal LEW.1W rats. Although recurrence of proteinuria is not immediate after transplantation, this model may be helpful to clarify the pathogenesis of the disease and the mechanisms of recurrence after transplantation in man. However, this putative factor has not yet been identified, and it is currently unclear whether INS may be caused by several different factors, and whether this or these factors are identical in MCD and FSGS (115).

Lagrue et al. first described the vascular permeability factor (VPF), a lymphokine found in the supernatant of concanavalin A-activated lymphocytes from patients with MCD which enhances vascular permeability when injected intradermally in the guinea pig (116). Heslan et al. showed that VPF was produced by T lymphocytes and was distinct from interleukin-2 (117, 118). Maruyama et al. showed that cyclosporine at concentrations ranging from 100 to 250 ng/ml was able to suppress the in vitro production of VPF by mononuclear cells from patients with MCD (119). VPF was also found in other diseases such as IgA nephropathy. Tanaka et al. found that the supernatants of concanavalin A-activated lymphocytes from patients with MCD or FSGS induced a marked proteinuria when injected in the renal artery of rats together with a reduction of the anionic charges of the GBM (120). Koyama et al. described a glomerular permeability factor (GPF) in the supernatant of T cell hybridoma derived from the fusion between peripheral T lymphocytes of a patient with MCD and a T cell line, CCRF-HSB2 (121). The GPF was identified by the ability of the supernatant to induce a proteinuria when injected intravenously in the rat. In addition, rats injected with the supernatants show a partial fusion of foot processes of glomerular epithelial cells and no immune deposits. GPF is different from the other known lymphokines. Its molecular weight is between 60 and 160 kDa.

Savin et al. found in some patients with FSGS the presence of a serum factor which increases the albumin permeability of isolated rat glomeruli. The presence of the factor was strongly predictive of the recurrence of proteinuria after renal transplantation (109). A vascular permeability factor, which induces proteinuria when injected into the renal artery of rats, was found in the serum from a transplanted patient who had recurrence of the nephrotic syndrome (113), but many similar attempts to isolate such a factor have failed. Dantal et al. treated patients who had recurrent nephrotic syndrome with plasma protein-A adsorption (122). The administration to rats of material eluted from the protein A columns increased urinary albumin excretion. The active fraction had a molecular weight below 100,000 Da. The factor or factors that may be responsible for recurrent nephrotic syndrome after transplantation seem to be bound to an immunoglobulin (123).

Proteomic analysis of the fractionated serum from children with FSGS identified ten proteins that maintain increased glomerular permeability to albumin including: fibulin, clusterin (apo J), vitronectin, albumin isoforms, γ chain of fibrinogen, and mannan-binding lectin-associated serine protease (124).

Several lymphokines may play a pathogenic role (*Table 28-5*) (125). Increased interleukin-2 levels have been found in lymphocyte culture supernatants from patients with INS and interleukin-2 can induce proteinuria and a reduction of the anionic sites of the GBM when injected into the rat kidney (126). A nephrotic syndrome has been described in several patients treated with

recombinant IL-2 and alpha-interferon. However, Heslan showed that the complete removal of IL-2 from concentrated supernatants by immunoadsorption experiments did not affect the VPF activity. More convincing is the upregulated IL-13 gene expression in both CD4+ and CD8+ T cells in children with steroid-sensitive INS during relapse (127). IL-13 is one of the cytokines secreted by T helper 2 (Th2) T cells, and it has been shown that activated T cell activation early evolves toward Th2 phenotype in minimal change disease (128). In addition, genetic polymorphisms in the *IL-13* gene correlate with long-term outcome of minimal change disease (129). Indeed, the frequency of the AAT haplotype was higher in children with persistent relapses after 5 years from onset, whereas the haplotype GCC was associated with long-term remission. Receptors for IL-13 have been found in podocytes, with direct effects of IL-13 on podocytes and their signaling pathways (130). The IL-13 promoter contains two NFkB responsive elements and high and sustained plasma levels of NFkB have been detected during relapse (131), suggesting a potential role of this pathway in INS. NFkB is down-regulated by IkBa. Sahali et al. demonstrated low levels of IkBa and down-regulation of its mRNA during relapse (131). This may lead to an explanation of the additive effects of steroids and cyclosporine treatment in INS since steroids are thought to induce a transactivation of the IkBa gene while cyclosporine blocks the degradation of the active form of IkBa (132).

The type of cell producing the circulating factor also remains unclear. Sellier-Leclerc et al. developed a humanized mouse model of INS by injecting CD34(+) stem cells or CD34(−) peripheral blood mononuclear cells from affected patients into immunocompromised NOD/SCID mice (161). Only the injection of CD34(+) stem cells induced albuminuria and effacement of podocyte foot processes. These data suggest that the cells involved in the pathogenesis of INS are more likely to be immature differentiating cells rather than mature peripheral T cells.

It was hypothesized that the increased glomerular permeability to albumin may be caused not only by the production of permeability factors but also by the lack of their inhibitors such as apolipoproteins. Sharma et al. showed in several vertebrate species that normal human serum prevents the increased permeability to albumin induced by FSGS serum (162). Inhibitors of the plasma factors may be lost in urine in patients with INS, and their presence in urine has been documented. Urine from patients but not normal urine can block the increased albumin permeability induced by serum from patients with INS in isolated rat glomeruli (163). Candiao et al. demonstrated that components of high-density lipoproteins prevent glomerular albumin permeability induced by serum from patients with FSGS (164). Decreased plasma levels and glomerular expression of clusterin (ApoJ) was demonstrated in FSGS; this suggests a possible role of this protein as the inhibitor of plasma PF (165). In conclusion, the potential of FSGS serum to increase glomerular albumin permeability may result from an imbalance between permeability factors and their natural inhibitors.

Treatment

Symptomatic Treatment

Diet

Dietary therapy should include a protein intake of around 130–140% of the recommended daily allowance according to statural age. Salt restriction is advised for the prevention and the treatment of edema. A very low salt diet is only necessary in cases of massive edema. Fluid restriction is recommended for moderate to severe hyponatremia (plasma sodium concentration less than 125 meq/l). A reduction of saturated fat is recommended. Carbohydrates should be given preferentially as starch or

dextrin-maltose, avoiding sucrose which increases lipid abnormalities.

Hypovolemia

Hypovolemia occurs as a consequence of rapid loss of protein, and is sometimes aggravated by the use of diuretics. This complication needs emergency treatment by rapid infusion of plasma (20 ml/kg) or albumin 20% (1 g/kg) administrated with control of heart rate, respiratory rate and blood pressure.

Diuretics

Diuretics should only be used in cases of severe edema, after hypovolemia has been corrected. Furosemide is administered at a dose of 1–2 mg/kg. If not effective, spironolactone (5–10 mg/kg) or amiloride (0.2–0.5 mg/kg) may be prescribed if the plasma creatinine concentration is normal (166). Patients with severe edema may be treated with furosemide or, if necessary, furosemide plus albumin to increase the rate of diuretic delivery to the kidney. This approach is immediately effective but not long-lasting. Moreover, respiratory distress with congestive heart failure have been observed in some patients (167).

Refractory edema with serious effusions may require drainage of ascites and/or pleural effusions. Immersion of the body up to the neck in a bath may be helpful in these cases (168).

Thromboemboli

Nephrotic patients with severe hypoalbuminemia are at risk for thromboembolic complications. Prevention of this complication includes mobilization, avoidance of hemoconcentration due to hypovolemia and early treatment of sepsis or volume depletion. Prophylactic warfarin therapy may be given to high risk patients with a plasma albumin concentration below 20 g/l, a fibrinogen level over 6 g/l, or an antithrombin III level below 70% of normal. Patients at risk may also be treated with low-dose aspirin and dipyridamole.

Heparin is given initially if thrombi do occur, alone or with thrombolytic agents. The heparin dose necessary to obtain a therapeutic effect is often greater than normal due to decreased the antithrombin III level.

Antihypertensive Drugs

Any arterial hypertension has to be carefully controlled, using preferably a β-blocker or a calcium channel blocker during acute episodes. In cases of permanent hypertension, an angiotensin converting enzyme inhibitor is preferred.

Infections and Immunisations

Prophylaxis of S pneumoniæ with oral penicillin is often applied in patients during the initial treatment with corticosteroids. Pneumococcal vaccine may be performed and is not associated with an increased risk of relapse (169). In cases of peritonitis, antibiotics against both S pneumoniæ and gram-negative organisms are started after peritoneal liquid sampling. Varicella is a serious disease in patients receiving immunosuppressive treatment or daily corticosteroids. Varicella immunity status should be checked in these patients. In cases of exposure, early preventive treatment by acyclovir must be instituted. Varicella vaccination is safe and effective if the child is in remission even if he is on low-dose alternate day steroids (170, 171).

Hyperlipidemia

Persistent hyperlipidemia is a risk factor for atherosclerosis and may play a role in the progression of chronic renal failure. Experience with hypolipidemic drugs in nephrotic patients is still limited but it seems that statins are effective and able to decrease hypercholesterolemia (172, 173). Although long-term side effects of these drugs are not known, it is reasonable to consider a lipid-lowering regimen in children with a persistent nephrotic syndrome (174).

Miscellaneous

Calcium metabolism may be altered by the urinary loss of 25-hydroxycholecalciferol and its carrier protein. Preventive treatment with vitamin D supplements is therefore useful but does not completely prevent bone loss (175). Thyroxine substitution may be indicated, but only in patients with documented hypothyroidism due to urinary loss of iodinated proteins.

Specific Treatment

Steroid therapy is applied in all cases of INS whatever the histopathology, even in patients with FSGS. The majority of patients are steroid-responsive (*Table 28-6*). Urine protein profile (proteome) may in the future help to predict the response to steroid therapy (176). Steroid responders may relapse, but the majority still responds to steroids over the subsequent course. Only 1–3% of patients initially steroid-sensitive subsequently become steroid-resistant and are defined as "late non-responders" (177).

Initial Treatment

Although steroid therapy is often started immediately following the diagnosis of nephrotic syndrome, it should be stressed that spontaneous remission occurs in 5% of cases within 1 or 2 weeks. Therefore, initiation of steroid therapy may be delayed for a few days (178). Some of these early spontaneous remissions are definitive. Infection must be treated before starting steroids, not only to prevent the risk of overwhelming sepsis during treatment, but also because occult infection may be responsible for steroid resistance (17).

Steroid therapy is started when the diagnosis of INS is most likely in a child older than 1 year and younger than 11 years of age, without hypertension, gross hematuria or extra-renal symptoms and normal complement levels. In some cases, the treatment is started after a renal biopsy has been performed. Prednisone remains the reference drug. Prednisolone has the advantage of being soluble in water, making treatment easier in young children, but it may fail to induce remission in some patients who respond quickly to the same dosage of prednisone. The differences in intestinal absorption and drug interactions, for instance with aluminum gels, may explain lesser efficacy in some children.

The ISKDC regimen consists of prednisone, 60 mg/m^2/day with a maximum of 80 mg/day, in divided doses for 4 weeks followed by 40 mg/m^2/day with a maximum of 60 mg/day in divided doses, on three consecutive days per week for 4 weeks (97). The Arbeitsgemeinschaft für pädiatrische Nephrologie showed that an alternate day regimen (40 mg/m^2 every other day for 4 weeks) resulted in a significantly lower number of patients with relapses and fewer relapses per patient (179). It also showed that on alternate days prednisone could be given in a single dose rather than in divided doses.

A response occurs in most cases within 10–15 days (median 11 days) (*Table 28-6*). According to the International Study of Kidney Disease in Children, approximately 90% of responders enter in remission within 4 weeks after starting steroids whereas less than 10% go into remission after 2–4 more weeks of a daily regimen (97). A few more patients go into remission after 8–12 weeks of daily steroids (13, 15), but prolongation of daily steroid treatment beyond 4 or 5 weeks increases the risk of side-effects. An alternative for patients who are not in remission after 4 weeks is to administer three to four pulses of methylprednisolone (1 g/1.73 m^2). This additional regimen seems to be associated with fewer side effects than prolongation of daily high-dose steroids and probably produces remission more rapidly in the few patients who would have entered into remission during the second month of daily therapy (180).

The duration of initial steroid therapy influences the risk of relapse.

The APN compared a standard regimen of 4-week daily prednisone and 4 weeks of alternate day prednisone with a longer initial course of 6 weeks of daily prednisone at a dose of 60 mg/m^2/day followed by 6 weeks alternate day

Table 28-6

Definitions

Nephrotic syndrome: proteinuria >40 mg/h/m^2 or >50 mg/kg/day or protein/creatinin ratio >0.2 g/mmol (>2 g/g) and hypoalbuminemia <25 g/l with or without edema
Remission: proteinuria <4 mg/h/m^2 or 0-trace on Albustix for 3 consecutive days
Steroid responsive: complete remission achieved with steroid therapy
Steroid resistant: failure to achieve remission following 4 week' prednisone 60 mg/m^2 followed by 3 methylprednisolone pulses
Relapse: proteinuria > >40 mg/h/m^2 or >50 mg/kg/day or Albustix +++ for 3 consecutive days after having been in remission
Frequent relapser: 2 or more relapses within 6 months of initial response or 4 or more relapses within a period of 1 year
Steroid dependence: 2 consecutive relapses during corticosteroid therapy or within 14 days after cessation of therapy
Early nonresponder: steroid resistance during the first episode
Late nonresponder: steroid resistance in a patient who had previously responded to corticosteroid therapy

prednisone at a dose of 40 mg/m^2/day (179). The subsequent relapse rate within 12 months following discontinuation of therapy was lower with the prolonged course of therapy compared to the standard course (36 vs. 61%).

Following an 8-week steroid regimen, 50–70% of children experience relapses. Several controlled studies have compared the 8-week regimen with longer duration of steroid regimen (3–7 months) including 4–8 weeks of daily prednisone followed by alternate day prednisone (181–185). With a follow-up of 2 years, a significant reduction of 25–30% in the relapse rate was observed with a prednisone regimen of 3 months or more.

The number of children with frequent relapses is also decreased with a longer course of prednisone. A longer duration is more important than the cumulative dose of prednisone in reducing the risk of relapse. This relative risk decreases by 0.133 (13%) for every additional month of treatment up to 7 months (97). There are no data showing that treating for more than 7 months is beneficial. However, an alternate-day regimen over a year did not reduce the rate of relapse compared to a 5-month alternate day regimen (186, 187). Although the studies were not designed to analyze the side effects of glucocorticoids, the authors did not report increased toxicity with longer duration of treatment.

A slow tapering phase to avoid adrenal suppression may maintain long-term remission as a study showed that moderate to severe adrenal suppression was associated with an increased risk of relapse (188). Some authors have suggested a possible prevention by low-dose maintenance hydrocortisone (189, 190). Another study also concluded that adrenocortical suppression increases the risk of relapse in children on long-term alternate day steroid therapy (191).

Increasing initial immunosuppression by adding cyclosporine to steroid therapy does not change the 2-year relapse rate (192).

Treatment of Relapses

About 30% of children experience only one attack and are definitively cured after a single course of steroids. Persistent remission for 18–24 months after stopping treatment is likely to reflect definitive cure, and the risk of later relapses is low. Ten to 20% of patients relapse several months after stopping treatment and are most often cured after three or four episodes, which respond to a standard course of steroid therapy. The remaining 50–60% experience relapses as soon as steroid therapy is stopped or when dosage is decreased. In some cases, exacerbation of proteinuria is only transient, and spontaneous remissions are observed (193). The risk of relapse is greater in children aged less than 5 years at onset and in males. These steroid dependent patients often raise difficult therapeutic problems.

Steroid-dependent patients may be treated with repeated courses of prednisone, 60 mg/m^2/day, continued 3 days after the urine has become protein free, followed by alternate day prednisone, 40 mg/m^2, for 4 weeks as proposed by the International Study of Kidney Disease in Children (97). Another option consists of treating relapses with daily prednisone, 40–60 mg/m^2, until proteinuria has disappeared for 4–5 days. Thereafter, prednisone is switched to alternate days and the dosage is tapered to 15–20 mg/m^2 every other day, according to the steroid threshold, that is, the dosage at which the relapse has occurred. Treatment is then continued for 12–18 months. The first approach allows better definition in terms of number of relapses but is associated with more relapses. The latter regimen is associated with less steroid side effects as the cumulative dosage is lower. Prolonged courses of alternate day steroid therapy are often well tolerated by young children and growth velocity is not affected. However, prednisone dosage must be as low as possible in order to reduce the side effects. In adolescents, steroid therapy is often accompanied by decreased growth velocity.

A controlled trial has shown that deflazacort reduces the risk of relapse in comparison with equivalent doses of prednisone, without additional side effects (194). Unfortunately, deflazacort is not available in many countries.

The role of upper respiratory tract infections in exacerbating nephrotic syndrome has been highlighted in all series: 71% of relapses were preceded by such an event in a prospective study, although only 45% of respiratory infections were followed by an exacerbation of proteinuria (195). The risk of relapse is decreased during upper respiratory tract infections when steroid therapy is given daily for 5–7 days rather than on alternate days (196, 197).

Steroid Side Effects

Side effects of prolonged steroid therapy are well known and are observed in children with a steroid dependent course. Growth retardation is observed with prolonged daily steroid therapy and alternate day therapy may preserve growth (198). However, when the dose needed to maintain remission is too high, growth may be impaired (199, 200). Osteoporosis has been reported in adults who had suffered from nephrotic syndrome during childhood (201). However, a study in children and adolescent with

steroid dependent nephrotic syndrome failed to find a deleterious effect of alternate day steroid therapy on bone mineral content (202). Biyikli et al. reported that steroid treatment causes a dose dependent decrease in bone formation, as shown by the changes in osteocalcin and alkaline phosphatase levels and low 25-hydroxyvitamin D levels (203). A randomized controlled trial compared vitamin D and calcium supplements with no prophylaxis in children receiving high dose steroid therapy during a relapse. The authors found a decrease in bone mineral content in both groups but less pronounced in the treated group ($4.6 \pm 2.1\%$ vs. $13.0 \pm 4.0\%$, respectivelly; $P<0.001$) (175). Another controlled study showed that biphosphonates are effective in preventing steroid-induced osteoprosis in children receiving long-term steroid therapy (204). The other side effects include weight gain, cataracts, behavior disturbances, and hypertension.

Alternative Treatments (*Fig. 28-9*)

An alternative treatment is indicated in children who develop severe side effects of steroid therapy, in children at risk of toxicity (diabetes or during puberty), in children with severe relapses accompanied by thrombotic complications or severe hypovolemia and in those with poor compliance.

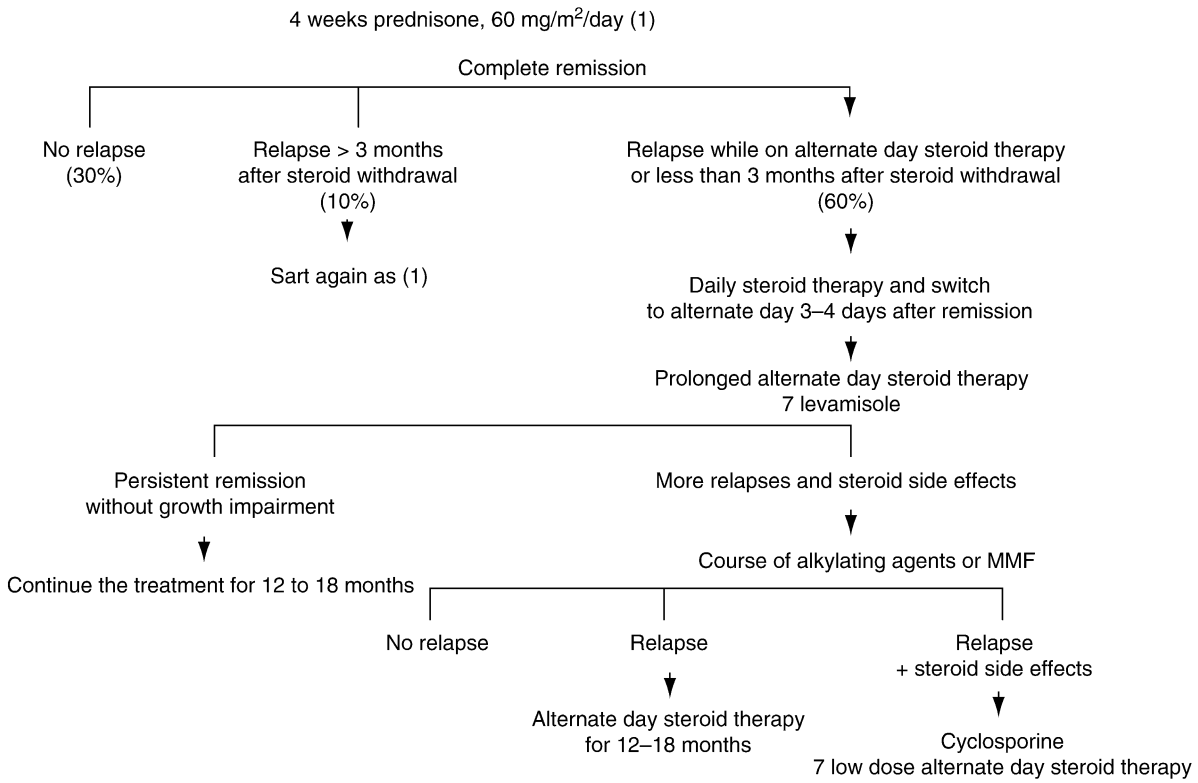
Alternative treatments include levamisole which has a steroid sparing effect, alkylating agents such as cyclophosphamide or chlorambucil, cyclosporine, mycophenolate mofetil and, more recently, rituximab.

Levamisole

The beneficial effect of levamisole was first described by Tanphaichitr et al. (205). Levamisole was subsequently reported to reduce the risk of relapse in steroid dependent patients (206–210). A significant steroid-sparing effect at a dose of 2.5 mg/kg every other day was demonstrated in a prospective controlled trial of the British Association for Paediatric Nephrology (211). Another controlled study confirmed the efficacy of levamisole for preventing relapses (212). However, the beneficial effect of levamisole is not sustained after stopping treatment.

Levamisole given for 6 months was compared with cyclophosphamide given for 8–12 weeks in a retrospective

Figure 28-9



study involving 51 children with steroid dependent nephrotic syndrome (213). The relapse rate and the cumulative dose of prednisone were reduced to the same extent with both drugs.

Levamisole is well tolerated in most children. Side effects occasionally include neutropenia, agranulocytosis, vomiting, cutaneous rash, vasculitis, neurological symptoms including insomnia, hyperactivity and seizures (214, 215). However, levamisole is not widely used due in part to the difficulty in obtaining the drug.

Alkylating Agents

Alkylating agents have been used for more than 40 years to achieve long-lasting remission.

Cyclophosphamide

The efficacy of cyclophosphamide for preventing relapses of INS was reported more than 40 years ago (216), and was proven in a prospective study by Barratt and Soothill who compared an 8-week course of cyclophosphamide to prednisone alone in children with frequent relapses (217). An International Study of Kidney Disease in Children trial found a 48% relapse rate after a mean follow-up of 22 months in children treated with a combination of cyclophosphamide and prednisone compared to a 88% relapse rate in patients on prednisone alone (218). Pennesi et al. showed that the duration of cyclophosphamide treatment had an influence on the duration of remission (219). Several other studies have addressed the relation between dose and duration of treatment and therapeutic efficacy. Treatment for 12 weeks at a daily dose of 2 mg/kg was found more effective than an 8-week course, with 67% of patients as compared to 22% remaining in remission after 2 years (220, 221). However, a randomized trial showed that prolonging the course of cyclophosphamide from 8 to 12 weeks did not further reduce the proportion of children experiencing relapses.

The duration of remission is higher when cyclophosphamide is given in association with steroids compared to cyclophosphamide given alone (218, 222, 223). Cyclophosphamide is less effective in patients with steroid dependency compared to patients with frequent relapses (224). The incidence of relapse after cyclophosphamide is significantly higher in patients with FSGS (73%) or mesangial proliferation, compared to children with minimal change (22%) (225).

More recent data show disappointing results of cyclophosphamide treatment for steroid dependent patients. Kemper et al. reported that only 6 out of 20 children had a sustained remission following a 12-week course of cyclophosphamide. In a retrospective study (226), Vester et al. reported that 24% of 106 children who had received a course of cyclophosphamide were still in remission after 10 years (227, 228). A younger age than 3 years at onset is associated with lower response rate (229).

Cyclophosphamide has also been administered as monthly boluses at 500 mg/m^2 for 6 months. Gulati et al. reported a remission rate of 38% at 5 years among the 29 steroid dependent patients (230). However, Donia et al. reported a remission rate of only 5% at 2 years in a group of 20 steroid dependent patients (231). Prasad et al. compared cyclophosphamide given orally or as boluses in 47 children (232). The remission rate 6 months after the end of treatment was higher following the cyclophosphamide boluses (73% vs. 38%) but was similar with a follow-up of 2 years.

Chlorambucil

Beneficial results have also been achieved with chlorambucil in steroid responsive INS. Grupe et al. reported on the efficacy of chlorambucil given for 2.5–12 weeks, with a relapse rate of only 13% (233). Two trials showed that chlorambucil reduces the risk of relapse at 6 and 12 months compared with placebo or prednisone alone (233, 234). Baluarte et al. obtained similar results in relapsing, steroid-responsive patients (235). Williams et al. showed that low daily doses are preferable: 91% of patients on a dose of 0.3 mg/kg and 80% of those on 3 mg/kg were still in remission 4 years later (236).

A review of 26 controlled trials and cohort studies found that the 2- and 5-year relapse rates following treatment with cyclophosphamide or chlorambucil were 72 and 36% in frequently relapsing nephrotic syndrome compared with 40 and 24% in steroid dependent nephrotic syndrome (237).

Side Effects

Cyclophosphamide toxicity includes bone marrow depression, hemorrhagic cystitis, gastrointestinal disturbances, alopecia, and infection. Leucopenia is frequently observed, but weekly hematological monitoring may limit its severity and concomitant steroids help blunt marrow depression. Hemorrhagic cystitis rarely occurs. Alopecia, which is variably pronounced, remits a few weeks after stopping treatment. Viral infections can be overwhelming if cyclophosphamide is not stopped in due time.

Long-term toxicity includes malignancy, pulmonary fibrosis, ovarian fibrosis, and sterility. Gonadal toxicity is well established and the risk of sterility is greater in boys than in girls. The cumulative threshold dose above which oligo/azoospermia may be feared is between 150

and 250 mg/kg (238–240). Azoospermia is reversible in some patients (241). In females the cumulative dose associated with sterility is greater, but not well defined. Pregnancies have been reported after treatments longer than 18 months (242).

Acute toxic effects are less frequent with chlorambucil than with cyclophosphamide. Leucopenia and thrombocytopenia may occur, and are reversible within 1–3 weeks. Severe microbial and viral infections have been reported, including malignant hepatitis and measles encephalitis.

Long-term toxic effects include the risk of developing cancer or leukemia, which has only been reported in patients who had prolonged courses of treatment. Gonadal toxicity, as with cyclophosphamide, essentially affects boys. Azoospermia is total and probably irreversible at cumulative doses above 10–20 mg/kg. No case of azoospermia was reported in patients given less than 8 mg/kg.

Cyclosporine

Cyclosporine have been shown in a number of uncontrolled studies to reduce the incidence of relapses in 75–90% of patients with steroid dependent INS (243). However, most patients experience relapses when the dosage is tapered or when cyclosporine is withdrawn. The patients thus behave with cyclosporine as they did with steroids; that is, they become cyclosporine dependent. The relapse rate usually returns to the pretreatment rate. Hulton et al. found that patients in whom cyclosporine had been discontinued and later restarted had more relapses, requiring steroids in addition to cyclosporine in order to maintain remission (244).

The effects of cyclosporine have been evaluated in two comparative trials in steroid sensitive patients. Cyclosporine at a dosage of 6 mg/kg/day for 3 months, then tapered over 3 months was compared with chlorambucil given for 2 months. At 12 months, 30% of patients who had received chlorambucil and only 5% of those who were still in remission on cyclosporine (245). A multicenter randomized controlled trial compared cyclosporine for 9 months then tapered over 3 months, with oral cyclophosphamide for 2 months (246). After 2 years, 25% of the patients (50% of adults and 20% of children) who had received cyclosporine had not relapsed, whilst 63% of those treated with cyclophosphamide (40% of adults and 68% of children) were still in remission. During the year following treatment, the relapse rate (1.8 vs. 0.7) and the steroid dosage required (109 vs. 23 mg/kg/year) were significantly higher in children who had received cyclosporine.

Tejani et al. performed a randomized controlled trial comparing low dose prednisone and cyclosporine versus high dose prednisone for 8 weeks as first line treatment in 28 children (247). Thirteen of the 14 children receiving the combined treatment went into remission compared to only 8/14 receiving prednisone alone ($p < 0.05$). The duration of remission after ending treatment was comparable in both groups. Severe hypercholesterolemia may inhibit cyclosporine efficacy and require higher dosages for similar results (248, 249).

A prospective, open multicenter trial from Japan compared the efficacy and safety of two cyclosporine regimen, a dose adjusted to maintain trough level between 60 and 80 ng/ml (group A) and a fixed dose of 2.5 mg/kg (group B) in children who had initially received cyclosporine for 6 months with a trough level of 80–100 ng/ml (250). After 2 years, the rate of sustained remission was significantly higher in group A.

Considering cyclosporine dependency, this treatment must be pursued to prevent new relapses. Indeed, cyclosporine exposes to nephrotoxicity. In case of decreased renal function, it is advisable to reduce dosage or even stop the treatment. Renal function improvement of is in favor of functional renal insufficiency or drug nephrotoxicity. Nevertheless, lesions of chronic nephrotoxicity can develop without any appreciable decline of the glomerular filtration rate (251–253). As it is often necessary to continue treatment for a long time, repeat renal biopsies are highly advisable to detect these lesions. They most often consist of tubulointerstitial injury, characterized by stripes of interstitial fibrosis containing clusters of atrophic tubules and by vascular lesions.

Other side-effects are of less concern: hypertension, hyperkalemia, hypertrichosis, gum hypertrophy, and hypomagnesemia are common but easily manageable. Cyclosporine treatment has no deleterious effect on bone mineral content (254).

Tacrolimus

In a retrospective study of ten children, it was observed that tacrolimus was not better than cyclosporine for the management of severe steroid dependent nephrotic syndrome (255). In a series of five children treated with tacrolimus, two developed insulin dependent diabetes mellitus which resolved after stopping tacrolimus therapy (256).

Azathioprine

Two controlled trials in children showed that azathioprine does not reduce significantly the number of children who relapse at 6 months compared to steroids alone or placebo (257–259).

Mycophenolate Mofetil

During the past 10 years, several reports have shown that mycophenolate mofetil (MMF) treatment may have a beneficial effect in children with steroid dependent INS

(260–272) These studies have shown that MMF allowed to decrease or stop steroid therapy in 40–75% of children. However, relapses were nearly constant after cessation of treatment. MMF was shown to have a significant cyclosporine and/or steroid sparing effect in children with cyclosporine dependent INS with a beneficial effect on renal function (263, 266). These studies confirm the efficacy and safety MMF in patients with steroid dependent nephrotic syndrome and supports its use for a longer duration than 12 months. Doses of 450–600 mg/m^2/day in two divided doses are usually given. Side effects including gastrointestinal disturbances (abdominal pain, diarrhea) and hematologic abnormalities are rare. Many authors now recommend the use of MMF rather than alkylating agents in children with steroid dependent nephrotic syndrome who suffer from side effects of steroid therapy. However, randomized trials should be performed before such recommendations can be made.

Rituximab

During the past 3 years, there have been several case reports of successful treatment of patients with severe steroid dependent nephritic syndrome (273–277). Most of the patients received 1–4 injections of rituximab at a dose of 375 mg/m^2. The duration of remission lasted 9–28 months after the treatment. The safety and efficacy of rituximab were assessed in a multicenter series of 22 patients aged 6.3–22 years with severe steroid-dependent nephrotic syndrome or steroid-resistant but cyclosporin-sensitive INS (278). Patients were treated with two to four infusions of rituximab. Seven patients were nephrotic at the time of treatment. Remission was induced in three of the seven proteinuric patients. One or more immunosuppressive treatments could be withdrawn in 19 patients (85%), with no relapse. Rituximab was effective in all patients when administered during a proteinuria-free period in association with other immunosuppressive agents. When relapses occurred, they were always associated with an increase in CD19 cell count. Adverse effects were observed in 45% of cases, but most of them were mild and transient.

Long-Term Outcome of Children with Steroid Sensitive Nephrosis

About one third of patients have only one attack and are definitively cured after the course of corticosteroids. Ten to 20% of patients experience relapses several months after stopping the treatment and a cure takes place after three or four episodes which respond to a standard course of corticosteroids. The remaining 40–50% of patients experience frequent relapses either as soon as steroid therapy is stopped (frequent relapsers) or when the dose of steroids is decreased (steroid dependent). These steroid dependent patients may have a prolonged course. However, if the patient continues to respond to steroids, the risk of progression to chronic renal failure is minimal.

Schärer and Minges found that 22% of patients had only one attack and 35% of the relapsing patients continued to relapse after 10 years (279). Trompeter et al. reported the late outcome of 152 children steroid-responsive nephrotic syndrome after a follow up of 14–19 years: 127 (83%) were in remission, four had hypertension, 10 were still relapsing, and 11 had died (280). The duration of the disease was longer in children who had started before the age of 6 years. Wynn et al. found that 15% of 132 patients had a persistent relapsing course with a mean follow-up of 27.5 years (281). Lewis et al. reported on 26 patients over the age of 20 years, of whom 5 were still relapsing in adulthood (282).

Koskimies et al. reported on the follow-up of children with INS observed in Finland from 1967 to 1976: 94 of 114 cases had responded to corticosteroids. Twenty-four percent of steroid responders had no relapse, 22% had infrequent relapses and 54% frequent relapses. More than two-thirds were in remission at time of report (283). None of these patients developed renal insufficiency and none died from the disease. Lahdenkari et al. reported a 30-year follow-up of the patients reported previously by Koskimies et al. (284). Of 104 patients, 10% had further relapses in adulthood.

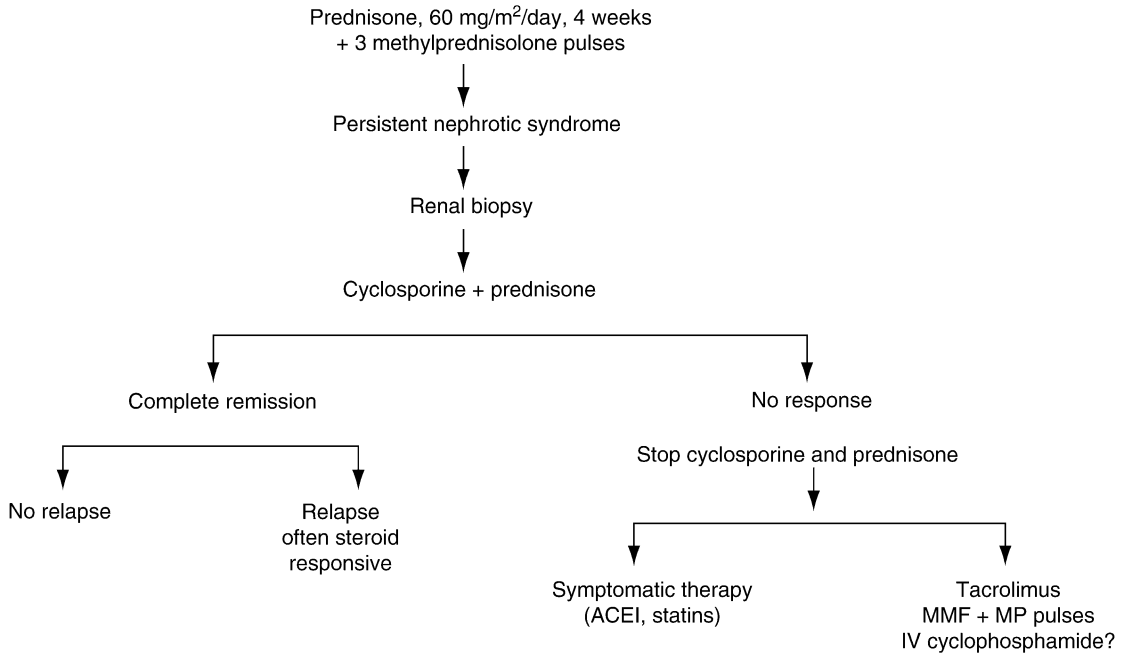
Fakhouri et al. reported on the outcome in adulthood of 102 patients born between 1970 and 1975 (201). Fourty-two percent presented at least one relapse in adulthood. A young age at onset and a high number of relapses during childhood were associated with a high risk of relapse in adulthood. Similarly, Ruth et al. in a study of 42 patients found that 14 (33%) relapsed in adulthood (285). The higher relapse rates in these two reports probably reflect patient selection with more steroid dependent cases compared to Koskimies' series.

This generally good long-term prognosis is also observed in patients with steroid-responsive focal and segmental glomerulosclerosis: the 19 children reported by Arbus et al. remained responders, and none had renal insufficiency after a mean follow-up of 10 years (286).

Treatment of Steroid Resistant INS (◉ *Fig. 28-10*)

Resistance to steroid therapy is defined by the absence of remission after 1 month of daily prednisone therapy at a dose of 60 mg/m^2/day (97). Some authors continue the

Figure 28-10



treatment for 1 or 2 weeks while others favor a series of three methylprednisolone pulses (1,000 mg/1.73 m^2) every other day (287). Indeed, the side effects of this regimen are less than those induced by an increase in the daily prednisone dose. Persistence of proteinuria 1 week after this treatment defines steroid-resistance.

Overall, the prognosis of steroid resistant idiopathic nephrotic syndrome is poor, with a high proportion of children progressing to end stage renal failure. This explains that intensive treatment regimens have been tried. The results of immunosuppressive treatments should take into account the fact that children with genetic forms of INS most often fail to respond to any therapy. However, many published trials include patients who had not been tested for mutations in the different genes involved in steroid resistant INS. Moreover, most studies are nonrandomized and include a small number of patients.

The interpretation of treatment is also complicated by the fact that some studies include patients with minimal change disease, diffuse mesangial proliferation and FSGS while other only include patients with FSGS.

Pulse Methylprenisolone

Methylprednisolone pulse therapy has been advocated for steroid resistant patients. The protocol proposed by Mendoca et al. consists of methylprednisolone (30 mg/kg intravenously), administered every other day for 2 weeks, weekly for 8 weeks, every other week for 8 weeks, monthly for 9 months, and then every other month for 6 months in association with oral prednisone and, if necessary, cyclophosphamide or chlorambucil (288). At an average of over 6 years of follow-up, 21 of 32 children were in complete remission and the 5-year incidence of end-stage renal disease was approximately 5% versus 40% in historical controls (289). Side effects included nausea during the infusion of methylprednisolone in almost all, slowed growth in four, small cataracts that did not interfere with vision in five, and infections in two. There were no cases of abdominal striae, diabetes mellitus, or aseptic necrosis of bone.

A retrospective study of 11 children with steroid resistant INS found pulse methylprednisolone therapy to be safe and effective in inducing remission (290). Similarly, Pena et al. reported that 22 out of 30 children with idiopathic steroid resistant INS entered into complete remission following methylprednisolone pulses and oral cyclophosphamide (291). Although these results are better than those seen in any other study, other reports described less favorable results. Waldo et al. found that pulse methylprednisolone pulse therapy was not effective in inducing remission in black patients (292), whilst Hari et al. in India reported a 65% response rate (293).

Alkylating Agents

Although alkylating agents have little therapeutic effect in steroid resistant patients, they are still widely used either alone or in combination with corticosteroids. Cyclophosphamide has been more often been used than chlorambucil. The rate of full or partial remission is higher in patients with partial steroid resistance, those with late steroid resistance, or those in whom initial renal biopsy has shown minimal changes, by comparison with those showing initial resistance to corticosteroids and/or FSGS. The International Study of Kidney Disease in Children recently reported on 60 children with steroid resistant FSGS who were randomly allocated to receive either prednisone 40 mg/m^2 on alternate days for 12 months (control group) or cyclophosphamide, 2.5 mg/kg BW for 3 months plus prednisone 40 mg/m^2 on alternate days for 12 months (294). Complete remissions were observed in 28% of children in the control group and in 25% of children who received cyclophosphamide. The authors concluded that there was no beneficial effect of cyclophosphamide in these patients. Geary et al. reported full or partial response to cyclophosphamide in 12 of 29 steroid-resistant patients with FSGS (295). Renal failure developed less frequently in partial responders (one of nine) than in those who did not respond at all (seven of eight). Siegel et al. observed complete remissions in six steroid-resistant patients with minimal changes, three of whom relapsed but became steroid responsive (11). Similarly, Bergstrand et al. reported that some patients with steroid-resistant nephrosis treated with cyclophosphamide had become steroid-responsive (296). Conversely, White and Glasgow observed no improvement after cyclophosphamide treatment in 15 steroid-resistant children with focal sclerosis (297). Cameron et al. reported only one responder out of 13 children with steroid-resistant nephrosis and FSGS who received cyclophosphamide (222). Similarly, Tejani et al. reported no remission with cyclophosphamide in ten steroid-resistant children (298). In a controlled trial involving 13 children with steroid resistant minimal change nephrotic syndrome, intravenous pulse cyclophosphamide was shown to be beneficial when compared to oral cyclophosphamide (299). Another report concerning five patients with steroid resistant minimal change disease found no benefit from pulse cyclophosphamide therapy (300). Rennert et al. treated ten children with steroid resistant FSGS with cyclophosphamide pulses. Only two of the five patients who were initial nonresponders went into remission whereas all five late nonresponders achieved complete remission (301). In a prospective study of 24 patients, Bajpai et al. found that therapy with intravenous cyclophosphamide had limited efficacy in patients with initial corticosteroid resistance while Sustained remission was likely to occur in patients with late resistance and those with absence of significant tubulointerstitial changes on renal histology (302).

Chlorambucil may be effective. Williams et al. treated six children who all went into remission with a follow up of 1.3–9.4 years (236). We treated 74 steroid-resistant children with chlorambucil, 0.2 mg/kg, for 2–6 months, and only 14 of them went into complete or partial remission during or shortly after the treatment.

Azathioprine

Azathioprine was considered to be ineffective in steroid-resistant patients after the report of Abramowicz et al. who found no difference between a 3-month course of azathioprine and a placebo (257). However, Cade et al. reported complete remission in 13 adult patients with steroid-resistant INS (303).

Cyclosporine

Cyclosporine has been given to steroid resistant patients and the first reports showed that only 20% of 60 steroid-resistant children achieved complete remission (304–309). A partial response was observed in 13% of cases, but it was usually transient.

The Collaborative Study of Sandimmun in Nephrotic Syndrome analyzed the data from different clinical studies, including 226 steroid resistant patients, adults and children (310). The study showed that the rate of complete remission was significantly higher when cyclosporine was given in combination with steroids: 24% compared to 14%.

The French Society of Pediatric Nephrology reported the results of a prospective trial including 65 children treated with cyclosporine, 150–200 mg/m^2, and prednisone, 30 mg/m^2/day for 1 month and on alternate days for 5 months thereafter (287). Twenty-seven patients (42%) went into complete remission and four (6%) partial remission whereas 34 (52%) failed to respond to the combined treatment. Complete remission occurred in more than half of the patients within the first 2 months of this treatment, which makes it likely that the treatment was responsible for the remission, although spontaneous remission cannot be excluded. Interestingly, eight patients who relapsed after cyclosporine treatment responded to steroid and experienced a steroid dependent course. Progression to renal failure was observed only in patients who

had not responded (12 patients) or had only a partial response (1 patient) to the combined treatment.

Ingulli et al. reported that prolonged cyclosporine treatment in children with steroid resistant FSGS reduces proteinuria and blunts the progression to end stage renal failure (311). The dose of cyclosporine (4–20 mg/kg/day) was titrated to the serum cholesterol level to achieve a remission. In this study, only 5 of the 21 treated patients (24%) progressed to ESRF compared to 42 of 54 patients from an historical group who had not received this treatment. Cattran et al. compared the effects of a 26-week regimen with cyclosporine and prednisone or prednisone alone in 49 adults with steroid resistant FSGS (312). Seventy percent patients of the treatment group versus 4% of the placebo group had a partial or complete remission. Although the rate of relapse was high, preservation of renal function was observed in a significant proportion of treated patients.

Ponticelli et al. compared cyclosporine to supportive therapy in a randomized trial (313). Seven of the 22 treated patients went into complete remission, 6 in partial remission and 9 failed to respond. Only 38% of the patients who responded had sustained remissions. In the control group, only 3 of the 19 patients achieved partial remission. Liberman and Tejani compared cyclosporine and placebo in 25 children with steroid resistant FSGS (314). All 12 patients who were treated achieved a decrease of proteinuria compared to only two in the placebo-treated patients, without a significant decrease in glomerular filtration rate in the cyclosporine treated group.

Gregory et al. treated 15 children with steroid resistant INS with an association of moderate doses of cyclosporine and prednisone. They observed a remission in 13 children after a mean duration of treatment of 2 months (315). Singh et al. reported the effect of cyclosporine in 42 children with steroid resistant FSGS (316). The mean proteinuria decreased from 7.1 g/day to 1.8 g/day while the serum albumin increased from 2.1 g/dl to 3.5 g/dl. The mean serum creatinine increased from 0.85 mg/dl to 1.26 mg/dl. Twenty five patients achieved complete remission. Ehrich et al. reported a retrospective study including 25 children with steroid resistant FSGS who received prolonged and intensified treatment with combined cyclosporine and steroids including methylprednisolone pulses. This treatment resulted in sustained remission in 84% of children with non-genetic forms of steroid resistant INS (317).

Tacrolimus

There is evidence that tacrolimus is effective in a significant proportion of patients. Loeffler et al. found tacrolimus to be effective and well-tolerated for children with steroid resistant INS, with a complete remission rate of 81% and a partial remission rate of 13% (318). Bhimma et al. treated 20 children with tacrolimus and observed a complete remission in 40% of them and a partial remission in 45% of them (319). Similarly, Gulati et al. reported the results of tacrolimus treatment in 22 children, 16 of whom achieved complete remission and 2 partial remission whereas therapy had to be stopped in 3 because of side effects (320).

Mycophenolate Mofetil

There is no convincing data for the beneficial effect of mycophenolate mofetil in these patients. Menzibal et al. treated five patients with steroid resistant INS and only one achieved complete remission (268). Mycophenolate mofetil in association with methylprednisolone pulses and angiotensine converting enzyme inhibitors was reported to significantly reduce proteinuria (321). Cattran et al. reported on a 6-month trial in 18 adults. A reduction of proteinuria was observed in eight patients but no complete remission occurred (322). A prospective trial of the NIH comparing cyclosporine and mycophenolate mofetil in combination with pulse steroids is in progress.

Sirolimus

Tumlin et al. performed a prospective, open trial with oral sirolimus given for 6 months to 21 patients with steroid resistant FSGS. Complete remission was observed in 4 patients (19%) and partial remission in 8 (38%) (323). Glomerular filtration rate in responding patients was maintained whereas it tended to decrease in nonresponders.

Rituximab

Nakayama et al. reported two patients who were successfully treated with rituximab for steroid resistant FSGS (324). Bagga et al. treated five children including three with initial resistance to steroids and two with late resistance to steroids (325). All children had received several other therapies with partial or complete response. Following 4 weekly doses of rituximab, four patients achieved complete remission and one a partial remission. Complete remission persisted in three patients. However, there are several reports of patients who failed to respond to

rituximab and it is too early to recommend such therapy in steroid resistant INS.

Non-steroidal Anti-inflammatory Drugs

These drugs may decrease proteinuria. Several authors have used indomethacin in the treatment of INS with variable results. Donker et al. found a reduction of proteinuria in patients with FSGS but with a simultaneous reduction of glomerular filtration rate (326). Velosa et al. also found a clear reduction in proteinuria in patients treated with meclofenamate (327).

The detrimental effect of non-steroidal anti-inflammatory agents on renal function is well known, and patients with renal disease seem more vulnerable (328, 329). Positive sodium balance, increased edema and risk of arterial hypertension are recognized complications. The decrease of glomerular filtration rate observed with non-steroidal anti-inflammatory drugs is usually reversible in salt-sodium depleted patients. However, irreversible renal failure has been reported with a high incidence in a prospective study in children with steroid resistant FSGS (330).

Angiotensin Converting Enzyme Inhibitors

Numerous studies in adults have demonstrated that angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) slow the rate of progression of proteinuric chronic renal disease. Captopril was reported to decrease dramatically nephrotic range proteinuria due to renovascular hypertension and secondary FSGS (331). A decrease in proteinuria, and even complete remission, have also been observed in patients with chronic glomerulopathies with or without hypertension (332). A 50% decrease of proteinuria without a concomitant decrease in glomerular filtration rate was reported in children with steroid resistant INS (333). Marked benefits with an ACE inhibitor and/or ARB therapy, plus mycophenolate were observed in nine children with steroid-resistant FSGS (321). At 6 months, mycophenolate plus angiotensin blockade resulted in a 72% decrease in proteinuria from baseline values, a benefit that was maintained for a minimum period of 24 months.

Lipid-Lowering Agents

Hyperlipidemia has been shown in experimental animals to accelerate the progression of glomerular sclerosis. Controlled trials in adult patients have shown that lipid-lowering agents can prevent the decline of renal function. No such studies have been performed in children.

Recurrence of INS in Transplanted Kidneys

The major problem of patients with INS who progress to end stage renal failure and who undergo renal transplantation is the risk of recurrence of the nephrotic syndrome in the graft. The overall risk of recurrence is estimated to be between 20 and 30% (334). The risk is different in children and in adult patients. Senggutuvan et al. found that 8 of 16 children had experienced recurrence compared to 3 of 27 adults (335). In children, recurrence is more frequent when the disease has started after the age of 6 years than before (336, 337). Similarly, a rapid progression of the disease to end stage renal failure seems a major factor associated with recurrence: in most series, when the duration of disease has been shorter than 3 years, the nephrotic syndrome recurs in half of the patients (336, 338). Recurrence is less frequent in African-Americans than in whites and Hispanics (339). The histopathological pattern observed on the first biopsy during the course of the disease is also an important predictive factor (335–337, 340, 341). Recurrence occurs in 50–80% of patients in whom initial biopsy showed diffuse mesangial proliferation but in only 25% of patients with minimal changes on first biopsy. Most patients who experience a recurrence in a first graft also show recurrence in a second graft (342–344). Conversely, when the graft has been lost due to rejection without recurrence, a second graft can be performed safely as recurrence is exceptional in this setting. Patients with podocine mutations or other genetic forms of INS have a very low risk of recurrence (345).

In children, recurrence of proteinuria occurs in most cases within the first hours or the first days after transplantation. A high proportion of patients with immediate recurrence show delayed graft function (344, 346). In some patients, proteinuria recurs several months later. Proteinuria is most often associated with a nephrotic syndrome. Transplant biopsy when performed early shows minimal glomerular changes with foot process fusion (347–349). Lesions of FSGS appear after several days or weeks which is a strong argument to consider these lesions as secondary rather than the cause of heavy proteinuria (348).

Graft failure occurs in about 60% of patients with recurrence versus 23% of those without recurrence

(335, 344, 350). Some patients may show good renal function for several years despite persistent nephrotic syndrome.

The beneficial role of cyclosporine in recurrent steroid resistant INS is still debated. There is no evidence that cyclosporine can prevent the recurrence of nephrotic syndrome following transplantation (351–356). Following the introduction of cyclosporine, the incidence of recurrence did not change, but graft survival was improved (351, 352, 355). In patients who have recurrent disease, high doses of cyclosporine may be effective. Mowry et al. reported on 11 children who received 12 renal transplants and who had been treated with high dose cyclosporine, plasma exchanges or a combination both (357). Remission was observed in 10 of the 12 recipients. Ingulli and Tejani reported on two children with recurrent nephrotic syndrome who both achieved remission when the dose of cyclosporine was gradually increased from 15 mg/kg/day to 27 and 35 mg/kg/day (358). A similar experience was reported by Srivastava et al. (359). In our group, seventeen children with recurrence have been treated with intravenous cyclosporine at an initial dose of 3 mg/kg/day which was afterward adapted in order to maintain whole blood levels between 250 and 350 ng/ml. In 14 of the 17 cases (82%), proteinuria completely disappeared after 20.8 $\pm$ 8.4 days (range: 12–40 days). The treatment was ineffective in the remaining three patients. Plasma exchanges were performed in four patients during the first 2 months and proteinuria regressed in three cases and persisted in one. Persistent remission was observed in 11 patients with a follow-up of 3.7 $\pm$ 3 years. Actuarial graft survival was 92 and 70% at 1 and 5 years (360). We advocate the early use of intravenous cyclosporine as a first-line treatment in recurrent INS after renal transplantation. Similarly, Raafat et al. reported that high doses of oral cyclosporine was effective in inducing long-lasting remission of recurrent nephrotic syndrome (361). There is limited experience with the use of tacrolimus (FK 506) in recurrent nephrotic syndrome after transplantation (362).

Plasma exchange has been performed in a number of patients, in some cases combined with increased immunosuppression (350, 363–368), with often partial or transient remissions. Better results are observed when the treatment is started early. Dantal et al. treated eight kidney-transplant recipients with recurrent nephrotic syndrome with plasma protein adsorption (122). The treatment consistently decreased urinary protein excretion by an average of 82% at the end of a cycle. The effect of adsorption was short-lived, with a return of proteinuria to pre-treatment levels within a maximum of 2 months.

Conclusion

Most children with INS respond to corticosteroid therapy. Although about half of them experience relapses requiring corticosteroids and several corticosteroid sparing agents, these children maintain normal renal function and the severity of the disease is mainly related to the complications of the treatments needed to maintain remission.

There is evidence to suggest that minimal changes and FSGS represent a spectrum of diseases with FSGS at the severe end (369). Indeed, it is likely that several disease entities are included in the term "steroid resistant INS." Defects in podocyte proteins have been identified in some cases and these patients do not respond to any therapy. In other patients, circulating factor(s) produced by immune cells increase the glomerular basement membrane permeability to proteins. Cyclosporine may be effective. However, more than 50% of the patients progress to end stage renal failure. Recurrence of the nephrotic syndrome occurs in 30–40% of patients after renal transplantation.

29 Immune-mediated Glomerular Injury

Michio Nagata

Overview

Glomerular injury is the central basis of renal insufficiency. Accumulated immunohistopathologic evidence from human kidney diseases and experimental glomerular disease models indicates that immunologic mechanisms are often pivotally involved in glomerular injury. Founded on the classical evidence, recent advances in basic immunology, the molecular and cellular biology of intrinsic glomerular cells, and genetic engineering in mice have provided significant clues to understanding the immune mechanisms that target the glomerulus.

The pathogenesis of immune-mediated glomerular injury involves two major steps: antibody deposition on glomerular components, and the subsequent activation of secondary inflammatory mediators. Under certain circumstances, the activation of inflammatory process occurs in the absence of tissue antibody deposition (pauci-immune). For instance, membranoproliferative glomerulonephritis (MPGN) type II by the inherited defects in complement regulation and ANCA-related glomerulonephritis represent an immune-mediated, but pauci-immune glomerular injury. Basic immunology has promoted research into the complex immunopathogenesis of glomerular injury mediated by the two axes of the adaptive immune system, i.e., antibody-mediated and cell-mediated immunity.

The glomerular deposition of antibodies is promoted by the humoral immune process of Th2 activation, which leads to antibody production via B-lymphocyte activation. This deposition may be composed of preformed immune complexes from the circulation, which are trapped in the glomerulus, or antibodies (autoantibodies) that bind to intraglomerular antigens or interact with intrinsic glomerular cell surface antigens, as a result of changes to the cell surface.

Among the four mechanisms underlying hypersensitivity, immune-mediated glomerular injury is primarily of the type II and III mechanisms. As seen in type III hypersensitivity reactions, antibody deposition on glomerular capillary walls or the mesangium activates the complement cascade and intrinsic cell-derived chemotactic factors result in inflammatory cell influx, which is a crucial event in the glomerular injury by production/activation of pro-inflammatory cytokines, chemokines, growth factors, reactive oxygen species (ROS), eicosanoids, and nitric oxides (NO). These secondary mediators not only stimulate intrinsic cells to proliferate and/or produce matrix materials, but they also induce the synthesis of similar molecules by intrinsic glomerular cells. The secondary mediators involves severe endothelial injury which potentially result in dysregulation of local coagulation system, accompanied by exudation and the formation of cross-linking fibrins. This end-products of the extrinsic coagulation cascade also damage glomeruli particularly tuft necrosis, the common forerunner of crescentic formation.

An alternative immune mechanism is cell-mediated immunity, with Th1 activation promoting cytotoxic glomerular injury. Proliferative glomerulonephritis in the absence of immune complexes or antibodies suggests a role for cell-mediated immune injury. This is supported by the experiment showing that transfer of sensitized T cells successfully induced glomerular injury in the host. Although the precise mechanism remains unclear, ANCA-related crescentic glomerulonephritis appears to involve T-cell-mediated glomerular injury. It is clear that the antibody- and cell-mediated immune systems are not independent, and often interact in glomerular injury.

Immune mechanisms may also be involved in glomerular diseases that are typically considered to have a non-immunologic basis. For example, although diabetic nephropathy is categorized as a metabolic disease, it involves glomerular macrophages and/or lymphoid cell infiltration, and the expression of adhesion molecules, all of which are mediators of inflammatory processes and significantly involved in this disease. Recent experiments have shown that the inhibition of pro-inflammatory cytokines or macrophages suppresses the progression of diabetic glomerulopathy. Similarly, monocyte/macrophage or foam cell influx is sometimes observed in idiopathic focal segmental glomerulosclerosis, which usually shows no evidence of antibody deposition. Thus, immune mechanisms may be linked to a wide variety of glomerular diseases, even those typically considered to be non-immune-mediated conditions.

© Springer-Verlag Berlin Heidelberg 2009

This chapter provides a review of our basic understanding of and up-dated information regarding immune-mediated glomerular injury, with emphasis on the pathogenic mechanism(s). Although numerous scientific advances have come out of animal experiments, it should be kept in mind that experimental models of immune-mediated glomerular injury are largely relevant to the acute phases of anti-GBM antibody nephritis, nephrotoxic serum nephritis or anti-Thy1 nephritis of mesangial proliferation. Furthermore, the molecular profiles of the immune systems of mice and humans are significantly different. This review of our basic knowledge of immune-mediated glomerulonephritis may help to explain some aspects of the mechanism(s) underlying chronic glomerulonephritis in humans.

Glomerular Components

Glomerulonephritis arises from the responses of intrinsic glomerular cells to inflammatory reactions. Glomerular deposition, hypercellularity (intrinsic and inflammatory cells), and capillary destruction are typical features of glomerular injury (*Fig. 29-1*). The biologic characteristics of the intrinsic glomerular cells are implicated in this process. Although the cellular components of the glomerulus are anatomically defined by three cell types, mesangial cells, endothelial cells, and podocytes, parietal cells are also involved in glomerulonephritis, particularly in cellular crescent formation and adhesion (the renal corpuscle comprises these four cell types). In addition, the biochemical profiles of the extracellular matrices, glomerular basement membrane, and mesangial matrices are unique, and may be targets for antibody deposition, leading to effects on the corresponding intrinsic cells. Ultrastructural analyses provide a good opportunity to define the involvement of extracellular matrices in glomerular injury.

The Glomerular Basement Membrane (GBM)

The GBM, which is a central component of the filtration barrier based on charge and size, is composed of extracellular matrix materials, including collagen IV, nidogen (entactin), heparan sulfate proteoglycans (HSPG), laminin, and perlican. GBM is synthesized by podocytes and endothelial cells; however, the details of the formation of the membrane from the individually synthesized proteins remain unknown. Nevertheless, this unique permeability system traps macromolecules and antibodies and is responsible for their glomerular deposition.

The GBM also contains potentially harmful antigens. Pathogenic autoantibodies directed against the C-terminal globular non-collagenous domain 1 (NC1) of the α3-chain of type IV collagen, which has a distinct GBM molecular composition, promote severe glomerulonephritis in patients with Goodpasture syndrome by epitope-specific autoantibody binding and effector T cell reaction (*Fig. 29-2*) (1). Similar epitopes are targeted by alloantibodies in a subset of patients with Alport nephritis who have received allografts. GBM is also the target of bioactive substances released from inflammatory cells and intrinsic cells during inflammation. GBM changes may directly influence the physiologic stability of filtration, thereby reducing the glomerular filtration rate and causing proteinuria. Electron microscopy has revealed GBM alterations in association with immune deposits, and inflammatory cell influx can directly alter the morphology of the GBM (*Fig. 29-3*). Proteolytic enzymes derived from neutrophils may directly alter the GBM, resulting in membranolysis, lamination, gaps, and edema (typical features of GBM injury), which may lead to urinary abnormalities. Immune deposition on the GBM, as seen in membranous glomerulonephritis and lupus nephritis, can also alter the GBM by changing its barrier of charge and size properties.

Mesangial Cells

The mesangium is the axis of the glomerulus, holding the capillaries in a developed dense network of matrix, which includes microfibrils and fibronectin. Mesangial cells are derived from the metanephric mesenchyme and there are one or two cells within each mesangial area. The biological properties of mesangial cells have some similarities with vascular smooth muscle cells. Both cell types show contraction and cell proliferation in response to vasoactive substances and cytokines In vitro.

The lack of intact GBM between endothelial cells and the mesangium enables bone marrow-derived inflammatory cells and macromolecules to access the mesangium (*Fig. 29-4*). Early studies showed that resident cells in the mesangium expressed the phenotype of bone marrow cells (Ia-positive) in the normal state, and that their numbers were increased in glomerulonephritis. GFP-tagged bone marrow cell transplantation in rat anti-Thy1 nephritis, a model of mesangial proliferative glomerulonephritis, have provided evidence that bone marrow-derived cells are responsible for mesangial hypercellularity.

The mesangial fluid pathway was discovered in an experiment involving the ligation of lymph vessels around

Figure 29-1

the renal artery. This leaky barrier and fluid pathway allow circulatory macromolecules, including antibodies, to be trapped in the mesangium as mesangial deposits. The phenotypes and behaviors of cells in the mesangium are also modulated by the glomerular scaffold of self-produced extracellular matrix materials.

In glomerular injury, deposition, cell proliferation, matrix production, and cell death occur in the mesangium. Mesangial proliferation is a typical feature of glomerular injury. Activation of cell cycle molecules, as revealed by immunohistochemical detection of proliferating cell nuclear antigen or Ki-67, is detected in the

Figure 29-2

Structure of Goodpasture antigen epitopes in collagen Type IV. a. c. GP epitope is localized in the NC1 domain of α3(IV) chain of type IV collagen. In the GBM, the α3(IV) chain is associated with the α4(IV) and α5(IV) chains, forming protomers and networks. The GP epitopes are cryptic within the α3·α4·α5(IV) NC1 hexamer and inaccessible for autoantibody binding unless the NC1 hexamer dissociates. Several hydrophobic amino acids were found critical for the epitope of the immunodominant GPA autoantibodies (inset); which appears to be sequestered by an interaction with an α5 (IV) chain in the same protomer b. mesangial cells in glomerulonephritis, indicating mesangial cell proliferation In situ. Cell cycle is ultimately regulated by the balance of cell cycle promoter (cyclins) and inhibitors (cyclin dependent kinase inhibitors) (*Fig. 29-5*). Cyclin D1, coupled with cyclin-dependent kinases (CDK4 and CDK6), promotes the re-entry of quiescent mesangial cells in G0 to G1. The normal mesangium expresses the cyclin-dependent kinase inhibitor (CKI) p27 and $p27^{-/-}$ mutant mice with glomerulonephritis show higher levels of mesangial cell proliferation and matrix deposition. The mechanism of PDGF-stimulated mesangial cell proliferation is apparently through the down-regulation of p27. Together, cell cycle quiescence in mesangial cells is regulated by CKIs, p27. A study showed that activation of T-type calcium channels in smooth muscle cells promoted cell cycle progression in mesangial cells. (2)

Mesangial activation occurs though receptor-mediated mechanism. Mesangial cell proliferation is stimulated by various cytokines and growth factors, including interleukins (ILs), PDGF, and fibroblast growth factor (FGF). In addition, Fc fragments of IgG and IgA binds the receptor in mesangium and stimulate the cells. For example, PDGF binds to a tyrosine kinase receptor, which activates a number of downstream effectors, including the Ras/MAPK

Figure 29-3

Changes of filtration barrier in glomerulonephritis by EM. (a) Lytic change in GBM is accompanied with endothelial swelling with loss of fenestra on the background of inflammatory cells in the capillary. pathways, to activate various transcription factors (c-fos, c-myc, c-jun) and proto-oncogenes. Activated mesangial cells synthesize cytokines and growth factors similar to those produced by inflammatory cells, as well as various vasoactive substances, such as angiotensin, endothelin, and vasopressin. As soluble cytokines and growth factors act in autocrine, paracrine, and juxtacrine manners, mesangial inflammatory cells effectively activate resident cells, and both cell types accelerate cell proliferation and matrix production In situ. During active glomerulonephritis with mesangial proliferation, mesangial cells frequently express α-smooth muscle actin (α-SMA), desmin, calponin, and matrix-binding integrin receptors. This may not only be an example of phenotypic changes in mesangial cells reflecting cell activation, but may also represent involvement in further glomerular injury. Mesangial proliferation is recognized as a forerunner of glomerulosclerosis, and several In vitro experiments have revealed that mesangial cells synthesize matrix components in response to various inflammatory cytokines and growth factors. Hyperplastic mesangial cells reduce cell numbers by apoptosis mediated via a variety of signaling mechanisms.

Podocytes

Podocytes have many intrinsic properties sustained by actin cytoskeleton and some unique molecules that participate in the glomerular pathophysiology. Podocytes are located outside of glomerular capillaries and do not affect directly the bloodstream; instead, they face the primary ultrafiltrate, which contains various biochemical substances. Podocytes are an important component of the filtration barrier, in that they have slit membranes and

synthesize GBM components. Podocytes are highly specialized post-mitotic cells that are derived from the metanephric mesenchyme. Indeed, podocytes have a negligible capacity to proliferate, in that they undergo nuclear division but cytokinesis is not evident In vivo. Up-regulation of the p27 and p57 is closely associated with the podocyte differentiation phenotype at the capillary loop stage. Metanephric organ cultures of mice that lack p27 and p57 have revealed enlarged glomeruli, with increased podocyte numbers, and the expression of WT1 and synaptopodin, indicating that cell cycle inhibitor per se control podocyte number, but not cell differentiation in podocytes. Actin dynamics in podocytes has been intensively investigated and its role for cell integrity and function emerged. Podocytes are rich in actin filaments, and the cytoskeletons of their intermediate filaments are linked to foot process maintenance and slit membrane function. Several podocyte markers, such as WT1, CALLA, CD10, synaptopodin, podocalyxin, podoplanin and nestin have been identified. The slit membrane-related molecules nephrin and podocin are also sometimes used as specific markers. In addition, the podocyte is a major source of growth factors, such as VEGF, TGF-β and CTGF. Podocyte also expresses angiotensin II type 1 receptor which mediates local renin-angiotensin system for podocyte function. Podocyte injury is the base of proteinuria and podocyte loss from GBM (podocytopenia) may leads to glomerulosclerosis.

Immunologic mechanisms including GBM deposition, complement activation, and inflammatory mediators involve podocyte damage, and alteration of podocyte molecules results in the proteinuria and sclerosis. Podocyte injury is visible by morphology. Electron microscopy reveals cytoplasmic vacuolation, pseudocyst formation, foot process effacement with actin accumulation and detachment. In addition, phenotypic changes, namely, expression of desmin also represents podocyte injury in the rodents. These changes are induced not only by hemodynamic effects, but also by immune-mediated properties. Membranous glomerulonephritis is an example of immune-mediated podocyte injury, which results from complement activation. The antigen responsible for experimental membranous glomerulonephritis (Heyman nephritis) is the podocyte membrane protein megalin. Similarly, the recently identified neural endopeptidase (NEP), which is located in podocytes, is potentially an intrinsic antigen that forms In situ the immune complexes that cause membranous glomerulonephritis in humans (3). Podocytes express B7-1, which is a costimulatory molecule for T cells that is up-regulated in injured podocytes and causes dysregulation of the actin cytoskeleton, leading to proteinuria (4).

Endothelial Cells

The glomerular endothelial cell is the only intrinsic glomerular cell type that directly faces the circulation. These endothelial cells are different from those in other organs because of their extraordinary flatness and highly

Figure 29-5

Cell cycle cascade and its changes in the glomerular diseases. (a). Cell cycle progression is processed by four phases, G1, S, G2 and M. Cell cycle is controlled phase-corresponding molecules and check points. Cell cycle exit in G1 phase results in cell hypertrophy or apoptosis and exit in G2, (b) cellular response in mesangial cells and podocytes to injury is associated with the changes in cyclin A/CDK2 and p21 family (p21, p27 and p57). fenestrated features, allowing effective filtration. The fenestration (70–100 nm in size) is maintained by vascular endothelial growth factor A (VEGF-A), which is derived from the podocytes. The endothelial cell surface layer provides a negatively charged mesh of polysaccharide moieties of glycoproteins, glycosaminoglycans (heparan sulfate, sialic acid, chondroitin sulfate, hyaluronan) which determine vascular rheology and are probably involved in permselectivity. The charge and various adhesion molecules on the cell surface permit interactions between endothelial cells and blood-borne factors, including leukocytes, platelets, the third component of complement, antigens, and immune complexes (*Table 29-1*, *Fig. 29-6*). Endothelial cells physiologically synthesize several coagulation proteins, growth factors, extracellular matrix components, and various substances, including nitric oxide, prostaglandins, and endothelin, to maintain cell integrity and the vascular environment. Angiotensin converting enzyme (ACE) and endothelin converting enzyme participate in the local formation of bioactive angiotensin II and mature endothelin, respectively.

Endothelial cells are involved in immune-mediated glomerular injury by many aspects, including characteristic cell surface which is a feasible target of inflammatory reaction, expression of MHC proteins, and changes of variety of bioactive/physiologic substances.

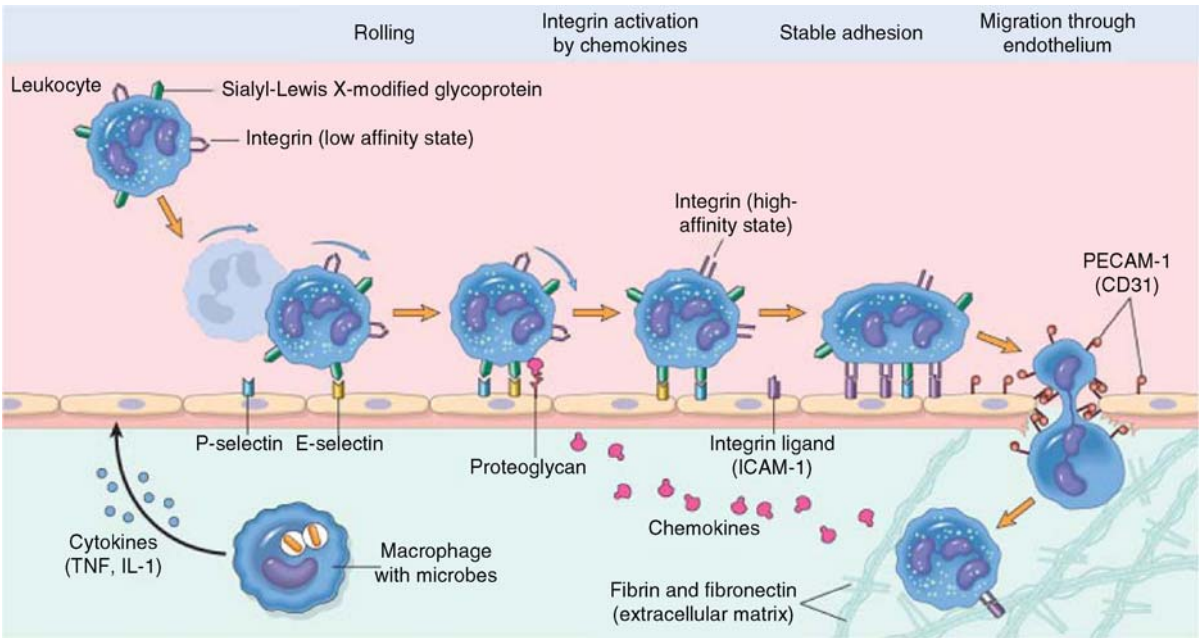
Endothelial cell proliferation, typically observed in endocapillary proliferative glomerulonephritis and preeclampsia (also known as endotheliosis) is considered as post-injury regenerative responses. Since endothelial cells actively regenerate and cell loss is replaced either by neighboring cells or bone marrow-derived cells, endothelial cell injury may be usually reversible. Endothelial cell injury is also evidenced by fibrin deposition, as seen in thrombotic microangiopathy. An additional feature of endothelial injury is the double contour of the GBM, as typically seen in transplant glomerulopathy. The mechanism of this humoral-mediated rejection is unclear, but MHC class II antigens on the endothelial surface interact with anti-donor antigens and form an In situ immune complex that persistently activates or injures endothelial cells, resulting in matrix production and subendothelial widening. These features have also been noted in MPGN, in which persistent complement activation is the trigger for endothelial cell injury.

Parietal Epithelial Cells (PECs)

Parietal cells, also known as Bowman's epithelium, are located in the continuous epithelial lining between the podocytes and proximal tubular cells. PECs and podocytes share a common phenotype during glomerular differentiation until the S-shaped body stage. Although PECs seem to play a role in glomerular injury, little is known about their biologic and physiologic properties. PECs express receptors for PDGF and FGF, and their ligands derived from inflammatory or intrinsic cells can stimulate cell proliferation and matrix synthesis. PECs are the major constituent of the cellular crescent, which expresses connective tissue growth factor (CTGF) mRNA, suggesting a growth factor-mediated mechanism for glomerular scar formation. An In vitro study revealed that FGF-2 stimulated PECs proliferation and PDGF stimulated matrix production in PECs in culture. In addition, tissue factor or cross-linked fibrin stimulates proliferation in PECs In vitro. The experimental model of crescentic glomerulonephritis has shown that PECs undergo an epithelial mesenchymal transition, which is involved in scar formation in glomerular crescents (5) PEC proliferation has also been

Figure 29-6

Endothelial cell inflammatory cell interaction and migration. The complex process of leukocyte migration through blood vessels is shown. The leukocyte first roll, then become activated and adhere to endothelium, then transmigrate across the endothelium, pierce the basement membrane, and migrate towards chemoattractants emanating from the source of injury. Different molecules, namely chemokines and adhesion molecules, play pivotal roles for stepwise processes of this inflammatory action. Similar mechanism may work in the glomerular injury. (The figure was published in Kumar et al. Robbins Basic Pathology, 8 edn. 2007, pp. 36, Copyright Elsevier.)



demonstrated in non-immune-mediated glomerulonephritis, particularly in focal segmental glomerulosclerosis and other immune-/non-immune-mediated glomerulosclerosis conditions. Cell cycle stability in PECs is controlled by p21, and mice with glomerulonephritis that lack p21 exhibit PEC hyperplasia, as shown by genetic tagging experiments in nephrin-Cre mice. In addition, a recent investigation has proposed the multipotency of PEC differentiation (6). Cell proliferation, matrices production and distortion of functional architecture in PECs involve in the glomeruloeclerosis by immune or non-immune mechanisms.

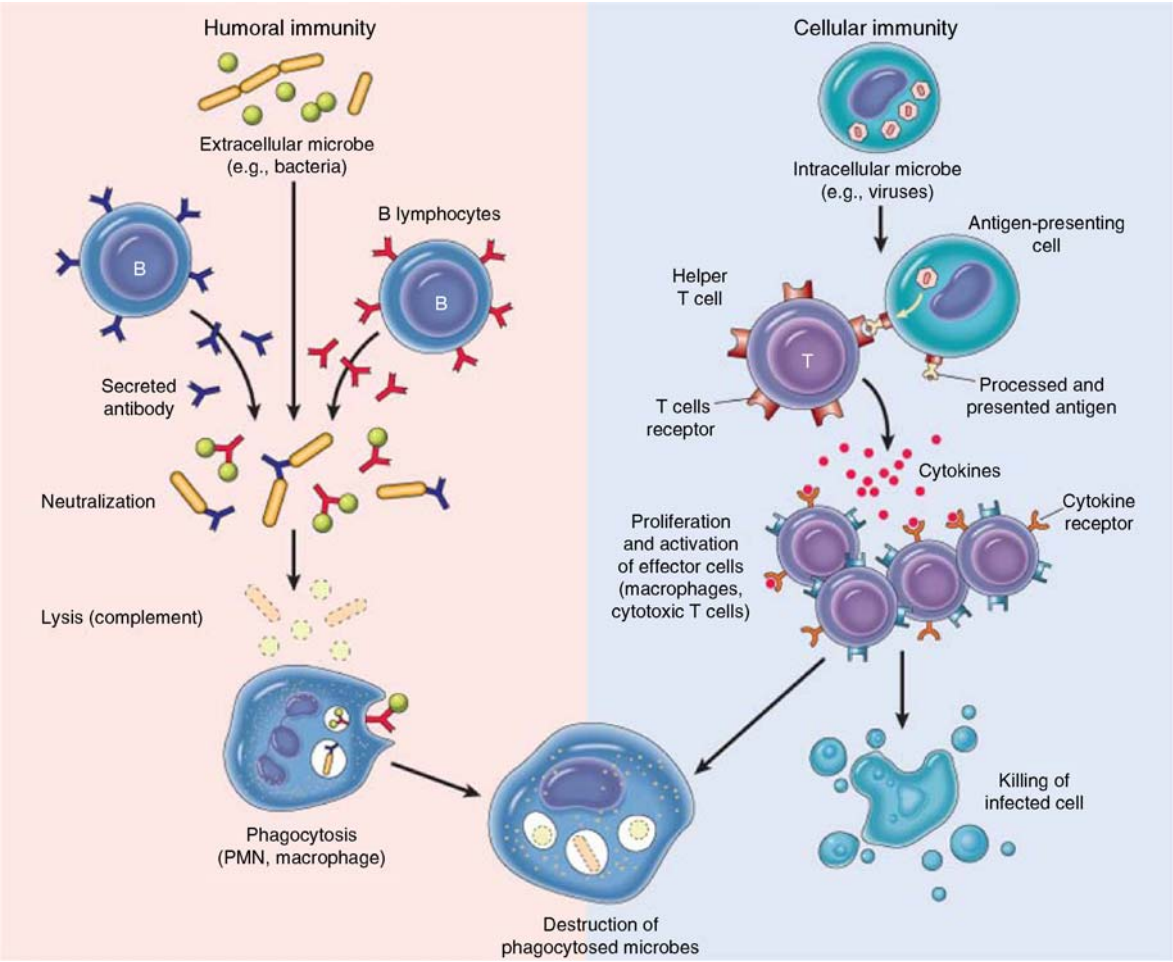
Immune System and Animal Models

Innate and adaptive immune systems are the pathogenic background of immune-mediated glomerular injury. Although molecular and cellular mechanism of immune system is substantially complex, it may be convenient to follow the mechanism of glomerular injury by two steps, initiation and promotion. Lymphocytes mainly drive an initiation and neutrophils and monocyte/macrophages largely participate in promotion as secondary mediators.

Lymphocyte mediated injury is processed by antibody-mediated (B cells driven) or cell-mediated (T cells driven) mechanisms and they usually interact and synergistically involved in the tissue damage (*Fig. 29-7*). B cell system promotes production and In situ deposition of antibodies (majority forms antigen-antibody complexes) in the glomerulus. This initiation induces the secondary inflammatory mediators, including cytokines and chemical mediators, derived from activated leukocytes. T cell mediated glomerular injury may include rather wide ranged processes, since T cell regulates B cell system. However when we concern about T cell-dependent glomerular injury as a narrow meaning, it is less common. One example of this mechanism is cytotoxic action of T cells which may damage the intrinsic glomerular cells or alter glomerular filtration barrier, causing proteinuria. This complex immune system profiled by Th1/Th2 subsets may determine the type of glomerular injury.

Figure 29-7

Antibody-mediated immunity and cell mediated immunity. In antibody-mediated immunity, B lymphocytes secrete antibodies that eliminate extracellular microbes or antigens. In cell-mediated immunity, T lymphocytes injure intrinsic cells via activation of macrophages to destroy phagocytosed microbes or kill infected cells. Cytotoxic T cells may directly damage intrinsic cells. (The figure was published in Kumar et al. Robbins Basic Pathology, 8 edn. 2007, pp. 109, Copyright Elsevier.)



There are varieties of experimental models of immune-mediated glomerulonephritis that have been used to analyze the nephritogenic mechanisms. Nephrotoxic serum nephritis, a classical model initially established by Masugi in 1933, is induced by injection of duck anti-rabbit kidney anti-sera to rabbits resulting in crescentic glomerulonephritis. Anti-GBM antibody nephritis is induced by administration of anti-GBM IgG showing proliferative (usually crescentic) glomerulonephritis. Both are the basic and widely examined models of glomerulonephritis. There are two phases of immune reaction in these models, heterologus and autologus phase. Former is provoked by the binding of injected allo-antibody to GBM, whereas the latter is caused by host-produced autoantibody binds to the GBM. Heterologus phase alone cause mild and self limiting nephritis, but prolongation or acceleration of autologus phase by pre-immunization with IgG of immunized animals provokes severe glomerulonephritis. Autoantibody may be important to induce severer nephritis. Several mice models of lupus, including (NZBXNZW) F1, BXSB, and MRL/lpr mice, reveal spontaneous and proliferative glomerulonephritis with immune complex deposition, similar to the human lupus nephritis. Heyman nephritis is a model of

membranous glomerulonephritis and responsible antigen is identified as megalin. In this model, complement activation plays significant roles for proteinuria and proliferative nephritis is not usually seen. All these models are immune complex-mediated glomerulonephritis as revealed by immunoglobulin or complement deposition, regardless of whether circulating or In situ immune complex formation. On the contrary, widely used model of anti-Thy1 nephritis reveals mesangial proliferative glomerulonephritis but pauci-immune. In this model, antibody against thymus immediately binds to receptor on mesangial cells resulting cell lysis (mesangiolysis) associated with transient activation of complements, however immune complex and complements are lost immediately. Mesangial proliferation in this model may reflect repair process from mesangiolysis to reconstruct glomerular architecture mimicking glomerulogenesis, rather than the result of mitogenic stimuli of inflammatory mediators (unlike immune-mediated glomerulonephritis). Since majority of experimental works using these models investigated an acute phase of the diseases, it is necessary to understand the pathogenetic difference in each model and recognize the limitation of the results to translate human chronic glomeurlonephritis.

Antibody-Mediated Immunity

Antibody (humoral) -mediated immune glomerular injury is initiated by antigen-antibody complex formation within the glomerulus. B-cell activation by interleukins (IL-4, IL-5), which are synthesized by antigen-specific $CD4^+$ T cells, is a prerequisite for antigen-specific antibody production. Many glomerular lesions result from the glomerular binding of antibodies. Immune-mediated glomerular injury is seen in a wide spectrum of glomerular diseases, with various histologic patterns, and the clinical outcomes may be related to the nature of the antigen(s) and their glomerular binding site(s).

Circulating Immune Complexes

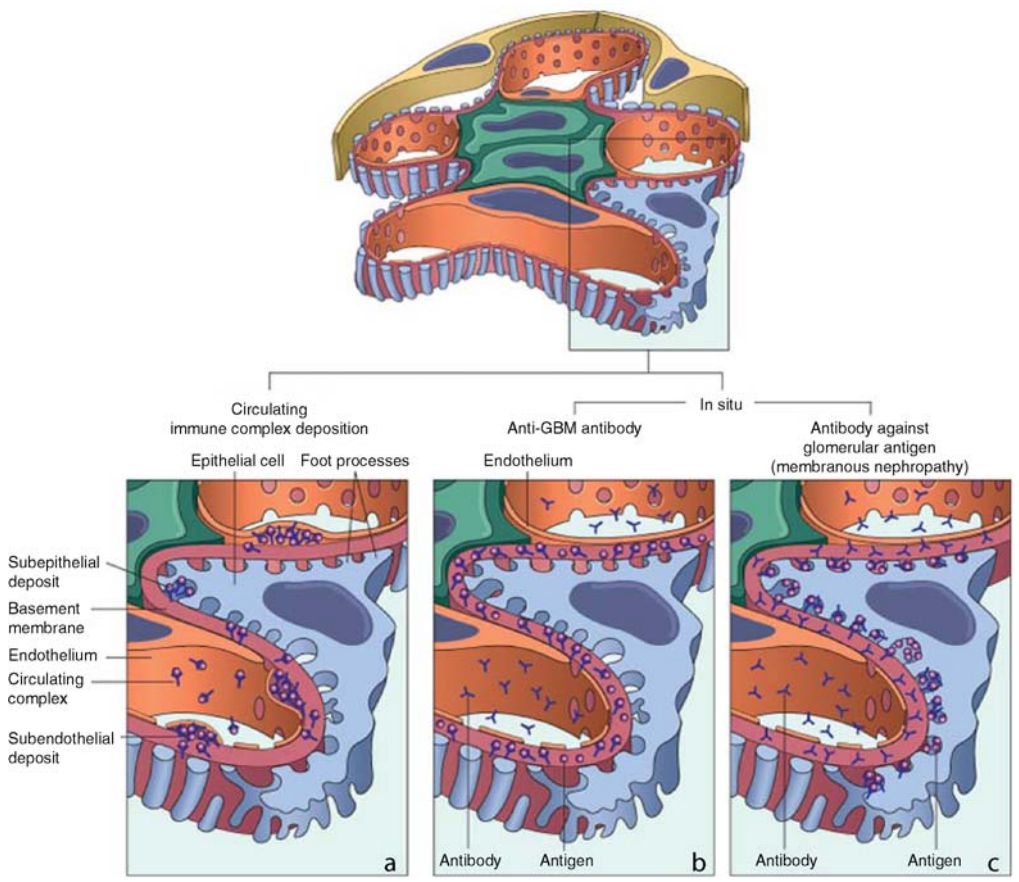
If the immune system produces autoantibodies, immune complexes can be formed. Circulating immune complex-mediated glomerulonephritis is primarily seen as a type III hypersensitivity reaction (*Fig. 29-8*). As known in the serum sickness disease model, high amount of foreign serum injection resulted in the appearance of immune complex in the circulation which accumulates in the glomerulus and induces acute glomerulonephritis and vasculitis. Regardless of whether they are endogenous or exogenous, the antigens are not glomerular in origin. Exogenous antigens can be bacterial (*Streptococcus* and *Staphylococcus spp.*), viral (hepatitis B), parasitic (*Plasmodium spp.*) or spirochete (*Treponema spp.*) in origin. In contrast, DNA and histones are endogenous antigens that are typically seen in lupus nephritis.

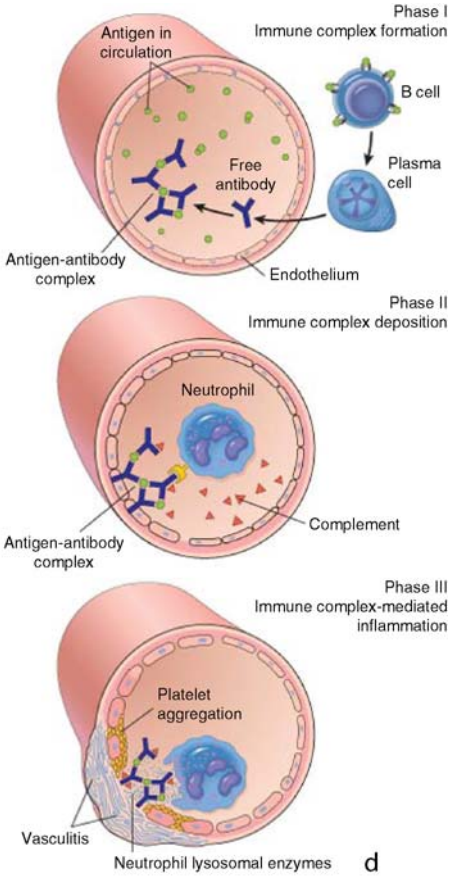
The highly permeabilized glomerular filter is susceptible to passive trapping of preformed immune complexes from the circulation. The highly negative charge of the capillary wall also attracts circulating macromolecules with positive charges.

The biological activities of circulating immune complexes depend largely on the biochemical and quantitative features of the circulating antigens. The size of an immune complex is determined by the ratio of antigen to antibody. When the antibody is present in excess, cross-linking of immune complexes occurs and the complex becomes large. The primary site of such a large immune deposition is either the subendothelium or the mesangium and efficiently activate the complement cascade by binding to Fc receptors (the Arthus reaction), thereby further stimulating the inflammatory processes. In contrast, when an antigen bears few epitopes or when there is an excess of antigen relative to antibody, the immune complexes formed tend to be smaller in size and soluble. These small immune complexes may be deposited within the GBM or subepithelial areas, but they often fail to induce inflammation, because the deposition and complements are isolated from circulation. When the antigen to antibody ratio nears equivalence, the immune complexes formed tend to be of maximal size and insoluble. The net charge of the complex is an additional determinant of immune complex deposition, based on the interactions with the negatively charged GBM and endothelial surface. The levels of circulating immune complexes have been shown to correlate with glomerular injury in lupus glomerulonephritis. The size and biochemical characteristics of immune complexes may change with disease activity or with therapeutic modulation. Indeed, immune complex deposition in subendothelial or mesangial cells occasionally shifts to the subepithelial cells in lupus nephritis, such as Class IV to Class V transformation. Acceleration of glomerular capillary permeability in the process of glomerulonephritis may be an alternative factor to change the site of immune deposition. Although experimental models suggest induction of glomerulonephritis by glomerular immune complex deposition, it remains unclear as to whether passive trapping of preformed immune complexes alone is sufficient to induce glomerulonephritis in humans.

Figure 29-8

Mechanism of immune deposition and inflammatory reaction in the glomerulus. (a) Circulating immune complex interaction with endothelium results in deposition in GBM, (b) in case of anti-GBM antibody glomerulonephritis (Goodpasture syndrome), fixed antigen is a component of GBM (NC1 domain of α3 (IV) chain of type IV collagen). Thus antibody binds GBM and show linear distribution, (c) in case of membranous glomerulonephritis (Heyman nephritis), antigen is podocyte component (megalin). Antigen-antibody complex is formed in situ and complex shift to accumulate at subepithelial area (d), antigen-antibody complex in the circulation deposits on the endothelial surface is an initiation of immune-mediated glomerular injury. Local activation of complement system chamoattracts inflammatory cells followed by secretion of secondary messengers which injure glomerular component. (The figure was published in Kumar et al. Robbins Basic Pathology, 8 edn. 2007, pp. 545 and 127, Copyright Elsevier.)





In situ immune complexes

In situ immune complex formation is basically the result of the combination of unbound circulating soluble antibody and antigen within the tissue. In situ tissue antigens are either fixed (components of the glomerulus) or planted (exogenous) (*Fig. 29-8*). The best example of an In situ immune complex disease is anti-GBM antibody-induced glomerulonephritis (anti-GBM antibody nephritis). In this condition, antibodies are directed against a fixed antigen of a component of the GBM, i.e., the non-collagenous domain of the α3 chain of collagen type IV. These antibodies occasionally cross-react with the lung alveolar basement membrane, and the resulting simultaneous inflammation of the kidneys and lungs represents a severe clinical phenotype, known as Goodpasture syndrome. Another example of an In situ immune complex disease is Heyman nephritis, which serves as a model of membranous glomerulonephritis in humans. Combine this model with isolated perfused kidney system provided first evidence for In situ immune complex induced glomerulonephritis (7). Auto-antigenic target in this model is 516kD protein megalin that binds receptor associated protein (RAP); a podocyte-membrane glycoprotein (8). However megalin is not expressed in humans and may not be the antigen in human membranous glomerulonephritis.

In clinical practice, various antibodies are detected in the blood, while circulating immune complexes are generally undetectable. It seems that In situ immune complex formation is the major process for immune deposition in various glomerular diseases in humans.

Cell-Mediated Immunity

Cell-mediated immunity can be summarized as the T-cell-dependent interaction of antigen-presenting cells and CD4 helper T cells through the T-cell receptor (TCR), which promotes cytokine release and stimulates the proliferation and activation of effector cells, macrophages, and $CD8^+$ cytotoxic T cells (9).

T-cell-mediated glomerular injury includes several mechanisms, such as T-cell-mediated B-cell activation, cytotoxic effects, and the direct actions of lymphokines on the glomerular filtration barrier. The first process is T-cell-driven, antibody-mediated immunity, as described above, and the latter two processes are narrowly defined, basically because of the paucity of antibody deposition In situ.

Inappropriate T-cell responses may cause hypersensitive immune reactions and provoke glomerulonephritis. In humans, T-cell infiltration is observed in the glomeruli in pauci-immune glomerular diseases, such as ANCA-related glomerulonephritis, and therapeutic interventions suppress glomerular inflammation and T-cell infiltration. Anti-GBM antibody nephritis in Wistar Kyoto rats revealed infiltration of $CD8^+$ T cells in the glomeruli and suppression of circulating $CD8^+$ T cells resulted in decreased glomerular inflammation. However in mice model of anti-GBM antibody nephritis, glomerular injury is $CD8^+$ T cell independent. These observations provide circumstantial evidence to establish the basis of a T-cell-dependent glomerular injury mechanism. Transfer of rat $CD4^+$ cell line specific for Col4α3NC1 successfully induced severe nephritis without glomerular IgG and C3 deposition, which may be the direct evidence for T cell mediated glomerular injury (10). Conversely, T-cell-mediated injury cannot be excluded, even when antibodies (reflecting a B-cell response) are present.

Regulatory T cells (Treg) suppress effector T cells through receptor-mediated mechanism and thus, failure of Treg to control T-cell activity can provoke autoimmunity. Transfer of $CD4^+$CD25 Treg inhibited murine anti-GBM antibody nephritis via T-cell and macrophage suppression, with significant reductions in the levels of INF-γ, TNF-α and TGF-β mRNA (11). This may be the mechanism of the protective roles of T reg in autoimmune-mediated glomerulonephritis. However Treg transfer to Lupus-prone mice suppressed autoantibody production but not glomerulonephritis (12).

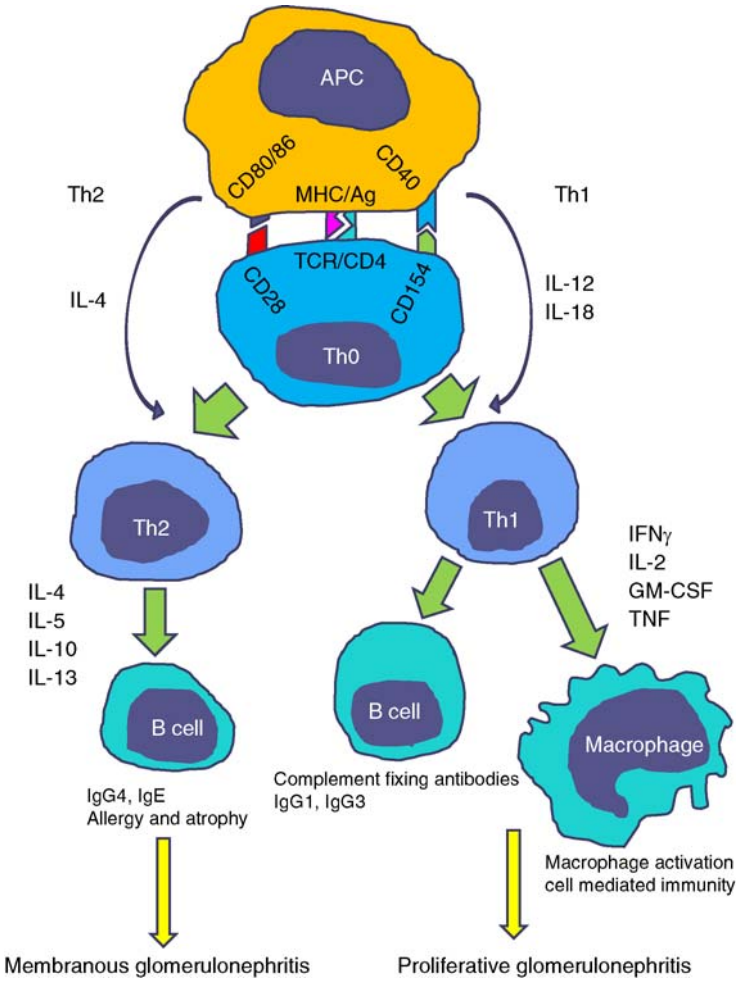
$CD4^+$ T cells can license dendritic cells to stimulate cytotoxicity in auto-reactive $CD8^+$ T cells. Dendritic cells act on uptake, transport, and processing and antigen presentation to T cells (13). Intrinsic dendritic cells in the kidney stimulate IL-10 production, which attenuates nephrotoxic serum nephritis in mice, and depletion of dendritic cells aggravates nephrotoxic serum nephritis (14). Thus, Tregs and renal dendritic cells may provide clues to renal protection in immune-mediated glomerular injury. The T-cell-mediated immune mechanisms of glomerulonephritis have been analyzed in an acute nephritis model, and the role of T cells in chronic glomerulonephritis, particularly in humans, remains largely unknown.

Th1 and Th2 Subsets

The complex immunologic network-driven immune-mediated glomerular injury involves the Th1 and Th2 subsets (*Fig. 29-9*). Although both pathways interact, the predominance of a particular subset may explain the different patterns of glomerular histology and disease activity, which are related to disease outcome (15).

Figure 29-9

Th1/Th2 subset in cytokines. Th1 and Th2 cells are subsets of primed CD4$^+$ T-helper cells, which can be distinguished based on their cytokine, chemokine, and antibody isotype profiles and which generate different immune effector responses. Antigen presenting cells (APC) interact with naïve precursors of Th0 cells by specific antigen stimulation via their α/β T-cell receptors. Th1 cells differentiate macrophages and B cells by several cytokines indicated. Th1 subset predominancy tends to resulted in proliferative glomerulonephritis. Th2 subset differentiate B cells by specific cytokines and tend to result in membranous glomerulonephritis.



Th1 and Th2 cells are subsets of primed CD4$^+$ T-helper cells, which can be distinguished based on their cytokine, chemokine, and antibody isotype profiles and which generate different immune effector responses. Both cell types differentiate from naïve precursors, "Th0" cells, following specific antigen stimulation via their α/β T-cell receptors. Antigen-presenting dendritic cells in humans are derived from monocytes or plasmacytoid cells, with a bias towards the stimulation of either INF-γ or IL-4, IL-5, and IL-10 production by naïve T cells, as demonstrated In vitro (*Table 29-2*).

Th1 development is promoted primarily by INF-γ and IL-12, and partially by IL-18, IL-27, and IL-23, indicating complex and overlapping mechanisms for Th1 immunologic activities. Th2 responses are driven by IL-4, IL-10 and INF-γ and they inhibit Th1 responses. IL-10 appears to be more active in inhibiting Th1 differentiation than in promoting Th2 responses. Differences in chemokine receptor expression between Th1 and Th2 cells also influence the activation patterns of these cells by different chemokines. CXCR3, the receptor for INF-γ-inducible chemokines, is expressed at high levels on INF-γ-producing

Table 29-2

Characteristics of T helper subsets

Characteristics	Th1 cells	Th2 cells
Inducing stimuli	IL-12, INF-γ, IL-18, IL-27, PRR signaling	IL-4
Transcription factors	STAT4, STAT 1, T-bet, NFκB	STAT6, GATA3
Cytokine produced	INF-γ, IL-2, TNF, lymphotoxin-β	IL-4, IL-5, IL-13
Chemokine receptor expression	CXCR3, CCR5, CCR1	CCR3, CCR4, CCR8
Antibody isotypes	Human: IgG1, IgG2, IgG3	IgG4, IgE
	Mouse: IgG2a, IgG2b, IgG3	IgG1, IgE
Effector response	Cell mediated immunity, macrophage activation, antibody-mediated cellular cytotoxicity	Eosinophils activation, allergy

(Modified from Scholz J, Lukacs-Kornek V, Engel DR et al. Renal dendritic cells stimulate IL-10 production and attenuate nephrotoxic nephritis. *J Am Soc Nephrol* 2008;19:527–537.)

Th1 cells and at low levels on Th2 cells. The CCR3 and CCR4 chemokine receptors are expressed by Th2 cells that produce IL-4.

The roles of Th1 and Th2 cells in glomerular injury have been studied using different strain for Th1 (mice: C57BL/6, rats: Lewis) and Th2 (mice: BALB/c, rats: Brown Norway) dominance. Induction of nephrotoxic serum nephritis in Th1-predominant C57BL/6 mice results in severe glomerular injury. Anti-GBM antibody nephritis in Lewis (Th1) and Brown Norway (Th2) rats resulted in more severe glomerulonephritis, with monocytic and T-cell influx and Th1-profile cytokine production, in Lewis rats than in Brown Norway rats. Mice deficient in Th2 cytokines show more pronounced crescentic glomerulonephritis, while the administration of Th2 cytokines ameliorates this disease. Mercuric chloride-induced autoimmune glomerulonephritis in congenic strains of Brown Norway rats resulted in a membranous-like form of glomerulonephritis. These experiments indicate that Th1 predominance is related to crescentic glomerulonephritis, and that Th2 predominance tends to be involved in membranous glomerulonephritis.

In human anti-GBM antibody nephritis, there is an INF-γ-predominant, antigen-specific effector cell response in the active stage and IL-10 predominance in remission. In humans, $CD4^+$ cells and macrophages are present in the cellular crescents of crescentic glomerulonephritis. In ANCA-related glomerulonephritis, a T-cell response with Th1 predominance is involved. In the renal tissues of ANCA-related glomerulonephritis, the level of INF-γ mRNA is high and the level of IL-4 mRNA is low. Peripheral blood T cells show a high INF-γ:IL-4 ratio in patients with ANCA-associated glomerulonephritis, as compared with patients with non-proliferative glomerulonephritis. Corticosteroids diminish this ratio, which suggests that Th1 predominance is linked to ANCA-associated glomerulonephritis in humans.

For full activation of $CD4^+$ cells, engagement of T cell receptor with the antigenic peptide-MHC molecule complex in antigen presenting cells need a secondary costimulatory signals for full activation. T cell costimulatory molecules include CD28-B7 family/CD80 (B7-1) + CD86 (B7-2), and CD40 (TNF-receptor on B cells)/CD154 (ligand of CD40 on T cells) that determines Th1 and Th2 polarity. Protection of anti-GBM nephritis in CD28 deficient mice is due to inhibition of autologous antibody production (16). Selective blockade of B7-1 prevented the development of crescentic glomerulonephritis in anti-GBM nephritis in Wistar Kyoto (WKY) rats (17). In the same nephritis in mice, administration of either CD80 or CD86 revealed no effect on glomerulonephritis, however administration of anti-CD80/CD86 antibody attenuated glomerulonephritis (18). Anti-GBM antibody nephritis in CD80 (B7-1) deficient mice reveals attenuation of crescentic glomerulonephritis in concert with reduction of glomerular $CD4^+$ cells accumulation. By contrast, same nephritis in CD86 (B7-2) deficient mice show disease exacerbation (19). Thus CD80 is pathogenic in crescentic glomerulonephritis by enhancing survival and proliferation of $CD4^+$ cells, whereas CD86 is protective by enhancing Th2 and attenuating Th1 responses. Inducible costimulatory molecule (ICOS) and ICOS ligand (ICOSL) are a receptor-ligand pair that belongs to the CD28/B7 family. Administration of antibody against inducible costimulatory molecule ligand in mice with anti-GBM nephritis increased glomerular accumulation of T cells and macrophages without affecting systemic

immune response. This suggests that ICOSL plays protective roles during induction of anti-GBM nephritis by locally reducing accumulation of T cells and macrophages (20). Blockade of CD154-CD40 costimulatory signals in anti-GBM antibody nephritis in WKY rats prevented glomerulonephritis (21). In addition, antiGBM nephritis in CD40 chimeric mice (CD40 is absent in glomeruli but intact in bone marrow) revealed suppression of glomerulonephritis accompanied by reduced level of MCP-1, IL-10 mRNA and T cell and macrophages influx. This indicates that CD40 expression in intrinsic glomerular cells promote Th1 effector cell response in glomerulonephritis (22).

Inflammatory Cells

Leukocytes

Leukocytes are bone marrow-derived cells that include granulocytes, lymphocytes, and monocytes/macrophages. Granulocytes include neutrophils, eosinophils, and basophils. Neutrophils (polymorphonuclear cells, PMNs) and macrophages play central roles in the acute inflammation process. Neutrophils and macrophages have common effects in terms of tissue injury, but macrophages more actively involved in glomerular injury by their immunologic functions. Usually, PMNs predominate in the acute phase of glomerulonephritis, e.g., in acute post streptococcal glomerulonephritis and ANCA-related glomerulonephritis. Macrophages appear in acute and chronic glomerulonephritis and both cell types are sometimes co-presented in the two phases of glomerulonephritis, particularly acute phase on chronic glomerulonephritis.

In the variety of pathogenesis of glomerulonephritis, leukocytes are involved in the loss of immune tolerance, T cell directed adaptive immune responses, cellular effectors inducing injury in delayed type hypersensitivity-like reactions, and macrophage/neutrophil recruitment via the deposition of circulating or In situ immune complexes through receptor-mediated fashion (23). Leukocytes express Fc-γ receptor on cell surface and it binds Fc portion of IgG and lack of Fc-γ R protects immune complex mediated glomerulonephritis (24). In addition, ANCA have been postulated to activate neutrophils, leading to glomerular capillaritis.

Polymorphonuclear Cells

PMNs are implicated in glomerular injury owing to their numerous bioactive/toxic products. PMNs are chemoattracted by anaphylatoxin (C5a and C3a), CXC chemokines, the immune adherence of complement receptors, and Fc receptor-dependent binding to antibodies. The corresponding receptors include FcR for IgG, CR1, CR2, and CR3 for complement fragments, and C1q for the collectins. Locally activated PMNs express sialyl-Lewis X-modified proteins and interact with endothelial cells, through selectin or integrin ligands on the endothelial surface. Various cytokines stimulate endothelial cells to express these adhesion molecules (*Table 29-1*, *Fig. 29-6*). Occasionally, PMNs on endothelial cells migrate to the mesangium and stimulate cells there, through bioactive or toxic products. Among the PMN-derived substances, lysosomal enzymes and reactive oxygen species (ROS) are the most harmful for glomerulus. Lysosomal enzymes include metalloproteases and other proteases, which along with cathepsin G exert proteolytic activities and damage endothelial cells or promote lysis of the GBM and mesangium. Microbes, cytokines, immune complexes, and various inflammatory stimuli promote ROS synthesis in PMNs through the NADPH oxidase pathway. ROS ordinarily function to destroy phagocytosed microbes and bring about cell death. Low-level secretion of ROS accelerates the inflammatory cascade by up-regulating the expression of cytokines, chemokines, and adhesion molecules. At high levels, ROS damage endothelial cells, activating the coagulation cascade and increasing glomerular permeability, with consequent breakdown of the ECM, which links mesangiolysis and GBM changes, and injuring the intrinsic cells. Activation of antioxidant mechanisms that involve catalase, superoxide dismutase, and glutathione peroxidase ordinarily protects tissues from oxidant stress. The role of ROS in glomerular injury is separately discussed.

A good example of neutrophil-mediated glomerular injury is ANCA-related glomerulonephritis. ANCA activates cytokine-primed neutrophils and monocytes through Fab'2 binding and Fc receptor engagement In vitro (25). These PMNs adhere to endothelial cells and release ROS, proteolytic enzymes, and inflammatory cytokines, which promote cytotoxic tissue damage.

Intravenous injection of mouse antibodies or splenocytes specific for mouse MPO alone induces necrotizing crescentic glomerulonephritis in $Rag2^{-}$ mice (lack functioning B cells and T cells). In this model, it appeared that PMNs infiltration was conspicuously associated with glomerular necrosis and crescent formation with macrophages, whereas lymphocytes were not prominent. Mice depleted of circulating PMNs with rat monoclonal anti-neutrophil antibody (NIMP-R14) were completely protected from anti-MPO IgG-induced necrotizing crescentic

glomerulonephritis (26). Local pretreatment of cremaster muscle with TNF-α followed by systemic administration of anti-MPO IgG in wild type mice leads to enhancement of leukocyte-endothelial cell interaction in the cremasteric microvessels, whereas this effect were not seen in Fc receptor γ chain deficient mice. In addition, co-administration of anti-MPO antibody with anti-CD18 antibody (CD18; integrin β2) has no effect on the local leukocyte-endothelial cell interaction (27). This indicates Fc-γ receptor and integrin β2 are important for processing MPO-induced small vessel vasculitis. Immunization of MPO in mice with bone marrow transplantation of MPO-positive cells to MPO deficient recipient (chimera) developed crescentic glomerulonephritis, whereas chimeric mice of MPO-negative bone marrow cells into wild type mice did not, (28) indicating that bone marrow cells are the necessary target to mediate MPO antibody induced crescentic glomerulonephritis. The local inflammation induced by cytokines (e.g., TNF-α) primed PMNs and anti-MPO antibody via FcR-γ effectively promotes cytotoxic endothelial cell damage and activate coagulation cascade. This occasionally results in fibrinoid necrosis followed by breakdown of GBM and subsequent crescentic formation.

Monocytes/Macrophages

Macrophages are derived from circulating blood monocytes. In normal rat mesangial areas, tissue-resident macrophages are occasionally present, but they are uncommitted. When inflammation occurs, monocyte-derived macrophages are recruited, programmed, and activated, largely by INF-γ. Examination of anti-Thy1 nephritis reveals that infiltration per se is insufficient to promote macrophage programming, but this is completed shortly after localization to the appropriate local microenvironment.

Human renal biopsies and experimental models of glomerulonephritis reveal glomerular macrophage accumulations, which may be indicative of disease activity or severity. IgA glomerulonephritis in children represents relatively acute inflammation, and the mesangial influx of macrophages leads to mesangial proliferation, as demonstrated by electron microscopy and immunohistochemistry (*Fig. 29-10*). Local activation of macrophages occurs in various glomerular diseases, including non-immune-mediated conditions, such as diabetic glomerulosclerosis. Macrophages are blood-borne, and it has been suggested that they proliferate In situ. Macrophages may change phenotype to one that resembles fibroblasts, and some intrinsic glomerular cells can acquire macrophage-like phenotypes.

Macrophages produce a wide range of potentially cytotoxic products, including pro-inflammatory cytokines and chemokines, proteolytic enzymes, ROS, eicosanoids, and growth factors (*Table 29-3*, *Fig. 29-11*). Experiments on the suppression or depletion of macrophages in acute and chronic glomerulonephritis models have demonstrated reduced glomerular injury (29, 30). In crescentic glomerulonephritis in rats, liposome-MDP (dichrolomethylene diphosphonate) attenuated glomerular macrophage influx accompanied by suppression of CD8 and expression of adhesion molecule (31). These findings circumferentially support the role of macrophages in the glomerulonephritis. In this context adoptive transfer of macrophages in leukopenic rats with

Figure 29-10

Macrophage infiltration in IgA glomerulonephritis. (a) Immunohistochemical detection of macrophages by CD68 in IgA glomerulonephritis. Note many immunolabelled cells (brown) locate predominantly in the mesangial proliferation and less in the capillary. (PAS stain), (b) EM reveals monocytes/macrophages in the mesangium and in the capillary (*allowhead*).

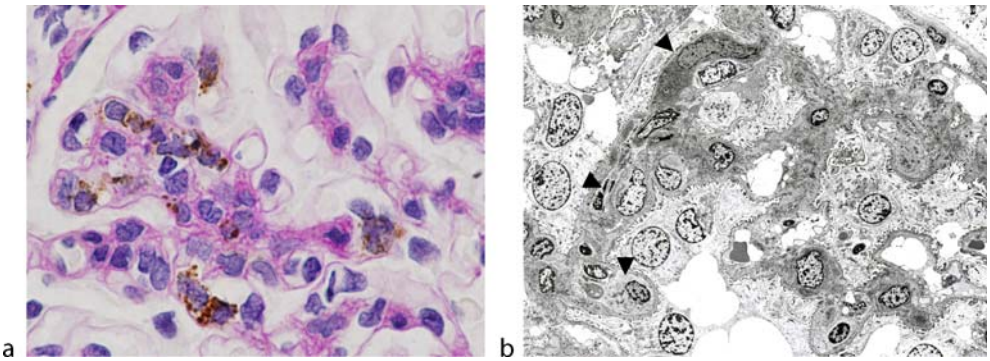


Table 29-3

Macrophage activation status

Status	Alteration	Product
Classically activated (M1)	Up-regulation	iNOS, IL-1β, TNF-α, IL-6, HMGB1, IL-8, MCP-1, MHC class I
Alternatively activated (M2)	Up-regulation	Mannose receptor, MHC class II, arginase, FIZZ1/Ym1, IL-ra
	Down-regulation	iNOS, TNF-α, IL-6
IL10 activated	Up-regulation	Soluble TNF receptors, IL1ra
	Down-regulation	IL-b, TNF-α, IL-12, IL-6, IL-8, iNOS, MHC class I
Type II activated	Up-regulation	IL-10, TNF-α, IL-6, MHC class I
	Down-regulation	IL-12
Uptake of apoptotic cells	Up-regulation	TGF-b, PGE2
	Down-regulation	TNF-α, IL-8, MCP1
Steroid treated	Up-regulation	IL-10, uptake of apoptotic cells
	Down-regulation	IL-12, TNF-α, IL1-β, IL-6

HMGB1, high mobility group B1; IL-1ra, IL-1 receptor antagonist

anti-GBM nephritis revealed proteinuria and glomerular cell proliferation and indicates direct evidence for macrophage to induce glomerulonephritis (32). Given these results, it has long been suggested that the scale of macrophage influx promotes glomerular injury. However, it has recently become clear that it is the functional properties, rather than the total number, of macrophages that determine the severity of inflammation (30). In vitro studies have led to the hypothesis of functional heterogeneity in macrophages. Polarized macrophages can be subdivided into several phenotypes, particularly classically activated (M1) and alternatively activated (M2) macrophages (33, 34). The difference in activators determines the heterogeneous phenotype (*Table 29-4*, *Fig. 29-12*). Innate activation is promoted by Toll-like receptor (TLR) ligands, which induce the production of pro-inflammatory cytokines, NO, and ROS. INF-γ TNF-α and/or LPS primes macrophages to convert classical activation (M1 polarization) and leads to increased production of pro-inflammatory cytokines, iNOS, and ROS, as well as the up-regulation of MHC class II molecule expression and co-stimulatory CD86 molecules, thereby promoting antigen presentation. In contrast, IL-4- or IL-13-primed macrophages undergo alternative activation (M2 polarization), which is associated with increases in endocytosis, arginase, anti-inflammatory cytokines, and the synthesis of extracellular matrix, thereby promoting angiogenesis. M2 polarization also leads to decreased iNOS and NO production, and is involved in anti-inflammatory effects, cell growth, and tissue repair. Although the molecular regulation of such macrophage heterogeneity has been largely demonstrated In vitro, transfer experiments with programmed macrophages (M1 or M2) in adriamycin nephropathy in SCID mice (lack endogenous T or B cells) have provided evidence that M1 macrophage infusion aggravates the disease, whereas M2 macrophages reduce histologic and functional damage (35). This phenotypic heterogeneity of macrophages may be switched during the course of chronic glomerulonephritis, depending on the background pathophysiology.

Macrophage migration inhibition factor (MIF) is a kind of pro-inflammatory cytokines to induce cytokines, chemokins and adhesion molecules in the inflammatory environment. Neutralizing antibody for MIF or MIF deficient mice resulted in prevention of immune mediated glomerulonephritis (36, 37). Activator protein (AP-1) transcription factor JUND is a major determinant of macrophage activity and associated with susceptibility to glomerulonephritis (38).

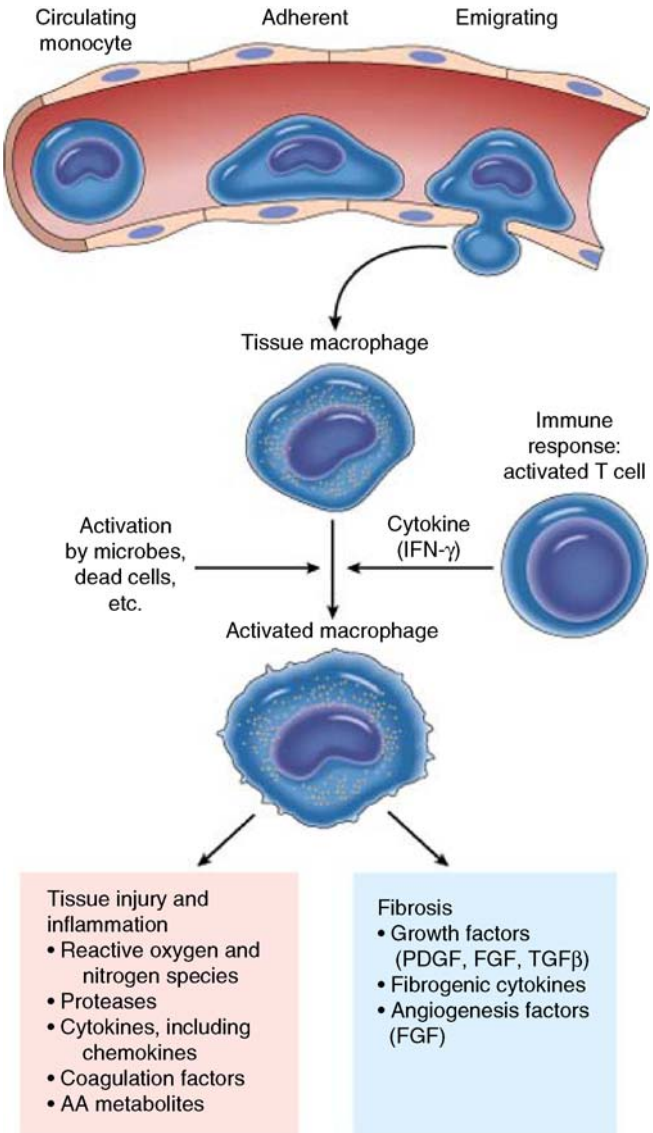
During the process of glomerular injury, macrophages take up apoptotic cells, most of which are infiltrated inflammatory cells. This uptake causes the macrophages to exert anti-inflammatory effects, through increased expression of TGF-β and prostaglandin E2 (PGE2) and decreased production of IL-8, TNF-α, and IL-1β. Suppression of T-cell proliferative responses also results from the anti-inflammatory effects of macrophages that have taken up apoptotic cells.

Mast Cells

Mast cells are bone marrow-derived cells that play significant roles in innate and adaptive immune responses. Mast

Figure 29-11

Activation of macrophages and production of various cytokines. Circulation monocytes transmigrate to the site of inflammation and T cell derived cytokines (INF-γ) stimulate activation in monocytes/macrophage and produce many soluble factors for tissue cell injury/tissue fibrosis. In glomerulus, macrophages are able to migrate into mesangium, subendothelial space or urinary space. (The figure was published in Kumar et al. Robbins Basic Pathology, 8 edn. 2007, p55, Copyright Elsevier.)



cells secrete various inflammatory mediators, including chemical vasomotor mediators, cytokines, growth factors, and eicosanoids. These substances attract inflammatory cells and are involved in mediating tissue remodeling. Mast cell detection in tissues is typically performed by staining with toluidine blue, Alcian blue, and safranin, all of which enable the visualization of cell granules. Immunohistochemistry to detect enzymes specific for mast cells, such as tryptase and chymase, can be used to subdivide mast cells into MCT (containing tryptase) and MCTC (containing tryptase plus chymase) cells. This enzyme visualization method reveals many more mast cells than classic

Table 29-4

Macrophage polarized activation

Phenotypes	Classical (M1 polalization)	Alternative (M2 polalization)

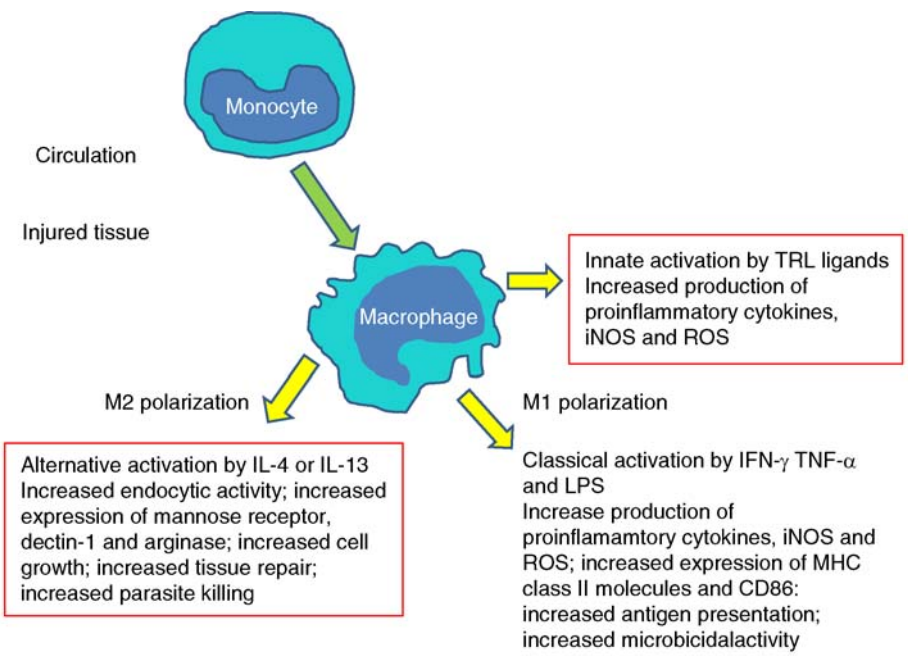
(Modified from Montaviani et al., Eur J Immunol 2007; 37:14–16)

Figure 29-12

Macrophage heterogeneity during inflammation. Monocytes attracted to the injured tissue are thought to be able to acquire distinct phenotypes and physiological functions. Largely there are two major phenotypes in macrophages, M1 and M2. In M1 polarization, macrophages are stimulated with INF-γ and reveal high microbicidal activity and produce ROS, and iNOS for proinflammatory action. By contrast M2 polarization is promoted by IL-4, IL-10, IL-13 or TGF-β and it acted on the tissue repair and parasite killing. However, these hypothesis has been drawn by the in vitro experiments and still remain undetermined in vivo. (Modified figures from reference Gordon et al (33).)



toluidine blue staining. Mast cells are present in human glomerulonephritis, primarily in the interstitium, and are probably involved in fibrosis. The role of mast cells in glomerulonephritis has been examined in anti-GBM antibody nephritis in congenitally mast cell-deficient mice (W/Wv). W/Wv mice with nephritis show a higher mortality rate and enhanced disease activity, as compared with wild-type mice (39). This condition can be rescued by mast cell reconstitution, suggesting a protective role for mast cells in immune complex-mediated glomerulonephritis.

Toll-Like Receptors (TLRs)

The recently identified TLR families provide receptor-mediated pathogen recognition and activation of the immune system. Ten human and nine murine TLR proteins related to the original Drosophila Toll gene have been identified to date. Inflammatory cytokines and chemokines are induced through the activation of TLRs by a variety of ligands (40). The biologic activities that result from TLR binding include activation of antigen-presenting cells, dendritic cell maturation, B-cell activation, and different cytokine production profiles. The responsibility of TRL in the innate and adaptive immune response may be a likely background in the immune-mediated glomerular injury. Small nuclear RNA and autoantigen for lupus activate B cells and dendritic cells via TLR-7. TLR-7 overexpression is associated with antinuclear autoantibody production and lupus-like disease in mice and backcrossing TLR-7 deficient mice with MRL lpr/lpr mice attenuated kidney and lung disease. Administration of synthetic oligodeoxynucleotides with immunoregulatory sequences (IRS) which specifically blocks TLR-7 suppressed autoimmune kidney and lung diseases (41). Endogenous or exogenous CpG-DNA activates TLR-9 and administration of CpG DNA to MRL-Fas(lpr) mice resulted in disease progression accompanied by MCP-1 and RANTES expression and leukocyte recruitment (42). In ddY mice of spontaneous IgA glomerulonephritis, genome-wide scan revealed myeloid differentiation factor 88 (MyD88) as a candidate gene for disease progression and TRL-9, the receptor for MyD88, was increased in a conventionally housed condition. Nasal challenge with CpG-oligonucleotide (a ligand for TRL-9) aggravated renal injury with strong Th1 polarization and increased mesangial IgA. TRL-9 polymorphism in the TLR-9 gene associated with disease progression of IgA in humans. TLR-9 pathway may be involved in the pathogenesis and determination of severity of IgA glomerulonephritis (43).

TLR-3 recognizes dsDNA of viral origin and is expressed in mesangial cells. Cytokines stimulate TLR-3 mRNA in mesangial cells In vitro. TLR-3mRNA is significantly upregulated in glomeruli associated with enhanced mRNA of RANTES/CCL5 and MCP-1/CCL2 in hepatitis C-associated glomerulonephritis in humans. This suggests that immune complex containing viral RNA activate mesangial cells via TLR-3 mediated chemokine/cytokine effects (44).

Complement Cascade

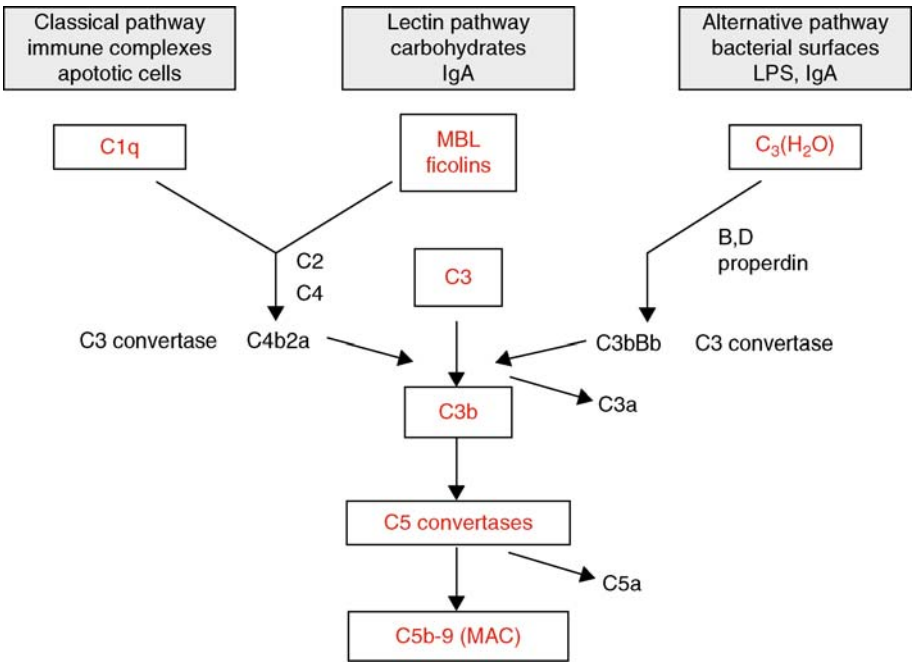
The complement system, which is a cascade of plasma proteins, involves approximately 30 plasma and membrane-bound proteins that play a pivotal function in antimicrobial defense and immune complex clearance. Complement components are largely liver-derived and are present in inactive forms (numbered C1 through C9) in the plasma and local complement production occurs in the inflammatory milieu involved in tissue damage, including leukocyte recruitment, cell necrosis, and apoptosis. Immune complex clearance and proinflammatory functions of complement system provide its complex participation in immune-mediated glomerulonephritis.

The biologic actions of complement ultimately generate a pore-like membrane attack complex (C5-9, MAC), which punches holes in invading microorganisms. Among the several important complement fragments produced in the MAC-generating processes are the cleavage products of C3 and C5 (C3a, C5a), collectively termed anaphylatoxin, which promote vascular permeability (C3a, C5a) and leukocyte chemotaxis and activation (C5a).

The presence of complement components in the tissue of glomerular diseases represents local activation of complement system that involved in the pathogenesis of glomerular injury. Classically, inhibition of the complement cascade by cobra venom factor attenuated various glomerulonephritis models. Complement depletion, by aggregated human IgG, protected against complement/PMN-dependent glomerular injury in anti-GBM antibody nephritis, with marked attenuation of leukocyte influx. In addition, defective complement regulation system, as seen in human and animal models with specific complement component deficiencies have provided evidence of a complement-mediated/-dependent pathway in glomerular injury. This includes certain forms of hemolytic uremic syndrome and MPGN II (45).

Figure 29-13

Three pathways of complement cascade. The early activation steps of each pathway converge in a common terminal pathway towards MAC formation. The classical pathway is initiated by C1 binding to an antigen-antibody complex (IgG or IgM), acute phase proteins (CRP) or apoptotic cells, leading to conformational changes that result in the activation of the associated serine proteases C1r and C1s. C1s cleaves C4 into C4a and C4b. C4b binds to C2, resulting in the C4bC2a complex, which is the classical pathway C3 convertase. Mannan-lectin pathway activation begins with recognition of carbohydrate ligands by mannose-binding lectin (MBL) and ficolin, which are present on various microorganisms. MBL activates MBL-associated serine proteases (MASP-1, MASP-2, MASP-3) and MASP-2 cleaves C4, resulting in the formation of the same C3 convertase as in the classical pathway. Alternative pathway activation is triggered by C3b binding to various activating surfaces, such as microbial endotoxins, aggregated immunoglobulins, and complex polysaccharides (e.g., LPS). This pathway involves a distinct set of serum positive regulator components, called the properdin system (properdin P, factor B, factor D). In this pathway, the C3 molecule is spontaneously activated by hydrolysis of the internal thioester. Hydrolyzed C3 binds to factor B, making it susceptible to cleavage by factor D, resulting in initial C3 convertase C3 (H2OCb) formation. This initial convertase further cleaves C3 into C3a and C3b, the latter interacts with factor B to form the more active alternative pathway C3 convertase, C3bBb. The presence of C3 convertase in the individual complement pathways leads to the formation of C3bBbC3b (alternative pathway) and C4bC2aC3b (classical and lectin pathways), also called C5 convertase. Through this molecule, C5 is split into C5a and C5b. C3a and C5a works as a potent anaphylotoxin to promote inflammatory processes and cytotoxic effects. (After Berger et al. (45) with permission.)



The complement system consists of three distinct pathways: the classical, mannan-lectin, and alternative pathways (*Fig. 29-13*). These pathways sometimes synergistically involved in the glomerulonephritis, such as simultaneous activation of lectin pathway and alternative pathway in IgA glomerulonephritis and purpura nephritis (46).

Of the four classical types of hypersensitivity reactions, complement is thought to be involved in types II and III. Type II hypersensitivity, antibody-mediated hypersensitivity, targets intrinsic glomerular cells or extracellular matrix, provoking tissue damage by a complement-dependent mechanism. This mechanism typically includes Goodpasture Syndrome and Heyman nephritis. In type III hypersensitivity, antigen-antibody complexes within the glomerulus (glomerular capillary endothelium or mesangium) and complement bind the C3b receptor or the Fc receptor of immune-competent cells and activate the production of chemical mediators or cytokines that lead to tissue injury. Lupus nephritis and post streptococcal acute glomerulonephritis are promoted by this mechanism.

The complement activation-involved glomerular injury is thought to be mediated by leukocyte recruitment via C5a, which accelerates the inflammatory process (leukocyte-dependent) or through direct attack by complement fragments on intrinsic glomerular components (leukocyte-independent).

Leukocyte-dependent tissue injury mechanisms are involved in injury to the glomerular capillary. C5a affects the chemotaxis of neutrophils, monocytes/macrophages, and eosinophils, and accelerates the release of inflammatory mediators. C5a also increases the adhesion of leukocytes to endothelium, by activating the leukocytes and increasing the avidity of the surface integrin for the ligands C3b and C3bi deposited on endothelial surface. C5 deficient mice show reduction of glomerular PMNs infiltration in cryoglobulin-induced immune complex glomerulonephritis (47). Complement anaphylatoxins binds several receptors including G-protein-coupled receptors (C3aR and C5aR). C5a binds two receptors, C5aR and C5L2, and most of the functional effects of C5a are mediated by C5aR. Transplantation of C5aR-deficient marrow suppressed glomerulonephritis in MPO deficient mice immunized with MPO, indicating C5a involves leukocyte activation via C5aR (48). These inflammatory process involves GBM breakdown and activation of the coagulation system, due to endothelial injury, lead to proliferative and matrix changes in the mesangium and parietal cells, and accelerate podocyte damage. MAC stimulates NF-κB, which is linked to the activation of the pro-inflammatory cytokines IL-8 and MCP-1. In humans, C3aR is upregulated in the glomerular endothelial region in lupus nephritis, but not other glomerular diseases (49).

Leukocyte-independent mechanism of glomerular injury is seen in Heyman nephritis. Like type II mechanisms, antigen (megalin) on podocyte surface is a target of complement cytotoxicity and results in direct injury for filtration barrier and complement depletion attenuated Heyman nephritis. In addition, sublyric levels of MAC damage the DNA in podocytes (50).

Glomerulonephritis in complement deficiency provides a clue to understand the roles for complement in glomerular injury. C6-deficient/-depleted rats with anti-Thy1 nephritis or Heyman nephritis show attenuated disease activity. By contrast occurrence of IgA glomerulonephritis even in the hereditary C6 or C9 deficiency in humans indicated that MAC per se is not essential in the IgA glomerulonephritis.

Interestingly, C1q or C4 deficiency develops lupus-like disease in mice, and C1q, C2 and C4 deficiency in humans increased risk of developing SLE. Although the phenomenon may be contradict to the many literatures suggesting complement system injures the glomerulus, it may be explained by the scenario that complement deficiency may leads to auto-immune phenomena due to defective clearance of apoptotic cells which are rich source of autoimmunity in SLE.

Glomerular cells are normally protected from complement-mediated injury by cell-surface defense mechanisms and complement regulatory proteins are expressed in intrinsic glomerular cells. CR1 (CD35) preferentially binds to C3b and C4b, which are normally expressed in podocytes and protect against complement-dependent cellular damage. CR2 is also expressed in intrinsic glomerular cells, including podocytes and mesangial and endothelial cells, and is up-regulated in membranous nephropathy. In addition, ER (endoplasmic reticulum) stress protein may have protective role for MAC mediated cell injury as shown in podocytes (51).

In human glomeruli, decay accelerating factor (DAF or CD55) and membrane cofactor protein (MCP or CD 46) regulate C3 and C5 activation. CD59, which is a membrane protein inhibitor of the MAC of complement, inhibits at the level of C8 activation, preventing MAC formation. Glomerular resident cells normally express MCP and CD59, and these molecules are up-regulated in glomerular disease. Nephrotoxic serum nephritis in mice deficient for either DAF1 or CD59a or both DAF1 and CD59a gene reveal that mice lacking DAF1 gene developed severer proteinuria and histology compared to wild type or CD59a deficient mice. Severe disease in DAF1 gene deficiency is associated with glomerular C3 and C9 deposition, whereas immunoglobulin deposition is comparative (52). Crry is a rodent homolog with activities similar to DAF and MCP. Blocking CD59 or Crry accelerates complement-dependent glomerulonephritis, and the soluble forms of these molecules effectively inhibit complement and attenuate glomerular damage. Double knockout mice with DAF and Crry revealed exacerbation of nephrotoxic serum nephritis despite marked reduction of systemic complement activation (53) and transgene of Crry in MRL/lpr mice protect renal disease (54).

Clusterin is a plasma protein that is frequently found within glomerular immune deposits, in association with vitronectin and soluble C5b-9. Clusterin depletion enhances immune complex glomerulonephritis in mice.

Alternative mechanism of complement-dependent glomerular injury is defective complement regulatory proteins. Protective proteins against the complement cascade include factor H, factor H-like protein, factor I, and C4 binding protein, and functional defects in these proteins

are the background. Factor H is a soluble glycoprotein that regulates complement, both in the fluid phase and on the cellular surface. It acts in the amplification loop of the alternative pathway to regulate C3bBb through dissociation of C3bBb into inactive factor Bb and C3bfH, followed by irreversible inactivation by factor I. Factor H has affinity for polyanions on the cell surface and protects the cell from alternative pathway-mediated injury.

MPGN type II is a peculiar disease with persistent complement activation without immunoglobulin deposition, as revealed by immunofluorescence (55). Electron microscopy reveals a characteristic continuous, electron-dense deposition along the lamina densa of the GBM (thus, it is also known as dense deposit disease). The disease has a poor prognosis, with chronic renal failure and frequent relapses after renal transplantation, which suggests that genetic or humoral factors cause the disease. Systemic and persistent alternative pathway activation in MPGN type II is generally caused by either the presence of autoantibodies to C3 convertase (C3bBb), C3NeF, which stabilizes it, or by inherited mutations in or the presence of antibodies against factor H, resulting in the inhibition of convertase inactivation (56). C3NeF mediated convertase stabilization may be dependent on the factor H-mediated inactivation of the convertase.

The genes for the factor H family of proteins localize to the "regulators of complement activation" (RCA) region at 1q32. Few reports have addressed the potential association between human MPGN type II and factor H mutations, although such mutations are important in the pathogenesis of the disease. A 13-month-old Native American boy with MPGN type II, who had a C518R mutation in the factor H short consensus repeat (SCR)9 in trans with a C941Y mutation in factor H SCR16, showed retention of the defective factor H in the endoplasmic reticulum. A relationship between MPGN type II and factor H has also been demonstrated in animal models. Norwegian Yorkshire piglets with the I1166R mutation in SCR20 developed MPGN type II; this mutation prevented extracellular release of factor H, resulting in intracellular accumulation. These findings in humans and animals suggest that mutated factor H is not delivered to the cell surface and/or is unable to bind to surface-bound C3b, resulting in incomplete convertase inactivation. Factor H-deficient mice show significant reductions in C3 and reproducible MPGN type II, with C3 deposition in the GBM, whereas combined factor H and factor I deficiency or factor I deficiency alone did not show MPGN II (57). Spontaneous MPGN in factor H deficient mice was attenuated in additional deficient with C5, but not those with C6. Severe nephritis of antiGBM nephritis in factor H deficient mice is blocked by administration of anti C5 antibody (58). Notably, the site of pathologic lesions is limited to the glomerulus, suggesting a unique requirement in the GBM for factor H-mediated protection against complement attack.

Another type of glomerular injury with persistent complement activation is atypical hemolytic uremic syndrome (aHUS), which is typically seen as a familial condition. A factor H mutation has been implicated in aHUS, and the HUS database (http//:www.FH-HUS.org) lists more than 100 mutations related to factor H: 69 factor H mutations, 12 factor I mutations, and 25 MCP mutations linked to aHUS, as well as 6 factor H mutations linked to MPGN type II, as of December 2008. Factor H mutations apparently generate different glomerular injury phenotypes in MPGN type II and aHUS. In contrast to the factor H mutations in patients with MPGN type II, aHUS patients with factor H mutations are usually heterozygous (few cases with homozygous mutation are reported) for the mutation, and these patients have normal levels of circulating factor H protein (59). In addition, factor H mutations in aHUS patients are typically located in the C-terminal region, which is important for binding to the cell surface. Transgenic mice that lack the exons encoding the C-terminal region of factor H develop aHUS, closely resembling the human disease. These mice show preservation of fluid-phase complement activation, associated with defects in endothelial protection against complement attack, leading to persistent endothelial injury. This corresponds to the pathogenic background of aHUS, unlike MPGN type II. Similarly, heterozygous mutations in MCP have been reported in cases of familial aHUS. These mutations resulted in three amino acid changes (positions 233–235) and the insertion of a premature stop codon, resulting in loss of the transmembrane domain of the protein and severely diminishing the cell-surface expression of MCP (60). Thus, persistent complement activation on the endothelial surface may promote aHUS.

Soluble, Secreted Peptides

Following the initiation of immune-mediated glomerular injury, regardless of whether it is cell-mediated, antibody-mediated or both, soluble and secreted peptides are significantly involved in the promotion of glomerular injury as second messengers. Recent developments in the molecular and biochemical aspects of inflammatory mediators have been applied to glomerulonephritis and In vitro experiments effectively reproduce In vivo tissue injury

mechanisms. Not only do interactions between these molecules occur among inflammatory cells, but their direct actions on intrinsic cells and cellular responses are also important in the pathogenic background of glomerular injury.

Various cytokines, chemokines, and growth factors are soluble, secreted peptides that promote the responses of intrinsic cells, including cell proliferation, cell death, and matrix production/degradation. They are also involved in protection against glomerular tissue damage. These peptides are produced by inflammatory cells, platelets or intrinsic glomerular cells and bind to specific receptors on the cell surface, acting in paracrine, autocrine, and/or juxtacrine fashions. The cellular responses of intrinsic cells and the features of inflammatory cells lead to the glomerular pathology that defines the stage and grade of glomerulonephritis.

Interleukins

Interleukins (ILs), initially identified as cytokines secreted by leukocytes, are important signaling molecules. To date, approximately 35 subtypes have been identified. ILs are known to mediate cellular immune/inflammatory reactions and they play key roles in immune-mediated glomerular injury. Many cells synthesize ILs that act locally, resulting in the proliferation or maturation of T cells, T-cell interactions with B cells, antibody production by B cells, and changes in the Th1 and Th2 subset balance.

In the kidneys, ILs stimulate mesangial cells and endothelial cell proliferation, and stimulate the production of oxygen radicals, collagenase, cytokines, chemokines, adhesion molecules, and extracellular matrix, and they may accelerate cell injury/death. Among the ILs, IL-1, -2, -4, -6, -8, -10, -11, -12, and -13 are known to be involved in many aspects in glomerular injury.

IL-1, IL-6, IL-8, IL-12, and IL-18 primarily act to promote glomerular injury, whereas IL-4, IL-10, IL-11, and IL-13 have anti-inflammatory actions. These molecules act on glomerulus by similar but occasionally different mechanisms and their roles are sometimes disease specific. For example, IL-10, IL-12, and IL-18 are pathogenesis-specific ILs in lupus nephritis and are involved in glomerular injury by mediating leukocyte infiltration.

IL-1 is produced by macrophages, neutrophils, and dendritic cells and accelerates helper T-cell co-stimulation, B-cell maturation, and macrophage and endothelial cell activation, via the specific receptors Cd121a/IL1R1 and CD121b/IL1R2. IL-1β is involved in macrophage-mediated glomerular injury, as is TNF-α. IL-1 is transiently expressed during acute glomerular injury, and correlates with the degree of glomerular inflammation; it is not expressed during chronic glomerular damage. IL-1 accelerates leukocyte adherence to endothelial cell surface, resulting in mesangial proliferation, activation of pro-coagulant activity, and the synthesis of prostaglandins. Indeed, IL-1 mRNA is expressed in acute glomerular injury and the administration of a soluble IL-1 receptor antagonist attenuates the damage. In addition, IL-1 stimulates mesangial VEGF synthesis via the PI3-K/mTOR pathway and stimulates matrix production by epithelial cells (61).

IL-6 is produced by several types of blood-borne cells, glomerular endothelial cells, and mesangial cells. IL-6 is a multifunctional cytokine that is important for B-cell differentiation and maturation, immunoglobulin synthesis, acute-phase protein production, bone marrow progenitor stimulation, mesangial proliferation, and the activation of monocytes/macrophages. IL-6 is detected in the serum and urine in both animals and humans with glomerulonephritis. Overproduction of IL-6 results in lupus and Castleman's disease in mice and IL-6-transgenic mice demonstrate glomerulonephritis. Blockade of IL-6 receptors using a neutralizing antibody ameliorates lupus glomerulonephritis in NZB/W F1 mice. The promotive role of IL-6 for mesangial proliferation or glomerulonephritis may largely mediated by activation of monocyte/macrophages.

IL-8 is synthesized by macrophages, lymphocytes, epithelial cells, and endothelial cells. IL-8 stimulates the activation and chemotaxis of granulocytes via CXCR1/IL8RA. In addition, activated mesangial cells in glomerular injury synthesize IL-8 and neutralization of IL-8 by a specific antibody attenuates immune-complex type glomerulonephritis, concomitant with the suppression of leukocytes. Glomerular podocytes express IL-8 in the normal state, and they express high levels in MCNS (62). In post streptococcal acute glomerulonephritis in children, increased levels of IL-8 were detected in the urine and plasma particularly in the acute phase and up-regulation of glomerular IL-8 is associated with endocapillary proliferative lesions (63). Thus, IL-8 acts to promote the acute and active phases of glomerulonephritis.

IL-12, which is a heterodimeric molecule composed of the p35 and 40 subunits, plays a key role in uncommitted T cells of the Th1 phenotype. Antigen-presenting cells are the dominant source of the IL-12 but intrinsic renal cells are also the effector to produce IL-12. Anti-GBM antibody nephritis induced in IL-12p40−/− mice reveals attenuation of glomerulonephritis associated with suppression of leukocyte infiltration (64).

IL-18 is produced by macrophages and stimulates INF-γ synthesis by Th1 cells and NK cells, resulting in NK-cell activation. IL-18 is overexpressed in patients with lupus nephritis associated with higher INF-γ and lower IL-4 production (65). Anti GBM nephritis in $IL18^{-/-}$ mice reveals reduction of local synthesis of TNF, IL1β, IFN-γ and MIP1 (66). IL-18 deposition in tissues is observed in ANCA-related glomerulonephritis and IL-18 is involved in the priming or recruiting of neutrophils in this disease (67). IL-18-primed neutrophils synthesize MPO and PR3 ANCA via p38 MAP-kinase activation In vitro.

IL-4 acts by promoting Th2 responses and it inhibits the various pro-inflammatory effects of macrophages. Macrophages primed with IL-4 become unresponsive to pro-inflammatory cytokines, including INF-γ and TNF-α. Glomerular-resident cells, i.e., mesangial cells and podocytes, synthesize IL-4. IL-4 ameliorated crescentic glomerulonephritis in Wistar Kyoto rats and this is associated with macrophage suppression (68) and transfection of IL-4 expressing macrophages in rats with nephrotoxic serum nephritis prevented glomerulonephritis with reduction of ED-1 positive macrophage influx (69). The aggravation of glomerulonephritis in IL-4-deficient mice is attenuated by treatment with recombinant IL-4. These findings indicate a renoprotective role for IL-4 in glomerulonephritis.

IL-10, a pluripotent cytokine, is produced by various activated immune cells, including T-helper cells, B cells, monocytes/macrophages, and keratinocytes. IL-10 down-regulates the co-stimulatory molecules that participate in T-cell activation. IL-10 suppresses mesangial cell proliferation in anti-Thy1 nephritis and also attenuates glomerular injury in nephrotoxic serum nephritis. C-reactive protein suppresses nephrotoxic serum nephritis in B6 mice and the effect is abolished in IL-10 deficient mice (70). Renal dendritic cells stimulate $CD4^+$ T cells, inducing IL-10 production. Nephrotoxic serum nephritis in mice depleted renal dendritic cells by diphtheria toxin revealed advanced tubulointerstitial and glomerular lesions, without any effects on the macrophages. Production of IL-10 by renal dendritic cells is mediated by promotion of the IL-10 inducer molecule, inducible costimulatory molecule ligand (ICOS-L). Long-term expression of IL-10 by a recombinant adeno-associated virus modulated glomerulosclerosis in a subtotal nephrectomy model accompanied by suppressing the INF-α and IL-2 mRNA levels. This suggests a renoprotective role for IL-10 in non-immune-mediated chronic models of glomerulosclerosis (71).

IL-11 is a bone marrow-derived, multifunctional, anti-inflammatory cytokine that is involved in acute inflammatory responses mediated by acute-phase protein production. Rat mesangial cells and macrophages express the IL-11 receptor α-chain. IL-11 suppresses the expression of the pro-inflammatory cytokines TNF-α, IL-1β and IL-12 in LPS-stimulated peritoneal macrophages. Recombinant human IL-11 attenuates crescentic glomerulonephritis in WKY rats, showing reduced necrosis, macrophage infiltration, and apoptosis (72). Subcutaneous IL-11 injection in mice with nephrotoxic serum nephritis in mice attenuated glomerular injury via suppression of NF-kappa B activity (73).

Interferons

Interferon (INF) stimulate the immune response, activating NK cells and macrophages, and increasing antigen presentation to lymphocytes and is now known to comprise three subtypes, αβ and γ. INF-γ is a key molecule for Th1 cells and is synthesized by many cell typesunder various conditions, although macrophages are the most important source in inflammation. INF-γ is important in the effector phases of nephritogenic immune responses, including IgG2a generation, T-cell and macrophage recruitment, and macrophage activation. Evidence suggests that INF exerts different effects in various nephritogenic conditions.

In human lupus nephritis, laser microdissection of glomeruli shows up-regulation of glomerular INF-γ in association with IL-10, IL-12 and IL-18 and that was correlated with glomerular leukocyte influx (74). INF-γ is also up-regulated in the mice model of lupus nephritis and blocking INF-γ attenuated the kidney disease. INF-γ enhanced autoimmunity, generating damaging autoantibodies in lupus model. Lymphocyte depletion in the anti-Thy1 nephritis model revealed attenuation of glomerular injury through the suppression of INF-γ. Endogenous INF is pathogenic in anti-GBM antibody nephritis. In contrast, anti-GBM antibody nephritis in INF-γ receptor-deficient mice showed aggravation of the nephritis and progressive crescentic glomerulonephritis (75). Both aggravating and protective effects for INF-γ in glomerulonephritis is probably depending on the mechanistic background of the diseases. INF-γ may be an effector for other cytokines or may modify the reactions of macrophages, rather than having direct actions on glomerular cells.

Role of INF-β in glomerulonephritis is not well known. Recombinant rat INF-βreduces proteinuria in the different models of glomerulonephritis (nephrotoxic nephritis in WKY rats, anti-Thy1 nephritis and puromicyn nephrosis) via direct action for glomerular filtration barrier (76).

Tumor Necrosis Factor (TNF)

TNF is a monocyte/macrophage-derived, pro-inflammatory cytokine and an important mediator of inflammatory tissue damage. There are three family members; TNF-α, TNF-β and lymphotoxin-β, and TNF-α is the best characterized TNF among them. Two receptors for TNF (TNFR1 and TNFR2) have been identified and are involved in mediating local inflammatory injury and systemic immune-regulatory functions in the kidney. Many experimental studies and clinical observations support roles for TNF-α in the pathogenesis of acute and chronic renal disease. TNFR1 attenuates LPS-enhanced nephrotoxic nephritis with down-regulation of IL-1β. Anti-GBM glomerulonephritis is attenuated in TNF-α-deficient mice, and blocking TNF-α in nephrotoxic serum nephritis in Wistar Kyoto rats attenuated glomerulonephritis accompanied by down-regulation of urinary MCP-1 (77). Wild type bone marrow transplantation to TNF deficient recipients (intact bone marrow but absent renal-derived TNF) resulted in attenuation of anti-GBM nephritis, whereas the effect was not seen in mice with TNF deficient leukocytes but intact intrinsic renal cells. This suggests intrinsic renal cells are the major source of TNF and participate in TNF-mediated renal injury (78). Likewise TNF stimulates cytokine production in mesangial cells In vitro. TNF-α probably activates pro-inflammatory cytokines and participates in the progression of glomerulonephritis.

Although TNF-α generally plays a stimulatory role in glomerulonephritis, it can also act as an immune modulator. The fact that blockade of TNF-α in human rheumatoid arthritis or Crohn's disease leads to the development of autoantibodies, a lupus-like syndrome, and glomerulonephritis in some patients suggests a B cell modulator of TNF-α (79).

Given these apparent dual functions of TNFs, balance between the pro-inflammatory and immunosuppressive effects of TNF may participate in immune-mediated glomerulonephritis.

Chemokines and their Receptors

Chemokines (chemotactic cytokines) are small proteins (8–10 kDa) that are now known to constitute a superfamily of leukocyte subset-specific activating and/or chemoattractant cytokines (*Table 29-5*). The four classes of chemokines (CXC, CC, C, and CX3C) are classified

Table 29-5

Intervention of chemokine receptors on experimental glomerulonephritis

	Target	Intervention procedures	Outcome
Immune complex glomerulonephritis	IL-8/CXCL8	Neutralizing antibody	Improved
	RANTES/CCL5	Met-RANTES	Worse
		Amyno-oxyopentane-RANTES	Worse
Crescentic glomerulonephritis	CINC	Neutralizing antibody	Improved
	IL-8/CXCL8	Neutralizing antibody	No effect
	MIP-2/CXCL2	Neutralizing antibody	Improved
	SR-PSOX/CXCL16	Neutralizing antibody	Improved
	MCP-1/CCL2	Neutralizing antibody	Improved
		Gene targeting	No effect
	CCR2	Gene targeting	Worse
	MIP1 alfa/CCL3	Neutralizing antibody	Improved
	RANTES/CCL5	Met-RANTES	Improved
	CCR1	Gene targeting	Worse
	MDC/CCL22	Neutralizing antibody	Improved
Anti-Thy1nephritis	IP-10/CXCL10	Neutralizing antibody	Worse
	MCP-1/CCL2	Neutralizing antibody	Improved
	RANTES/CCL5	Amyno-oxyopentane-RANTES	Improved

(Modified from Huber TB, Reinhardt HC, Exner M et al. Expression of functional CCR and CXCR chemokine receptors in podocytes. *J Immunol* 2002;168:6244–6252.)

based on similarities in their amino acid sequences; specifically, they share patterns of paired cysteine repeats and two internal disulfide bridges.

The CC and CXC chemokines have been extensively investigated in kidney diseases. In humans, urinary CC chemokines are detected in crescentic glomerulonephritis and glomerulosclerosis. Increased levels of urinary CXC chemokines are associated with glomerular deposition in cases of active glomerulonephritis. Important roles for chemokines and their receptors have been established in the progression of glomerulonephritis in experimental glomerulonephritis models and In vitro studies.

The CC chemokines (β-chemokines), comprising to date a family of 27 members, are involved in the recruitment of monocytes/macrophages and T cells. Monocyte chemoattractant protein (MCP-1/CCL2), macrophage inflammatory protein (MIP1/CCL3), and regulated upon activation normal T cells expressed and secreted (RANTES/CCL5) are the major CC chemokines involved in glomerulonephritis. There are five receptors for CC chemokines. CCR1 is expressed on monocytes, CCR3 and CCR5 are expressed on Th1 cells, and CCR3 and CCR4 are expressed on Th2 cells.

MCP-1 accelerates glomerular injury. Expression of MCP-1 has been observed in proliferative glomerulonephritis and crescentic glomerulonephritis. Urinary and serum MCP-1 levels are increased in post streptococcal acute glomerulonephritis (PSAGN) in children and urinary, but not serum MCP-1 levels correlate with proteinuria in acute phase (80). MCP-1 and MIP1-α have been detected in human crescentic glomerulonephritis and correlate with the degree of macrophage influx into the glomeruli (81). MCP-1 deficient MRL-Fas/lpr mice showed decreased disease severity, with suppression of macrophage and T-cell recruitment, resulting in decreased local levels of cytokines and chemokines. Dermal transplantation experiments with MCP-1 antagonist-transfected MRL/N-1 cells resulted in attenuated glomerulonephritis via the suppression of T cells and macrophages in murine lupus nephritis. An MCP-1 antagonist attenuated glomerulonephritis in MRL-Fas/lpr mice (82) and a neutralizing antibody to MCP-1 attenuated the disease in a mouse model of crescentic glomerulonephritis. Gene therapy with NH2-terminal deletion mutant of the MCP-1 gene for MRL/lpr mice attenuates glomerulonephritis with reduction of leukocyte infiltration (83). A Spiegelmer (L-enantiomeric RNA oligonucleotide, mNOX-E36) that binds to murine CCL inhibited its function and improved the survival rate of lupus mice by modulating nephritis (84). In addition, P38MAPK ameliorates crescentic GN by suppressing MCP-1, independently of TNF-α and IL-1β (85). An AT1 receptor antagonist and prostaglandin E1 suppressed MCP-1 expression, suggesting that MCP-1 is the target of such blockade.

RANTES binds CCR1 and CCR5 in monocytes. Inhibition of RANTES leads to protective effects in experimental glomerulonephritis, and CCR5 deficiency aggravates T cell-dependent nephrotoxic serum nephritis via enhanced CCL3/CCL5-CCR1 driven renal T cell recruitment. (86). CCR1 antagonist prevents lupus nephritis by inhibiting interstitial inflammation but not affect on glomerular injury (87), suggesting the role of CCR1 is different in the pathogenic background.

CXC chemokines exert chemoattractant effects on PMNs by intracellular phosphatase activation, via CXCR1 and CXCR2. IL-8 interacts with CXCR1 and CXCR 2, advancing PMN chemotaxis. Immunohistochemistry revealed expression of CXCR1 predominantly in MPGN and lupus nephritis in humans and that CXCR-1 expressing cells are mainly PMNs (88). The INF-γ-inducible protein of 10 kDa (IP-10) binds to CXCR3. Renal microvascular endothelial injury model provided evidence that neutralizing antibody against IP-10 attenuated renal dysfunction through reduced the number of infiltrating tubulointerstitial T cells without affecting monocytes/macrophage migration (89). Fractalkine (CX3CL1), the only CX3C chemokines, binds CX3CR1 on NK cells. Mesangial cells express fractalkine In vitro, and its expression is up-regulated in anti-Thy1 nephritis, in parallel with mesangial proliferation (90).

Cytokines stimulate glomerular resident cells to express chemokines, including IL-8, MCP-1, MIP-1α, and macrophage inflammatory protein (MIL)-1α, which can lead to local inflammation and glomerular injury. Podocytes express CCR2 and CXCR1, 3, 4, 5 and these set of chemokine receptors are upregulated in podocytes in membranous glomerulonephritis (91). IP-10 protects podocytes against proteinuria and progressive glomerular damage (92). CXC chemokine-primed mesangial cells express CC chemokines In vitro. This indicates that a chemokine network is involved in acute and chronic glomerulonephritis. Chemokines are also involved in non-immunologic renal injuries, including ischemia-reperfusion models and interstitial nephritis (93).

Growth Factors

Growth factors are cytokines that function as cell-to-cell signaling molecules, regulating cellular processes, such as maturity, proliferation, differentiation, and polarity. Growth factors bind to specific receptors on cell membranes. Several

growth factors are involved in acute and chronic glomerular injuries, and affect the survival, proliferation, migration, and matrix production in both bone marrow-derived cells and intrinsic glomerular cells. Tissue expression of growth factors has been examined by immunohistochemistry in humans and in animal models of glomerular injury, cell culture experiments, and transgenic models with glomerulonephritis, demonstrating the involvement of growth factors in glomerular injury.

Platelet-Derived Growth Factor (PDGF)

PDGF acts primarily on mesenchymal cells, driving cell migration and mitogenesis, extracellular matrix production, anti-inflammatory mediator production, tissue permeability, and hemodynamic regulation. Intrinsic glomerular cells that are mesenchyme-derived are plausible targets of PDGF. PDGF is released by activated platelets, activated macrophages, endothelial cells, and smooth muscle cells. PDGF exists in five isoforms (A, B, C, D, AB), which bind two receptor chains ($-\alpha$, $-\beta$) on the cell surface (receptor tyrosine kinases). PDGF-B is a ligand for PDGF α-and β -receptor, whereas PDGF-D binds β receptor. PDGF activates intranuclear protooncogenes and immediate-early gene expression, which are effectors of the receptor tyrosine kinase and responsible for particular downstream functions. PDGF-A and -B are secreted as homo- or hetero-dimers, whereas PDGF-C and -D are homodimers. The impressive glomerular structures seen in PDGF-B- and PDGFR-β-deficient mice reveal a lack of mesangium and aberrantly developed glomerular tufts, indicating a key role for PDGF in glomerular angiogenesis and cell migration. The intra-renal distribution of PDGF varies among species. PDGF-A is absent from the glomerulus in humans and rodents, whereas PDGFR is expressed in mesangial cells and endothelial cells. Podocyte expression of PDGF-A and B is limited to humans.

In experimental glomerular diseases, intense up-regulation of PDGF-B and PDGFRβ is observed. PDGFR-β is expressed in normal human glomeruli, and this expression is up-regulated in all resident glomerular cells. Anti-Thy1 nephritis shows expression of PDGF in areas of mesangial proliferation, and blockade of PDGF by neutralizing antibodies or aptamers (PDGF receptor IgG) attenuates mesangial proliferation in the acute and chronic phase. (94) PDGF antagonists also prevent glomerular damage in anti-Thy1 nephritis, nephrotoxic serum nephritis, and lupus nephritis models. PDGF-C is expressed in podocytes and mesangial cells in areas of glomerular injury (95). PDGF-D has a similar action as PDGF-B by β-receptor-mediated activation (96). Treatment with PDGF-D-neutralizing antibody in chronic progressive anti Thy1 nephritis resulted in attenuation of glomerulosclerosis accompanied by suppression of monocytes/macrophage influx and complement activation (97). Stimulation of mesangial cells In vitro with different PDGF ligands leads to cellular proliferation and migration. PDGF induces extracellular matrix production in mesangial cells, parietal cells, and tubular cells. PDGF-AB stimulates the production of TGF-β, CCL2, CXC3CL1, plasminogen activator inhibitor-1 (PAI-1), IL-6, endothelin, and iNOS in mesangial cells. The roles of PDGF in renal disease is extensively reviewed (98).

Transforming Growth Factor (TGF)

TGF is known to be a superfamily of cytokines, consisting of about 40 molecules, including the TGF-β, activin, and BMP subfamilies. Several family members involve many aspects in the kidney, i.e., morphogenesis, cell differentiation, inflammation and remodeling. TGF-β is produced by a variety of cell types in an inactive (latent) form and proteolytic cleavage renders it functional. TGF-β exerts its functions through its type I and type II receptors. An intracellular signaling pathway, involving Smad proteins, transduces the TGF-β signal to the target genes, including PAI-I and collagen type I (α2). TGF-β has pleiotropic functions and the effects differ by cell type and dosage. It acts as a growth inhibitor in epithelial cells, whereas it sometimes stimulates cell proliferation and matrix synthesis in the mesenchyme. The net result of TGF-β action in damaged tissue tends to be the formation of scars.

TGF-mediated glomerular injury includes inhibition of cell growth/proliferation, apoptosis, cell differentiation, angiogenesis, and fibrosis. TGF-β stimulates proteoglycan, biglycan, and decorin production in mesangial cells In vitro. The role of TGF-βin immune-mediated glomerular injury is not well understood. Latent TGF-β transgenic mice have no renal disease, despite high levels of circulating TGF-β. Over-expression of active TGF-β results in severe renal damage. Neutralizing antibodies to TGF-β attenuate anti-Thy1 nephritis. Latent TGF-β over-expression in anti-GBM antibody nephritis showed suppression of inflammatory cells and cytokines, by Smad7-mediated inhibition of NF-κB-dependent inflammation (99). In contrast, blockade of TGF-β by adenovirus-mediated gene transfer of the TGF-β IIR failed to attenuate anti-GBM antibody nephritis. Blockade of TGF-β signaling in the T cells of Smad7 transgenic mice inhibited glomerulonephritis, only with a medium dosage of anti-GBM antibodies. Smad 7 gene therapy ameliorates

autoimmune crescentic glomerulonephritis (100). Furthermore, TGF-β IIR knockout heterozygous mice with anti-GBM antibody nephritis showed attenuated glomerulonephritis, accompanied by suppression of ERK and the transcripts of target genes (101). The pleiotropic and complex functions of TGF-β are thought to be differentially regulated in the phases and pathogenetic background of the renal diseases.

Fibroblast Growth Factor (FGF)

The FGFs are a family of growth factors involved in angiogenesis, wound healing, and embryonic development. The FGFs are heparin-binding proteins that interact with cell surface-associated heparan sulfate proteoglycans, which are a prerequisite for FGF signal transduction. FGFs are key players in the processes of proliferation and differentiation in a wide variety of cells and tissues. Among the 22 FGFs identified to date, FGF-2 (basic-FGF) is the major factor investigated in glomerular injury.

As a potent angiogenic factor, FGF-2 mediates proliferation and matrix synthesis through binding with receptors FGF-R1 to R4. FGF-2 is increased in mesangial proliferative glomerulonephritis. Nephrotic syndrome, induced by the puromycin aminonucleoside, leads to FGF-2 expression in podocytes. Recombinant FGF-2 injection in rats leads to podocyte mitosis, without cytokinesis, resulting in severe nephrosis and focal segmental glomerulosclerosis. Parietal epithelial cells express FGF-R2, and FGF-2 stimulates matrix synthesis (102). FGF-1 and its receptor are expressed in the glomeruli, but precise function is still unknown.

Vascular Endothelial Growth Factor (VEGF)

VEGF is known to regulate vasculogenesis and angiogenesis, through effects on endothelial mitogenesis. It is involved in the chemotaxis of macrophages and granulocytes. Vasomotor activity for VEGF has also been noted.

The VEGF family consists of five members (A, B, C, D, PIGF), and VEGF A is the most intensively investigated. VEGF A has four isoforms, VEGF121, 165, 189, and 206; the former two are soluble and the latter two are cell-bound. In glomeruli, VEGF is constitutively and most abundantly expressed by podocytes, and occasionally by activated mesangial cells. The VEGF receptors, flt and flk-1, are expressed on endothelial cells. Inhibition of VEGF worsens anti-Thy1 nephritis, and treatment with VEGF attenuates thrombotic microangiopathy. Systemic administration of VEGF 165 in anti-GBM antibody nephritis reduced inflammation and advanced glomerular repair (103). Administration of sFlt-1 affected neither the infiltration of macrophages nor the crescents.

Connective Tissue Growth Factor (CTGF)

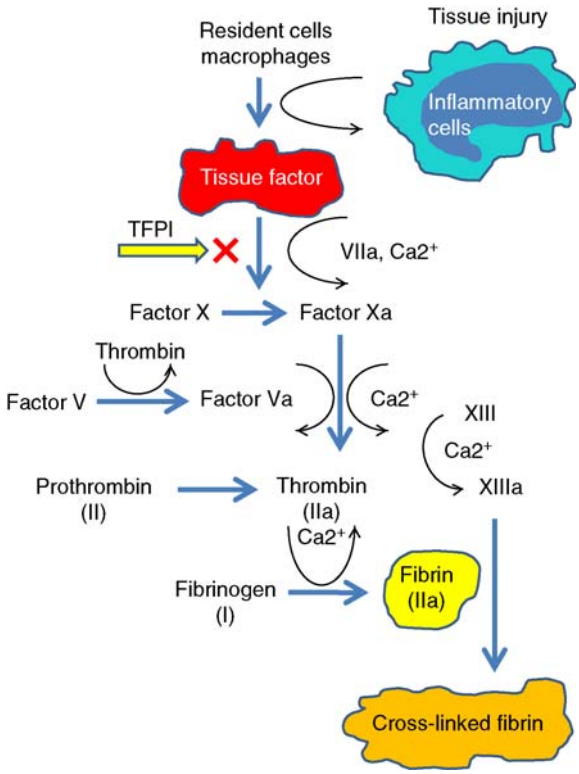
CTGF (CCN2) is a secreted, cysteine-rich, matrix-associated, heparin-binding protein of 38 kDa. A primary function of CTGF is to modulate and coordinate signaling responses involving cell surface proteoglycans. CTGF operates the downstream of TGF-β and directly enhances the TGF-β/Smad signaling pathway or independently acts to promote fibrosis and wound healing (104). CTGF is expressed in the intrinsic glomerular cells and tubular cells, and potentiates to promote renal scar formation (105). TNF-α is an up-regulator of CTGF in mesangial cells. (106) CTGF rapidly activates intracellular signaling and transcription of TGF-β inducible early gene through neurotrophin receptor TrkA in human mesangial cells. (107). CTGF enhances TGF-β action by blocking negative feedback loop of Smad 7 provided TGF-β/Smad signaling pathway in mesangial cells (108). CTGF is expressed in podocytes and PECs in normal glomeruli and binds perlican, a known component of the GBM. Increased CTGF in PECs is associated with matrix production. Up-regulation of CTGF mRNA is found during crescent formation in humans and rats and the expression is diminished when the crescents become scars (102). CTGF promotes TGF-β-dependent mesangial dysfunction and is involved in diabetic nephropathy.

Epidermal Growth Factor (EGF)

EGF is a 53-kDa aminopeptide that was initially identified in mice submandibular glands and human urine. The renal production sites of EGF are the Henlé loop and distal convoluted tubule. EGF is known to be involved in cell survival and the differentiation of tubular cells. Although the urinary levels of EGF are a marker of renal injury and urinary MCP-1/EGF seems to be a prognostic factor in IgA nephropathy, the function(s) of EGF in the glomeruli and its role in glomerular injury are not well understood. EGF induces mesangial cell contraction In vitro. Heparin-binding EGF is a strong mitogen that stimulates mesangial proliferation In vitro. However, immunostaining in human glomerular disease failed to detect glomerular EGF expression.

Figure 29-14

Coagulation is the cascade promoting the transformation of soluble fibrinogen into insoluble fibrin monomers. The cascade is initiated in the injured tissue by exposure of tissue factor (TF) at the surface of the injured endothelium. TF synthesis is stimulated by inflammatory cells, which activated resident cells or macrophages for production. Tissue factor activated conversion of X to Xa, which further converts prothrombin to thrombin. Thrombin participate conversion of fibrinogen to fibrin, which finally forms cross-linked fibrin by XIIIa. TF pathway inhibitor (TFPI) is a potent inhibitor of this cascade.



Platelets and the Coagulation Cascade

As for vascular endothelial cells in general, glomerular endothelial cells normally possess anti-platelet, anticoagulant, and fibrinolytic properties, to maintain the microcirculation in the glomerulus and this is very consistent background that coagulation and the fibrinolysis system are involved in immune-mediated glomerulonephritis. Local activation of the coagulation cascade of the extrinsic pathway eventually produces fibrin or thrombi (*Fig. 29-14*) Glomerular thrombi are occasionally observed in the active phase of glomerulonephritis, reflecting severe endothelial damage. Fibrin deposition is more frequently noted in glomerular injury, with tuft necrosis and thrombotic microangiopathy. The influences of these products in glomerular injury are to accelerate inflammation, rather than ischemia due to glomerular capillary obstruction. In human glomerulonephritis, localization of coagulation system-related molecules has been described, and their functions have been tested in experimental models, using neutralizing antibodies or knockout mice.

Platelets

Platelets are involved in glomerular injury, through leukocyte recruitment, increased vascular permeability, and the vasoactive effects of their intrinsic chemical substances. Platelets contain two types of cytoplasmic granules, α and σ. The α granules express P selectin on their membranes and contain fibrinogen, fibronectin, factors V and VIII, platelet activating factor (PAF), platelet factor 4, PDGF, and TGF-αl. The σ granules contain adenosine diphosphate (ADP), calcium ions, histamine, and serotonin. In local injury in glomerular capillaries, platelets adhere to the extracellular matrices at sites of endothelial injury and become activated. Activated platelets secrete granular products and synthesize TXA2, PDGF, and PAF, which together stimulate clot formation, cell proliferation, and matrix production. PAF is bioactive and increases leukocyte chemotaxis, vascular permeability, and vascular spasms. Platelets include phospholipid complexes that are important in the intrinsic coagulation pathway. Injured or activated endothelial cells trigger aggregation of platelets, forming a clot, and exposing tissue factor, which provokes capillary necrosis and fibrin exudates, leading to GBM breaks and extraglomerular lesions and cellular crescent formation. In addition, platelets activate complement as well as the intrinsic coagulation pathway, and release vasoactive amines.

Fibrin

Fibrin is an insoluble fibrous protein that is the end-product of a locally accelerated coagulation system. Fibrin stabilizes and anchors aggregated platelets. In glomerular diseases, fibrin is occasionally deposited in the capillary or mesangium. In IgA glomerulonephritis soluble fibrin deposition is located in the mesangial proliferation of active stage (109). Fibrin is detected in the capillary necrosis in cellular crescentic formation. Cross-linked fibrin, immunoglobulin deposition, and C3 are occasionally seen in

glomerulonephritis and co-localization of Factor V with fibrin in the mesangium indicates local activation of the coagulation cascade in glomerulonephritis.

Fibrin deposition is mediated largely by the stimulation of macrophage pro-coagulant activity. Most of the fibrin deposition associated with immunologic glomerular injury is mediated by activation of the extrinsic coagulation cascade, commencing with tissue factor pro-coagulants (110). In crescentic glomerulonephritis, fibrin deposition, renal pathology, and dysfunction are synchronous with glomerular macrophage and T-cell influx. In experimental models, glomerulonephritis is attenuated by the administration of anti-Factor V antibody. Defibrinogenation suppresses proteinuria in crescentic glomerulonephritis, although it has no effect on the inflammatory influx, indicating that the coagulation system promotes crescentic glomerulonephritis independently of the inflammatory reaction (111). Activation of the local coagulation system can be initiated by immunologic effects, although secondary events, which include intrinsic glomerular cell proliferation, microcirculation defects, and cell necrosis, are promoted by bioactive molecules of the coagulation system. In the activation of coagulation system, the fibrinolytic cascade also limits clot formation. Fibrinolytic agents have shown relatively consistent efficacy in attenuating immune-mediated glomerular injury in several models.

Tissue Factor

Tissue factor is a cellular lipoprotein that is present at sites of tissue injury, and activates extrinsic coagulation processes. In glomerular injury, inflammatory cell-derived cytokines induce tissue factor secretion by resident cells and macrophages. Endothelial tissue factor release initiates glomerular fibrin deposition, through activation of the extrinsic coagulation pathway, by binding circulating factor VII and facilitating its allosteric conversion to factor VIIa. Tissue factor converts X to Xa and factor V is a cofactor for the Xa, which is responsible prothrombin activation. Factor Va then converts prothrombin to thrombin, which further converts fibrinogen to fibrin (*Fig. 29-14*). Tissue factor also has fibrin-independent pro-inflammatory effects, mediated by MHC class II protein expression and leukocyte accumulation.

Specific Xa inhibitor ameliorates anti-Thy 1 nephritis by inhibiting macrophage infiltration and fibrin accumulation, suggesting that tissue factor promotes mesangial proliferation by function of proinflammatory and procoagulant mechanism of factor X (112). Administration of anti-factor V neutralizing antibody suppressed profibrotic cytokines in glomeruli (113). Inhibition of tissue factor activity by an antibody or tissue factor pathway inhibitor (TFPI) significantly ameliorates the development of crescentic glomerulonephritis, accompanied by decreased glomerular inflammatory cell influx. Infusion of recombinant TFPI ameliorates glomerular fibrin deposition and glomerular pathology in experimental glomerulonephritis.

The Enzymatic Fibrinolysis System

In addition to the progression of coagulation processes in tissues, the clotting cascade simultaneously sets into motion a fibrinolytic cascade that restricts final clot size, which may influence tissue scarring. The fibrinolytic system consists of an inactive proenzyme (plasminogen), which can be converted to an active enzyme (plasmin) that degrades fibrin into soluble fibrin products. This system is under the control of tissue-repair-related molecules, including plasmin. Plasmin is derived from the enzymatic breakdown of its inactive circulating precursor, plasminogen, either by a factor XII-dependent pathway or by plasminogen activators. Plasmin is involved in fibrinolysis. Activation of plasmin significantly involves matrix degradation and fibrinolysis, which influences the fate of tissue injury. Activation of plasmin inhibits fibrosis by enhancing matrix metalloproteinase 2 activation, thereby promoting ECM degradation. Plasminogen activator (PA) is a serine protease that converts plasminogen to plasmin to regulate ECM tissue deposition. Two plasminogen activators, tissue type (t-PA) and urokinase-type (u-PA), are known. t-PA is synthesized primarily by endothelial cells and is active when attached to fibrin, which it dissolves. Plasminogen binds to the plasminogen activator receptor (PAR), which belongs to the G protein-coupled receptor family, and activation of PAR leads to cytoskeletal rearrangements, proliferation of fibroblasts, and glomerular epithelial cell proliferation. Thrombin also interacts with PAR.

PA and plasmin are suppressed in some glomerulonephritis conditions and may be involved in mesangial matrix accumulation via α_1-antitrypsin, α_2-macroglobulin or plasminogen activator inhibitor (PAI). PAI is synthesized by endothelial cells to modulate the coagulation/anti-coagulation balance by blocking fibrinolysis. PAI-1 is a single glycoprotein of about 45 kDa consisting of 379 or 381 amino acids. It is a member of the serpin family with reactive site peptide bound Arg345-Met346. Activation of PAI-1 requires complex processes. PAI-1 promotes fibrosis by inhibiting plasmin generation, through the suppression of plasminogen activator. PAI-1 is also activated by interaction with TGF-β and it can modulate fibrosis and PAI-1, down-regulating TGF-β activity in a

negative feedback loop. PAI-1 deficiency leads to pathogenic over-activation of TGF-β

PAI-1 is increased in glomerulonephritis and plasmin-independent pro-fibrotic action of PAI-1 in glomerular injury involves the recruitment of fibroblasts and macrophages. Experimental cryoglobulin-associated mesangial proliferative glomerulonephritis reveals upregulation of the protease Nexin-1, t-PA, and PAI-1 (114). Induction of crescentic glomerulonephritis in PAI-1-deficient mice resulted in improvements in nephritis, accompanied by depressed inflammatory infiltrates and collagen accumulation.

Protease-activated receptor-2 (PAR-2), receptor of factor Xa, is expressed in epithelial, mesangial, and endothelial cells, and macrophages. PAR-2 is activated by serine proteases, such as trypsin, tryptase, and factors VIIa and Xa, and increases PAI-1 expression and macrophage-derived cytokine induction. PAR-2 is involved in human mesangial cell proliferation (115). Experiments with PAR-2-deficient mice revealed that PAR-2 promoted glomerular fibrin deposition and the progression of crescentic glomerulonephritis, due to stimulation of renal PAI-1 expression and MMP-9 activation (116) Thrombin-activatable fibrinolysis inhibitor (TAFI) is a potent inhibitor of plasmin generation, and immune complex-mediated glomerulonephritis is ameliorated in TAFI-deficient mice.

Although the coagulation cascade/fibrinolysis system is substantially involved in the acute and exudative phases of glomerular injury, by interacting with inflammatory cells, its roles in chronic progressive glomerulonephritis remain unknown. Further studies are needed to investigate the coagulation/fibrinolysis-independent actions of PAI-1 and tissue factor, such as inflammatory responses, cell migration, cell proliferation, angiogenic actions, and matrix remodeling in glomerular injury.

Eicosanoids

Eicosanoids are short-acting, hormone-like substances. They are arachidonic acid (AA) metabolites, and have effects in inflammation and hemostasis. AA is a 20-carbon polyunsaturated fatty acid that is present mainly in cell membrane phospholipids. Mechanical, chemical, and physiologic stimuli release AA from the cell membrane into the cytoplasm and specific enzymes then synthesize the metabolites. The AA cascade branches into two major pathways, the cyclooxygenase and lipoxygenase pathways, both of which are involved in glomerular injury (*Fig. 29-15*).

The cyclooxygenase pathway products include prostaglandins (PG) E_2, PGD_2, PDF_2a, PGI_2 (prostacyclin), and thromboxan (TX) A_2. The lipoxygenase pathway begins with 5-lipoxygenase, a well-characterized AA-metabolizing enzyme. Three major products, 5-hydroxyeicosatetraenoic acid (HETE), the leukotriene (LT) family of compounds, and the lipoxins, are known.

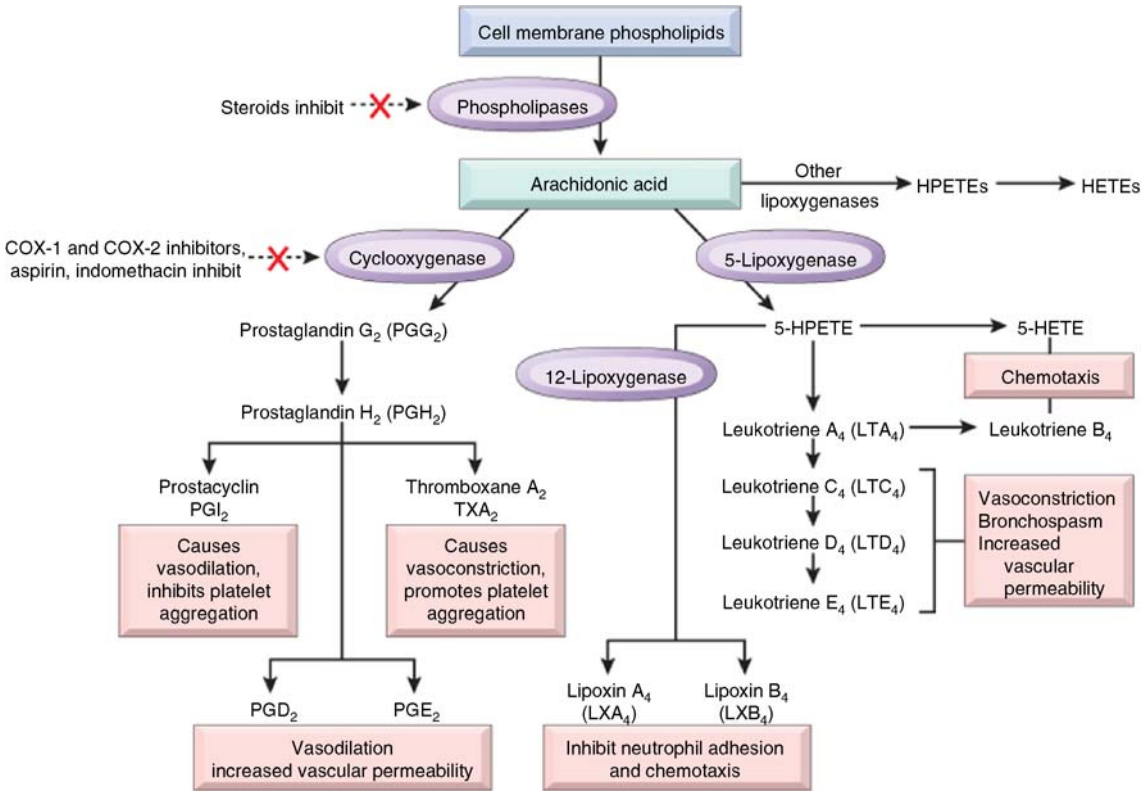
The restricted distribution of enzymes may determine the cell-specific synthesis of certain substances and cell to cell transaction to produce active endoproducts. For example, the AA in neutrophils is converted into LTA4 followed by LTB4, which is the end-product in neutrophils, since neutrophils lack the further converting enzyme of LTC4 synthase, and it is then secreted from the neutrophils. In contrast, platelets lack the 5-lipoxygenase enzyme but have 12-lipoxygenase and LTC4 synthase. Thus, in platelets, the LTB4 derived from neutrophils is converted into lipoxin and LTC4, both of which are final platelet products. This transcellular interaction of AA metabolites promotes inflammation In situ, resulting in biologic responses by the cells. Inflammatory mediators, such as complement components, also accelerate the release of these metabolites. Common functions among the eicosanoids are vasomotor effects; TXA_2 and LTs cause vasoconstriction, whereas PGs, PGI_2, and lipoxin participate in vasodilatation. LTB4 and lipoxins also promote chemotaxis and leukocyte adhesion. LTs affect vascular permeability. All these functions of AA products are involved in the processes of glomerular inflammation and renal function.

Considering wide ranged actions of AA metabolites for inflammation and tissue damage/repair, their roles for glomerular injury are likely important. AA involvement in glomerulonephritis has been extensively investigated before 2000 mainly using cell lines to demonstrate proliferation and macrices production, or administration of inhibitors in experimental models.

There are two forms of cyclooxygenase, COX-1 (constitutive) and COX-2 (inducible). COX-1 is constitutively expressed in the kidney, including in the mesangial cells, arterioles, PECs, and cortical and medullary collecting ducts. COX-2 is an inducible protein; its mRNA is detectable in the macula densa and the cortical thick ascending limb cells immediately adjacent to the macula densa, whereas it is not detected in the glomeruli. COX-2 expression in the glomeruli may appear in glomerulonephritis. In particular, podocyte expression of COX-2 is prominent in renal ablation models and anti-Thy1 nephritis. Furthermore, podocyte-specific COX-2 expression, driven by the nephrin promoter, aggravates proteinuria and upregulates endogenous COX-2. Podocyte COX-2 expression is induced by glomerular inflammation or various stresses and renders podocytes susceptible to further injury (117).

Figure 29-15

The arachidonic acid cascade and metabolites. Generation of arachidonic acid metabolites and their roles in inflammation. Note enzymatic activities whose inhibition through pharmacologic intervention blocks major pathways. (Denoted with COX-1 and COX-2, cycloxygenase 1 and 2; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid. (The figure was published in Kumar et al. Robbins Basic Pathology, 8 edn. 2007, pp. 48, Copyright Elsevier.)



PGE_2 is primarily produced by mesangial cells. In acute glomerular inflammation, PGE_2 is increased to maintain effective renal circulation by relaxing vascular smooth muscle cells. Another important function of PGE_2 is its anti-inflammatory actions in suppressing inflammatory cell recruitment, chemokines synthesis, and NO production. PGI_2 is a vasodilator and a potent inhibitor of platelet aggregation. Glomerular damage with endothelial injury may result in decreased PGI_2 In situ and may promote further glomerular injury. TXA_2 has largely opposite effects to PGI_2 and is abundantly synthesized in nephritic glomeruli. TXA_2 is produced by inflammatory cells and intrinsic glomerular cells and accelerates glomerular injury, through platelet aggregation and vasoconstriction. The LTs, a family of compounds converted by 5-lipoxygenase, include LTA4, LTB4, LTC4, LTD4, and LTE4. LTB4 is a potent chemotactic compound that promotes the recruitment of neutrophils, and is elevated in experimental models with glomerular damage. LTC4, LTD4, and LTE4 participate in vasoconstriction and increase vascular permeability. Receptor antagonists of LTs attenuate glomerular injury.

Lipoxins are the products of a two-step lipoxygenation, i.e., 5-lipoxygenase followed by 12-lipoxygenase. Lipoxins are produced locally at sites of inflammation by the transcellular interaction of neutrophils, platelets, and intrinsic cells. The platelets themselves cannot produce lipoxin, so they take up neutrophil-derived LTA4 and convert it into lipoxin. Lipoxins have both pro- and anti-inflammatory actions. Lipoxin A4 inhibits cytokine-induced mesangial cell proliferation In vitro and has been implicated as anti-inflammatory function in glomerulonephritis. (118, 119) And anti-inflammatory action of blocking LT-mediated neutrophil chemotaxis predominates. The vasodilatory actions of lipoxin may occur partly through the promotion of vasodilatory prostaglandins (prostacyclin) and NO. Inhibition of the AA cascade can be archived using specific inhibitors,

antagonists or even dietary manipulation. Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) inhibit all the steps upstream of COX activity. Specific inhibitors of TXA_2 and LTs have been shown to attenuate experimental glomerulonephritis. Dietary manipulation, leading to changes in eicosanoid metabolites, has been reported to affect glomerulonephritis in humans. Dietary fish oil that contains omega-3 fatty acids (eicosapentanoic acid and docohexanoic acid) modulates both COX and lipoxygenase metabolism. In addition, dietary restriction of essential fatty acids impairs renal production of a specific lipid-derived macrophage chemoattractant and LTB4, resulting in decreased production of cytokines, ROS, and NO in macrophages.

Reactive Oxygen Species (ROS)

ROS are chemical species with a single unpaired electron in an outer orbital. They are extremely unstable and readily react with various chemicals. Generation of ROS can occur via the rapid activation of NADPH oxidase, which oxidizes NADPH and reduces oxygen to the superoxide anion (O_2^-). ROS are produced within the lysosome and may be released from leukocytes by exposure to chemotactic agents, immune complexes, complement, and other factors. In addition, ROS are occasionally released by intrinsic glomerular cells. ROS are inherently unstable and generally decay spontaneously. The influence of oxygen-derived free radicals in inflammatory reactions depends on the balance between the production and inactivation of the related metabolites.

The biologic actions of ROS include the stimulation of expression of chemokines, cytokines, and endothelial leukocyte adhesion molecules. In addition, ROS stimulate intracellular signaling molecules that are involved in mitogenic pathways. The superoxide anion, hydrogen peroxide, and the hydroxyl radical are major species of ROS. The superoxide anion typically being the most abundant, though its potential for tissue injury is limited. Hydroxyl radicals induced by the Haber Weiss reaction promote considerable tissue damage. Activated leukocytes in the inflammatory milieu synthesize ROS and stimulate endothelial ROS production through xanthine oxidation, resulting in increased vascular permeability. Activation of NADPH oxidase is involved in cell proliferation and extracellular matrix production, mediated by intracellular signaling that includes the mitogen-activated protein kinase (MAPK) and activator protein 1 (AP-1) or TGF-β. Angiotensin II increases superoxide production in mesangial cells, through activation of NADPH oxidase activity. Antioxidants suppress proliferative anti-GBM glomerulonephritis (120). PDGF BB, TNF-α and IL-1 β stimulate ROS production in mesangial cells In vitro. In the acute phase of anti-Thy1 nephritis, ROS and NADPH-dependent oxidase activity are increased. In glomerulonephritis, inhibition of oxidative stress activates ERK and reduces fibrotic growth factors, resulting in attenuation of anti-Thy1 nephritis (121). Direct infusion of H_2O_2 in rat renal arteries causes proteinuria, and H_2O_2 depletion by catalase reduces neutrophil-dependent proteinuria, suggesting that ROS play a particularly significant role in the promotion of neutrophil-dependent glomerular injury. Likewise, ROS are involved in ANCA-associated glomerulonephritis.

Tissue fluids and the target cells of oxygen-derived radicals have antioxidant mechanisms to protect against harmful species. Several enzymatic and non-enzymatic antioxidant systems inactivate free radicals. Superoxide dismutase (SOD) significantly accelerates the spontaneous decay of ROS. Glutathione peroxidase also protects against ROS-mediated cell injury by catalyzing free radical breakdown. Catalase, which is present in cytoplasmic peroxisomes, directs the degradation of hydrogen peroxide. Exogenous antioxidants (vitamins E, A, C, β-carotene) block the formation of free radicals or scavenge such products. The effects of these antioxidants on glomerulonephritis have been reported, although presently there is insufficient evidence regarding their effects.

Nitric Oxide (NO)

NO, which is a pleiotropic mediator of inflammation initially discovered as the endothelial cell-derived factor relaxing vascular smooth muscle cells, produces vasodilatation. NO is a soluble gas that is produced by endothelial cells and macrophages and is a typical cytotoxic substances of macrophages. NO production is stimulated by acute inflammatory molecules, including TNF-α, ILs, and INFs. As the half-life of NO is extremely short, NO action is limited to the immediate proximity of the production site. NO acts on target cells through a paracrine mechanism and induces stable products, such as nitrates, nitrites (NO_2), and cyclic GMP-mediated intracellular alterations.

Three NO synthase isoforms have been distinguished in mammalian species: the constitutive calcium-dependent neuronal NOS (nNOS) and endothelial NOS (eNOS), and the inducible calcium-independent iNOS. In the glomerulus, eNOS is constitutively expressed in endothelial cells and occasionally, iNOS transcripts are detected.

In acute phase glomerulonephritis, macrophages are the major source of NO. iNOS is induced in glomerular capillary inflammation and glomerular NO_2 is increased in anti-GBM antibody nephritis models. NO_2 expression is relatively acute and transient. Early studies showed that decreasing NO production by L-arginine depletion in rat nephrotoxic serum nephritis exacerbated proteinuria. Increased NO synthesis observed in acute models of glomerular injury is not only a promotive factor, but also has protective roles. In fact, iNOS inhibitor in Wistar-Kyoto rats with nephrotoxic serum nephritis showed reduced crescentic formation and eNOS-deficient mice with anti-GBM nephritis reveals attenuation of nephritis indicating protective roles for NOS in glomerular injury. Anti-Thy1 nephritis shows an association between NO synthesis and mesangiolysis and suppression of NO resulted in reduced mesangiolysis. Another experiment using anti-GBM antibody nephritis in iNOS-deficient mice revealed no effect on glomerular histology, macrophage-mediated proteinuria or glomerular tissue damage. In humans, iNOS expression has been observed in proliferative lupus nephritis and IgA glomerulonephritis, although iNOS expression is not associated with the presence of macrophages and its function remains to be investigated more thoroughly (122). Attenuation of diabetic nephropathy in eNOS knock-out mice indicates involvement of eNOS-derived NO in the progression of diabetic nephropathy (123).

30 Acute Postinfectious Glomerulonephritis

Bernardo Rodríguez-Iturbe · Sergio Mezzano

Introduction

The term acute postinfectious glomerulonephritis includes a large group of glomerulonephritis that result from a variety of infectious agents. In this chapter we will deal only with the most common glomerulonephritis that result from bacterial infections. The term acute glomerulonephritis defines a pathological process that may be manifested clinically as an acute nephritic syndrome, nephrotic syndrome or rapidly progressive glomerulonephritis. Since post-streptococcal glomerulonephritis is the best known of the acute postinfectious glomerulonephritis and its most frequent clinical picture is the acute nephritic syndrome, the terms poststreptococcal glomerulonephritis, acute glomerulonephritis and acute nephritic syndrome are often, and incorrectly, used interchangeably.

In acute postinfectious glomerulonephritis the inflammatory process that takes place in the glomeruli is triggered by antigen-antibody reactivity that results in local activation of the complement system and of the coagulation cascade. Immune complexes causing glomerulonephritis may be formed in circulation or in situ in the glomerular basement membrane (GBM). Classic experimental studies in the acute (one-shot) (1, 2) and chronic serum sickness (3) have demonstrated that glomerular deposition of circulating immune complexes depend on the size of the complexes (300–500 kDa, on antigen load and the intensity of the antibody response (antigen/antibody ratio). The development of the glomerular inflammation and severity, as well as the progression to chronic renal lesions depends, on a large measure, on the duration of antigen exposure and the host's capacity to remove the deposited complexes. In situ formation of immune complexes result from the deposition of the antigen in the GBM and its penetration to the epithelial side of the GBM where is met by the corresponding antibody to form immune complexes that present a characteristic subepithelial electron dense deposits. In situ formation of immune complexes occur in conditions of antigen excess and are typical of cationic antigens that have electrostatic charge-facilitated penetration of the polyanionic GBM (4).

Immune complexes may be predominantly located in the mesangium or in the GBM or in both and by immunofluorescence the imunoglobulin deposition is of the granular (not linear) type. When heavy, these deposits in the GBM have a garland appearance (5) and are usually associated with heavy proteinuria, while mesangial deposits with speckled appearance are usually associated with only mild-to-moderate proteinuria and with features of the acute nephritic syndrome.

Acute Poststeptococcal Glomerulonephritis

Dark urine and suppression of urine output was a feared complication of the convalescent period of scarlet fever recorded in the medical literature more than six centuries ago (6). The findings that acute glomerulonephritis followed streptococcal upper respiratory and skin infections (7–9) clarified the etiology of the disease as acute poststreptococcal glomerulonephritis (APSGN) and the seminal theoretical contribution of Clemens von Pirquet (reviewed in 10), attributing APSGN to antigen-antibody complexes of nephritogenic potential defined the pathogenesis of this condition and opened the era of immune complex-mediated diseases.

Epidemiology

APSGN may occur in sporadic cases or in epidemic outbreaks. Usually the cases occur in communities that are poor, with deficient hygienic conditions and with uneasy access to opportune medical care. Epidemic outbreaks tend to appear periodically in closed populations as the Red Lake Indian Reservation in Minnesota and in specific areas in less developed countries as Port of Spain in Trinidad and in Maracaibo, Venezuela. The risk of nephritis in epidemics range from 5% in throat infections, to as high as 25% in pyoderma caused by M type 49 streptococci.

© Springer-Verlag Berlin Heidelberg 2008

In recent years the epidemiology of APSGN has changed along with a decline in its incidence worldwide and particularly in industrialized countries where the disease now is associated with debilitating conditions such as alcoholism or diabetes (11). In under privileged communities the most recent epidemic have been caused by *Streptococcus zooepidemicus* and associated with the consumption of unpasteurized milk from cows with mastitis (12).

The reduction in the incidence of APSGN is attributed to a variety of factors, including easier and earlier access to competent medical treatment of streptococcal infections and the widespread use of fluorination of water since virulence factors in *Streptococcus pyogenes* are reduced with fluoride exposure (13). Despite the lower incidence of the disease, endocapillary glomerulonephritis of demonstrated or assumed poststreptococcal etiology is the most common histological presentation of primary renal disease in most countries in the underdeveloped world. In these countries the global burden of APSGN continues to be significant. Two recent studies (14, 15) have calculated the global burden of APSGN and came to almost similar conclusions, with lower estimates of 9.3–9.8 cases per 100.000 population per year in underdeveloped countries and higher estimates that could be as high as three times these values. Furthermore, clusters of cases are more frequently reported in poor communities in industrialized countries while epidemics of more than 100 cases are reported from countries in the middle range of Human Development Index and a mean annual health expenditure per capita of about 550 $US (15).

Pathogenesis

Streptococcal Antigens and Immune Reactivity

APSGN has an immune complex pathogenesis. The identity of nephritogenic antigens has been the subject of considerable investigation and controversy. Specific M proteins in group A streptococci were initially considered "nephritogenic," a notion that originated from the observation that group A streptococcal infections could cause rheumatic fever (rheumatogenic streptococci) or glomerulonephritis but only exceptionally both (16, 17). Studies in epidemics revealed that APSGN was associated with pyodermitis due to Group A streptococci of M types 47, 49, 55 and 55 and with upper respiratory infections due to streptococci of M types 1, 2, 4 and 12. However, more recently it has been found that glomerulonephritis may result from group C streptococci, as noted earlier making thus evident that antigenic fractions capable of causing nephritis are shared by a large variety of streptococci.

While M proteins were initially investigated extensively, more recent research has focused in two antigenic fractions: the so-called nephritis associated plasmin receptor (NAPlr), identified as glyceraldehyde 3-phosphate dehydrogenase (GAPDH) and the streptococcal pyrogenic exotoxin (erythrotoxin) B (SPEB) and its zymogen precursor (zSPEB). The characteristics of these fractions and their nephritogenic potential have been reviewed recently (15). NAPlr as well as SPEB have been identified in early biopsies and elicit antibody response that may be detected in the vast majority convalescent sera. The frequency of the antibody response to SPEB/zSPEB has resulted in optimum ROC curves and the best antistreptococcal antibody response for the purposes of identifying a potentially nephritogenic infection (18). In a recent study, back-to-back testing of both these fractions in renal biopsies of APSGN patients and convalescent sera indicated that in the population of patients tested, antibody response to and glomerular deposits of SPEB were frequent while NAPlr were unusual (19). The discordant results may be due to the role of host-related factors in the development of APSGN since NAPlr studies were done in a relatively homogenous Japanese population while the SPEB studies were done in populations of patients in Latin America and Europe. In fact, studies in biopsies of Japanese patients did demonstrate the deposits of both putative nephritogens (15).

SPEB is co-localized in the glomeruli with complement and Ig deposits and is the only streptococcal antigen that has been localized within the electron dense subepithelial deposits (humps) (19) that are characteristic of APSGN and the cationic (pk > 8.0) nature of this component favors the penetration of the anionic barrier in the GBM. The nephritogenic potential of the NAPlr may reside in its plasmin binding characteristics since it is not co-localized with either Ig or complement (20, 21) and, in fact this characteristic is shared by both NAPlr and SPEB (15). Increased plasmin binding may promote the local inflammatory reactivity and facilitate the penetration of nephritogenic antigen-antibody complexes.

Finally, the possibility that more than one streptococcal antigen is nephritogenic was recently emphasized by the demonstration that the gene encoding for SPEB was absent in the *S. zooepidemicus* causing the recent APSGN epidemic in Brazil which would indicate that this antigen was not involved in this epidemic (12).

Immune complexes formed against nephritogenic streptococcal antigen(s) may be formed in circulation,

and deposited in the glomeruli, or formed in situ against antigenic fractions planted in the glomeruli. The relevance of the circulating immune complex mechanism derives from the classic experiments of the glomerulonephritis in acute serum sickness; however, glomerular deposition of free antigen and in-situ immune complex formation has been more recently proposed as an important pathogenetic mechanism in APSGN. Such a mechanism would easily explain the formation of subepithelial electron dense deposits (humps) which are extremely difficult to produce by the injection of preformed immune complexes and are, in contrast, the rule with the injection of cationic antigens (4). Since the existence of a large number of humps in biopsies is associated with heavy proteinuria and worse prognosis (see later), the in-situ mechanism may have significant clinical relevance.

APSGN results from the inflammatory reactivity induced by the immune complexes involving complement activation. Complement activation occurs preferentially by the alternate pathway. Ig-binding proteins in streptococcal surface interfere with the classical pathway of complement activation (22, 23). Recent studies suggest that complement regulatory proteins that play a role in protecting streptococci may be removed by SPEB. Recent investigations have shown that the lectin pathway of complement may also be activated in APSGN by the recognition of glucosamine residues (24).

In addition to humoral immunity, cell-mediated mechanisms are also involved in the development of APSGN. Glomerular infiltration of lymphocytes and macrophages has long been recognized as a feature of the disease (25). Intercellular leukocyte adhesion molecules, such as ICAM-1 and LFA are over expressed in glomeruli and tubulointerstitial regions and correlated with the intensity of the inflammatory infiltration (26).

Autoimmune Reactivity

A number of autoimmune findings have been reported in APSGN (reviewed in 15). Among them, anti-IgG reactivity is the best studied. Cryoglobulins are high titers of rheumatoid factor are present in about two-third of the patients in the first week of the disease; furthermore, anti-IgG glomerular deposits are frequently found in biopsies (see later) and anti-IgG reactivity has been documented in the IgG eluted from the kidney in a fatal case of the disease. The anti-IgG reactivity may be the result of autoantigenic modification of Ig that occurs with its desialization caused by streptococcal neuraminidase. This possibility was raised by experimental studies showing that injection of neuraminidase-treated autologus IgG causes the appearance of anti-IgG reactivity and received support from the demonstration of plasma neuraminidase activity and increased free sialic acid levels in patients with APSGN. Another potential cause of anti-Ig reactivity is the binding of IgG to type II receptors in the streptococcal wall. Anti-IgG reactivity is a constant feature of injections of streptococci cultured in a medium with autologous serum.

Additional autoimmune phenomena have been found in APSGN patients. Anti-DNA antibodies, antiCiq antibodies and anti-neutrophil cytoplasmic antibodies (ANCA) are present in some patients. Interestingly, the later has been found in two-third of the patients with azotemia and 70% of the patients with APSGN that develop crescentic glomerulonephritis (27).

Cytokines and Chemokines

The pathogenetic importance of cellular immune mechanisms was suggested by early studies that demonstrated lymphocyte and macrophage infiltration in renal biopsies of patients with the disease (28). The infiltration of immunocompetent cells is facilitated by overexpression of intercellular adhesion molecules ICAM-1 and LFA-1 in APSGN (29). Cytokine and chemokine production is a central process in damage induced by immune cells. IL-6 plays an important role in proliferative glomerulonephritis (30) and one of the putative nephritogenic antigens, SPEB, induces increased production of IL-6 and proliferation on mesangial cells (31). Mezzano et al. (32) have shown that glomerular IL-8 correlates with neutrophil infiltration and transforming growth factor – β with mesangial expansion and Yokohama et al. (33) found a direct correlation between serum TNFα levels and glomerular ICAM-1 expression.

Clinical Characteristics

Children from 4 to 14 years are more frequently affected by APSGN. It is rare below the age of 2 and above the age of 20 and is twice more frequent in males than in females. The usual sites of antecedent infection are the skin and the throat, although any location of streptococcal infection is possible. The latent period between infection and nephritis is longer after skin infections (3–5 weeks) than after upper respiratory infections (7–15 days). During the latent period asymptomatic children may have microscopic hematuria.

ASPGN may have subclinical course or may present with the acute nephritic syndrome, and more rarely with

nephrotic syndrome or, exceptionally, with a rapidly progressive (crescentic) glomerulonephritis (34). Subclinical disease is characterized by a reduction of serum complement, microscopic hematuria and normal or increased blood pressure in asymptomatic patients. In epidemic conditions occurs 1.5 times more frequently than clinically apparent disease (35). Prospective studies in household members of index cases have shown that in non-epidemic situations the patients without symptoms are 4–5 times more frequent than symptomatic patients (36, 37).

The most typical clinical picture in APSGN is the acute nephritic syndrome (hematuria, edema, hypertension and moderate proteinuria). *Glomerular hematuria* is an almost universal finding and gross hematuria is present in one-third of the patients. The absence of red cells in the urine is usually due to delays in the examination of the urinary sediment since red cells are rapidly destroyed, especially in alkaline urine. As a rule, red cell casts are present in association with dysmorphic of red cells, frequently presenting doughnut shape with one or more blebs. Macroscopic hematuria usually disappears after a few days but microscopic hematuria may persist for a year and occasionally exacerbates during febrile episodes and more rarely after strenuous exercise. *Edema* is the chief complaint more frequently in children (90%) than in adult patients (75%). Younger children tend to have more often anasarca than adolescents or adult patients but ascities is uncommon, except in the cases with nephrotic syndrome. *Hypertension* is present in 60–80% of the children and is severe enough to require specific antihypertensive treatment in about half of the cases. Edema and hypertension typically disappear in 5–10 days. *Oliguria* is referred on admission by the patient or their family in less than half of the patients. Other nonspecific symptoms include general malaise, weakness, headache, dull lumbar pain and nausea.

Massive proteinuria with or without other features of the nephrotic syndrome are found in about 2–4% of the cases and its persistence is a risk factor for progression to chronic renal disease. *Azotemia* occurs in 25–30% of the patients but the need of dialysis is infrequent. A rapidly progressive azotemia occurs in less than 0.5% of the cases and when present is due to the development of crescentic glomerulonephritis.

Pathophysiology of the Acute Nephritic Syndrome

The acute nephritic syndrome results from the reduction of the glomerular filtration rate caused by the inflammatory reaction in the glomeruli. The renal blood flow it is usually normal and therefore the filtration fraction is depressed, frequently below 1%. The reabsorption is appropriately reduced in the proximal tubule and assumed to be maintained at the distal areas of the kidney inaccessible to micropuncture. While the reduction in glomerular filtration has long been assigned a central role in the fluid retention in acute glomerulonephritis, the participation of additional more distal factors that remain undefined is required. It is obvious that the reduction of glomerular filtration is a feature of renal conditions that are not necessarily associated with fluid retention and, conversely, severe fluid retention may some times occur in association with mild reduction in glomerular filtration rate. Potential influences that may modulate sodium and fluid retention at more distal levels are endothelial or mesangial factors released by glomerular injury (38), overexpression of the epithelial sodium channel (39) and interstitial inflammatory cells capable of maintaining an increased intrarenal angiotensin activity (40). At any rate, the net result of the hemodynamic changes in glomeruli and tubules is a tendency to sodium and water retention that results in expansion of the extracellular volume, edema and hypertension. The potential additional effects of hypoalbuminemia are not present in the acute nephritc syndrome and, accordingly, the plasma levels of hormones that regulate the extracellular volume (renin-angiotensin, aldosterone and atrial natriuretic peptide) show an appropriate response for an expanded extracellular volume. The suppression of plasma renin activity and aldosterone and the stimulation of atrial natriuretic peptide are correlated with the severity of edema. Renal prostaglandin and kallikrein activities are suppressed (reviewed in 41). In accordance with this pathophysiology, the improvement of volume retention with the development of spontaneous or induced diuresis results in a prompt reduction of the edema and correction of the hypertension.

Serological Findings

The most constant serological finding is the reduction in serum complement levels that occurs in more than 90% of the cases. The activation of the complement system is usually via the alternative complement pathway and reduced C3 with normal C1 and C4, but, as mentioned earlier, the classic pathway and the lectin pathways of complement activation may also be engaged. There are no clinical characteristics associated to a specific complement activation modality and complement levels return to normal usually within one month of the development

of acute glomerulonephritis. IgG and IgM serum levels are elevated 80–90% of the patients with APSGN.

Rising antistreptococcal antibody titers are the usual clinical indication of a preceding streptococcal infection since positive cultures are obtained in only 20–25% of the cases, except during epidemics. Anti-zSPEB/SPEB serum titers have been found to be the best markers of nefritogenic streptococcal infections in multicentric studies in LatinAmerica (18), but these tests are not generally available. Antistreptolysin O titers and anti-DNAse B titers are the most frequently elevated antibody titers after streptococcal throat infections and after streptococcal impetigo, respectively. Two-thirds of the patients with APSGN in the first week of the disease present cryoglobulins and elevated IgG-antiIgG rheumatoid factor titers (41).

Pathology

Renal biopsy is usually not done in patients with APSGN with well defined clinical picture. Biopsy is indicated when specific features raise the possibility of a different diagnosis. For instance, if the serum complement is normal a biopsy may define if the acute nephritic syndrome has a different etiology, such as IgA nephropathy and if the serum complement remains low after one month the biopsy may help to rule out hypocomplementemic mesangiocapillary glomerulonephritis or lupus nephritis. In patients with proteinuria in the nephrotic range a biopsy may serve to confirm the diagnosis of APSGN and to raise awareness of a worse long-term prognosis. Finally, if the patient has a rising serum creatinine, the diagnosis of crescentic glomerulonephritis needs biopsy confirmation. Biopsy findings in APSGN are those of endocapillary proliferative glomerulonephritis. Glomerular basement membrane is normal. Macrophages and lymphocytes can be found in increased numbers in the glomeruli and in tubulointerstitial areas but the more remarkable histologic characteristics are found in the glomeruli that present a diffuse increment in cellularity. Occasionally, the glomeruli presents abundant infiltration of polymorphopnuclear neutrophils, a characteristic that has been named exudative glomerulonephritis.

Glomerular immune deposits C3, IgG and IgM and less frequently anti-IgG are usually present and they may be demonstrated in the mesangium and in the glomerular basement membrane. The immunofluorescent appearance of this deposits have been described by Sorger et al. (5) as resembling a starry sky (discrete mesangial and basement membrane deposits, usually of complement) or in more thick deposits in he mesangium (mesangial form) or forming heavy, garland-like deposits in the basement membrane. The garland form is clinically important because it associates with heavy proteinuria, numerous subepithelial electron-dense deposits and worse long-term prognosis (36, 42). Recent studies have co-localized SPEB deposits with complement and IgG and NAPlr with plasmin activity in the glomeruli. Electron microscopic studies reveal the hallmark lesion of APSGN, the subepithelial "humps" that represent subepithelial immune complex deposition. Immune electron microscopy has permitted to demonstrate IgG, C3 and SPEB within the subepithelial humps (19). It should be noted that this characteristic lesion is not pathognomonic of APSGN since it may also be found in other immune complex glomerulonephritis, notably lupus nephritis.

The resolution of the proliferative changes is by apoptosis and the number of apoptotic cells has a direct relationship with the number of proliferating cells (43). Prolonged oliguria or oligoanuria has been associated with mesangiolysis (44).

Follow-up studies performed several years after the initial episode of acute poststreptococcal glomerulonephritis, have revealed immune deposits and a variable degree of mesangial sclerosis and obliteration, even in the absence of clinical manifestations of renal disease (45).

Figure 30-1 shows the typical histopathologic, immunohistologic and electron microscopic characteristics of APSGN.

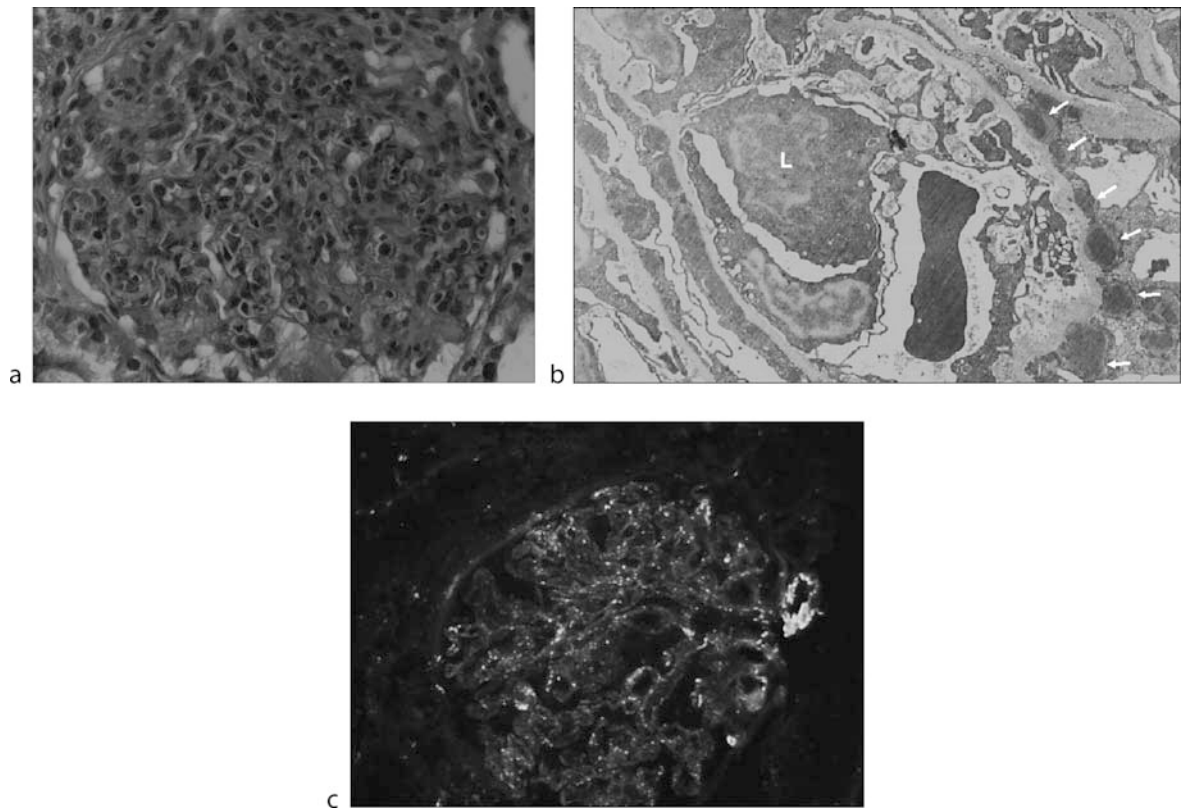
Diagnosis

The clinical presentation is that of a child of 4–15 years who suddenly develops dark and scanty urine and swelling of the face and legs. History and physical examination determines a high blood pressure and the absence of a systemic illness.

The diagnosis of glomerulonephritis should prompt to establish an etiological diagnosis. A history of a precedent upper respiratory infection and/or skin infections suggests a poststreptococcal etiology that maybe confirmed by a positive culture or rising anti-streptococcal antibody titers. Positive streptococcal cultures are frequent in epidemic conditions but in less than 25% of the sporadic cases. Consequently, the evidence of previous streptococcal infection usually resides in the demonstration of a rising titer of serum antistreptococcal antibodies. Anti-NAPlr and antiSPEB-zSPEB titers that have a greater specificity for nephritogenic infections (18) but are not generally available. Antistreptolysin O titers and

Figure 30-1

(b) Inmunofluorescence micrograph of a glomerulus from a patient with acute poststreptococcal glomerulonephritis showing coarsely granular capillary wall staining for C3. (FITC anti-C3, × 200) (c) Electron micrograph of a portion of a glomerular capillary from a patient with acute poststreptococcal glomerulonephritis showing subepithelial dense deposits, so called "humps" (*arrows*), and a luminal leukocyte (L) (magnification × 4,000). (See color plate 11)



anti-DNAse B titers are the most frequently elevated in upper respiratory infections and pyodermitis, respectively. Streptozyme test which includes four antigens (DNAse B, Streptolysin O, hyaluronidase and streptokinase) is reported to be positive in more than 80% of the cases.

The initial diagnostic approach should attempt to define if the acute nephritic syndrome is associated with a systemic condition or if is resulting from a primary renal disease. The complement is a first line diagnostic test that permits consideration of acute glomerulonephritides that present low complement (APSGN, Lupus nephritis, shunt nephritis, endocarditis, cryoglobulinemia, hipocomplementemic membranoproliferative glomerulonephritis) and those that present normal complement (IgA nephropathy, Mesangioproliferative GN, hemolytic uremic syndrome, Henoch-Schoenlein purpura, vasculitis, anti gomerular basement disease). The finding of profoundly depressed C4 levels in association with normal or mildly reduced C3, suggests the diagnosis of cryoglobulinemia type II and the reduction of C1, C4 and C3 levels, indicating activation of the classic pathway of complement, is characteristic of lupus erythematosus. Serum complement levels return to normal in less than 1 month and persistence of low complement levels should raise suspicion of a diagnosis different from APSGN.

Physical findings suggestive of nephrotic, rather than nephritic, are a soft, paper-like consistency of the ear cartilage and the existence of ascites, since both these signs are associated with long standing hypoalbuminemia.

Inasmuch as the nephrotic syndrome is rare in APSGN the demonstration of a massive proteinuria favors the diagnosis of lupus nephritis, nephritis associated with visceral abscesses and membranoproliferative glomerulonephritis.

Treatment

Antibiotic treatment. The first question to be considered is when to give antibiotic treatment to a suspected nephritogenic streptococcal infection. From a clinical view point, the diagnosis of active skin infection is usually straight forward. However, clinical judgment may miss half of the streptococal pharyngitis and may incorrectly diagnose a sore throat as due to streptococcal infection in 20–40% of the cases (46). Several clinical scores have been proposed to increase the accuracy of this diagnosis and among the most popular of them is the one proposed by McIsaac et al. (47). This score has a range from 0 to 4 and incorporates age as one of the criteria. The score gives a +1 to each one of the following: temperature >38°C, cervical adenopathy, no cough, tonsillar exudate and age between 3 and 14 years. Age > 44 years is assigned −1 point. Sensitivity and specificity of the score is 85 and 95%, respectively. Antibiotic treatment is recommended (without culture confirmation) when the score is 4, and antibiotic treatment is not indicated (and cultures unnecessary) when scores are 0–1.

Rapid, high sensitivity streptococcal test are good guide to treat if they are positive but a negative test requires confirmation (48). However, a recent report indicates that a decision to treat or not to treat based on the results of these tests is not associated with a higher incidence of poststreptococcal complication (49). The diagnosis of PSGN carries with it the indication of treatment with penicillin or, in allergic individuals, erythromycin. If infection is present at the time of diagnosis, it requires treatment. Early administration of penicillin is reported to prevent or ameliorate the severity of acute glomerulonephritis and at least one report suggests that APSGN patients that receive antibiotic treatment have a milder clinical course (50). If infection is not apparent at the time of diagnosis, antibiotic treatment should be given anyway because positive cultures are sometimes obtained in apparently healthy patients and cross infection of household members and siblings of index cases is very high (37). 1.2 million units of units of benzathine penicillin in adults or half this dose in small children, or alternatively, oral phenoxymethyl or phenoxyethyl penicillin G 125 mg, every 6 h for 7–10 days, are adequate treatment. Erithromycin (250 mg every 6 h in adults, and 40 mg/kg in children, for 7–10 days) is the treatment of choice in patients allergic to penicillin. It should be noted that the existence of erythromycin-resistant strains may be increasing in developing countries. The incidence of resistance to erythromycin in isolates of Streptococcus pyogenes is 9.7% in Japan (51), 21.7% in Spain (52) and ranges from 6.8% in the United States (53) to 11.6% in bacterial isolates from several European countries (54).

Preventive antibiotic treatment is indicated in epidemic situations and to household members of index cases in non-epidemic conditions since most of them present evidence of recent infection and about one-third of them develop nephritis (35, 41). In high risk communities the strategy of treating household contacts has resulted in a decrease in the number of cases of PSGN (55).

Treatment of the Acute Nephritic Syndrome

Patients with subclinical disease maybe followed as outpatients but patients with the acute nephritic syndrome require hospitalization. Bed rest is difficult to enforce and is of unproven value, yet most children keep it on their own while they are in the acute phase. Restrictions of fluid and sodium intake are the cornerstones of the treatment of patients with he acute nephritic syndrome. Cases that present significant edema, hypertension and circulatory congestion benefit from the administration of loop diuretics (40 mg IV or orally every 12 h). This therapy facilitates the resolution of edema and ameliorates the hypertension that is driven by extracellular volume expansion. Diuretic therapy seldom if ever is required for longer than 48 h. Other diuretics are without effect (thiazide diuretics) or dangerous because of the possibility of hyperkalemia (aldosterone antagonists).

Patients who present severe hypertension may require antihypertensive treatment and Nifedipine (5 mg in children, every 4–6 h) is usually effective. Parenteral hydralazine may be required but the possibility of tachycardia requires close observation. Angiotensin converting enzyme inhibitors and type 1 receptor blockers carry the risk of hyperkalemia. Exceptionally, nitroprusside is required to control hypertensive encephalopathy.

Another potential complication, frequently associated with hypertension is the posterior reversible leukoencephalopathy that has recently been reported in acute PSGN (56). This complication is manifested clinically with mental disturbances, visual hallucinations, headache and convulsions and may be confused with hypertensive

encephalopathy. The diagnosis requires the use of nuclear magnetic resonance image studies.

Pulmonary edema is rare and should be treated with oxygen therapy, rotating tourniquets and loop diuretics Digitalis is not indicated because is ineffective and may result in intoxication. Rarely overt heart failure and pulmonary edema may complicate the clinical course. Hemodialysis or peritoneal dialysis may be required occasionally in children for the treatment of hiperkalemia, uremia or severe circulatory congestion.

A rapidly progressive azotemia is usually associated with crescentic APSGN. While of unproven efficacy, there are anecdotal reports of beneficial effects of pulse methyprednisolone therapy.

Prognosis of APSGN

The short term prognosis of APSGN is excellent in children. Fatalities may occur as a result of hyperkalemia or pulmonary edema, but they are exceedingly rare. The long term prognosis of APSGN has been the subject of many reports since the initial studies in the first half of the twentieth century reported essentially a complete recovery, but the follow-up periods were short and the patients were only children in the majority of the studies. Subsequent observations gave widely different results and abnormal urinary findings in patients followed for extended periods of time ranged from 3.5% (57) to 60% (58). As recently summarized (15), APSGN followed for 10–20 years present frequently abnormal urine analysis (20%) but azotemia occurs in less than 1% of the patients. In our own follow-up studies (28) of 110 children followed for 15–18 years after the acute attack, non-nephrotic proteinuria was found in 7.2%, microhematuria in 5.4%. hypertension in 3.0% and azotemia in 0.9%. Studies in Australian aboriginal communities indicate that patients who had APSGN have an increased risk for albuminuria (adjusted odds ratio 6.1, 95% CI 2.2–16.9) and hematuria (OR 3.7, CI 1.8–8.0) in relation to controls that did not have APSGN (15).

The long-term prognosis of children of APSGN may be significantly worse in communities were other risk factors of chronic renal failure are prevalent. The superimposition of APSGN on other conditions such as diabetes and metabolic syndrome have been postulated to play a role on the high incidence of end stage renal disease in some aboriginal communities in Northern Australia (59).

The long term prognosis of APSGN is substantially worse in adults, particularly those with persistent proteinuria in the nephrotic range: 77% of these patients may develop chronic renal failure. Unfavorable course was also observed in the patients in the Nova Serrana epidemic, most of whom were adults. Chronic renal failure developed in 8% of these patients after 5 years (60).

Renal Disease Associated with Infective Endocarditis

Almost a century ago Max Friedererich Lohlein and George Baehr described focal, embolic, non suppurative glomerulonephritis caused by bacterial endocarditis. Subsequent descriptions two decades ago emphasized the immune complex pathogenesis causing diffuse glomerulonephritis (61, 62) and more recent studies have disclosed that the most common renal lesions associated with bacterial endocarditis are localized infarcts and vasculitic glomerulonephritis (without demonstrable immune complex deposits) and interstitial nephritis (63). Approximately 15,000 new cases of IE occur in the United States each year (64). In the United States and Western Europe the incidence of community acquired native-valve endocarditis is essentially unchanged at 1.7–6.2 cases per 100,000 person years (65) but there has been a decline in the proportion of cases associated with rheumatic heart disease and an increase cases associated with valve surgery (66). The most important epidemiological change in recent years has been the increment in cases associated with health care interventions and, particularly, the cases associated with hemodialysis and those caused by staphylococcus. Bacterial endocarditis is 20–60 times more common in hemodialysis patients than in the general population (67).

Etiology and Pathogenesis

The most common infecting bacteria are *Staphylococcus aureus,* and *S. epidermidis*, *Streptococcus viridans and pyogenes*, *Enterococcus fecalis* and less commonly *E. Coli, Proteus*, microorganisms of the *Bartonella* and *Candida* species. When an immune complex pathogenesis is involved, bacterial antigens may be demonstrated in the glomeruli (68) and the nephritogenic mechanisms are similar to those operating in APSGN. Polyclonal (type III) cryoglobulinemia may be found in roughly half of he patients. In addition, supernatigen-driven T cell activation with polyclonal gammopathy may occur in infections caused by methicillin-resistant *Staphylococcus aureus* (69, 70).

Microembolization is responsible for the localized infarcts and tubulointerstitial nephritis is usually secondary to antibiotic treatment. In the patients in hemodialysis

programs, the original infection is usually related to the vascular access. Calcifications of heart valves are significant risk factors and treatment directed to reduce the risk of ectopic calcification are important preventive measures of IE (71).

Clinical Characteristics

The classic clinical picture of subacute bacterial endocarditis include Osler's nodules, Janeway lesions and splinter hemorrhages; however, these findings are rare at the present time. Fever may be the only manifestation, accompanied or not with arthralgias, leukocytosis, increased sedimentation rate and purpura. Patients in hemodialysis who develop infective endocarditis usually have synthetic arteriovenous grafts or venous dialysis catheters and had the vascular access in place for more than 1 year (72, 73).

The cardiac lesion is best demonstrated by transesophageal echocardiography. Factors usually associated with higher mortality are a vegetation size ≥ 20 mm, age lower than 1 year, the existence of heart failure and *Staphylococcus aureus* as a causative organism (74). Embolization to the central nervous system with stroke may occur in 6% of the children; mortality is rare but recovery is variable (75). Systemic embolism maybe microscopic or large; the latter usually correspond to endocarditis caused by fungus or *Haemophilus*.

Microscopic hematuria and proteinuria are indicative of renal lesion. Azotemia may develop in one-third of the patients (76) but is usually mild except in cases that develop crescentic glomerulonephritis. Eosinophilia and eosinophiluria should rise the suspicion of antibiotic induced interstitial nephritis.

Serological findings include reduced C3 and C4 (except in superantigen mediated nephritis), high titers of rheumatoid factor, cryoglobulinemia (66, 77) and, on occasion positive anti-PR3 ANCA antibodies in the serum (78). The later finding in a patient suspected of having vasculitis has been considered an indication to rule out infective endocarditis (79).

Treatment

Antibiotic treatment needs to be given for 4–6 weeks (80). Urinary findings usually persist for weeks or months after eradication of the infection. The complement levels return to normal after the infection has been eradicated and this finding is associated with good prognosis of the renal lesion.

In patients who present crescentic glomerulonephritis and rapidly progressive course, pulse steroid therapy and plasmapheresis have been used with success but their overall value needs to be confirmed in more definite studies.

Pathology

In a retrospective study of 62 patients with infective endocarditis in whom renal tissue was available for evaluation (20 patients with renal biopsy and 42 autopsy specimens), the most common lesion were localized infarcts in 30% and glomerulonephritis was found in 26%. More than half of the infarcts were due to septic emboli, especially in patients with *S. aureus* endocarditis (63). Rather than focal or diffuse glomerulonephritis the authors (63) emphasize that lesions are of the vasculitis type without immunoglobulin deposition and proliferative or type I membranoproliferative glomerulonephritis with immunoglobulin (usually IgM) and complement deposition.

Glomerulonephritis may be present with subendothelial and subepithelial deposits. Crescent formation maybe found in about half of the proliferative glomerulonephritis. Electron dense deposits in subendothelial, mesangial and subepithelial locations are frequent in subacute forms of infective endocarditis.

Tubulointerstitial lesions are frequent in renal biopsies and they may be part of the glomerulonephritis, vasculitis or the microemboli in the nephropathy of infective endocarditis or result from the treatment with nephrotoxic agents. "Pure" interstitial nephritis may be found in 10% of the renal biopsies in recent retrospective studies and is characterized by inflammatory infiltrate with variable degrees of tubular dilatation and atrophy. If these findings are associated with eosinophilic infiltration, the interstitial nephritis is likely related to antibiotic therapy Cortical necrosis was present in 10% of the cases and all of them in autopsy material (63).

Shunt Nephritis

Infection develops in about one-third of the patients with vetriculoatrial (VA) and ventriculoperitoneal (VP) shunts used for amelioration of intracranial pressure in congenital or acquired hydrocephalus (81). The development of nephrotic syndrome in a patient with infected ventriculoatrial (VA) shunt used for the treatment of hydrocephalus was first described by Black et al. in 1965 (82) and is now recognized that this complication develops on 0.7–2% of the infected VA shunts.

The infecting microorganisms are *S. epidermidis* in about 75% of the cases in most series (70) and less frequently *Staphilococcus aureus*. More rarely *Propionibacterium acne*, diphtheroids, *Pseudomonas* and *Serratia* species are the infecting organisms. The renal complication occurs in a period of time that ranges from 2 months to many years after the shunt insertion (81). In contrast with VA shunts, VP shunts are rarely complicated with glomerulonephritis.

The clinical manifestations are recurrent episodes of fever, anemia, hepatosplenomegaly, skin rash and cerebral symptoms related to increased intracraneal pressure. Renal involvement is indicated by proteinuria, in most cases in the nephrotic range, and at times with a full nephrotic syndrome, hematuria, and hypertension. The combination of skin and renal manifestation may lead to the incorrect diagnosis of Henoch-Schönlein purpura and the possible association of a urinary tract infection frequently accompanying a neurogenic bladder may complicate the interpretation of the urinary findings. Serological findings include reduced C3 and C4 levels, indicating activation of he classic complement pathway, cryoglobulinemia, anemia, elevated sedimentation rate and high rheumatoid factor titers. Serum P3 ANCA titers are sometimes present.

The renal lesion demonstrated at biopsy is usually membranoproliferative glomerulonephritis. Deposits of complement and IgM are almost always present and IgG in about two-thirds of the cases (81). Electron microscopy reveals electron dense deposits in the subendothelial and mesangial regions (83). Bacterial antigens have been demonstrated in the glomeruli of patients with shunt nephritis (84, 85).

Treatment of shunt nephritis requires intravenous antibiotic therapy and removal of the infected shunt and, if possible, substituting it for a VP shunt. Rarely, if ever, are antibiotics alone capable of eliminating the infection. The long-term prognosis of the renal function is good if the shunt is removed within a few weeks of detecting the infection (81). In cases were the removal of the shunt is delayed the renal damage may progress to irreversible end stage renal failure.

Hemodialysis is the preferred modality in patients with end stage renal disease because peritonitis associated with peritoniteal dialysis carries the risk of meningitis if a VP shunt is in place. Given the high rate of complications in the VA shunts, the VP shunt is the preferred initial procedure but VA shunts may be the selected method in children with chronic renal failure in whom renal transplantation is considered. There are no reports of recurrence of shunt nephritis in the transplanted kidney.

Glomerulonephritis Associated with Other Bacterial Infections

Congenital and acquired syphilis cause glomerulonephritis. Congenital syphilis is usually manifested by rash, rhinitis and osteochondritis, but 8–10% of the patients may develop a full blown nephrotic syndrome that presents as anasarca 4–12 weeks after birth. In acquired syphilis the nephrotic syndrome occurs in less than 1% of the cases and the acute nephritis syndrome is very rare (86). The most common histologic appearance is that of membranous nephropathy and electron microscopy shows electron dense deposits along the glomerular basement membrane (87). Other types of glomerulonephritis, including mesangioproliferative, membranoproliferative and diffuse proliferative glomerulonephritis have been reported, especially in adult patients. Treponema antigens have been demonstrated in the glomerular immune deposits (88). Serological tests for syphilis are positive and complement levels are normal. Treatment of the syphilis is associated with improvement of the renal disease but recovery usually takes several months.

Acute typhoid fever may be associated with overt glomerulonephritis in about 2% of the cases but proteinuria and hematuria may develop in 25% of the patients (89).

Lobar pneumonia caused by *Strep. pneumoniae* has been reported to cause glomerulonephritis usually manifested by proteinuria and hematuria. Pneumococcal antigen type 14 has been localized in the glomeruli and the capsular antigen is capable of activating the alternative complement pathway (90).

Visceral abscesses and osteomielitis may be associated with glomerulonephritis that is usually manifested by the nephrotic syndrome. Complement levels are normal. The histological picture reveals membranoproliferative, diffuse proliferative or mesangial proliferative glomerulonephritis with or without crescent formation. Treatment of the infection, if started early, improves the renal disease (91).

31 Immunoglobulin A Nephropathy

Koichi Nakanishi · Norishige Yoshikawa

Introduction

Immunoglobulin A (IgA) nephropathy was first described in 1968 by Berger and Hinglais (1) and is now recognized as a distinct clinicopathologic entity with a higher frequency worldwide than any other primary glomerulopathy (2). It was initially considered a benign condition, but extended follow-up of patients indicated that 20–50% of adults would ultimately progress to end-stage renal failure (2, 3). Likewise, the favorable prognosis initially attributed to children with IgA nephropathy must be questioned in the light of studies (4–8).

Epidemiology

IgA nephropathy has been diagnosed all over the world, but its prevalence varies widely from one country to another. In the Pacific Rim (e.g., Japan, Singapore, Australia and New Zealand), IgA nephropathy accounts for as many as one-half of cases of primary glomerulonephritis. In Europe, it accounts for between 20 and 30% of all primary glomerulonephritis, whereas in North America, it is responsible for only 2–10%. The explanation for this apparent variability in incidence is uncertain, but it may be due to a racial difference in the incidence of IgA nephropathy or to differences in biopsy selection practices (9).

Genetic factors and environmental influences could contribute to geographic differences in prevalence. A lower prevalence among blacks than whites has been reported in the United States. However, in American children, similar incidences of IgA nephropathy in Caucasian and African-American children from Shelby County, Tennessee have been reported (10). In Australia (11), where the population is heterogeneous and includes many immigrants from Third World countries, all racial groups seem to be affected equally.

The high incidence of IgA nephropathy in certain countries may reflect the practice of routine urinalysis. In Japan, all children between the ages of 6 and 18 years are screened annually, and those found to have urinary abnormalities are referred for further investigation. Thus, IgA nephropathy is the most common primary glomerulonephritis in children seen in Kobe University and Wakayama Medical University Hospitals, detected in approximately 30% of biopsy specimens obtained. This periodic screening of urine of healthy populations and subsequent investigation of those found to have abnormalities is also an accepted routine amongst adults in Japan.

Etiology

IgA nephropathy is generally considered to be an immune complex-mediated or aggregated (polymerized) IgA-mediated glomerulonephritis. Because IgA is the main immunoglobulin directed against antigens (viral and bacterial) in the exocrine system, and because of the frequent association between upper respiratory tract or gastrointestinal infection and the onset of macroscopic hematuria, it has been suggested that certain viral or bacterial infections may lead to IgA nephropathy. Considerable effort has been directed towards the search for antigens and for the antibody specificity of the mesangial IgA, but it has met with limited success. Many antigens, including herpes simplex virus, cytomegalovirus, Epstein-Barr virus nuclear antigen, adenovirus and milk antigen, have been identified. The observation of numerous antigenic substances in the glomeruli indicates that the antigenic materials in IgA nephropathy may be heterogeneous. The presence of *Hemophilus parainfluenza* antigens in a diffuse and global distribution in the glomerular mesangium and the presence of IgA antibody against *H. parainfluenza* in sera of Japanese patients with IgA nephropathy have been demonstrated (12, 13). Recently, it has been reported that *Staphylococcus aureus* cell envelope antigen was localized in the glomeruli in 68.1% (79/116) of renal biopsy specimens from patients with IgA nephropathy and that the data confirmed that the antigen was colocalized with IgA antibody in the glomeruli. *Staphylococcus aureus* cell envelope antigen may be a new candidate for the induction of IgA nephropathy (14). These findings remain unconfirmed in children with IgA nephropathy yet.

Predisposing Genetic Factors

Predisposing genetic factors have been suggested as important in the development of IgA nephropathy (15). Moreover, it has been suggested that genetic factors may not only determine susceptibility to glomerulonephritis, but also influence the pathological severity and natural course of IgA nephropathy (16, 17).

Evidence for genetic factors being important in IgA nephropathy is provided by family studies (16–20). Rambausek et al. reported that 9.6% of patients with mesangial IgA nephropathy in Germany had one or more siblings with glomerulonephritis (16). Julian et al. described kindred from eastern Kentucky in which six patients with IgA nephropathy descended from one ancestor and eight other patients belonged to potentially related pedigrees (18). Moreover, they indicated that at least 48 (60%) of 80 IgA nephropathy patients who were born in same region were related to at least one other patient (19). Scolarim et al. reported that 26 (14%) of 185 patients with IgA nephropathy investigated in Italy were related to at least one other patient with the disease (20). These family studies suggest that familial predisposition is a very common finding and genetic factors are influenced in the pathogenesis of IgA nephropathy. Gharavi et al. (21) demonstrated linkage of IgA nephropathy to 6q22–23 under a dominant model of transmission with incomplete penetrance. Further linkage-based approaches to the study of familial forms of the disease have identified significant or suggestive loci on chromosomes 4q26–31, 17q12–22 (22) and 2q36 (23), but no causal gene has yet been identified.

Schena et al. (24) reported that familial IgA nephropathy had a poorer outcome than sporadic IgA nephropathy. This fact means that genetic factors are implicated in both disease susceptibility and disease progression (15). Polymorphisms of Ig heavy-chain switch region gene (25), Iα1 germ-line transcript regulatory region gene (26), genes of the renin angiotensin system (27–29), and platelet activating factor acetylhydrolase gene (30) have been reported. Associations among IgA nephropathy and genetic polymorphisms of other molecules, in which relation to disease susceptibility and disease progression are suggested, have been reported in sequence (31). Although some associations have emerged, they have been inconsistent (32). Some of the discrepancies may be caused by different sample sizes and different geographical regions of the patients included in the studies.

Recently in Japan, single-nucleotide polymorphisms have been screened on a genomewide scale to clarify various complex diseases, including IgA nephropathy. As a part of the benefit of this project, case-control association studies were designed, using single-nucleotide polymorphisms found in the selectin gene (33), the class II region of the major histocompatibility complex (34) and the polymeric immunoglobulin receptor gene (35), and haplotypes of these genes that might serve to identify regions containing loci responsible for IgA nephropathy phenotypes were estimated. Although these studies were conducted in adult patients with IgA nephropathy, these data may be beneficial even to children with IgA nephropathy. Further investigations for these genes in a large-scale number of children with IgA nephropathy are required.

Pathogenesis

Although the pathogenesis of IgA nephropathy remains uncertain, there is substantial evidence that it is an immune complex disease (2, 36). Granular electron-dense deposits are observed in the glomerular mesangial areas by electron microscopy, and confirmed as containing IgA and C3 by immunofluorescence microscopy. Circulating IgA immune complexes have been detected by several different specific assays often associated with IgG immune complex. Many immunological abnormalities that may lead to the formation of IgA immune complex have been reported in patients with IgA nephropathy. Recurrences of IgA nephropathy frequently occur in allografts (37), and a rapid disappearance of glomerular IgA deposits is observed when kidneys with mesangial IgA deposits are transplanted to patients without IgA nephropathy. These clinical observations have provided strong support for the notion that IgA nephropathy is a systemic disease. Although much of this work was performed in adults, there is no evidence to suggest that the findings cannot be extrapolated to children. Moreover, glomerular IgA deposits associated with histological lesions similar to those of human IgA nephropathy can be induced in laboratory animals by passive administration of preformed IgA immune complex or by active immunization (38–42).

Nature of Mesangial Immunoglobulin A Deposits

IgA is the second most common immunoglobulin and contributes to immunity at the level of the external secretory system. IgA exists in monomeric and polymeric forms. Monomeric IgA represents approximately 90% of the serum IgA and is produced mainly by the circulating lymphocytes and plasma cells in the spleen and bone

marrow. Polymeric IgA is produced mostly by lymphocytes and plasma cells in the gastrointestinal and respiratory tracts, where it is synthesized as monomers and then secreted as dimers linked by the J-chain, which is also produced within the plasma cells. During the passage of dimeric IgA molecules through the mucosal epithelium toward the external lumen, the secretory component is attached through specific noncovalent interactions; this component appears to protect the dimeric IgA from the proteolytic enzymes present in the external secretions. IgA has two subclasses, IgA1 and IgA2. Approximately 90% of serum IgA is composed of IgA1 mostly produced in the bone marrow, whereas IgA2 is mostly derived from the local mucosa of the gastrointestinal and respiratory tracts. Both IgA1 and IgA2 are produced in the mucosae.

The most prominent finding in the glomeruli of renal biopsy specimens from patients with IgA nephropathy is mesangial IgA deposition. The majority of investigators has indicated that IgA1 is the predominant subclass present in the glomeruli (43). The J-chain has also been identified in the mesangium in patients with IgA nephropathy (44). Secretory component is not present in the mesangial deposits, but immunofluorescence studies of renal biopsy sections from patients with IgA nephropathy have indicated that it binds to the mesangial areas in vitro (45). These observations suggest that the mesangial IgA deposits are polymeric, a hypothesis further supported by the immunochemical characterization of IgA eluted from renal biopsy sections (46). The onset of IgA nephropathy may be associated with infections in the upper respiratory tract. It has therefore been proposed that IgA nephropathy results from hyperactivity of the mucosal immune system. However, assessment of polymeric IgA1 production by in situ hybridization for J-chain messenger RNA in IgA plasma cells shows downregulation in the mucosa (47) and upregulation in the bone marrow (48). Impaired mucosal IgA responses allowing enhanced antigen challenge to the marrow shown by de Fijter et al. (49) could be the primary abnormality in IgA nephropathy, although this remains unproven (50).

A number of studies have suggested that the alternative complement pathway has a pathogenetic role in IgA nephropathy. This hypothesis is consistent with the typical immunohistologic demonstration of C3 and properdin in a pattern and distribution similar to that of IgA in the glomeruli, in the absence of C1q and C4. The detection of the membrane attack complex of complement further supports the pathogenetic role of complement activation in this disease (51). Certain types of IgA aggregates or IgA from patients with myeloma have been shown to activate complement in vitro (52). IgA has been reported to activate the complement system via the mannan-binding lectin pathway (53). However, there is no direct evidence that IgA deposits in the glomeruli mediate complement activation. Activation of C3 is observed in the majority of adult and pediatric patients with IgA nephropathy, but the mediator as well as the pathophysiologic significance of this complement activation remains to be determined. C3 is deposited in the kidney but is also produced by mesangial cells in IgA nephropathy (54).

With regard to antibody specificity, IgA eluted from cryostat sections of IgA nephropathy biopsies has been reported to react with mesangial areas of its own and other IgA nephropathy patients' biopsies, but not with normal kidney (55). Such eluates have also been shown to contain antibodies that react with tonsillar cells and cultured fibroblasts obtained from patients with IgA nephropathy (56).

Despite intensive investigation, the mechanism underlying glomerular IgA deposition in IgA nephropathy has not been defined. Proposed potential mechanisms on glomerular IgA deposition are as follows. Decreased IgA response to mucosal antigens may promote increased production of polymeric IgA1 by the bone marrow, leading to increased serum levels of IgA1. Defective galactosylation of IgA1 (later described in detail) may decrease hepatic clearance of IgA1 and promote binding of IgA1 complexes to glomerular mesangial cells. Aberrant IgA1 deposits in the kidney trigger the production of a variety of cytokines and growth factors by renal cells and by circulating inflammatory cells, leading to the characteristic histopathological features of mesangial-cell proliferation and extracellular-matrix deposition (57). Recently it has been proposed a model whereby two types of IgA receptors participate in sequential steps to promote the development of IgA nephropathy, with soluble IgA Fc receptor I (FcαRI/CD89) being initially involved in the formation and/or amplification of the size of circulating IgA-immune complexes and, subsequently, mesangial transferrin receptor (CD71), in mediating mesangial deposition of nephritogenic IgA-immune complexes (58–62).

In summary, the immunochemical nature of the mesangial deposits in IgA nephropathy is consistent with antigen-polymeric IgA complexes predominantly of A1 subclass, and perhaps, multispecific for ubiquitous mucosally derived antigens.

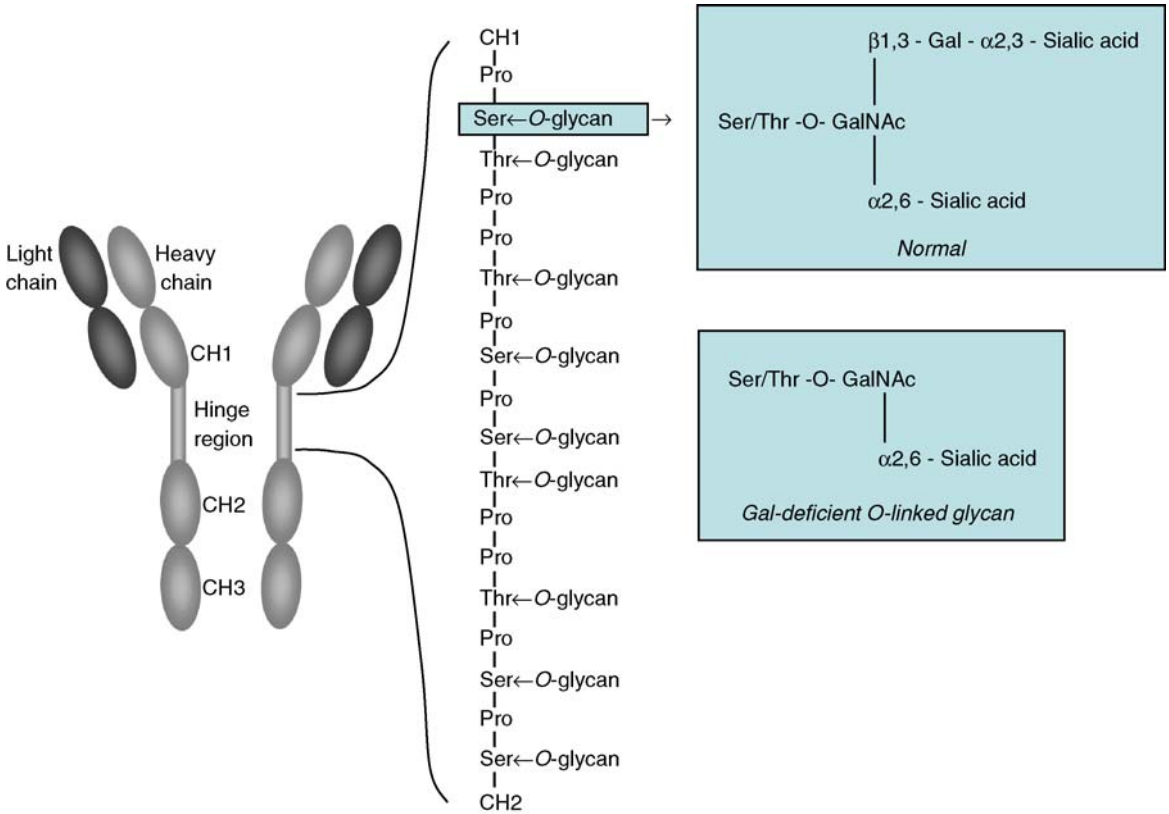
Immunoglobulin A Glycosylation

IgA glycosylation has received recent attention as a putative nonimmune feature of IgA, which may explain its

abnormal behavior and glomerular deposition in IgA nephropathy (63). IgA1 subclass is prominent in IgA nephropathy. IgA1 is unique among all Igs in its possession of a hinge region rich in proline, serine and threonine and characterized by *O*-glycosylation sites (*Fig. 31-1*). These *O*-glycosylation sites consist of *N*-acetylgalactosamine *O*-linked to the serine or threonine residues of hinge region. In patients with IgA nephropathy, mesangial IgA1 and a small fraction of circulating IgA1 contain incompletely galactosylated *O*-linked glycans in the hinge region (64–68). This glycosylation abnormality is absent in other glycoproteins with *O*-linked glycans, such as complement C1 inhibitor and IgD, indicating a defect specific for IgA1 (66, 69). Abnormal galactosylated IgA1 increases affinity for glomerular fibronectin, laminin and collagen IV (70) and may lead to accumulation of IgA in the mesangium (67). Preliminary data indicate that deficient galactosylation of hinge region glycans may be detected even in family members of patients with IgA nephropathy (64). Altered amino-acid sequence of the IgA1 hinge region is a possible mechanism to consider for abnormal galactosylation of IgA1. However, the hinge region is a highly conserved region of IgA1 molecule. There is no evidence for any nucleotide sequence alteration or transcriptional abnormality of the hinge region in IgA nephropathy (71). It has also been postulated that altered galactosylated IgA1 in IgA nephropathy may be due to a deficiency of structural modification of β1,3-galactosyltransferase, the enzyme responsible for the terminal galactosylation of GalNAc on *O*-linked

Figure 31-1

IgA1 molecules with hinge region *O*-glycosylation sites. IgA1 molecules have two heavy chains with three constant region domains CH1 to CH3 and a hinge region between CH1 and CH2. Each serine (Ser) and threonine (Thr) residue is a potential site for an *O*-glycan side chain. Although there are nine potential glycosylation sites, IgA1 contains up to six *O*-glycans per hinge region. *O*-glycosylation sites consist of *N*-acetylgalactosamine (GalNAc) *O*-linked to Ser or Thr residues of hinge region. The largest *O*-linked saccharide of IgA1 is a tetrasaccharide with GalNAc, galactose (Gal) and two sialic acid residues. Aberrant IgA1 molecules with Gal-deficient *O*-linked glycans can contain terminal GalNAc or sialylated GalNAc at one or more sites. Pro, proline.



glycans (72). This structural or functional deficiency may be genetically determined. The recent sequence of β1, 3-galactosyltransferase may help us to understand the genetic basis of these abnormalities (73, 74). Circulating IgA1 has reduced terminal galactose on *O*-linked hinge-region sugars in IgA nephropathy (66), apparently because of a B-cell defect in β1,3-galactosyltransferase, the enzyme responsible for placing terminal galactose on *O*-linked sugars (72). The IgA1 *O*-glycan chains are truncated in IgA nephropathy (75). Circulating immune complexes in IgA nephropathy consist of IgA1 with galactose-deficient hinge region, and the deficiency of galactose may result in the generation of antigenic determinants that are recognized by naturally occurring IgG and IgA1 antibodies (65). Sano et al. demonstrated that enzymatically deglycosylated human IgA1 molecules accumulate and induced inflammatory cell reaction (76); Amore et al. showed glycosylation of circulating IgA modulated mesangial proliferation in IgA nephropathy (77). Recently it has been showed that EBV-immortalized IgA1-producing cells from peripheral blood cells in IgA nephropathy patients secreted mostly polymeric IgA1 with galactose-deficient *O*-linked glycans (78). Until recently, although it has not been known whether the aberrant glycosylation is the result of an acquired or inherited defect, or whether the presence of aberrant IgA1 glycoforms alone can produce IgA nephropathy, recent studies have demonstrated that abnormal IgA1 glycosylation is an inherited rather than acquired trait and that abnormal IgA1 glycosylation clusters in most but not all families with IgA nephropathy suggests the possibility of IgA nephropathy patients with different pathogenic mechanisms of disease (79).

Immunoglobulin A Immune System

There is a general agreement that serum levels of IgA are increased in 50–70% of patients with IgA nephropathy, with elevations in both monomeric and polymeric IgA. There is an increase in polymeric IgA1-producing plasma cells in the bone marrow (48) and in the tonsils (80) of patients with IgA nephropathy. The proportion of IgA-λ in serum IgA is also increased. Serum IgA is more anionic, owing to the increased anionicity of λ- compared with κ-light chain (80). The binding of IgA to mesangial cells is charge dependent and anionic charge may play an important role for in IgA1 deposition in the mesangium (81). In addition to the increased levels of serum IgA, various types of autoantibodies of the IgA class have been recognized. These IgA autoantibodies include rheumatoid factor (82), antinuclear antibodies (83), and anticollagen antibody (84). However the IgA may be polyspecific, indicating a polyclonal increase rather than true antigen-specific autoantibodies (85). IgA immune complexes are also frequently detected (86). Cultured peripheral blood lymphocytes from patients with the disease produce more IgA than those of normal individuals, either spontaneously or after polyclonal stimulation in vitro. We also demonstrated an increased spontaneous and pokeweed mitogen-stimulated IgA production by peripheral blood lymphocytes in children with IgA nephropathy (87). This increased IgA production remained stable during the follow-up period in patients with persistent urinary abnormalities, but decreased toward normal in patients with clinical remission.

IgA production is T cell-dependent, and the increased production in IgA nephropathy may indicate altered T cell function. An increased circulating OKT4–OKT8 cell ratio, due to increased OKT4 helper T lymphocytes and decreased OKT8 cytotoxic-suppressor T lymphocytes, has been reported in patients (88). Increased IgA-specific helper T cell activity and decreased IgA-specific suppressor T cell activity have also been reported (89, 90).

Defective clearance of immune complexes from the circulation may also be important (91), but this seems more likely to be a consequence rather than the cause of the increased immune complex load.

Progression Mechanism

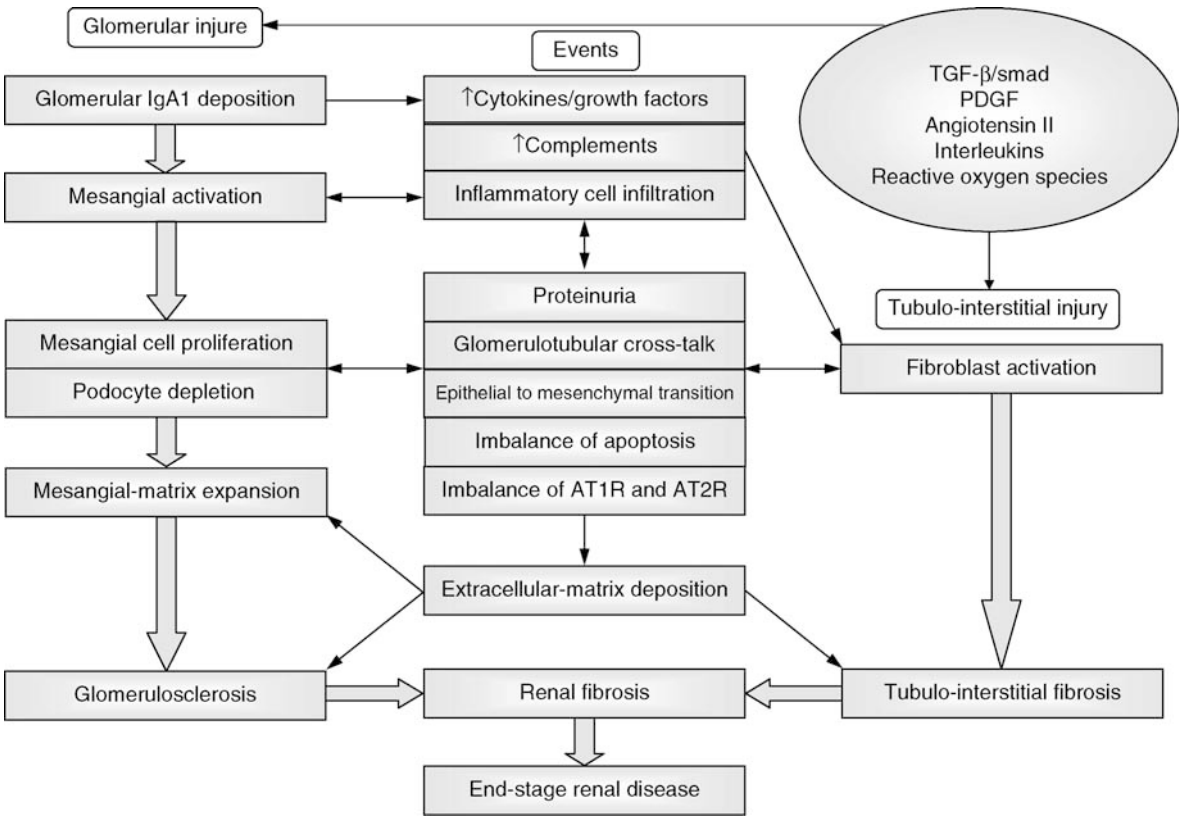
Renal fibrosis is the final common manifestation of chronic kidney diseases (92). There is little to suggest that the mechanisms of mesangial proliferative glomerulonephritis, progression, and scarring are distinct in IgA nephropathy compared with other types of chronic glomerulonephritis. A simplified scheme of progression mechanism in IgA nephropathy is shown (*Fig. 31-2*).

Initiation and Progression Mechanism of Glomerular Injure

As described above, deposition of polymeric IgA, but not of monomeric IgA, can induce the production and local release of a variety of cytokines, growth factors, complements, and angiotensin II by renal resident cells and by circulating inflammatory cells leading to inflammatory injury, characteristic histopathological features of mesangial cell proliferation and extracellular-matrix deposition (93–96). IgA alone also appears to be sufficient to provoke injury in susceptible individuals (97). Studies in vitro

Figure 31-2

A simplified scheme of progression mechanism in IgA nephropathy.



and in animal models of mesangial proliferative glomerulonephritis have shown the key role of cytokines and growth factors, particularly platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β), in the induction and progression of mesangial injury, and there is evidence that these are also involved in IgA nephropathy (98–100). Although the role of infiltrating activated monocyte/macrophage into glomeruli are also thought to be important in glomerular injure (101), it has been showed that resident glomerular cells (mesangial and endothelial cells) are predominantly the major source of up-regulated these growth factor production in IgA nephropathy (98).

Studies in children with IgA nephropathy suggest that mesangial proliferation may in part be the result of local production of cytokines, interleukin-1, interleukin-6, tumor necrosis factor (TNF), PDGF, TGF-β and vascular permeability factor/endothelial growth factor (VPF/VEGF) (102–104). C3 deposits in mesangium and activation of complement proteins in mesangium (105), excessive oxidant stress (106) may mediate glomerular injury in IgA nephropathy.

Glomerular injury and proteinuria in IgA nephropathy is related to the degree of podocyte depletion in humans (107). Recent study has supported for the concept that podocyte depletion could be a major mechanism driving glomerulosclerosis in human glomerular diseases (108). Dysregulation of apoptosis may have the important role in podocyte depletion. It has been shown that down-regulation of Bcl-2 by podocytes is associated with progressive glomerular injury and clinical indices of poor renal prognosis in human IgA nephropathy (109). Recently, it has been reported that IgA1 from IgA nephropathy patients may induce apoptosis of podocytes through direct and indirect pathways and that IgA1 may accelerate progression of IgA nephropathy by inducing apoptosis of podocytes (110).

It has been showed that enhanced gene expression for the renin-angiotensin system is detected in glomerular mesangial cells in IgA nephropathy (111). Recent studies

have demonstrated an altered angiotensin II subtype 1 receptor expression in human mesangial cells in response to raised intrarenal angiotensin II in IgA nephropathy. In vitro studies have also support that an imbalance of angiotensin II subtype 1 and 2 receptor activity in human mesangial cells following exposure to polymeric IgA plays a significant pathogenetic role in the inflammatory injury in IgA nephropathy (112).

Progression Mechanisms from Glomerular Injure to Tubulointerstitial Injury

It remains in part unclear how mesangial IgA deposition leads to tubulointerstitial injury in IgA nephropathy. Several mechanisms of tubulointerstitial injury may operate independently or synergistically (96). Recently, a glomerulotubular cross-talk has been proposed in addition to monocytic/macrophage infiltration, proteinuria, complement activation and direct inflammatory effect of IgA (113). The importance of infiltrating inflammatory cells in the tubulointerstitium in mediating tubular injury and renal fibrosis in IgA nephropathy has been demonstrated (96, 114). Especially, recent attention has been focused on the role of proximal tubular epithelial cells in organization inflammatory cell infiltration and renal fibrosis via production of inflammatory mediators upon activation (96).

Proteinuria is the major stimulus of proximal tubular epithelial cell activation and subsequent chemotaxis of infiltrating immunocompetent cells in most glomerular diseases (115). Endothelin-1 synthesis was enhanced in culture proximal tubular cells exposed to high concentrations of albumin, IgG, or transferrin. Similarly, monocyte chemoattractant protein (MCP-1) gene was up-regulated by albumin and transferrin. Very similar findings were reported for albumin-induced up-regulation of RANTES (Regulated upon Activation, Normal T cell Expressed and Secreted), an immunoregulatory cytokine with chemotactic properties for monocytes and memory T cells in culture proximal tubular cells (116). Albumin is also a strong stimulus for tubular interleukin-8 expression, which occurs with nuclear factor-kappaB-dependent pathways (115). Consistent with these in vitro studies, vasoactive and proinflammatory molecules was enhanced in renal tissue from rat models with proteinuric renal disease, particularly at proximal tubular level (117, 118).

Activation of complement proteins in the proximal tubule has major proinflammatory potential in interstitial damage with proteinuric conditions. Intracellular C3 staining was detected in proximal tubules of proteinuric rats with remnant kidneys early after 5/6 nephrectomy, and preceded the appearance of inflammation. C3 colocalized with IgG to the same tubular cells (119). Induction of tubular C3 during protein overload has also been reported (120).

Excessive protein reabsorption by proximal tubular cells promotes fibrogenesis by release of chemoattractants, which leads to local recruitment of mononuclear cells. Interstitial accumulation of inflammatory cells by release of TGF-β, PDGF, and other cytokines leads to interstitial cell transformation into myofibroblasts. In addition, proximal tubular epithelial cells interact with surrounding interstitial fibroblasts to promote fibrogenesis by paracrine release of profibrogenic molecules such as TGF-β, PDGF, and endothelin-1 (121).

The other possible contributory factor is the direct toxic effect following tubular binding of IgA. IgA nephropathy patients have increased urinary IgA concentration that correlates with serum creatinine concentration, as well as the urinary protein excretion (122).

Recently, a glomerulotubular cross-talk, a new mechanism in which mesangial IgA deposition may lead to tubulointerstitial injury in IgA nephropathy, has been proposed. It has been documented that inflammatory cytokines, including angiotensin II, are released from mesangial cells following binding to IgA from patients with IgA nephropathy. These mediators may alter the glomerular barrier pore size that allows the passage of these inflammatory mediators to the tubular lumen. These mediators then activate proximal tubular epithelial cells, which may amplify the inflammatory cascade by local production of chemotactic mediators, which attract more inflammatory cells. This glomerulotubular cross-talk will generate a positive feedback loop of activation in the renal tubules that leads to the overproduction of extracellular matrix components, resulting in fibrosis. This hypothesis was tested by conducting an experiment in which proximal tubular epithelial cells were cultured with medium prepared from mesangial cells incubated with IgA from IgA nephropathy patients (113). Contrary to the absent stimulatory effect on proximal tubular epithelial cells upon direct incubation with IgA, increased proliferation and enhanced expression of inflammatory mediators (including interleukin-6, tumor necrosis factor-α, soluble intercellular adhesion molecule-1 (ICAM-1), and angiotensin II) in proximal tubular epithelial cells cultured with medium prepared from mesangial cells incubated with IgA from IgA nephropathy patients were observed. Tubular and interstitial ICAM-1-positive cells may participate in adhesive interactions with interstitial leukocytes (123, 124). Upregulation of renal interleukin-6 expression correlates

well to the degree of tubulointerstitial damage in IgA nephropathy (125).

Renal Fibrosis

Glomerulosclerosis, tubulointerstitial fibrosis, inflammatory infiltration, and loss of renal parenchyma characterized by tubular atrophy, capillary loss, and podocyte depletion are constituent pathologic findings of renal fibrosis (92). The cellular events leading to these histologic findings include mesangial and fibroblast activation, tubular epithelial to mesenchymal transition (EMT), monocyte/macrophage/T-cell infiltration, and apoptosis (92). At present, renal fibrogenesis process is thought to be similar to wound-healing response to injury (92, 126, 127). The reason why the difference between a healthy wound-healing and fibrotic response occurs remains unknown. The duration of the injury may affect the course. Following the initial injury, affected kidney tissues attempt to repair and recover from damage. This process includes activation of resident kidney cells, which produce and secrete proinflammatory cytokines. Chemotactic cytokines generate a signal for monocytes/macrophages/T-cell infiltration to the inflammatory regions. Glomerular and interstitial infiltrated inflammatory cells become activated, and produce injurious molecules such as reactive oxygen species, as well as fibrogenic and inflammatory cytokines. These stimulate mesangial cells, fibroblasts, and tubular epithelial cells, which show activation or EMT. These cells produce a large amount of extra cellular matrix components. Extra cellular matrix proteins are in turn deposited in the extracellular compartment. Since they are often crosslinked, they are resistant to degradation. Continuous deposition of extra cellular matrix results in fibrosis and destroys the normal architecture of kidney tissues, leading to renal function loss (92).

Molecular Pathway in Renal Fibrosis

It is widely accepted that TGF-β and its downstream Smad signaling play an essential role in tissue fibrosis in general, and renal fibrosis in particular (92, 128, 129). Upregulation of TGF-β is a universal finding in every type of chronic kidney diseases, both in animal models and in humans. TGF-β induction also appears to be a main pathway that integrates, directly or indirectly, the effects of many other fibrogenic factors. Some of these, such as angiotensin II and high glucose, act as an upstream TGF-β inducer, whereas others such as connective tissue growth factor (CTGF) work as its downstream effector.

The TGF-β signal is transduced through its cell membrane type I and type II serine/threonine kinase receptors (128). Receptor activation triggers the phosphorylation and activation of its downstream signaling mediators, Smad2 and Smad3. Phosphorylated Smad2/3 bind to common partner Smad4, and then translocate into the nuclei, where they control the transcription of TGF-β-responsive genes.

Smad transcriptional corepressors including SnoN, Ski, and TGIF restrain Smad signaling tightly in normal kidney. These Smad antagonists effectively restrict Smad-mediated gene transcription with various mechanisms. It has recently demonstrated that SnoN and Ski are progressively diminished in the fibrotic kidney, suggesting that the loss of Smad antagonists is an important mechanism that amplifies the TGF-β signal (130). It is thought that the TGF-β/Smad signal in renal fibrosis is changed into such a way without control, much similar to the loss of tumor suppressor genes during tumorigenesis (92).

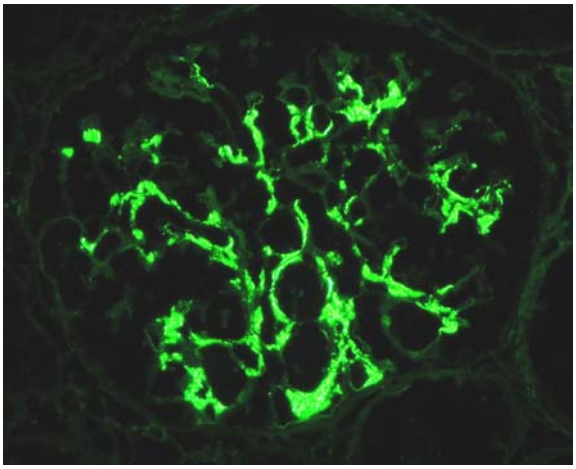
Pathology

Immunohistologic Findings

The diagnostic immunopathological pattern of IgA nephropathy is the presence of IgA in the glomerular mesangium as the sole or predominant Ig. IgA deposits often extend just beyond the mesangiocapillary junctions into the adjacent capillary walls (*Fig. 31-3*). There are also deposits of IgG and/or IgM with the same staining pattern as IgA but with lesser intensity and frequency. In our series, mesangial IgA deposits were associated with IgG in 32% of patients, IgM in 8%, and both IgG and IgM in 11% (131). C3 deposits were observed in a similar distribution pattern in 64% of cases. The early components of the classical complement pathway, C4 or C1q, are absent. Fibrin- or fibrinogen-related antigens are found in a diffuse mesangial distribution in 25–70% of patients and are believed to be one of the injurious agents in the glomeruli (132). Although, in most patients, IgA is present only in the mesangial regions, in approximately 10% of patients it is also observed in the peripheral capillary walls. Such peripheral capillary wall deposits, whether documented by immunofluoresence or electron microscopy, have been associated with more severe clinical manifestations and a poor renal outcome (133–136).

Figure 31-3

Immunofluorescence micrograph showing mesangial IgA deposits in a patients with IgA nephropathy. (See color plate 12)



Light Microscopic Findings

Various glomerular changes are observed. The most characteristic abnormality is mesangial enlargement, caused by various combinations of hypercellularity and increase in matrix (*Fig. 31-4*). Occasionally, small eosinophilic and PAS-positive fibrinoid mesangial deposits are also seen. Biopsies can be graded according to the amount of mesangial cell proliferation on the basis of the World Health Organization criteria (137).

1. Minimal glomerular lesions. The majority of glomeruli appear optically normal, although a few may show a slight increase of mesangial matrix, with or without accompanying hypercellularity. The number of mesangial cells per peripheral mesangial area does not exceed three. There are also small foci of tubular atrophy and interstitial lymphocyte infiltration in some patients.
2. Focal mesangial proliferation. Up to 80% of glomeruli show moderate or severe mesangial cell proliferation, (i.e., more than three cells per peripheral mesangial area). The degree of mesangial cell proliferation varies considerably among glomeruli as well as segmentally within individual glomeruli. The proliferation is usually associated with increased matrix. Small cellular or fibrocellular crescents are frequently found but rarely affect more than 20% of the glomeruli. Capsular adhesions are frequently seen overlying lobules showing mesangial proliferation. Segmental capillary collapse is often observed in association with crescents. A small number of glomeruli showing global sclerosis is often present. Tubular atrophy, interstitial fibrosis, and interstitial lymphocyte infiltration are frequently present but are not extensive.
3. Diffuse mesangial proliferation. More than 80% of glomeruli show moderate or severe mesangial cell proliferation, which varies in intensity in different regions of the mesangium in a given glomerulus as well as from one glomerulus to another. Mesangial cell proliferation is always accompanied by increased mesangial matrix. Cellular and fibrocellular crescents are often found, usually affecting less than 50% of the glomeruli, although in approximately 10% of patients, more than 50% are involved. Capsular adhesions are frequently seen in the absence of crescents. A small number of globally sclerosed glomeruli are often present. Tubular atrophy, interstitial fibrosis, and interstitial lymphocyte infiltration are frequently present and are extensive in 10% of patients.

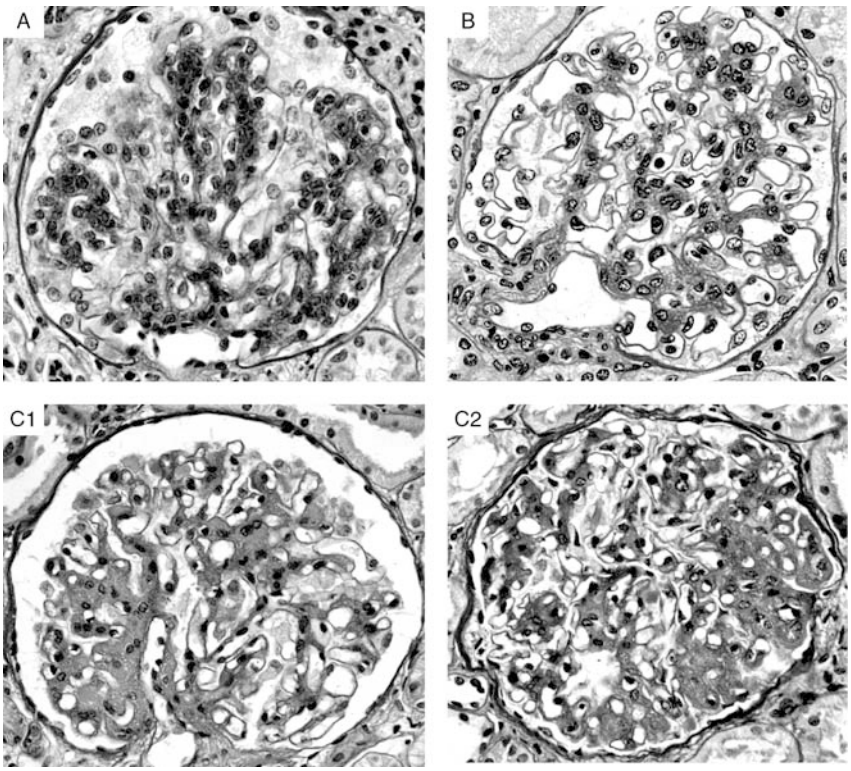
Three types of mesangial change are identified in children with IgA nephropathy (5) (*Fig. 31-4*): (1) Mesangial hypercellularity is more prominent than the increase in matrix, (2) the degrees of mesangial hypercellularity and matrix increase are similar, and (3) the increase in matrix is more prominent than the mesangial cellularity.

The first type of lesion is seen in biopsies in which the interval between onset of disease and biopsy is short. Serial pathologic observations reveal that prominent mesangial hypercellularity is almost exclusively seen in initial biopsies and disappears in follow-up biopsies. These observations suggest that predominant mesangial hypercellularity is characteristic of the early lesion of childhood IgA nephropathy and may disappear within a matter of months. An increase in mesangial cells, although sometimes present, is seldom striking in adult patients (138). In contrast, biopsies with a predominant matrix increase show a long interval between onset of disease and biopsy and a high percentage of glomerular sclerosis. Serial pathologic observations reveal that this type of change is usually seen in follow-up biopsies. An increase in the amount of mesangial matrix with duration of the disease has also been noted in adult patients (139). These findings suggest that progression of IgA nephropathy leads to gradual resolution of mesangial hypercellularity and an increase of matrix associated with the development of sclerosis (140).

The severity of tubulointerstitial changes usually reflects the severity of glomerular damage. Vascular lesions, such as arterial or arteriolar sclerosis, are reported to be common in adults (141) but are very unusual in

Figure 31-4

Light micrograph showing mesangial proliferation in patients with IgA nephropathy. Three types of mesangial change are identified: (a) mesangial hypercellularity is more prominent than the increase in matrix (b) the degrees of mesangial hypercellularity and matrix increase are similar (c) the increase in matrix is more prominent than the mesangial cellularity.



children with IgA nephropathy (135). This difference may be related to the age at biopsy and the duration of disease before biopsy.

Electron microscopy

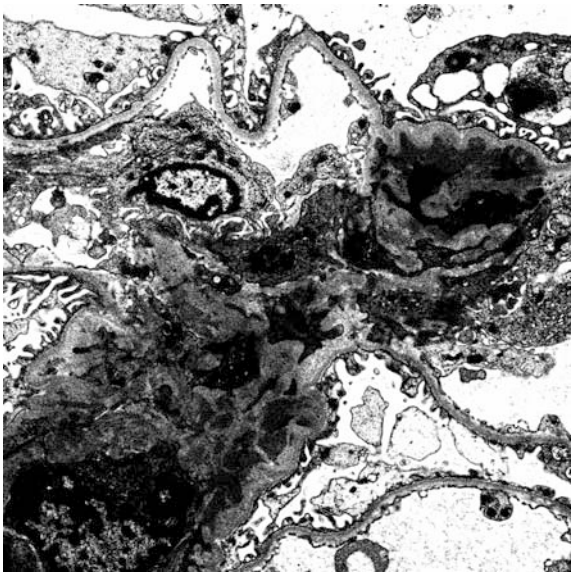
Electron microscopic abnormalities are mainly observed in the mesangium, which is variably enlarged by a combination of increased cytoplasm and matrix. Electron-dense deposits in the mesangium are the most constant and prominent feature and are seen in almost all patients (*Fig. 31-5*). They are granular masses situated immediately beneath the lamina densa in the perimesangial region and expanded mesangium. The size and extent of mesangial deposits varies from patient to patient; in some patients, they are large and produce localized protrusions. Peripheral glomerular capillary wall deposits are also found in the subendothelial and subepithelial regions. Subendothelial deposits occur most frequently in the capillary wall adjacent to the mesangium, although they are also observed in the peripheral part of the loop. Subepithelial deposits are reported to be unusual in adult patients but are frequently found in children with IgA nephropathy. They are generally small and flat and localized to a few capillary loops; the humps typical of acute poststreptococcal glomerulonephritis are never observed. Lysis of the glomerular basement membrane is also seen quite frequently in children (142). In affected areas of the glomerular capillary walls, the lamina densa is thin and irregular, and the epithelial aspect of the glomerular basement membrane shows irregular segments of low electron density with an expanded, washed-out appearance. The epithelial foot processes are generally well preserved, but diffuse foot process effacement may be seen in patients with the nephrotic syndrome.

Repeat Renal Biopsy Findings

There have been only a few reports on the results of repeat renal biopsies (143, 144). We previously reported our

Figure 31-5

Electron micrograph showing numerous electron-dense deposits in the mesangium in a patient with IgA nephropathy.



results in children with IgA nephropathy (6). At the time of the second biopsy, 23 patients had showed clinical remission, defined as complete disappearance of proteinuria and hematuria with normal renal function, whereas 38 had persistent urinary abnormalities with normal renal function. There were no differences between the two groups with regard to the initial clinical findings and the pathologic findings in the initial biopsy. The second biopsy of patients who were in clinical remission showed improvement of the glomerular changes on light microscopy, a disappearance of or a decrease in mesangial IgA deposits, and a decreased amount of electron-dense deposits. Conversely, light microscopy showed a progression of histologic lesions and the persistence of both mesangial IgA deposits and electron-dense deposits in patients with persistent urinary abnormalities. Clinical remission and histologic regression have been reported in adults with IgA nephropathy (145).

Differences between Childhood and Adult Patients with IgA Nephropathy

Significant differences in the early glomerular lesions of IgA nephropathy between children and adults have been demonstrated (146, 147). Glomerular hypercellularity in mesangial area is prominent in children and significantly greater than in adults. In contrast, glomerular matrix expansion, crescent formation and interstitial damage are more severe in adults compared to children. Glomerular hypercellularity correlated with proteinuria in children but not in adults, whereas glomerular matrix correlated with proteinuria and renal function in adults but not in children (146).

Clinical Features

IgA nephropathy occurs at all ages but is most common during the second and third decades of life; it affects boys more often than girls, with the reported male to female ratio varying from less than 2:1 to 6:1 (2). In a study of Japanese children (131), the mean age at presentation was 9.3 years in boys and l0.3 years in girls, and the male to female ratio was 3:2. The clinical presentation of IgA nephropathy varies. Some patients have asymptomatic microscopic hematuria with or without proteinuria. Other patients have recurrent epithodes of macroscopic hematuria. Some patients present with acute nephritic syndrome and, more rarely, with acute renal failure.

Sixty-two percent of our 258 Japanese children were found to have microscopic hematuria with or without asymptomatic proteinuria (131). Twenty-six percent presented with macroscopic hematuria and 12% with an acute nephritic syndrome or nephrotic syndrome. Several studies from Europe and the United States reported that more than 80% of the patients have episodes of macroscopic hematuria, and recurrent macroscopic hematuria is traditionally regarded as the hallmark of childhood IgA nephropathy (148–151). However, it was the initial feature in only 26% of our series, presumably because of the school screening program that detected a high prevalence of asymptomatic urinary abnormalities rather than regional variation in the expression of IgA nephropathy. During the observation period, 60% of patients had one or more episodes of macroscopic hematuria, whereas the other 40% remained asymptomatic.

Macroscopic hematuria often occurs in association with upper respiratory tract infections; less frequently, it occurs in association with other infections involving the mucosal system (e.g., diarrhea and sinusitis). Episodes of macroscopic hematuria are sometimes associated with loin pain. The interval between the precipitating infection and the appearance of hematuria ranges from 1 to 2 days compared with 1 or 2 weeks in acute postinfectious glomerulonephritis. Many patients have recurrent episodes of macroscopic hematuria, each often associated with the

same type of infection. The number of recurrences and the intervals between different episodes are variable. The incidence of macroscopic hematuria is lower in adults (151, 152). Emancipator et al. (3) summarized the previous reports of IgA nephropathy, in which most the patients were adults, and reported that 43% had macroscopic hematuria. However, in Japan, only 18–32% adult patients have been reported to have macroscopic hematuria (152, 153). The reason for the age-related differences in the incidence of macroscopic hematuria has yet to be elucidated.

In asymptomatic patients, microscopic hematuria is almost always present and persistent. Proteinuria is common. The blood pressure and renal function at onset are normal.

Patients with a nephritic or nephrotic onset have the most severe glomerular damage. The most common presenting symptom is macroscopic hematuria. Hypertension is infrequent and usually mild to moderate. Malignant hypertension is not a presenting feature in childhood. Nephrotic edema is reported in approximately 10% of patients. Acute renal failure is occasionally associated with episodes of macroscopic hematuria and is usually reversible. However, a number of investigators have documented a subset of patients with IgA nephropathy that is characterized by extensive crescents and a rapidly progressive course (153–155). A review of published cases of crescentic IgA nephropathy revealed that 41% of patients with this rapidly progressive form of disease were 16 years of age or younger (155).

Laboratory Investigation

Serum IgA levels are increased in 30–50% of adult patients but in only 8–16% in children with IgA nephropathy (131). For this reason, it is seldom of diagnostic significance. Serum complement component concentrations are usually normal, but the C3 level should be measured routinely if the patient has been referred for investigation after the first attack of hematuria to eliminate a diagnosis of postinfectious glomerulonephritis or membranoproliferative glomerulonephritis. Likewise, the antistreptococcal antibody titers should be determined after initial hematuria. These investigations are of little value when hematuria is known to have been present for more than 3 months. The serum creatinine should be measured routinely to estimate renal function; if necessary, the glomerular filtration rate should be determined. If present, proteinuria should be quantified, as proteinuria is associated with histologic lesions and a risk of progression. The plasma proteins should be measured routinely in the presence of heavy proteinuria.

Differential Diagnosis

The diagnosis of IgA nephropathy is based on the presence of IgA as the sole or predominant Ig in the glomerular mesangium. Because diffuse mesangial IgA deposits are observed in a variety of other disorders (*Table 31-1*), the diagnosis of IgA nephropathy can be made only by exclusion. The IgA deposits are often incidental findings and the pathogenesis and clinical significance is unclear.

Table 31-1

Diseases associated with diffuse mesangial IgA deposits

Primary
IgA nephropathy
Secondary
Multisystem disease
Henoch
Henoch-Schönlein purpura
Systemic lupus erythematosus
Cystic fibrosis
Celiac disease
Crohn's disease
Dermatitis herpetiformis
Ankylosing spondylitis
Neoplasms
Carcinomas of the lung and colon
Monoclonal IgA gammopathy
Mucosis fungoides
Non-Hodgkin's lymphoma
Infectious diseases
Mycoplasma infections
Leprosy
Toxoplasmosis
Others
Chronic liver disease
Thrombocytopenia
Pulmonary hemosiderosis
Mixed cryoglobulinemia
Polycythemia
Scleritis

Relationship between Immunoglobulin A Nephropathy and Henoch-Schönlein Purpura

There is a close relationship between IgA nephropathy and Henoch-Schönlein purpura (156). The morphologic and immunopathologic features are similar in the two conditions (156, 157), which are characterized by various degrees of focal or diffuse mesangial proliferation, the diffuse deposition of IgA in the mesangium, and electron-dense deposits in the mesangium. Elevated serum IgA levels are found in both IgA nephropathy and Henoch-Schönlein purpura nephritis, and IgA-containing circulating immune complexes have been demonstrated in both conditions. Infective episodes precede Henoch-Schönlein purpura nephritis in 30–50% of patients, and the presence of *H. parainfluenza* antigens in a diffuse and global distribution in the glomerular mesangium and the presence of IgA antibody against *H. parainfluenza* in sera of Japanese children with Henoch-Schönlein purpura nephritis have also been demonstrated (13). The two disorders have been reported to coexist in different members of the same family, including a pair of monozygotic twins who developed the disorders simultaneously after a well-documented adenovirus infection (158–161). Moreover, the evolution of IgA nephropathy into Henoch-Schönlein purpura nephritis in the same patient is described in both adults and children (162–164). It has been suggested that the two conditions are variants of the same process and that IgA nephropathy is Henoch-Schönlein purpura nephritis without the rash. Although there are similarities in their pathologic and immunologic features, the two conditions are clinically different, and the pathogenesis is not clear. Our study suggests that Henoch-Schönlein purpura nephritis is an acute disease, with glomerular lesions nonprogressive after the onset (165). Therefore, in most patients, the prognosis is associated with the severity of glomerular change at the onset. In contrast, IgA nephropathy is a chronic, slowly progressive glomerular lesion, which may eventually lead to chronic renal failure, whatever the presentation. A few patients with Henoch-Schönlein purpura nephritis have recurrent episodes of macroscopic hematuria and a progressive renal disease on repeat renal biopsies. Finally, Henoch-Schönlein purpura nephritis occurs mostly in young children and is rare in adulthood, whereas IgA nephropathy affects mainly older children and young adults. It is therefore reasonable that IgA nephropathy and Henoch-Schönlein purpura nephritis are treated as different clinicopathologic entities until pathogeneses of the two conditions are better understood.

Chronic Liver Disease

Glomerular IgA deposits may be observed in patients with various types of chronic liver diseases (166). The presence of glomerular IgA deposits in patients with hepatic cirrhosis was first demonstrated in 1970. Thereafter, many investigators have documented the presence of glomerular abnormalities in patients with various types of chronic liver disease (166). Mesangial proliferation and IgA deposits are the most common findings. The light, electron, and immunofluorescence microscopic features in patients with liver disease are similar to those in patients with primary IgA nephropathy. Most patients with chronic liver disease have clinically asymptomatic renal disease. Microscopic hematuria and mild proteinuria are commonest findings and macroscopic hematuria or a nephrotic syndrome is rare. Renal functional impairment is also rare. Glomerular lesions in children with chronic liver disease are very unusual. The pathogenetic mechanisms that contribute to mesangial IgA deposition in chronic liver diseases remain unknown. Significant elevations of the serum monomeric and polymeric IgA levels have been reported in patients with chronic liver disease (167, 168). Impaired hepatic clearance and increased synthesis of polymeric IgA, abnormalities of IgA metabolism, and portosystemic shunting of antigens and immune complexes have been suggested as possible causes of mesangial IgA deposition in chronic liver disease (168).

Idiopathic Nephrotic Syndrome

A few patients with steroid-sensitive nephrotic syndrome show mesangial deposits of IgA on renal biopsy. They are classified by some as IgA nephropathy, whereas others consider that mesangial IgA in patients with minimal changes (i.e., without cellular proliferation) is coincidental. This probably applies to idiopathic nephrotic syndrome associated with mesangial IgA deposits occurring in Asians and explains a favorable response to steroids, which is not the case in true IgA nephropathy (169).

Natural History and Prognosis

In adult series, the incidence of renal insufficiency varies from less than 10% to as high as 45% in patients followed up for more than 1 year. In long-term follow-up of adult patients, 30–35% have been found to develop progressive renal insufficiency 20 years after the initial discovery of disease (2, 170–172). It can be estimated that 1–2%

of adult patients will enter end-stage renal failure each year from time of diagnosis (173). The long-term prognosis of the 169 Japanese children with IgA nephropathy followed more than 10 years indicates that 9% of the patients had developed chronic renal failure by 15 years (*Fig. 31-6*).

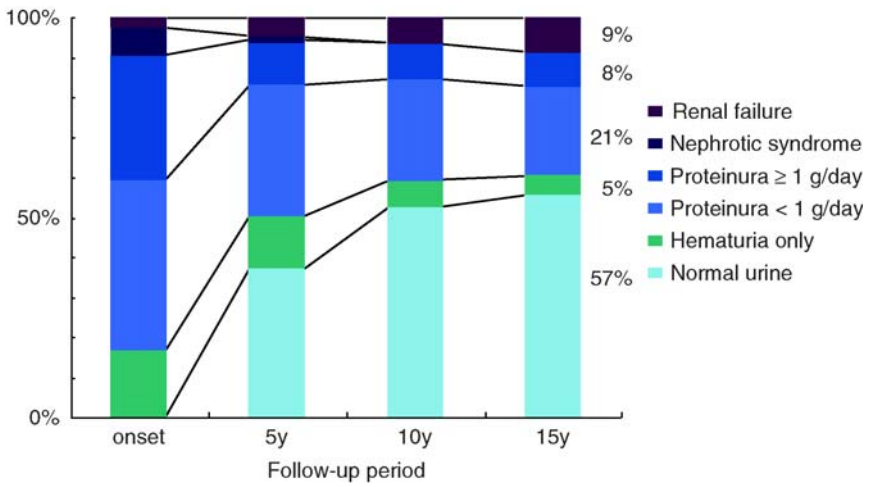
Because of the variable rate of progression to chronic renal failure, there have been attempts to identify features present at the time of diagnosis that would predict the ultimate outcome. The following clinical findings are regarded as poor prognostic indicators in adult patients (2): persistent hypertension, persistent heavy proteinuria, and reduced glomerular filtration rate at presentation (170–172, 174–179). In children, several studies have shown that the degree of proteinuria correlates with the severity of morphologic glomerular lesion (135, 150, 180), and heavy proteinuria at the time of biopsy predicts a poor outcome (136, 181). In contrast, slight proteinuria or its absence at the time of biopsy predicts a favorable outcome. There is general agreement that hypertension and low glomerular filtration rate at presentation are significant factors in determining the outcome of adult patients with IgA nephropathy. In children, acute renal failure at onset is usually transient and associated with macroscopic hematuria and reversible tubular lesions. Male gender has also been considered an unfavorable prognostic feature by some investigators (171), but we (136) and others (134) could not confirm it in large cohort of adult and pediatric patients. Schena et al. reported an increased risk of end-stage renal disease in familial IgA nephropathy (24).

Several pathologic features are associated with a poor outcome: diffuse mesangial proliferation; a high proportion of glomeruli showing sclerosis, crescents or capsular adhesions; the presence of moderate or severe tubulointerstitial changes; the presence of subepithelial electron-dense deposits; and lysis of the glomerular basement membrane by electron microscopy (136). Patients with diffuse mesangial proliferation have been reported to have a significantly worse prognosis than those with focal proliferation or minimal lesions by light microscopy in adults (170, 175, 182). In many adult studies (134, 141, 170, 178), glomerular sclerosis and crescents have also been associated with poor renal outcome. Levy and associates found that mesangial proliferative glomerulonephritis with crescents was associated with poor prognosis in children (150). Because the severity of the tubulointerstitial changes usually corresponds with the severity of the glomerular changes, tubulointerstitial changes in IgA nephropathy are believed to be secondary to the glomerular injury. Vascular lesions, such as arterial or arteriolar sclerosis, have been reported to play an important role in the progression of IgA nephropathy in adults. However, vascular changes are very unusual in children (5, 151, 154). This difference may be related to the age at biopsy and the duration of disease before biopsy.

Recurrence of mesangial IgA deposits is often observed in transplant recipients whose original disease was IgA nephropathy (37, 183). Clinically such recurrences are mild or even asymptomatic: despite this risk of recurrent glomerulonephritis, graft survival in patients with IgA nephropathy is considered good (37).

Figure 31-6

Long-term prognosis of the 169 Japanese children with IgA nephropathy followed more than 10 years.



At the beginning of the 1990s, use of angiotensin-converting enzyme inhibitors for focal mesangial proliferation and combined therapies including corticosteroids for diffuse mesangial proliferation increased dramatically in Japan. Our recent retrospective cohort study of 500 children with IgA nephropathy has clarified an improved renal survival in Japanese children with IgA nephropathy (184). Among all patients, the actuarial renal survival was 96.4% at 10 years, 84.5% at 15 years and 73.9% at 20 years. Diagnosed in 1976–1989, the renal survival was 94.0% at 10 years, 80.1% at 15 years and 70.1% at 20 years. Diagnosed in 1990–2004, the renal survival was 98.8% at 10 years, 98.8% at 15 years (p = 0.008). With diffuse mesangial proliferation, both the 10- and 13-year renal survivals were 97.8% in 1990–2004, compared with 78.5% and 68.6%, respectively, in 1976–1989 (p = 0.0003). In the same study, prognostic factors for end-stage renal disease-free survival were analyzed (184). Mesangial proliferation degree and initial renal biopsy year were significant in both the univariate and the multivariate analysis. For children with IgA nephropathy, the most influential prognostic variable was mesangial proliferation degree. Proteinuria at diagnosis was significant in the univariate, but not in the multivariate analysis. Multivariate analysis showed that initial renal biopsy year was a significant factor for renal survival independently of mesangial proliferation degree, proteinuria at diagnosis and estimate creatinine clearance at diagnosis (hazard ratio = 0.08, 95%CI 0.004–0.43).

Treatment

IgA nephropathy is a leading cause of chronic renal disease and end-stage renal disease in adult patients, and recent long-term studies assessing the prognosis in children have challenged earlier views that the condition represents a benign disorder. Thus, IgA nephropathy presents a therapeutic challenge in both adults and children. The most appropriate treatment for patients with IgA nephropathy is still a matter of controversy (185). At present, there is no curative therapy for IgA nephropathy (186). Because of the variable rate of progression to renal failure, and because of the probable multifactorial pathogenesis of the disease, the effectiveness of any treatment can only be properly evaluated by means of a randomized controlled trial (185). When considering treatment protocols, an issue of great importance is the selection of appropriate patients in whom the treatment is to be evaluated. Patients with heavy proteinuria at biopsy and the most severe glomerular lesions on renal biopsy appear to be at greatest risk of progressive renal deterioration and, therefore, the most appropriate candidates for specific therapeutic interventions. Patients with long-standing disease and extensive, irreversible glomerular damage are unsuitable for such treatments.

In a randomized controlled trial, another important thing is to select adequate endpoints. Although in a clinical trial of progressive IgA nephropathy the ultimate endpoint is development of chronic renal insufficiency, most pediatric patients do not develop it during the study period. Thus, studies of pediatric patients with IgA nephropathy may differ markedly from studies of adults with regard to the apparent risk of progressive disease (185). Therefore, due to the long time period from clinical onset of disease until progression to end-stage renal disease, surrogate markers of outcome must be used to evaluate efficacy of therapy for IgA nephropathy in clinical trials. It is a noteworthy fact that validation of these surrogate markers may be lacking, resulting in the potential for inappropriate conclusion with regards to therapeutic efficacy. Therefore, the careful investigation in detailed long-term outcome of previous randomized controlled trials is important.

With regard to treatment of IgA nephropathy, it is important to consider the differences in the nature of IgA nephropathy between children and adults. An "evidence-based" therapy is important in both chidren and adults. However, available evidence for treatment is partially, clearly, different between chidren and adults. Generally and roughly speaking, the evidence for treatments of IgA nephropathy in adults supports relatively passive treatments, whereas that in children supports relatively active treatments. The reason of this difference is unknown. Differences in the diagnosis timing and histological differences may be associated. Although we should refrain from radical treatments that are not based on evidence, however appropriate active treatments that are based on evidence are important in treatments for children with IgA nephropathy.

Fish oil/omega-3 Fatty Acids

Controlled double-blind trial in adult patients with IgA nephropathy (187–189) showed that treatment with fish oil for 2 years retarded the rate at which renal function was lost, but a meta-analysis showed that there was only a 75% probability that fish oil was beneficial (190). A recent randomized, placebo-controlled, double-blind trial by the Southwest Pediatric Nephrology Study Group in USA and Canada evaluated the role of omega-3 fatty

acids in children and young adults with IgA nephropathy, and the treatment group did not showed benefit over the placebo group with respect to time to failure, defined as estimated GFR < 60% of baseline (191). Furthermore, from analysis of these clinical trials, it was reported that efficacy of omega-3 fatty acids in children and adults with IgA nephropathy is dosage- and size-dependent (192).

Coagulation Modifying Agents

Warfarin, urokinase, and anti-platelet agents have all been assessed for the treatment of IgA nephropathy. At present there is no sufficient evidence to support the use of coagulation modifying agents (193, 194). However, coagulation modifying agents may have a role in combination therapy. To investigate this question, a randomized controlled trial is currently in progress in Japan to compare the effects of prednisolone, immunosuppressive agents, warfarin, and dipyridamole with those of prednisolone and immunosuppressive agents in children with severe IgA nephropathy.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

As already demonstrated in non-diabetic chronic nephropathies (195–197), studies including randomized controlled trials have indicated that angiotensin-converting enzyme inhibitors reduces urinary protein excretion (198, 199) and preserves renal function (200) in adult patients with IgA nephropathy. However, there is no randomized controlled study only in children with IgA nephropathy demonstrating that angiotensin-converting enzyme inhibitors preserve renal function. Recently, a randomized controlled trial has proved a significant benefit of angiotensin-converting enzyme inhibitor on the progression of IgA nephropathy in children and young people when it was assessed as a composite end point of 30% reduction in GFR or an increase of proteinuria over the nephrotic range. It has also showed the benefit of angiotensin-converting enzyme on remission of proteinuria below what is generally considered a harmful level (201). In adult setting a randomized controlled trial has showed that combination therapy with angiotensin-converting enzyme inhibitor and angiotensin II receptor blocker has an additive dose-dependent antiproteinuric effect compared to monotherapies in patients with IgA nephropathy (202). The *Cooperate* trial, a large randomized study of 336 patients with non-diabetic renal disease, in which 50% of subjects had IgA nephropathy, has demonstrated that combination treatment safely retards disease progression compared with monotherapy (203). A randomized controlled trial in 109 adults with IgA nephropathy showed that valsartan significantly slowed renal deterioration compared with placebo (204). Although there is no randomized controlled trial for angiotensin II receptor blockers in children with IgA nephropathy, some studies have demonstrated their antiproteinuric effect in combination therapies with angiotensin-converting enzyme inhibitor and angiotensin II receptor blocker (205, 206).

Corticosteroids

Corticosteroids have been widely used to treat moderate to severe IgA nephropathy, particularly in pediatric patients. To date, information concerning not only the effectiveness but also safety of corticosteroid therapy over a long time course has been largely defective. It has been difficult to assess the results of treatment trials with these agents in terms of preservation of renal function, due in part to wide variations in the length of therapy and the dosing regimens employed, and also to the use of corticosteroids in combination with other drugs (185). At present, however, some evidence has been obtained for the role of corticosteroids in the treatment of IgA nephropathy (207–209). In adults with IgA nephropathy, an Italian prospective randomized controlled trial demonstrated that a six-month course of steroid treatment protected against deterioration of renal function with no notable adverse effects during follow-up (207). Recently, the long-term follow-up data of the trial showed that corticosteroids significantly reduced proteinuria and protected against renal function deterioration (208). An English single-center randomized controlled trial has demonstrated that the value of combined immunosuppressive treatment with prednisolone and cytotoxic agents in reducing renal failure in IgA nephropathy (209). A homogeneous cohort of 38 patients who had mean blood pressure within 10% of current targets and estimated GFR 50% normal but losing 10% estimated GFR/year were randomly assigned; no patient had crescentic disease. Renal survival improved 12-fold at 5 year, with remission of nephritis by urinalysis.

With regard to children, our previous studies (193, 210) are the only randomized controlled trials so far to have demonstrated that treatment including corticosteroid for two years early in the course of disease reduces

immunologic renal injury and prevent any further increase of glomerular sclerosis. Up to now, however, it has been unclear whether corticosteroid alone is sufficient for treatment of IgA nephropathy in children, and there has been no reliable evidence for its effectiveness in this group of patients (185). High-dose intravenous methylprednisolone were shown to delay development of renal failure in a randomized controlled trial in adult patients (207). However, no convincing evidence has been published to date to support the use of high-dose intravenous methylprednisolone for the treatment of children with IgA nephropathy.

Immunosuppressants

The use of immunosuppressants other than corticosteroids for treatment of IgA nephropathy has still not been sufficiently evaluated, even in adult patients. Although the results of prospective trials of cyclophosphamide (209) and mycophenolate mofetil (211–213) for IgA nephropathy have been published, their efficacy is controversial. It has been difficult to assess the results of treatment trials with these agents in terms of preservation of renal function, due in part to wide variations in the length of therapy and the dosing regimens employed, and also to the use of corticosteroids in combination with other drugs (185). There is currently insufficient evidence to support the use of immunosuppressants alone for treatment of children with IgA nephropathy. Recently a meta-analysis of immunosuppressive treatments for IgA nephropathy suggested a benefit of corticosteroids and immunosuppressants (214).

Clinical Trials for Combination Therapy Including Corticosteroids and Immunosuppressant in Japan

There has been an even lower number of prospective studies for evaluation of immunosuppressants in children with IgA nephropathy. In this situation, prospective trials by The Japanese Pediatric IgA Nephropathy Treatment Study Group have provided some useful data regarding the treatment of children with IgA nephropathy (193, 210). In the trials, treatment was started early in the course of disease because the duration of the disease before treatment was short and the extent of glomerulosclerosis was low as a result of the Japanese school screening program. Also in the trials, the majority of patients presented with asymptomatic proteinuria and microscopic hematuria detected by this school screening program, which is one of the important factors considered in our prospective trials.

A randomized controlled trial by The Japanese Pediatric IgA Nephropathy Treatment Study Group demonstrated that treatment of children with severe IgA nephropathy showing diffuse mesangial proliferation with prednisolone, azathioprine, heparin-warfarin, and dipyridamole for 2 years early in the course of disease prevents immunologic renal injury and progression of the disease (193).

In a randomized controlled trial carried out sequentially by The Japanese Pediatric IgA Nephropathy Treatment Study Group, the effects of prednisolone, azathioprine, warfarin, and dipyridamole (combination) with those of prednisolone alone was compared in 80 children with newly diagnosed IgA nephropathy showing diffuse mesangial proliferation (210). Patients were randomly assigned to receive either the combination or prednisolone alone for 2 years. It has been conclude that the combination treatment including prednisolone, azathioprine, warfarin, and dipyridamole may be better for severe IgA nephropathy than treatment with prednisolone alone (210).

Based on the two previous randomized controlled trials described above, the immunosuppressant is considered to be important for the treatment in children with IgA nephropathy. Often, however, it was unable to complete azathioprine regimen due to toxicity. Therefore, a different but effective immunosuppressant may be worth trying. Mizoribine, like azathioprine, is an antimetabolite that exerts its immunosuppressant effect by inhibiting lymphocyte proliferation. In a recent prospective pilot study by The Japanese Pediatric IgA Nephropathy Treatment Study Group, mizoribine was administered instead of azathioprine as part of the combination therapy for treatment of 23 children with severe IgA nephropathy, and the efficacy and safety was evaluated (215). In conclusions, the efficacy and safety of the mizoribine combination seems to be acceptable for treatment of children with severe IgA nephropathy (215).

The detailed long-term outcome of previous randomized controlled trials is being investigated at present. One patient reached end-stage renal disease at 10-year after the start of treatment with the azathioprine combination. At the most recent follow-up, none of the 23 patients with the mizoribine combination in the current study had renal insufficiency.

Chinese Herbal Medicine (Sairei-to)

To determine the effect of the Chinese herbal medicine, Sairei-to (TJ-114) in children with newly diagnosed IgA nephropathy showing focal/minimal mesangial proliferation, a randomized controlled trial was undertaken by The Japanese Pediatric IgA Nephropathy Treatment Study Group (216). One hundred and one patients were randomly assigned to receive Sairei-to for 2 years or no drug for 2 years. The trial has demonstrated that 2-year Sairei-to treatment early in the course of disease is effective in children with IgA nephropathy showing focal/minimal mesangial proliferation (216).

Tonsillectomy

Several retrospective studies have analyzed the role of tonsillectomy in the treatment of IgA nephropathy mainly in adult (217, 218). Treatment was not, however, homogeneous between the study groups; patients who underwent tonsillectomy were also treated with steroid pulses, cyclophosphamide, antiplatelets and warfarin. At present studies provide conflicting data. Up to today there is no randomized controlled study demonstrating that tonsillectomy is beneficial even in adult patients with IgA nephropathy. Therefore, it cannot be recommended for widespread use for treatment of IgA nephropathy patients, especially for children with IgA nephropathy (219, 220). The results of an ongoing randomized controlled trial in Japan, which compares the combination therapy of tonsillectomy combined with steroid pulses versus steroid pulses monotherapy, are awaited (219).

Japanese Guidelines for the Treatment of Childhood IgA Nephropathy

Recently, the Japanese Society for Pediatric Nephrology has developed "Guidelines for the treatment of childhood IgA nephropathy." In these guidelines, the disease severity has been divided into two categories, i.e., mild and severe IgA nephropathy, and according to the severity treatments were proposed. A summary of the guidelines is shown in *Table 31-2*.

Concluding Remarks

Progression of IgA nephropathy leads to gradual resolution of mesangial hypercellularity and an increase of matrix and is associated with the development of sclerosis. The majority of children with IgA nephropathy in Japan are diagnosed early in the course of the disease, and the asymptomatic period before the discovery of urinary abnormalities is short. In our controlled trials, the average interval between onset and discovery of disease and start of treatment was 11 months, and no patient showed predominant matrix increase or extensive glomerulosclerosis. Adequate management seems to have improved

Table 31-2

Summary of guidelines for the treatment of childhood IgA nephropathy (ver. 1.0, by the Japanese Society for Pediatric Nephrology)

Mild cases
Definition: Patients who meet both clinical findings AND histological findings as follows
Clinical findings: Slight proteinuria (early morning urinary protein to creatinine ratio <1.0)
Histological findings: $<80\%$ of glomeruli showing moderate or severe mesangial cell proliferation, crescent formation, adhesion, or sclerosis AND $<30\%$ of glomeruli showing crescent formation
Treatments: Either lisinopril or saireito should be given for more than 2 years
Severe cases
Definition: Patients who meet either Clinical findings OR Histological findings
Clinical manifestations: Heavy proteinuria (early morning urinary protein to creatinine ratio ≥ 1.0)
Histological findings: $\geq 80\%$ of glomeruli showing moderate or severe mesangial cell proliferation, crescent formation, adhesion, or sclerosis OR $\geq 30\%$ of glomeruli showing crescent formation
Treatments: The combination therapy of prednisolone, azathioprine or mizoribine, warfarin, and dipyridamole should be given for 2 years

renal survival in Japanese children with IgA nephropathy. Patients with long-standing disease and extensive glomerulosclerosis are unsuitable for treatment. Early diagnosis including exact evaluation disease severity on renal histology and early treatment according to disease severity are very important in IgA nephropathy.

32 Membranoproliferative Glomerulonephritis

Michael C. Braun · Christoph Licht · C. Frederic Strife

Introduction

Membranoproliferative glomerulonephritis (MPGN) is characterized on histology by glomerular hypercellulatity, increased mesangial matrix, thickening of the peripheral capillary walls, and a splitting of the glomerular basement membranes (GBMs) due to mesangial interposition in the capillary walls. The term MPGN was originally used by Habib et al. (1) to describe the glomeruli in a group of patients with chronic nephritis. In 1965, this appearance was associated with hypocomplementemia (2, 3). In 1963, a second chronic nephritis, originally called *dense deposit disease* by Berger and Galle (4), was classified as a variant of MPGN (5) and later designated *MPGN type II*. The more common type, in which subendothelial deposits predominate, was designated *type I*. The terms *lobular* and *mesangiocapillary glomerulonephritis* have been used interchangeably with MPGN. A nephritis morphologically similar to type I found in patients with chronic antigenemia or malignancies lead to the additional classification of secondary as opposed to idiopathic MPGN (*Table 32-1*). In the 1970s, several observers (6–9) described a third type of MPGN. The defining lesion of type III as described by Burkholder et al. (6) was the presence of abundant segmental subepithelial deposits, which shared many features seen in membranous nephropathy. In the type III lesion described by Strife et al. (7) and Anders et al. (9) the subepithelial deposits were much less abundant. Using silver impregnated electron micrographs, they described complex disruptions or laminations of the GBM, together with subendothelial, subepithelial, and intramembranous deposits. This dichotomy within the classification has lead some to suggest there are two "variants" of type III. Although some aspects of MPGN types I and III are similar, the clinical and morphologic differences between the two make their separation feasible. Since this distinction is not universally accepted, this chapter will consider MPGN types I and III together, whereas type II, which is now accepted as a distinct disorder and called Dense Deposit Disease (DDD), will be discussed separately.

Complement Abnormalities in Membranoproliferative Glomerulonephritis

The distinctive feature of MPGN types I, III and DDD is hypocomplementemia (*Fig. 32-1*), caused in many by the presence of autoantibodies, called *nephritic factors* (NFs), directed at epitopes on complement proteins (*Fig. 32-2*). At presentation, the serum C3 concentration is low in 80–95% of patients with types I and III or DDD. In all, four distinct mechanisms are thought to be responsible for the hypocomplementemia: (1) circulating immune complexes which activate the classical complement pathway, (2) NFs which interfere with the normal control of the complement cascade, (3) inhibition of C3 synthesis mediated by circulating C3 breakdown products, and (4) genetic deficiencies or mutations in complement regulatory proteins(10–12).

Of patients with MPGN type I about 40% of those with a low serum C3 level will have a concurrent low serum level of C4, suggesting classical complement pathway activation (*Fig. 32-2*) (13). Reduced serum levels of other early classical complement proteins, such as C1q or C2, may be seen on occasion (14). A NF which acts to stabilize the activity of the classical pathway convertase (NF_c), C4bC2a, is also present in some patients (15).

The complement perturbation in MPGN type III is distinct from that in both type I and DDD; C4 levels are typically normal and severely hypocomplementemic patients (C3 $\leq$ 30 mg/dl) commonly have depressed levels of C5 and properdin and of one or more of the other terminal components, C6, C7, and C9 (16–18). Depression of the latter components is seen in only 10% of those with type I and is not seen in DDD. The NF in MPGN type III is presumably responsible for the low levels of

terminal components (NF_t) (*Fig. 32-2*). NF_t differs from that found in type I (NF_c) and DDD (NF_a) in that in vitro it converts C3 slowly with maximum conversion in 4 h rather than 30 min. The conversion is properdin dependent and is thought to stabilize a convertase with the composition, ($C3bBb_n$), PNF_t, and serves to cleave C5 preferentially (18).

The complement profile and the frequent presence of NF_a are distinctive in DDD (*Fig. 32-2*). The profile is characterized by levels of C3, which may be markedly depressed with normal or near normal levels of other components (16). Thus, the depressed properdin, C4, or C5 levels seen in the other types of MPGN, in acute post-infectious glomerulonephritis and in the nephritis of systemic lupus are not present in DDD. The depressed C3 is produced by activation of native C3 by the alternative pathway convertase, C3bBb, which has been stabilized by the NF of the amplification loop, NF_a (*Fig. 32-2*) or by functional abnormalities in complement Factor H, a key regulator of the alternative complement pathway. The NF_a stabilized alternative pathway C3 convertase, C3bBb, NF_a, has a half life more than 15 times that of the native convertase (19). The activated C3 it forms is quickly inactivated by Factors H and I and is subsequently degraded to the ultimate C3 breakdown products, C3c and C3dg. All three of these derivatives may be found in the circulation (20–22). Recent results obtained from in vivo studies in Factor H and I knock out mice (*Cfh*−/− and *Cfi*−/−) mice suggest a crucial role for these breakdown products for the formation of glomerular complement (C3) deposition (23). However, the relevance of this finding for the understanding of DDD in humans has still to be defined. Finally, heavily contributing to hypocomplementemia is an inhibition of C3 synthesis attributed to a negative feedback produced by the circulating C3 breakdown products (24, 25).

MPGN Types I and III

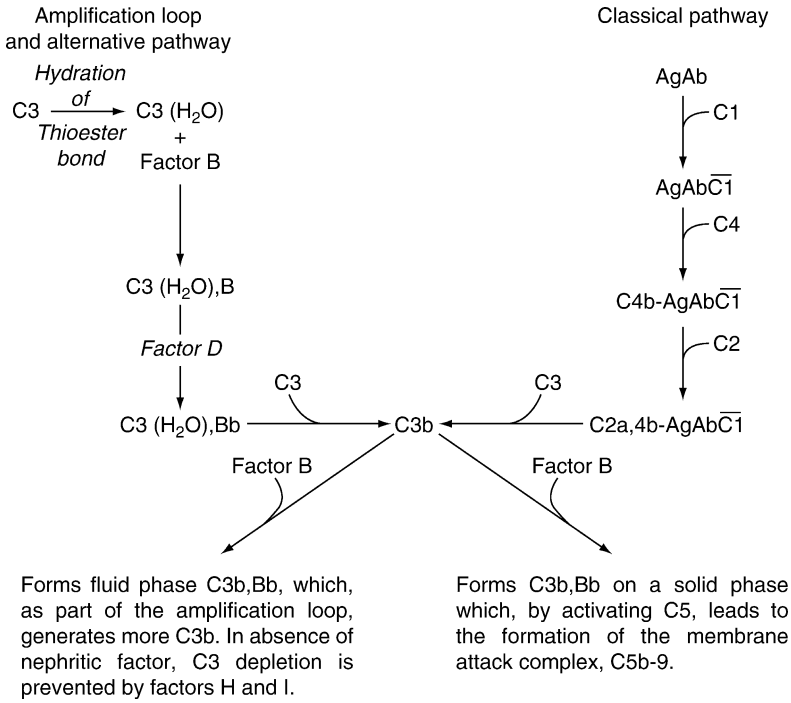
Epidemiology and Genetics

The incidence of MPGN is difficult to ascertain, however it is roughly estimated that there are 1–2 cases per 10^6 pediatric patients (26). There is considerable geographic variation in the frequency of MPGN worldwide. In the US, MPGN I accounts for approximately 1.5% of pediatric patients with ESRD (NAPTRCS Annual report 2007), while reports from India and Nigeria suggest that MPGN is diagnosed in 15 and 52%, respectively, of children with nephrotic syndrome (27, 28). This wide variation in incidence is likely due to secondary MPGN and not idiopathic disease. In most series, MPGN type I has been found to be the most common form (*Table 32-2*). In those studies which distinguished MPGN type I and III, the relative frequency of type III ranges from 14 to 37% (29–34) (*Table 32-2*). In our experience, type III is at least as common as type I (31). MPGN types I and III usually present in older children or adolescents. Occasionally they have been observed in patients older than 30 years or younger than 5 years.

Support for a genetic susceptibility for both MPGN types I and III was provided by the observation that an extended haplotype, HLA-B8, DR3, SCO1, GLO2, is

Figure 32-1

Activation of either the classical or alternative complement pathways produces activated C3, C3b, which can form fluid phase or solid phase C3b, Bb (convertase). Normally both fluid phase and solid phase C3b, Bb are rapidly inactivated by complement control proteins. Both can be stabilized by NF (*Fig. 32-2*). C3b, Bb stabilized on a solid phase can activate C5 and form the membrane attack complex, C5–C9 (Courtesy of John Bissler, M. D.).



significantly more frequent in patients with these two types than in the general white population (35). Also, patients with MPGN types I and III have a similarly high frequency of inherited complement deficiencies (36). Finally, there are a number of reports of familial clustering of MPGN type I (37–41). Reports of familial type III are rare (42). However, an Irish family with eight affected members in four generations was reported. Significant evidence for linkage was observed on chromosome 1q31–32 (43). Interestingly, linkage analysis identified a 22 cM region on chromosome 1 in this cohort which contains the regulators of complement activation (RCA) locus.

Presentation and Clinical Manifestation

The presentation of MPGN generally falls into three categories: nephrotic syndrome, acute nephritic syndrome or asymptomatic hematuria and proteinuria discovered by chance (*Table 32-3*). Due to extensive over-lap, specific MPGN types can not be distinguished solely by presenting clinical features (13).

Asymptomatic micro-hematuria and proteinuria: Almost 50% of patients with MPGN present with isolated hematuria and proteinuria in an otherwise healthy child (*Table 32-3*). This presentation is most common in MPGN type III patients (13). Renal function and serum albumin level are usually normal.

Nephrotic syndrome. Edema as the presenting symptom is present in about one third of patients with either MPGN type I or III. These patients have significant proteinuria usually accompanied by microscopic hematuria with red cell and granular casts. Serum concentrations of albumin and IgG are typically low and about 70–80% will have a low serum C3 level. In the absence of effective treatment, a nephrotic syndrome is strongly associated with a poor prognosis.

Acute nephritic syndrome: Gross hematuria with an acute nephritic syndrome is the presenting feature in about 25% of patients with MPGN. Mild hypoalbuminemia is common. Renal function is usually normal. However, rare patients may develop rapidly progressive glomerulonephritis. Such patients usually have a low serum level of C3, making distinction from acute

Figure 32-2

Fluid-phase activation of C3 in MPGN. In MPGN type II (DDD), the convertase stabilized by NF_a activates only C3. The convertase produced in type I by immune complexes and the nephritic factor complex produced in type III can form a C3, C5 convertase that activates both C3 and terminal components. This results in low C3 levels in DDD, low C3 and C5 levels in type I and low C3, C5 and terminal component levels in type III. On a solid phase such as the renal glomerulus, it is possible that in type I, a C3,C5 convertase is deposited and nephritogenesis is the result. Solid phase events which are nephritogenic in DDD and MPGN type III are not clear. NF_t, nephritic factor of the terminal pathway. P, properdin (Courtesy of John Bissler, M. D.).

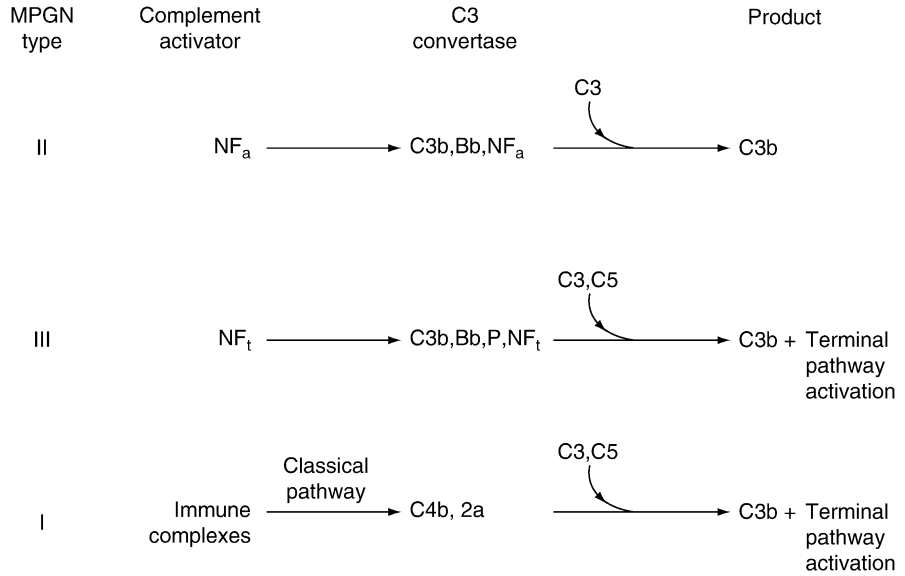


Table 32-2

Relative frequency of MPGN by type

Series	Patient #	Type I (%)	Type II (%)	Type III (%)
Iitaka (29)	41	78	5	17
ISKDC (31)	73	58	19	23
Braun (31)	78	36	23	41
Schwertz (32)	50	52	34	14
Antonovych (34)	100	55	35	10
Little (33)	70	43	33	24
Totals	412	213 (52%)	109 (26%)	90 (22%)

post-streptococcal glomerulonephritis difficult. A biopsy is often not performed until it is apparent that the C3 concentration has failed to return to a normal level as is typical for resolving acute post-streptococcal glomerulonephritis.

Associated clinical features (*Table 32-3*): Estimated glomerular filtration rate (GFR) is commonly lower at presentation in patients with MPGN type I when compared to those with type III (31). There is also a higher frequency of hypertension at presentation in patients with MPGN type I compared to type III. Hypertensive encephalopathy is rare at presentation, but has been reported during follow-up in both treated and untreated patients (30). Antecedent constitutional complaints, including

Table 32-3
Clinical presentation of MPGN types I and III

	Type I (%)	Type III (%)
Clinical Presentation		
Edema	19	32
Gross hematuria	28	24
Asymptomatic microhematuria/proteinuria	22	65
Additional Common Features at Presentation		
Symptoms of systemic disease	26	0
Hypertension	60	21
Low serum C3	68	86
Acute infection prior to presentation	33	26

fatigue, lassitude, and weight loss, characterize the onset in about 25% of patients with MPGN type I, but are not observed in those with MPGN type III (13). An occasional patient, especially with MPGN type I, will have a normochromic, normocytic anemia out of proportion to the degree of renal insufficiency.

Pathology

Glomeruli in MPGN type I by light microscopy (*Fig. 32-3*) usually have a uniform increase in cellularity due to an influx of leukocytes and mesangial proliferation. The mesangial proliferation causes glomerular enlargement and marked reduction in the number of open capillary lumens. With silver stain, capillary walls may show a double contour called *tram-tracking*. This is the result of new basement membrane formation at the site of mesangial interposition. With progression, the mesangial proliferation may become replaced by centro-lobular hyalinization, giving the glomeruli a progressively more lobular appearance. In MPGN type III the degree of mesangial proliferation is typically less in comparison to type I, and often focal in distribution (*Fig. 32-3*). Glomerular size is usually normal. Double contoured capillary walls are rare, due to less mesangial interposition. These differences, however, cannot reliably distinguish MPGN type I from type III by light microscopy.

Immunofluorescent microscopy (44) usually can distinguish type I from III (*Table 32-4*) in that C4 is usually present in type I, and staining for C3, C4, and IgG co-localize on the periphery of the glomerular lobules, the so called "fringe" pattern (*Fig. 32-4*). In MPGN type III, C3 deposition is typically in a mesangial and capillary loop pattern, C4 is rarely present and IgG is present in small amounts in about 50% of biopsies (13).

Ultrastructural studies are essential in order to distinguish MPGN type I from type III (*Table 32-5*). In MGPN type I uranyl-lead stained micrographs typically demonstrate a completely intact GBM without breaks or laminations (*Fig. 32-5*). There is prominent mesangial proliferation with extension of the mesangium at least partially around the glomerular capillaries (interposition) which, combined with the subendothelial deposits, causes narrowing of the capillary lumen.

In MPGN type III, uranyl-lead stains typically demonstrate a complex thickening and irregularity of the GBM. However, the type III lesion, characterized by a discontinuous fragmented, laminated appearance of the GBM (*Table 32-5*), is best seen with methenamine silver stains (*Fig. 32-5*). The distribution of deposits in this lesion has been shown to vary according to the C3 level at the time of the biopsy (*Table 32-5*).

Pathogenesis

Idiopathic MPGN type I is presumed to be secondary to circulating immune complexes composed of [IgG (antibody)-unknown antigen-C3] which deposit in the subendothelial glomerular space, giving rise to a response that includes marked mesangial proliferation. Evidence for this hypothesis is based on the observation that indistinguishable renal pathology is present in MPGN type I secondary to infectious, oncogenic and antigenic causes (*Table 32-1*). In addition, the pattern of complement activation is via the classical complement pathway in at least 40% of patients, favoring the presence of circulating immune complexes.

This hypothesis has been further strengthened by the clear association of MPGN type I and hepatitis C virus (HCV) infection (45). Recent studies have suggested that it is not the chronic antigen exposure, but rather the development of persistent cryoglobulinemia that is the critical pathogenic factor (46). In a large study of Italian patients with HCV and cryoglobulinemia, MPGN type I lesions were found in more than 80% of patients (47). Conversely in a study of French patients with chronic HCV infection renal disease was found only in those with detectable levels of cryoglobulins (48). However, there are no studies that convincingly identify circulating immune complexes in pediatric patients with MPGN type

Figure 32-3

Light microscopic appearance of MPGN type I (a) and type III (b). (a) The glomerulus is enlarged, very cellular, and has a lobulated appearance. The mesangium is markedly expanded. The capillary walls are thickened in appearance and frequently the capillary lumens are obscured by the mesangial expansion. In addition to the increase in mesangial cells, scattered neutrophils are also identified in many of the segments. (b) The glomerulus in type III is less cellular in appearance and there is less expansion of the mesangium. Most of the capillary loops are patent; however, thickened capillary walls are evident (Courtesy of David Witte, M.D.). (See color plate 13)

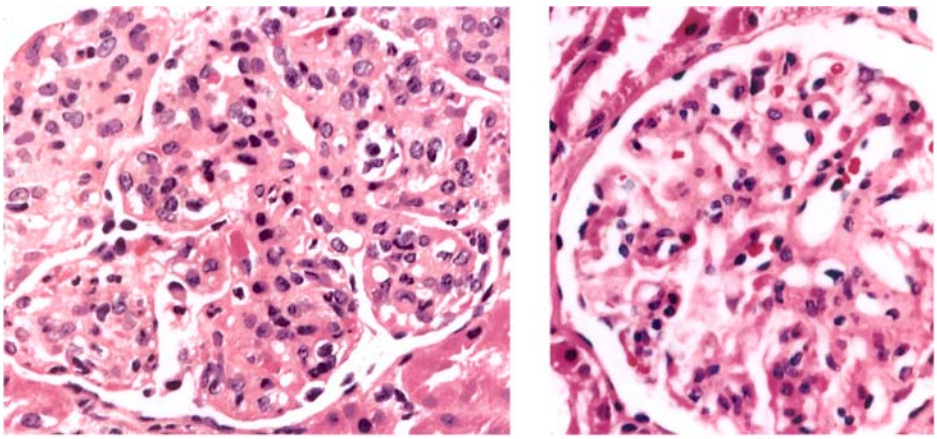

Table 32-4

Comparison of immunofluorescent microscopy in MPGN types I and III

MPGN	C4	C3	C5	IgG
Type I	75%	100%	100%	100%
Type III	0	100%	100%	50%

Adapted from reference (44)

I, and chronic HCV infection was not found retrospectively in a large cohort of pediatric patients with idiopathic type I (49).

Little is known regarding the pathogenesis of MPGN type III. Normal serum C4 levels and the absence of C4 in glomeruli suggest that immune complex formation does not play a major pathogenic role. West and associates (50, 51) have reported a strong association between hypocomplementemia and the presence of paramesangial and subendothelial deposits. Subendothelial deposits in particular were never found in normocomplementemic patients at biopsy (*Table 32-5*). This suggests that NF_t may play a significant role in the development and perpetuation of the ultrastructural changes that define MPGN type III. This hypothesis must be reconciled with other reports which have failed to demonstrate any relationship between the presence of NF, the duration or severity of hypocomplementemia, and either renal survival or disease progression in MPGN type III (31, 52).

Natural History

The natural history of MPGN was described in detail by Cameron et al. (53) in a report comparing the long-term outcome of 69 children and adults with MPGN type I (type III presumably was included in this group) to 35 with DDD (*Fig. 32-6*). The outcome was poor irrespective of type, with 50% losing renal function by 10 years and 90% by 20 years. Similar results have been observed by Habib et al. (5). Cameron et al. (53) noted that MPGN type I progressed more slowly in children than in adults during the first 10 years of follow-up. There are no reports that compare the courses of MPGN types I and III in the absence of effective treatment. Outcome has been shown to be worse in those presenting with nephrotic syndrome, renal insufficiency, and/or with crescents in their initial biopsy.

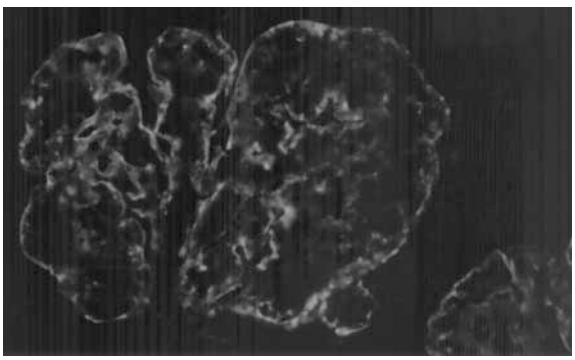
Treatment

The effectiveness of treatment regimens for MPGN has to be judged by the outcome of typically uncontrolled,

retrospective observational studies involving small numbers of patients. In several series, the effects of the treatment regimens were confounded by the inclusion of patients treated with other agents either prior to enrollment or during the study period. Despite these shortcomings, some consensus has emerged (54).

Figure 32-4

Immunofluorescence appearance of MPGN type I. The prominent peripheral distribution of IgG deposits in the capillary walls results in a "fringe" pattern (Courtesy of David Witte, M. D.). (See color plate 14)



Steroids. The treatment regimens that appear to improve outcome in patients with MPGN types I and III have used steroids. The Cincinnati group (31, 55–57) has used "high dose" (2 mg/Kg to a maximum of 80 mg) alternate day prednisone for a minimum of 2 years. Dose reduction thereafter is based on improvement of clinical parameters (urinalysis, serum albumin, serum C3 level) and glomerular morphology (degree of mesangial proliferation, number of open capillary lumens). Long-term, prednisone dose is slowly reduced if there is no evidence for disease reactivation (increase in proteinuria, and/or hematuria and/or decrease in serum C3 level). Since many, if not most patients will continue with at least some degree of proteinuria as a result of chronic glomerular damage, loss of microhematuria appears to be the best clinical indicator of disease remission (56). Most patients have continued on alternate day steroids for at least 5 years and many for much longer periods.

Reports of outcome with this regimen have been encouraging, but continue to be difficult to interpret because of small patient numbers, retrospective analysis of data, lack of a control group and use in some patients of adjunctive therapies. In the most recent report (31) using the same alternate day prednisone regimen, renal survival was 80% at 10 years in those with type I, and 70% in those

Table 32-5

Differences in glomerular ultrastructure in type I and type III MPGN as viewed in uranyl-lead and methenamine-silver stained preparations

	Type I	Type III
Uranyl-lead staining		
Basement membrane	*Intact*	Thickened areas with patchy dense deposits
Methenamine-silver staining		
Basement membrane	*Intact*	*Type III lesion*[a] present with both ↓ [C3] and nl [C3]
Uranyl-lead and methenamine-silver staining		
Subendothelial deposits	*Always present with ↓ [C3]* *Present in 50% with nl [C3]*	*Present in 50% with ↓ [C3]* *Never present with nl [C3]*
Subepithelial paramesangial deposits	*Very rare. Never with nl [C3]. In ~12% with ↓ [C3]*	*Present with ↓*[C3] *and in those with nl [C3] if level has been low in past year*
Subepithelial loop deposits	Frequent, accompany subendothelial deposits	May be present. Not clearly related to [C3]

↓ [C3], serum C3 level low at time of biopsy; nl [C3], serum C3 level normal at the time of biopsy

Note: Correlations of deposits with serum C3 levels are taken from references (4) and (50). Italics indicate key features differentiating types I and III

[a]Type III lesion is a complex lesion of the GBM that appears to originate from several generations of subepithelial and subendothelial deposits forming in conjunction with multiple interruptions of the lamina densa, such that the deposits are partially confluent. Lesions develop a complex laminated appearance because each generation of deposit is covered by new lamina densa-like material (From (31) with permission)

Figure 32-5

Ultrastructural features of MPGN type I and type III. (a) An electron photomicrograph of a glomerulus with MPGN type I. Note the prominent mesangial proliferation and deposits in the mesangium. The capillary walls are thickened due to extensive interposition (*arrow*) in addition to prominent subendothelial deposits (*asterisk*). In this silver-stained preparation, the lamina densa can be clearly identified and is generally intact. (b) The glomerulus with the type III lesion also shows by silver stain extensive mesangial proliferation and deposits. The capillary walls show extensive disruptions of the lamina densa with deposits that are subepithelial, subendothelial, and, at times, completely obscure the lamina densa (Courtesy of David Witte, M. D.).

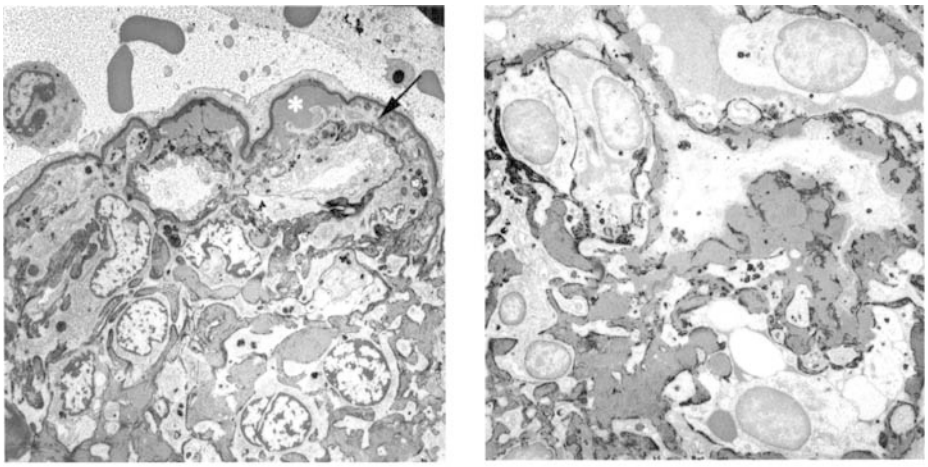


Figure 32-6

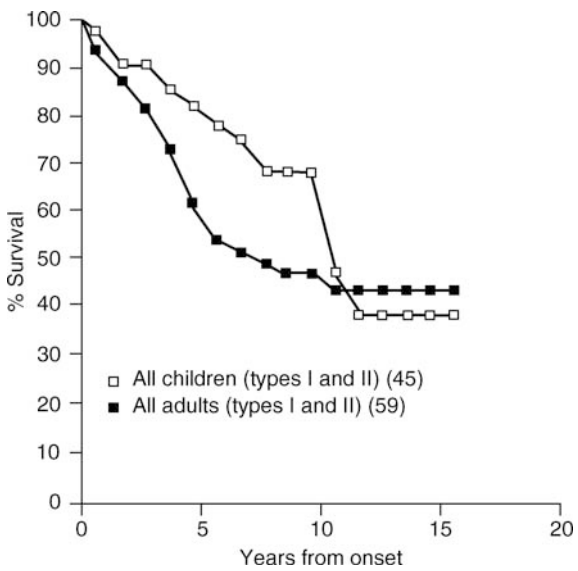
Comparison of renal survival between adults and children (From (53) with permission).



with type III. In addition to a lower renal survival, those with type III had at 10 years a significantly greater frequency of proteinuria and hematuria and a lower glomerular filtration rate.

Based on early reports of improved outcome with alternate day prednisone, the International Study of Kidney Disease in Children (ISKDC) sponsored a randomized, double-blinded, placebo-controlled 5-year trial of alternate day prednisone, 40 mg/m^2 versus placebo in 80 children with MPGN and heavy proteinuria (30). The study included 42 patients with MPGN type I and 17 with type III. Treatment failure was defined as an increase in serum creatinine of either $\geq$30% over baseline or $>$0.4 mg/dl. Outcome analysis evaluating patients with MPGN types I and III as a group showed that at last follow-up (mean 5.25 years) 33% of patients treated with prednisone and 58% in the placebo group were treatment failures ($p = 0.07$). The results favored treatment with prednisone.

Similar results were obtained by Mota-Hernandez et al. (58) who treated eight MPGN type I patients with alternate day prednisone and ten with placebo. After an

average follow-up of 6 years, treated patients had stable or improved renal function whereas 4 of 10 placebo-treated patients had progressed to end-stage renal disease. Recently a larger study of some 47 patients with MPGN type I by the Mexico City group reported similar findings (59).

Additional uncontrolled reports have favored the use of alternate day prednisone (29, 60–62). The observation that in the absence of treatment, the disease in those not nephrotic at presentation progresses more slowly (5, 53) has led to the recommendation that steroids be withheld in these patients (63) or used in a low dose (61, 62). However, others have shown significantly better outcome in patients treated with prednisone early in the course of the disease regardless of severity (29, 56).

Long term follow-up data on patients with MPGN type III has been published by a number of centers (31–33, 64). The report by Iitaka et al. (64) is by far the most promising with 100% renal survival after 16 years of follow-up. However, it is uncertain if the universally good outcome was due to early identification and aggressive therapy, or to an unknown factor which moderates the course of the disease in the Japanese population. The outcomes for patients with type III reported by Little et al. (33), Braun et al. (31) and Schwertz et al. (32) is less encouraging with renal survivals of 65% at 5 years, 70% at 10 years and 50% at 15 years, respectively.

Other therapies. Other controlled prospective treatment trials have shown no long-term benefit with the anti-platelet agent, dipyridamole (65) or with cyclophosphamide, warfarin and dipyridamole (66). Uncontrolled reports have suggested no or limited benefit from treatment with other cytotoxic agents, antimalarials, or anticoagulants. Cyclosporine was reported to improve the outcome of 8 patients with MPGN resistant to steroids and of 17 of 18 adult patients with idiopathic MPGN resistant to treatment with either steroids or anti-platelet agents (67). Two patients resistant to steroids were reported to improve after addition of tacrolimus (68). There have been several recent reports suggesting that mycophenolate may be of some benefit in the treatment of MPGN type I (69–71). While encouraging, these results should be viewed with caution as the follow-up times were brief, the numbers of patients small, and histologic and serologic characterization of the patient population was limited. There have been a number of larger treatment trials in adult populations with MPGN type I secondary to HCV (72). These studies, using either anti-viral agents combined with plasmapheresis or immunodepletion with anti-CD20 antibody, have shown promise in halting progression of disease. However, given the low frequency of secondary forms of MPGN type I in children, the rational for the use of these approaches in pediatrics is uncertain.

Disease Recurrence in Renal Transplant Recipients

MPGN type I frequently recurs after kidney transplantation (73). Lien and Scott (74) collated 61 reports of recurrence of MPGN (not separated into type I or III) in 218 renal transplants indicating the rate of recurrence to be about 30%. There is limited data on recurrence in type III; however the report by Little et al. suggests that the recurrence rates of type I and type III are similar, 36 and 34% respectively (33). Of those with recurrent type I, graft half-life was significantly shortened with graft loss from recurrence in more than half of patients (73). It is possible that the chance for recurrence may be decreased by the use of cyclosporine following transplantation (75). Once a recurrence manifests, however, the approach to treatment is unclear. Case reports have suggested that graft survival may be improved by the addition of cyclophosphamide to immunosuppressive drugs which include a calcineurin inhibitor (74, 76).

Dense Deposit Disease

Epidemiology and Genetics

Dense deposit disease (DDD) (MPGN type II) is the least frequent of the three MPGN types (*Table 32-2*). It constitutes 19–34% of the cases in whites and 5% in Japanese. DDD affects males and females equally and is primarily a disease of children and young adults with a median age at onset of approximately ten years (53, 54, 77, 78). In most patients there is no evidence for a genetic basis for the disease. Two families in which only one of a pair of identical twins has the disease have been reported (79). A small subset of patients with DDD has been identified to have mutations in the key complement regulator, Factor H, which results in un-inhibited C3 activation (80) Uninhibited C3 activation and glomerular pathology similar to DDD has been reproduced in mice and piglets with Factor H deficiency (reviewed in (11)).

A recently performed genotype-phenotype study suggested that there was co-segregation of specific allele

variants of the genes encoding for Factor H (*CFH*) and Factor H related protein 5 (*CFHR-5*) and DDD (81). Furthermore, the common Factor H variant H402Y, which has recently been identified as a susceptibility factor for age-related macular degeneration, is also found at higher prevalence in patients with DDD (70%) compared to healthy controls (29%) (82).

Presentation and Clinical Manifestation

Symptoms and signs at presentation can not distinguish DDD from MPGN types I or III. An upper airway infection or immunization may precede the clinical onset in about half of patients, suggesting that biological stress factors may initiate renal injury. Microscopic hematuria is always present and proteinuria is common. Nephrotic syndrome at onset is seen in 50% (32) and has been associated with a poor prognosis (83, 84). In 20% of patients onset is associated with macroscopic hematuria and 30% have hypertension (32). Occasionally, patients present with renal failure and have a rapidly progressive course (85, 86).

The clinical course frequently is characterized by persistent or evolving nephrotic syndrome and increasingly severe hypertension (83, 85, 87). Conversely, some patients may have periods after the onset of disease when their nephritis is "silent" (85); their urinary abnormalities completely disappear and only hypocomplementemia remains. Signs of overt nephritis may recur, most commonly with intercurrent infections, and these findings can persist.

In addition to renal injury, there is evidence of complement dependent injury in other organ systems such as the eye (82, 88), spleen (89, 90), and fat tissue (91) indicating the systemic nature of this disorder. Dense deposits similar to those found in the GBM can develop in the basement membranes of the retina which resemble those seen in adults with age-related macular degeneration (82, 88). Furthermore, dense deposits occur within the basement membrane of the sinusoids of the spleen (89, 90). It is of interest that these spleen and eye membranes, like the GBM, are unique in that they are bathed in plasma.

Partial lipodystrophy (PLD), characterized by the loss of fat tissue especially in the face and upper body, is associated with NFa, low C3, and subsequent development of DDD. A pathogenetic link between NFa and PLD is based on the fact that adipocytes produce key components of the alternative complement pathway, including Factor D, C3 and Factor B. In vitro, NFa containing sera results in adipocyte lysis associated with increased fluid-phase terminal complement complex formation (91). PLD may be present for years before clinical evidence for nephritis develops (92). Gerth et al. reported a female with PLD at age 11 who developed glomerulonephritis (DDD) at age 21, and eventually macular degeneration at age 54 (93). Recently a familial form of PLD also associated with DDD was reported in a patient with Dunnigan-Kobberling syndrome (94–96).

Pathology

In most cases, by light microscopy the glomeruli are uniformly hypercellular with increased mesangial matrix and the number of open capillary lumens is commensurately reduced. In contrast to MPGN type I, the proliferation is rarely great enough to increase glomerular size. The diagnosis of DDD can occasionally be made by light microscopy of silver stained preparations; the basement membrane is thickened and at sites of the intramembranous deposits, argyrophilia is lost. Deposits are located along the GBM, the Bowman's capsule, and the tubular basement membrane.

By immunofluorescence, IgG, IgA, IgM, and C4 are rarely found in glomerular deposits indicating that the classical pathway of complement is not activated. C3 deposits are abundant. Kim et al. (97) found C3 to be present along the margin but not within the central portion of the dense deposits in the GBM, giving a double linear appearance (railroad tracks). They also observed C3 deposits within the mesangium outlining circular structures that represent shed fragments of the basement membrane (mesangial rings). The railroad tracks are visualized with labeled anti-C3c and -C3d, indicating that they are composed of C3b, iC3b, and C3dg, whereas the paramesangial deposits stain only with anti-C3c, indicating that they are formed from C3c deposited from the circulation (98).

The diagnostic intramembranous deposits are best seen by electron microscopy of uranyl lead stained specimens (*Fig. 32-7*). They usually occupy only the lamina densa but occasionally may be present only in the lamina interna (99). The deposits may be discontinuous. Similar deposits may also be found in Bowman's capsule and in the basement membranes of isolated groups of tubules. If searched for, subepithelial deposits can be found on the parts of the basement membrane that overlay the mesangium (paramesangial) if the patient was biopsied when hypocomplementemic (100). Occasionally, hump-like subepithelial deposits are present on the capillary loops.

Pathogenesis

The pathophysiology of DDD *in humans* is still poorly understood. However, excessive activation of C3 by un-regulated C3 convertase, C3bBb, appears crucial for the pathogenesis (11, 12, 101). DDD is most often associated with NFa, an IgG autoantibody which binds to a neoantigen on the C3 convertase, C3bBb, making it resistant to inactivation by Factor H, resulting in continuous C3 activation. NFa is present in 55% of adult and 80% of child onset DDD (52). Whereas atypical HUS has commonly been observed in humans with deficient or dysfunctional Factor H, this association with DDD has only been rarely reported (11, 80, 102). Licht et al. described two siblings with DDD and mutation of the factor H gene resulting in functionally defective factor H protein. Both siblings were also positive for C3NeF (80). Meri et al. reported a patient with factor H autoantibody and hypocomplementemic DDD (103). Patients with Marder's disease have MPGN and a C3 mutation that renders the C3b molecule unable to bind factor H, resulting in permanent complement activation (104). Observations in a strain of Factor H deficient piglets that developed glomerular lesions similar to DDD support the hypothesis that unregulated C3 activation is important to the pathogenesis. In addition, Factor H deficient mice have also been shown to develop glomerular lesions similar DDD (105). In this model glomerular lesions were prevented when C3 activation was blocked by crossing Factor H deficient mice with Factor B deficient animals. Further observations in mice have shown that Factor I is required for GBM C3 deposition, confirming that C3b metabolites target the GBM (23). Last, in mouse kidney transplant studies, C3 deposited on the GBM was shown to be derived from plasma (11). Taken together, these observations support the hypothesis that in the pathogenesis of DDD C3 metabolites, formed from Factor I induced proteolytic breakdown of C3b to iC3b, C3dg, and C3c, are required, and deposit in the GBM. Currently however, it is not known if the deposition of C3 breakdown fragments on the GBM is responsible for formation of the dense deposits or if the dense deposits precede complement deposition. Finally, it is not understood why some individuals with un-regulated alternative pathway activation develop DDD while others develop atypical HUS or other glomerular lesions.

Natural Course

Children with DDD have a poor prognosis and half progress to end stage renal disease (ESRD) within 10 years with the degree of proteinuria and hypertension being negative predictors (32, 106). Interestingly, Little et al. recently reported that when comparing different MPGN types, the severity of the glomerular injury on the initial renal biopsy and presentation with nephrotic syndrome, rather than the MPGN type determined renal survival (33).

Treatment

Treatment options for patients with DDD are scarce and are primarily supportive in nature. Anti-platelet, anti-coagulant, and immunosuppressive drugs, usually in combination with corticosteroids, have been used but there is no clear evidence that such regimens are effective. Although not validated by a controlled trial (30), high dose alternate day prednisone is currently the most widely used treatment (107). However, response to treatment with this regimen is neither consistent nor unpredictable. In a series of 14 patients who have received this regimen, the disease in five is in remission; serial renal biopsies showed improvement in these patients to the extent that the dense deposit in the GBM was partially or completely lost (108). Experience with other immune suppressants including calcineurin inhibitors (109) and mycophenolate is either limited or not available.

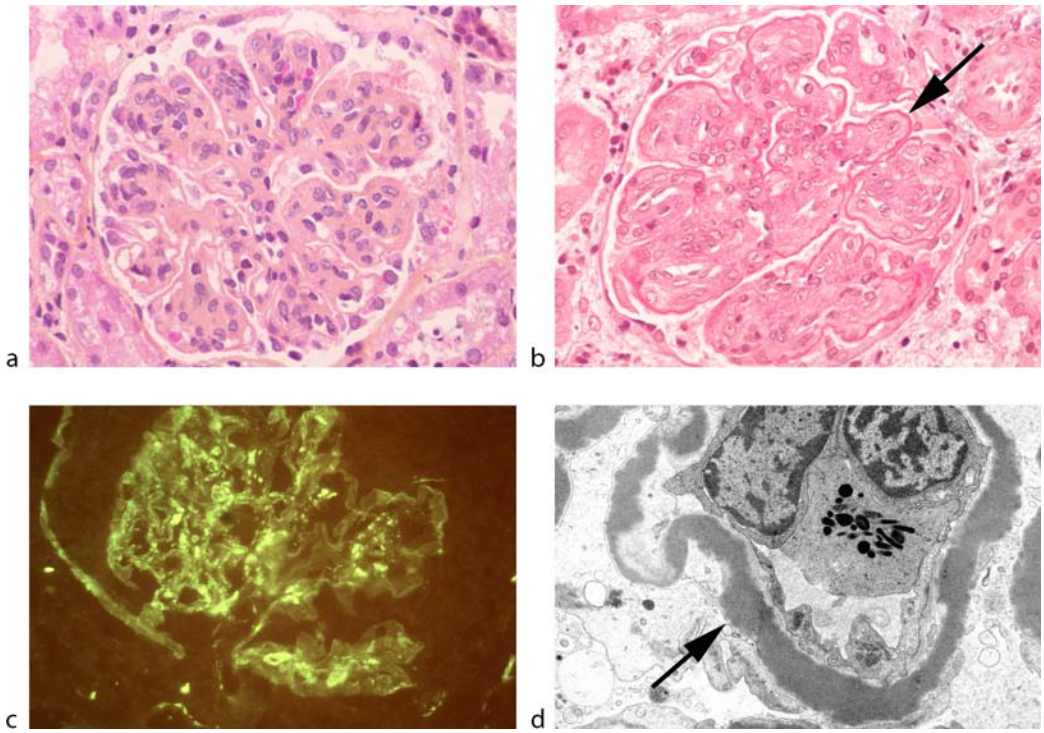
For patients with a genetic defect in the regulation of the alternative pathway, replacement of the abnormal protein by infusion of plasma, or the purified or recombinant protein has been successful. There are isolated case reports of the successful treatment of DDD with plasmapheresis (110–112) which reduces circulating NF. Novel therapies such as anti-CD20 antibody, humanized monoclonal anti-C5 IgG antibody, sulodexide (a combination of low molecular weight heparin and dermatan sulfate) with profibrinoloytic and antithrombotic activity, have been proposed (78). However their utility in the treatment of DDD is currently untested.

Disease Recurrence in Renal Transplant Recipients

The histological recurrence rate of DDD with occurrence of dense deposits within the GBM after renal transplantation is high, ranging from 50–100% (113, 114). Recurrence has been reported as early as 12 days posttransplantation (114). Histological recurrence can precede clinical recurrence of glomerulonephritis. It is uncertain, however, if the presence of dense deposits in the absence of clinical signs of active nephritis has an impact on overall graft survival. The development of

Figure 32-7

Pathology of dense deposit disease: (a) By light microscopy, glomeruli show accentuation of lobules with hypercellularity of mesangial regions and thickened capillary loops (hematoxylin-phloxine-safranin stain, original 600) (b) The capillary loop basement membranes often show a ribbon-like staining pattern (*arrow*) (Masson trichrome, original 600) (c) By immunofluorescence microscopy, glomeruli show mesangial and capillary loop deposition of C3, but immunoglobulins are usually negative (original × 600). By electron microscopy, capillary loop basement membranes show a characteristic electron dense transformation (*arrow*) that can vary from intramembranous to transmembranous and involve different loops to different degrees (original × 10,000) (Courtesy of Paul Thorner, M. D.). (See color plate 15)



dense deposits prior to C3 deposition within the GBM was described in 3 patients (114). A number of investigators have correlated disease recurrence with persistent or recurrent hypocomplementemia (115–117), whereas others could find no correlation with either low C3 levels or the presence of NF (118, 119). Published reports of graft loss due to recurrent DDD varies widely from 0–100% (83, 116, 117, 120–122). The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) transplantation database analyzed the long-term consequences of disease recurrence: five-year graft survival of DDD patients was worse than of the other patients in the database (50.0% vs. 74.3%). Five-year graft survival of living related donor grafts was better than with deceased donor grafts (65.9% vs. 34.1%). The primary cause of graft failure in 14.7% of patients was disease recurrence. While no correlation was found for pre- or posttransplant C3 levels and disease recurrence or graft failure, there was a strong association between the degree of proteinuria and disease recurrence (123). Little et al. (33) recently reported that the only factors predictive of recurrence risk were younger age at initial diagnosis and presence of cellular crescents on the initial native kidney biopsy.

33 Membranous Nephropathy in the Pediatric Population

J. Ashley Jefferson · William G. Couser

Introduction

Membranous nephropathy is a disease that typically presents with nephrotic syndrome, and although more common in the adult population, has been described in children, and even in the newborn. The disease is defined by the presence of subepithelial immune deposits (between the glomerular basement membrane (GBM) and the podocyte) with subsequent expansion of the GBM resulting in a membrane-like (membranous) thickening of the glomerular capillary wall. The subepithelial immune complexes which are separated from the circulation by the GBM, do not cause inflammation or recruitment of circulating leukocytes (nephritis), but rather lead to complement dependent podocyte injury and nephrotic syndrome.

Epidemiology

Membranous nephropathy is the most common cause of nephrotic syndrome in older adults (1), but is an uncommon condition in children, with less than 200 cases described (see *Table 33-1*). In adults, the disease is mostly idiopathic, although about 20% of cases are associated with clinical conditions such as cancer, infections, autoimmune disease and drugs. In childhood, MN is more often due to secondary causes such as systemic lupus erythematosis, hepatitis B, drugs and toxins. By contrast, idiopathic MN is a relatively rare cause of nephrotic syndrome in children. Single center studies of pediatric biopsy series report that around 5% (range 1–7%) of renal biopsies for nephrotic syndrome were due to MN (2–4, 8, 9) with an estimated incidence of less than 1 per million childhood population (10). It should be remembered however, that the majority of children with nephrotic syndrome have minimal change disease and do not undergo renal biopsy until they have failed a course of steroid therapy, and thus, the biopsy data greatly overestimates the incidence of MN as a cause of nephrotic syndrome. The strong male predominance in adult patients is not found in children, and the disease can occur in all ethnic groups. Age at presentation can vary from neonatal to young adulthood, but the mean age is typically 8–10 years.

Etiology and Pathogenesis

Mechanisms of Immune Complex Formation in the Subepithelial Space

Membranous nephropathy is characterized by the development of immune complexes in the subepithelial space on the outer surface of the glomerular basement membrane. The immune deposits consist of immunoglobulin (IgG, predominantly IgG4), complement components (C3, C5b-9), and presumably antigen, which in most cases has not been identified. The subepithelial space is separated from the circulation by a layer of endothelial cells and the GBM, and this provides an effective barrier to the passage of pre-formed circulating immune complexes. The presence of immune complexes in the subepithelial space therefore suggests either *in situ* formation involving podocyte antigens or planted exogenous antigens, or the reassembly of circulating immune complexes that have deposited in subendothelial areas, dissociated and crossed the GBM, to reform *in situ* beneath the podocytes (reviewed in (11)). However, circulating immune complexes are rarely detected in idiopathic MN (12) and, in an *ex vivo* model, the isolated perfused kidney, subepithelial immune complexes of Heymann nephritis (see below) were produced with nephritogenic anti-podocyte antibodies in the absence of circulating antigen (13). The most likely scenario in idiopathic MN, is that autologous antibodies react to an endogenous antigen on the podocyte foot process in a mechanism similar to the Heymann nephritis model (14). In this model a glomerular lesion indistinguishable from human membranous nephropathy can be produced by immunization of rats with extracts of proximal tubular brush border (active Heymann nephritis) or injection of heterologous anti-serum or IgG to a crude tubular preparation called

Fx1A (passive Heymann nephritis). This results in the development of subepithelial deposits of IgG, C3 and C5b-9 associated with heavy proteinuria. The immune deposits form *in situ* due to the binding of circulating IgG to antigenic epitopes expressed on the foot processes of the glomerular epithelial cell. Immune complexes may also form *in situ* by the reaction of antibody to an exogenous antigen which has become trapped in the subepithelial space (planted antigen). This mechanism may explain the association of membranous nephropathy with some infections and certain drugs (*Table 33-2*).

Potential Podocyte Antigens

In Heymann nephritis the antibodies are targeted against the Heymann nephritis antigenic complex (HNAC) consisting of two proteins, megalin and receptor associated protein (RAP) (15). Megalin is a 600 kDa molecular weight glycoprotein belonging to the LDL receptor family, which acts as a multi-functional receptor facilitating endocytosis. It is expressed in both the brush border of proximal tubular cells (16) and in the clathrin-coated pits on the sole of podocyte foot processes (17). Megalin forms a heterodimeric complex with RAP, and several epitopes on this complex seem to be involved in the formation of the immune deposits (18). Notably, in animal models, active immunization with megalin alone or passive immunization with anti-megalin antibody result in the accumulation of immune deposits in the subepithelial space, but no C3 or C5b-9 deposition is seen and no proteinuria occurs (19). We now recognize that other antibodies in the anti-Fx1A fraction inhibit complement regulatory proteins on the podocyte leading to local activation of the alternate complement pathway. Despite the similarities between Heymann nephritis and human disease, megalin, although expressed in human tubular cells, is not expressed by any human glomerular cells, and therefore, cannot be the pathogenic antigen responsible for human MN. However, recent studies by Salant et al. have identified antibodies to phospholipase A2 receptor (PLA2R) in a majority of patients with active MN and found correlations between this antibody and response to therapy or relapse of the disease (133). PLA2R is a transmembrane podocyte glycoprotein with a similar distribution to megalin and co-localizes with IgG in the subepithelial deposits in human MN.

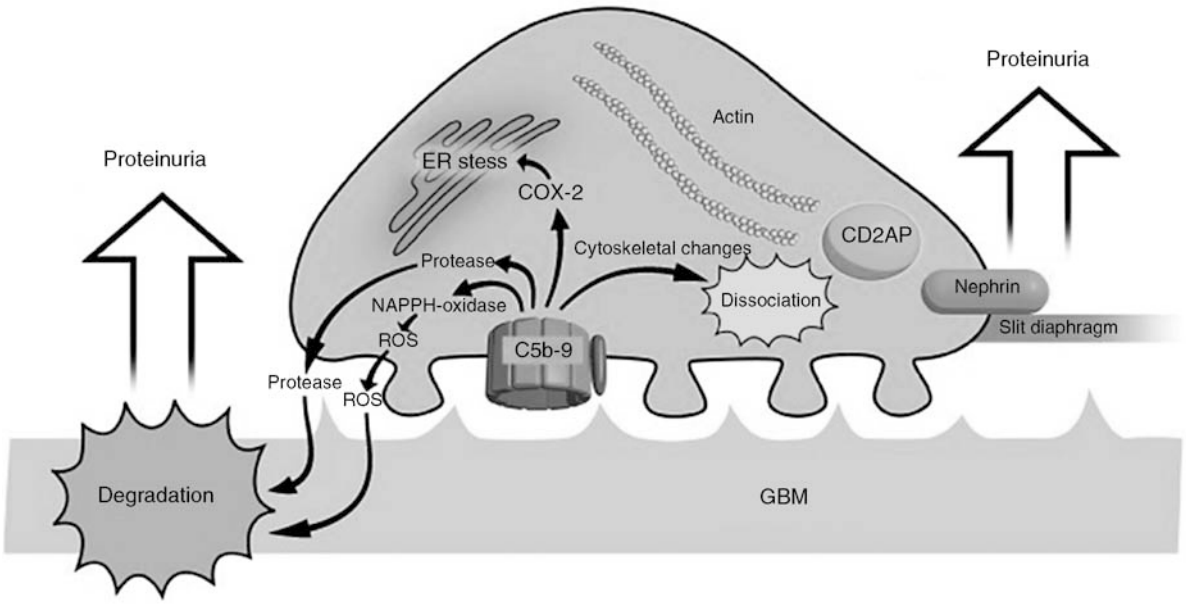
Two other animal models of MN have been produced by antibodies targeting dipeptidyl peptidase IV (DPPIV) in rats (20) and neutral endopeptidase (NEP) in rabbits (21). Importantly, both of these antigens are expressed on the human podocyte (as well as human glomerular endothelial cells). Subsequently, NEP was identified as the target antigen in several cases of neonatal MN (see below) (22).

Possible Antigens in Secondary Membranous Nephropathy

A range of antigens have been detected in the subepithelial immune deposits in the secondary forms of MN. These include tumor antigens (carcinoembryonic antigen, prostate specific antigen, others), thyroglobulin, infection antigens (hepatitis B, hepatitis C, helicobacter pylori, syphilis) and DNA associated antigens (dsDNA, histones, nucleosomes) (23). Although it has been postulated that

Figure 33-1

Pathogenesis of membranous nephropathy. Immune complex formation in the subepithelial space is associated with activation of complement, predominantly via the alternate pathway leading to the insertion of C5b-9 into the podocyte cell membrane. This results in podocyte cytoskeletal injury and alterations in slit diaphragm proteins leading to proteinuria. The release of reactive oxygen species (ROS) and proteases leads to remodeling of the glomerular basement membrane (GBM).



these antigens are pathogenic, they may merely reflect non-specific trapping of proteins due to the increased permeability of the glomerular endothelium and GBM.

Mediation of Injury: The Role of Complement and the Alternate Pathway

In MN, C3 and C5b-9, the membrane attack complex (MAC), can be detected in supepithelial immune deposits (24). The C5b-9 inserts into the podocyte membrane and causes cell activation with release of reactive oxygen species, proteases and eicosanoids which damage the GBM. C5b-9 is subsequently internalized by the cell, transported in multivesicular bodies to the luminal surface and exocytosed into the urinary space (25). Based on studies in rodent models, the urinary excretion of C5b-9 correlates with the period of active immune complex deposition (26, 27) Notably, generalized complement depletion with cobra venom factor (28) or specific C6 depletion with anti-C6 antibody (29) abolishes the proteinuria in passive Heymann nephritis (PHN). Similarly, C6 deficient rats are protected from Heymann nephritis (30) or the development of proteinuria is significantly delayed (31).

It had long been considered that the immune deposits in MN activate complement via the classical pathway with the production of C5b-9. Indeed, deposition of components of the MAC are detected in the subepithelial deposits in both Heymann nephritis (32) and human membranous nephropathy (24) However, in most cases of idiopathic MN, the predominant immunoglobulin deposited is IgG4 (which has little C1q fixing ability) (33). Similarly, there is minimal, if any, detectable deposition of C1q and C4 suggesting that the classical pathway is not the predominant means of complement activation in this disease (34).

Evidence in experimental MN suggests that inhibition of complement regulatory proteins allows complement activation to occur and C5b-9 to be assembled via the alternate pathway. Thus, proteinuria in the PHN model of MN cannot be induced by IgG antibody unless blocking antibody to Crry, the rodent analog of the human podocyte complement regulatory protein CR1, is also present. Of course, complement regulatory activity may also be inhibited by other mechanisms, and a complete

absence of the entire CR1 protein has been demonstrated in some forms of glomerulonephritis including MN (35).

Podocyte Response to Injury & Mechanisms of Proteinuria

Of the three cell types in the glomerulus, MN is a complement dependent disease of the podocyte. Following C5b-9 insertion into the lipid bilayer of the podocyte cell membrane, instead of cell lysis, a series of signaling events result in cell activation and changes in podocyte structure and function.

Extracellular Matrix and Glomerular Basement Membrane

The GBM is an acellular structure synthesized by the podocyte and the glomerular endothelial cell, and it is the GBM thickening that gives rise to the term "membranous" nephropathy. The extension of the GBM between the subepithelial immune deposits also leads to the prototypical "spike" formation seen with silver methenamine staining. The GBM matrix that accumulates in MN consists of normal GBM components that are produced by the podocyte, in particular, type IV collage and laminins (36, 37). Notably, this matrix accumulation occurs in the setting of an increase in matrix degrading proteases, suggesting a marked increase in matrix production or an increase in protease inhibitors (for example, tissue inhibitors of matrix metalloproteinases (TIMPs)). A marked upregulation in the production of laminins and type IV collagen *in vitro* has been confirmed in podocytes under C5b-9 attack (38). Transforming growth factor beta (TGF-β) plays a key role in the accumulation of matrix and a marked increase in the TGF-β2 isoform and its receptor has also been shown in podocytes in experimental MN (39).

Production of Oxidants, Proteases and Eicosanoids

The insertion of C5b-9 into the podocyte membrane leads to the production of reactive oxygen species (ROS). An increase in hydrogen peroxide (via NADPH oxidoreductase) (40) and superoxide ion (via xanthine oxidase) (41) have been described in the PHN model. ROS may directly injure the GBM, potentiate the effects of proteases. or cause further injury by lipid peroxidation of the podocyte cell membrane (reviewed in (42)). In the PHN model, the administration of scavengers of ROS (deferioxamine (43), DMTU (44)), inhibitors of lipid peroxidation (45) or inhibitors of xanthine oxidase (41) have all been shown to markedly decrease urine protein excretion.

Proteases have also been proposed to mediate some of the GBM injury in MN. In PHN, increased gelatinase activity (46) and enhanced expression of matrix metalloproteinase-9 (MMP-9) prior to the onset of proteinuria have been documented (47). There is also an increase in the amount of proinflammatory eicosanoids with increased inducible cyclooxygenase (COX2) (48), leukotriene B4 (49), prostaglandin E2 and thromboxane B2 (50, 51).

Reduction in Podocyte Number (Podocytopenia)

The podocyte has a limited ability to proliferate, and therefore, any process leading to podocyte loss (apoptosis, detachment) will result in a reduction in podocyte number. This podocytopenia has been associated with the development of glomerulosclerosis and is associated with progressive renal dysfunction in a range of glomerular diseases (52). The paucity of podocytes on the outer surface of the capillary loop may result in loss of support for the capillary loop and further podocyte injury from mechanical stress. In addition, the resulting uncovered areas of GBM promote both protein traffic across the glomerular filtration barrier and the development of glomerulosclerosis (53).

a. *Cell detachment.* Podocytes adhere to the outer side of the GBM due to interactions between GBM matrix proteins and the podocyte foot processes (notably via α3β1 integrins and α-dystroglycan). The detachment of podocytes from the GBM with a resultant decrease in podocyte cell number has been described in MN and may result in focal areas of increased protein permeability, (54, 55) in addition to promoting the development of glomerulosclerosis (53). The cells detach due to a combination of cytoskeletal changes in the podocyte and alterations in GBM structure which interfere with cell matrix interaction (56, 57) Once detached into the urinary space, the podocytes may subsequently be excreted and detected in the urine. Notably many of these cells are viable and can be cultured *in vitro* (58).
b. *Podocyte apoptosis.* Podocyte apoptosis has been difficult to demonstrate in MN, but this may be because

apoptotic cells may quickly detach into the urinary space (59). An imbalance between pro-apoptotic (e.g., ROS, TGFβ) and pro-survival factors (e.g., vascular endothelial growth factor) may mediate podocyte apoptosis (reviewed in (60)).

c. *Failure of podocyte proliferation.* A key characteristic of the podocyte is its limited ability to proliferate, and as podocyte loss is not readily replaced, this may lead to podocytopenia. In MN, this anti-proliferative phenotype may be augmented by upregulation of cyclin kinases inhibitors (p21 and p27) which inhibit progression through the cell cycle (59). Podocytes become arrested at the G2/M phase preventing cytokinesis (cell division) and bi-nucleated podocytes may be detected (61). Attempts at cell division may also result in weakening of attachment to the GBM, and loss of podocytes into the urinary space. C5b-9 has also been shown to induce DNA damage in podocytes further impairing the proliferative response (62).

Alterations in Podocyte Slit Diaphragm

The slit diaphragm between adjacent podocyte foot processes is now recognized as one of the major impediments to protein permeability across the glomerular capillary wall. Nephrin is a major component of the slit diaphragm, bridging the filtration slit, and is linked to the actin cytoskeleton by CD2AP and podocin. Studies have shown a reduction and redistribution of nephrin, and a dissociation from both podocin (63) and the actin cytoskeleton (64) in the PHN model of MN. Notably, this disruption in the slit diaphragm can be detected at the onset of proteinuria, prior to the development of foot process effacement (65).

Mechanisms of Progressive Renal Dysfunction

The podocyte and GBM abnormalities above can largely explain the marked proteinuria that typically develops in MN. The loss of renal function, however, is only partly explained by podocyte injury leading to glomerulosclerosis, but also reflects mechanisms leading to tubulointerstitial fibrosis. The rate of decline in renal function in MN correlates with the degree of proteinuria, and although this may reflect greater glomerular injury, there is increasing evidence that proteinuria itself may be injurious to tubular epithelial cells (reviewed in (66)). Proteinuria may be accompanied by intra-tubular complement activation leading to C5b-9 mediated injury to tubular epithelial cells and interstitial damage. Although most complement proteins are too big to be filtered at the glomerulus, tubular epithelial cells are able to synthesize complement components and may become activators of the alternate pathway (67). Proximal tubular cells only weakly express the complement regulatory protein CD59 on their apical membrane (68). Notably, rats that are deficient in C6 are protected from tubulointerstitial injury in several models of glomerular disease including the remnant kidney (69).

Pathology

Light Microscopy

At early stages, the glomeruli and interstitium look essentially normal, and MN may be impossible to differentiate from minimal change disease by light microscopy alone. As the disease progresses, the pathognomonic thickening of capillary loops becomes evident due to the accumulation of sub-epithelial immune complexes and the deposition of new basement membrane material by the podocyte (*Fig. 33-2b*). Staining with silver methenamine may reveal spikes representing basement membrane material projecting between the immune deposits (*Fig. 33-2c* and *d*). Glomerular cellularity is typically normal. The presence of mesangial hypercellularity or leukocyte infiltration (70) suggests a secondary form of MN. In some patients with heavy proteinuria and progressive disease, a reduction in podocyte number, partly due to detachment of podocytes into the urinary space, may lead to areas of denuded GBM, glomerular hypertrophy, attachment to Bowman's capsule, and subsequent capillary collapse, with an appearance similar to idiopathic focal segmental glomerulosclerosis (FSGS) (53, 71).

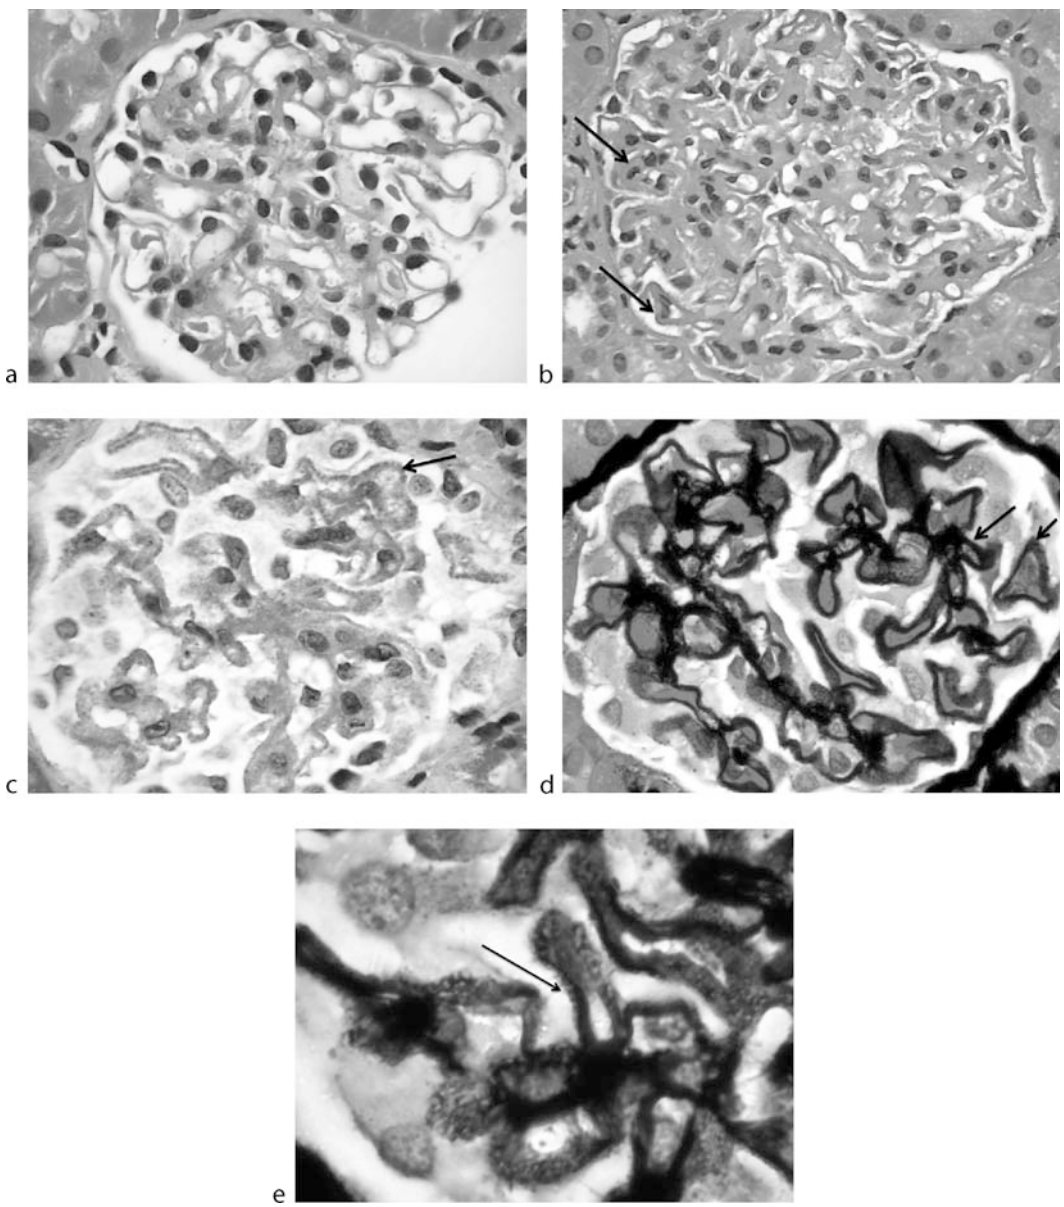
Interstitial changes are not specific to membranous nephropathy, and as in other nephrotic diseases, correlate better with renal function and prognosis than the glomerular abnormalities. Interstitial infiltrates consist of T cells, macrophages and B cells, and are typically associated with areas of tubular degeneration and interstitial fibrosis (mostly Type I collagen).

Immunofluorescence

Immunofluorescence reveals finely granular deposits of IgG (predominantly IgG4) in a subepithelial distribution on the outer surface of the capillary basement membrane (*Fig. 33-3*). Staining for IgA or IgM is negative, but if

Figure 33-2

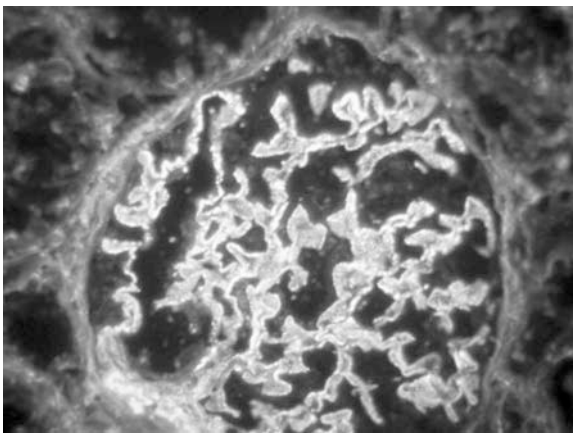
Light microscopy in a 12-year-old girl with membranous nephropathy and nephrotic syndrome. (a) Normal control. A normocellular glomerulus from an age matched control has thin, delicate glomerular capillary walls. Note that early membranous nephropathy may appear normal by light microscopy (hematoxalyn and eosin; x 400). (b) Membranous nephropathy. The normocellular glomerulus has relatively preserved architecture with only slight mesangial expansion. There is diffuse thickening of the glomerular capillary wall (arrows), that imparts a ''stiff'' appearance (hematoxalyn and eosin; x 400). (c) Numerous small subepithelial deposits (arrow), which appear as red dots studding the basement membrane, are highlighted by histochemical stains that differentiate the basement membrane from other proteins (masson trichrome; x 500). (d) The glomerular basement membranes are thick and mottled (arrows) as a result of small peripheral projections (methenamine silver-hematoxalyn; x 400). (e) ''Spikes'' project from the basement membrane (arrow), separating and surrounding the deposits of nonargyrophilic material that contribute to the membrane thickness (methenamine silver-hematoxalyn; x 1,000). (Generously provided by Dr. Laura Finn, Renal Pathologist, Children's Hospital, University of Washington, Seattle, WA.) (See color plate 16)



present suggests a secondary form of MN such as lupus. Complement C3 is present in about 50% of adult patients and usually reflects staining for C3c, a breakdown product of C3b that is rapidly cleared. Consequently, the presence C3 staining may suggest active, ongoing immune deposit formation and complement activation (72). Notably, C1q and C4 are typically absent in keeping activation of complement through the alternate pathway.

Figure 33-3

Immunofluorescence in membranous nephropathy. Immune complex deposits are detected as intense fine granular staining along the outer surface of the capillary loops (fluorescein conjugated anti-IgG; x 400). (See color plate 17)



Electron Microscopy

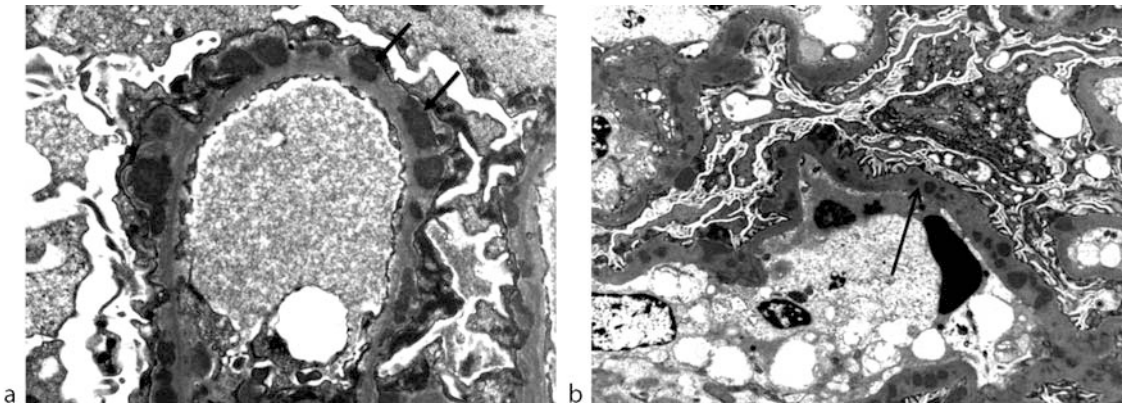
The characteristic feature of MN, subepithelial immune deposits, are seen on electron microscopy. These are initially small without a prominent basement membrane response, however with time, projections of basement membrane protrude around and enclose the immune deposits (*Fig. 33-4a* and *b*). Effacement of podocyte foot processes is found overlying the areas of electron dense deposits. The immune deposits typically involve the entire glomerular tuft (global), but in a subset of children, a segmental pattern has been described (8). Interestingly, an increase in C1q staining has been described in this group in the absence of any features of lupus. It has been argued that this may reflect a different disease entity with a more benign prognosis, but it may simply reflect an early, or resolving, stage of the disease. Electron dense deposits found in mesangial or subendothelial areas are suggestive of a secondary form of MN such as lupus or malignancy.

Genetics and Familial Membranous Nephropathy

A number of studies have shown associations of MN with various HLA antigens, particularly HLA DR3, HLA B8 and HLA B18 (73). There have also been reports of families with two affected family members (typically brothers), (74, 75) but these are relatively rare. The largest

Figure 33-4

Electron microscopy in membranous nephropathy. (a) Subepithelial electron-dense deposits (arrows) are separated by irregular projections of basement membrane material. The glomerular epithelial cells (podocytes) have diffuse foot-process effacement (Uranyl acetate-lead citrate; x 11,000). (b) Deposits become incorporated into the GBM (arrow) when new layers of GBM are laid down over the electron-dense deposits (Uranyl acetate-lead citrate; x 4,200).



family reported describes four affected male family members and suggests that there may be an X-linked susceptibility gene (76). Notably, in this family, the ages of onset were variable (1, 3, 10 and 67 years). The three children all initially responded to immunosuppression, however, with time a relapsing course of nephrotic syndrome occurred, with the development of stage four chronic kidney disease in one and ESRD in another by age 23 years.

Clinical Features of Idiopathic MN

Membranous nephropathy in childhood affects males and females fairly equally and typically presents with either asymptomatic proteinuria on screening, or with features of nephrotic syndrome (*Table 33-1*). Proteinuria is typically within the nephrotic range (90%). Microhematuria is common (80%) and gross hematuria occurs in approximately 40% (9). Hypertension at onset is uncommon (21%, range 6–50%), and may herald a worse prognosis (2–9), whereas renal function is typically normal at presentation. Children are at risk for complications of nephrotic syndrome including infection, however, renal vein thrombosis is a rare complication in children (77).

Natural History and Prognosis

The course of membranous nephropathy in adults is variable, but about 30–40% develop progressive disease (78–80). Prognostic risk factors for progression include a greater degree and duration of proteinuria, impaired renal function at presentation, age older than 50 years, non-Asian race and certain renal biopsy features (glomerulosclerosis, focal segmental glomerulosclerosis, Stage III/IV disease, tubulointerstitial fibrosis) (81–83). It has been argued that the pathological features on renal biopsy do not give further prognostic risk stratification independent of the clinical variables (83). The urinary excretion of biomarkers such as beta-2 microglobulin and/or IgG may be more accurate prognostic indicators than total urinary protein excretion, although these assays are not widely available (84).

The prognosis in children is much better than in adults, however, overall about 25% (10–28%) progress to chronic kidney disease (*Table 33-1*) (2–9). The most important prognostic indicator in children is the presence of nephrotic syndrome. Other adverse risk factors that have been reported include the renal biopsy findings (degree of glomerular sclerosis and interstitial fibrosis), age (older than 10 years), hypertension at onset and the presence of renal vein thrombosis. Children who present with asymptomatic proteinuria have a much more favorable outcome and progressive disease is rare (7, 9, 85). Proteinuria in this group often resolves around 12–18 months, although relapse has been described. Remission may occur earlier in those treated with steroids. By contrast, in children with nephrotic syndrome, the overall remission rate is only around 50% (26–74%), with progressive renal dysfunction developing in around one third (2–9). Of note, children with nephrotic syndrome typically have higher levels of proteinuria and greater glomerulosclerosis and tubulointerstitial fibrosis on renal biopsy.

Treatment of Idiopathic Membranous Nephropathy

The management of idiopathic MN in children relies on the exclusion of secondary causes of the disease. All children with idiopathic MN should be considered for therapy with the non-immunosuppressive strategies described below, and immunosuppression is usually reserved for those with adverse risk factors for disease progression.

Exclusion of Secondary Causes (see *Table 33-2*)

Idiopathic MN is uncommon in children and a thorough search for secondary causes, including medications, should be considered. Investigations may include liver function tests, hepatitis B and C serologies, serum complement levels, anti-nuclear antibody and anti-double stranded DNA (dsDNA), and fluorescent treponemal antibody or VDRL. Depressed complement levels may be found with lupus, hepatitis B or syphilis. Certain features on the renal biopsy may be suggestive of a secondary form of MN including the presence of mesangial cell proliferation, cellular infiltration, IgA or C1q deposition by immunofluorescence, or the presence of electron dense deposits in subendothelial or mesangial sites, or tubuloreticular structures in endothelial cells by electron microscopy. The treatment of secondary forms of the disease is directed at the underlying etiology.

Table 33-2

Conditions associated with membranous nephropathy in children

	Common	Uncommon
Autoimmune diseases	Systemic lupus erythematosis	Rheumatoid arthritis, mixed connective tissue disease, Sjogren's syndrome, Graves disease, Hashimoto's thyroiditis, dermatomyositis, primary biliary cirrhosis, Bullous pemphigoid, dermatitis herpetiformis, ankylosing spondylitis, Guillain-Barre syndrome, myasthenia gravis
Infections	Hepatitis B congenital syphilis	Tuberculosis, Streptococcus, hepatitis C, quartan malaria, schistosomiasis, filariasis, hydatid disease, leprosy
Drugs and toxins	Non-steroidal anti-inflammatory drugs (NSAID), penicillamine	Gold, captopril, probenecid, tiopronin, lithium, mercury, formaldehyde, hydrocarbons
Miscellaneous	–	Tumors, diabetes mellitus, sarcoidosis, sickle cell anemia, Kimura disease, sclerosing cholangitis, systemic mastocytosis, Gardner-Diamond syndrome

Non-Immunosuppressive Therapy

Angiotensin converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy are renoprotective in adult patients with both diabetic (86, 87) and non-diabetic (88) glomerular disease. Although the use of ACE inhibitors or ARBs can be expected to reduce urine protein expression by about one third in adults, patients with MN may be resistant to RAS blockade (89), and this may not result in a clinically significant reduction in the rate of disease progression in MN (90, 91). Children with MN are frequently treated with renin angiotensin system (RAS) blockade, however, there is still no consensus on specific indications. Blood pressure should be controlled. Lipid lowering therapy with HMG-CoA reductase inhibitors (statins) is routinely used in adults, but the benefit of lipid lowering drugs in children remains controversial, particularly in pre-pubertal children. The incidence of renal vein thrombosis is lower in children and prophylactic anticoagulation is not recommended, although low dose aspirin therapy may be used. The risk of infection in children with nephrotic syndrome is significant, and if not already immunized, pneumococcal vaccination and varicella zoster immune globulin should be given to those receiving immunosuppression.

Immunosuppressive Therapy

Since MN is a rare condition in children, there are no randomized clinical trials to provide an evidence based approach to the treatment of this condition in childhood. However, the approach to immunosuppressive therapy can be extrapolated from controlled studies in adults (92–99), and from a series of uncontrolled studies in children (2–7, 9, 85, 100).

In adults, immunosuppressive therapy is typically reserved for patients with adverse prognostic factors as described above. It is generally accepted that steroid therapy alone is ineffective in adults (92, 94, 95), although this is typically the first line treatment in children who often do not undergo renal biopsy until they fail a course of steroids. Adults at a high risk for progression are typically treated with either a combination of steroid and an alkylating agent (most commonly cyclophosphamide) or a combination of steroid and cyclosporin. These combination therapies are typically reserved for children who have failed empiric steroid alone therapy. A rational approach to immunosuppression in children with MN may be based on the presence of nephrotic syndrome at presentation.

Children with asymptomatic proteinuria. In general, these children have a much better prognosis, and in the absence of evidence of disease progression, are typically treated with non-immunosuppressive therapy and do not receive immunosuppression.

Children with nephrotic syndrome. The majority of children with nephrotic syndrome will have received empiric steroid therapy (e.g., prednisone 60 mg/m^2 or 1 mg/kg) for presumed minimal change disease before MN is diagnosed on renal biopsy. This group has a worse prognosis and most children who respond (steroid sensitive) will do so within 2–3 months, although it is difficult to exclude spontaneous remissions in this group. In those who fail to respond to steroid therapy (steroid resistant), the addition of a second line immunosuppressive agent such as cyclophosphamide (2 mg/kg orally) or cyclosporin (3–5 mg/kg/d in two divided doses) may be considered.

There is only limited data on the use of cyclosporin in children with MN (9). If cyclosporin is going to be effective, children will typically enter remission within 6 months, although there is a risk of relapse when this medication is discontinued. Cyclosporin should be used with care if the renal function is already impaired.

We should also recognize when we are considering immunosuppressive therapy for MN, that although the patient may have nephrotic syndrome, the active immune process leading to antibody deposition may already have resolved. The resolution phase of MN, with reabsorption of the subepithelial deposits may take many months to years before the proteinuria resolves. This is best demonstrated by the example of drug induced MN, in which proteinuria may continue for a year or two after discontinuation of the offending agent. In idiopathic MN, ongoing immune activation may be suggested by the presence of glomerular C3c deposition (72) or the detection of urinary C5b-9 (26, 101). Many patients with MN may exhibit persistent injury to the glomerular filtration barrier and proteinuria in the absence of an active autoimmune process, and therefore would not be expected to respond well to immunosuppression. Unfortunately, at this time, we do not have the tools to accurately identify these patients.

Neonatal Membranous Nephropathy

Infants who are born with nephrotic syndrome typically have congenital abnormalities of the slit diaphragm or perinatal infections. A few cases of neonatal MN have been described secondary to feto-maternal alloimmunization with antibodies to neutral endopeptidase (NEP) (22, 102). MN associated with congenital syphilis should be considered in the differential diagnosis.

Clinical Presentation

Infants with antibodies to NEP may be born with oliguric acute renal failure and respiratory distress on the first day of life. Antenatal ultrasound shows oligohydramnios and enlarged fetal kidneys. As the renal failure improves they develop massive proteinuria and nephrotic syndrome. Hypertension may be present. The disease rapidly improves over the first few weeks of life as the maternal antibody disappears, however, some children have residual proteinuria and chronic kidney disease, possibly as a result of podocyte injury, nephron loss and focal segmental glomerulosclerosis.

Renal pathology shows the typical subepithelial immune deposits and GBM abnormalities, but additional renal arterial lesions and glomerular capillary tuft collapse may be present suggesting glomerular ischemia which may also lead to chronic kidney disease. It has been suggested that maternal antibodies inhibit the enzyme activity of NEP with failure to degrade various vasoactive peptides (22).

Pathogenesis

The presentation with antenatal MN suggested the possibility of feto-maternal alloimmunization, where the mother becomes sensitized to an antigen on the fetal podocyte, and produces anti-podocyte antibodies which cross the placenta. In the index case described, an IgG fraction from the mother produced immune deposits and proteinuria when injected into rabbits. Subsequently, antibodies to neutral endopeptidase, a membrane bound peptidase expressed on the podocyte surface, were identified in the maternal serum, and transiently in the infants serum in keeping with the maternal origin (22). Further investigations confirmed that each of the mothers in these cases had truncating mutations in the *MME* gene encoding NEP, and presumably developed anti-NEP antibodies due to prior exposure to this antigen (previous miscarriage or paternal sperm) (102). Notably, the NEP deficiency in the mothers was not associated with any obvious phenotype. The neonatal MN was more severe in mothers with high titer antibody, and in those with more IgG1, as opposed to IgG4 deposition. It is unclear if antibody mediated enzyme inhibition plays any role in this condition.

The possibility of MN secondary to alloimmunization to podocyte antigens should also be considered in *de novo* MN in the allograft following renal transplantation, and in native kidneys following stem cell transplantation.

Membranous Nephropathy Associated with Hepatitis B

Hepatitis B (HBV) infection is associated with a variety of renal diseases including membranous nephropathy, polyarteritis nodosa, membrano-proliferative glomerulonephritis and a serum sickness-like syndrome. MN is the most common renal manifestation and develops in the chronic carrier state (HBeAg + ve; HBsAg + ve).

In adults, HBV accounts for less than 1% of MN in the US, but in children idiopathic MN is uncommon and HBV accounts for about 20% of MN in children in the US (103).

In patients with HBV associated with MN (HBV-MN), the pathogenesis is considered to be due to the formation of immune complexes of HBeAg and HBeAb in the subepithelial space. Immunostaining reveals predominantly HBeAg deposition along glomerular capillary walls, but HBsAg and HBcAg may also be detected (104). Immunoelectron microscopy has co-localized HBeAg and C5b-9 to the subepithelial deposits (105) and the deposits presumably form *in situ*. The possibility that the disease results from autoimmune mechanisms involving podocyte antigens, and that the glomerular deposition of HBV antigens is secondary, has not been excluded as many patients with chronic liver disease also exhibit a variety of autoantibodies.

Clinical Features

HBVMN in children (typically boys aged 2–12 years) usually presents with proteinuria and edema, with hematuria in 40–60%. Renal function is usually normal. Children may have a mild transaminitis, but no evidence of chronic liver disease.

Hepatitis serology reveals the presence of HBsAg and anti-HBc antibody in most patients. The majority of patients also have circulating HBeAg (60–80%). Circulating HBeAg correlates with clinical activity and loss of antigen and conversion to HBeAb status correlates with recovery of nephrotic syndrome. This is followed by seroconversion to HbsAb (106). Complement studies commonly reveal a low C3 and C4 (15–64%) and circulating immune complexes (80%) (103), both of which are typically not found in idiopathic MN.

Renal biopsy reveals features similar to idiopathic MN with subepithelial deposits, although minor subendothelial and mesangial deposits are frequently present as well. Electron microscopy may reveal viral-like particles in subepithelial and subendothelial spaces and within glomerular cells (reviewed in (103)).

It should be recognized that proteinuria in patients with HBV may not be exclusively the result of HBV infection. A high incidence of proteinuria in non-HBV infected family members has been reported suggesting that other environmental or infectious agents may be contributing (107). Co-infection with hepatitis B and C in children with MN has been reported with no increase in severity of the disease (108).

Treatment

Most children with HBV associated MN undergo spontaneous resolution with a cumulative remission rate of 64% at 4 years (106, 109). Initial observation of these children is appropriate with general supportive measures. Anti-viral therapy can be considered in those who remain HBeAg positive and have persistent disease (for example greater than 1 year) or in those who are likely to progress (older children with focal sclerosis on biopsy). Interferon α therapy was shown to be effective in an open randomized study of children with hepatitis B associated MN (age <14 years) (110). Treated patients were free of proteinuria by 3 months with HBeAg seroconversion by 5–6 months. The interferon α therapy was surprisingly well tolerated in this study. Case reports of treatment with lamivudine are also described (111, 112). The treatment of HBV-associated MN with steroids may cause more harm than good by enhancing viral replication and impairing seroconversion, but may still be considered (113).

Syphilis & Other Infections

MN in neonates and infants may be secondary to congenital syphilis. In this setting it may be associated with other clinical features of treponemal infection such as rash, periostitis, nasal discharge and hepatosplenomegaly. Hypertension may be present.

The etiology is suggested by the presence of hypocomplementemia and may be confirmed by the demonstration of fluorescent treponemal IgM antibodies. Treponemal antigens have been localized to the subepithelial space, but it is unclear if this is merely non-specific trapping. Early treatment with penicillin leads to the resolution of the proteinuria.

MN has also been reported with a number of other infections although some of these associations remain debatable (*Table 33-1*). Although Hepatitis C (HCV) typically causes a membrano-proliferative glomerulonephritis (MPGN) related to mixed cryoglobulinemia, there are several reports of MN associated with HCV in adults (114–116). Glomerular disease and nephrotic syndrome occur much more commonly in tropical countries than in industrialized countries (reviewed in (117)). Most tropical glomerulonephritides are due to chronic parasitic infection. MN has been reported with quartan malaria and hepatosplenic schistosomiasis, although a steroid resistant membrano-proliferative lesion is much more typical with these infections. In general, these chronic

immune complex glomerulonephritides respond poorly to therapy for the underlying infection.

Lupus Membranous Nephropathy

MN accounts for 15–20% of lupus nephritis in children (118, 119) and several small series have been described demonstrating a variable prognosis. (118,120) The clinical presentation is typically with nephrotic syndrome with hematuria (50%), and hypertension and renal impairment are variable. Serum complement levels are often normal. Lupus membranous is commonly associated with, or evolves to, proliferative lupus nephritis lesions on biopsy which are associated with a worse prognosis. Notably, MN may be the initial presentation of lupus, with subsequent development of extra-renal manifestations at a later stage, particularly in women (9). Pathological features that may suggest the presence of lupus as the underlying etiology include mesangial hypercellularity, the presence of IgA, C1q or C4 by immunofluorescence, and on electron microscopy, the presence of subendothelial or mesangial immune deposits, or tubuloreticular structures in endothelial cells. This topic is covered in detail in Chapter 47.

Membranous Nephropathy in the Renal Allograft

MN may occur in the renal allograft as a result of recurrence of the original idiopathic disease or as a *de novo* condition. In adults, MN is the commonest de novo glomerulonephritis, occurring in about 2% of allografts (121) and typically presents with nephrotic syndrome late after transplantation (36–48 months). By contrast, recurrent disease occurs in 10–30% of those with prior MN, may be more common in living related donor kidneys, and tends to occur earlier in the post transplant course (12–24 months) (122, 123).

In view of the rarity of this condition in children, the recurrence rate following transplantation is unknown. De novo MN has been described in children and is estimated to be in the 1–2% range (124), although the incidence may be as high as 9% in patients who undergo protocol surveillance biopsies (125). De novo MN in the graft is generally associated with rejection (121). Given the recent demonstration of alloantibodies to a podocyte antigen (NEP) in neonatal MN, it remains to be determined if the development of MN represents a more generalized loss of tolerance to the graft with the development of anti-podocyte antibodies in addition to other anti-donor antibodies. De novo MN has also been associated with ureteral obstruction (124, 126). The clinical course is variable, but in general, graft loss may be more likely from the associated rejection process.

The treatment of de novo MN in children usually consists of intensified immunosuppression, for example, switching the calcineurin inhibitor to cyclophosphamide for a short period of time. In general, the use of intensified immunosuppression in the children with MN in the renal allograft needs to be balanced with the cumulative exposure to immunosuppression and the lifetime risks of lymphoma.

Membranous Nephropathy Associated with Other Conditions

MN is commonly associated with malignancy in older adults, but only a few cases have been described in children. In some cases, the disease has resolved following excision of the tumor (127). MN is also associated with drugs and toxins (*Table 33-2*), and cases are described with penicillamine treatment in children (128, 129). MN has also been described with a range of other autoimmune conditions other than systemic lupus erythematosis (*Table 33-2*).

A rare form of MN in early childhood has been described associated with an anti-tubular basement membrane (TBM) nephritis with linear or granular IgG and C3 deposition along the TBM (130). Antibodies directed against the tubulointerstitial nephritis antigen (TIN-Ag), a glycoprotein component of tubular basement membrane matrix found predominantly in proximal tubules (131), are detected in most cases. The disease typically affects young males and may be associated with a proximal tubulopathy, and with extrarenal manifestations including pulmonary hemorrhage and diarrhea (intestinal villous atrophy or autoimmune enteropathy). A familial form of this disease has been described (132).

34 Crescentic Glomerulonephritis

Arvind Bagga

Crescentic glomerulonephritis (GN) is a rare condition in children, clinically characterized by features of rapidly progressive GN (RPGN) with rapid loss of renal function. Renal histology shows extracapillary proliferation in the Bowman's space resulting in formation of crescents in most glomeruli. These crescents are formed when breaks in glomerular capillaries allow leakage of cells and plasma proteins into Bowman's space, as might occur in almost any glomerulonephritis, and sometimes in diseases that do not primarily affect the glomeruli.

Improvements in our understanding have enabled categorization of crescentic GN into three broad entities (immune-complex GN, pauci-immune GN, antiglomerular basement membrane antibodies mediated GN) based on glomerular findings on immunohistology. A complete diagnosis of crescentic GN requires the integration of clinical data, renal biopsy findings and serological tests, which has significant implications for therapy and outcome. In all three groups, the severity of renal failure at presentation, the proportion of glomeruli containing crescents and the extent of tubulointerstitial scarring and fibrosis are considered important prognostic signs. RPGN is a medical emergency, which if untreated rapidly progresses to irreversible loss of renal function.

Definition

Crescentic GN is characterized by the presence of large epithelial crescents in the Bowman's space involving 50% or more glomeruli. However, criteria for histological appearance and the number of affected glomeruli required for diagnosis vary from 20 to 75% in various pediatric studies. The presence of crescents is a histologic marker of severe glomerular injury, which may occur in a number of conditions, including postinfectious GN, systemic and renal vasculitis, IgA nephropathy, systemic lupus erythematosus (SLE) and membranoproliferative GN (1, 2). The severity of clinical features correlates with the proportion of glomeruli that show crescents. While patients with circumferential crescents involving more than 80% of glomeruli present with severe renal failure, those with crescents in less than 50% of glomeruli, particularly if these are noncircumferential, often have an indolent course.

The clinical correlate of crescentic GN is RPGN, characterized by an acute nephritic syndrome with rapid loss of renal function over days to weeks (1). The terms RPGN and crescentic GN are often used interchangeably. *Table 34-1* lists the common conditions that present with crescentic GN.

Pathogenesis of Crescent Formation

The chief participants in formation of crescents are coagulation proteins, macrophages, T cells, fibroblasts and parietal and visceral epithelial cells (1, 3). Perturbations of humoral immunity as well as the Th1 cellular immune response contribute to the pathogenesis (1, 2).

The initiating event is the occurrence of a physical gap in the glomerular capillary wall and glomerular basement membrane (GBM), mediated by macrophages and T lymphocytes. Breaks in the integrity of the capillary wall lead to passage of plasma proteins and inflammatory mediators into the Bowman's space with fibrin formation, influx of macrophages and T cells, and release of proinflammatory cytokines, e.g., interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α). Breaks in the Bowman's capsule allow cells and mediators from the interstitium to enter Bowman's space and for contents of the latter to enter the interstitium, resulting in periglomerular inflammation.

Apart from macrophages, the other cellular components of the crescents are proliferating parietal and visceral epithelial cells (4). The development of a crescent results from the participation of coagulation factors and proliferating cells, chiefly macrophages, parietal glomerular epithelial cells and interstitial fibroblasts. The presence of coagulation factors in the Bowman's space results in formation of a fibrin clot and recruitment of circulating macrophages. Activated neutrophils and mononuclear cells release procoagulant tissue factor, IL-1 and TNF-α, serine proteinases (elastase, PR3) and matrix metalloproteinases. The proteases cause lysis of the GBM proteins and facilitate the entry of other mediators in the Bowman's space. Release of IL-1 and TNF-α also result in

Table 34-1

Causes of crescentic glomerulonephritis (GN)

Immune complex GN
Post infectious GN. Poststreptococcal nephritis, infective endocarditis, shunt nephritis, visceral abscesses, *Staphylococcus aureus* sepsis, other infections: human immunodeficiency virus, hepatitis B and C, syphilis, legionella, mycoplasma, tuberculosis, leprosy
Systemic disease. Systemic lupus erythematosus, Henoch-Schonlein purpura, cryoglobulinemia, mixed connective tissue disorder, juvenile rheumatoid arthritis, Behcet's syndrome, relapsing polychondritis, mixed connective tissue disease, dermatomyositis
Primary GN. IgA nephropathy, membranoproliferative GN, membranous nephropathy, C1q nephropathy
Pauci-immune crescentic GN
Microscopic polyangiitis, Wegener's granulomatosis, renal limited vasculitis, Churg Strauss syndrome
Idiopathic crescentic GN
Medications: penicillamine, hydralazine, hydrocarbons, propylthiouracil
Anti glomerular basement membrane (GBM) GN
Anti-GBM nephritis, Goodpasture's syndrome, postrenal transplantation in Alport syndrome
Postrenal transplantation
Recurrence of IgA nephropathy, Henoch Schonlein purpura, membranoproliferative GN, systemic lupus erythematosus

upregulated expression of adhesion molecules, leading to macrophage recruitment and proliferation.

The stage of inflammation is followed by the development of fibrocellular and fibrous crescents. The expression of fibroblast growth factors and transforming growth factor (TGF-β) is important for fibroblast proliferation and production of type I collagen, responsible for the transition from cellular to fibrocellular and fibrous crescents. The transition from cellular to fibrous crescents, which occurs over days, is clinically important since the latter is not likely to resolve following immunosuppressive therapy. The plasminogen-plasmin system enables fibrinolysis and resolution of crescents.

Role of ANCA

Antineutrophil cytoplasmic autoantibodies (ANCA) are a heterogeneous group of circulating antibodies directed against antigens in the primary granules of neutrophils and the monocytes' lysosomes. The demonstration of ANCA in the blood in a proportion of patients with crescentic GN raises the issue of their pathogenicity. Evidence for pathogenicity includes the correlation between ANCA titers and increased surface expression of PR-3 on neutrophils and disease activity, and the induction of oxygen radical release, cell degranulation and inhibition of microbicidal function following ANCA binding to neutrophils and monocytes (5, 6). Experimental data suggest that ANCA binding to endothelial cells induces injury and that increased circulating endothelial cell concentration correlates with disease activity (7). Further evidence for their pathogenicity is derived from mice that are deficient in T and B lymphocytes. When these mice were induced to generate ANCA with myeloperoxidase specificity (8), they showed histological evidence of glomerulonephritis and vasculitis. On the other hand, there is evidence against the pathogenicity of ANCA, including the fact that (i) high titers of ANCA can be found in patients without active vasculitis (9) and (ii) the absence of disease in newborns of pregnant women with ANCA-associated vasculitis. It is likely that these autoantibodies are necessary but not sufficient for the development of crescentic GN and vasculitis.

Classification and Causes

Based on renal histology and patterns on immunofluorescence staining, crescentic GN may be classified into three types, reflecting different mechanisms of glomerular injury.

1. Immune-complex GN with deposits of immune complexes along capillary wall and mesangium.
2. Pauci-immune GN with minimal or no immune deposits, with or without systemic vasculitis.
3. Anti-GBM GN with linear deposits of anti-GBM antibodies.

Immune Complex Crescentic GN

These patients form a heterogeneous group in which multiple stimuli lead to proliferative GN with crescents. Immunohistology shows granular deposits of immunoglobulin and complement along capillary walls and in the mesangium. The causes include infections, systemic diseases and preexisting primary GN.

Poststreptococcal GN can rarely be complicated by the occurrence of crescentic GN. While most patients recover completely, the presence of nephrotic range proteinuria, sustained hypertension and crescents is associated with an unsatisfactory outcome (10, 11). Other infectious illnesses associated with crescentic GN include infective endocarditis, infected atrioventricular shunts and visceral abscesses. Crescentic GN associated with other infectious agents including methicillin resistant *Staphylococcus aureus,* hepatitis B and C virus, leprosy and syphilis are reported anecdotally.

RPGN with glomerular crescents might be seen in patients with class IV lupus nephritis, less commonly in type III, and rarely in patients with isolated membranous nephropathy. The outcome of disease in patients with class IV lupus nephritis and crescents is not satisfactory and the natural history of crescents is unclear. The presence of crescents is not uncommon in Henoch Schonlein purpura in both adults and children, but most series are biased towards patients with more severe disease in whom renal biopsies have been performed (10). Extensive crescent formation in patients with Henoch Schonlein purpura is associated with a poor prognosis. Patients with IgA nephropathy, membranoproliferative GN and rarely membranous nephropathy may present with rapid deterioration of renal function and crescentic GN (10, 12); the long-term outcome in such cases is unsatisfactory.

Pauci-Immune Crescentic GN

Microscopic polyangiitis, Wegener's granulomatosis and renal limited vasculitis are characterized by small vessel vasculitis that, if involving glomerular capillaries, results in necrotizing crescentic GN with few or no immune deposits on immunofluorescence microscopy (2, 13). Most patients have circulating ANCA.

The majority of patients with pauci-immune crescentic GN has or will develop clinical features of vasculitis. This variety is considered a part of the microscopic polyangiitis/Wegener's granulomatosis spectrum, since the histological features are similar and some patients who present with renal-limited vasculitis might later show systemic vasculitis (2). Some cases of ANCA positive disease might be induced by drugs, including penicillamine, propylthiouracil, minocycline and penicillamine.

Approximately 10–20% patients with pauci-immune crescentic GN do not have circulating ANCA (14). Such patients are, however, considered part of the spectrum of vasculitis, since they show similar clinical and histological features (15). Some reports suggest that patients with ANCA negative, pauci-immune crescentic GN show more proteinuria, higher prevalence of nephrotic syndrome and less extrarenal involvement than those who are ANCA positive (16). There is also evidence that the mechanism for negative-ANCA, pauci-immune RPGN might involve a primary defect within the glomerular podocytes (17). The deletion of the Von Hippel-Lindau gene (Vhlh) from glomerular cells of mice induces a necrotizing crescentic glomerulonephritis. Loss of Vhlh leads to stabilization of hypoxia-inducible factor alpha subunits (HIFs) and de novo expression of the HIF target gene Cxcr4 in glomeruli. The course of the disease is markedly improved in mice treated with a blocking antibody to Cxcr4, whereas overexpression of Cxcr4 alone in podocytes of transgenic mice is sufficient to cause glomerular disease. These data indicate an alternative mechanism for the pathogenesis of RPGN and glomerular disease in an animal model and suggest novel molecular pathways for intervention in this disease.

Anti-GBM Crescentic GN

This condition is uncommon in childhood, accounting for less than 5–10% of cases in children (10, 18–21). The nephritogenic autoantibody is directed against a 28 kDa monomer located on the α3 chain of type IV collagen (Goodpasture antigen). Pulmonary involvement (Goodpasture syndrome) is uncommon.

Approximately 5% of patients with Alport syndrome who receive a renal allograft show anti-GBM autoantibodies and anti-GBM nephritis within the first year of the transplant (22). Unlike de novo anti-GBM nephritis, pulmonary hemorrhage is not observed in these patients since the patient's lung tissue does not contain the putative antigen. The risk of post transplantation nephritis is low in subjects with normal hearing, late progression to end stage renal disease, or females with X-linked Alport syndrome.

Epidemiology

Crescentic GN comprises approximately 5% of unselected renal biopsies in children (21). While there are no

population based studies in children, a recent report suggests an annual incidence of 3.3 per million adult population (23). The 2006 NAPRTCS database shows that idiopathic crescentic GN accounts for 1.8% of all transplanted patients (24). This figure is an underestimate since other conditions, including membranoproliferative GN (2.7%), SLE (1.6%), systemic immune disorders (0.4%), Wegener's granulomatosis (0.5%), chronic glomerulonephritis (3.4%) and IgA nephropathy and Henoch Schonlein purpura (2.5%), often show crescentic GN.

Table 34-2 outlines the underlying etiologies in five series of patients with crescentic GN reported from India (10, 21), United States (18), United Kingdom (19) and France (20). Immune complex GN is the most common pattern of crescentic GN in children accounting for 75–80% cases in most reports. Pauci-immune crescentic GN, while common in adults, is infrequent in children, accounting for 15–20% cases. The decline in the incidence of postinfectious GN has resulted in a change in the etiological profile of crescentic GN, and a recent survey of 73 patients between 1 and 20 year old showed similar frequencies of immune complex (45%) and pauci-immune crescentic GN (42%) (1).

Clinical Features

Patients with crescentic GN typically present with the clinical syndrome of RPGN. The presenting symptoms are those of an acute nephritic syndrome. The spectrum of presenting features is variable, and includes macroscopic hematuria (in 60–90% patients), oliguria (60–100%), hypertension (60–80%) and edema (60–90%) (10, 13, 18). The illness may be complicated by the occurrence of hypertensive emergencies, pulmonary edema and cardiac failure. Occasionally, RPGN has an insidious onset with the initial symptoms being fatigue or edema. Nephrotic syndrome is rare and seen in patients with less severe renal insufficiency.

Systemic complaints, involving the upper respiratory tract (cough, sinusitis), skin (vasculitic rash over lower limbs), musculoskeletal (joint pain, swelling) and/or the nervous system (seizures, altered sensorium) are common in patients with pauci-immune crescentic GN, with or without ANCA positivity. Sixty to seventy five percent patients with Wegener's granulomatosis have crescentic GN, and 80% show pulmonary features. Relapses of systemic and renal symptoms occur in one-third of patients with vasculitis (2, 13).

Patients with anti-GBM antibody disease may present with hemoptysis and, less often, pulmonary hemorrhage. Similar complications may be found in Wegener's granulomatosis, SLE, Henoch Schonlein purpura and severe GN with pulmonary edema.

The severity of clinical, laboratory and histological features at presentation vary with the underlying cause, the most severe being anti-GBM disease, followed by pauci-immune GN and finally immune complex crescentic GN (1, 25).

Investigations

Gross or microscopic hematuria with red cell casts is present in all patients. Most patients have a variable degree of nonselective proteinuria (2+ to 4+), with leukocyte, granular and tubular epithelial cell casts. Renal insufficiency is present at diagnosis in almost all cases. The degree of renal failure is usually more than that estimated by the serum creatinine. Anemia is mild; peripheral smear shows normocytic normochromic red cells.

Serology

Serological investigations assist in the evaluation of the cause and the monitoring of disease activity (*Table 34-3*, *Fig. 34-1*). Low levels of total hemolytic complement (CH50) and complement 3 (C3) are seen in postinfectious GN, SLE and membranoproliferative GN, and inversely correlate with disease activity. Positive antistreptolysin O titers and anti-deoxyribonuclease B suggests streptococcal infection in the past 3 months. Patients with SLE show antinuclear (ANA) and anti-double stranded DNA autoantibodies.

Elevated levels of ANCA suggest underlying vasculitis, and are present in patients with pauci-immune crescentic GN. Most ANCA have specificity for myeloperoxidase (MPO) or proteinase-3 (PR3). ANCA should be screened by indirect immunofluorescence and positive tests confirmed by both PR3-ELISA and MPO-ELISA. In patients with pauci-immune crescentic GN, negative results from indirect immunofluorescence should be tested by ELISA, because 5% of serum samples are positive only by the latter. Wegener's granulomatosis is associated with PR3 ANCA, which produces a cytoplasmic staining pattern on indirect immunofluorescence (c-ANCA) in 85% cases. Renal limited vasculitis and drug induced pauci-immune GN are associated with MPO ANCA that shows perinuclear staining on immunofluorescence (p-ANCA). Patients with microscopic polyangiitis have almost equal distribution of MPO ANCA/p-ANCA and PR3 ANCA/c-ANCA. Approximately 10% of patients with Wegener's granulomatosis or microscopic polyangiitis have negative assays for ANCA.

ANCA (usually p-ANCA) are also found in 20–30% patients with anti-GBM GN, and occasionally in idiopathic immune complex RPGN, inflammatory bowel disease, chronic liver disease, rheumatoid arthritis and SLE (26). Several medications have been associated with the induction of MPO ANCA, including propylthiouracil, hydralazine, minocycline and penicillamine.

Apart from diagnosis, ANCA titers have also been used for monitoring activity of systemic vasculitis. The risk of relapse in patients who show persistently negative ANCA titers is low. On the other hand, persistent or reappearing ANCA positivity in patients in remission may be associated with disease relapse in ANCA-associated vasculitides. The presence of a positive ANCA titer at the time of switch from cyclophosphamide to azathioprine increases chances of recurrent disease, particularly in those who are PR3-positive. Based on review of multiple studies, it is recommended that isolated rise in ANCA titers not be used for modifying treatment in patients with systemic vasculitis (27). Patients with ANCA-associated crescentic GN in remission, with persistent or reappearing ANCA positivity or rise in its titer, should be closely followed up and diagnostic efforts intensified to detect and treat relapses.

High titers of anti-GBM IgG antibodies, demonstrated by immunofluorescence or ELISA, are seen in anti-GBM nephritis or Goodpasture's syndrome and correlate with disease activity. About 5% of ANCA positive samples are

Table 34-3

Diagnostic evaluation of patients with crescentic and/or rapidly progressive GN

Complete blood counts; peripheral smear for type of anemia; reticulocyte count
Blood levels of urea, creatinine, electrolytes, calcium, phosphate
Urinalysis: proteinuria; microscopy for erythrocytes and leukocytes, casts
Complement (C3, C4, CH50)
Antistreptolysin O, antinuclear antibody, anti-double stranded DNA antibodies
Antinuclear cytoplasmic antibodies (anti-proteinase 3, anti-myeloperoxidase)
Anti-GBM (IgG) antibodies
Blood levels of cryoglobulin, hepatitis serology
Radiographs, CT scan for chest, sinuses (patients with Goodpasture's syndrome, Wegener's granulomatosis)
Renal biopsy (light microscopy, immunofluorescence, electron microscopy)

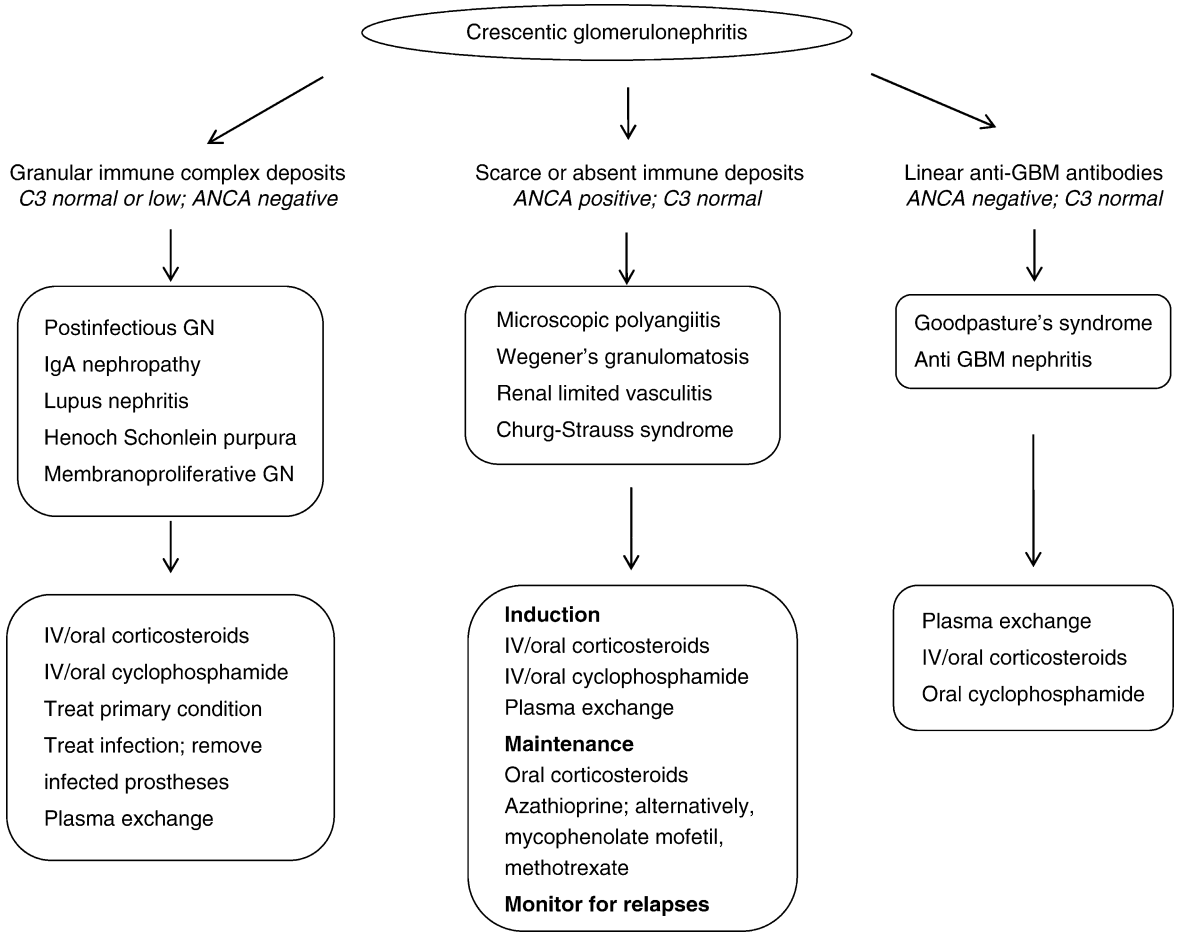
Diagnostic categories and principles of therapy of crescentic glomerulonephritis. The diagnostic categories are distinguished based on renal immunofluorescence findings and serology. Therapy is tailored to the specific diagnosis.



also anti-GBM positive and approximately 20–30% of anti-GBM positive samples are ANCA positive. Serology for ANCA is therefore recommended in all patients with either anti-GBM antibodies in blood or linear IgG deposition along the GBM. The initial clinical outcome for these patients is similar to that of anti-GBM disease, though relapses may occur as in systemic vasculitis (1).

Histopathology

Light Microscopy

A glomerular crescent is an accumulation of two or more layers of cells that partially or completely fill the Bowman's space. The crescent size varies from circumferential to segmental depending on the plane of the tissue section and the underlying disease. Crescents in anti-GBM nephritis or ANCA associated disease are usually circumferential, while they are often segmental in immune complex GN. Once the glomerular capillary loop is compressed by the crescent, tubules that derive their blood flow from that efferent arteriole show ischemic changes.

Crescents may be completely cellular or show variable scarring and fibrosis. Cellular crescents are characterized by proliferation of macrophages, epithelial cells and neutrophils (*Fig. 34-2a, b*). Fibrocellular crescents show admixture of collagen fibers and membrane proteins amongst the cells (*Fig. 34-3a, b*). In fibrous crescents, the cells are completely replaced by collagen (*Fig. 34-4a*). Interstitial changes range from acute inflammatory infiltrate (*Fig. 34-4b*) to chronic interstitial scarring and tubular atrophy.

Renal biopsies from patients with vasculitis often show crescents in various stages of progression indicating

Figure 34-2

(a) Large, cellular crescent with compression of glomerular tuft (PAS ×200); (b) cellular crescent compressing tuft (Silver methenamine ×200). (See color plate 18)

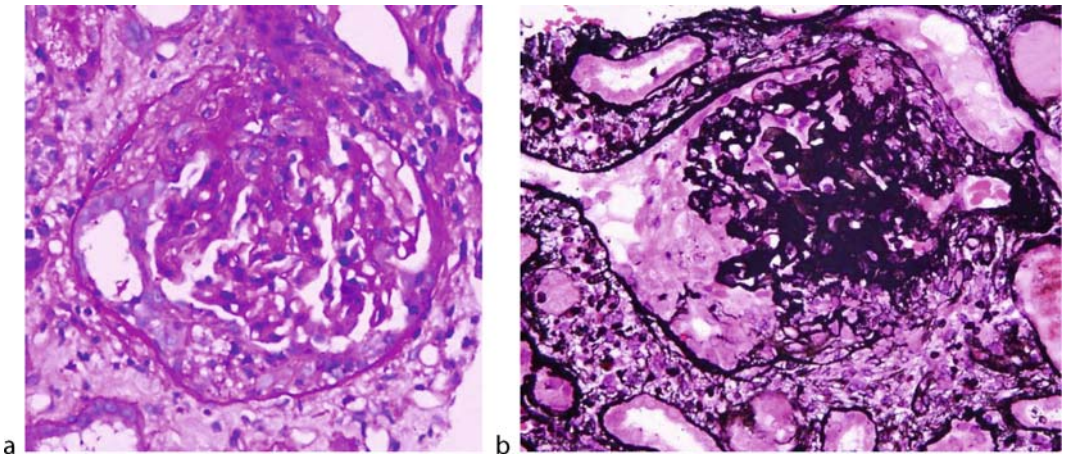


Figure 34-3

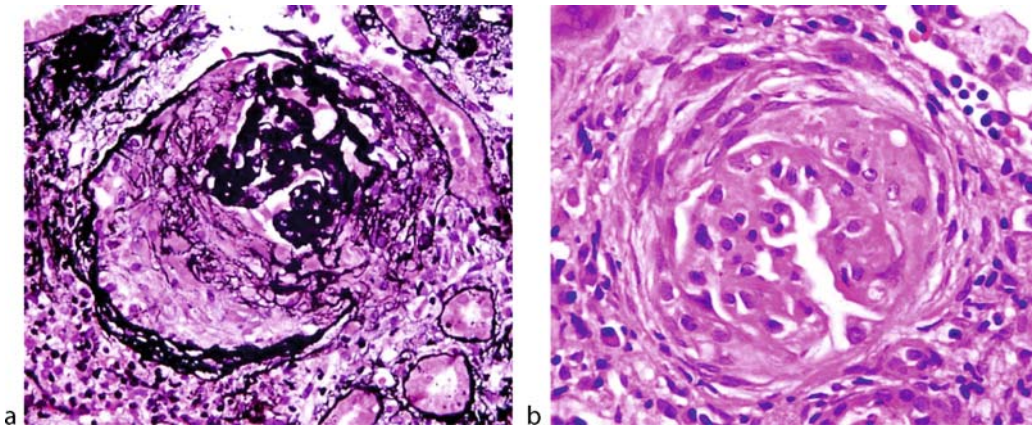
(a) Circumferential, fibrocellular crescent (Silver methenamine ×200). (b) Fibrocellular crescent with sclerosed glomerular tuft and fibrin deposition (Hematoxylin & eosin ×200). (See color plate 19)



episodic inflammation. Early lesions have segmental fibrinoid necrosis with or without an adjacent small crescent (*Fig. 34-5*). Severe acute lesions show focal or diffuse necrosis in association with circumferential crescents. Features of small vessel vasculitis, affecting interlobular arteries and rarely angiitis involving the vasa recta might be seen.

Immunofluorescence Microscopy

These investigations assist in determining the cause of crescentic GN, based on presence, location and nature of immune deposits. Crescents stain strongly for fibrin on immunofluorescence. Mesangial deposits of IgA are found in IgA nephropathy and Henoch Schonlein purpura; granular, subepithelial deposits of IgG and C3 in postinfectious GN; mesangial, subendothelial and intramembranous deposits of IgG and C3 in MPGN; and "full house" capillary wall and mesangial deposits of granular IgG, IgA, IgM, C3, C4 and C1q in SLE (*Fig. 34-6*). Glomeruli of patients with vasculitis, both with and without ANCA positivity, have few or no immune deposits. Anti-GBM disease is characterized by linear staining of the GBM with IgG (rarely IgM and IgA) and C3.

Figure 34-4

(a) Predominantly fibrous crescent in a partially sclerosed glomerulus (Hematoxylin & eosin ×200). (b) Fibrous crescent and glomerulosclerosis. Note the periglomerular mononuclear infiltrate (Hematoxylin & eosin ×200). (See color plate 20)

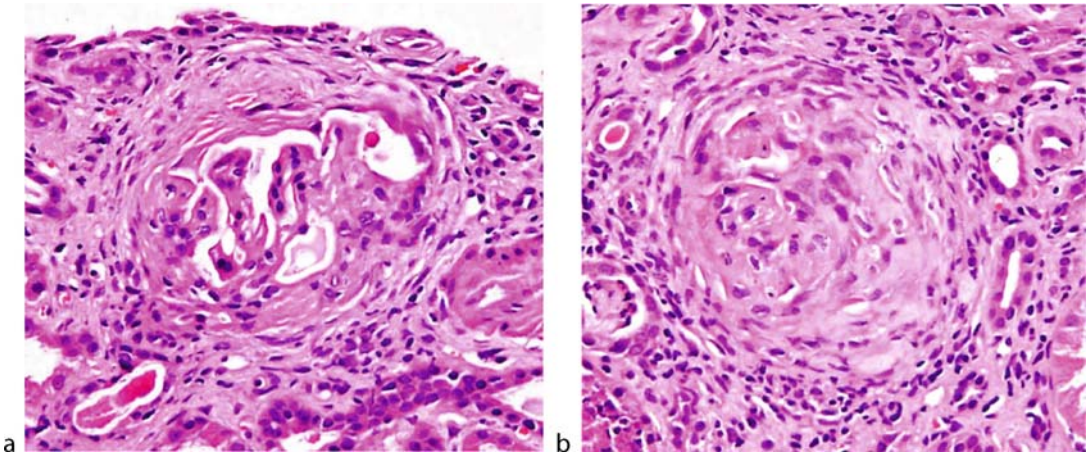


Figure 34-5

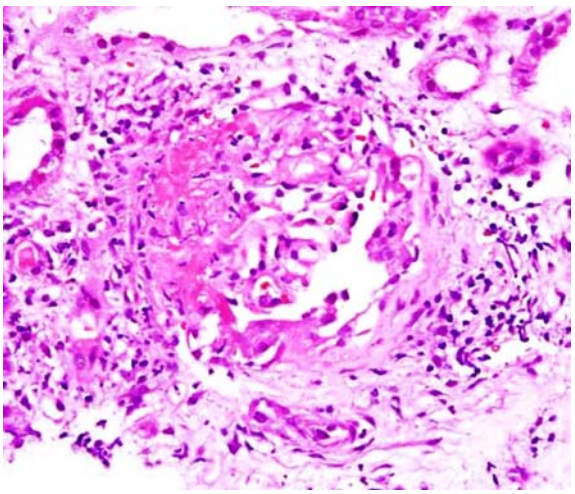
Glomerulus showing fibrocellular crescent with fibrinoid necrosis of part of the glomerular tuft. Note the disruption of the Bowman's capsule (Hematoxylin & eosin ×200). (See color plate 21)



Electron Microscopy

The findings on electron microscopy confirm those on immunofluorescence staining. Immune deposits are scant in ANCA-associated diseases and anti-GBM disease, but are common in immune complex GN, including SLE (where they are prominently present), postinfectious glomerulonephritis (chiefly subepithelial), and IgA and C_1q nephropathy disease (mesangial). Electron microscopy shows the ruptures of the Bowman's capsule and GBMs, wrinkling of the GBM and areas of mesangiolysis.

Diagnosis

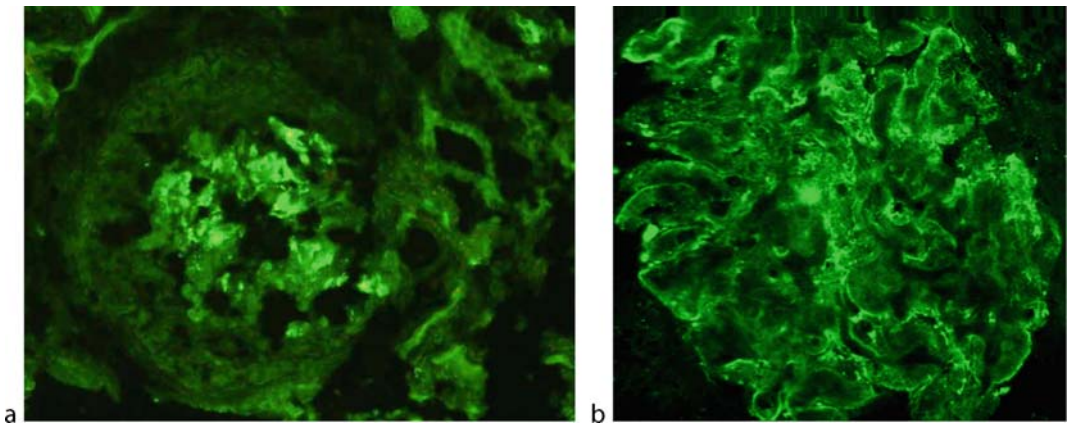
It is necessary to make an accurate and rapid diagnosis in RPGN as treatment strategies vary and delay in instituting treatment results in irreversible disease. All patients with RPGN should undergo a kidney biopsy promptly. While the majority shows the presence of crescentic GN, the detection of thrombotic microangiopathy (affecting interlobular arteries and arterioles) or diffuse proliferative GN is not unusual.

The diagnosis of the etiology of crescentic GN depends on integration of clinical data and findings on serology and renal histology (*Fig. 34-1*). In this way, anti-GBM disease or ANCA-associated RPGN can be distinguished from other causes of crescentic GN.

Patients with Wegener's granulomatosis have anemia, thrombocytosis and elevated acute-phase reactants (high erythrocyte sedimentation rate and C-reactive protein). The majority of these patients are positive for c-ANCA and for antibodies to proteinase 3. In the past, the diagnosis of Wegener's granulomatosis required biopsy of tissue from the lung, kidney, skin, nerve, sinus or nose. Currently the diagnosis is often made by the presence of typical clinical features, consistent

Figure 34-6

Immunofluorescence staining. (a) IgM deposits in a 7-year-old boy with rapidly progressive glomerulonephritis (GN) secondary to immune complex crescentic GN. (b) 12-year-old girl with class IV lupus nephritis; crescent formation shows granular deposition of IgG on the capillary wall ×1,200. (See color plate 22)



imaging studies (CT scans) and positive serology. When tissue is available, the characteristic pathologic features include the triad of granulomas, neutrophilic vasculitis and necrosis.

Microscopic polyangiitis is characterized by glomerulonephritis in 90% patients, pulmonary capillaritis and gastrointestinal involvement in 40–50% each; and skin and musculoskeletal features in 60% each. Microscopic polyangiitis is the most common cause of acute pulmonary-renal syndrome, although the differential diagnosis includes Wegener's granulomatosis, Churg-Strauss granulomatosis, lupus erythematosus and Goodpasture's disease.

Timely and appropriate therapy is indicated in view of the widely recognized unsatisfactory outcome in untreated patients.

Treatment

Evidence based data is limited and specific treatment guidelines for children are based on data from case series and prospective studies in adults (25). Besides specific therapy, supportive management includes maintenance of fluid and electrolyte balance, providing adequate nutrition, and control of infections and hypertension.

The specific treatment of RPGN comprises two phases: *induction* of remission and its *maintenance* (*Table 34-4*). The first phase aims at control of inflammation and the associated immune response. Once remission is induced, the maintenance phase attempts to prevent further renal damage and relapses.

Induction

Therapy with high dose corticosteroids is used initially. Treatment includes IV pulses of methylprednisolone (15–20 mg/kg, maximum 1 g/day) for 3–6 days, followed by high-dose oral prednisone (1.5–2 mg/kg daily) for 4 weeks, with tapering to 0.5 mg/kg daily by 3 months and alternate day prednisone for 6–12 months.

Cyclophosphamide is an important part of induction regimen for many authors, depending on the underlying disease, though there is debate on benefits of oral versus IV treatment. A meta-analysis of nonrandomized studies in ANCA positive pauci-immune GN showed that IV cyclophosphamide was significantly more likely to induce remission (odds ratio 0.29; 95% CI 0.12–0.73) and had a lower risk of infection and leukopenia. Pulse cyclophosphamide dosing was however associated with a greater risk of relapses, exposing patients to further immunosuppression (28). Oral and IV administration of cyclophosphamide were compared in the CYCLOPS trial of the European Vasculitis Study Group (EUVAS). Analysis of data from this trial shows that IV pulse cyclophosphamide is equally effective as daily oral treatment for induction of remission, but with significantly reduced dose and thereby lower toxicity (29). Cyclophosphamide is administered at an oral dose of 2 mg/kg/day, or IV starting at 500 mg/m^2 and increased every 3–4 weeks to a maximum dose of 750 mg/m^2. The dose should be adjusted to maintain a nadir leukocyte count, 2 weeks' post treatment, of 3,000–4,000/cu mm.

The patients are transferred to maintenance therapy at 3 months when receiving oral cyclophosphamide and

Table 34-4

Treatment of crescentic glomerulonephritis

Induction phase (3–6 months)	Maintenance phase (2–5 year)
Methylprednisolone 15–20 mg/kg (maximum 1 g) IV daily for 3–6 doses	Azathioprine 1.5–2 mg/kg/day for 12–18 months
Prednisone 1.5–2 mg/kg/day PO for 4 weeks; taper to 0.5 mg/kg daily by 3 months; 0.5–1 mg/kg on alternate day for 3 months	Prednisone 0.5–1 mg/kg on alternate days; later taper
[a]Cyclophosphamide 500–750 mg/m^2 IV every 3–4 weeks for 6 pulses	Consider mycophenolate mofetil (1,000–1,200 mg/m^2/day), if disease activity is not controlled
[b]Plasmapheresis (double volume) on alternate days for 2-weeks	
Agents for refractory disease	
Intravenous immunoglobulin, TNF-α antibody (infliximab), anti CD20 (rituximab)	

[a]The dose of cyclophosphamide is increased to 750 mg/m^2 if no leukopenia. Dose reduction is necessary in patients showing impaired renal function. Alternatively, the medication is given orally at a dose of 2 mg/kg daily for 12 weeks

[b]Plasmapheresis should begin early, especially if patient is dialysis dependent at presentation or if biopsy shows severe histological changes (>50% crescents). Plasma exchange is particularly useful in anti-GBM nephritis and ANCA-associated vasculitis. It might be considered in patients with immune complex GN with unsatisfactory renal recovery after steroid pulses

at 3–6 months when receiving the IV medication, once successful disease remission is achieved.

Plasmapheresis

Plasmapheresis or plasma exchange has been used for the treatment of crescentic GN with variable success. The mechanism of action is not clear, but is believed to involve removal of pathogenic autoantibodies, coagulation factors and cytokines. Plasma exchange has been shown, in randomized controlled trials in adults, to have therapeutic benefit in patients with anti-GBM disease with clearance of anti-GBM antibodies, lower serum creatinine and improved patient and renal survival (30). The benefits were limited in adults who were anuric with severe azotemia, dialysis dependent or having more than 85% crescents on renal biopsy.

The experience in other categories of crescentic GN is discussed below. Retrospective data in children with RPGN show benefits of plasma exchange if commenced within 1 month of onset of the disease (31). Prospective studies in pauci-immune crescentic GN suggest that discontinuation of dialysis and renal recovery was 91% and 38% when patients received plasma exchange with immunosuppression and immunosuppression alone respectively (32). Anecdotal reports confirm the effectiveness of plasmapheresis in patients with RPGN due to SLE, Henoch Schonlein purpura and severe proliferative GN, and in life-threatening pulmonary hemorrhage.

The role of intensive plasma exchange versus IV methylprednisolone, in addition to oral steroids and cyclophosphamide, was examined by the EUVAS MEPEX trial on 137 patients with renal vasculitis (33). This study investigated whether plasma exchanges were more effective than IV methylprednisolone in patients with ANCA-associated vasculitis and a serum creatinine >500 μmol/L (5.8 mg/dL). Patients were randomized to receive seven plasma exchanges ($n = 70$) or 3,000 mg of IV methylprednisolone ($n = 67$). Both groups received oral cyclophosphamide and oral prednisolone. At 3 months, 49% of those receiving IV methylprednisolone compared with 69% of the plasma exchange group were alive and independent of dialysis (95% CI for the difference 18–35%; $P = 0.02$). At 12 months, patients receiving plasma exchanges had a 24% lower risk for progression to ESRD (95% CI 6.1–41%). While this study supports the use of plasma exchange in the treatment of ANCA-associated vasculitis that presents with RPGN, it is important to note that there was no significant difference between the two groups in terms of rates of mortality at 3- and 12-months.

The role of combined induction with IV methylprednisolone, plasmapheresis and cyclophosphamide requires to be examined. It is emphasized that plasma exchanges have not been shown to be more effective than standard therapy in patients with less-severe renal dysfunction, or to benefit patients with advanced disease. In patients with extensive scarring and little or no activity on biopsy, intensive immunosuppression and/or plasma exchange should be avoided.

Maintenance

The requirement for maintenance therapy in crescentic GN depends on the underlying disease. Most patients with ANCA-associated disease need long-term maintenance immunosuppression, due to the risk of relapses. Extended treatment with cyclophosphamide has been used in adults, but carries significant risks and is currently not preferred for children. While azathioprine is not recommended during the induction phase, it is useful during the maintenance phase.

The timing of the switch from cyclophosphamide to azathioprine was clarified by the CYCAZAREM trial, which compared switching from cyclophosphamide to maintenance azathioprine at 3 versus 12 months (34). The conclusion of the trial was that, for patients in remission, the withdrawal of cyclophosphamide after 3 months and its substitution by azathioprine did not increase the rate of relapse; renal function and patient survival were also similar in the two groups.

The duration of maintenance treatment is debatable, with most patients of pauci-immune crescentic GN treated for 2 or more years (35). The length of maintenance therapy is extended in those with Wegner's granulomatosis or persistent PR3-ANCA positivity.

Supportive Treatment

Intensive immunosuppression is associated with an increased risk of infections. Prophylactic antimicrobials especially against *Pneumocystis carinii* and *Candida* may be required during induction. In areas of high prevalence, patients should be screened for tuberculosis. Patients on long-term therapy with corticosteroids should receive dietary calcium supplements. They should be counseled about the possibility of infertility following cyclophosphamide treatment. MESNA should be administered to patients receiving IV cyclophosphamide to protect against urothelial toxicity (35).

Specific Therapies

Immune Complex Crescentic GN

There are limited evidence-based recommendations on treatment for these patients. Therapy for immune complex GN largely depends on the underlying disease. The treatment of lupus nephritis, Henoch Schonlein purpura and IgA nephropathy presenting with RPGN is discussed in their respective chapters.

Postinfectious RPGN

Poststreptococcal GN presenting with extensive crescents is rare and the benefits of intensive immunosuppressive therapy are unclear, since most patients recover spontaneously. Nevertheless, immunosuppressive therapy with corticosteroids and alkylating agents has been used in patients with renal failure and extensive glomerular crescents (18, 36). Despite the lack of evidence-based data, patients with poststreptococcal RPGN and crescents involving 50% or more glomeruli should be treated with 3–6 IV pulses of methylprednisolone, followed by tapering doses of oral steroids. Some authors recommend the addition of cyclophosphamide to the therapeutic regimen.

Eradication of the infection and removal of infected prostheses are necessary for resolution of immune complex GN associated with active infections.

Pauci-Immune Crescentic GN

Induction therapy comprises of treatment with IV methylprednisolone (administered daily for 3–6 days) followed by oral prednisone and cyclophosphamide (given either orally for 3 months or by the IV route every 3–4 weeks for 6 months) (2, 25). Intensive PE for 2 weeks is advised for children who are dialysis dependent, those with pulmonary hemorrhage or not responding satisfactorily to induction treatment (33, 35).

Two recent studies compared the efficacy of treatment with mycophenolate mofetil, as an alternative to cyclophosphamide, for induction of remission (37, 38). These preliminary studies suggest that initial treatment with mycophenolate mofetil is promising in ameliorating disease activity and improving renal function in patients with crescentic GN.

Therapy is continued during the maintenance phase, with tapering doses of oral prednisone and azathioprine, for at least 24 months following successful disease remission (35). A longer duration of therapy, extended up to 5 year, is required in patients with Wegner's granulomatosis showing relapses, elevated ANCA titers and those with PR3-ANCA (2).

Treatment with mycophenolate mofetil, during the maintenance phase, has been examined in patients with systemic vasculitis. In an open-label investigation of the use of this agent for maintenance therapy of 11 patients with

Wegener's granulomatosis or microscopic polyangiitis and crescentic GN, treatment was associated with sustained remission in 91% (39). A National Institutes of Health (USA) trial on 14 patients examined the role of mycophenolate mofetil as maintenance therapy after induction with cyclophosphamide. While the agent was well tolerated, the relapse rate was high (43%) (40). Currently, the EUVAS IMPROVE trial is prospectively recruiting patients to compare the efficacy of mycophenolate mofetil to azathioprine for remission maintenance (41).

Approximately one-third patients with pauci-immune crescentic GN have one or more relapses. Minor relapse is treated with an increase in prednisone dosage. Major relapse is treated with reinstitution of induction therapy with cyclophosphamide with an increase in prednisone; IV methylprednisolone or plasma exchange may also be considered (35). Less intensive treatment with mycophenolate mofetil is proposed for relapses that are diagnosed early.

Anti-GBM Crescentic GN

Prompt institution of plasma exchange is necessary in subjects with anti-GBM nephritis. Double volume exchange is done daily, and subsequently on alternate days until anti-GBM antibodies are no longer detectable (usually 2–3 weeks) (1, 25). The patients are also treated with IV methylprednisolone (described above) followed by high-dose oral prednisone, with subsequent tapering over several months. Co-administration of cyclophosphamide (2 mg/kg daily for 3 months) is effective in suppressing further antibody production. Pulmonary hemorrhage responds to therapy with three-doses of methylprednisolone (20 mg/kg on alternate days); plasmapheresis is beneficial in these patients.

As anti-GBM disease does not usually have a relapsing course, prolonged maintenance therapy is not required and treatment with steroids is tapered over the next 6–9 months. Patients treated early in the course of their illness do satisfactorily. In patients who develop end stage renal disease, transplantation should be deferred until anti-GBM antibodies are undetectable for 12 months, at which point disease recurrence is unlikely.

A proportion of patients with anti-GBM nephritis also show positive ANCA, most often p-ANCA. While the precise significance of the dual positivity is unclear, the initial clinical outcome for these patients is similar to that for classical anti-GBM disease. In view of a higher risk of relapses, these patients require a longer course of maintenance immunosuppresive therapy (as for pauci-immune crescentic GN) (42).

Newer Agents

A number of studies have examined the efficacy of intravenous immunoglobulin in subjects with ANCA positive systemic vasculitis and RPGN, with benefit lasting for up to 3-months (43). The EUVAS NORAM study compared the effectiveness of orally administered methotrexate and cyclophosphamide in adult patients with early systemic vasculitis and mild renal involvement. Induction of remission were similar in the two groups at 6 months (90 vs. 94% respectively), but relapses were significantly more frequent after treatment withdrawal in the methotrexate treated patients (44). Methotrexate, however, accumulates in renal impairment and is therefore not recommended for patients with moderate or severe renal dysfunction.

Rituximab, a monoclonal antibody directed against CD20 antigen on B cells, has been used successfully in therapy resistant lupus nephritis and refractory Wegener's granulomatosis. Eleven patients with refractory small vessel vasculitis, not controlled by maximally tolerated doses of cyclophosphamide and corticosteroids or a contraindication to treatment with cyclophosphamide received treatment with 4 weekly injections of rituximab. Disease remission and reduction of ANCA titers were induced in all patients within 6 months; remission persisted if B cells remained absent and acute-phase reactants (C-reactive protein, sedimentation rate) were reduced (45).

The efficacy of other agents, including cyclosporin, leflunomide, mizoribine, deoxyspergualin, anti-thymocyte globulin, anti-CD52 antibodies and infliximab is being examined (46, 47). Although potentially useful for treatment of individual patients, there is insufficient evidence to recommend general use of these agents.

Outcome

The outcome of these patients has improved in the last decades, as almost 60–70% patients recover renal function. The course is largely determined by the severity of renal failure at presentation and the promptness of intervention, renal histology and the underlying disease (1, 2, 25). Patients with poststreptococcal crescentic GN have a better prognosis, most of them showing spontaneous improvement after supportive management. The outcome in patients with pauci-immune crescentic GN, membranoproliferative glomerulonephritis and idiopathic RPGN is less favorable than Henoch Schonlein purpura or systemic lupus erythematosus.

The potential for recovery is related to the relative proportion of cellular or fibrous crescents, and the extent

of tubular atrophy, interstitial fibrosis and glomerulosclerosis. In patients with severe crescentic GN, the presence of normal glomeruli are a positive predictor of dialysis independence and recovery of renal function, suggesting that the unaffected part of the kidney is vital in determining renal outcome (48).

Post Transplant Recurrence

The use of potent immunosuppressive medications following transplantation and antigenic characteristics of the graft prevent posttransplant recurrence in most patients. Better graft survival has however increased the likelihood of disease recurrence in the allografts. A positive ANCA titer at the time of transplantation does not increase the risk of posttransplant recurrence. Conditions associated with risk of histological recurrence include membranoproliferative GN type II, IgA nephropathy, Henoch Schonlein purpura and systemic lupus erythematosus.

Tubular Disease

35 Nephronophthisis and Medullary Cystic Kidney Disease

Friedhelm Hildebrandt

Natural History of Nephronophthisis and Medullary Cystic Kidney Disease

Nephronophthisis (NPHP) is an autosomal recessive cystic kidney disease that constitutes the most frequent genetic cause for end-stage kidney disease (ESKD) in the first 3 decades of life (1–4). Three clinical forms of NPHP have been distinguished by age of onset of ESKD: infantile (5, 6), juvenile (7), and adolescent NPHP (8), which manifest with ESKD at median ages of 1 year, 13 years, and 15 years, respectively. Initial symptoms are relatively mild with the exception of infantile NPHP type 2. They consist of polyuria, polydipsia with regular fluid intake at nighttime, secondary enuresis, and anemia (9). A slightly raised serum creatinine is noted at an average age of 9 years, before ESKD invariably develops within a few years (› *Fig. 35-1*). Renal ultrasound reveals increased echogenicity (› *Fig. 35-2*). Beyond the age of 9 years cysts appear at the corticomedullary junction within kidneys of normal or slightly reduced size (› *Fig. 35-2*) (10). Renal histology reveals a characteristic triad of tubular basement membrane disruption, tubulointerstitial nephropathy, and cysts (› *Fig. 35-3*) (11, 12). In nephronophthisis cysts arise from the corticomedullary junction of the kidneys (› *Fig. 35-2*). Because kidney size is normal or slightly reduced (except in infantile NPHP type 2, where there is moderate renal enlargement), cysts seem to develop *e vacuo* through loss of normal tissue. This is in contrast to polycystic kidney disease, where cysts are distributed evenly and lead to gross enlargement of the kidneys (13).

NPHP is inherited in an autosomal recessive mode. This includes NPHP variants with extrarenal manifestations (1, 13). In more than 10% of cases NPHP can be associated with extrarenal involvement, primarily including retinal degeneration (Senior-Loken syndrome) (14, 15), cerebellar vermis aplasia (Joubert syndrome) (16, 17), liver fibrosis (18), and cone-shaped epiphyses (19). The extrarenal manifestations will be discussed below in light of the cilia/centrosome theory of NPHP. NPHP has previously been grouped together with the clinical entity of medullary cystic kidney disease (MCKD) (7, 11), due to similarities of clinical and pathologic features (20). Both, NPHP and MCKD, feature corticomedullary cysts in kidneys of normal or slightly reduced size. However, MCKD is clearly distinct from NPHP regarding multiple aspects: (1) MCKD follows autosomal dominant inheritance, (2) ESKD occurs in the fourth decade or later, and, (3) in MCKD there is no extrarenal involvement other than hyperuricemia and gout.

Nephronophthisis and dominant MCKD seem to be distributed evenly among males and females. Nephronophthisis has been reported from virtually all regions of the world (21)with an incidence of 9 patients/8.3 million (22) in the United States or 1 in 50,000 live births in Canada (23). The condition constitutes the most frequent genetic cause for ESKD in the first two decades of life, and is a major cause of end-stage renal disease in children, accounting for 10–25% of these patients (21, 24, 25). In the North American pediatric ESKD population pooled data indicate a prevalence of less than 5%. MCKD appears to be somewhat more rare.

NPHP was first described by Smith and Graham in 1945 (2) and by Fanconi et al. (3), who introduced the term "familial juvenile nephronophthisis". Since then over 300 cases have been published in the literature (11). In NPHP the earliest presenting symptoms are polyuria, polydipsia, decreased urinary concentrating ability, and secondary enuresis. They occur in over 80% of cases (21) and start at around 6 years of age. Anemia and growth retardation develop later in the course of the disease (9). Regular fluid intake at nighttime is a characteristic feature of the patients' history, and starts around age 6 years. Due to the mild nature of symptoms and the lack of edema, hypertension, and urinary tract infections there is often a delay in the diagnosis of NPHP. This may cause a risk of sudden death from fluid and electrolyte imbalances. Disease recurrence has never been reported in kidneys transplanted to NPHP patients (26). By positional cloning nine different recessive genes (*NPHP1-9*) have been identified

© Springer-Verlag Berlin Heidelberg 2009

to cause NPHP types 1–9 (see below). This has made definite molecular genetic diagnostics possible (www.renalgenes.org). Homozygous deletions in the *NPHP1* gene account for approximately 25% of all cases of NPHP, whereas the other genes contribute less than 3% each. As expected in a recessive disease, penetrance of the renal phenotype seems to be 100%.

In NPHP, chronic renal failure develops within the first 3 decades of life (8, 27, 28). Infantile NPHP, which is characterized by mutations in *NPHP2/inversin*, leads to ESKD between birth and 3 years of age (28, 29). In a study conducted in 46 children with juvenile NPHP type 1 caused by mutations of the *NPHP1* gene, a serum creatinine of 6 mg/dl was reached at a median age of 13 years of age, (range 4–20 years) (*Fig. 35-1*) (7, 27). Similarly, the median age of ESKD in patients with mutations in the *NPHP5* gene was 13 years (30). The median time lapse between a serum creatinine of 2 and 4 mg/dl was 32 months, and between 4 and 6 mg/dl 10 months (*Fig. 35-1*) (31). In patients with adolescent NPHP due to mutations in the *NPHP3* gene ESKD developed by 19 years of age (8). If renal failure has not developed by the age of 25 years, the diagnosis of recessive NPHP should be questioned and autosomal dominant MCKD considered as a differential diagnosis. In MCKD, which follows autosomal dominant inheritance, ESKD occurs later in life. MCKD types 1 and 2 show a median onset of ESKD at 62 years (32) and 32 years (33), respectively. MCKD type 2 can be positively diagnosed by detection of mutations in the *UMOD* gene encoding uromodulin/Tamm-Horsfall protein (34).

Figure 35-1

Progression chart representing the average course of deterioration of renal function in 19 patients of 8 families with NPHP type 1 as proven by homozygous deletion of the *NPHP1* gene. Median (solid line) and quartile (dashed lines) curves were calculated from 308 serial SCR values (Reproduced with permission from (27)).

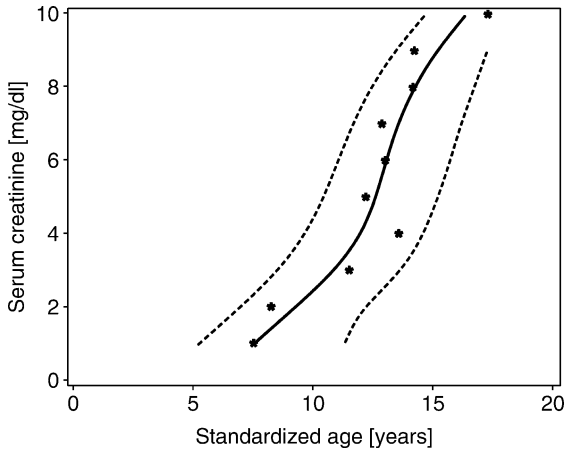

Figure 35-2

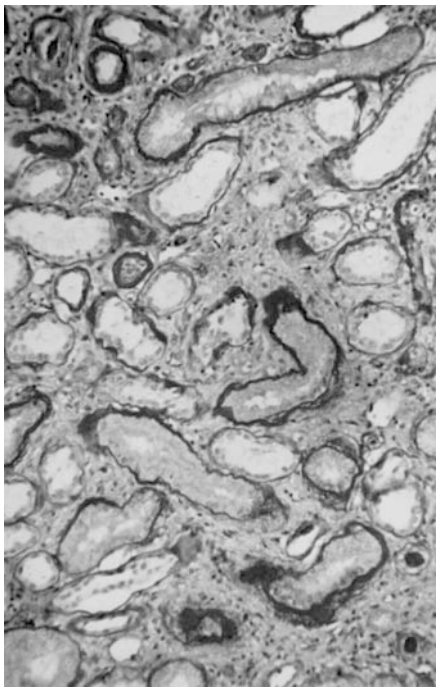
Renal ultrasound in nephronophthisis. Note kidney of normal size (12 cm between markings), loss of cortico-medullary differentiation, presence of cysts at the cortico-medullary border of the kidney, and increased echogenicity, which renders the ultrasound pattern similar to the pattern of liver (Courtesy of Dr. U. Vester, Essen).

Figure 35-3

Renal histology of nephronophthisis. Note the characteristic triad of tubular basement membrane disruption, tubular cell atrophy with cysts, and interstitial infiltration with fibrosis. Hematoxylin/eosin stain (Courtesy of Prof. R Waldherr, Heidelberg).



Pathology and Histopathology

Renal histopathology is very similar in NPHP and MCKD, and has been described comprehensively in 27 patients with NPHP by Waldherr and associates (11, 12) (*Fig. 35-3*). Kidney size is normal or moderately reduced. There is always bilateral renal involvement. Macroscopically, the kidney surface has a finely granular appearance, most likely due to the protrusion of dilated cortical collecting ducts. There are between 5 to approximately 50 cysts of 1–15 mm in diameter, located preferentially at the corticomedullary border. The cysts arise primarily from the distal convoluted and medullary collecting tubules as shown by microdissection (35), but may also appear in the papilla. Cysts are observed only in about 70% of autopsy cases, and seem to arise late in the course of the disease (36). Therefore, the presence of cysts is not a prerequisite for diagnosis. No cysts are present in organs other than the kidney. The histologic changes of NPHP are characteristic but not specific for the disease and seem to develop only postnatally. Typically, there is pronounced thickening and multilayering of the tubular basement membrane (TBM), which represents the most characteristic histologic feature of NPHP and MCKD (*Fig. 35-3*). By light microscopy there appears to be a sequence of events, TBM disruption is followed by lymphocytic and histocytic peritubular infiltration. Subsequently, atrophic or dilated and tortuous tubules develop predominantly at the corticomedullary junction. In advanced stages the picture merges into a diffuse sclerosing tubulo-interstitial nephropathy. TBM changes and cyst formation are most prominent in distal tubules, where cysts are lined with a single layer of cuboidal or flattened epithelium (37–40). Glomeruli demonstrate periglomerular fibrosis with splitting and thickening of Bowman's capsule. Glomerular obsolescence is only present in nephrons that have been destroyed by tubular alterations. Leakage of Tamm-Horsfall protein from damaged collecting tubules into the interstitium has been demonstrated in patients with MCKD (41). On transmission electron microscopy there is thickening, splitting, attenuation, and granular disintegration of the tubular basement membrane without clear stages of transition (12). A marked increase of microfilaments is seen at the base of the tubular epithelial cells.

Molecular Genetics and Pathophysiology

A positional cloning approach was used to gain insight into the pathogenesis of NPHP and MCKD (*Table 35-1*). This has revealed recessive mutations in nine different novel genes as causing NPHP. These are *NPHP1* (42, 43), *NPHP2/inversin* (6), *NPHP3* (44), *NPHP4* (45, 46), *NPHP5* (30), *NPHP6/CEP290* (47, 48), *NPHP7/GLIS2* (49), *NPHP8/RPGRIP1L* (50–52), and *NPHP9/NEK8* (53), defining NPHP types 1 through 9, respectively (*Table 35-1*). These are monogenic recessive genes, implying that mutations in each single gene is sufficient in itself to cause NPHP in a patient, indicating that their gene products are necessary for normal kidney function. Gene identification thereby generated new insights into disease mechanisms of NPHP, and revealed that they are related to signaling mechanisms of primary cilia, centrosomes, and planar cell polarity (1, 6, 54, 55) (see below and *Fig. 35-4*). Gene identification has made definite molecular genetic diagnostics possible (www.renalgenes.org) for approximately 30% of cases. Homozygous deletions in the *NPHP1* gene account for approximately 21% of all NPHP cases, whereas the other genes (*Table 35-1*) contribute less than 3% each. Thus the causative genes are still unknown in about 70% of cases, indicating that

Table 35-1

Disease variants, gene loci, extrarenal manifestations, and mouse models of nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD)

Disease	Gene	Onset of ESRD (Median in Years)	Chromosome	Gene (Product)	Extrarenal Association	Mouse Model
Nephronophthisis						
Type 1 (juvenile)	*NPHP1*	13	*2q12.3*	NPHP1/nephrocystin-1	SLSN, OMA, JBTS, MKS	–
Type 2 (infantile)	*NPHP2/ INVERSIN*	1–3	*9q22-q31*	NPHP2/Inversin	SLSN, ventricular septal defect, *situs inversus*	*inv/inv*[76]
Type 3 (adolescent)	*NPHP3*	19	*3q22*	NPHP3	SLSN, LF	*pcy*[82], *Nphp-/-*[83]
Type 4	*NPHP4*	20	*1p36*	NPHP4/nephroretinin	SLSN	–
Type 5	*NPHP5/ IQCB1*	13	*3q13.33*	NPHP5/IQ motif containing B1	SLSN (all patients)	–
Type 6	*NPHP6/ CEP290*	<13	*12q21.32*	NPHP6/centrosome protein Cep290	SLSN, JBTS, MKS	*rd16*[87]
Type 7	*NPHP7/ GLIS2*	~17	*16p13.3*	NPHP7/GLIS familiy zinc finger 2	–	*Glis*[2]*/-*[5]
Type 8	*NPHP8/ RPGRIP1L*	<13	*16q12.2*	NPHP8/RPGRIP1-like	JBTS, MKS	*Ftm*[51]
Type 9	*NPHP9/ NEK8*	~13	*17q11.2*	NPHP9/NIMA-related kinase 8	–	*jck*[93]
Medullary Cystic Kidney Disease						
MCKD type 1	*?*	62	*1q21*		Hyperuricemia, gout	
MCKD type 2	*UMOD*	32	*16p12*	Uromodulin/Tamm-Horsfall protein	Hyperuricemia, gout	*Umod-/-*[148]

AD autosomal dominant, *AR* autosomal recessive, *ESKD* end-stage kidney disease, *JBTS* Joubert syndrome, *LF* liver fibrosis, *MKS* Meckel syndrome, *OMA* oculomotor apraxia type Cogan, *SLSN* Senior-Loken syndrome, *UMOD* uromodulin/Tamm-Horsfall protein – = no data

further genes are involved in the pathogenesis of NPHP. Recently, evidence has been generated that more than one recessive gene may be mutated in individual patients with NPHP (56) as has been proposed for the related disorder Bardet-Biedl syndrome (BBS) (57, 58). In the following, the pathogenesis of NPHP will be discussed in the context of the discovery of each of the genes *NPHP1* – *NPHP9* (*Table 35-1*). The structure and function of primary cilia and basal bodies is delineated in *Fig. 35-2*.

NPHP1

In juvenile nephronophthisis (NPHP type 1) a gene locus has been mapped to chromosome 2q12.3 (59). This locus was further refined (60–64) and the gene (*NPHPP1*) responsible for NPHP1 was identified by positional cloning (42, 43). About 85% of patients with NPHP type 1 carry large homozygous deletions of the *NPHP1* gene (65, 66). Spontaneously occurring deletions of the *NPHP1* locus (67) as well as specific loss-of-function point mutations of *NPHP1* have been characterized (27, 68). In a subset of patients with large deletions in *NPHP1* there is an association with oculomotor apraxia type Cogan (66) (*Table 35-1*). Another subset shows an association with retinitis pigmentosa (68). Mutations in *NPHP1* were identified as causing juvenile nephronophthisis type 1 (42, 43). *NPHP1* encodes nephrocystin-1, a protein that interacts with components of cell-cell and cell-matrix signaling, including p130Cas (69), focal adhesion kinase 2 (70), tensin, filamin A and B (71, 72). It is located at adherens junctions and focal adhesions of

Figure 35-4

Cilia structure and intraflagellar transport. The cilium is a hair-like structure that extends from the cell surface into the extracellular space. Virtually all vertebrate cell types can produce cilia. Cilia consist of a microtubule-based axoneme covered by a specialized plasma membrane. The axoneme has nine peripheral microtubule doublets. There may be two central microtubules (9 + 2 vs. 9 + 0 axoneme). 9 + 2 cilia usually have dynein arms that link the microtubule doublets and are motile, while most 9 + 0 cilia lack dynein arms and are non-motile (''primary cilia'') with a few exceptions. The ciliary axoneme is anchored in the basal body, a microtubule-organizing center derived from the mother centriole. The transition zone at the junction of the basal body acts as a filter for the molecules that can pass into or out of the cilium. Nephrocystin-1 is localized at the transition zone of epithelial cells (73). During ciliogenesis, cilia elongate from the basal body by the addition of new axonemal subunits to the distal tip, the plus end of the microtubules. Axonemal and membrane components are transported in raft macromolecular particles (complex A and B) by so-called intraflagellar transport (IFT) along the axonemal doublet microtubules (159). Anterograde transport towards the tip is driven by heterotrimeric kinesin 2, which contains motor subunits Kif3a and Kif3b and a non-motor subunit. Mutations of Kif3a cause renal cysts and cerebellar vermis aplasia in mice (160). Retrograde transport back to the cell body occurs via the motor protein cytoplasmic dynein 1B (161) (modified from Bisgrove and Yost, 2006) (162).

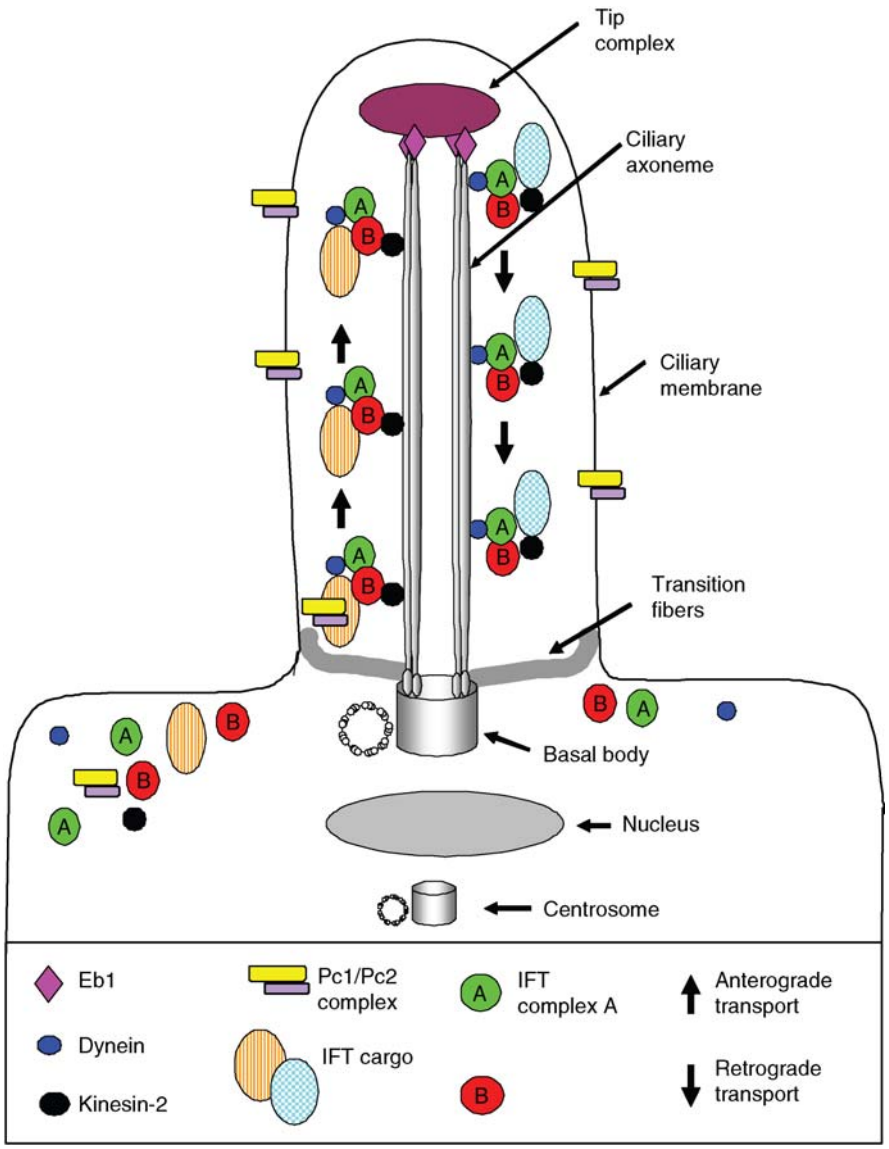


Figure 35-5

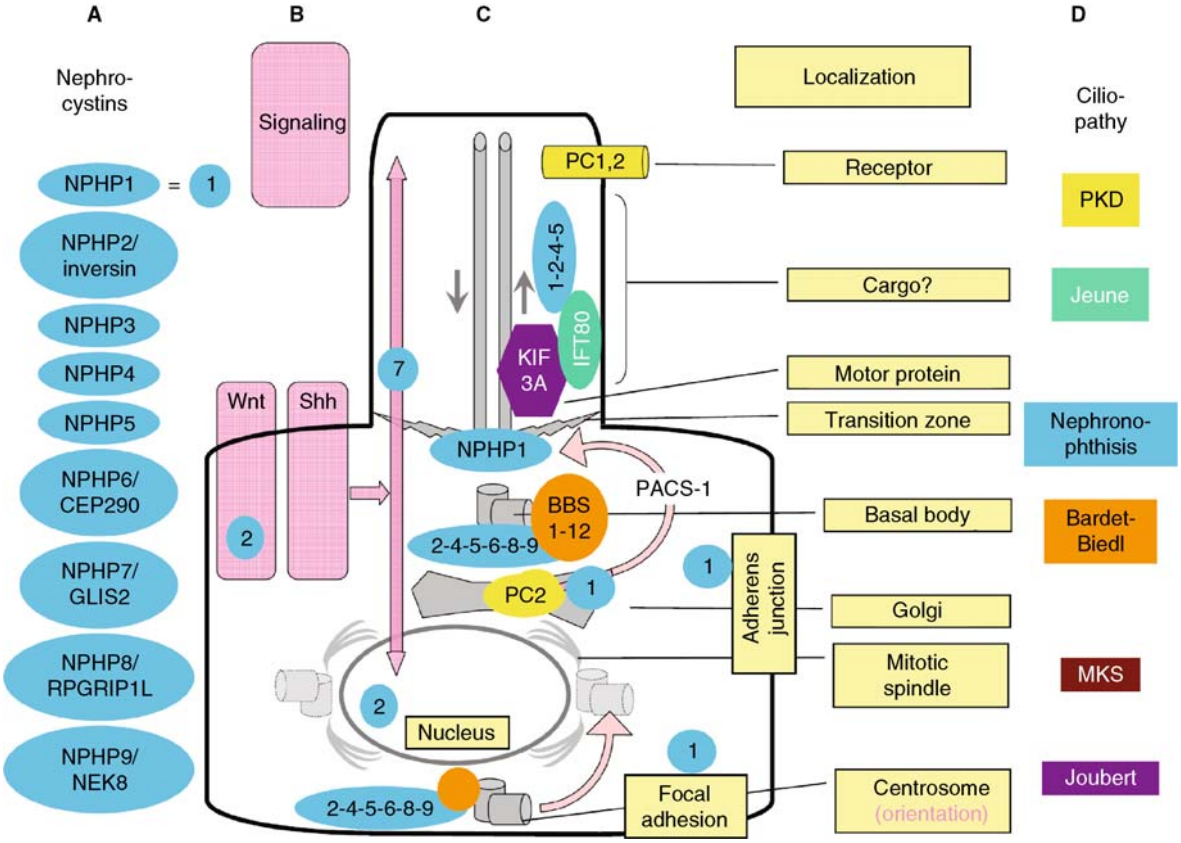
Subcellular localization of nephrocystins to primary cilia, basal bodies, the mitotic spindle, focal adhesions and adherens junctions, and functional interaction with other proteins mutated in renal "ciliopathies". "Cystoproteins" are proteins of genes mutated in cystic kidney diseases of humans, mice, or zebrafish. Depending on cell cycle stage, cystoproteins are localized at different subcellular organelles (shown in grey) (47, 163) including primary cilia, basal bodies, endoplasmic reticulum, the mitotic spindle, centrosomes, adherens junctions or focal adhesions. Arrows in the primary cilium indicate the direction of anterograde transport along the microtubule system mediated by kinesin-2 and retrograde transport by cytoplasmic dynein 1b. (A) Most nephrocystins (blue) are located at cilia, the basal body, and centrosome in a cell cycle dependent manner. NPHP1 is also at the transition zone, focal adhesions and adherens junctions. (B) Sensory cilia (*Fig. 35-4*) perceive and process cell external signals, and "cystoproteins" are involved in signaling mechanisms downstream of cilial signal recognition. Downstream of cilia (pink), Wnt signaling (*Fig. 35-6*) and hedgehog signaling play a role in planar cell polarity, which is mediated (C) partially through orientation of centrosomes and the mitotic spindle poles. (D) Cilia-dependent mechanisms of planar cell polarity seem to be the central to the pathogenesis of the ciliopathies, the most prominent of which are listed on the right. Wnt, the Wnt signaling pathway; Shh, the sonic hedgehog signaling pathway.



renal epithelial cells (71, 72), which are involved in cell-cell and cell-basement membrane contacts, respectively (*Fig. 35-5*). Nephrocystin-1 also interacts with the product of other nephronophthisis genes such as nephrocystin-2/inversin (6), nephrocystin-3 (44) and nephrocystin-4 (45, 46). More recently, it was shown that nephrocystin-1 is targeted to the transition zone of motile and primary cilia by the protein PACS-1 (phosphofurin acidic cluster sorting protein-1) (73, 74) (*Fig. 35-5*). This is initiated by casein kinase 2-mediated phosphorylation of three critical serine residues within a cluster of acidic amino acids in nephrocystin, leading to PACS-1 binding, and to colocalization of nephrocystin with PACS-1 at the base of cilia (74).

NPHP2/Inversin

Infantile nephronophthisis (NPHP type 2) was recognized as a distinct disease entity, in which end-stage renal failure occurs within the first 3 years of live (5, 75) (*Table 35-1*). Macroscopically, NPHP type 2 differs from other forms of NPHP by the presence of enlarged kidneys and cortical microcysts, and by the absence of medullary cysts. Histologically, there is no disruption of tubular basement membranes. Mutations of *NPHP2/inversin* (*INVS*) were identified as the cause of infantile NPHP (type 2) with and without situs inversus (6) by positional cloning (28) and using candidate gene data (76, 77). The renal cystic changes of infantile nephronophthisis combine clinical features of NPHP and of PKD (5). The gene products nephrocystin-1 and NPHP2/inversin interact with β-tubulin, which constitutes the microtubule axoneme of primary cilia (*Fig. 35-4*), and they are localized at primary cilia of renal tubular cells (*Fig. 35-5*) (6). These findings supported a unifying theory of renal cystogenesis (1, 54, 78, 79), which states that proteins ("cystoproteins") which are mutated in renal cystic disease in humans, mice or zebrafish, are expressed in primary cilia, basal bodies, or centrosomes (6, 54). Basal bodies are the foundations from which cilia are assembled. Once mitosis and cell division are completed, basal bodies derive from the *mother* centriole of the centriole pair that had previously organized the mitotic spindle in cell division. When cilia are formed from the basal body, the *daughter* centriole is placed on the side of the nucleus opposite to the basal body, thus specifying cell polarity (*Fig. 35-5*). It is becoming apparent that primary cilia are highly conserved structures that sense extracellular cues in a broad spectrum of epithelial tissues. There is a wide range of cues that can be received by specific ciliary receptors, including photosensation, mechanosensation, osmosensation, and olfactory sensation. In general, it seems that the pathogenesis of ciliopathies is based on an inability of epithelial cells to sense or process extracellular cues (80). Inversin was shown to localize to different subcellular locations, in a cell cycle dependent manner. Specifically, it is found at the mitotic spindle in mitosis, at the midbody in cytokinesis, and in cilia, at the basal body and centrosome in interphase (*Fig. 35-5*). All of these subcellular organelles are involved in regulation of planar cell polarity or the cell cycle (see below). In this context, a major breakthrough was made for the understanding of the pathogenesis of renal cystic diseases when Simons et al. demonstrated a role of inversin/NPHP2 in signaling mechanisms of planar cell polarity necessary to maintain normal tubular development and morphology (81) as outlined in *Fig. 35-6* (55, 81). As a consequence of this model, when inversin is defective (as in NPHP type 2) the canonical Wnt pathway will prevail (*Fig. 35-6*), which will interfere with proper apical-basolateral polarity of the renal epithelium (55) (*Fig. 35-7*).

NPHP3

In a large Venezuelan kindred we identified by positional cloning mutations in *NPHP3* as responsible for adolescent nephronophthisis (*Table 35-1*) (8, 44). The *pcy* mouse model demonstrated that mutations in the mouse ortholog *Nphp3* cause the renal cystic mouse mutant *pcy* (44), which was demonstrated to be responsive to treatment with a vasopressin receptor antagonist (82). Recently, it was shown that complete loss of *Nphp3* function results in *situs inversus*, congenital heart defects, and embryonic lethality in mice (83) and that truncating mutations of *NPHP3* in humans can cause a broad clinical pattern that resembles Meckel syndrome. This included *situs inversus*, polydactyly, central nervous system malformations, structural heart defects, preauricular fistulas, and congenital anomalies of the kidney and urinary tract (83).

NPHP4

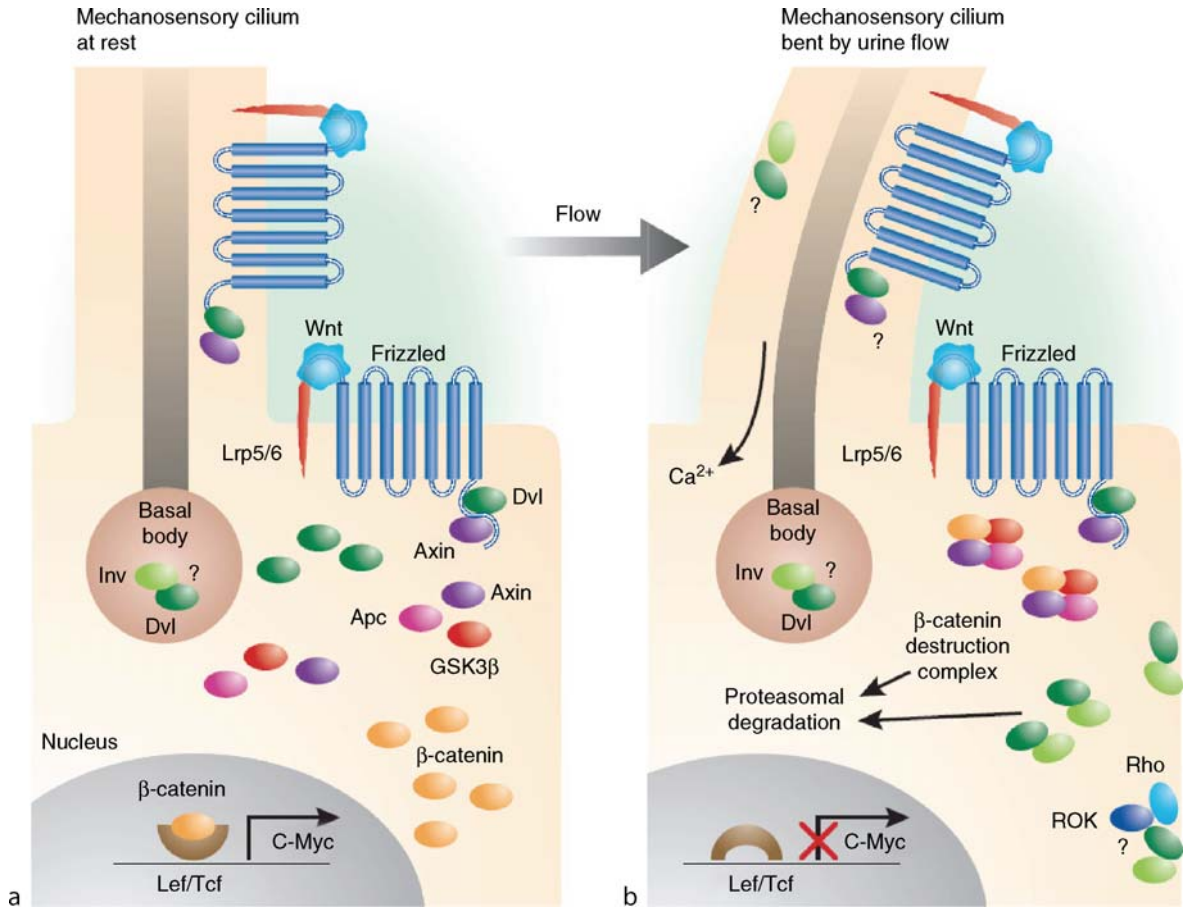
Mutations in the novel gene *NPHP4* were identified by homozygosity mapping and total genome search for linkage (45, 46, 84) (*Table 35-1*). Nephrocystin-4, like inversin, localizes to primary cilia, basal bodies, centrosomes, and the cortical actin cytoskeleton (85) (*Fig. 35-5*).

NPHP5

Recessive mutation in the novel gene *NPHP5* were identified as mutated in nephronophthisis type 5 (30). All mutations detected were truncations of the encoded protein nephrocystin-5, and all patients had an association with early-onset retinal degeneration. Thus, *NPHP5* represents the gene mutated in the typical early-onset form of Senior-Loken syndrome (SLSN) (*Table 35-1*). Nephrocystin-5 contains an IQ domain, which directly interacts with calmodulin (30), and is in a complex with the retinitis pigmentosa GTPase regulator (RPGR), which when defective causes X-linked retinitis pigmentosa. Both, nephrocystin-5 and RPGR are localized in connecting cilia of photoreceptors and in primary cilia of renal epithelial cells (30) (*Fig. 35-5*). The fact that connecting

Figure 35-6

Inversin/NPHP2 mediates a switch from the canonical the non-canonical Wnt signaling pathway, which plays a role in planar cell polarity maintenance (81). (a) This cartoon of a renal tubular epithelial cell shows how Wnt signaling occurs primarily through β-catenin–dependent pathways in the absence of urine flow. Ligand binding by the frizzled receptor results in inactivation of the β-catenin destruction complex through the presence of disheveled (Dvl), increased β-catenin levels, and upregulation of effector gene expression of the canonical Wnt signaling pathway. (b) Stimulation of the primary cilium, e.g. by urine flow, results in increased expression of inversin (Inv), which then reduces levels of cytoplasmic Dvl by increasing its proteasomal degradation. This allows reassembly and activation of the β-catenin destruction complex, thereby switching from the canonical to the non-canonical Wnt signaling pathway. The model is consistent with the finding that overexpression of β-catenin (equivalent to canonical Wnt signaling) leads to renal cysts in a mouse model (164) (from (55)).



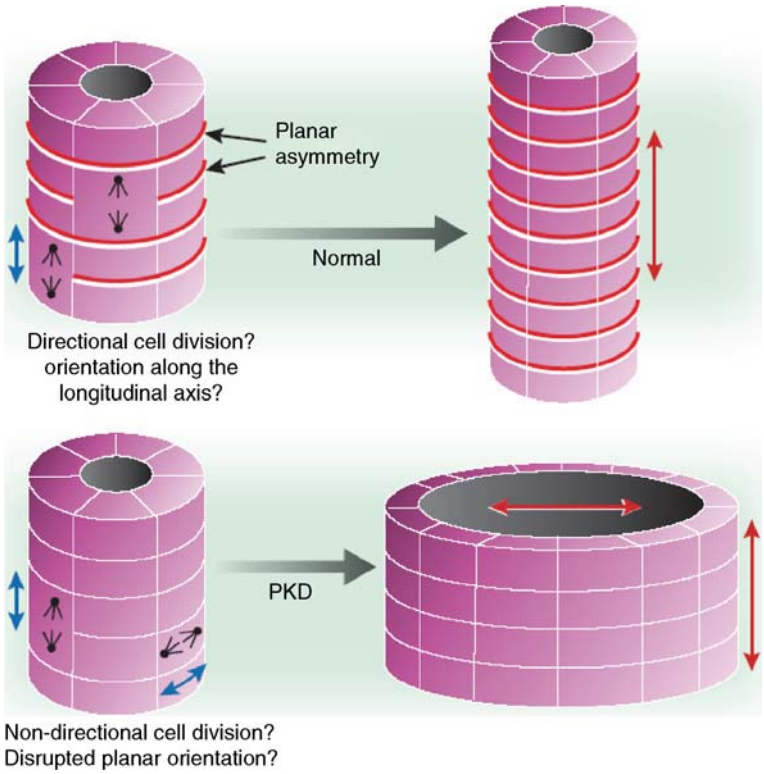
cilia of photoreceptors are the structural equivalents of primary cilia of renal epithelial cells rendered an explanation for retinal involvement in the retinal-renal syndrome Senior-Loken syndrome (*Fig. 35-8*).

NPHP6/CEP290

Recessive truncating mutations in the novel gene *NPHP6/CEP290* were identified as the cause of NPHP type 6 and Joubert syndrome type 5 by positional cloning (47). Its gene product nephrocystin-6/CEP290 is part of the centrosomal proteome (86) (*Table 35-1*). Similar to NPHP2/inversin and NPHP4, NPHP6/CEP290 is expressed in centrosomes and the mitotic spindle in a cell-cycle dependent manner. Abrogation of *NPHP6* function in zebrafish caused planar cell polarity defects and recapitulated the human phenotype of NPHP type 6, including renal cysts, retinal degeneration, and cerebellar defects (47). Nephrocystin-6 modulates the activity of ATF4/CREB2, a transcription factor that may be implicated in cAMP-dependent renal cyst formation (82).

Figure 35-7

Defects of cystoproteins lead to disruption of planar cell polarity, and thereby to renal cysts through to malorientation of the centrosome or mitotic spindle complex. Correct orientation of the mitotic spindle and centrosomes with respect to the longitudinal axis of the tubule is critical for proper planar cell polarity (i.e., the orientation of an epithelial cell layer in 3-dimensional space). Non-canonical Wnt signaling (see *Fig. 35-6*) is involved in regulation of planar cell polarity during renal tubular morphogenesis, when in rodents 2 weeks post partum the tubules still elongate. The structure that would result from disruption of this longitudinal orientation is a dilated tubule or cyst (from (55)).



Interestingly, a 300-amino acid in-frame deletion of *Nphp6/Cep290* caused retinal degeneration only, without renal or cerebellar involvement in the *rds16* mouse model (87) (*Table 35-1*). This is in accordance with the recent finding that a hypomorphic mutation of *NPHP6/CEP290* represents the most frequent cause of Leber's congenital amaurosis (88). Mutations in *NPHP6/CEP290* have been confirmed as causing JBTS with and without renal involvement (48). Furthermore, truncating mutations in *NPHP6* were shown to cause Meckel syndrome (89).

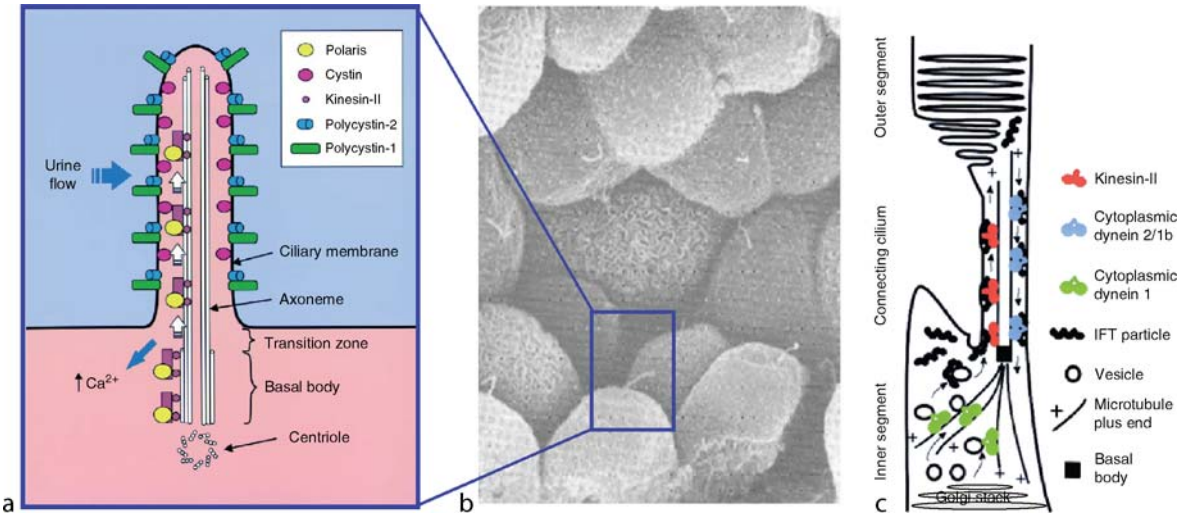
Correct orientation of the mitotic spindle and centrosomes with respect to the longitudinal axis of the renal tubule is critical for proper apical-basolateral polarity (*Fig. 35-7*). Non-canonical Wnt signaling (*Fig. 35-6*) is involved in these processes in renal tubular morphogenesis, when in rodents postnatally renal tubules still elongate. The structure resulting from disruption of the longitudinal growth would be a dilated tubule or cyst (*Fig. 35-7*). Recently, evidence was generated for a role of planar cell polarity in renal cystic diseases (90) by measuring orientation of the mitotic spindle through 3-D imaging of renal tubules. Comparison of the distribution of the mitotic angles in wild-type animals and rodent cystic kidney disease models revealed that mitotic angles of two rodent models of cystic kidneys, the HNF1β-deficient mouse model and the *pck* rat model where clearly different from wild-type littermates (90).

NPHP7/GLIS2

Recently, mutations in the *NPHP7/GLIS2* gene, encoding the transcription factor Gli-similar protein 2 were discovered as the cause of NPHP type 7 (*Fig. 35-4*) (49).

Figure 35-8

Primary (non-motile) cilia of renal epithelial cells and connecting cilia of retinal photoreceptors are analogous structures. In the primary cilium (a) of renal epithelial cells (b) "cargo" proteins are trafficked along the microtubule tracks from the region of the Golgi stack to the tip of the cilia via the motorprotein kinesin II and back down via cytoplasmic dynein 1b. (c) In an analogous fashion approximately 10^9 molecules of the visual pigment rhodopsin are transferred up and down the connecting cilia per human retina per day (modified from Somlo & Igarashi (78) and Pazour (165)).



In analogy, *Glis2* mutant mice showed severe renal atrophy and fibrosis resembling human nephronophthisis (49) (*Table 35-1*). Differential gene expression studies on *Glis2* mutant kidneys demonstrated that genes promoting epithelial-to-mesenchymal transition and fibrosis are upregulated in the absence of *Glis2* (49). There was also prominent apoptosis present in distal tubular segments of the kidney, which might provide an explanation why in PKD kidneys are enlarged with hyperproliferation prevailing, whereas in NPHP kidney size is reduced. As GLIS2 is related to the GLI transcription factor these findings implicated the hedgehog signaling pathway in the pathogenesis of cystic kidney diseases (91). It is a signaling pathway that controls, cell determination and tissue patterning during embryogenesis.

NPHP8/RPGRIP1L

Missense and truncating mutations in the *NPHP8/RPGRIP1L* gene were shown to cause Joubert syndrome and Meckel syndrome (*Table 35-1*) (51). RPGRIP1L colocalized at the basal body and centrosomes with the protein products of both *NPHP6* and *NPHP4* (51) (*Fig. 35-4*). Whereas the presence of two truncating mutations caused Meckel syndrome, missense mutations were seen in patients with Joubert syndrome (50, 51). These findings confirmed that there is a continuum for the multiorgan phenotypic abnormalities found in Meckel syndrome, Joubert syndrome, and nephronophthsisis on the basis of distinct mutations of identical genes (multiple allelism).

NPHP9/NEK8

Three different highly conserved amino acid changes were identified in the gene *NEK8* (never in mitosis kinase 8) as causing NPHP type 9 (*Table 35-1*) (53). One of the mutations identified is positioned in the same RCC1 domain, in which the missense mutation causing the renal cystic mouse model *jck* is positioned (92, 93). The notion that mutations in *NEK8* cause nephronophthisis (type 9) was supported by the finding that, upon expression in medullary collecting duct cells, all three mutant forms of *NEK8* showed defects in ciliary and centrosomal localization to varying degrees (53). As NEK8 plays a major role in cell cycle regulation, these data establish a direct link between a protein defective in renal cystic disease and the role of centrosomes for cell cycle regulation (*Fig. 35-4*). In this context it is interesting that two mouse models of polycystic kidney disease (*jck* and *cpk*) can be efficiently treated with the cyclin-dependent kinase inhibitor roscovitine (94).

Animal Models

Several spontaneously occurring mouse models of mutated genes that exhibit an NPHP-like phenotype or a phenotype of SLSN-like retinal degeneration were shown to represent orthologs of human NPHP genes. Examples are shown in *Table 35-1* for the genes *NPHP2/INVS*, *NPHP3*, *NPHP6/CEP290*, *NPHP7/GLIS2*, *NPHP8/RPGRIP1L*, and *NPHP9/NEK8*. Nephrocystin-4 is conserved in *C. elegans* and expressed in ciliated head and tail neurons of the nematode (95). Upon knockdown it exhibits a male mating phenotype, similar to the phenotype found upon knockdown of the polycystin-1 and polycystin-2 orthologs (96). Localization of nphp-1 and nphp-4 to some of these ciliated neurons also overlaps with localization of the cystoprotein orthologs polycystin-1 (*lov-1*), polycystin-2 (*pkd-2*), and with many orthologs of Bardet-Biedl syndrome (BBS) proteins (95, 97) similar to what has been described for *lov-1* and *pkd-2* mutants (96). These data have been recently refined for specific neuronal cell type (98, 99) and the necessity of *nphp-1* and *nphp-4* for morphologic integrity of ciliated neurons in *C. elegans* was demonstrated (100, 101). In addition, a role for *nphp-4* in life span of the worm has been demonstrated (102). Evolutionary conservation of nephrocystins and other cystoproteins goes even further: Some cystoproteins have been conserved over more than 1.5 billion years of evolution from the unicellular organism *Chlamydomonas Reinhardtii* to vertebrates. *Ch. Reinhardtii* uses two motor cilia (flagella) for locomotion. Strikingly, nephrocystin-4 and at least six proteins mutated in BBS are conserved in *Ch. Reinhardtii* where they are part of its basal body proteome (97, 103). Defects of cystoprotein orthologs in *Ch. Reinhardtii* have deficient intraflagellar transport and flagellar propulsion (104). This further supports the notion that cystoproteins play a role in functional modules that are conserved throughout evolution.

Extrarenal Clinical Manifestations of NPHP Occur on the Basis of Cilial Defects

A prominent feature of NPHP is involvement of multiple organs (pleiotropy) outside the kidney. Infantile NPHP type 2 (6) can be associated with *situs inversus* (29), retinitis pigmentosa (105), or cardiac ventricular septal defect (6). Defects in other organs are usually of degenerative or developmental nature. Specifically, NPHP may beassociated with tapetoretinal degeneration (Senior-Loken syndrome (14, 15), cerebellar vermis aplasia (Joubert syndrome (16, 17), ocular motor apraxia type Cogan (106), mental retardation (47), liver fibrosis (18), or cone-shaped epiphyses of the phalanges (Mainzer-Saldino syndrome (19)). In some instances there appears to be a genotype/phenotype correlation regarding pleiotropy. For instance, there is involvement of the retina in all known cases with mutations of *NPHP5* or *NPHP6*. In other instances, such as *NPHP1* mutations, the molecular basis of eye involvement is unknown.

Retinal Involvement (Senior-Loken Syndrome)

The renal-retinal involvement in Senior-Loken syndrome can be explained by the fact that the primary cilium of renal epithelial cells is a structural equivalent of the connecting cilium of photoreceptor cells in the retina (107) (*Fig. 35-8*). We have shown that nephrocystin-5 and nephrocystin-6 are expressed in the connecting cilia of photoreceptors (30, 87).

Cerebellar Vermis Aplasia (Joubert Syndrome)

In Joubert syndrome (JBTS) NPHP is associated with coloboma of the eye, with aplasia/hypoplasia of the cerebellar vermis causing ataxia, and with the inconstant symptoms of psychomotor retardation, and episodic neonatal tachy/dyspnea (16, 17, 108–110). The radiographic feature of JBTS on axial magnetic resonance brain imaging is the so-called "molar tooth sign" of the midbrain-hindbrain junction (110, 111). Ocular motor apraxia type Cogan, defined as the transient inability of horizontal eye movements in the first few years of life, may also be associated with JBTS. This symptom has been described in patients with mutations in the *NPHP1* (66, 106) ("JBTS4") and *NPHP4* (46) genes. Three different recessive genes, *NPHP1* (17, 110, 111), *AHI* (112, 113) (JBTS type 3), and *NPHP6* (48, 114), have been found mutated in JBTS. Three further loci for JBTS have been identified: *JBTS1* on chromosome 9q34.3 (115), *JBTS2/CORS2* on chromosome 11p12-q13.3 (116). In addition, mutations of *NPHP8/RPGRIP1L* can cause JBTS if at least one mutation is non-truncating (50, 51).

Liver Fibrosis

NPHP can be associated with periductal liver fibrosis (18, 117–119), as has been described for a patient with *NPHP3*

mutation, e.g. in NPHP type 3 (44). Children develop hepatomegaly and moderate portal fibrosis with mild bile duct proliferation. This pattern differs from congenital hepatic fibrosis, where biliary dysgenesis is prominent, and from hepatic involvement in ARPKD, Arima syndrome (cerebro-oculo-hepato-renal syndrome) (120–122), and Meckel syndrome, which exhibits bile duct proliferation. Bile duct involvement in these cystic kidney diseases may be explained by the ciliary theory, as the epithelial cells lining bile ducts (cholangiocytes) possess primary cilia.

Brain Malformations (Meckel Syndrome)

Within the spectrum of NPHP-associated ciliopathies Meckel syndrome (MKS) is the most severe. It leads to perinatal mortality with renal cystic dysplasia, occipital encephalocele, polydactyly, and biliary digenesis. Two recessive genes have been identified, *MKS1* (123) and *MKS3* (124), and another gene locus, *MKS2* (125), has been mapped. Recently, a Meckel-like phenotype has been described for truncating mutations of *NPHP3* (83), *NPHP6/CEP290* (89), and *NPHP8/RPGRIP1L* (50, 51). MKS represents the ciliopathy of the group that encompasses defects in most organs, and organ involvement is of developmental rather than degenerative nature. For instance, organ defects reveal cystic dysplasia rather than NPHP in the kidneys, microphthalmia of the eyes, bile duct dysgenesis in the liver, occipital encephalocele in the brain, bones involvement by postaxial polydactyly (126). The notion that MKS is at the most pronounced end of the clinical spectrum, is supported by the finding that the presence of two truncating mutations in *NPHP8/RPGRIP1L* causes MKS, whereas one "mild" mutation (missense rather than truncating) may cause the less severe phenotype of JBTS (51). In addition, the presence of 2 truncating mutations in *NPHP6/CEP290* may cause an MKS-like phenotype (MKS4) (89).

Cardiac Defects and *Situs Inversus*

In a patient with mutation of *NPHP2* a ventricular septal defect as a congenital cardiac malformation has been described (29). Thus, the role of inversin for left-right axis specification known from mouse models was confirmed in humans (76, 77). As this was associated with *situs inversus* cardiac ventricular septal defect may be viewed as a "heterotaxy" (left-right orientation) phenotype caused by the same mechanism (127). We confirmed the phenotypic combination of cystic kidney disease, *situs inversus,* and cardiac septal defect on the basis of *inversin* mutations is observed in humans, mice, and zebrafish (6).

Skeletal Defects

NPHP can be associated with skeletal defects, including Jeune syndrome (asphyxiating thoracic dysplasia) (128–131), Ellis van Creveld syndrome (132), RHYNS syndrome (retinitis pigmentosa, hypopituitarism, NPHP, skeletal dysplasia) (133), Meckel-Gruber syndrome (123, 124), and Sensenbrenner syndrome (cranioectodermal dysplasia) (134, 135). This strongly suggests a role of primary cilia function in skeletal development. The association of NPHP with cone-shaped epiphyses of the phalanges (type 28 and 28A) is known as *Mainzer-Saldino syndrome*, and occurred in patients who also had retinal degeneration and cerebellar ataxia (19). Interestingly, mutations in the ortholog of the intraflagellar transport protein IFT80 of *Ch. Reinhardtii* was found to be the cause of Jeune syndrome (136) (*Fig. 35-4*), which emphasized the strong evolutionary conservation of "ciliopathy genes".

Medullary Cystic Kidney Disease

Goldman and associates were the first to report a large kindred with dominant inheritance exhibiting an adult-onset medullary cystic kidney disease (MCKD) (137), followed by publication of two large pedigrees from the United States by Gardner et al. (138, 139). Whereas histopathology is very similar in MCKD and NPHP, MCKD differs from NPHP by its dominant mode of inheritance, and its onset of ESKD in the third decade of life, with an average at age 28.5 years (138). In MCKD penetrance appears to be very high by the age of 45 years. Another feature distinguishing NPHP from MCKD is the lack of extrarenal involvement in dominant disease, with the exception of hyperuricemia and gout (*Table 35-1*). A gene locus for MCKD type 1 has been mapped to chromosome 1q (32), but the responsible gene has not yet been identified (140–145). The locus for MCKD type 2 resides on chromosome 16 (146, 147). Recently, mutations in the *UMOD* gene encoding uromodulin/Tamm-Horsfall protein have been identified as responsible for MCKD type 2 (34, 148) and a group of "uromodulin associated kidney diseases" including familial juvenile hyperuricemic nephropathy (FJHN) and glomerulocystic kidney disease (GCKD) (149–152). Thus, MCKD type 2 can be positively diagnosed by mutation analysis of the UMOD gene.

Diagnosis

Laboratory Studies

Patients with NPHP are usually diagnosed when an increased serum creatinine value is detected fortuitously. Patient history generally reveals prolonged nocturia since school age. Specific gravity of a morning urine specimen will be low. Renal ultrasound will then corroborate the diagnosis (*Fig. 35-2*), which can be subsequently confirmed by molecular genetic diagnostics (www.renalgenes.org). A diagnostic algorithm for nephronophthisis has been suggested (153). Hematuria, proteinuria, and bacteriuria are uncommon in NPHP. In rare cases, where proteinuria is present, it is usually mild and of the tubular type. Laboratory studies are needed to assess the severity of renal failure and generally demonstrate elevation of serum creatinine, blood urea nitrogen and phosphorus, together with metabolic acidosis, hypocalcemia, and anemia. In SLS retinitis pigmentosa is diagnosed by its specific findings on ophthalmoscopy including increased retinal pigment, attenuation of retinal vessels, and pallor of the optic disc. If retinitis pigmentosa is present, electroretinography and electro-oculography can be employed to evaluate severity. Retinal degeneration is characterized by a constant and complete extinction of the electroretinogram, preceeding the development of visual and fundoscopic signs of retinitis pigmentosa. Ophthalmoscopy should be performed in any patient to evaluate for signs of retinal degeneration. Liver function test and hepatic ultrasonography are important to facilitate detection of patients with hepatic fibrosis.

Imaging

The most useful imaging technique in NPHP or MCKD is renal ultrasonography. Kidneys are of normal or moderately reduced size, show increased echogenicity, loss of cortico-medullary differentiation and, in later stages, cyst formation at the cortico-medullary border of the kidneys (10) (*Fig. 35-2*). Garel and associates have described medullary cysts in 13 of 15 children studied at the time of renal failure (mean age 9.7 years) (154). Roentgenography contributes little to the diagnosis of the disease. Medullary cysts can sometimes also be demonstrated on magnetic resonance imaging or computed tomography (155, 156). Histology is characteristic but not pathognomonic in NPHP or MCKD, because cysts may be absent and tubulointerstitial disease can be relatively unspecific. Renal biopsy can be circumvented as an initial procedure due to the availability of molecular genetic diagnostics in NPHP (www.renalgenes.org). If molecular genetic diagnostics do not detect a molecular defect, the diagnosis can be based on the combined results of typical history with polyuria, polydipsia and anemia, and the classical appearance of the kidney on ultrasound, and renal histology. A thorough pedigree analysis should be documented for each of three successive generations, to rule out autosomal dominant MCKD.

Molecular Genetic Diagnosis

Recently, molecular genetic diagnosis has become available mostly for NPHP type 1, but is theoretically possible also for the very rare forms of NPHP type 2 through 9 (see above). A diagnostic algorithm should be followed to avoid unnecessary renal biopsy (153). Molecular genetic analysis is the only diagnostic procedure, by which the diagnosis of NPHP can be made with certainty. However, due to the presence of additional loci for NPHP, the lack of detection of mutations in the *NPHP1* gene does not exclude the diagnosis of NPHP. If renal disease with features of the NPHP or MCKD complex occurs in a person older than 25 years, its presence should be thoroughly sought in preceding generations. This may frequently result in detection of a pattern of autosomal dominant inheritance. In this case mutation analysis in the *UMOD* gene is warranted.

Genetic Counseling

Molecular genetic testing should be performed only following consent within the guidelines of the National and International Societies for Human Genetics (http://www.ashg.org/press/healthprofessional.shtml). The acceptance of molecular genetic diagnostics may be strongly enhanced in the US due to the recent passing of the Genetic Information Nondiscrimination Act (GINA) by congress (http://www.ashg.org/press/ginaupdate.shtml). Before genetic counseling, a thorough pedigree analysis to distinguish recessive (early-onset) from dominant (late-onset) disease is mandatory, and extrarenal organ involvement should be sought. Since non-symptomatic potential carriers of recessive defects should not be examined by molecular genetic diagnostics, unaffected siblings below 25 years of age should be re-evaluated yearly for maximal urinary concentrating ability and renal ultrasound. If symptoms evolve and serum creatinine increases, molecular genetic diagnostics following informed consent is

warranted, to allow early prevention of complications from electrolyte disturbances, dehydration, anemia, and growth retardation. If a transplant recipient's renal histology suggests NPHP and a living related donor is considered, molecular genetic diagnostics may help to exclude or detect renal disease within the family. Because there is genetic locus heterogeneity in diseases of the NPHP and MCKD, prenatal diagnosis can only be performed by direct genetic testing. This requires a setting, in which a specific mutation or deletion of the *NPHPP1–9* genes have already been characterized in an affected sibling.

Differential Diagnosis

On histopathology NPHP and MCKD have to be differentiated from other forms of interstitial nephropathies like chronic pyelonephritis or drug injury. In oligomeganephronic dysplasia kidney size is reduced and histology is distinct from NPHP. The paucity of urinary abnormalities, the frequent lack of hypertension, normal kidney size, and the localization of renal cysts (if present) readily differentiate variants of the NPHP and MCKD from recessive or dominant polycystic kidney disease. Finally, medullary sponge kidney (157) can easily be distinguished from NPHP or MCKD, since it does usually not lead to chronic renal failure and shows calcifications and calculi on renal ultrasound.

Prognosis and Therapy

There is no causative therapy for NPHP or MCKD. Therapy is symptomatic and is directed towards the treatment of hypertension, if present, as well as the correction of disturbances of electrolyte, acid-base and water balance. Hypokalemia may contribute to the polyuria, so that oral potassium supplementation may alleviate this symptom. Metabolic acidosis should be corrected, and osteodystrophy and secondary hyperparathyroidism treated with adequate calcium supplementation, phosphorus restriction, phosphate binders, and vitamin D therapy. Anemia will be treated with iron supplementation and erythropoetin, and growth retardation may require administration of growth hormone. Adequate nutrition should be maintained with the help of a dietician. Psychological counseling of the patients is an integral part of therapy, because of the poor self-image associated with growth retardation and to alleviate pressures resulting from the need to comply with complicated medications and dietary prescriptions. All patients will require renal replacement therapy by dialysis and renal transplantation during childhood, adolescence or, in dominant disease, in early adult life.

Gattone et al. have recently shown that the renal cystic phenotype of *pcy* mice, which is the equivalent of human NPHP type 3 (*Table 35-1*) can be strongly mitigated or even reversed by treatment with the vasopressin V2 receptor antagonist OPC31260 (82). Similar results were obtained using a *pkd2* mouse model (158). This effect is thought to be mediated by a reduction in intracellular cAMP levels (47). An important future challenge will be the development of therapies that capitalizes on what has been learnt about the pathobiology of NPHP, MCKD and other cystic diseases of the kidney.

36 Polycystic Kidney Disease

Katherine MacRae Dell · William E. Sweeney · Ellis D. Avner

Introduction

Polycystic kidney disease (PKD) is a heritable disorder with diffuse cystic involvement of both kidneys without dysplasia (1). All forms of PKD can have clinical manifestations in infants and children. The major clinical entities of autosomal-recessive polycystic kidney disease (ARPKD) and autosomal-dominant polycystic kidney disease (ADPKD) have considerable overlap in clinical presentation and radiographic features. Glomerulocystic kidney disease (GCKD) can be a feature of several inherited, sporadic, and syndromal conditions, as well as an expression of ADPKD.

Differential Diagnosis of Polycystic Kidneys in Childhood

The clinical presentation of polycystic kidneys and/or enlarged echogenic kidneys can be associated with a number of kidney disorders. Not all of these represent the classic genetic disorders of polycystic kidney *disease* (i.e., ARPKD and ADPKD). Additional diagnoses to consider include bilateral cystic dysplasia, which is often associated with congenital syndromes, and multicystic dysplastic kidney (MCDK). Both of these diseases generally occur sporadically and are reviewed in detail in Chapter 5. The inherited disorder of juvenile nephronophthisis (JN) is associated with cystic kidneys, but these are usually small or normal in size. JN is reviewed in Chapter 35. Other rarer causes of polycystic and/or enlarged echogenic kidneys are outlined in *Table 36-1*.

In most clinical settings, the major challenge in the differential diagnosis of polycystic kidneys in the pediatric patient is clearly delineating ARPKD from ADPKD. In fact, ADPKD presenting in the neonatal period may be indistinguishable clinically from ARPKD (2, 3). In such instances, a staged evaluation including careful history, physical examination, imaging, and histologic examination is recommended. As shown in *Table 36-2*, certain clinical features can help differentiate between ARPKD and ADPKD, although no single finding is diagnostic. A complete family history is often the most important element in difficult cases. Parents should have standard, or if available, high resolution renal ultrasonography. If the parents of a child with undiagnosed PKD are under 30, the grandparents should also be evaluated because 4–5% of patients with ADPKD may not have visible renal cysts before age 30. The absence of any cystic disease in family members makes the diagnosis of ARPKD more likely. It does not, however, exclude the diagnosis of ADPKD, since approximately 8–10% of all ADPKD cases are the result of new gene mutations (4). Radiographic studies, particular MRI imaging if the kidneys and liver, may clearly distinguish ARPKD and ADPKD in some cases (*Table 36-2*). However, in clinical practice, up to 20% of all cases will show certain features of both diseases on radiographic studies of the kidneys, making definitive diagnosis difficult unless extra-renal features of either disease are present (see below). Tissue diagnosis (biopsy of kidney and liver) is generally deferred given the availability of molecular diagnostics. Molecular genetic testing for ARPKD and ADPKD is available and is increasingly utilized given mutation detection rates of 85–90% in high quality laboratories (5). Such testing is indicated for the subset of patients in whom the clinical and/or tissue diagnosis is equivocal, and/or additional information is needed for genetic counseling. In the United States, passage of recent legislation (2008) preventing discrimination by employers or insurers against any individual with a genetic disorder (Genetic Information Non-Discrimination Act or GINA) will remove a major obstacle to diagnostic testing of asymptomatic, at risk PKD patients. Early diagnosis of asymptomatic individuals with ADPKD and ARPKD affords the current opportunity for maximal anticipatory care (i.e., BP control), and the future opportunity to benefit from new therapies (i.e., early treatment with therapies that will limit cyst development and enlargement) (6).

Pathophysiology of Cyst Formation in PKD

In the last decade, major advances have been made in understanding the molecular genetics of PKD. Through

Juvenile nephronophthisis (JN)/medullary cystic disease (MCD) complex
Von Hippel-Lindau Syndrome
Hajdu-Cheney Syndrome
Sporadic Disorders Associated with Cystic Kidneys
Isolated cystic dysplasia
Multicystic dysplastic kidney (MCDK)
Unilateral/localized cystic kidney disease
Caliceal diverticula
Miscellaneous Causes of Cystic and/or Enlarged Echogenic Kidneys
Nephroblastomatosis
Bilateral Wilms' tumor
Leukemia or lymphoma
Pyelonephritis
Glomerulonephritis
Radiocontrast nephropathy
Bilateral renal vein thrombosis
Transient nephromegaly
Congenital nephrotic syndrome
Glycogen storage disease
Acquired cystic kidney disease

Table 36-2
Differential Clinical Features of Childhood PKD

Major clinical features of *both* ARPKD and ADPKD
Enlarged kidneys
Hypertension
Concentrating defect
Sterile pyuria
Clinical features suggesting ARPKD rather than ADPKD
Neonatal presentation
Progression to end-stage renal disease as a child
Hepatosplenomegaly
Portal hypertension and esophageal varices
Bacterial cholangitis
Negative family history
Clinical features suggesting ADPKD rather than ARPKD
Positive family history
Extrarenal cysts
Cerebral aneurysms
Asymptomatic presentation
Unilateral renal presentation
Hematuria
Urinary tract infection

Adapted from Avner ED. Polycystic kidney disease. In Pediatric Nephrology. Drukker A, Grushkin A (eds.). In Pediatric and Adolescent Medicine. Branski D (series ed.). Basel, AG Karger, 1993

a combination of positional cloning, direct sequencing and utilization of the rapidly expanding genome databases, the major causative genes for both ADPKD (*PKD1* and *PKD2*) as well as ARPKD (*PKHD1*) have been identified (7–10) (*Table 36-3*). Details specific to the molecular genetics of ARPKD and ADPKD are addressed in the respective sections that follow. Numerous studies have demonstrated that the protein products of the ADPKD and ARPKD genes are membrane-bound proteins which interact and generally exist in multimeric protein complexes at various sites in cells. The primary sites of "cystoprotein complex" localization have been reported to be apical cell membranes (particularly on or adjacent to the primary cilium), adherins junctions, desmosomes, and focal adhesions (11–15). Multimeric cystoprotein complexes thus interact with a number of distinct signal transduction pathways which appear to be critical in normal tubular growth and differentiation. Mutations in PKD genes result in abnormal cystoprotein structure and function, with subsequent aberrant integration of complex signaling events resulting in the unique phenotype of the cystic epithelial cell. Although the precise mechanisms by which specific PKD gene mutations result in cyst formation have not yet been fully elucidated, considerable progress has been made in understanding the pathophysiology of cyst formation. Key pathogenic

Table 36-3
Human Polycystic Kidney Disease Genes and Proteins

Disease	Gene	Mode of inheritance	Chromosome location	Protein	Function/Role
ADPKD	*PKD1*	AD	16p13.3-p13.12	Polycystin 1	?Receptor
ADPKD	*PKD2*	AD	4q21-q23	Polycystin 2	Cation channel
ARPKD	*PKHD1*	AR	6p21	Fibrocystin (polyductin)	?Receptor
GCKD (hypoplastic variant)	*HNF-1β*	AD	17cen-q21.3	Hepatocyte nuclear factor – 1beta	Transcription factor

AD, Autosomal Dominant, *AR*, Autosomal Recessive

features of the cystic phenotype have been identified (6, 15, 16). Such features are critical as targets for the development of future therapies, and include:

- Abnormalities of expression and function of the epidermal growth factor (EGFR) – axis
- Decreased intracellular calcium with aberrant intracellular cAMP signaling
- Abnormal structure and/or function of the primary cilia
- Alterations in cell-cell, and cell-matrix interactions

Each of these pathogenic processes likely contributes to some extent to one or more of the fundamental features of renal cyst formation and progressive enlargement, namely: (1) tubular cell hyperplasia; (2) tubular fluid secretion; and (3) abnormalities in tubular extracellular matrix, structure, and/or function (*Fig. 36-1*) (16–20). As the following sections will illustrate, key insights into the pathogenesis of cyst formation in PKD have been provided by rodent models of ARPKD and ADPKD (*Table 36-4*). This Table does not include the increasing number of reported genetically-manipulated "knockout" or conditionally targeted genetic models, many of which have not been fully characterized as of this writing. The interested reader is referred to the following readings which review the most significant of these models produced to date (21–24). Several of these models have been used to test the efficacy of novel therapies.

Renal Tubular Cell Hyperplasia

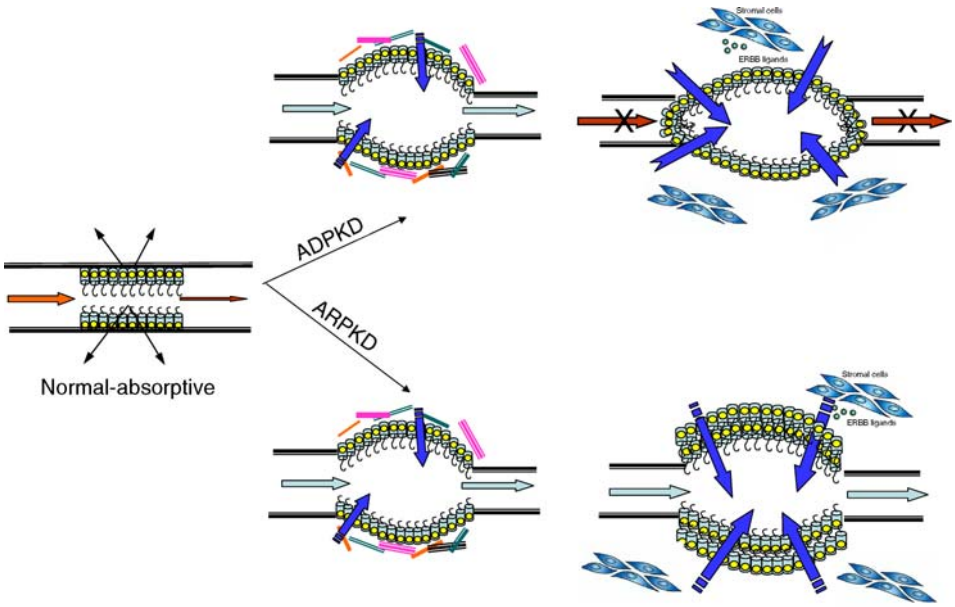
Renal tubular hyperplasia is a central morphologic feature of all described human renal cystic diseases (25, 26). On the basis of mathematic modeling of cyst growth, it has been shown that tubular cell hyperplasia, with expansion of tubular wall segments to accommodate an increased cellular mass, is an essential factor in cyst formation and enlargement (27). Multiple studies in vivo and *in vitro* have demonstrated abnormal renal tubule epithelial proliferation. Increased renal tubular epithelial cell proliferation is a feature of both cystic and non-cystic tubular epithelium from ADPKD and ARPKD kidneys (28). Cyst-derived epithelial cells from ADPKD and ARPKD demonstrate increased cell growth potential compared with controls (29, 30).

The EGFR-Axis

Dysregulation of growth factors/receptors have a primary role in tubular cell hyperplasia. A growing body of evidence implicates one or more members of the ErbB receptor family, including the epidermal growth factor receptor (EGFR), as well as the related receptors, ErbB2 and ErbB4. In both human ADPKD and ARPKD and in every rodent models of PKD published to date, cystic kidneys display characteristic alterations in EGFR expression. Both quantitative abnormalities, including increased mRNA and protein, and qualitative differences, in particular, the appearance of "mislocalized" EGFR expressed on the apical surface of tubular epithelium, are seen (31–33). Apical EGFR is functional and capable of transmitting mitogenic signals *in vitro* (34). Inhibition of EGFR function *in vitro* by treatment with either an inhibitor of tyrosine kinase function or a blocking antibody inhibits formation of proximal tubule cysts and significantly decreased explant growth and distal nephron differentiation in metanephric organ culture models (35, 36). Additional support for a central role for EGFR in the pathogenesis of cyst formation is provided by *in vivo* data. Inhibition or reduction of EGFR function, either by treatment with a novel tyrosine kinase inhibitor (37), or genetic manipulation (38), leads to a marked reduction in cyst formation and progressive enlargement in animal models.

Figure 36-1

Pathophysiology of renal cyst formation. Studies in a variety of experimental models, in addition to human ADPKD and ARPKD tissue, implicate three major factors in renal cyst formation and progressive enlargement. Normal renal tubular absorptive epithelium can become cystic if (a) hyperplasia, localized to a distinct nephron segment, requires accommodation of increased renal mass; (b) secretion, as opposed to absorption, leads to the accumulation of intratubular fluid; and (c) extracellular matrix (ECM) abnormalities alter the epithelial microenvironment to further stimulate proliferation and secretion. The figure depicts the difference between ADPKD epithelia, where proliferation leads to isolated cysts which are not connected to intratubular flow and can grow only through transtubular fluid movement; and ARPKD epithelia, where proliferation leads to thickened tubular ectasia and where fluid secreted across tubular walls remains part of urinary flow. These processes are not mutually exclusive, may reflect characteristics of undifferentiated epithelium, and operate in concert during tubular cysr formation and progressive enlargement.



The central role of EGFR-family members in the pathogenesis of ARPKD has been recently confirmed by the demonstration that ErbB2, rather than EGFR (or ErbB1) is predominantly overexpressed and apically mislocated in the PCK rat, an orthologous ARPKD rodent model. This model, which does not respond to ErbB1 inhibition (39) responds dramatically in-vivo to therapies which decrease active phosphorylated ErbB2 (40, 41) This response includes a dramatic reduction in renal cyst formation and progressive enlargement, an improvement in biliary tract ectasia and periportal fibrosis, and dramatic improvements in renal function and renal concentrating ability. Given the importance of G-protein coupled receptors in cystogenesis previously noted, it is significant that activation of such receptors leads to significant transactivation of the EGFR family (42).

ErbB2 (HER-2) overexpression is seen in some cysts of ADPKD kidneys but not seen in late-stage ARPKD kidneys (43). Late-gestation/early post-natal human ARPKD kidneys samples, however, show increased ErbB2 expression compared with normal human fetal and postnatal kidneys (44). Wilson et al. (45) demonstrated that apical localized EGFR complexes in normal fetal and ADPKD epithelia are heterodimers of EGFR (ErbB1) and ErbB2, while basal membrane localized EGFR in normal adult renal epithelia are comprised of EGFR (ErbB1) homodimers. They further showed that inhibition of ErbB2 corrected the migratory phenotype seen in ADPKD cells. Overexpression and mislocalization of another ErbB family member, ErbB4, has been demonstrated in cystic collecting tubule epithelia of two ARPKD rodent models (46).

Overexpression of several EGF related growth factors/ErbB ligands, is also a prominent feature of both ARPKD and ADPKD cystic epithelia. Renal cyst fluid contains EGF or EGF-like peptides in mitogenic concentrations, despite apparent reductions in EGF tissue expression

Table 36-4
Rodent Models of PKD[a]

Mouse model	Mode of inheritance	Chromosome location	Gene	Protein product	Function/Role/Comments
bpk	AR	10	*Bicc1*	bicaudal C	RNA-binding protein

AD Autosomal Dominant, *AR* Autosomal Recessive
[a]"Knockout" models for PKD are not included in this listing

(29, 47–50). Treatment with EGF transiently improves renal function in murine models (51), but has no effect on histopathologic abnormalities and continued EGF treatment worsens disease and shortens survival (52). TGF-α and EGF are cystogenic in both murine embryonic organ cultures (53) and normal human kidney cells grown in a unique collagen gel system in vitro (54). ADPKD kidneys and cells derived from ADPKD have increased mRNA or protein levels of TGF-α (31, 55), and transgenic mice that overexpress TGF-α develop cystic kidneys (56). Loss of TGF-α, however, does not modify cystic kidney disease in an ARPKD mouse model, suggesting that there is significant redundancy in EGFR ligands which can promote cyst formation or growth in ARPKD (57).

Additional data suggest that inhibiting EGFR-ligand function may also partially ameliorate cystic disease. Treatment with an inhibitor of TACE, a metalloproteinase implicated in the processing of several EGF-related growth factors, decreased cystic kidney disease in a murine model, less effectively than EGFR inhibition (58). Combining inhibition of EGFR ligand release with EGFR inhibition maximized therapeutic effectiveness while minimizing toxicity (59). Additional EGFR ligands, including amphiregulin and heparin-binding EGF, are abnormally expressed in PKD and may prove to also have a role in proliferation of cystic epithelium (50).

c-Src is an important intermediate in several key cystogenic signaling pathways. Src is a critical intermediate which integrates proliferation from both G-coupled protein receptors and the EGFR-axis (6, 16). Increased Src activity (pY418) was found to be associated with a more severe renal cystic disease in two ARPKD rodent models. Furthermore, treatment of these models with an inhibitor of Src ameliorated both the renal and hepatic disease through inhibition of G-protein coupled receptor and EGFR-axis triggered phosphorylation cascades (41).

cAMP and Intracellular Calcium Ion

Another major contributor to cellular proliferation in both ADPKD and ARPKD is intracellular cyclic AMP (cAMP). Unlike normal renal epithelia, ADPKD and ARPKD cystic epithelia respond to increased intracellular cyclic AMP (cAMP) with an increase, rather than decrease, in proliferation due to phosphorylation of B-Raf (60–62).

Normal and polycystic kidney epithelia from an ARPKD rodent model also demonstrate differences in regulation of cAMP-dependent protein kinase (PKA), which is associated with increased proliferation *in vitro* (63).

Intracellular calcium concentrations have been identified as a critical component of the pro-mitogenic cAMP response of cystic epithelia. Several studies have demonstrated that calcium restriction induces a switch to this cAMP dependent growth phenotype, whereas addition of calcium to PKD cells in culture restores the normal anti-mitogenic response to cAMP (64, 65). In addition, cells that do not express *PKHD1*, the mutated gene in ARPKD, have decreased intracellular calcium and increased epidermal growth factor (EGF)-induced proliferation, suggesting that loss of one or more PKD proteins may lead to abnormal proliferation by modulation of intracellular calcium (66). In addition, Leuenroth et al. (67) recently showed that triptolide (a Chinese herb) induces calcium release in a polycystin-2 dependent manner. Further, triptolide treatment of a mouse model of ADPKD resulted in attenuated cyst formation and decreased tubular cellular proliferation.

The cAMP pro-mitogenic response in PKD cells is associated with phosphorylated B-Raf activation of the mitogen-activated protein kinase (MAPK) pathway, which can mediate a variety of cellular processes, most notably cell proliferation. There is considerable "cross talk" between the cAMP and MAPK signaling pathways in both normal and disease states (68). Increased phosphorylation of several MAPK pathway members is a prominent feature of rodent and human ADPKD and ARPKD kidneys and tubular epithelial cells (23, 69, 70). There are conflicting animal data, however, as to whether inhibition of ERK 1/2 impacts progression of cystic kidney disease (23, 71).

Apoptosis

Dysregulation of apoptosis, or the balance between apoptosis and proliferation, may also contribute to the progression of ARPKD and ADPKD (72–74). Increased rates of apoptosis and increased caspase 3 and 4 activity have been demonstrated in kidneys from ARPKD rodent models (75, 76). A marked increase in caspase 3 and 7 activity has also been reported in an ADPKD rodent model (77, 78). Furthermore, caspase inhibition reduced tubular apoptosis and proliferation and slowed cystic kidney disease progression in that same model (79).

Mice deficient in the anti-apoptotic molecule, bcl-2, develop severe multicystic hypoplasia characterized by proximal and distal tubular cysts and hyperproliferation of epithelium and interstitium (80). Alternatively, increased bcl-2 expression has been demonstrated in animal models of both ARPKD and ADPKD (73, 76, 77). These finding suggest that the balance of pro- and anti-apoptotic mediators, rather than the absolute expression levels, may be a critical factor in the development of cystic kidney disease (77).

Proto-oncogenes

Abnormal expression of proto-oncogenes, in particular, c-Myc may also contribute to abnormalities in proliferation and apoptosis, leading to cyst development. In both murine ARPKD and human ADPKD kidneys, c-Myc is overexpressed in cystic tissue (73, 81, 82) and is associated with a marked increase in both tubular cellular proliferation and apoptosis (83–85). In addition, c-Myc antisense oligonucleotides have been used to ameliorated cystic kidney disease in a murine ARPKD model (85).

mTOR

The target of rapamycin (mTOR) pathway is currently a growing area of interest in the pathophysiology PKD because it integrates signals from growth factors (including EGFR), G-protein coupled receptors (which generate cAMP), cellular energy levels, nutrient status and stress conditions to stimulate protein synthesis and cell growth through activation through phosphorylation of S6K1 and eIF4E (86, 87). The *TSC1* and *TSC2* genes, when mutated, cause tuberous sclerosis, a disease in which renal cystic lesions may accompany the more classical angiomyolipomas. *TSC1/2* mutations upregulate mTOR signaling. The fact that the *TSC2* and *PKD1* genes lie adjacent to each other on human chromosome 16p13.3, as well as the fact that the cytoplasmic tail of polycystin-1 interacts with mTOR led to an evaluation of mTOR activity in polycystic kidney disease. In a variety of animal models, as well as in human ADPKD and ARPKD cyst-lining epithelia, expression of phospho-mTOR and p70S6K is increased (88). The mTOR pathway is regulated by polycystin-1, and its inhibition reverses renal cystogenesis in polycystic kidney disease. These findings, combined with therapeutic efficacy of rapamycin (an mTOR inhibitor) in ameliorating cystic disease in the orpk, bpk and Han:SPRD rodent models has led to the development of pilot clinical trials for rapamycin in patients with ADPKD (87).

Arachidonic Acid Metabolites

20-hydroxyeicosatetratraenoic acid (20-HETE), is formed by the ω-hydroxylation of arachidonic acid by cytochrome P450 (CYP) 4A and 4F enzymes (89). Recent evidence has implicated 20 HETE as a mediator of cellular proliferation in normal and malignant renal cells (90–94). Further, norepinephrine, angiotensin II, and EGFR activity (all upregulated in PKD) stimulate the synthesis and release of 20-HETE and increase proliferation in both vascular smooth muscle cells and renal tubular epithelial cells (90–92, 95). With this rationale, recent studies have demonstrated a significant role of 20-HETE in mediating collecting tubular epithelial proliferation in the murine BPK and rodent orthologous PCK models of ARPKD (96); Further, in these studies, when 20-HETE synthesis was selectively decreased, or 20-HETE activity was specifically inhibited using genetic or pharmacological inhibition, both in vitro and in vivo, cystic epithelial proliferation, cyst formation, and progressive cystic enlargement were markedly inhibited (96). Notably, the decrease in proliferation and amelioration of cystic disease was associated with a dramatic decrease in EGFR-activity and downstream signaling. Clinical development of 20-HETE inhibitors as potential therapeutic agents in PKD is being actively pursued.

Fluid Secretion

In addition to epithelial hyperplasia, tubular fluid secretion is an important feature of renal cyst formation and progressive enlargement (25, 26, 29). Given the anatomical differences discussed below, it is likely that tubular fluid secretion is quantitatively and qualitatively different in the pathophysiology of cyst formation in ADPKD and ARPKD. On a theoretical basis, tubular fluid secretion in addition to hyperplasia, fulfills the requirements for cyst growth predicted by mathematic modeling (27). Cellular proliferation without tubular secretion would produce solid tumor nests of epithelial cells rather than cysts. In ADPKD more than 70% of cysts have no afferent or efferent tubular connections, and thus must fill by transepithelial secretion of solute and fluid (97, 98). In contrast, microdissection studies confirm that enlarged, ecstatic collecting tubules in ARPKD are in continuity with the urinary space (99). One would not expect transtubular secretion to be as critical in the pathogenesis of changes in ARPKD as in ADPKD, unless there is downstream obstruction (which is not a characteristic finding in ARPKD). Studies in a variety of model systems have evaluated possible mechanisms involved in PKD tubular fluid secretion. These include alterations in ciliary structure and function, intracellular calcium transport, cyclic-AMP activity, epithelial sodium channel function, and sodium potassium ATPase localization and activity.

Cilia

Studies in ARPKD and ADPKD animal models, and human kidneys and cells, (as well as studies in other renal cystic diseases, such as nephronophthisis), have demonstrated that many of the disease-associated proteins appear to be present as multimeric complexes on, or in close proximity to, the primary cilia that are present on the apical membranes of renal tubular epithelial cells (100). In tubular epithelial cells, cilia project into the lumen and are thought to have a mechanosensory role (101, 102). Abnormalities in ciliary structure and/or function have been demonstrated in many PKD animal models, as well as in epithelium isolated from human ADPKD and ARPKD kidneys (103–107).

Pkd1 −/− cells have normal-appearing cilia, but lack the flow-induced Ca^{++} response noted in normal cells (101, 108). This finding suggests that polycystin complexes in or near the cilia act as flow-sensors, and that Ca^{++} influx occurs via a functional polycystin channel (predominantly mediated by polycystin 2). The Ca^{++} influx consequently induces release of Ca^{++} from intracellular stores. As previously noted, the polycystin complex is also found at desmosomes, adherens junctions, and focal adhesions (11–15). Primary cilia can sense changes in shear stress and fluid flow at the apical cell surface, whereas focal adhesions can sense tensile strength of cell-matrix attachments, and cell-cell junctional complexes sense forces between cells. Therefore, polycystin complex localization to these sites suggests a complex integration of mechanosensation with multiple signal transduction pathways.

It should be noted that data localizing a large number of cystoproteins to apical cilia have recently been called into question. To co-localize proteins of interest to cilia, tagged-antibodies have often been mixed with an anti-acetylated alpha tubulin antibody prior to tissue staining. It now appears that this procedure gives many false positives through non-specific protein-protein interactions of the antibodies prior to tissue staining (personal communication, Joel Rosenbaum PhD; Yale University, August 2008).

At the time of this writing, a primary role for isolated ciliary abnormalities in cystogenesis remains controversial in ADPKD and ARPKD. One cannot ignore the findings

that ciliary structural and functional abnormalities appear to be present in cystic tissue. However, in addition to the methodological problems noted above in protein co-localization studies, recent data suggest that polycystin-fibrocystin complexes may be found in subapical endosomes adjacent to, but not superimposed upon, ciliary basal bodies (centrosomes) in electron micrographs of human ADPKD and ARPKD kidneys. These endosomes bud around cilial axonema and appear in cyst fluid and urine. (Chris Ward, PhD, Mayo Research Foundation, personal communication, August 2008). Current data suggest that ciliary abnormalities may have a more primary role in syndromic renal cysts and other organ abnormalities seen in so called "ciliopathies" such as Meckel-Gruber syndrome, Bardet-Biedl syndrome, Oral-facial-Digital syndrome and perhaps nephronophthisis (see chapter 6 on Syndromes in Section One of this Textbook and Chapter 36 on Nephronophthisis in this Textbook). However, as suggested above, in ADPKD and ARPKD, it appears that cilia are part of a complex pathophysiological process linking mechanosensation to integration of multiple cell-signaling pathways emanating from multiple sites within the cell.

cAMP and Transport

Several studies support a major role for cyclic adenosine monophosphate (cAMP)-mediated chloride secretion during *in vitro* cyst formation (60, 109–111). A putative lipid "secretagogue" isolated from cyst fluid of human ADPKD kidneys was found to stimulate intracellular cAMP and stimulate fluid secretion (112) and more recently was confirmed to be the cAMP agonist forskolin (113).

Pharmacologic interventions directed towards down-regulating cAMP levels in cystic epithelia are therapeutic in both ARPKD and ADPKD animal models. Inhibitors of the vasopressin V2 receptor, a G-protein coupled, adenylate cyclase activating receptor present in the collecting duct, which modulates levels of intracellular cAMP, ameliorates renal cyst disease in the PCK rat model of ARPKD and the $Pkd2^{(-/WS25)}$ model of ADPKD (114–116). In both models, improvement in cystic kidney disease was associated with decreased levels of cAMP and aquaporin 2. Interestingly, increased water intake, which functionally down-regulates V2R activity, also improved cystic kidney disease and decreased kidney cAMP levels (117). In a related study, orthologous ARPKD (PCK) rats were bred to a Brattelboro rat strain (which lacks a functional renal vasopressin axis), and resultant double mutants demonstrated significant amelioration of renal cystic disease (118). Although background genetic modifiers may have influenced the results, such genetic complementation studies further support the primary role of G-protein mediated increases in renal epithelial cAMP in cystogenesis. Accordingly, controlled Phase 3 clinical trials with a VPV2R inhibitor (Tolvaptan) in patients with ADPKD have been initiated in both the United States and Japan. In addition, studies in animals and European pilot studies in ADPKD patients suggest that octreotide, a somatostatin analogue that decreases cAMP activity in both renal and biliary epithelium, may be effective in ameliorating cystic kidney and liver disease in ADPKD (119–121). However, recent data suggest that increased cAMP activity may not be the final "effector" for mediating cyst growth. The therapeutic effect of Src inhibition on renal and biliary disease in bpk and PCK rodent models, was not associated with significant changes in intracellular cAMP levels. These findings suggest that Src activity in PKD is downstream and independent from cAMP activation (41).

It has been hypothesized that cAMP-stimulated chloride and fluid secretion occurs in PKD through activity of the CFTR (cystic fibrosis transmembrane receptor), the chloride channel mutated in cystic fibrosis (122). CFTR Cl- channels exist in apical membranes of epithelial cells and are major mediators of forskolin-stimulated chloride and fluid secretion by epithelial cells of human polycystic kidneys *in vitro* (122, 123). CFTR is required for cAMP-dependant *in vitro* renal cyst formation (124). *In vivo* support for a role of CFTR in the pathogenesis of PKD was provided by a report of an ADPKD kindred in which cystic fibrosis was also present. Patients with ADPKD and CF (which results in a loss of functioning CFTR) were found to have less severe disease than those with ADPKD who did not have CF (125). However, a subsequent report failed to confirm such a protective effect (126). An *in vitro* study of CFTR inhibitors and cyst growth in 3D collagen gels demonstrated that cyst growth inhibition correlated with cAMP-stimulated chloride current inhibition, but not cell proliferation, suggesting that an effect, if present, is related to inhibition of fluid secretion only (127). Studies of ARPKD rodent models bred with a CFTR null mouse failed to show improvement in kidney disease in cystic animals lacking CFTR compared to those that expressed CFTR (128). Thus, these data demonstrate that CFTR does not have a significant impact on ARPKD cyst formation and expansion. The most attractive alternative hypothesis to date, supported by an increasing body of electophysiological data in normal and cystic tissue implicates abnormal EGFR-mediated down-regulation of the amiloride-sensitive Na^+ channel in tubular secretion in ARPKD (129–131). EGFR-expression

leads to decreased ENac subunit production at both the mRNA and protein level with consequent electrophysiological alterations. A block in active Na^+ transport at the luminal membrane results in intratubular Na^+ accumulation which obligates anion and fluid transport through active channels and perhaps, the paracellular pathway. With the availability of new reagents and technologies to perform definitive transport studies in human kidney epithelia, studies are underway in many laboratories to delineate both the similarities and differences underlying abnormal tubular secretion in ADPKD and ARPKD.

Additional *in vivo* and *in vitro* studies demonstrate a potential role for quantitative and qualitative alterations in Na^+-K^+-ATPase activity in mediating tubular fluid secretion in cystogenesis (132–137). In proximal tubules, it has been postulated that increases in Na^+-K^+-ATPase activity modulate tubular secretion and cyst formation through activation of a secondary active transport process (e.g., tubular organic anion secretion), which osmotically obligates intratubular fluid accumulation cystogenesis (132–134). In collecting tubules, apical, as opposed to normal basolateral cell surface Na^+-K^+-ATPase expression may mediate basal to apical vectorial sodium transport and thus directly drive fluid secretion in affected nephron segments in ADPKD and ARPKD (135–137). Apical Na^+-K^+-ATPase expression in murine ARPKD may reflect an exaggeration of the normal developmental profile of collecting tubule sodium pump expression (137). This, in association with the relatively undifferentiated ultrastructural and genetic profile of cystic tubular epithelium (18), suggests that abnormalities in the differentiation program of cystic tubular cells are fundamental to the process of cystogenesis.

Alternatively, apical misclocation of the Na^+-K^+-ATPase in many PKD specimens from end stage kidney (or those shipped under less than optimal conditions may), may reflect the results of ischemic injury. As ADPKD kidneys enlarge and vessels splay around enlarging tubular cysts, there are parenchymal areas which are underperfused and chronically ischemic. These changes not only result in mislocalization of the Na^+-K^+-ATPase and many additional changes, but contribute to the characteristic chronic fibrosis in ADPKD kidneys which leads to end stage renal disease. Similar alterations of the Na^+-K^+-ATPase and other polarized proteins can also artificially result from 24–48 h of cold ichemia time in ADPKD kidneys studied post-nephrectomy. These variables may explain, in part, conflicting reports demonstrating normal, basolateral Na^+-K^+-ATPase expression in freshly isolated PKD kidneys and some PKD models (138).

Extracellular Matrix

The third major mediator of tubular cyst formation and progressive enlargement is abnormalities involving the extracellular matrix (18, 25, 139, 140). Diffuse ultrastructural and biochemical abnormalities of tubular basement membranes have been demonstrated in human and animal models of PKD. Specific defects in the biosynthesis and transport of sulfated proteoglycans have also been identified (141–143). Renal tubular cells from patients with ADPKD grown *in vitro* produce increase amounts of extracellular matrix when compared with normal tubular epithelia (144).

It does not appear that matrix abnormalities mediate simple changes in the compliance or viscoelastic properties of tubular basement membranes leading to distension under normal intratubular pressures (145). Rather, it would appear that altered matrix composition modulates cyst formation through altered tubular epithelial cell–matrix interactions. These interactions regulate various aspects of cell growth, cell surface protein expression, cytodifferentiation, and gene expression (18, 19). Conceivably, altered epithelial cell-matrix interaction could modulate or amplify the processes of hyperplasia and fluid secretion discussed above. β-4 integrin and its ligand, laminin α-5, a component of the basement membrane, are aberrantly expressed in polycystic kidney disease and may have a role in cell adhesion and migration abnormalities seen in ADPKD cyst-lining epithelial cells (146). A recent study reported the development of PKD in a mouse harboring a hypomorphic mutation in the laminin α-5 gene (147). These and other findings suggest that a primary defect in one ECM component is sufficient to cause aberrant cell proliferation and development of renal cysts (148).

Experimental evidence suggests that matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) may also play a role in progression of disease in PKD (149–151). Elevated serum levels of MMPs, including MMP-1, TIMP-1 and MMP-9 have been demonstrated in a cohort of ADPKD patients when compared to normal controls (152). Although it is difficult to determine whether abnormal MMP expression is a reflection of a primary abnormality or a secondary effect, data suggest that inhibition of MMPs may have an impact on the severity of disease in animal models of ADPKD and ARPKD (58, 153). Overexpression of other basement membrane, extracellular matrix and cell adhesion components have also been demonstrated in PKD. Tenascin, an ECM glycoprotein, is abnormally expressed in human ARPKD and ADPKD fetal kidneys and in a

murine model of ARPKD (154, 155). Irregular expression of alpha-integrin subunits has also been demonstrated in fetal PKD kidneys (156).

Abnormal processes within the interstitium leading to interstitial inflammation and fibrosis contribute to progression in all cystic kidney diseases. For instance, MCP-1, a chemoattractant and mediator of interstitial inflammation, is upregulated in ADPKD rats (157). In addition, oxidant stress is increased and protective effects of antioxidants decreased in the kidneys of animal models of both ARPKD and ADPKD models (158). Abnormalities in steroid and lipid metabolism have also been demonstrated in murine ARPKD (159–161).

Angiogenesis may also have a role in the pathogenesis of cyst expansion in ADPKD. When cysts enlarge, their nutrient requirements may outstrip their blood supply, in a manner analogous to tumor progression in cancer. ADPKD kidneys show increased vascularity around cysts and evidence of ongoing angiogenesis (162). Endothelin levels are increased in human and rodent ADPKD kidneys (163). ET-1 overexpressing mice also develop polycystic kidneys and interstitial fibrosis, although they do not develop hypertension. Yet, interestingly, blockade of either endothelin A or B increased the severity of polycystic kidney disease in two ADPKD animal models (164, 165). The authors speculated that acceleration of cystic kidney disease was due to altered balance between ETA and ETB. Whether angiogenesis has a role in cyst expansion in ARPKD remains to be determined.

Theories of renal cyst formation generated in experimental models are not mutually exclusive and are largely complementary. A mutant gene or environmental factors can directly lead to alterations in tubular epithelial proliferation. In addition, there is increasing recognition that modifying genes can significantly alter the cystic kidney disease caused by the mutated PKD gene (161, 166–171). Environmental factors can also modulate the expression of a mutant gene or directly lead to tubular cell death. Resultant alteration of tubular cell metabolism may subsequently lead directly to the abnormal sorting of transport proteins, growth factor receptors, or cell adhesion molecules, with resultant abnormal extracellular matrix production, or production of growth factors mediating tubular hyperplasia. Induced changes in transtubular transport energetics may lead to hyperplasia secondary to increased transmembrane sodium flux, whereas programmed cell death may lead to further hyperplasia secondary to tubular regeneration. Alterations in sodium or chloride-mediated transtubular transport could lead to net intratubular fluid accumulation. Subsequent increases in tubular wall tension may further increase stimulation of epithelial proliferation, leading to tubular hyperplasia. The presence of a particular pattern of tubular hyperplasia, along with necrotic debris from cell death, may lead to partial tubular obstruction and further increases in tubular wall tension. Finally, abnormal extracellular matrix production could alter the epithelial microenvironment, further increasing hyperplasia and transtubular transport, thereby contributing to cyst formation and progressive cyst enlargement. Such an overall hypothetical schema of renal cyst formation appropriately focuses future investigations on the molecular mechanisms by which tubular epithelial hyperplasia is controlled and tubular metabolism are altered in both experimental and human cystic diseases.

The Cystic Phenotype and Targeted Future Therapy

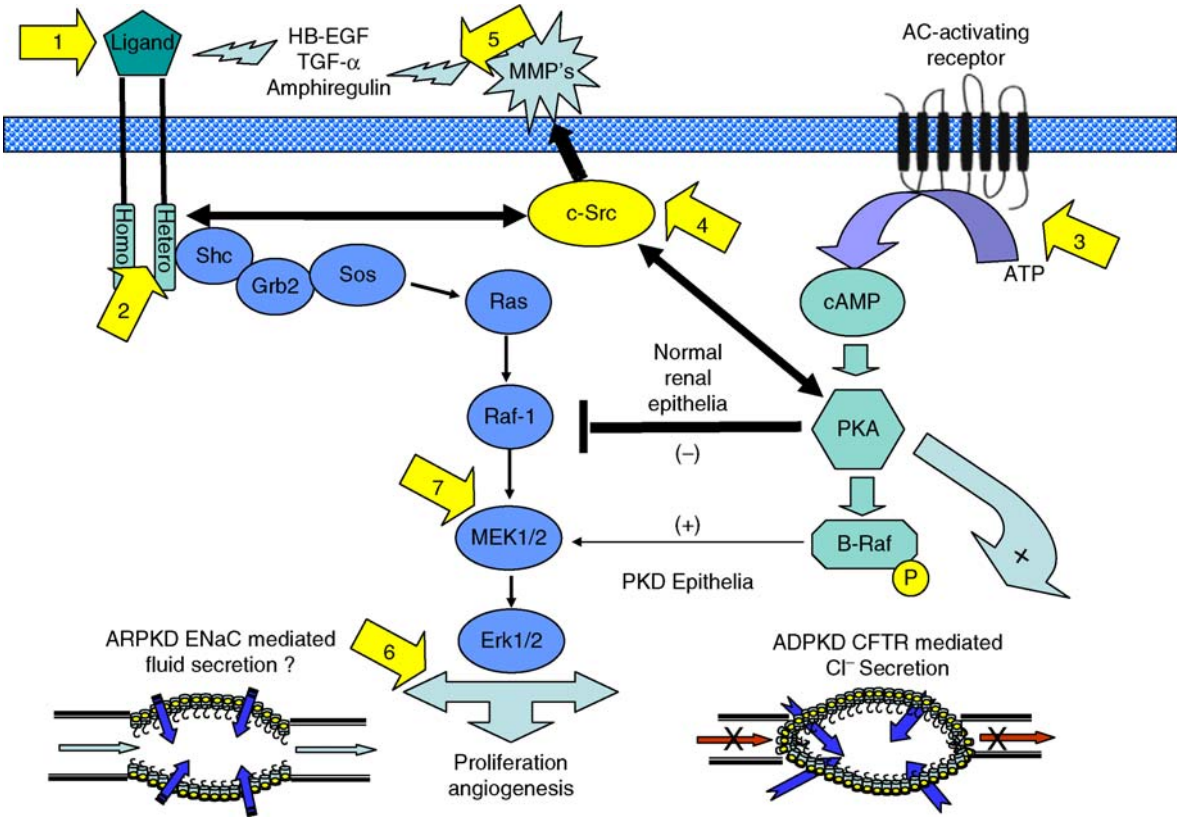
As discussed in the previous sections, the extensive studies delineating the molecular and cellular biology of ADPKD and ARPKD over the past decade have defined a unique "cystic phenotype", which provides a number of potential targets for future genetic and pharmacological therapy (*Fig. 36-2*). Relative to controls, the cystic ADPKD and ARPKD epithelial cell:

1. Demonstrates quantitative (increased amount) and qualitative (apical vs. basolateral) expression of various members of the EGFR-family of receptors and ligands. This initiates an autocrine-paracrine cycle of proliferation through activation of the Ras-Raf-MEK-ERK pathway and stimulates tubular fluid secretion by inhibiting amiloride sensitive sodium transport.
2. Demonstrates increased intracellular cAMP, which mediates proliferation through activation of PKA, phosphorylation and activation of the B-Raf/MEK-ERK pathway and stimulates tubular fluid secretion through activation of PKA and apical CFTR-mediated chloride transport.
3. Interacts with an abnormal microenvironment which includes poorly characterized abnormalities of ECM structure and function, increased cytokines, and angiogenesis that secondarily increases proliferation and tubular secretion.

Delineation of the "cystic phenotype" identifies key targets for future therapeutic intervention. As noted in the text and *Fig. 36-2*, the most promising therapies for future development and clinical trial target the abnormal

Figure 36-2

The Cystic Phenotype and Therapeutic Interventions. The figure depicts the two primary signaling pathways which mediate progressive cyst formation and enlargement in ADPKD and ARPKD: Abnormal expression of the EGFR-axis and adenylate cyclase activating receptor activity leading to increased cAMP (see text for details). Superimposed on the figure are key sites of therapeutic targeting: 1. Monoclonal antibodies against the EFGR-family (e.g., cetuximab; transtuzumab; nimotuzumab); 2. Small molecule inhibitors of EGFR-family tyrosine kinase activity (e.g., erlotinib, lapatinib, HKI-272); 3. Inhibitors of adenylate cyclase activating receptors (e.g., tolvaptan; somatostatin analogues); 4. Inhibitors of c-Src kinase activity which decrease EGFR-family ligand availability and inhibit tyrosine kinase activity, as well as decrease B-Raf activity (e.g., bosutinib, SKI-758, SU-6656); 5. Matrix metalloproteinase inhibitors which inhibit release of bioavailable EGFR-ligands (e.g., XL-784); 6. mTOR inhibitors (e.g., rapamycin); 7. Inhibitors of MEK kinase activity (e.g., UO126, PD98059). Additional therapies described in the text and recent reviews (21, 173, 285) but not depicted include: 20-HETE inhibitors (96); CDK inhibitors (458), Reactive Oxygen Species inhibitors and TNF-alpha inhibitors (459).



EGFR-axis and adenylate cyclase activation at multiple sites. Perhaps the most promising therapies will target key signaling intermediates which appear to integrate these separate pathways, such as Src kinase (*Fig. 36-2*) (6, 16, 21, 41, 172, 173) and/or utilize multiple agents in combination. At this writing, a number of agents are in advanced states of pre-clinical development or Phase 2–3 pilot clinical trials. The interested reader is referred to regularly updated listings of ongoing clinical trials for ADPKD and ARPKD at (www.pkdcure.org; and http://clinicaltrials.gov/.).

Autosomal Recessive Polycystic Kidney Disease (ARPKD)

ARPKD is an inherited disorder characterized by cystic dilations of renal collecting ducts and varying degrees of hepatic abnormalities consisting of biliary dysgenesis and periportal fibrosis (5). ARPKD has alternatively been referred to as "infantile" polycystic kidney disease. This term, however, is generally no longer used because of recognition that the disease can present any time from the prenatal period through adolescence, and rarely even

in adulthood. Furthermore, other forms of PKD, including ADPKD, can present in the neonatal period (2, 174).

Epidemiology and Genetics

Based on published reports, the incidence of ARPKD is 1:10,000–1:40,000 (175, 176). The frequency of the gene in the population is estimated to be approximately 1:70 (177). However, the exact incidence is unknown, since published reports vary in the populations studied (e.g., autopsied patients versus survivors), and affected children may die in the perinatal period without a definitive diagnosis. With improvements in neonatal management leading to improved survival rates, as well as formal reporting mechanisms (such as a newly developed ARPKD registry (178)), more accurate incidence rates may become established.

Consistent with autosomal recessive disease, heterozygotes (carriers) are unaffected. The recurrence risk for subsequent pregnancies is 25%, and unaffected siblings have a 66% risk of being a carrier for ARPKD (5). Males and females are affected equally and ARPKD affects all racial and ethnic groups.

ARPKD is caused by mutations in *PKHD1* (polycystic kidney and hepatic disease 1), a large, novel gene that localizes to chromosome 6p21 (179). To date, all kindreds with features typical of ARPKD have demonstrated linkage to this locus (177). Thus, there is no evidence for genetic heterogeneity in patients with the typical features of ARPKD. Of note, kindred with features of ARPKD as well as additional extrarenal abnormalities including skeletal and facial anomalies has been described and linkage to the 6q21 locus excluded (180). Intrafamilial variability in ARPKD disease phenotype was originally reported to be unusual (181) in contrast to the wide variability often seen in some ADPKD kindreds (see below). However recent data suggest that up to 20% of ARPKD multiplex pedigrees exhibit significant intrafamilial phenotypic variability (182). Among families with at least one neonatal survivor, the risk for perinatal demise of a subsequent affected child is 37%. These data are important for appropriate genetic counseling.

PKHD1 was cloned by two independent research groups in 2002 (9, 10). The gene spans a region of over 400-kb of genomic DNA and contains at least 66 and possibly over 86 exons. The mRNA for the gene is produced as multiple alternative transcripts. The primary transcript of approximately 14–16 kb in length encodes a novel protein termed fibrocystin (alternatively named polyductin). Several alternative transcripts have also been described, several of which lack the transmembrane domain, suggesting that (if translated) they may result in production of secreted forms of fibrocystin (10). Fibrocystin is a very large protein with a predicted molecular weight of 447 kD, similar in size to polycystin 1. The precise function of fibrocystin is unknown at present. However, protein modeling suggests that it is a membrane-bound protein with immunoglobulin-like properties including the presence of several TIG/IPT domains (immunoglobulin-like folds shared by plexins and transcription factors). These motifs suggest that fibrocystin may function as a receptor (9, 10). Recent studies have demonstrated that fibrocystin undergoes proteolytic cleavage and that the C-terminal fragment of fibrocystin translocates to the nucleus (183). In addition, further studies have shown that fibrocystin regulates the expression and function of polycystin-2 (184). The precise functional significances of these observations are as yet undefined but they again highlight the complexities of PKD protein and signal transduction biology.

Pathogenesis

With the cloning and identification of *PKHD1* as the causative gene in ARPKD, detailed observations about mutations and genotype-phenotype correlations have begun to emerge. Several published series of multiple ARPKD kindreds have demonstrated different *PKHD1* mutations throughout the gene, without a clear clustering at specific sites, and the majority of families have unique ("private") mutations (9, 185–187). In addition, most patients studied in an ethnically diverse population are compound heterozygotes (188), i.e., has a different mutation on each *PKHD1* allele. Mutations identified include both missense and truncating mutations.

Genotype-phenotype analyses have also been performed, although these studies are complicated by the large number of mutations and high rate of compound heterozygotes. The locus-specific database for *PKHD1* contains over 350 different mutations (www.humgen.rwth-aachen.de). Several studies have confirmed, however, that patients with more pathogenic mutations (those with two truncating mutations) displayed a very severe phenotype, associated with a high rate of perinatal/neonatal mortality (185, 188, 189). In contrast, amino acid substitutions (missense mutations) were found to be more commonly associated with a nonlethal presentation (190). The actual position of the mutation along the gene, however, did not appear to correlate overall with phenotype (188).

Despite recent advances in the understanding of the molecular genetics of ARPKD, the pathogenesis remains

poorly defined. Northern analyses and RT-PCR demonstrated that *PKHD1* is expressed in both fetal and adult kidney, and to a much lesser extent in liver, pancreas and lung. Expression in other organs was not seen (9, 10). With the development of antibodies to the fibrocystin protein, additional tissue and cellular localizations have been delineated. During development, fibrocystin is expressed in the branching ureteric bud/collecting ducts of the developing kidney and is also present in developing neural tube, gut, bronchi and vascular system (191, 192). In the postnatal kidney, fibrocystin is primarily expressed in the collecting duct, the site of cyst formation in ARPKD. It is also present in the bile ducts and pancreatic ducts and islets. This expression pattern persists into adulthood (191). On a cellular level, fibrocystin localizes to primary cilia of renal collecting tubule and loop of Henle epithelia as well as biliary and pancreatic ductal epithelia (191–193). On a subcellular level, fibrocystin colocalizes with polycystin 2 in the polycystin complex adjacent to the basal bodies of cilia on the apical cell surface, as well as at adherens junctions and focal adhesions (192, 194). Recent data suggest that fibrocystin can undergo a complex pattern of Notch-like processing in which a large extracellular domain is shed in a process mediated by ADAM family metalloproteinases. Concomitantly, an intracellular fragment is release by gamma secretase actions (195). A similar pattern of processing is also seen with polycystin 1, which appears to translocate to the nucleus where it presumably affects expression of multiple genes (196).

Studies of animals with *PKHD1* mutations (either spontaneous or genetically engineered) have provided important insights into the abnormalities that can develop when fibrocystin is not expressed normally. The PCK rat harbors a 157-bp deletion in exon 36 of the rat orthologue of the human ARPKD gene, and developed spontaneously in a colony of Sprague-Dawley rats (9, 197). Although it is a genetic model of ARPKD, this model has clinical features of both ARPKD and ADPKD kidney and liver disease (9, 197). Affected animals develop progressive cystic enlargement of the kidneys after the first week of life. Renal cysts develop predominantly in distal tubules and collecting ducts. The animals also develop features consistent with Caroli's disease/congenital hepatic fibrosis (198). Several *Pkhd1* "knockout" models have also been developed and harbor mutations at various points along the gene. Interestingly, the phenotypes are quite varied and quite dissimilar to human ARPKD (199, 200). Insights into the regulation of *PKHD1* expression, have been provided by the observation that mice with mutations in hepatocyte-nuclear factor 1(HNF-1β), the gene mutated in the human disease MODY5, develop renal cysts and show a decrease in *PKHD1* expression (201). Further data demonstrate that HNF-1β itself directly regulates the activity of the *PKHD1* promoter (202).

Recent studies have provided new information regarding the pathogenesis of congenital hepatic fibrosis in ARPKD. CHF is characterized primarily by fibrosis and bile duct proliferation although biliary cyst formation is not a prominent feature. Increased expression of pro-fibrotic molecules transforming growth factor-beta (TGF-β) and thrombospondin–1 have been demonstrated in human ARPKD livers (203). Livers from orthologous PCK rats show a pattern consistent with the ductal plate malformation of patients with CHF. Intrahepatic bile duct dilatation with cystic changes and marked portal fibrosis are particularly prominent (198, 204). Biliary epithelium in the PCK show abnormalities in proliferative activity, related to abnormal EGFR-axis expression as well as apoptosis (41, 198, 205). Cholangiocytes in this model have abnormal cilia, the length of which is related to the level of *PKDH1* expression (206).

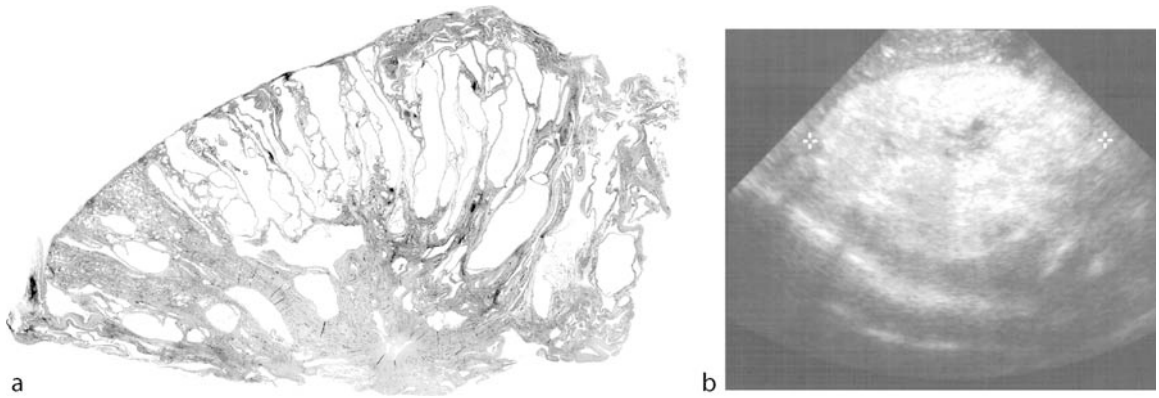
Liver disease is also evident in other ARPKD models, including the *bpk* and *cpk* mouse models. (170, 207–209). Biliary epithelial hyperplasia, like renal tubule hyperplasia appears to be mediated by a mitogenic cycle driven by abnormal EGFR-axis expression (205, 210).

Pathology

In infants and young children, the kidneys are reniform but grossly enlarged. Pinpoint opalescent dots are visible on the capsular surface and correspond to cystic cortical collecting ducts (211). Microscopically (see *Fig. 36-3a*), the cysts are usually less than 2 mm in size ("microcysts") and have been shown by microdissection, histochemical, and immunologic studies to be dilated collecting ducts lined by low columnar or cuboidal epithelium (212–215). The glomeruli and other tubular structures appear to be decreased in number because of marked collecting duct ectasia and interstitial edema. In fetal kidneys, proximal tubular cystic lesions have also been identified (216), but are largely absent by birth. The pelvicaliceal system and renal vessels appear normal. Unlike ADPKD, in which the cysts become discontinuous with the tubule, the cystic tubules in ARPKD are fusiform in shape and remain in contact with the urinary stream. Microdissection studies and scanning electron microscopy demonstrate that obstruction of urinary flow is not a component of ARPKD (211, 212). With increased patient survival, the development of larger renal cysts, interstitial fibrosis, and

Figure 36-3

Kidney histology and ultrasonography of autosomal recessive polycystic kidney disease (ARPKD). (a) Microscopic appearance of a kidney biopsy from a 7-month-old with ARPKD demonstrating multiple radially oriented collecting tubule cysts extending from the medulla to the peripheral cortex. A small amount of residual parenchyma contains glomeruli and noncystic tubules situated between the cysts. No glomerular cysts or signs of renal dysplasia are present. (Hematoxylin and eosin stain; original magnification x1.) (Specimen kindly provided by Dr. Steven Emancipator, Case Western Reserve University.). (b) Renal ultrasound (right kidney) of a newborn with ARPKD demonstrates the typical appearance of echogenic, enlarged kidneys (length = 6.5 cm; normal for age = 4.48 ± 0.62 cm) with poor corticomedullary differentiation.



hyperplasia produces a pattern more like ADPKD (see below) (217). Gang and Herrin (218) describe increasing fibrosis and inflammation in later specimens from patients who had typical collecting duct microcysts during infancy.

Some degree of biliary dysgenesis and hepatic fibrosis is always present in ARPKD. Although hepatic involvement is invariably present microscopically at birth, it is clinically evident in only 40–50% of neonates (219). The classic liver lesion shows a typical ductal plate abnormality consisting of portal fibrosis surrounding increased numbers of hyperplastic, ectatic biliary ducts with normal hepatocellular histology (217, 220, 221). With time, hepatomegaly and portal hypertension become evident in many patients. Intrahepatic biliary ectasia may result in macrocysts and dilation of extrahepatic bile ducts sometimes resulting in an enlarged gallbladder (222) or choledochal cysts (223). Although the combination of collecting tubule and biliary ectasia with periportal fibrosis is unique to ARPKD, portal fibrosis and bile duct proliferation may be associated with other types of renal disease, including ADPKD (224, 225).

Clinical and Radiographic Features

Historically, ARPKD was originally separated into four distinct clinical entities based on age at presentation and relative degrees of renal and hepatic involvement (226). Although such distinctions were useful as clinicopathological classifications, they are now recognized to be the result of different mutations within the same gene and are not used clinically (5, 227).

The majority of patients with ARPKD present in infancy (178, 219, 228, 229). A subset of patients with ARPKD may present as older infants with abdominal enlargement secondary to enlarged kidneys or hepatosplenomegaly without the full spectrum of clinical symptoms outlined below (178, 229). A smaller, though increasingly recognized subset of patients with ARPKD are diagnosed as older children or adults (178, 230, 231). These patients typically present with signs and symptoms related to congenital hepatic fibrosis, including hepatosplenomegaly and portal hypertension (177, 232). A recent series showed that almost one-third of individuals with mutations in *PKHD1* and hepatic involvement were 20 years or older at the time of initial presentation, suggesting that the clinical spectrum of the disease is broader than previously appreciated (231).

With the widespread use of prenatal ultrasound, most patients with ARPKD are now detected *in utero*. Prenatal ultrasound may demonstrate the findings of oligohydramnios, large renal masses, or absence of fetal bladder filling (233). At birth, patients usually have large, palpable flank masses that may be large enough to complicate delivery. Urine output is usually normal; however,

oliguric acute renal failure may occur (175). In such patients, increased urine output and a corresponding improvement in renal function may be seen following improvement in respiratory status (234). Most patients (70–80%) have some evidence of impaired renal function in the newborn period (3, 219). However, death from renal insufficiency is uncommon (226). Transient hyponatremia related to a urinary dilution defect is often present, but usually resolves over time (219, 228). The treatment consists of water restriction. Metabolic acidosis has also been reported (3, 228). As might be predicted from a pathological process that affects the collecting tubule, most patients have a urinary concentrating defect and symptoms of polyuria and polydipsia (3, 217, 228, 229).

Hypertension, which may be severe, is common in both infants and children and may well be a presenting feature (175, 217). It can be present in patients with normal renal function and eventually affects almost all children with the disease (3, 178). However, the pathophysiology of hypertension in ARPKD is poorly understood (172). In ADPKD patients the renin-angiotensin aldosterone system (RAAS) is upregulated and thought to occur as the result of expanding cysts causing local ischemia (235). The role of the RAAS in mediating hypertension in ARPKD is less clear. Systemic renin levels are not usually elevated in hypertensive ARPKD patients or in an ARPKD rat model (228, 229, 236). In addition, kidney size in ARPKD stabilizes over time and does not show the progressive macrocystic enlargement classically seen in ADPKD. Thus, it is unknown whether the same mechanism accounts for hypertension in both ADPKD and ARPKD. Local (intrarenal) RAAS activation is suggested by a recent histologic study that demonstrated increased expression of several renin-angiotensin axis components in two kidneys of individuals with ARPKD (237). Similarly, intrarenal RAAS activation has also been demonstrated in the orthologous PCK rat (238).

Pulmonary insufficiency, as manifest by respiratory distress, is a major cause of morbidity and mortality in neonates with ARPKD. Oligohydramnios results in pulmonary hypoplasia, which may be complicated by restriction of diaphragmatic movement due to massively enlarged kidneys. Additional causes of respiratory distress in these patients include pneumothorax and atelectasis, or a variety of common neonatal pulmonary disorders such as surfactant deficiency, bacterial pneumonia, meconium aspiration, or persistent fetal circulation. Severely affected infants may demonstrate all features of the "oligohydramnios sequence", including pulmonary hypoplasia, abnormal extremities and characteristic Potter's facies (239). Infants with true pulmonary hypoplasia often die soon after birth secondary to pulmonary insufficiency.

The typical appearance of ARPKD by ultrasonography is one of large echogenic kidneys with poor corticomedullary differentiation (*Fig. 36-3b*). Macrocysts, a feature of ADPKD, are usually not present at birth, but are not uncommon with progression of disease (240). In a study of sonographic features of adult patients with ARPKD, Nicolau et al. (241) noted the presence of multiple small cysts in normal-sized kidneys, increased cortical echogenicity and loss of corticomedullary differentiation as common features. Stein-Wexler and Jain (242) proposed that the ultrasonographic findings of "focal rosettes," corresponding to the macroscopic appearance of radially-oriented collecting tubule cysts, are specific for ARPKD. In addition, although kidneys may be markedly enlarged at birth, over time, the majority show stable to decreased renal size (243, 244). In a preliminary report from a prospective, NIH-supported study of the natural history of ARPKD, kidney volumes of enlarged kidneys increased at approximately 1/3 of the normal rate for age over 2–4 years (245).

Findings on magnetic resonance imaging include enlarged kidneys with hyperintense T2-weighted signals (246). Kern et al. showed that ARPKD kidneys have a characteristic hyperintense, linear radial pattern in the cortex and medulla by RARE-MR urography that may reflect the microcystic dilatation seen histologically (246, 247).

ARPKD kidneys have also been reported to have characteristic features by nuclear medicine studies. DMSA scanning demonstrated loss of the normal kidney outline and internal structure and patchy tracer uptake with focal defects throughout the kidneys, particularly at the poles. In the majority of cases, these DMSA changes did not correlate with the ultrasonographic findings, in which the kidneys appeared more uniformly affected (248).

Ultrasonographic findings in the liver include hepatomegaly, increased echogenicity and poor visualization of the peripheral portal veins. Reversal of normal venous flow by Doppler study, suggestive of portal hypertension, may also be seen. Hypertrophy of the left lateral segment of the liver is also occasionally seen (249) and a subset of patients will have overt evidence of biliary ductal dilatation (Caroli's disease) (249). In a preliminary report of the NIH-supported natural history study, over 75% of ARPKD patients demonstrated intra and extra-hepatic biliary dilatations, with dilated common bile ducts and enlarged gall bladders (245). Macroscopic liver cysts are uncommon (250), although choledochal cysts have been reported (223), and MRCP demonstrates diffuse intrahepatic bile duct dilatation with periportal fibrosis (249).

Diagnosis

With the advent of modern obstetrical ultrasonography, many patients with ARPKD are identified in the prenatal period. Enlarged echogenic kidneys, oligohydramnios, and the absence of urine in the bladder, are very suggestive of ARPKD (251). Older literature suggests that sonographic features of ARPKD may present in the second trimester but usually are not apparent until after 30 weeks' gestation (252). Both false-positive and false-negative results have been reported (253). However, with newer high-resolution obstetrical ultrasonography it is probable that diagnostic sensitivity and detection rates will improve. Wisser et al. (254) reported a case of a fetus with pathologically-confirmed ARPKD who demonstrated echogenic, normal sized kidneys at 15 + 4 weeks gestation.

As noted previously, other cystic kidney diseases in infancy, including ADPKD and cystic dysplasia, may have antenatal sonographic appearances that are difficult to distinguish from ARPKD (2). It has been proposed that fetal MRI may be a useful additional diagnostic study in fetuses with inconclusive ultrasonography in the third trimester of pregnancy (255). However, its accuracy in confirming the diagnosis earlier in pregnancy has not been assessed. Increased maternal alpha fetoprotein and amniotic fluid trehalase activity have been identified as potential markers for ARPKD, but neither has been confirmed as specific or sensitive for disease detection *in utero* (256, 257).

Definitive diagnostic criteria for ARPKD have not been established. Those proposed by Zerres et al, with modifications (5, 219), are used by many pediatric nephrologists, and include:

1. Ultrasonographic features typical of ARPKD, including enlarged, echogenic kidneys, with poor corticomedullary differentiation; and
2. One or more of the following:
   a) Absence of renal cysts in both parents, particularly if they are at least 30 years old,
   b) Clinical, laboratory or radiographic evidence of hepatic fibrosis,
   c) Hepatic pathology demonstrating characteristic ductal plate abnormality,
   d) Previous affected sibling with pathologically confirmed disease,
   e) Parental consanguinity suggestive of autosomal recessive inheritance

As noted above, renal ultrasonography may be less diagnostic in children who present later in childhood. Furthermore, in the subset of patients who present as older children and adolescents, hepatic abnormalities are often the prominent presenting feature.

Although renal biopsies will clearly differentiate the isolated fusiform cortical collecting tubular cysts of ARPKD (*Fig. 36-3*) from the heterogeneous cystic nephron involvement of ADPKD (*Fig. 36-4*) (214, 258), they are generally not indicated for patients who fulfill the classic criteria for ARPKD and/or those for whom genetic testing is definitive (see below) (5). In certain instances, liver biopsy may provide additional information and reveal the characteristic biliary dysgenesis of ARPKD. However, hepatic portal fibrosis and bile duct ectasia have been associated with other types of renal cystic disease, including ADPKD.

Genetic testing is also typically not required for patients with classic ARPKD diagnostic criteria. Genetic testing is useful, however, for families who already have an affected child, in identifying sibling carriers and in instances in which the diagnosis is less clear. Prenatal diagnosis may be made in a family with at least one known affected child through the techniques of linkage analysis or mutation analysis. Linkage analysis uses analysis of polymorphic markers that flank the location of a known disease gene to "track" the disease. This technique can also be used to identify whether the unaffected sibling is a carrier of the disease. In informative families, the accuracy of prenatal diagnosis using linkage analysis was >95% (259). An accurate genetic diagnosis by linkage analysis, however, is critically dependent on the diagnosis of ARPKD in the affected sibling (259).

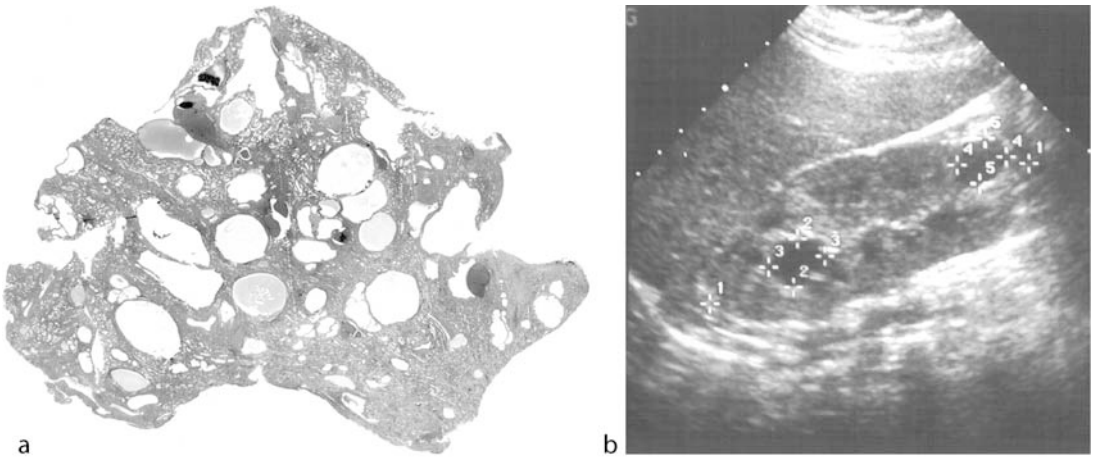
With the identification and cloning of *PKHD1*, molecular analysis is now available. Although initial studies reported a relatively low mutation detection rate (40–60%) by sequencing methods, newer studies using mutation screening by DHPLC demonstrate an overall mutation detection rate of 82–87% in individuals (including fetuses) with ARPKD (188, 260–263). In addition, pre-implantation genetic diagnosis (PGD) is now offered by a limited number of genetic laboratories (264). A complete list of laboratories offering clinical and research testing for ARPKD is available at www.geneclinics.org.

Treatment and Complications

Survival of neonates with ARPKD has improved in concert with overall medical advances in neonatal artificial ventilation and intensive care. It is currently impossible to predict which neonates with ARPKD who require immediate artificial ventilation have critical degrees of pulmonary hypoplasia incompatible with survival (3, 5). In some

Figure 36-4

Kidney histology and ultrasonography of autosomal dominant polycystic kidney disease (ADPKD). (a) Microscopic appearance of a kidney biopsy from an adult with ADPKD demonstrating multiple thin-walled cysts of varying sizes involving different nephron segments. Focal hemorrhage is noted within some cysts. (Hematoxylin and eosin stain; original magnification x1.) (Specimen kindly provided by Dr. Steven Emancipator, Case Western Reserve University.). (b) Renal ultrasound (right kidney) of a 13- year-old with ADPKD demonstrates several cysts (the largest measuring 1.5 cm × 1.6 cm). The left kidney also had several cysts not present on an ultrasound 2 years before this study. Kidneys are 11.4 cm (*right*) and 11.7 cm (*left*) (normal for age = 9.79 cm ± 1.5 cm).



instances, severe pulmonary distress may be secondary to potentially reversible fluid overload, neonatal lung disease, or restricted diaphragmatic motion secondary to massively enlarged kidneys. In selected cases, some authors have advocated continuous venovenous hemofiltration, unilateral or bilateral nephrectomy coupled with peritoneal dialysis to allow optimal ventilation and thereby assess the long-term pulmonary prognosis of the patient (265–268).

Infants and young children with ARPKD, including those without significant renal insufficiency must be followed closely. Because most children with ARPKD have urinary concentrating defects, significant dehydration is a particular risk during intercurrent illnesses, which may increase insensible water loss (fever), limit free water intake (nausea), or increase extrarenal water loss (vomiting, diarrhea). In patients with severe polyuria, thiazide diuretics may be of benefit to decrease distal nephron solute and water delivery. Supplemental bicarbonate therapy is required for those with metabolic acidosis.

Hypertension can be difficult to manage and may require multiple medications (175). Despite the fact that peripheral renin values are not usually elevated in hypertensive ARPKD patients, most patients respond well to angiotensin-converting enzyme inhibitors or angiotensin-II receptor blockers, which are considered by many to be the treatments of choice. It should be noted, however, that the safety of ACEi or ARBs in neonates has been called into question by recent studies in neonatal rats that demonstrated adverse effects on tubular maturation and exacerbation of injury associated with obstructive uropathy (269). In addition, ACEi can precipitate acute renal failure in PKD patients (270), as well as in infants in general (271), particularly with dehydration. If additional medications are required, second-line agents include calcium channel blockers, β-blockers (in those without chronic lung disease or signs of congestive heart failure), and diuretics. Recent studies on the pathophysiology of cyst formation (see above) raise the theoretical concern that Ca^{++} channel blockers may exacerbate low intracellular Ca^{++} in cystic renal epithelia and increase abnormal proliferation and disease progression.

Urinary abnormalities may be present or develop over the course of disease. Pyuria is a relatively common finding and can be seen in the absence of demonstrable bacteriuria or documented infection (217). Urinary tract infection has been reported as a common complication in at least one uncontrolled series (3), but it is unclear whether children with ARPKD truly have an increased incidence of upper or lower urinary tract infections (UTIs) when compared with appropriately age-matched controls. Thus, as in any child with an abnormal urinalysis, clinical features and

appropriately obtained urine cultures must guide antibiotic therapy. If a UTI is documented, a voiding cystourethrogram and renal ultrasound should be performed to determine the possible presence of vesicoureteral reflux and rule out obstruction or superimposed upper tract structural abnormalities (218). Microscopic or gross hematuria and proteinuria may also be seen (3, 175). In infants and children who develop chronic kidney disease, the consequences of progressive CKD (e.g. growth failure, anemia, and renal osteodystrophy) become apparent as renal function decreases.

Dialysis and/or transplantation are indicated when children with ARPKD reach symptomatic end-stage renal failure or if progressive uremia results in growth failure or developmental delay. Peritoneal dialysis is often the preferred method of dialysis and may be the only practical long-term option in the young child. Peritoneal dialysis in ARPKD is usually successful even in the face of large kidneys and hepatosplenomegaly. Kidney transplantation offers definitive renal replacement therapy in children with ARPKD. Successful kidney transplantation prolongs survival and often accelerates growth and development in young uremic children. Nephrectomies may be indicated prior to, or at the time of, transplantation to control hypertension and/or to permit room for transplant placement in patients with massively enlarged kidneys.

Difficulties in feeding, even in patients without renal insufficiency, are often noted. This is presumably due to the presence of enlarged kidneys and or liver, interfering with normal gastrointestinal function. Supplemental feeding via nasogastric or gastrostomy tubes is often required to optimize weight gain and growth. Although growth failure in ARPKD may also occur as the result of chronic kidney disease, a study by Lilova et al. (272) suggests that growth failure in this population is common, may be attributable to factors other than CKD alone, and responds well to growth hormone treatment. In contrast, the preliminary report from the NIH-supported Natural History Study of ARPKD suggests that completely normal growth curves may not be uncommon (245).

With improved patient survival and advances in renal replacement therapy, hepatic complications progressively dominate the clinical picture of many patients with ARPKD (178, 219, 221, 232, 273). These include hepatosplenomegaly, bleeding esophageal varices, portal vein thrombosis, and hypersplenism causing thrombocytopenia, anemia, and leucopenia. Data from two recent series showed that portal hypertension occurred in 37–44% of neonatal survivors and was age-related (178, 274). Although significant complications related to portal hypertension develop, liver synthetic function is usually intact.

One serious and potentially lethal complication in ARPKD patients with significant hepatic involvement is bacterial cholangitis, which has been reported as early as a few weeks of age (3). Fever or elevation of liver function tests at any time should lead to the suspicion of cholangitis and result in complete evaluation and appropriate antimicrobial therapy. However, patients may not present with the classic clinical findings of cholangitis and the diagnosis should be strongly considered in ARPKD patients with unexplained recurrent sepsis with gram negative organisms (275). Caroli's disease (dilated intrahepatic bile ducts) has been identified as a potential risk factor for bacterial cholangitis (276, 277). Cholangiocarcinoma has also been reported in patients with CHF/Caroli's (278).

In infants and children with hepatic involvement, close monitoring for complications of portal hypertension is mandated, particularly since typical "liver function" tests (such as serum albumin and transaminases) may be normal. Yearly ultrasonography to determine changes in liver or spleen size to identify portal hypertension by reversal of venous flow is non-invasive and may be of value. Endoscopy is necessary to evaluate suspected esophageal varices that can be treated by sclerotherapy or banding prior to life-threatening hemorrhage. Periodic monitoring should reveal the hematologic profile of hypersplenism. Sudden worsening of anemia should raise the possibility of occult gastrointestinal blood loss secondary to splenic sequestration or variceal bleeding. Porto-systemic shunting may be indicated in some cases (228, 279), but concerns have been raised about reported cases of ultimately fatal recurrent hepatic encephalopathy in children with porto-caval shunts who progressed to ESRD (280). It has been hypothesized that the loss of kidney function results in impaired clearance of toxins that are shunted from the liver. This finding has raised concerns about whether liver transplantation should be considered as an alternative therapy for ARPKD patients with portal hypertension being evaluated for possible shunts or those with recurrent episodes of cholangitis (281). The increased use and successful outcome of living-related partial liver transplants makes this a more realistic option. In fact, successful sequential liver and kidney living-related transplants have been reported (282).

In addition to the significant medical problems, the psychosocial stresses of ARPKD on the patient and family can be overwhelming. Social support measures and periods of respite care are often necessary. A team approach using the skills of pediatric nephrologists in concert with

other pediatric medical subspecialists, specialized nurses, dietitians, social workers, psychiatrists, and other support staff is required to provide optimal comprehensive care for children with ARPKD.

Prognosis

Prognosis is difficult to assess, although it is now clear that survival of all but the most severely affected neonates who demonstrate pulmonary hypoplasia is possible (1, 217). Published reports vary with respect to neonatal survival rates, but suggest that approximately 70–80% of patients survive the newborn period with aggressive neonatal intensive care (3, 228, 232). Actuarial survival rates calculated from birth for 55 patients with ARPKD referred to a pediatric tertiary care center revealed that 86% were alive at 3 months, 79% at 1 year, 51% at 10 years, and 46% at 15 years (228). Calculations based on patients who survived to 1 year of age showed that 82% were alive at 10 years and 79% at 15 years (228). Similar findings were reported in a more recent study of 164 neonatal survivors with confirmed *PKHD1* mutations. Patients in that cohort had a 1 year survival rate of 85% and a 10 year survival rate of 82% (274). In a cohort of 166 ARPKD patients born after 1990, 75% were alive at a median age of 5.4 years (178).

Patients who survive the neonatal period usually have a decreased glomerular filtration rate (GFR), but studies have demonstrated subsequent improvement in renal function consistent with some degree of continued renal maturation (175). However, a significant number of patients with ARPKD will progress to end-stage kidney disease. In a cohort of patients surviving the first month of life, Roy et al. (232) reported renal survival of 86% at 1 year and 67% at 15 years. A more recent study of patient with confirmed *PKHD1* mutations showed actuarial renal survival rates of 86% at 5 years, 71% at 10 years, and 42% at 20 years (274).

With the success of renal transplantation and improved survival of patients with ARPKD, morbidity and mortality of complications related to congenital hepatic fibrosis are more common and clinically relevant. Whether these complications result in significant mortality post-kidney transplant is a subject of some debate. Khan et al. reported the outcome of 14 patients with ARPKD after renal transplantation (283). With a mean follow-up of 14 years, the study showed 1 and 5 year patient survival rates of 93% and 86% respectively. Overall 36% of patients died and, in 4 of 5 of those patients, death was directly related to complications of hepatic disease. In those who survived, 63% had portal hypertension. Thus, complications of CHF developed in almost 80% of patients following renal transplantation for ARPKD. In contrast, in a retrospective study of patients included in the North American Pediatric Renal Transplantation Cooperative Study (NAPRTCS) registry, Davis et al. (284) reported similar patient and graft survival rates in kidney transplant patients with ARPKD compared to those without. It is interesting to note, however, that among those patients who died, sepsis was the cause in 64% of those with PKD versus 32% in those without PKD, suggesting that ARPKD patients may be at increased risk of infection compared to the general pediatric transplant population.

Autosomal Dominant Polycystic Kidney Disease (ADPKD)

ADPKD is a systemic inherited disease characterized by progressive renal cystic enlargement of all nephron segments coupled with variable extrarenal manifestations involving the gastrointestinal tract, cardiovascular system, reproductive organs and the brain (4, 173, 285). ADPKD has alternatively been called "adult" polycystic kidney disease. However, this term is a misnomer because ADPKD has been diagnosed in the fetus, newborns, older children and adolescents (175, 229, 286, 287).

Epidemiology and Genetics

ADPKD is the most common inherited human kidney disease and occurs at an incidence of approximately 1:400 to 1:1000. It affects all races and males and females are both affected; however, the kidney phenotype may be more severe in males (288). ADPKD is a rare cause of ESRD in the pediatric population, but accounts for approximately 5–10% of ESRD in adults. The two major disease-causing genes are *PKD1* and *PKD2*. In the general population, *PKD1* accounts for approximately 85% of ADPKD and *PKD2* the remaining 15%. A third ADPKD locus has been suggested by a few case reports (289–291), but has not been substantiated (4). Mutations in *PKD1* and *PKD2* produce similar phenotypes, however, the age of onset of cystic disease, hypertension, and renal insufficiency is delayed in the latter (21, 292–294).

PKD1 has been mapped to chromosome 16p13.3 (295). Like *PKHD1*, *PKD1* is a very large gene, spanning 53 kb of genomic DNA with 46 exons encoding a 14.5 kb transcript (7). A portion of the gene is duplicated in the proximal portion of chromosome 16. The gene encodes a large, novel 4304 amino acid protein product,

polycystin-1 (PC-1), a 460 kD protein with a large extracellular domain that contains motifs likely to function as protein and carbohydrate binding sites. The PKD repeats in the extracellular domain may mediate homodimerization of PC-1. The extracellular domain of PC-1 also contains a physiologically important G-protein-coupled receptor proteolytic site (GPS). Taken together these motifs suggest that PC-1 may function as a receptor and/or have roles in cell-cell interactions. *PKD2* has been linked to chromosome 4q13-q23 (8, 296) and expresses a 5.4 kb mRNA, which encodes a 968 amino acid polypeptide, polycystin-2 (PC-2) (8). Polycystin-2, also called TRPP2, is a calcium permeable, non-selective cation channel (297, 298) whose NH2 and COOH termini are both cytoplasmic.

Pathogenesis

ADPKD is characterized by considerable intrafamilial and interfamilial phenotypic variation (189, 299). Several studies have supported a role for genetic background/genetic modifiers as a cause of this variability (300). A number of candidate genes have been examined as potential modifiers of the disease phenotype. These include members of the renin-angiotensin system, including the angiotensin converting enzyme (ACE) gene, the endothelin system and the cystic fibrosis gene, *CFTR*. However, positive results suggesting an effect have not been reproducible (189).

One gene that has been found to influence disease severity is the tuberous sclerosis 2 (*TSC2*) gene. Several kindred's were identified that had co-existent *TSC2* and *PKD1* mutations with severe childhood-onset ADPKD. These kindreds were subsequently found to have large deletions in an area containing both *PKD1* and *TSC2*, resulting in a contiguous gene syndrome (301).

One explanation for phenotypic variability may be related to the so-called "second hit" theory of ADPKD which result in heterozygous mutations at the level of individual cysts. By analyzing two closely linked polymorphic markers within the PKD1 gene, Qian et al. revealed that the renal epithelia from single cysts are monoclonal, containing only the mutant haplotype (302). A subsequent study by Brasier et al. (303) confirmed these findings. These two studies suggest that patients harboring a germline mutation in the one allele of a PKD gene undergo a somatic "second hit", which results in the loss of the remaining normal allele and genetic heterozygosity in those affected cells. These studies provide a possible molecular explanation for both the focal nature of cysts (<5% of tubules are cystic in ADPKD) as well as the phenotypic variability within families harboring the same germline mutation. The extent to which this two-hit phenomenon contributes to the overall phenotypic variability remains a subject of some debate (304).

Because of the significant intrafamilial variability in ADPKD, including kindreds with more severe disease noted in successive generations, the genetic phenomenon of anticipation has been postulated to be an explanation for this heterogeneity. However, a recent study of ADPKD patients with *PKD1* mutations failed to find evidence for anticipation in this disease (305).

PKD1

Numerous different mutations throughout the *PKD1* gene have been identified in patients with ADPKD with no specific mutational "hot spots" identified (306). The majority of mutations are predicted to result in truncation of the PC-1 protein. Substantial phenotypic variability has made genotype-phenotype correlations unachievable, but a number of recent studies have made significant observations about the nature of *PKD1* mutations and disease phenotype. Rosetti et al. (307) found that, even taking into consideration the significant inter- and intrafamilial phenotypic heterogeneity, patients with mutations in the 5′ region of *PKD1* had significantly more severe kidney disease than those with mutations in the 3′ portion of the gene. Thus, the location, rather than the type of *PKD1* mutation, was found to be the factor that correlated with the onset of ESRD. In addition, 5′ *PKD1* mutations have also been reported to be predictive for the development of cerebral aneurysms (308).

PC-1, the protein product of *PKD1*, is expressed in multiple tissues, including kidney, liver, pancreas, intestine and cerebral blood vessels (all sites of pathologic changes in ADPKD), as well as in the lung, testis, and other tissues (309–312). Localization studies demonstrated robust PC-1 expression in human fetal renal tubular epithelia that diminished with age, but persisted at low levels into adulthood (309, 313), suggesting a role in renal development and tubular maintenance.

PC-1 possesses a large extracellular domain, multiple transmembrane spanning regions, and an intracellular carboxy-terminus (314, 315). The extracellular domain is dominated by immunoglobulin-like repeats (the PKD domain) as well as a leucine-rich repeat, a LDL-A domain, a REJ domain, and a calcium-dependent lectin domain. These structural components, taken as a whole, suggest that the extracellular portion of PC-1 may be capable of

binding an as yet undefined ligand (315). PC-1 is anchored to the cell membrane by 7–11 putative transmembrane domains. These numerous features suggest that PC-1 is a large, multifunctional molecule involved in carbohydrate motif recognition, ligand binding, and Ca^{2+} regulation. It may engage in cell–cell and/or cell–matrix interactions, which regulate signal transduction pathways mediated by cell surface protein–protein interactions or directly participate in regulating transcriptional programs.

PC-1 has been localized to the plasma membrane of renal epithelial cells in a basal distribution at areas of cell-cell contact (adherens junctions), cell-matrix contacts (focal adhesions), and in the primary cilia. PC-1 has been shown to bind to polycystin 2 (316, 317) and regulate the channel activity of polycystin-2 (a non-selective cation channel) (318). The polycystin complex at the cilia appears to play a role in mechanosensation as previously discussed and loss of function of one of the complex members can result in loss of flow induced-calcium response (101). Interestingly, Chauvet et al. (319) showed that mechanical stimuli can induce proteolytic cleavage and nuclear translocation of the polycystin-1 carboxy terminus tail suggesting that polycystin-1 may have a role in regulating gene expression.

PC-1 co-localizes with and forms multimeric complexes with a wide variety of other proteins at other sites along the plasma membrane as previously discussed. These include those involved with cell-matrix interactions (such as $\alpha_2$beta 4 integrins and focal adhesion complexes) as well as cell-cell interactions (including E-cadherin-β-catenin complexes) (11, 13, 315, 320). PC-1 has also been shown to interact with intermediate filaments at the desmosomes (321) and cells lacking polycystin 1 show mislocalization of desmosomal proteins (14).

Additional data demonstrate that polycystin-1 induces resistance to apoptosis via the phosphatidylinositol 3-kinase/Akt signaling pathway and promotes spontaneous tubulogenesis in MDCK cells (322, 323). The carboxy terminal of polycystin-1 triggers branching morphogenesis and migration of inner medullary collecting duct (IMCD) cells, and supports *in vitro* tubule formation (324).

Both under- and over-expression of polycystin-1 is associated with cyst formation and/or developmental abnormalities. In cystic epithelium of human ADPKD kidneys (309), polycystin 1 is overexpressed and data from animal studies suggest that *PKD1* overexpression is sufficient to induce cysts (325). "Knockout" mouse models, in which a variety of PKD1 mutations have been introduced that result in the loss of functional polycystin, have also provided important clues to its function, particularly during development. Animals lacking polycystin-1 die *in utero* or soon after birth and demonstrate abnormalities in multiple organs, including the heart, blood vessels kidneys and pancreas (326–328). To overcome this lethal phenotype, investigators have developed PKD1 mutant mice that either produce low levels of PC-1 (hypomorphs) or have a "conditional" mutation (floxed allele) that is controlled via breeding with a Cre-recombinase expressing mouse or by pharmacologically driven Cre-gene expression. These animals survive, but develop kidney, pancreatic and vascular disease of variability severity (22, 329). Interestingly, the timing of the loss of PC-1 post-natally has a significant impact on the disease phenotype. Neonatal mice that lose PC-1 develop massive cystic kidney enlargement within 4 weeks, whereas older mice who lose PC-1 expression develop only mild cystic kidney disease (330). These observations suggest that cyst formation requires not only loss of PC-1, but also concomitant cell proliferation, such as is seen during early post-natal kidney development.

PKD2

Multiple mutations in *PKD2* have been identified in affected families, and as with *PKD1*, most families have unique mutations (331, 332). These mutations truncate polycystin-2 (PC-2) and appear to be loss-of-function mutations. As with PKD1, considerable intrafamilial phenotypic variability is reported in families with PKD2 mutations (189, 332). Genotype-phenotype studies have suggested that, unlike *PKD1*, the location of *PKD2* mutations does not appear to influence the age of onset of ESRD.

Similar to PC-1, PC-2 is widely expressed. The highest levels of expression within the kidney are the thick ascending loop of Henle and the distal convoluted tubule, where PC-2 localizes to the basolateral plasma membrane of renal tubular epithelium (333). PC-2, like polycystin-1, is expressed in the vasculature, including porcine aorta and normal human elastic and intracranial arteries (334). On a subcellular level, PC-2 localizes to the plasma membrane as well as to the endoplasmic reticulum and Golgi apparatus (12, 333).

PC-2 contains six transmembrane regions and has intracellular domains at both its amino- and carboxy-termini. The transmembrane regions share significant homology with voltage-activated Ca^{2+}/Na^{+} channels, which suggested that polycystin-2 may be a channel protein. The carboxy-terminus contains an EF-hand domain

that binds Ca^{2+} in addition to several potential phosphorylation sites. Koulen et al. (297) confirmed by single channel studies that PC-2 (a member of the subfamily of the transient receptor potential (TRP) channel superfamily) functions as a calcium-activated intracellular ion release channel *in vivo* and hypothesized that polycystic kidney disease results from the loss of regulation of an intracellular calcium release signaling pathway.

As noted previously, PC-2 interacts with PC-1 to form a complex located at the cilia. Data suggest that PC-2 located on the endoplasmic reticulum also interacts with PC-1 present at the plasma membrane (173). Recent data also demonstrate that PC-2 has a role in regulating the cell cycle through direct interaction with Id2, a member of the helix-loop-helix (HLH) protein family known to regulate cell proliferation and differentiation. This interaction requires PC-1-dependent phosphorylation of PC-2 (335). PC-2 also interacts with the protein, kidney injury molecule-1 (KIM1), a chemosensor present on the cilia (336, 337). Finally, Li et al. (338) reported that intracellular portions of PC-2 associate with alpha-actinins, which are actin-binding and actin-bundling proteins. They hypothesized that the aberrant interactions between PC-2 and alpha-actinins could play a role in the cell proliferation, adhesion and migration abnormalities seen in PKD epithelia.

Animal models with reduced or absent *PKD2* expression have also provided important insights into the function of PC-2. Similar to *PKD1*, PKD2 knockout mice die *in utero* or soon after birth and demonstrate cardiac defects in septum formation as well as kidney and pancreatic cysts (339). Studies of two *PKD2* mutant models expressing variable levels of PC-2 demonstrate that increased cell proliferation is an early event associated with the loss of *PKD2* expression and precedes cyst formation (340). This *in vivo* finding was supported by *in vitro* studies of cell lines lacking PC-2. In those cell lines, the loss of *PKD2* was associated with increased proliferation rates, suggesting that PC-2 is a negative regulator of cell growth (341). In addition, loss of *PKD2* has been reported to induce changes in the localization of *PKD1*, suggesting it has a role in mediating *PKD1* subcellular localization (342).

Pathology

In ADPKD (see *Fig. 36-4a*), kidney cysts form in glomeruli and all tubular segments. Glomerular cysts may be seen as a component of ADPKD or as a separate disease entity. Unlike ARPKD, in which the cystic dilatations are fusiform in nature and remain in connection with the tubular lumen, in ADPKD the enlarging cysts eventually "pinch off" and become disconnected from the tubular lumen and urinary space.

Clinical and Radiographic Features

Patients with ADPKD are usually diagnosed and become symptomatic in adulthood (173). However, children affected with ADPKD may also become symptomatic or be diagnosed as an incidental finding. The clinical spectrum of pediatric ADPKD ranges from severe neonatal manifestations indistinguishable from ARPKD to renal cysts noted on ultrasound in asymptomatic adolescents (2, 175, 229, 286, 343, 344).

As with ARPKD, hypertension can present during the newborn or infant periods and is common in pediatric and young adult ADPKD patients, despite the presence of normal renal function (229, 286, 345, 346). The acceptance of ambulatory blood pressure monitoring (ABPM) as an important tool for blood pressure assessment has allowed for more in depth studies of blood pressure abnormalities in patients with ADPKD. A significant proportion of normotensive young adults with ADPKD have "prehypertension" by ambulatory blood pressure monitoring (347). Blunted "nocturnal dipping" on ambulatory blood pressure monitoring has also been reported to be associated with endothelial dysfunction in this population (348). It is also notable that in a study of adults with ADPKD, a history of hypertension in affected parents was associated with an earlier onset of hypertension in their affected offspring (349).

Hypertension in ADPKD has been hypothesized to be due to reduced renal blood flow due to cyst compression with subsequent activation of the renin?angiotensin system, and increased sodium retention (350, 351). Recent case–controlled studies that have specifically controlled for sodium intake have shown no differences in the systemic RAS activation in hypertensive ADPKD patients compared to patients with essential hypertension (352). It is still possible, however, that local (intrarenal) RAS activation could still play a role in the pathogenesis of both hypertension as well as progressive kidney damage associated with ADPKD (353, 354). In addition, increased ACE independent generation of angiotensin II (via mast cell production of chymase) has been reported (355).

Increased left ventricular mass been reported to occur in normotensive children and young adults with ADPKD (356) and is associated with impaired relaxation time during exercise testing (357). Doppler abnormalities

consistent with early diastolic dysfunction has been reported in some patients, although the data are conflicting (356, 358). In addition, Oflaz et al. (359) reported an increased rate of biventricular dysfunction in both hypertensive and normotensive ADPKD patients, suggesting early cardiac involvement prior to the development of overt hypertension. An intrinsic cardiac abnormality is not unexpected given the diffuse vascular localization of *PKD1* and *PKD2* and the severe vascular phenotypes associated with null mutations in these genes. On the other hand, in light of the data about prehypertension diagnosed by ABPM in apparently normotensive ADPKD patients, it is possible that patients who were reported to be "normotensive" may, in fact, have had subtle blood pressure abnormalities not recognized by standard casual blood pressure measurements.

The increased incidence of cardiac valvular abnormalities such as mitral valve prolapse, commonly seen in the adult ADPKD population (360, 361), has also been reported in children with ADPKD (362). There have also been several reports of endocardial fibroelastosis in children with ADPKD (363, 364). An increased risk of coronary aneurysms has been reported in adults, but no pediatric cases have been reported, to date (365). An increased risk of pericardial effusion has also been reported in adults with ADPKD (366). Although rarely detected before the age of 20, there are reports of clinically significant cerebral vessel aneurysms in pediatric ADPKD patients as well (367).

In addition to hypertension, other presenting symptoms can include abdominal pain, palpable abdominal masses, gross or microscopic hematuria, UTIs, abdominal or inguinal hernias. The occurrence of gross hematuria after seemingly minor trauma to the flank region should raise the possibility of ADPKD. Renal insufficiency is rare, but can occur in childhood (286, 344). A renal concentrating defect, which may be associated with clinical evidence of polyuria and polydipsia, may be present in up to 58% of children with ADPKD (3, 368) and its presence correlates with the presence of hypertension by ABPM as well as the number of renal cysts (369). These findings suggest that impaired renal concentrating ability may be another clinical indicator of cystic kidney disease severity in children with ADPKD. Renal infections are common in adult patients with ADPKD and can be a presenting feature in the affected infant and child (229). Pain can also result from urolithiasis, a common finding in adults with ADPKD, as well as cyst rupture.

The typical appearance of ADPKD in children by ultrasonography is one or more renal cyst. ADPKD renal involvement in children is commonly asymmetric and may be unilateral in a small minority (370). The Consortium for Radiologic Imaging Studies in Polycystic Kidney Disease (CRISP) is a longitudinal prospective study of adult ADPKD patients, which uses high-resolution magnetic resonance (MR) imaging (371). This series of studies has demonstrated that individual cysts, as well as total cyst and kidney volumes, are well-delineated by magnetic resonance imaging (MRI), which can also be used to monitor cyst and kidney growth and blood flow over time (372, 373). These insights have allowed the development of clinical trials with novel therapeutic agents by providing a non-invasive means of monitoring response to therapy over a relatively short (one to three) year period.

The extrarenal cysts seen commonly in adults with ADPKD (360, 374) are uncommon in pediatric patients. Although hepatic, pancreatic, or testicular cysts are rarely detected before puberty, they have been reported in affected children, even in the first year of life (375, 376). Although liver cysts (detected by ultrasonography) were thought to be uncommon in children, a recent MRI study suggested that liver cysts may be present in up to 55% of adolescents and young adults (377). The prevalence in that study was reported to be directly related to the kidney volume. Liver cysts in children, when present, are not generally associated with pain, infection, and hepatomegaly as noted in adult patients. Congenital hepatic fibrosis with severe portal hypertension in children and adults with ADPKD has been reported rarely (224, 225). The presence of pancreatic cysts has been found exclusively in *PKD1* patients and do not appear to contribute to morbidity or mortality (378).

Diagnosis

There are no specific clinical diagnostic criteria for children with suspected ADPKD. As noted previously, ADPKD can present in any age group, including fetuses and neonates. The diagnosis of ADPKD has been made *in utero* by ultrasound, and affected newborns can present with Potter's phenotype and die from pulmonary hypoplasia. Affected infants can be born with large hyperechoic kidneys with or without macrocysts and variable degrees of renal insufficiency. Prenatal diagnosis is suggested by antenatal ultrasound findings of moderately enlarged hyperechogenic kidneys with or without cysts, with increased corticomedullary differentiation (379). However, these findings may not be evident until the third trimester (380, 381).

In families with known ADPKD, asymptomatic children may be identified by ultrasonographic examination

or as an incidental finding during evaluation for an unrelated problem (*Fig. 36-4b*). In pediatric patients with a 50% risk of ADPKD, the finding of one cyst or enlarged echogenic kidneys without cysts may be considered diagnostic (4, 286).

Even in families not known to have ADPKD, the finding of one or more kidney cysts in a fetus or child should alert the clinician to the possibility of ADPKD, since approximately 8–10% of patients with ADPKD will have *de novo* (new) mutations (4). Although radiographic studies may report the presence of a "simple cyst" and note it as a normal finding, in fact, such cysts are extremely rare in childhood (382). If ADPKD is clinically suspected in a child, the parents (and/or grandparents if the parents are younger than 30) should be considered for radiographic evaluation (383). It is not uncommon that the diagnosis of ADPKD in a child can lead to the diagnosis of ADPKD in asymptomatic adults following parental radiographic studies. Additional rare causes of solitary or even grouped unilateral cysts in a patient without a family history should also be considered. These include caliceal diverticula or isolated renal cystic disease (384, 385). In such instances, additional diagnostic studies, including contrast enhanced CT or IVP can help to exclude these diagnoses (385).

Screening evaluations of asymptomatic children at risk for ADPKD is currently not recommended. Because cysts may not be evident until adulthood, the finding of a negative ultrasound may be falsely reassuring (386). Conversely, there may be significant psychosocial and financial implications of the diagnosis of ADPKD in an asymptomatic patient who may not develop clinical signs of disease for several decades (387, 388). Some adults with ADPKD choose not to be tested, and testing of asymptomatic children eliminates their ability to make that decision as an adult. Thus, it is currently recommended that for "adult onset" genetic diseases such as ADPKD, screening should not be done unless a there is anticipated benefit to the child (389). With the emergence of novel, potentially disease-modifying therapies for ADPKD, and the passage of legislation in the United States preventing discrimination against individuals with genetic disorders (Genetic Information Nondiscrimination Act, or GINA) recommendations regarding screening are being re-evaluated as previously noted.

Genetic testing (including prenatal testing) is available for ADPKD. Previously, genetic testing was via the technique of linkage analysis (229). However, because of the need for a relatively large number of family members willing to be tested, this technique may be appropriate for fewer than 50% of families (173). With improvement in mutation detection techniques, direct sequence analysis is now the more commonly used methodology. Current mutation detection rates are approximately 85% using this methodology (331, 390).

While prenatal genetic testing, including preimplantation genetic diagnosis (PGD) (391) is available, it is not widely used. In the majority of kindreds, fetuses harboring an ADPKD mutation will not show any obvious renal or other abnormalities and patients may be asymptomatic for 2–3 decades. Surveys of ADPKD families indicate that only 4% would consider pregnancy termination if the fetus were affected (392). An up-to-date listing of laboratory currently performing genetic testing of ADPKD patients for clinical or research purposes is available at www.geneclinics.org.

Treatment and Complications

Treatment of ADPKD is primarily focused on detecting and managing renal and extra-renal complications. Asymptomatic children at risk for ADPKD should be followed annually for the development of hypertension, hematuria (gross or microscopic), polyuria, proteinuria or palpable abdominal masses. Any of these findings is an indication for ultrasound examination and close clinical follow-up.

As with other forms of chronic kidney disease, identification and treatment of hypertension is essential in slowing progression to ESRD in ADPKD. In adults with ADPKD, more intensive blood pressure control (<120/80) has been reported to have a greater impact on LVH reduction than standard control (<140/90)(393). It has been suggested that ACE inhibitors and AII receptor antagonists (ARB), alone or in combination, may offer benefits in addition to anti-hypertensive effects (394–396); however, the data are not entirely conclusive (397). A longitudinal study of children with ADPKD treated with ACE inhibitors is currently underway. A larger-scale multicenter NIH trial (HALT/PKD) is underway to address the question of whether ACE inhibitor plus ARB is more beneficial than ACE alone in modifying disease progression. In addition, a smaller study of 49 hypertensive ADPKD patient: found that treatment with an ARB appeared to be more favorable than that of a calcium channel blocker (CCB) in terms of rates of decline in renal function and proteinuria. As previously noted, reports in rodent PKD models suggested that CCBs exacerbate cystic kidney disease because of depletion of intracellular calcium (398). Although the results of these animal studies are intriguing, avoidance of CCBs is not

currently recommended for ADPKD, or as previously noted, ARPKD (399). It is also notable that reversible acute renal failure may be precipitated by ACE inhibitors in ADPKD patients with diminished kidney function and massive cystic involvement (270). Although acute renal failure would be extremely unlikely in children (given the absence of massive cystic involvement and intact renal function during childhood), it is prudent to obtain follow-up serum chemistries after initiation of ACE and/or ARB therapy.

Urinary tract infection, in particular, cyst infection may occur in children and adults with ADPKD. It has been reported that the risk of pyuria and bacteriuria in ADPKD increases progressively from 2% in the second decade to 32% in the seventh decade. Most adult ADPKD patients have some degree of renal insufficiency when UTIs develop (213). Although no data are available regarding specific features of UTIs or renal cyst infections in pediatric ADPKD patients, it is reasonable to presume that their clinical course is similar to that described for adult ADPKD patients (400). Sterile pyuria is common, and appropriate cultures are needed to determine whether an infection is present. Most renal infections are caused by Gram-negative enteric organisms and can be complicated by cyst infection. Eradication of cyst infections is often difficult, despite *in vitro* sensitivity of responsible organisms; thus, the use of antibiotics that penetrate cyst walls is mandated (401). Antibiotics that generally penetrate cyst walls include ciprofloxacin (402) and sulfonamides. Penicillins and aminoglycosides (standard treatments for urinary tract infection) are generally ineffective in treating cyst infection (401, 403). Aggressive antibiotic treatment is critical because recurrent or ineffectively treated UTIs appear to be a definite risk factor in progression of renal disease (404). Occasionally, cyst drainage may be required to control infection, and MRI or PET scan may be a useful in identifying which cyst is infected (405, 406). In extreme cases, nephrectomy may be indicated (401). Prophylactic antibiotics should be considered before the introduction of any urinary tract instrumentation in children with ADPKD.

Episodes of flank pain are unusual in pediatric patients with few cysts. However, with progressive disease, particularly in adolescents, flank pain may become a more prominent feature. In the majority of instances, the painful episodes will resolve within a few days. Pain relief is accomplished with acetaminophen or brief courses of oral narcotics. Non-steroidal anti-inflammatory agents should be avoided. Long term narcotic use is discouraged, due to abuse potential. Non-pharmacologic interventions and referral to a chronic pain management center should be considered (407). In cases of severe pain, laparoscopic denervation and nephropexy has been reported to significantly relieve pain in adolescents (408, 409). Laparascopic cyst decortication is an addition therapeutic option, particularly in instances of recurrent pain and infection (410). Renal calculi, a common finding in adult patients with ADPKD (411), and a frequent cause of flank pain, are rare in childhood.

Hepatic cysts are relatively uncommon in the pediatric population, but have been recognized more frequently with the increased resolution of imaging studies. Patients with hepatic cysts may develop cyst infections, which typically present as right upper quadrant pain, fever, leukocytosis, and a rise in liver enzymes (412). Antibiotics alone may be ineffective, and the addition of surgical drainage is generally recommended (413). Intestinal diverticular disease (360) has not been reported in pediatric ADPKD patients, to date.

Cerebral aneurysms occur in approximately 10% of ADPKD patients. The risk of rupture of asymptomatic aneurysms in adults is related to the size, with the risk ranging from 0.05% per year for those less than 10 mm to 6% within one year for those greater than 25 mm (414). The risk of rupture for symptomatic aneurysms is about 4% per year (414). Although aneurysms are found in patients with negative family histories, intrafamilial clustering of aneurysms and aneurismal bleeding has been reported in ADPKD populations (415–417). Use of magnetic resonance angiography (MRA) may permit effective, noninvasive detection of significant aneurysms (418). However, routine screening of all ADPKD patients is not recommended, since many patients are asymptomatic and the incidence of rupture is low (419). Screening MRA may be recommended for patients with symptoms or a positive family history (415).

The incidence of clinically significant aneurysms and/or aneurismal rupture in children with ADPKD is thought to be very low, although data are limited. Ruptured aneurysms have been reported in children as young as 4 years old (420). Given the intrafamilial clustering of aneurysms, it is important to obtain a detailed family history. If such a history is present, and/or the patient complains of headache, further evaluation by MRA should be considered.

There are currently no disease-specific treatments available for ADPKD. Newer therapies, however, are being investigated in preclinical studies, and Phase II and III trials of adults with ADPKD. As previously noted (see *Fig. 36-2*) these include trials of inhibitors of the EGFR-axis, the vasopressin receptor antagonist, Tolvaptan, the mTOR inhibitor, Rapamycin, and the somatostatin analogue, octreotide (120, 421–423). A regularly

updated list of clinical trials in the US and around the world is available at www.clinicaltrials.gov, and www.pkdcure.org. A number of dietary interventions have been shown to slow progression of disease in animal models. These include dietary flaxseed, soy protein or protein restriction, sodium citrate, or caffeine restriction. To date, none has proven to significantly alter the clinical course of disease in humans (424).

Prognosis

The prognosis of ADPKD presenting in the fetus or neonate was once thought to be very poor. However, a number of recent studies of "very early onset" ADPKD suggest that it may be compatible with favorable long-term patient and renal survival (425, 426). Prognosis in the older child is also very favorable and progression to ESRD in childhood is rare in ADPKD (427). However, disease progression does occur in childhood, particularly in children with evidence of severe renal enlargement at a young age (427). Proteinuria has been identified as a potential early marker of severe cystic disease in children (428). The CRISP studies confirm that significant cyst growth, parenchymal damage and volume progression occurs in ADPKD well before changes in measured GFR are seen. Thus assessments of renal function, such as serum creatinine measurements are poor indicators of overall disease severity. Recent data, including that of the CRISP investigators, has shown that kidney volume and its rate of change are the most predictive factors for subsequent decline in renal function and clinical outcomes (288, 429) (430, 431). The CRISP study established that mean renal volume increases 5.3% per year in patients with ADPKD, providing a valuable non-invasive, short term parameter to monitor effectiveness of new therapies.

Approximately 50% of adult patients with ADPKD will progress to ESRD. On average, patients with PKD1 typically progress at an earlier age, with a mean age at ESRD of 53.0 years, whereas those with PKD2 progress to ESRD at a mean age at ESRD of 69.1 years (293). In light of the significant inter- and intrafamilial phenotypic heterogeneity, it is difficult to predict at what age a given patient with ADPKD will develop renal failure.

Glomerulocystic Kidney Disease

The term *glomerulocystic disease* (GCKD), coined by Taxy and Filmer in 1976, is used to describe the morphologic appearance of glomerular cysts, which occur in a variety of conditions (432). GCKD was first described clinically by Ross in 1941(433). Glomerulocystic kidney disease can be categorized into three major groups: *(a)* nonsyndromal inherited and sporadic forms of GCKD; *(b)* GCKD as the major component of congenital malformation syndromes; and *(c)* glomerular cysts as a minor component of abnormal or dysplastic kidney disease, some of which are syndromic.

Epidemiology and Genetics

Primary GCKD with isolated renal involvement can be an autosomal dominant disease, a familial hypoplastic disease, as well as a sporadic occurrence. Reports exist of infants with GCKD who have family members affected with ADPKD, which raises the question of whether these two entities are different expressions of the same genetic defect. Sporadic GCKD and GCKD occurring in the context of familial ADPKD are clinically, sonographically, and histopathologically indistinguishable. However, several recent studies of kindreds with autosomal dominant inheritance of GCKD excluded mutations in one or more of the PKD genes, including *PKD1*, *PKD2* and *HNF-1beta* (434, 435). Thus, with emerging molecular diagnostic techniques, the genetic basis for this rare and heterogenous disease may be more fully defined.

An apparently distinct entity is hypoplastic glomerulocystic kidney disease, a dominantly inherited disease reported in only a few families (436, 437). These kidneys, apart from being glomerulocystic, are small, and imaging studies show abnormal pyelocaliceal anatomy. Mutations in the hepatocyte nuclear factor-1beta (HNF-1β) gene were been identified in 4 kindreds with this hypoplastic GCKD variant (438).

GCKD can be associated with congenital syndromes such as orofaciodigital syndrome, type I (439); brachymesomelia–renal syndrome (440); trisomy 13 (441); Majewski-type short rib–polydactyly syndrome (441); and Jeune syndrome (442) and can be seen as a component of the renal abnormalities in nephronophthisis (443). Although tubular sclerosis generally includes tubular cysts, glomerular cysts can be present (443). Glomerular cysts also occur as a minor component in several other syndromes including Zellweger cerebrohepatorenal syndrome (441, 442) in which the cysts are typically present but rarely serious enough to affect renal function.

Other syndromes that may be associated with glomerular cysts as a component of renal dysplasia include Meckel syndrome, glutaric aciduria type II and renal–hepatic–pancreatic dysplasia (443). The glomerular cysts

are minor in comparison with the dysplastic components of the renal disease, although they may be present in sufficient numbers to create confusion with other glomerulocystic conditions.

Pathogenesis and Pathology

The pathogenesis of GCKD remains unknown. Clinically, GCKD can be difficult to distinguish from other cystic kidney diseases. The diagnosis can only be established by histologic examination of renal tissue. Sporadic GCKD in young infants is histopathologically indistinguishable from ADPKD-related GCKD. The kidneys in both the familial and sporadic forms are variably enlarged, with the degree of renal enlargement related to the degree of cyst formation (443). The cysts in both groups may be diffuse but can also be clustered, which may be responsible for asymmetric and asynchronous clinical presentations. Diffuse involvement is associated with interstitial edema, whereas patchy involvement is associated with better preservation of overall renal structure and function.

Characteristically, the cysts are dilated Bowman's spaces, comprising a sphere lined with cuboidal or columnar cells and containing abortive or primitive-appearing glomeruli (432), which occur as small scattered cysts separated by normal parenchyma. The cysts are located in the cortex, with preservation of the medulla. This lack of tubular involvement differentiates GCKD from other cystic diseases in which cysts generally arise from tubular dilation. In rare cases, they are more diffuse, surrounded by atrophic and fibrotic parenchyma. They may be found in association with tubular cysts and dysplasia (443).

The kidneys in sporadic GCKD and the GCKD form of ADPKD often contain abnormally differentiated pyramids, a type of medullary dysplasia. Both forms of GCKD are associated with biliary dysgenesis in approximately 10% of cases (443).

Clinical and Radiographic Features

Most GCKD patients described in the literature have some degree of renal failure and many have hypertension at presentation. The typical presentation is that of an infant with abdominal masses, renal insufficiency, and enlarged cystic kidneys on sonography. GCKD may manifest in adulthood with hypertension, flank pain, and hematuria. Variable degrees of renal dysfunction are seen. Later detection may be consistent with a milder course (286, 444). Clinically, hepatic cysts have also been described (443).

Patients with the familial hypoplastic glomerulocystic kidney disease variant have small kidneys with abnormal collecting systems and abnormal or absent papillae (436, 437). Family studies show a pattern compatible with autosomal-dominant inheritance. Most patients appear to have chronic kidney disease with some degree of renal impairment early in life but subsequently have stable courses without progression to ESRD.

Several reports of GCKD describe patients with no clear familial or syndromic association (441, 445, 446). Histologically and clinically, these patients resemble familial cases with large, hyperechoic kidneys. It remains unclear whether these sporadic cases are a distinct entity or are associated with unrecognized syndromal or familial cases. Reports on an infant with GCKD and multiple cardiac rhabdomyomas and an infant with severe GCKD who later developed skin findings consistent with tuberous sclerosis strongly suggest an association of GCKD with tuberous sclerosis (447, 448). This, together with the new information regarding the molecular basis of ADPKD and tuberous sclerosis and the reported familial association of GCKD and ADPKD, raises the possibility that autosomal dominant GCKD, ADPKD, and tuberous sclerosis are genetically linked in some kindreds. Single case studies have also reported GCKD in association with Henoch-Schoenlein purpura (449), hepatoblastoma (450), and as a sequelae of hemolytic-uremic syndrome (451, 452).

Ultrasonography demonstrates bilateral renal enlargement without distortion of the renal contour, increased echogenicity of the cortex and medulla, loss of corticomedullary junction differentiation, and small cortical cysts (445, 453). Radiographically, a feature that can help distinguish GCKD from ARPKD is abnormal medullary pyramids in the latter. In the future, CT and nuclear MRI may be of some value in differentiating between these two diseases (454). Reduced intensity of cortex on T1-weighted images and abnormalities of corticomedullary differentiation may help confirm the diagnosis.

In summary, GCKD represents a heterogeneous collection of heritable and nonheritable clinical entities. This clinical course and prognosis is quite variable and often dependent on the presence of associated disorders.

Polycystic Kidney Disease Associated with Congenital Syndromes

Many diseases can present with enlarged kidneys or cysts in the infant and young child and can initially be confused

with PKD (*Table 36-1*). Most syndromic and other inherited disorders can usually be differentiated from ARPKD and ADPKD by associated clinical features, with the exception of GCKD, occasionally tuberous sclerosis and von Hippel-Lindau disease (1, 5, 455). GCKD can be a feature of several inherited, sporadic, or syndromic conditions as discussed above. In addition, GCKD may be an early histopathologic expression of the ADPKD gene in young patients. Tuberous sclerosis is an autosomal-dominant neurocutaneous disorder, in which hyperplastic cystic lesions may affect any portion of the nephron (447). Genetic linkage of the chromosome 16 loci for tuberous sclerosis and ADPKD1 has been demonstrated (456). The tuberous sclerosis 2 (TSC2) gene has been identified and encodes a novel protein, tuberin. Uncommonly, patients show polycystic renal involvement without clinical neurocutaneous involvement or positive family history. Several kindreds have been identified with tuberous sclerosis and severe childhood-onset ADPKD; they have large deletions in the area containing *PKD1* and adjacent tuberous sclerosis 2 (TSC2) gene (301). Analysis of the deletions indicates that they inactivate *PKD1*, in contrast to mutations reported in ADPKD patients in which abnormal transcripts have been detected. Von Hippel-Lindau disease is a dominantly inherited cancer syndrome characterized by renal cell carcinoma, pheochromocytoma and hemangioblastomas of the eye, spine and cerebellum. Cystic kidneys and pancreas may be seen and, rarely, patients may present with "typical" features of ADPKD (457). To differentiate GCKD, tuberous sclerosis and von Hippel-Lindau from ARPKD and ADPKD, detailed family history, physical examination and close clinical follow-up are necessary.

Acknowledgments and Disclosures

K. Dell is supported in part by the NIH-funded UAB Recessive PKD Research and Translational Core Center (NIH-P30DK074038; P.I. L.M. Guay-Woodford). W.E. Sweeney, Jr. and E.D. Avner are supported by the NIH-funded Children's Research Center of Excellence in Pediatric Nephrology at the Children's Research Institute and the Medical College of Wisconsin (NIH-P50DK076; P.I.- E.D. Avner); the Polycystic Kidney Research Foundation, the Advancing a Healthier Wisconsin Program of the Medical College of Wisconsin, and the Children's Research Institute of the Children's Hospital Health System of Wisconsin.

The Avner-Sweeney laboratory at the Children's Research Institute has received, or currently receives, Research Grants administered entirely through the Medical College of Wisconsin from the following Pharmaceutical Companies: Wyeth-Ayerst Research, Calesca Research, Glaxo-Smith-Kline, OSI, and YM Biosciences.

E.D. Avner serves as the Director of the Medical and Scientific Advisory Board of Calesca Pharmaceuticals (without compensation).

37 Aminoaciduria and Glycosuria

Israel Zelikovic

Introduction

Only negligible amounts of amino acids and glucose are normally present in the final urine, reflecting very efficient reabsorption mechanisms for these organic solutes in the proximal tubule. Renal tubular transport defects or specific metabolic abnormalities result in excretion of significant quantities of amino acids or glucose in the urine. Although hereditary defects in renal tubular transport of most of these substances are uncommon, they are of major biologic importance. First, some of these membrane transport disorders (e.g., cystinuria, lysinuric protein intolerance, Hartnup disease) are associated with significant morbidity. Second, the study of these disorders has provided much insight into the physiology of renal tubular reclamation of amino acids and glucose and into the specific metabolic pathways that control their reabsorption and has been crucial in understanding the genetics of tubular transport systems.

This chapter summarizes the general characteristics of renal tubular transport of amino acids and glucose, outlines the three main classifications used for amino acid transport systems (based on chemical properties, substrate specificity/ion dependence and sequence homology), reviews recent studies on the molecular biology of the transporters, describes the ontogeny of these transport processes, and discusses the specific hereditary membrane transport disorders that result in abnormal aminoaciduria and glycosuria. Special emphasis is given to classic cystinuria, lysinuric protein intolerance and Hartnup disease, including molecular genetic aspects of these diseases. Not discussed in this chapter are overflow aminoaciduria and glycosuria, which occur when the filtered load of these solutes exceeds the transport capacity of the renal tubule. This tubular overload is characteristic of various inborn errors of amino acid metabolism and diabetes mellitus, which result in elevated plasma levels of amino acids and glucose, respectively. Fanconi syndrome, a proximal tubular disorder characterized by generalized aminoaciduria, and urinary hyperexcretion of glucose, bicarbonate, phosphate, and other solutes, is discussed in Chapter _____.

Aminoaciduria

General Characteristics of Tubular Amino Acid Transport

Circulating free amino acids are derived from dietary protein that is hydrolyzed and absorbed in the intestine, from intracellular catabolism of peptides, and from de novo synthesis within cells. More than 99% of the load of free amino acid filtered by the kidneys of humans and other mammals is reabsorbed in the renal tubule and returned to plasma (1–3). Amino acid reabsorption occurs predominantly in the pars convoluta of the proximal tubule and, to a small extent, in the pars recta (1, 2). Amino acids are reabsorbed primarily from tubular lumen by an active uphill transport across the luminal membrane (1). In studies using renal brush-border membrane vesicles (BBMV) from various animals to explore amino acid transport across this membrane, the rate of accumulation by vesicles and the magnitude of the overshoot, which indicates active concentrative transport, was greatly augmented by an external Na^+ gradient across the vesicle membrane (1). Hence, it is widely accepted that uptake of most amino acids at the brush-border surface occurs by Na^+-amino acid cotransport driven by the electrochemical Na^+ gradient from tubular lumen to cell (1, 2) (*Fig. 37-1*). The energy maintaining the Na^+ gradient is established by the Na^+-K^+-ATPase, which is located at the basolateral membrane and translocates Na^+ out and K^+ into the cell. An additional driving force for amino acid transport across the luminal membrane is the H^+ gradient (luminal > intracellular) which has been shown to drive uptake of proline (4) and glycine (5) by BBMV. Finally, cationic acids and cystine are reabsorbed across the luminal membrane in exchange for recycled neutral amino acids (3, 6) (see Molecular Structure of Amino Acid Transporters *Fig. 37-1*).

Active amino acid transport across the brush-border membrane is followed by efflux, mainly via carrier-mediated, Na^+-independent, facilitated diffusion or exchange from the cell into the peritubular space across the basolateral membrane (3, 7) (*Fig. 37-1*). Thus, under

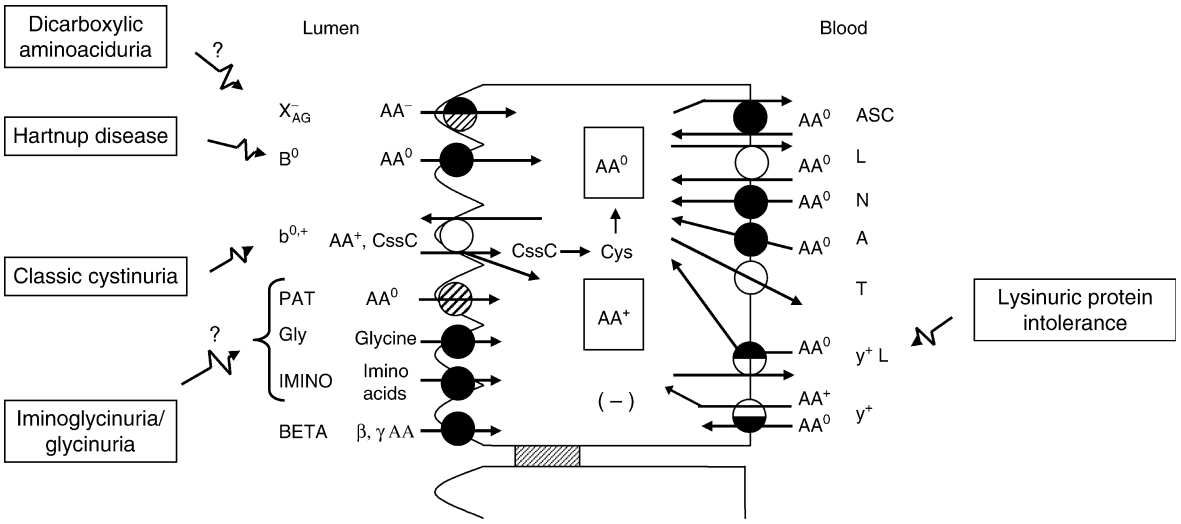
Figure 37-1

Summary of amino acid transport mechanisms in the proximal tubule. *Filled circles* indicate Na^+-dependent, active, carrier mediated cotransport or antiport. *Dashed circles* indicate H^+-dependent, active, carrier – mediated cotransport. *Empty circles* indicate Na^+-independent antiport or uniport (facilitated diffusion). *Half-filled*, *half dashed* or *half-empty circles* indicate various combinations of the above. Depicted are hereditary amonoacidurias known or postulated to be caused by defects in these transport mechanisms; AA^0 neutral amino acids, AA^+ basic amino acids, AA^- acidic amino acids, *CssC* cystine, *Cys* cysteine. See text for details.



normal conditions, net transepithelial movement of amino acids occurs from the tubular lumen to the peritubular space. However, net transepithelial flux of amino acids is composed of amino acid transport in both directions, namely lumen to interstitium and interstitium to lumen (3, 7, 8). Indeed, the basolateral membrane harbors active Na^+-dependent and Na^+-independent transport and exchange systems mediating amino acid uptake in the tubular cell (*Fig. 37-1*), and diffusional backflux of amino acids from cell into the tubular lumen is a well-documented phenomenon (3, 7). Interstitium to lumen oriented backflux through paracellular pathways also occurs. The sum of these vectorial fluxes determines the direction and the rate of transepithelial amino acid transport. This notion may be of major importance in understanding renal tubular amino acid transport, particularly in disease states and during maturation (8, 9).

Na^+-amino acid symport across the luminal membrane is a carrier-mediated saturable process obeying Michaelis-Menten kinetics (1, 2). The effectiveness of the active reabsorption process for a specific amino acid depends on the ratio V_{max}:K_m (1). A low V_{max} (decreased transport capacity) or a high K_m (diminished transporter-substrate affinity) for a given amino acid results in decreased reabsorption rate of this amino acid. Changes in efficiency or capacity of amino acid transport also play an important role in both neonatal aminoaciduria and hereditary aminoacidurias.

In analyzing the data obtained from microperfusion and micropuncture experiments and studies using BBMV for various amino acids (1), two or more Na^+-linked transport systems with different kinetic characteristics have been described. The demonstration of multiple transport systems for the same amino acid becomes meaningful if the reduced concentrations of filtered amino acid presented to the proximal straight tubule are considered. Thus, in the case of glycine, for example, two Na^+-dependent, active transport systems have been demonstrated along the luminal membrane of the isolated perfused proximal tubule (10): a low-affinity, high-capacity system in the convoluted segment and a high-affinity, low-capacity system in the straight segment. The latter system, which also operates in parallel to lower apical membrane backflux permeability in the proximal straight tubule (7), absorbs less glycine against a greater concentration gradient and probably permits the reduction of the luminal glycine concentration to lower levels than could be achieved in the proximal convoluted tubule (7, 10). This axial heterogeneity of Na^+-linked amino acid uptake systems with respect to kinetic characteristics has been demonstrated for several amino acids in BBMV derived from pars convoluta and pars recta of the

proximal tubule (1). The recognition of several transport systems for the same amino acid as well as their axial heterogeneity is of major importance in understanding the pathophysiology of hereditary aminoaciduria.

One or more Na^+ ions are transported for each amino acid molecule translocated, and with most amino acids this process is electrogenic-positive favored by a negative cell interior (1, 11). Na^+-amino acid stoichiometry determines the electrogenicity and efficiency of the transport system (7). Additional ions besides Na^+ are involved in the translocation of the amino acid carrier complex across the brush-border membrane (1). Taurine (12), glycine (13), and proline (14) transport, for example, operates by means of 2 or 3 Na^+:1 Cl^-:1 amino acid carrier complex.

Specificity of Transport

It has been well established that several distinct chemical group-specific Na^+-dependent transport systems for amino acids exist in the tubular luminal membrane (1–3). Evidence for these systems has been derived from a variety of microperfusion experiments and vesicle studies and, in humans, from the existence of inborn errors of renal tubular transport that can be explained only by defects in specific transport pathways (1, 3, 15). These include systems for dibasic (cationic) amino acids, cystine, acidic (anionic) amino acids, neutral α-amino acids, imino acids, glycine, as well as β- and γ-amino acids.

Ample evidence exists that in addition to separate systems for L-cystine and the dibasic amino acids (L-lysine, L-arginine, and L-ornithine), these amino acids share a common transport pathway (16–18), as also suggested by the urinary hyperexcretion of all four amino acids in classic cystinuria (see Classic Cystinuria). Transport of L-cystine but not L-cysteine can also proceed via Na^+-dependent transport pathways for neutral amino acids (1, 3). L-Cysteine is probably reabsorbed by an additional, separate, and specific transport system (2, 3).

The broad-specificity transport pathway for neutral α-amino acids, which is a low-affinity, high-capacity system, is located in the proximal convoluted tubule (15). However, there are several alternative specific renal transport systems for neutral amino acids, including high-affinity systems located in the proximal straight tubule. The presence of such pathways is also suggested by the finding of isolated transport defects for neutral amino acids (see Neutral Aminoaciduria). The imino acids proline and hydroxyproline are reabsorbed by at least three systems: a low-affinity/high-capacity system in the proximal convoluted tubule shared with glycine, an imino acid-specific, high-affinity/low-capacity system in the proximal straight tubule (10, 19) as well as a separate high-affinity/low-capacity system for glycine in the late proximal tubule (10).

The investigation of amino acid transport pathways in the plasma membrane of mammalian cells has delineated several transport systems which are classified according to their substrate specificity (3, 6, 20–24) (*Table 37-1*; *Fig. 37-1*). Most of these transport systems also have been identified in the kidney (3, 6, 20, 21, 23, 25). These systems include the Na^+-dependent, concentrative B^0 system (for most neutral amino acids), A and ASC systems (for small neutral amino acids), and N system (for glutamine, asparagine and histidine), the Na^+- and H^+-dependent X^-_{AG} system (for acidic amino acids), the Na^+- and Cl^--dependent IMINO system (for proline and hydroxyproline), Gly system (for glycine and sarcosine), and β system (for taurine, β-alanine and γ-amino butyric acid), the H^+ gradient-dependent PAT system (for imino acids), as well as the Na^+-independent, nonconcentrative L system (for bulky neural, branched chain amino acids and cysteine), T system (for aromatic amino acids), $b^{0,+}$ system (for dibasic and neutral amino acids including cystine), y^+ system (for the dibasic amino acids lysine, arginine, and ornithine), and y^+L system (for dibasic and neutral amino acids excluding cystine). Systems B^0, X^-_{AG}, IMINO, Gly, β, PAT, and $b^{0,+}$ operate in the luminal membrane, whereas systems A, ASC, N, L, T, y^+, and y^+L operate in the basolateral membrane (3, 22, 23, 25) (*Fig. 37-1*). The basolateral membrane-bound systems ASC, L, y^+ and y^{+L} as well as the luminal membrane-bound $b^{0,+}$ system function as antiport (exchange) systems (3, 23, 24) (*Fig. 37-1*). Recent progress in molecular cloning of amino acid transporters has helped to characterize, classify, and define the nature and the role of most of these tubular amino acid transport mechanisms at the cellular/molecular level (see Molecular Structure of Amino Acid Transporters).

Adaptation and Regulation of Amino Acid Transport

Although the exact mechanisms regulating renal tubular amino acid reclamation have not been established, several factors are known to modulate transmembrane amino acid transport (1, 26–28). These include ionic and voltage conditions (discussed earlier), as well as availability of amino acid substrate, osmotic changes, and protein phosphorylation.

Table 37-1

Amino acid transport systems operating in the renal tubule

Amino acid transport system	Cloned cDNA	Gene	Amino acids transported	Mechanism of action	Localization in proximal tubule	Cellular localization
I. Neutral						
B^0	B^0AT1, 2	SLC1A19, 15	Most neutral	Na^+-AA cotransport	EPT	BBM
ASC	ASCT 1, 2	SLC1A4, 5	Short chain neutral	Na^+-dependent AA antiport	EPT and LPT	BLM
L	4F2hc/LAT-1	SLC3A2/ SLC7A5	Large, branched chain neutral	AA antiport	EPT	BLM
	4F2hc/LAT-2	SLC3A2/ SLC7A8				
A	SNAT2, 4	SLC38A2, 4	Short chain neutral	Na^+-AA cotransport	EPT and LPT	BLM
N	SNAT 3, 5	SLC38A3, 5	Glutamine, asparagine, histidine	1 Na^+/AA cotransport 1 H^+ antiport	LPT	BLM
T	TAT1	SLC16A10	Aromatic	AA uniport	EPT	BLM
PAT	PAT1, 2	SLC36A1, 2	Proline, glycine, alanine	H^+- AA cotransport	EPT	BBM
Gly	XT2	SLC6A18	Glycine, sarcosine	2–3 Na^+/1Cl^-/1AA cotransport	LPT	BBM
Imino	IMINO	SLC6A20	Proline, hydroxyproline	2–3 Na^+/1Cl^-/1AA cotransport	EPT and LPT	BBM
Beta	TAUT	SLC6A6	Taurine, β-alanine	2–3 Na^+/1Cl^-/1AA cotransport	LPT	BBM
	BGT-1	SLC6A12	betaine, GABA,			
II. Cationic						
$b^{0,+}$	rBAT/$b^{0,+}$ AT	SLC3A1/ SLC7A9	Cationic and neutral (including cystine)	AA antiport	EPT and LPT	BBM
y^+L	4F2hc/y^+LAT-1	SLC3A2/ SLC7A7	Cationic and neutral (excluding cystine)	Na^+-dependent AA antiport	EPT	BLM
	4F2hc/y^+LAT-2	SLC3A2/ SLC7A6				
y^+	CAT 1	SLC7A1	Cationic and neutral (excluding cystine)	AA uniport (facilitative transport)	EPT and LPT	BLM
III. Anionic						
X^-_{AG}	EAAT 3, 2	SLC1A1, 2	Anionic	3 Na^+/1 H^+/AA cotransport 1 K^+-antiport	LPT	BBM

EPT – Early proximal tubule (S1, S2 segments); LPT – Late proximal tubule (S3 segment); BBM – Brush border membrane; BLM – Basolateral membrane

Reabsorption of amino acids in the proximal tubule increases during periods of reduced amino acid intake and decreases with dietary excess (1). This renal adaptive response to diet is expressed at the tubular luminal membrane surface. It has been suggested (26, 29) that both new synthesis of transporter protein and shuttling of preformed transporters are required for expression of the adaptive response. An expression study in *Xenopus*

oocytes (30) has demonstrated that the rat renal taurine transporter is regulated by dietary taurine at the level of both mRNA accumulation and protein synthesis.

Amino acids are known to serve as regulatory osmolytes in mammalian cells, including kidney cells (31–33). The main amino acids involved in this function are taurine, proline, and glutamic acid (31, 32, 34). Studies using MDCK cells, a cell line of distal tubular origin, demonstrate changes in taurine transport in response to changes in osmolarity of the medium (35). It has been shown that osmotic regulation of taurine transport depends on changes in taurine transporter gene expression (36).

Serine/threonine protein kinases play a central role in signal transduction by phosphorylating and thereby activating effector proteins (37, 38). It has been shown that the three main groups of serine/threonine protein kinases, namely cyclic adenosine monophosphate (cAMP)-dependent protein kinase (protein kinase A: PKA), Ca^{2+}- and phospholipid-dependent protein kinase (protein kinase C, or PKC), and multifunctional Ca^{2+}/calmodulin-dependent protein kinase II (CaMK II) alter amino acid transport across the tubular brush-border membrane (39–41). However, the exact role of protein kinase-induced phosphorylation in renal tubular amino acid transport remains to be established.

Molecular Structure of Amino Acid Transporters

Extensive efforts to isolate and identify the amino acid transport proteins in various tissues, including the kidney, have been largely unsuccessful. The isolation and molecular characterization of amino acid carrier proteins has been hindered by their very low abundance in the membrane, their poor stability in vitro, and the lack of specific tight-binding labels or inhibitors. Indirect approaches such as solubilization of proteins by organic solvents and incorporation into proteoliposomes, lectin-affinity chromatography, immunoprecipitation using monoclonal antibodies, and radiation inactivation analysis (42, 43) have yielded little structural data. Over the past two decades, however, by using molecular biology techniques, much progress has been made in elucidating the molecular structure of various membrane-bound transport proteins, including amino acid transporters. This new area in the study of brush-border membrane transporters was pioneered by Hediger et al. (44), who cloned the small intestinal Na^+-glucose cotransporter using the powerful method of expression cloning in *Xenopus* oocytes. This strategy involves isolation of mRNA from the tissue of interest, microinjection into *Xenopus* oocytes, and analysis of expressed transport activity by measuring uptake of radiolabeled substrate. After size fractionation of mRNA, cDNA synthesis, and cDNA library screening by functional expression in oocytes, a single clone encoding the transporter activity is isolated. A similar approach has been used to clone, functionally express, and sequence various amino acid transporters. This has led to the classification of amino acid transporters based on gene homology using the solute carrier family (SLC) nomenclature introduced be the Human Genome Organization (HUGO) (45).

The scquence homology and structural features of amino acid transporters have led to their categorization into seven different gene families (3, 6, 23, 24, 46–48): The SLC6 family (Na^+- and $C1^-$-dependent and "orphan" transporters), the SLC1 or EAAT/ASCT family (Na^+-dependent anionic/neutral amino acid transporters), the SLC36 or PAT family (proton-coupled imino acid transporters), the SLC7 or CAT family (cationic amino acid transporters), the SLC3/SLC7 or HAT family (cationic/neutral amino acid transporters), the SLC38 or SNAT family (Na^+-coupled neutral amino acid transporters), and the SLC16 or TAT family (aromatic amino acid transporters). Investigation of the primary structure of amino acid transporters has elucidated that as opposed to all other SLC families outlined here, which present multiple transmembrane domains (*Fig. 37-2*) and are therefore considered to function as monomeric carriers, members of the SLC3 family do not fit this model (*Figs. 37-3* and *37-4*) and are known to function as components or subunits of heteromeric carriers (see later).

The SLC6 Family (the Na^+- and CI^--Dependent and "Orphan" Transporters)

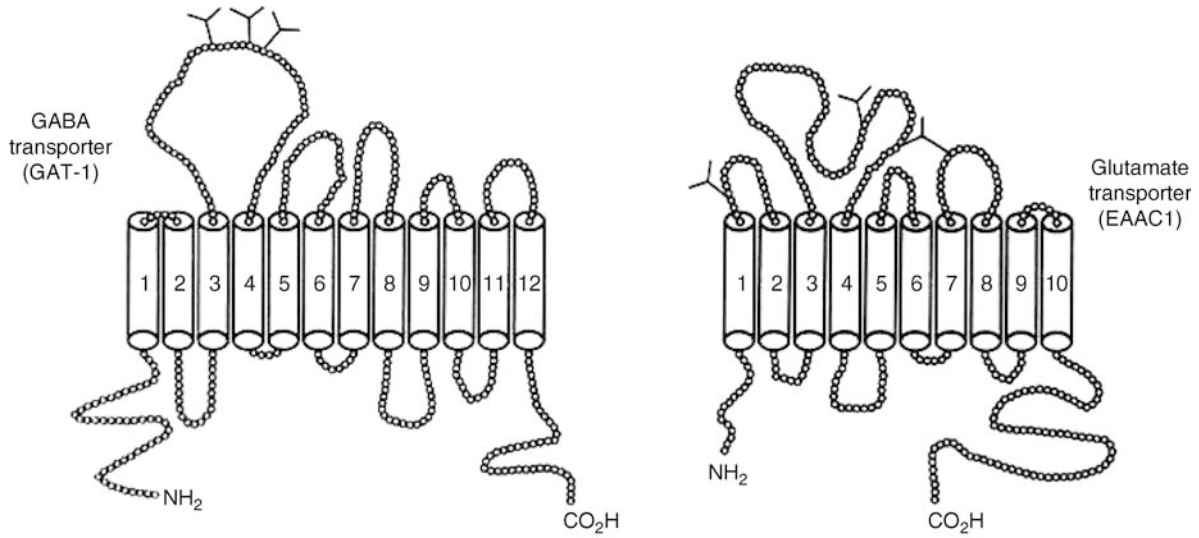
The SLC6 family is a diverse set of amino acid transporters comprising 20 members (51, 52). The family includes, among others, the Na^+- and CI^--dependent transporters for the neurotransmitters GABA (GAT; 53) glycine (GLYT; 54) and proline (PROT; 55), the Na^+- and CI^--dependent transporters for the osmolytes taurine (TAUT; 56, 57) and betaine (BGT; 58) operating in the brain and kidney, as well as a group of "orphan transporters," some of which play an important role in amino acid transport in the kidney (see later).

All these transporters show high homology in sequence and structure, and most of them have an absolute requirement for Na^+ and Cl^-.

The proposed model of the GABA transporter (GAT1; SLC6A1) is shown in *Fig. 37-2*. It is a 655-residue

Figure 37-2

The putative transmembrane orientations of the GABA transporter (GAT-1; SLC6A1), and the glutamate transporter (EAAC1; SLC1A1) are shown as representative of the SLC6 and SLC1 families, respectively, of amino acid transporters (modified with permission from (46)).



protein with a relative molecular mass of 73,925 Da. The predicted secondary structure shows 12 hydrophobic, membrane-spanning domains with a large extracellular hydrophilic loop between spans 3 and 4. The molecular structure contains putative *N*-glycosylation and phosphorylation sites. Recent studies investigating the crystal structure of the Na^+- and Cl^--dependent neurotransmitter transporters (59) and site-directed mutation analysis (60) have identified distinct domains which are similar between the family members and are important in Na^+, Cl^-, and substrate coupling.

The expression and function of various SLC6 family members in the kidney have been extensively investigated. Northern hybridization and polymerase chain reaction analysis have identified two GABA transporter isoforms, called GAT 2 (SLC6A13) and GAT 3 (SLC6A11) (61, 62), as well as glycine transporter isoforms called GLYT 1 (SLC6A9) and GLYT 2 (SLC6A6) (63–65) in the kidney. However, the physiological role of the GAT and GLYT transporters in renal amino acid handling has not been established.

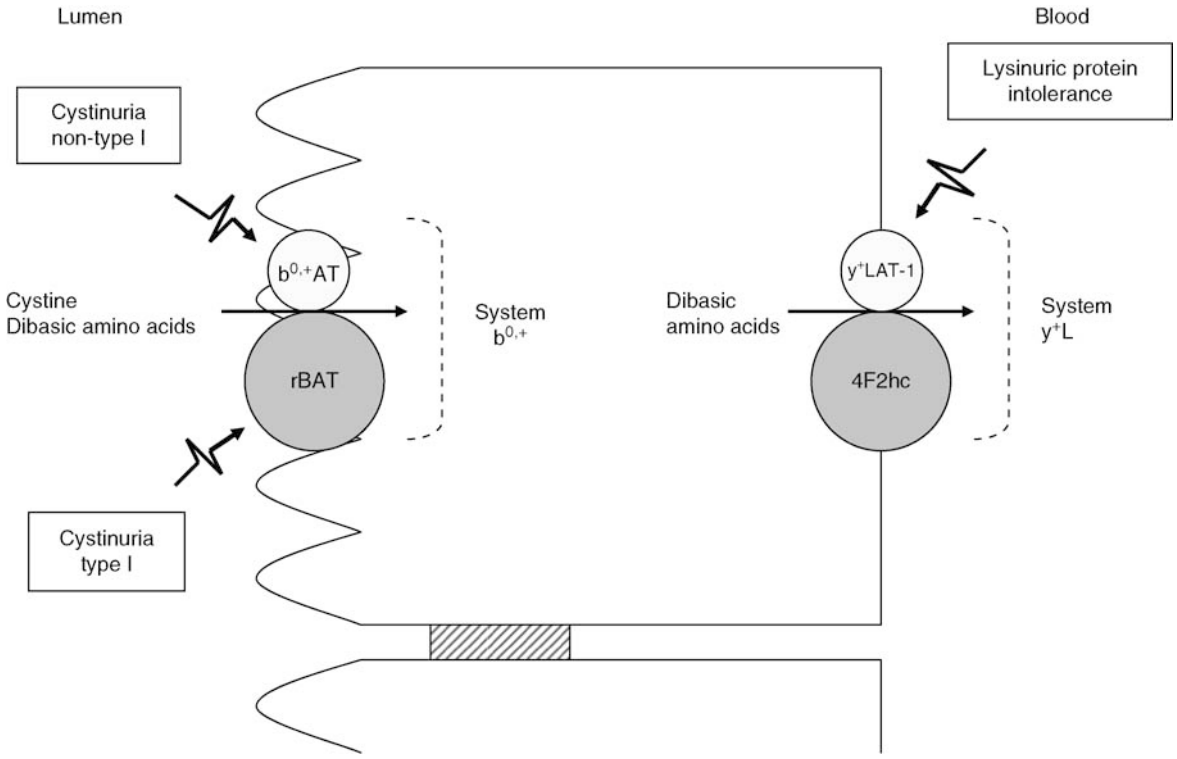
The mRNAs for the Na^+–Cl^- – taurine (TAUT; SLC6A6) and Na^+–Cl^- – betaine (BGT; SLC6A12) transporters are expressed in the kidney medulla (2) and TAUT mRNA is expressed also in the S3 segment of the proximal tubule (57). Both transporters are known to play a major role in cell volume regulation in the renal medulla (32, 35, 57). Upregulation of the activity of these transport systems by tonicity is mediated by a tonicity – responsive enhancer element (TonE) on the promoters of BGT1 (66) and TAUT (67) genes. TAUT and BGT1 (the latter transports also GABA) appear to be the molecular correlates of the amino acid transport system β (see Specificity of Transport).

The "orphan transporters" branch of the SLC6 family has been recently the subject of thorough investigation and several of its members have been cloned and shown to play an important role in amino acid transport in the kidney (3, 6, 48).

Following the mapping of Hartnup disorder to the tip of chromosome 5 (5p 15) (68), Bröer's group focused on a region in the mouse genome (chromosome 13), syntenic with this 5p15 locus in humans, and cloned a new member of the SLC6 "orphan transporters" group termed B^0AT1/SLC6A19 (69). The transporter has been further characterized by flux studies and electrophysiological techniques (70, 71). B^0AT1 has been shown to be the molecular correlate of the major apical neutral amino acid transport system B^0 (see Specificity of Transport). It is a Na^+-dependent but, unlike other SLC6 family members, Cl^--independent transporter (70). Immunohistochemical analysis demonstrated strong expression of B^0AT1 in the

Figure 37-3

Transport pathways for cystine and dibasic amino acids at the luminal and basolateral membranes of a proximal tubular cell. *Large circles* represent the heavy subunits and *small circles* the light subunits of the heteromeric amino acid transporters $b^{0,+}$ and y^+L. Depicted are hereditary aminoacidurias caused by defects in these transporters (modified with permission from (49)).



apical membrane of early segments (S1, S2) of the proximal (convoluted) tubule and intestinal microvilli (69, 72). SLC6A19 has been indeed identified as the mutated gene in Hartnup disorder (see Neutral Aminoaciduria).

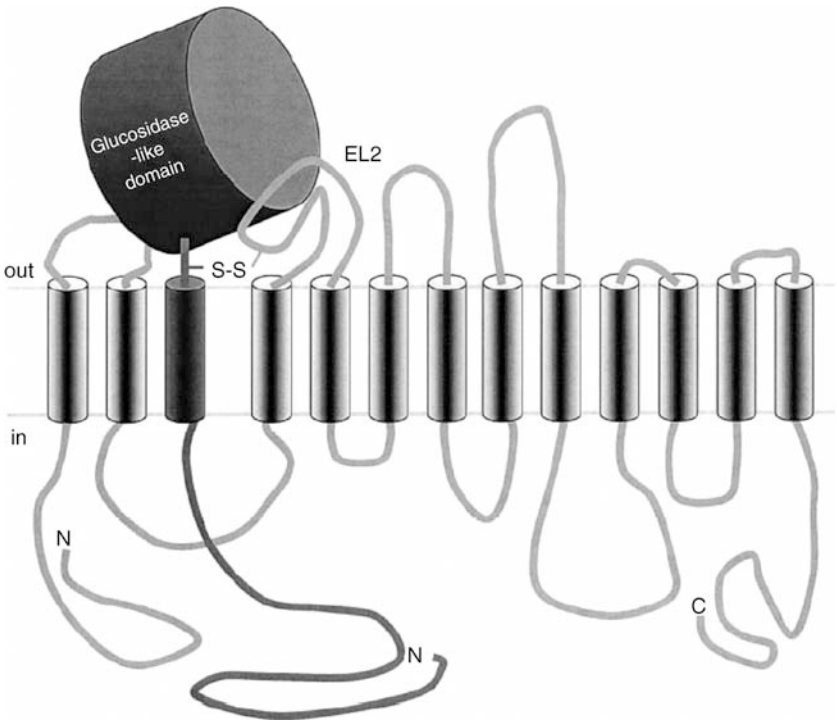
An additional orphan transporters, B^0AT2 (SLC6A15), which is functionally similar and sequence-related to B^0AT1, has been shown to transport branched – chain amino acids and proline and to be expressed in the brain and the kidney (73). Its exact function and localization, however, remain to be established.

Two additional members of the SLC6 "orphan transporter" branch have been recently cloned and characterized:

1. IMINO (SLC6A20, SIT1, XT3), the molecular correlate of system IMINO (see Specificity of Transport) is a high affinity (low Km), Na^+- and Cl^--dependent transporter for proline, hydroxyproline and other *N*-methylated amino acids (but not glycine) (74, 75), and is expressed in the brush border membrane of the early and late proximal tubule and the intestine (72, 74). SLC6A20 has been proposed as a candidate gene for iminoglycinuria (see Iminoaciduria and Glycinuria) (3, 48).
2. XT2 (SLC6A18, ROSIT) is a Na^+- and Cl^--coupled organic solute transporter (ROSIT) in the rat kidney (76) which is expressed in the luminal membrane of the late proximal tubule (S3 segment) (76, 77). XT2 knockout mice show hyperglycinuria as well as decreased glycine transport in BBMV derived from the kidney cortex of these mice (78), suggesting a role for this transporter in renal glycine transport. The potential involvement of SLC6A18 in hereditary iminoglycinuria or isolated glycinuria remains a subject for investigation (see Iminoaciduria and Glycinuria) (3, 48).

Figure 37-4

Schematic representation of the heteromeric amino acid transporters (HAT). The heavy subunit of HAT (HSHAT; *dark gray*) is linked by a disulfide bridge to the corresponding light subunit of HAT (LSHAT; *light gray*). The cysteine residues involved in this bond (S-S) are located extracellularly, just after the transmembrane (TM) domain of HSHAT and in the proposed extracellular loop 2 (EL2) of LSHAT. Loops and TM domains are not drawn to scale. See text for details (adapted with permission from (50)).



The SLC1 Family [Na^+-Coupled Anionic (EAAT)/Neutral (ASCT) Amino Acid Transporters]

This family of transporters is made up of five Na^+-, H^+-, and K^+-dependent, Cl^--independent anionic amino acid transporters and two Na^+-dependent neutral amino acid transporters (3, 23, 24, 79). The anionic amino acid transporters include the GLAST (or EAAT1; SLC1A3) (80), GLT-1 (or EAAT2; SLC1A2) (81), EAAC1 (or EAAT3; SLC1A1) (82), as well as EAAT4 (SLC1A6) (83), and EAAT5 (SLC1A7) (84), which serve as neurotransmitters and show marked similarity in sequence and structure. EAAC1, a neuronal and epithelial high-affinity glutamate transporter, first cloned from rabbit small intestine (82), was also identified in the kidney by Northern hybridization analysis (82). In situ hybridization and immunofluorescence studies revealed that EAAC1 is expressed predominantly in the apical membrane in the S2 and S3 segments of the proximal tubule (85). It mediates transport of glutamate and aspartate and is coupled to $3Na^+$ and $1H^+$ in exchange for $1K^+$ (79).

The proposed model of EAAC1 (*Fig. 37-2*), the prototype of the SLC1 family, shows a protein of 524 amino acids with a predicted molecular mass of 57,000 Da and 10 hydrophobic, membrane-spanning domains. The kinetics and specificity of this protein when expressed in *Xenopus* oocytes were similar to those of the X^-_{AG} transport system (see Specificity of Transport; *Fig. 37-1*). The gene for human EAAC1 (SLC1A1) has been localized to chromosome 9p24 (86). A defect in the EAAC1 gene is a likely, albeit unproven, cause of dicarboxylic aminoaciduria (see Dicarboxylic Aminoaciduria).

The neutral amino acid transporters include the ASCT1 (SLC1A4 or SATT) (87), and ASCT2 (SLC1A5 or AAAT) (88). ASCT1 and ASCT2, which were cloned from human brain (87) and mouse testis (88), respectively, have structural similarity to the anionic amino acid transporter gene group and appear to encode Na^+-dependent neutral amino acid transporters with specificity characteristics

of system ASC (see Specificity of Transport; *Fig. 37-1*). Northern blot analysis (87, 88) revealed ubiquitous expression of these genes in several tissues, including expression in the kidney, consistent with the general metabolic role ascribed to system ASC. While ASCT1 accepts only small neutral amino acids, ASCT2 also transports L-glutamine and L- asparagine at high affinity. In one study (89), ASCT2 has been reported to be expressed in the brush border membrane of the proximal tubule. However, it has been hypothesized that, in line with ASC system properties, ASCT2 is likely involved in transepithelial amino acid transport at the basolateral membrane level (6).

It is noteworthy that the transport systems EAAT1-5 (90), and ASCT1 (91) have a Cl^- channel mode of action in addition to their amino acid transport mode of activity. The Cl^- transport is not thermodynamically coupled to and is not necessary for amino acid translocation (79).

The SLC36 Family (Proton-Coupled Imino Acid Transporters; PAT)

The SLC36 family comprises several, recently identified proton-coupled amino acid transporters operating in the lysosomal and plasma membrane of cells (3, 92). The first member of the SLC36 family, SLC36A1, was identified independently as a lysosomal amino acid transporter (LYAAT1) in rat brain responsible for the export of lysosomal proteolysis products into the cytosol (93) and as a proton –amino acid transporter (PAT1) responsible for amino acid absorption in the gut (94, 95).

The proton–amino acid transport activity of PAT1 is electrogenic and operates with a stoichiometry of 1:1 (94). PAT1 transports proline, glycine, alanine as well as GABA at low affinity (high Km) and is expressed in several organs including brain (mainly lysosomes), liver, small intestine and kidney. The PAT1 protein was found apically in small intestinal Caco-2 cells (96). PAT1 appears to be the major shared imino acid/glycine carrier expressed in the brush border membrane of the small intestine and the kidney proximal tubule (6, 48) and corresponds to the H^+ gradient-driven proline (4) and glycine (5) transport demonstrated in renal BBMV. It is noteworthy that the H^+ gradient (luminal > intracellular) necessary for PAT1-mediated amino acid transport into the epithelial cell is likely generated by the activity of the Na^+/H^+ exchanger operating in the luminal membrane (6, 92).

Based on its substrate specificity, PAT1 has been proposed, like SLC6A18 and SLC6A20 (see earlier), as a candidate for the transporter mutated in iminoglycinuria (see Iminoaciduria and Glycinuria) (3, 48).

An additional member of the PAT family, PAT2 (SLC36A2), has significant sequence and functional similarity to PAT1 (94, 97). PAT2 is, however, expressed in the kidney, but not the intestine (92), and its physiological role remains to be determined.

The SLC7 (CAT) Family

The SLC7 family is divided into two subgroups: (1). Cationic amino acid transporters (CAT; SLC7A1–4) (98, 99) (discussed in this section), and (2). The glycoprotein-associated amino acid transporters (SLC7A5–11) also called the light subunits of the heteromeric amino acid transporters (LSHAT) (99, 100) are discussed in the next section. The associated glycoproteins (heavy chains) form the SLC3 family (101). The heavy (SLC3) and light (SLC7A5–11) subunits combined to the heteromeric amino acid transporters (HAT) constitute the distinct SLC3/SLC7 family (see later).

The CAT genes were the first mammalian amino acid transporters cloned (47, 98). Expression studies in *Xenopus* oocytes identified the ecotropic murine leukemia virus as the ubiquitous y^+ system (now called CAT1; SLC7A1), a Na^+-independent transport system that accepts dibasic amino acids and excludes cystine (102, 103). In addition, it catalyzes transport of neutral amino acids only in the presence of Na^+ (23) (*Fig. 37-1*). Northern hybridization analysis revealed the CAT1 gene in various mouse tissues including the kidney (102). Since then, four other homologous murine cDNAs have been found to express a similar y^+ system amino acid transport activity, namely CAT2A, CAT2B, CAT3 and CAT4 (SLC7A2–4), which are not expressed in the kidney (23, 47, 98, 104). The CAT transporters allow accumulation of cationic amino acids within the cell for general metabolic purposes. CAT-mediated arginine flux into cells plays a role in modulating nitric oxide synthesis in various cell types including kidney cells (98, 104, 105). The CAT1 cDNA predicts a 629 amino acid protein with 14 membrane-spanning domains and a molecular mass of 68,000 Da.

The SLC3/SLC7 Family (HAT)

As indicated earlier, the heteromeric amino acid transporters (HAT) are composed of a heavy subunit (SLC3; HSHAT) and a light subunit (SLC7; LSHAT) (98, 99).

1. *The SLC3 (rBAT/4F2hc; HSHAT) Family*: To gain insight into the transport defect in cystinuria, research has focused on the molecular structure of the family of carrier proteins responsible for transport of cystine and other dibasic amino acids. Several groups have demonstrated the expression of cystine (106) and dibasic and neutral amino acids (107–109) in *Xenopus* oocytes injected with mRNA of small intestine and kidney. In 1992 (110, 111), kidney cortex cDNAs from rabbit and rat (named rBAT (110) and D2 (111), respectively) have been cloned. Upon in vitro transcription to cRNA and injection into oocytes, they induce system $b^{0,+}$, the Na^+-independent transporter for neutral amino acids, dibasic amino acids, and cystine (see Specificity of Transport; *Figs. 37-1* and *37-3*). The predicted proteins for rBAT and D2 demonstrate significant homology with a family of the carbohydrate-metabolizing enzymes α-glucosidases. Similarly, cRNA from the human 4F2 heavy chain (4F2hc) surface antigen, a glycoprotein highly regulated at the onset of cell proliferation, stimulated system y^+L amino acid transport (see Specificity of Transport; *Figs. 37-1* and *37-3*) in *Xenopus* oocytes (112).

The rBAT cDNA contains an open reading frame of 2,049 nucleotides coding for a protein of 685 amino acids with a molecular mass of about 90,000 Da (47). The predicted proteins for rBAT and D2, as well as the 4F2 heavy chain antigen (all of which show high structural similarity), were found to contain only one putative membrane-spanning domain (23, 101). This structure, which is atypical of the known membrane transport proteins, raised the possibility that these proteins function as activators of transport systems y^+L and $b^{0,+}$ or as regulatory subunits of these transporters. The functional promoter of the rat rBAT gene has been identified (113), and the gene for the human rBAT, named D2H, was localized to chromosome 2p21 (113, 114). The human rBAT (D2H) gene has been termed SLC3A1 (see later).

In situ hybridization and immunolocalization studies have localized rBAT mRNA expression in the brush border membrane of the proximal straight tubule (S3 segment) and the small intestinal mucosa (115, 116). In contrast to rBAT, 4F2hc mRNA is almost ubiquitous with marked expression in kidney, where it localizes to the basolateral membrane of proximal tubular cells (23). The human 4F2hc gene has been termed SLC3A2. Studies from several laboratories have demonstrated that both rBAT and 4F2hc are type II membrane glycoproteins, which constitute heavy subunits of heteromeric amino acid transporters (HSHAT) (50, 117–119). These studies showed that rBAT (90 kDa) and 4F2hc (85 kDa) associated by disulfide bridges with a light subunit (40 kDa) forming a heterodimeric complex of 125 kDa (50, 101, 119) (*Fig. 37-4*).

2. *The SLC7 family (LSHAT)*:The light subunit of rBAT, termed $b^{0,+}$ AT, (SLC7A9), and the light subunit of 4F2hc, termed y^+LAT-1 (SLC7A7), which were identified in 1998–1999 (120–122), are members of the family of light subunits of the heteromeric amino acid transporters (LSHAT) (50, 99, 100, 119). To date, nine members of the LSHAT family have been identified (99, 100). Recent research on the characteristics of LSHATs (50, 99) has revealed that they are unglycosylated proteins, which contain 12 putative transmembrane domains (*Fig. 37-4*), they need coexpression with the corresponding heavy subunit to reach the plasma membrane, they confer the specific amino acid transport activity to the heteromeric complex and, finally, all the amino acid transport activities associated with the LSHATs behave as amino acid exchangers (50, 99, 119, 123–125). In the kidney, the apical membrane-bound system $b^{0,+}$ (induced by rBAT and $b^{0,+}$ AT; *Figs. 37-1* and *37-3*) acts as tertiary active exchange mechanism of tubular reabsorption of dibasic amino acids and cystine. This tertiary transport mechanism is linked to a high intracellular concentration of neutral amino acids (*Fig. 37-1*). System $b^{0,+}$-mediated efflux of neutral amino acids from renal epithelial cells is the driving force for cystine and cationic amino acid reabsorption from lumen to cell (118, 126, 127) (*Fig. 37-1*). Reabsorption of cystine and cationic amino acids is also favored by the intracellular negative membrane potential and by the reduction of cystine to cysteine (*Fig. 37-1*) (118, 127). The basolateral membrane-bound system y^+L (induced by 4F2hc and y^+LAT-1; *Figs. 37-1* and *37-3*) mediates an electroneutral exchange mechanism in which efflux of cationic amino acids (against the intracellular negative voltage) is enhanced by the influx of neutral amino acids in the presence of Na^+ (*Fig. 37-1*) (118, 127). The tissue distribution of rBAT/$b^{0,+}$ AT and 4F2hc/y^+LAT-1 and their role in renal uptake of cystine and dibasic amino acids have made them candidates for the defective genes in cystinuria and lysinuric protein intolerance, respectively (see Cationic Aminoaciduria).

The family of LSHATs includes, among others, the light subunits LAT-1(SLC7A5) and LAT-2 (SLC7A8) that combine with 4F2hc (SLC3A2) to form the L system (see Specificity of Transport; *Table 37-1*; *Fig. 37-1*). The 4F2hc/LAT2 transporter is an obligatory exchanger found in the basolateral membrane of the intestine and the kidney proximal tubule (128). The transporter has a broad substrate specificity including all neutral amino acids except proline (129). A study using the proximal

tubular cell line, OK, has demonstrated that 4F2hc/LAT2 mediates basolateral efflux of L-cysteine (130). This finding suggests that this transporter may play an important role in exchanging intracellular cysteine for extracellular neutral amino acids thereby participating in the transepithelial flux of cysteine in the proximal tubule (3, 6).

Two additional members of the LSHATs include asc1 (SLC7A10) (131) and xCT (SLC7A11) (132) both of which combine with the heavy subunit 4F2hc (SLC3A2) to form the basolateral membrane-bound amino acid transport system asc and x_c^-, respectively. 4F2hc/asc1 is expressed in the loop of Henle, distal tubule and collecting duct, but not in the proximal tubule (133), where it functions as a Na^+-independent exchanger of small neutral amino acids, thereby contributing to the nutritional supply and/or osmotic adaptation of kidney cells (3, 133). 4F2hc/xCT is a Na^+- independent exchanger for anionic amino acids that is expressed in plasma membrane of various cells including kidney cells (132, 134). Cystine/glutamate exchange mediated by this transporters plays an important role in controlling the intracellular level of glutathione which protects the cell against oxidative stress (134). These two biologically important transporters do not appear to be involved in reabsorbing the bulk of amino acids in the proximal tubule.

The SLC 38 (SNAT) Family

The recently cloned Na^+-coupled neutral amino acid transporters (SNAT; SLC38) are the molecular correlates of system A and system N activities (135) (see Specificity of Transport), as follows:

1. The system A subfamily includes SNAT1(SLC38A1), SNAT2 (SLC38A2) and SNAT4 (SLC38A4) subtypes of which only the latter two are expressed in the kidney (3, 135). Hydropathy analysis of SNAT1 sequence predicts a transporter with 11 transmembrane domains (135). System A transports small neutral amino acids (in particular alanine, serine and glutamine) in an electrogenic and pH-sensitive mode with a Na^+: amino acid stoichiometry of 1:1 (135). SNAT3 is expressed in the medulla and, to a lesser extent, in the cortex of the kidney (136) and is upregulated by amino acid deprivation (137). SNAT2 and SNAT4 most likely localize to the basolateral membrane to provide amino acids to renal cells (2) (*Fig. 37-1*).
2. The system N subfamily includes, among others, SNAT3 (SLC38A3) and SNAT5 (SLC38A5) both of which are expressed in the kidney (3, 135). Substrates for system N include glutamine, asparagine, and histidine (3). SNAT3 operates with coupling stoichiometry of 1 Na^+:1 glutamine in exchange for 1 H^+ (138). It is expressed in the basolateral membrane of the late (S3 segment) proximal tubule (139) (*Fig. 37-1*). Recent studies have demonstrated a marked induction in renal SNAT3 mRNA level (140, 141) and increased uptake of glutamine (NH_4 precursor) by renal cortical membrane vesicles (140) of acidotic rodents, providing evidence that this transporter plays an important role in the renal adaptive response to metabolic acidosis.

The SLC 16 (TAT) Family

The aromatic amino acid transporter TAT1 (SLC16A10), which was cloned in 2001 (142), is the molecular correlate of system T (see Specificity of Transport) (143). It is a member of the SLC16 family of monocarboxylate transporters (143). TAT 1, which is a protein of 534 amino acids with 12 transmembrane domains, is expressed in the basolateral membrane of the proximal convoluted tubule (144) and functions as an electroneutral, Na^+- and H^+-independent facilitative diffusion (uniport) system mediating efflux of aromatic amino acids across the basolateral membrane (144) (*Fig. 37-1*). A recent study has provided evidence that TAT1 can also control neutral amino acid efflux via the neighboring exchanger 4F2hc-LAT2 by recycling the aromatic influx substrates of the exchanger (145).

Future investigations into the molecular and biochemical characteristics of this expanding group of cloned amino acid transporters may yield important insight into the inherited human diseases that result from a defective transport of amino acids (see Hereditary Aminoacidurias).

Maturation of Tubular Amino Acid Transport

Urinary fractional excretion of almost all amino acids in humans (146) and animals (8) is higher in the newborn than later in life. A very high rate of urinary amino acid excretion is found in immature, very-low birth weight infants (147). Some amino acids, including glycine, alanine, proline, dibasic amino acids, and taurine (8, 147), have been shown to contribute more to neonatal aminoaciduria than other amino acids. Theoretically, a structural, quantitative, or regulatory change in any one

of the membrane-related events depicted in *Fig. 37-1* may underlie the diminished reabsorptive capacity of the renal tubule during early life (8, 9).

As indicated earlier, (see Specificity of Transport), proline and glycine reabsorption in the proximal tubule occurs predominantly by a shared low-affinity/high-capacity transport system in the proximal convoluted tubule (likely PAT2/SLC36A2) as well as by two specific, high-affinity/low-capacity systems located in the proximal straight tubule, one for proline (likely IMINO/SLC6A20) and one for glycine (likely XT2/SLC6A18) (1, 3, 10, 48). Lasley and Scriver studied infants affected with familial renal iminoglycinuria to explore the ontogeny of proline and glycine reabsorption in the renal tubule (148). In iminoglycinuria the shared transport system for proline and glycine (possibly PAT1), which normally seems to be the dominant transporter for these amino acids in the proximal tubule of the newborn, is affected by mutation (see Iminoaciduria and Glycinuria). Using the occurrence of ontogeny and transport defect together, Scriver's group provided evidence for the appearance of the two specific high-affinity transport systems in succession, the proline transporter (possibly IMINO) by 3 months of age and the glycine transporter (possibly XT2) by 6 months of age (148). Similarly, earlier studies on glycine and proline transport in rat renal cortical slices (8) showed that the specific high-affinity transporters were not present at birth yet appeared when amino acid reabsorption reached adult levels. In contrast, subsequent animal studies demonstrated the existence of both low-affinity/high-capacity and high-affinity/low-capacity systems for several amino acids (8) in neonatal and adult kidneys; no new systems were acquired with maturation.

Studies using cortical slices and isolated tubules from several species have provided evidence for an impaired basolateral membrane exit step of amino acids from immature tubular cells (8). Decreased Na^+-dependent taurine transport has been demonstrated in basolateral membrane vesicles from hypertaurinuric mice (149). It remains to be established whether a similar alteration in basolateral membrane amino acid transport during early life contributes to neonatal hyperaminoaciduria.

Several studies explored the maturation of the first step of amino acid reabsorption, namely transport across the brush-border membrane. A gradual age-related increase in Na^+-coupled uptake of taurine (150) and proline (151) by rat renal BBMV and of cystine by isolated dog renal cortical tubules (152) has been demonstrated. Whereas the maturation of proline transport involved an increase in affinity (decrease in K_m) of transport (151), the maturation of cystine transport was associated with an increase in capacity (increased V_{max}) of transport (152).

Alterations in phospholipid composition have been documented during rat tubular brush-border membrane maturation (8), suggesting that changes in membrane fluidity may account for the observed maturational changes in Na^+-linked tubular amino acid transport. In addition, an increased permeability to Na^+ (151) and an enhanced amiloride-sensitive Na^+–H^+ exchange activity (153) has been demonstrated in neonatal rat renal BBMV. This alteration in ionic permeability and the increased luminal membrane Na^+–H^+ antiport (coupled with a diminished Na^+–K^+-ATPase activity known to exist in the basolateral membrane of the neonatal proximal tubular epithelium (154)) may result in a rapid dissipation of the electrochemical Na^+ gradient necessary for Na^+-amino acid cotransport, thereby contributing to the aminoaciduria of early life (151, 153).

Protein kinases modulate renal tubular amino acid transport (see above). Recent studies (38, 155) demonstrate higher activity of PKC and CaMK II in the cytosol and the brush-border membrane derived from immature kidneys than in adult kidneys. Furthermore, the studies provide evidence for differential regulation of PKC (155) and CaMK II (38) isoenzymes during kidney development. Age-related changes in the activity and expression of protein kinases may underlie the developmental changes in tubular reclamation of amino acids and other solutes.

In summary, hyperaminoaciduria is a characteristic of the immature mammalian tubule. Although the mechanisms governing the developmental changes in tubular amino acid transport have not been fully established, evidence has accumulated that both luminal and antiluminal membrane-related events play a role in the maturation of amino acid transport. Most studies indicate that transport maturation does not represent the acquisition of new transport systems but rather a change in affinity or capacity of transporters. The role of protein kinase-induced phosphorylation in the maturation of renal tubular amino acid transport remains to be established. The exact cellular mechanisms and the biologic signals responsible for the observed developmental changes await future studies. Studies into the molecular structure of amino acid transporters will undoubtedly shed light on the mechanisms underlying the development of tubular amino acid reclamation.

Hereditary Aminoacidurias

Aminoacidurias are a group of disorders in which a single amino acid or a group of amino acids are excreted in excess amounts in the urine. The defective tubular reabsorption is assumed to result from a genetic defect in a

specific transport system that directs the reabsorption of these amino acids under normal conditions. Some of these disorders also involve a similar transport abnormality in the intestine. As opposed to inborn errors of amino acid metabolism, in which plasma levels of amino acids are elevated, resulting in overflow aminoaciduria, plasma levels of amino acids in hereditary aminoacidurias are largely normal.

The aminoacidurias are generally categorized into five major groups according to the group-specific transport pathway presumed to be affected (*Table 37-2*). The groups are further subdivided into several disorders, based on the profile of the affected amino acids within that group (*Table 37-2*; *Fig. 37-1*).

Cationic Aminoaciduria

Five distinct inborn errors of cationic amino acid transport have been identified: (1) classic cystinuria, (2) isolated cystinuria, (3) hyperdibasic aminoaciduria, (4) lysinuric protein intolerance, and (5) isolated lysinuria. These diseases differ in defined or putative transport systems affected, pathophysiology, organs involved, and clinical features. Classic cystinuria is the prototype for this group of hereditary aminoacidurias.

Classic Cystinuria: Cystinuria is a disorder of amino acid transport characterized by excessive urinary excretion of cystine and the dibasic amino acids lysine, arginine, and ornithine. The pathogenic mechanism of cystinuria is defective transepithelial transport of these amino acids in the proximal tubule and the small intestine (156, 157). The very low solubility of cystine in the urine results in cystine stone formation in homozygous patients. Lysine, arginine, and ornithine do not form urinary stones. Urinary cystine calculi may produce considerable morbidity including urinary obstruction, colic, infection, and in severe cases, loss of kidney function. Cystinuria accounts for 1–2% of all urolithiasis and 6–8% of urolithiasis in children (158, 159). The defective gastrointestinal transport of cystine and dibasic amino acids in cystinuria does not result in intestinal disease.

The disease was first recognized in 1810 by Wollaston (160) and later by Berzelius (161), who called the stones "cystic oxide" and "cystine," respectively, assuming that the stones they analyzed originated in the bladder. In 1908, Garrod (162) postulated that cystinuria was an inborn error of cystine metabolism. In the 1950s, Dent and Rose (163) first recognized the true nature of the disease, suggesting that cystine and the dibasic amino acids lysine, arginine, and ornithine that have structural similarity (two amino groups separated by 4–6 chemical bonds) share a carrier protein in the brush-border membrane of the renal tubule and the small intestine. They postulated that this transport mechanism was defective in cystinuria.

Transport Defect: Normally 1% of the filtered cystine and dibasic amino acids is excreted. In classic cystinuria, cystine clearance may be near or equal to the glomerular filtration rate (GFR), and in some patients even twice as high as the GFR, suggesting active cystine secretion (164). Lysine and ornithine clearance is 30–80% of the GFR, and arginine excretion is less abnormal.

Dent's postulate about a defective shared transport system for cystine and dibasic acids in cystinuria has been supported by the in vivo experiments of Kato (165) and Robson and Rose (166), demonstrating that in normal subjects and cystinuric patients, increasing the filtered load of one of these amino acids decreased reabsorption of the others. However, this hypothesis was challenged by studies showing that cystine uptake was not impaired in kidney slices from cystinuric patients (167) and that cystine and dibasic amino acids did not share a common transport system in kidney slices of normal and cystinuric patients (167). The reports of isolated cystinuria (168), isolated dibasic aminoaciduria (169), and isolated lysinuria (170) cast further doubts on Dent's hypothesis and suggested the existence of specific transport systems for these amino acids. Furthermore, the occurrence of several transport systems for cystine and dibasic amino acids was supported by the observations of Brodehl (146) and Scriver (171) that tubular reabsorption capacity matures at different rates for different amino acids.

Subsequent studies using isolated cortical tubules and BBMV (16, 17, 172) have clarified the picture of tubular amino acid transport. These studies, coupled with the recognition that kidney slices preferentially expose the basolateral membrane, provided evidence for three brush-border membrane-bound and two basolateral membrane-bound carrier systems for cationic amino acids in the kidney. Transport at the brush-border membrane occurs by a system shared by cystine and the dibasic amino acids, a system specific for cystine, and a system specific for dibasic amino acids. It is the shared high-affinity, low-K_m system located in the S3 segment of the proximal tubule and identified as system $b^{0,+}$ (see Specificity of Transport; *Figs. 37-1* and *37-3*), that is defective in classic cystinuria. The low-affinity, high-K_m, unshared cystine system, and the low-affinity, unshared dibasic amino acid system, both located in the S1-S2 segments of the proximal tubule (and both unidentified at the molecular level) may be abnormal in isolated cystinuria and dibasic aminoaciduria, respectively (see later). The antiluminal membrane harbors two specific

Table 37-2

Hereditary aminoacidurias

Disorder	Defective gene	Locus	Amino acid transport system defective	Individual amino acids affected	Localization of defect	Mode of inheritance	Prevalence	Clinical manifestations	Organs involved	OMIM No.[a]
I. Cationic aminoaciduria										
1) Classic cystinuria Type I	SLC3A1	2p16.3	rBAT (heavy subunit of $b^{0,+}$)	Cystine, lysine, arginine, ornithine	BBM	Autosomal recessive	1:7,000–1:15,000	Urolithiasis	Kidney, intestine	220100
Non-type I	SLC7A9	19q13.1	$b^{0,+}$ AT (light subunit of $b^{0,+}$)		BBM	Autosomal dominant (incomplete penetrance)				600918
2) Isolated cystinuria			Cystine	Cystine	BBM	Autosomal recessive	2 siblings reported	Benign	Kidney	238200
3) Hyperdibasic aminoaciduria Type I			Dibasic amino acids	Lysine, arginine, ornithine	BBM	Autosomal dominant	2 families reported	Mental retardation	Kidney, intestine	222690
4) Lysinuric protein intolerance (Hyperdibasic aminoaciduria Type II)	SLC7A7	14q11	y^+LAT-1 (light subunit of y^+L)	Lysine, arginine, ornithine	BLM	Autosomal recessive	1:60,000 (Finland)	Protein malnutrition, failure to thrive, hyperammonemia, seizures, coma	Kidney, intestine, lungs, bones	222700
5) Isolated lysinuria			Lysine (?)	Lysine	BBM (?)	Autosomal recessive	1 patient reported	failure to thrive, seizures, mental retardation	Kidney, intestine	

II. Neutral Aminoaciduria										
1) Hartnup Disease	SLC6A19	5p15.33	B^0(neutral, monoamino monocarboxylic α-amino acids)	Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine tyrosine, tryptophan, histidine, glutamine, asparagine	BBM	Autosomal recessive	1:20,000	Skin rash, cerebellar ataxia, psychiatric illnesses	Kidney, intestine	234500
2) Methioninuria			Methionine	Methionine	BBM	Autosomal recessive	2 cases reported	Edema, seizures, mental retardation	Kidney, intestine	250900
3) Histidinuria			Histidine	Histidine	BBM	Autosomal recessive	4 cases reports	Mental retardation	Kidney, intestine	235830
III. Iminoaciduria and Glycinuria										
1) Imino-glycinuria	SLC36A1 (PAT1) (?)	5q33.1	Imino acids, and glycine	Proline, hydroxyproline, glycine	BBM	Autosomal recessive	1:15,000	Benign	Kidney, intestine	242600
	SLCA20 (IMINO) (?)	3p21.3								
2) Isolated glycinuria	SLC6A18 (XT2) (?)	5p15.33	Glycine	Glycine	BBM	Autosomal dominant	2 families reported	Benign	Kidney	138500
IV. Dicarboxylic aminoaciduria	SLC1A1 (EAAT3) (?)	9q24	X^-_{AG} (acidic amino acids)	Glutamate, aspartate	BBM	Autosomal recessive	1:29,000 (French-Canadian)	Benign	Kidney, intestine	222730
V. β-amino-aciduria (mouse)			β-amino acids	Taurine	BLM (?)	Autosomal recessive		Benign	Kidney	

BBM brush border membrane; *BLM* basolateral membrane

systems, one for dibasic amino acids identified as system y^+L (see Specificity of Transport; *Figs. 37-1* and *37-3*), and one for cystine, but no shared system. These transport mechanisms mediate uptake and efflux of these amino acids across the basolateral membrane. The brush-border membrane of the intestinal cell has a single high-affinity, low-K_m, shared $b^{0,+}$ transport system for cystine and dibasic amino acids that is defective in classic cystinuria. Like kidney cells, intestinal cells have two basolateral membrane-bound, unshared specific transport systems, one (system y^+L) for dibasic amino acids and one for cystine (2, 3). The basolateral membrane-bound y^+L transporter for dibasic amino acids in the kidney and the intestine is defective in lysinuric protein intolerance (see Lysinuric Protein Intolerance). Amino acid transport in parenchymal cells and leukocytes from cystinuric patients is not impaired (2, 3) because the defect is not expressed in the plasma membrane of these cells.

Genetics: Classic cystinuria is inherited in an autosomal-recessive fashion. It is a common disorder with an overall prevalence of 1:7,000 to 1:15,000 and estimated gene frequency of 0.01 (156). A very high prevalence, 1:2,500, is observed in Israeli Jews of Libyan origin (173).

Although it is a recessive disease, phenotypic heterogeneity in homozygotes and heterozygotes is evident. The excretion patterns of cystine and dibasic amino acids in heterozygotes have delineated the traditional classification into three cystinuric subtypes (174). In type I, the most common phenotype, heterozygotes have normal urinary amino acid excretion. In type II, heterozygotes have high excretion of cystine and dibasic amino acids. Type III heterozygotes have excretion rates intermediate between the other two. The three subtypes were considered to be allelic, namely mild, moderate and severe mutations at a single cystinuria gene locus (15). However, Goodyer et al. (175) provided evidence that type I and type III cystinuria mutations might involve two distinct genetic loci. This was demonstrated by the finding that type I/III compounds excreted less cystine than type I/I probands, although type III/N heterozygotes excrete higher levels of cystine than their type I/N counterparts. These findings could be explained by genetic complementation between nonallelic cystinuria genes. Subsequent genetic studies have supported this hypothesis (see later – Molecular Genetics) and have resulted in a revision of the above classification of cystinuria to type I (OMIM # 220100) and non-type I (OMIM # 600918) (100, 157) (*Table 37-2*). While type I cystinuria is inherited as a fully recessive trait, type II and type III (collectively now termed non-type I) subtypes are inherited as autosomal domainant traits with incomplete penetrance (100).

Renal ontogeny has important implications for genetic counseling in cystinuria. This was demonstrated by Scriver's finding that heterozygous infants under 6 months of age who have immature tubular function can excrete cystine and dibasic amino acids at levels equivalent to those found in homozygous adults (171). Urinary excretion of these amino acids decreased steadily with age, to reach the variant parental value in heterozygous infants, but not in homozygotes. Hence, final classification of a cystinuric phenotype should not be done before the age of 6 months.

Molecular Genetics: The identification and characterization of the rBAT/D2H gene have led to the speculation that a defect in the human form of rBAT (SLC3A1) causes cystinuria. Pras et al. (176), using linkage analysis in 17 cystinuric families, demonstrated linkage between cystinuria and three genetic markers on chromosome 2p, providing strong evidence that SLC3A1 was indeed the gene causing the disease. Calonge et al. (177) identified six specific mutations in the SLC3A1 gene that segregated with a cystinuria phenotype thereby establishing the rBAT gene as the cystinuria gene (*Fig. 37-3*). Subsequent studies over the past decade have revealed numerous additional mutations in SLC3A1 (178–181). To date, over 100 different rBAT mutations have been reported in patients with type I cystinuria (100, 181). These mutations include nonsense, missense, splice site, frameshift mutations, as well as large deletions and chromosome rearrangements (100, 156, 181, 182). A recent exhaustive mutation analysis on 164 probands of the International Cystinuria Consortium (ICC) identified 90.5% of the affected alleles in type I cystinuria patients (181). Defective transport of cystine and dibasic amino acids has been demonstrated for many of these mutations when expressed in *Xenopus* oocytes (118). The most commonly occurring mutation is methionine 467 to threonine (M467T), which causes a defect in trafficking to the plasma membrane (49, 183). This trafficking defect, which has also been demonstrated for other rBAT mutations (182, 184), is consistent with the proposed role of rBAT as a chaperon of the corresponding light subunit in the heteromeric amino acid transporter. To date, no SLC3A1 mutations have been found in non-type I patients (180, 181, 185). Recently, a mouse model homozygous for the rBAT mutation D140G, which displays type I cyctinuria with urolithiasis, has been reported (186).

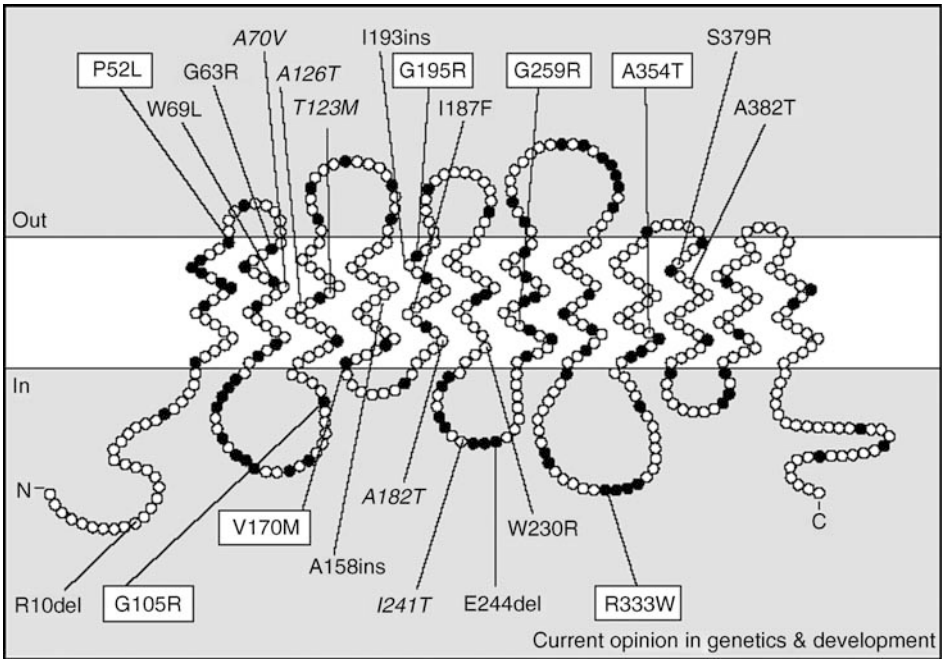
In 1997 Wartenfeld et al. (187) and Bisceglia et al. (188) demonstrated that cystinuria type III (and possibly

also cystinuria type II) is linked to a locus on chromosome 19q13.1. Subsequently, the ICC (189) identified the gene SLC7A9 which encodes the 487 amino acid protein $b^{0,+}$ AT that belongs to the family of light subunits of amino acid transporters (see Molecular Structure of Amino Acid Transporters; *Fig. 37-3*). The gene localized to the non-type I cystinuria 19q locus. Cotransfection of $b^{0,+}$ AT and rBAT in COS cells resulted in trafficking of rBAT to the plasma membrane and induced L-arginine uptake by cells. SLC7A9 mutations were found in Spanish, Italian, North American and Libyan–Jewish cystinuria patients (189, 190). Mutation G105R is the most frequent SLC7A9 mutation in the ICC cohort of patients (100). The mutation in Jews of Libyan origin is valine 170 to methionine (V170M), which leads to complete loss of $b^{0,+}$ AT amino acid uptake activity when cotransfected with rBAT in COS cells. To date, over 60 different $b^{0,+}$ AT mutations have been identified in non-type I cystinuria patients (400, 181) (*Fig. 37-5*). These mutations have explained 87.6% of the alleles in non-type I cystinuria patients of the ICC included in a recent study (181). The unexplained alleles in non-type I (and type I) patients might be due to mutations outside the open reading frame of the SLC7A9 (and SLC3A1) genes (intronic or promoter regions) or due to mutations in unidentified genes (50, 100, 182). Two patients with I/III phenotype had a dual mutation in both SLC3A1 and SLC7A9, suggesting the existence of digenic form of the disease (181, 189).

Interestingly, although most heterozygotes for SLC7A9 mutation show type II or III trait, a minority (about 15%) have type I phenotype (181, 191). Moreover, mutations in SLC7A9 have been shown to cause all three phenotypic subtypes (192). These data, indicating the lack of a direct relationship between the mutated cystinuria gene and the type of cystinuria, have prompted the ICC

Figure 37-5

Representation of the cystinuria-specific missense or single amino-acid point mutations identified in the $b^{0,+}$AT amino-acid transporter. Twenty-three missense or single amino-acid point mutations in *SLC7A9* ($b^{0,+}$AT) are depicted. Amino-acid residues conserved in all the human members of the LSHAT family are indicated in *black*. Mutations that are associated mainly with a severe urinary phenotype in heterozygotes (urine cystine levels similar to or below 200 μmol/g of creatinine and the sum of urine levels of cystine and the three dibasic amino acids similar to or below 1000 μmol/g of creatinine) are boxed. Mutations that are associated mainly with a mild urinary phenotype in heterozygotes (urinary levels of amino acids below the above indicated limits) are indicated in italics. The rest of mutations (with undefined or ambiguous phenotype) are indicated in smaller font. See text for details (adapted with permission from (182)).



to introduce an additional classification of cystinuria subtypes based on genotype rather than phenotype. This new classification includes: Type A – due to two mutations on SLC3A1 on chromosome 2; Type B – due to two mutations on SLC7A9 on chromosome 19; and type AB with one mutation on each SLC3A1 and SLC7A9 (compound heterozygote) (191). The ICC has reported that type A, type B, and type AB account for 38, 47 and 14% of cystinuria patients in their registry, respectively (100, 181).

Similar to the human disease, the SLC7a9 knockout mouse displays non-type I cystinuria with urolithiasis (193). This mouse model (and the cystinuria type I mouse model (186)) may prove to be very important tools in exploring the pathophysiology of cystinuria, the various factors influencing the formation of cystine stones and the efficacy of therapy (194).

Noteworthy is the recently described autosomal recessive disorder, hypotonia-cystinuria syndrome, characterized by generalized hypotonia at birth, failure to thrive, growth retardation and cystinuria type I (195). The syndrome is caused by microdeletions of SLC3A1 and a prolyl oligopeptidase-like gene (PREPL) which are adjacent on chromosome 2p21 (195).

Diagnosis and Clinical Features: The simplest diagnostic test is the microscopic examination of the urinary sediment of a freshly voided morning urine (156). The presence of typical flat hexagonal cystine crystals is diagnostic. Acidification of the urine precipitates cystine crystals and may improve the yield of the test. The best screening procedure is the cyanide-nitroprusside test (156). A positive reaction occurs with as little as 75–125 mg cystine per gram of creatinine, which is well below that of homozygotes, who excrete at least 250 mg/g creatinine. Some heterozygotes may also be detected by this procedure (160). The test is not specific and may detect acetone or homocystine as well. The definite test is a measurement of urine cystine and dibasic amino acid concentration by ion exchange chromatography. The upper limits of normal are 18, 130, 16, and 22 mg/g creatinine for cystine, lysine, arginine, and ornithine, respectively (159). In establishing the diagnosis of classic cystinuria, it is important to exclude other conditions associated with increased urinary cystine excretion, including isolated cystinuria, tubular immaturity in young infants, generalized aminoaciduria (Fanconi syndrome), and organic acidemias (156, 159).

Cystine stones are radiopaque because of the density of the sulfur molecule, and on a roentgenogram, they appear smooth. Occasionally, they form staghorn calculi. Cystine also may act as a nidus for calcium oxalate so that mixed stones may be found (196). Factors contributing to mixed stone formation in cystinuria include alkalinization of urine and urinary tract infections.

The disease usually presents with renal colic. Occasionally, infection, hypertension, or renal failure may be the first manifestation (156). Cystinuria occurs with equal frequency in males and females, but males are more severely affected because of a greater likelihood of urethral obstruction in the male. Clinical manifestations usually occur in the second and third decades of life, with a 62% probability of stones by age 25 years (197). Most patients have recurrent stone formation. Cystinuric patients who receive a kidney transplant have normal urinary cystine and dibasic amino acid excretion following transplantation (198, 199).

Treatment: Cystine crystalluria occurs when the cystine content of the urine exceeds 300 mg/L at pH 4.5–7. Cystine solubility increases sharply at a urine pH above 7 (159). The major therapeutic approaches to cystinuria are designed to increase the solubility of cystine, reduce excretion of cystine, and convert cystine to more soluble compounds (156). Therapies used in the management of cystinuria include the following:

1. Increased oral fluid intake to increase urine volume and cystine solubility. Because cystinuric patients excrete 0.5–1 g cystine/day, intake of 3–4 L could be required to keep the urinary cystine concentration below 300 mg/L. Patients should develop a 24-h schedule for drinking and voiding, with particular attention to night time hours, when urine may become supersaturated with cystine. Water should be taken at bedtime and whenever the patient awakens at night. Rigid adherence to fluid therapy is effective in approximately 70% of patients (156).
2. Oral alkali in addition to high fluid intake to further increase cystine solubility in the urine (159). A urine pH of 7.5–8 can be maintained by the provision of 1–2 mEq/kg/day of bicarbonate or citrate in divided doses. Because high sodium intake increases cystine excretion (see later), potassium citrate is preferred (159). Because urine alkalinization may result in formation of mixed calcium-containing stones, adherence to high fluid intake is crucial.
3. Dietary therapy to reduce cystine production and excretion. Studies examining the effect of dietary restriction of methionine (a metabolic precursor to cystine) on urine cystine excretion have yielded variable results (159). Also, diets low in methionine are very difficult to follow and may be harmful to growing children. Therefore, dietary methionine restriction is not recommended (159). Urinary excretion of cystine

and dibasic amino acids in cystinuric patients has been shown to correlate with urinary sodium excretion (200, 201). Hence, dietary sodium restriction has been recommended by some authors as a safe approach to the treatment of cystinuria (156). L-Glutamine administered orally or intravenously in conjunction with low salt intake reduces cystine excretion (200, 202), but this effect was not observed in patients receiving a normal salt diet (203). The mechanism of the anticystinuric effect of glutamine is unclear.

4. Pharmacologic therapy to increase cystine solubility and decrease cystine excretion. The sulfhydryl-binding compound D-penicillamine (β-dimethylcysteine) leads to the formation of the mixed disulfide penicillamine-cysteine following a disulfide exchange reaction. This mixed disulfide is far more water-soluble than cystine. Hence, penicillamine acts by reducing cystine excretion as well as by permitting the excretion of a more soluble compound. Penicillamine, given at a dosage of 1–2 g/24 h (30 mg/kg in children), is highly effective and reduces urinary cystine excretion to under 200 mg/g creatinine (204). Unfortunately, penicillamine produces serious side effects in 50% of patients (205). These reactions include rashes (including pemphigus), fever, arthralgia, nephrotoxicity (including nephrotic syndrome in up to 30% of patients, and rapidly progressive glomerulonephritis), pancytopenia, and loss of taste. Penicillamine also increases copper and zinc excretion in the urine. The loss of taste may be reversed by copper administration (159). Pyridoxine metabolism may be impaired, and pyridoxine supplementation should be provided for patients receiving D-penicillamine. Most of these side effects revert to normal upon discontinuation of the drug. Because of the serious side effects, D-penicillamine therapy should be reserved for patients unresponsive to conservative management, and stepwise dosing is recommended (156). D-Acetyl penicillamine, another anticystinuric sulfhydryl agent, has fewer side effects than D-penicillamine. Mercaptopropionyl glycine (MPG), another agent undergoing a disulfide exchange reaction, is as effective as D-penicillamine in the treatment of cystinuria (206). MPG has the same toxicity as D-penicillamine, but serious renal and hematologic reactions requiring cessation of therapy are much less common with MPG (206). Because of the lower incidence of side effects and because this compound can be used in patients who develop allergic reactions to D-penicillamine, MPG is the pharmacologic agent of choice in the therapy of cystinuria (206, 207).

Several studies have examined the effect of captopril, an angiotensin-converting enzyme inhibitor, on urinary cystine excretion in cystinuric patients (208–210). This nontoxic sulfhydryl compound builds highly soluble captopril-cysteine disulfides. Although a reduction in cystine excretion has been demonstrated in some studies (208, 209), others (210) have failed to show an effect. Further studies are needed to evaluate the efficacy of captopril therapy in cystinuria. It has been proposed that *meso*-1,3 dimercaptosuccinic acid (DMSA), an additional compound forming disulfide linkage with cysteine, might be a useful therapeutic agent in cystinuria (211). The efficacy of this agent in cystinuria remains to be established.

Ascorbic acid, which acts as a reducing agent to convert cystine to the more soluble cysteine, has been suggested as a therapeutic modality in patients with cystinuria (207). To date, the results of the use of this compound on a limited number of patients have been variable (159, 207). Also, concerns have been raised that ascorbic acid therapy in cystinuria is potentially lithogenic because of the hyperoxaluric and hypocitraturic effect of this agent.

Several urologic procedures have been used to treat cystine stones:

1. Chemolysis of stones by irrigation through a percutaneous nephrostomy. Successful dissolution of stones has been achieved using *N*-acetylcysteine, D-penicillamine, α-MPG, and a very alkaline agent, tromethamine (158, 159).
2. Extracorporal shock wave lithotripsy (ESWL). This therapeutic modality has been only partially successful because of the organic nature and the uniform crystal structure of cystine stones (158, 212). Percutaneous ultrasonic lithotripsy has been somewhat more effective (213).
3. Lithotomy. Surgical removal of stones is necessary only in rare patients with obstructing or infected stones unresponsive to a more conservative approach.

In summary, the mainstays of therapy in cystinuria include hydration, alkalinization of the urine, and dietary sodium restriction. Full compliance with this regimen results in significantly reduced urinary cystine excretion and good long-term prognosis in most patients. Pharmacologic treatment with sulfhydryl agents should be reserved for patients in whom conservative therapy fails. Urologic intervention may be indicated in selected patients.

Isolated Cystinuria: Brodehl et al. (168) report two siblings who showed high urinary excretion rates of

cystine but normal dibasic amino acid excretion. The children did not develop renal stones. This report, along with the detection of a similar abnormality in dogs (214), provides evidence of a separate cystine transporter not shared with dibasic amino acids in the tubular brush-border membrane, which appears to be defective in isolated cystinuria. The molecular nature of this proposed transporter is unknown.

Lysinuric Protein Intolerance (LPI) (Hyperdibasic Aminoaciduria Type II): Lysinuric protein intolerance is a rare autosomal-recessive disorder characterized by excessive urinary excretion of dibasic amino acids (especially lysine), normal cystine excretion, and poor intestinal absorption of dibasic amino acids (215–217). Plasma values of dibasic amino acids are low. The disease is relatively common in Finland, where the prevalence of the disease is 1:60,000 (217). About 130 patients, Finish as well as non-Finish, have been described (217, 218). Homozygous patients show massive dibasic aminoaciduria as well as hyperammonemia after a protein overload; heterozygotes have normal urinary amino acid excretion but impaired renal and intestinal transport of dibasic amino acids at increased loads. The clinical manifestations in homozygotes for LPI are those of protein malnutrition and postprandial hyperammonemia. They include failure to thrive, marked protein intolerance, anorexia, vomiting, diarrhea, hepatosplenomegaly, muscle hypotonia, interstitial lung disease, osteoporosis, seizures, and coma (217).

The pathogenic mechanism of LPI appears to be a defective transport of dibasic amino acids in the basolateral membrane of renal and intestinal epithelial cells, resulting in impaired efflux from cell to interstitium (219, 220). This has been confirmed by a measurement of fluxes in jejunal biopsy specimens from LPI patients (219) as well as by the observation that infusion of citrulline to these patients results in massive argininuria and ornithinuria (220). Citrulline is reabsorbed from the tubular lumen by a neutral amino acid transport mechanism and is converted to arginine and ornithine in the renal cell. Impaired exit at the antiluminal membrane results in backflux of accumulated arginine and ornithine at the brush-border membrane surface. It is the high-affinity, specific dibasic amino acid transporter y^+L that is affected in this disease (100, 221). Because basolateral membrane transporters of epithelial cells and plasma membrane transporters of parenchymal cells are homologous carriers, it is not surprising that granulocytes (222), and cultured skin fibroblasts (223) from patients with LPI show impaired transport of dibasic amino acids. Erythrocytes from LPI patients, which do not have the y^+L system, show normal cationic amino acid transport (224).

It is presumed that the poor intestinal absorption and excessive renal loss of dibasic amino acids deprive hepatic cells of ornithine and arginine, which are necessary for urea production (217). This results in protein intolerance, hyperammonemia, and low urea formation. This notion is supported by the observation that L-citrulline supplements improve protein tolerance in LPI patients (220). This amino acid, a metabolic precursor of ornithine and arginine, is absorbed in the intestine, enters the hepatic cell via neutral amino acid transport mechanisms, is metabolized in the liver to ornithine and arginine, and restores the pathway for ammonia disposal (217). Several manifestations of LPI patients including glomerular dysfunction (225), erythroblastophagia and alveolar proteinosis (226) suggest that the immune system is deranged in some patients.

In 1992, the rBAT homologous protein, the human cell surface glycoprotein 4F2 heavy chain (4F2hc, encoded by the gene CD98, now termed SLC3A2), was shown to induce y^+L cationic amino acid transport in *Xenopus* oocytes (112). Like rBAT, 4F2hc represents the heavy subunit of a disulfide linked heteromeric amino acid transporter (HAT) (100, 227) (see Molecular Structure of Amino Acid Transporters; *Figs. 37-3* and *37-4*). Molecular analysis excluded SLC3A2, which has been localized to chromosome 11, as a candidate gene for LPI (228). Linkage studies in Finnish and non-Finnish LPI families placed the gene of the disease to 14q11–13 (229, 230).

In 1998, Torents et al. (120) identified a human cDNA, SLC7A7, as encoding y^+LAT-1, a member of the family of light subunits that combine with 4F2hc to form heteromeric amino acid transporters (see Molecular Structure of Amino Acid Transporters; *Fig. 37-3*). The 4F2hc/y^+LAT-1 transporter has been shown to have the activity of amino acid transport system y^+L that is responsible for the efflux of basic amino acids at the basolateral plasma membrane of epithelial cells (49) (see Specificity of Transport; *Figs. 37-1* and *37-3*). The SLC7A7 gene localized to the LP1 locus (120). Subsequently, two groups (228, 231) have demonstrated that mutations in SLC7A7 cause LPI in Finnish, Italian and Spanish patients. To date, more than 40 SLC7A7 mutations, spread along the entire SLC7A7 gene, have been found in LPI patients from different ethnic groups (100, 218). Expression studies in *Xenopus* oocytes showed that various LPI mutations result in proteins that fail to co-induce amino acid transport activity when expressed with 4F2hc (232). Two of the mutants reached the oocyte plasma membrane when coexpressed with 4F2hc demonstrating that they are transport inactivating mutations (232). While

4F2hc (SLC3A2) is ubiquitously expressed, y^+LAT1 (SLC7A7) is primarily expressed in tissues affected in LPI including kidney, small intestine, lung and white blood cells (100, 120).

LPI is characterized by poor genotype/phenotype correlation. Even Finnish patients, who share the same founder mutation, show variation in the clinical picture (232). Similarly, both interfamilial and intrafamilial phenotypic variability were observed in Italian LPI patients heterozygotes for the same mutation (218). This suggests that, in addition to SLC7A7 mutations, hitherto unknown factors play a role in the pathogenesis of LPI (49, 182). A recently reported SLC7A7 knockout mouse model (233) had severe growth retardation leading to neonatal death in most SLCA7−/− mice. Surviving mice that received high protein diet displayed human LP1-like metabolic dysfunction.

Therapy of LPI consists of protein restriction to prevent hyperammonemia, as well as oral supplements of lysine (234), arginine, ornithine, and most important, citrulline (235). Administration of the latter amino acid, which corrects the hepatic deficiency in ornithine and arginine, results in clinical improvement and catch-up growth.

Hyperdibasic Aminoaciduria Type I:An autosomal-dominant cationic aminoaciduria has been described in two families containing several heterozygotes and a single homozygote (169, 236). This disease, called hyperdibasic aminoaciduria type I (HDBA I), is characterized by impaired renal reabsorption and intestinal absorption of the dibasic amino acids lysine, arginine, and ornithine, but not of cystine. Plasma values of dibasic amino acids are normal, and there is no protein intolerance or hyperammonemia. The reported homozygous patient had mental retardation (236). HDBA I heterozygotes have modest cationic aminoaciduria, whereas LPI heterozygotes have no hyperaminoaciduria. It has been speculated that the brush-border membrane-bound high-capacity transporter for dibasic amino acids, which excludes cystine, is defective in this disease. The molecular nature of this transporter is unknown.

Isolated Lysinuria: Omura et al. (170) report a single child with increased urinary excretion of lysine, impaired intestinal absorption of this amino acid, low plasma lysine levels, and normal renal and intestinal transport of ornithine, arginine, and cystine. The patient did not have hyperammonemia but had failure to thrive and mental retardation, probably secondary to the deficiency of the essential amino acid lysine. This case implies a defect in a selective transport system for lysine in the kidney and the intestine. Such a system has not been identified in physiologic or molecular studies.

Neutral Aminoaciduria

Three distinct disorders of neutral amino acid transport have been identified: Hartnup disorder, methioninuria, and histidinuria.

Hartnup Disease: Hartnup disease, which may have afflicted Julius Caesar and his family (237), was first recognized in two siblings in England in 1956 (238). This disease is characterized by intestinal malabsorption and massive aminoaciduria of the neutral monoamino monocarboxylic amino acids: alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine, glutamine, and asparagine (239). Most patients also have increased excretion of indolic compounds that originate in the gut from bacterial degradation of tryptophan (240). Transport of other neutral amino acids including cystine, imino acids, glycine, and β-amino acids is unaffected. The disease is inherited as an autosomal-recessive trait and has an estimated incidence of 1:20,000 live births. Heterozygotes have normal urinary acid excretion under physiologic conditions. Clinical features in homozygotes may include photosensitive rash, cerebellar ataxia, and a variety of psychiatric manifestations-the features of pellagra (239). The pellagra- like manifestations are primarily caused by intestinal malabsorption and urinary loss of tryptophan, an amino acid that is required for niacin synthesis. The diagnosis should be suspected in any patient with pellagra who has no history of niacin or nicotinamide deficiency and should be made by chromatographic analysis of the urine (239).

A defect in the broad-specificity neutral, α-amino acid transport mechanism in the renal and intestinal brush-border membrane was presumed to be the pathogenic mechanism underlying this disorder (15, 241). Two lines of evidence have supported the hypothesis that the lesion is localized in the brush-border membrane (15). First, plasma amino acid response in patients with Hartnup disease was attenuated after oral feeding of free α-amino acids but not when appropriate dipeptides were given orally (242). The dipeptides are presumed to be reabsorbed by a dipeptide-specific brush-border membrane transporter and hydrolyzed in the enterocyte; the free amino acids exit the cell via a nondefective basolateral membrane-bound carrier. Second, tryptophan transport is normal in various parenchymal cells from patients with Hartnup disease including leukocytes, placenta, and cultured skin fibroblasts (239, 243). As indicated earlier, carriers in plasma membranes of parenchymal cells are homologous to basolateral membrane carriers in epithelial cells, which are supposed to be normal in Hartnup disease.

The transport characteristics and the epithelial distribution of the Na^+-dependent neutral amino acid transport B^o (see Specificity of Transport; *Fig. 37-1*), have led to the conclusion that this transporter is the defective one in Hartnup disorder. In 2001, the gene responsible for Hartnup disease was localized to chromosome 5p15 (68). Subsequently, Bröer's group (69) cloned from the syntenic region in the mouse the B^oAT1 (SLC6A19) gene (see Molecular Structure of Amino Acid Transporters). This SLC6 "orphan transporter" gene encodes a Na^+-dependent neutral amino acid transporter which is expressed in the brush border membrane of the early proximal tubule and the intestine and corresponds to the B^o transport system (3) (see Specificity of Transport).

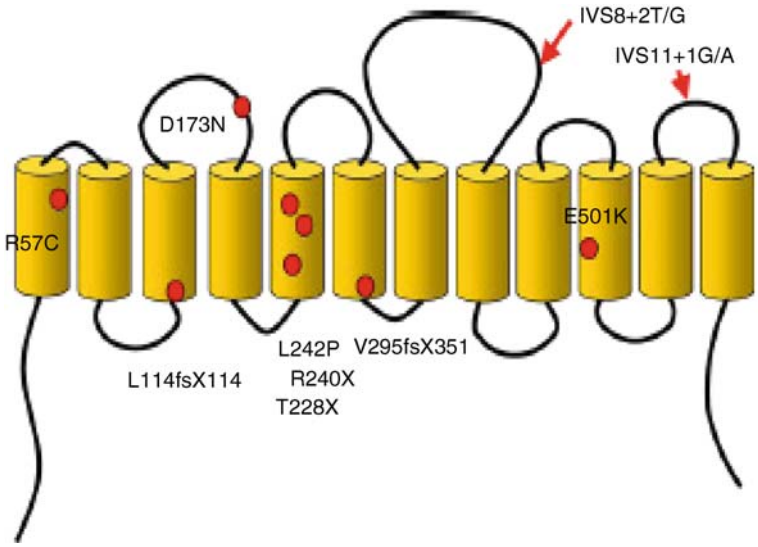
In 2004, two groups (244, 245) cloned the human SLCA19 gene from chromosome 5p15 and have found several mutations in this gene in British, Japanese and Australian patients with Hartnup disease, thereby identifying SLCA19 as the disease causing gene. To date, a total of 17 mutations have been identified that cause Hartnup disorder (246, 247) (*Fig. 37-6*). Interestingly, it has been demonstrated (247) that most of the probands with Hartnup disease analyzed so far display allelic heterogeneity in that they are compound heterozygotes for the SLC6A19 mutation.

Very recently, it has been demonstrated that collectrin (Tmem 27), a transmembrane glycoprotein with homology to angiotensin converting enzyme II, which is highly expressed in the collecting duct as well as the proximal tubule, is required for expression of the B^oAT1 protein and other SLC6 family members in the renal brush border membrane (248, 249). Collectrin knockout mice displayed decreased expression of B^oAT1 in the luminal membrane derived from the kidneys of the mice as well as massive generalized aminoaciduria (248, 249). Expression of collectrin in *Xenopus* oocytes and MDCK cells enhanced B^oAT1-mediated amino acid transport (248). These data identify collectrin as a regulator of amino acid reabsorption and may shed light on the molecular pathogenesis of deranged amino acid transport in various hereditary aminoacidurias including Hartnup disorder (250, 251).

The presence of alternative transport pathways for neutral amino acids in the renal tubule explains why the defect in the broad-specificity neutral amino acid transport in Hartnup disease results in only partial loss of some amino acids (e.g., phenylalanine) (15). These alternative systems, as well as the oligopeptide-preferring carriers in the kidney and intestine, are responsible for normal plasma amino acid values and lack of symptoms in most patients (252). As suggested by Scriver et al. (252), Hartnup disease is multifactorial in its pathogenesis, and only patients genetically predisposed to low plasma amino acid levels and impaired tryptophan metabolism develop symptoms. Given the phenotypic heterogeneity of patients with Hartnup disorder (246, 251), it is likely

Figure 37-6

SLC6A19 mutations associated with Hartnup disorder. A topological model of B^oAT1 (SLC6A19) is depicted, containing mutations associated with Hartnup disorder; *X* stop codon, *fs* frameshift mutation, *IVS* splice mutations (adapted with permission from (246)).



that other mutations (or, alternatively, polymorphisms) in other genes encoding for transport systems for neutral amino acids will be identified in the near future.

Patients with Hartnup disease respond well to oral therapy with nicotinamide 40–100 mg/day (253). Also, oral administration of tryptophan ethylester, a lipid-soluble form of tryptophan, has been shown to increase serum tryptophan and reverse clinical symptoms in patients with Hartnup disease (254).

Methioninuria: There are two case reports of patients with isolated increased urinary excretion of methionine and its metabolic breakdown products (255, 256). The patients had malodorous urine, edema, episodic hyperventilation, seizures, and mental retardation. The underlying defect appeared to be abnormal transport of methionine in the kidney and in the intestine. α-hydroxybutyric acid, a bacterial degradation product of unabsorbed intestinal methionine, appeared in the urine of these patients. This organic acid may have been responsible for the neurologic manifestations in these patients. Low-methionine diet resulted in significant clinical improvement. These cases of isolated methioninuria, as well as the observation that methionine, which shares the broad-spectrum amino acid transport system with other neutral amino acids, is not hyperexcreted in Hartnup disease, provide evidence for the existence of a specific transport pathway for methionine in renal and intestinal epithelium.

Histidinuria: Two siblings (257) and two other patients (258, 259) have been reported with isolated histidinuria. All showed significant mental retardation. Investigation revealed impaired transport of histidine in the kidney and intestine. Parents of the two affected siblings showed normal urinary histidine excretion under normal conditions, but hyperhistidinuria after an oral histidine load. The mode of inheritance of this disease is uncertain, but autosomal-recessive inheritance has been suggested (15). Although the broad-specificity transporter of neutral amino acids is the major carrier for histidine, as suggested by in vitro studies as well as by fractional excretion rates above 50% for this amino acid in Hartnup disease (15), the case reports of histidinuria suggest that an isolated histidine carrier is operating in the renal tubule and the intestine.

Iminoaciduria and Glycinuria

Two distinct disorders belong to this group of aminoacidurias: iminoglycinuria and isolated glycinuria.

Iminoglycinuria: Iminoglycinuria is an autosomal-recessive membrane transport defect characterized by excretion of excessive amounts of proline, hydroxyproline, and glycine in the urine (260). Iminoglycinuria is a benign condition with an estimated incidence of 1:15,000 live births (260, 261). It is the shared, brush-border membrane-bound, group-specific transport pathway for imino acids and glycine (see earlier) that is most likely defective in this condition (148, 260). The selective glycine-specific and imino acid-specific transport systems are not affected. The activity of these selective transporters accounts for the normal plasma levels of glycine and imino acids observed in iminoglycinuria. As discussed earlier, the late maturation of these selective transporters in normal infants is responsible for neonatal physiologic iminoglycinuria (146, 148). The absence of the selective transporters during early life also explains why infants with iminoglycinuria who lack the shared transporter have fractional excretion values for glycine and proline approaching 100%, which decline after the first months of life (15). Defective intestinal transport of proline has been found in some patients with iminoglycinuria (260). As expected, proline transport is not defective in leukocytes or skin fibroblasts because these cells do not possess carriers corresponding to a brush-border membrane carrier (15).

Iminoglycinuria is a genetically and pathophysiogically heterogenous condition with several mutant alleles (15, 260). This view is supported by several observations. First, obligate heterozygotes may have hyperglycinuria (but not iminoaciduria) or may have normal urinary amino acid excretion (262). Second, some homozygous patients have an intestinal transport defect and others do not have such defect. Third, a variant exists with normal transport maximum (Tm) for proline and a defect affecting glycine transport more than proline transport, indicating a K_m defect (263) (see later).

The genetic defect responsible for iminoglycinuria is unknown. The transport characteristics of the amino acid transport system expected to be defective in this disorder best fit either the low affinity, proton gradient–driven PAT1 (SLC36A1) imino acid/glycine transporter expressed in the brush border membrane of the early proximal tubule or, alternatively, the high affinity, Na^+- and Cl-dependent SIT1 (IMINO; SLC6A20) imino acid transporter expressed in the brush border membrane throughout the length of the proximal tubule (3, 48, 97) (see Molecular Structure of Amino Acid Transporters). To date, no direct evidence exists that these transporters are implicated in iminoglycinuria.

Differential diagnosis of iminoglycinuria includes neonatal iminoglycinuria, Fanconi syndrome in which generalized aminoaciduria occurs, and hyperprolinemia,

an inborn error of proline metabolism that exhibits overflow prolinuria as well as hydroxyprolinuria and glycinuria secondary to a proline-induced inhibition or hydroxyproline and glycine transport. This inhibition occurs at the shared luminal carrier for these amino acids.

Isolated Glycinuria: Isolated glycinuria without iminoaciduria has been reported in two families (263, 264). It has been suggested that this condition is a manifestation of a mutation affecting the specific high-affinity carrier for glycine, the molecular identity of which remains to be established (15). It is possible, however, that hyperglycinuria represents a defect in the shared, iminoacid-glycine transport system affecting affinity rather than capacity of the system (K_m variant). Because the condition appears to be inherited as an autosomal-dominant trait, it also is possible that these cases represent hyperglycinuric heterozygotes for the iminoglycinuria allele. Glycinuria has also been reported in association with glycosuria, called glycoglycinuria (265). The Na^+- and Cl^--dependent XT2 (SLC6A18), which likely transports glycine and is expressed in the brush border membrane of the late proximal tubule (see Molecular Structure of Amino Acid Transporters) could potentially be involved in the pathogenesis of isolated glycinuria (48). However, the genetic defect underlying this autosomal dominant condition remains unknown.

Dicarboxylic Aminoaciduria

Selective urinary hyperexcretion of the acidic amino acids glutamate and aspartate was first reported in two children (266, 267). One of the children also had impaired intestinal absorption of these amino acids. The condition is inherited as an autosomal-recessive trait and appears to be benign; screening in a French-Canadian population revealed a large number of healthy probands with hyperdicarboxylic aminoaciduria and an incidence of 1:35,000 live births (268).

The pathogenic mechanism appears to be a defect in the dicarboxylic amino acid transport system in the brush-border membrane. The excretion of dicarboxylic amino acids in homozygous patients may greatly exceed the GFR, suggesting tubular secretion or backflux of dicarboxylic amino acids from cell to lumen (15). Treatment with glutamate and aspartate corrected the hypoglycemia observed in one patient (266). This hypoglycemia probably resulted from the absence of these gluconeogenic amino acids.

The Na^+/H^+ and K^+-dependent EAAC1 (SLC1A1; EAAT3) glutamate/aspartate transporter expressed in the luminal membrane of the late proximal tubule (see Molecular Structure of Amino Acid Transporters) is an obvious candidate for the transporter defective in dicarboxylic aminoaciduria (3, 9, 48). Interestingly, Peghini et al. (269) have shown that EAAC1 deficient mice develop dicarboxylic aminoaciduria, a finding that strongly suggests that the EAAC1 gene is a candidate gene for dicarboxylic aminoaciduria. No direct evidence exists, however, for the involvement of EAAC1 in this disease.

An interesting feature of dicarboxylic aminoaciduria is the decreased uptake of anionic amino acids by cultured skin fibroblasts from patients with this condition (270). It has been shown that anionic amino acid-preferring carriers in epithelial brush-border and parenchymal cells have similar characteristics (15, 270). As pointed out by Scriver (15), the apparent expression of the mutant gene in both the brush-border membrane of the epithelium and the plasma membrane of parenchymal cells is unique and contrary to the expected pattern of analogy between basolateral membrane-bound and plasma membrane-bound carriers (see Classic Cystinuria, Hartnup Disease, and Lysinuric Protein Intolerance). The possibility that other transporters of anionic amino acids expressed at the basolateral membrane of the proximal tubule could be implicated in dicarboxylic aminoaciduria awaits future investigation.

β-Aminoaciduria

No inborn error of the luminal membrane-bound, Na^+- and Cl^--dependent transport systems that carry taurine/β-alanine (TAUT; SLC6A6) and betaine/GABA (BGT1; SLC6A12) have been reported in humans. An impaired taurine transport, however, has been found in an inbred mouse strain (C57BL/6J) (271). Studies using kidney slices (271) and isolated basolateral membrane vesicles (149) have localized the transport defect to the antiluminal membrane of the proximal tubular epithelium. In analogy with the defect in LPI, an impaired taurine exit across the basolateral membrane and backflux from cell to lumen may underlie the hypertaurinuria observed in the C57BL/6J mouse (149, 271). A transporter mediating such an exit from cell to interstitium remains to be identified.

Glycosuria

General Characteristics of Renal Glucose Transport

Under normal conditions, the reabsorption of filtered glucose by the renal tubule is almost complete. Less than

0.05% of the renal glucose load is excreted in the human urine (272); 90% of the filtered glucose is reabsorbed in the proximal convoluted tubule and the rest is reclaimed in the proximal straight tubule, the loop of Henle and, to some extent, the collecting duct (273).

Reabsorption of glucose across the proximal tubular brush-border membrane occurs by an active, carrier-mediated, concentrative, Na^+-dependent transport process (272, 273). The Na^+ electrochemical gradient driving glucose transport across the brush-border membrane is maintained by the activity of the basolateral membrane-bound Na^+–K^+-ATPase that pumps Na^+ out and K^+ into the cell. Na^+-glucose cotransport across the luminal membrane is electrogenic positive and phlorizin inhibitable. Glucose exit from the cell occurs by an Na^+-independent, facilitated diffusion down the glucose concentration gradient (273). This diffusional exit of glucose is mediated by a carrier that is distinct from that found at the luminal membrane surface (see later).

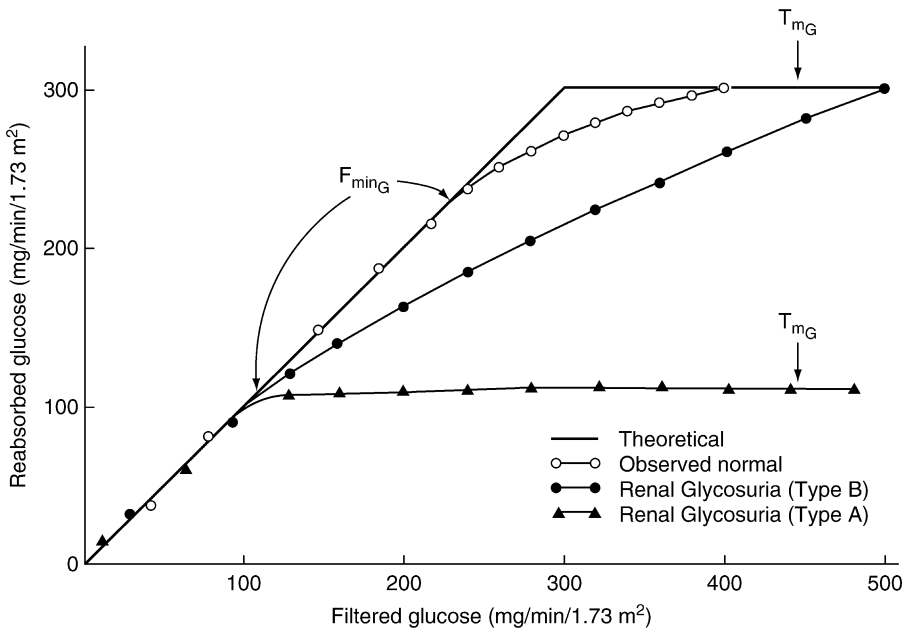
The mammalian kidney is characterized by a limited capacity to reabsorb D-glucose (272). As plasma glucose concentration is progressively elevated, the amount of glucose reabsorbed increases linearly until a maximum value is reached (*Fig. 37-7*). Beyond this maximum rate of glucose reabsorption, further increases of filtered D-glucose are excreted in the urine. As shown in *Fig. 37-7*, the glucose titration curve provides parameters of glucose transport such as minimum threshold (F_{minG}), defined as the filtered glucose load at which 1 mg of glucose per min appears in the urine, and the tubular maximum for glucose reabsorption (Tm_G). Reported Tm_G values for glucose in human adults and children have ranged between 260 and 350 mg/min/1.73 m^2 (275–277), with lower values in infants (277, 278). When corrected for the GFR (Tm/GFR), transport maximum value for glucose in infants, children, and adults is approximately 2.5 mg/mL (277).

The glucose titration curve (*Fig. 37-7*) is characterized by a splay, a rounding of the curve during the transition from virtually complete reabsorption of filtered D-glucose to complete excretion of excess glucose load. This deviation from the theoretical curve is explained by the nephron functional heterogeneity (the gradual progression from the first to the last nephron to saturate) as well as by the variation in affinity for glucose or K_m values between carriers (the magnitude of the splay is inversely proportional to the affinity of the transporter for the D-glucose) (272).

Studies in isolated perfused tubules (279) and later experiments using isolated BBMV from pars convoluta

Figure 37-7

Renal glucose titration curves. Theoretical and observed normal curves are compared to abnormal curves observed in type A and type B renal glycosuria. Tm_G, maximum rate for glucose reabsorption; F_{minG}, minimum threshold (reprinted with permission from (274)).



(S1 and S2 segments) and pars recta (S3 segment) of the proximal tubule (280–282) demonstrate that the kinetic properties and stoichiometric relationships of D-glucose reabsorption change along the length of the nephron. These studies provide evidence for two Na^+-dependent transport mechanisms, a low-affinity/high-capacity cotransport system in the early proximal tubule and a high-affinity/low-capacity system in the late proximal tubule. The Na^+-glucose coupling ratio was found to be 1:1 in the convoluted proximal tubule and 2:1 in the straight proximal tubule (281, 282).

The efficiency of a coupled carrier system increases as the power of the stoichiometry (273, 282). Whereas the early proximal tubule glucose transporter is responsible for the reabsorption of the bulk of filtered D-glucose from the tubular lumen, the late proximal tubule glucose transporter is responsible for the removal of the last traces of glucose from the urine (282). The arrangement of transporters in series along the proximal tubule enables the kidney to reabsorb glucose from the urine in a more energy-efficient mechanism than can be achieved by either of the cotransporters acting alone.

Molecular Biology of Na^+-Glucose Cotransporters

Various approaches have been used to identify and isolate the Na^+-glucose cotransporters. Earlier methods including solubilization and reconstitution techniques, semiselective and photoaffinity labeling, phlorizin affinity chromatography, radiation inactivation, and immunoaffinity absorption (273) have been inconclusive and yielded very limited biochemical data. However, considerable progress has been made in the past two decades in elucidating the molecular structure of membrane proteins that catalyze sugar transport processes, including the Na^+-glucose cotransporter (272, 283–285). Hediger et al., using expression cloning in *Xenopus* oocytes (see earlier), cloned and sequenced the first to be identified Na^+-dependent D-glucose transporter from rabbit (44) and human (286) intestine. Subsequently, molecular analysis revealed that rabbit intestinal and renal Na^+-glucose cotransporters are essentially identical (287). The transporter was later termed SGLT1 and the gene encoding it, SLC5A1 (284).

The Na^+-glucose cotransport proteins belong to the SLC5 family of sodium cotransport proteins, which includes more than 220 eukaryotic and prokaryotic homologues (284, 285). Included in the SLC5 family are 11 human genes most of which are plasma membrane, Na^+- substrate cotransporters for solutes such as glucose, *myo*-inositol and iodide. The group contains six Na^+-glucose cotransporters (SGLTs) all of which are expressed in the kidney among other organs (284, 285).

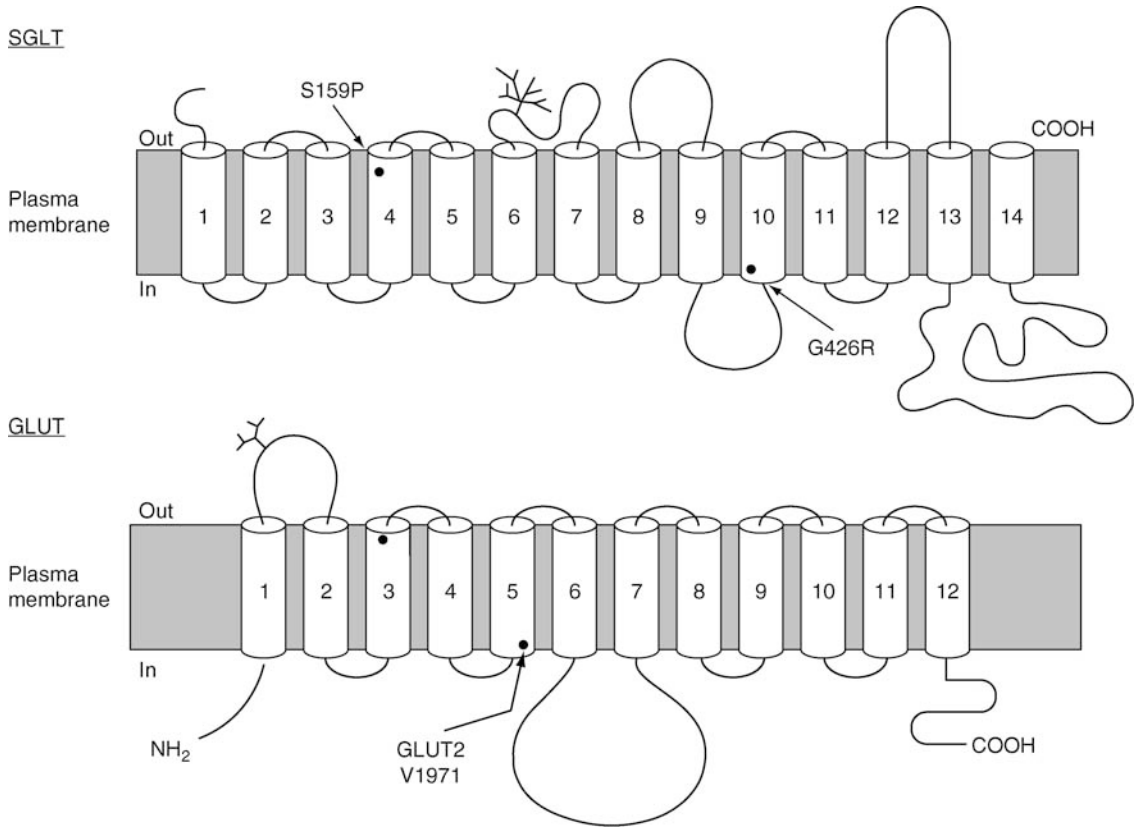
The SGLT1 (SLC5A1) transporter, the prototype of the SGLT group (*Fig. 37-8*), consists of 662–664 amino acids and has 14 membrane-spanning sequences that are presumed to be α-helical, with the NH_2 and COOH termini located on the cytoplasmic side of the membrane. A simple glycosylation site is found in the hydrophilic domain between transmembrane segments 5 and 6 (288). SGLT1 from rabbit (44), rat (289), pig (290), and human (286) show high homology in sequence and structure. The gene encoding the human intestinal SGLT1 has been localized to the q11.2lqter region of chromosome 22 (291). Studies using *Xenopus* oocytes (292) demonstrate that protein kinases (PKA and PKC) regulate SGLT1 activity by controlling the distribution of transporters between intracellular compartments and the plasma membrane and that this occurs by exocytosis and endocytosis.

Studies by Pajor et al. (293) and Lee et al. (289) using expression studies in *Xenopus* oocytes, Western and Northern analysis, and in situ hybridization and immunocytochemistry have provided evidence that the renal Na^+-glucose cotransporter SGLT1 is the high-affinity/low-capacity transporter found predominantly in the straight proximal tubule (S3 segment). Evaluation of the stoichiometry of SGLT1-mediated transport in *Xenopus* oocytes revealed a Na^+ to glucose coupling ratio of 2:1 (289). Recent structure – function studies, using functional analysis of mutated and truncated proteins as well as chimeras, have revealed that the COOH terminal domain containing the 5 terminal transmembrane helices is involved in sugar binding and translocation (294, 295). The SGLT1 (SLC5A1) gene has been implicated in hereditary glucose – galactose malabsorption (see Glycosuria).

A second low-affinity Na^+-glucose cotransporter named SGLT2 (SLC5A2) was isolated from rat (296) and human (297, 298) kidney. The amino acid sequence of SGLT2 is 59% identical to that of SGLT1 (297). SGLT2 has a Na^+ glucose coupling ratio of 1:1, does not recognize galactose (which is a substrate for SGLT1), and is strongly expressed in proximal tubule early (S1 and S2) segments (298). Human SGLT2 gene was mapped to chromosome 16p11.2 close to the centromere (299). SGLT2 is poorly expressed in cultured cells and oocytes which has precluded thorough investigation of its properties and function. It has been hypothesized that a second protein is required for the insertion of SLGT2 into the membrane (284). The accumulating clinical, physiologic and molecular data

Figure 37-8

Schematic structure of the Na^+/glucose cotransporter (SGLT) and the facilitative glucose transporter (GLUT). The two mutations shown in SGLT were identified in one of the original families with glucose-galactose malabsorption (adapted with permission from (308)).



made the SGLT2 gene, SLC5A2, a candidate for the affected gene in hereditary renal glycosuria (see Glycosuria).

A third Na^+-dependent glucose transporter, termed SGLT3 (SLC5A4), was isolated from a LLC-PK_1 pig renal cell line (300). It is a low-affinity, Na^+-glucose (not galactose) cotransporter with a very low expression level in renal tissue (272, 301). Human SGLT3 gene is located on chromosome 22 (284). It should be noted that human SGLT3 has been shown to function as a glucose – gated ion channel in muscles and neurons rather than a Na^+/glucose cotransporter (302). Two additional SGLT proteins expressed in the kidney are SGLT4 (SLC5A8) and SGLT5 (SLC5A10), the properties of which in general and in the kidney, in particular, have not been explored (283).

It is noteworthy that some of the SGLT proteins display unexpected properties in addition to their Na^+-glucose cotransport activity. SGLT1 (SLC5A1) has been shown to serve as a water channel, a urea channel and a cotransporter of both water and urea (303–305).

Facilitative Glucose Transporters

Glucose concentrated inside tubular epithelial cells flows to the interstitium down its concentration gradient through facilitative glucose transporters located in the basolateral membrane (272, 306). The basolateral Na^+-independent and the luminal Na^+-dependent glucose transport systems also differ with respect to inhibition and specificity (273). The basolateral glucose transporter is inhibited by the mold metabolite cytochalasin-B, but not by phlorizin. It also accepts D-glucose.

The basolateral membrane glucose transporters belong to the SLC2 family of Na^+-independent facilitative hexcose (and polyol) transporters which comprises 13 members including 12 facilitative glucose transporters GLUT1–12 (306–309). All these isoforms have extensive structural homologies but differ in their tissue distribution, specific function, insulin sensitivity, sugar specificity, and kinetic characteristics (309). The human erythrocyte

glucose transporter GLUT1 (SLC2A1) was the first glucose transporter to be cloned and sequenced (310). It is the most ubiquitously distributed of the transporter isoforms (307, 309). Isoforms GLUT2–5 were subsequently cloned by screening cDNA libraries from various tissues and species with a GLUT1 DNA probe and this was followed by cloning GLUT6–12 (306, 309). The facilitative glucose transporters (*Fig. 37-8*) have 12 membrane-spanning domains, with both the NH_2 and the COOH termini of the protein facing the cytoplasm (309). A single glycosylation site is located between transmembrane domains 1 and 2.

GLUT1 (SLC2A1) is ubiquitors with different levels of expression in different cell types (309). Studies using antipeptide antibodies specific for GLUT1 have detected this high-affinity transporter in the kidney (311–313). It was found in the basolateral membrane of cells forming the proximal straight tubule (S3 segment). GLUT2 (SLC2A2), a low-affinity transporter, is the predominant facilitative glucose transporter in hepatocytes and in the basolateral membrane of intestinal and renal tubular cells (311, 312). In the kidney, GLUT2 is present only in the basolateral membrane of cells in the proximal convoluted tubule (S1 and S2 segments) (311, 312). SLC2A2 has been identified as the mutated gene in Fanconi – Bickel syndrome (see Glucosuria). GLUT5 has also been identified in the kidney (314).

Thus, it appears that transepithelial glucose transport in the proximal tubule occurs by two different pairs of apical Na^+-dependent and basolateral Na^+-independent glucose transporters (272, 306) (*Fig. 37-9*). A luminal Na^+-dependent, low-affinity/high-capacity glucose transporter designated SGLT2/SLC5A2 and a basolateral Na^+-independent, low-affinity GLUT2/SLC2A2 are responsible for the bulk of glucose reabsorption in the early part of the proximal tubule. A luminal Na^+-dependent, high-affinity/low-capacity SGLT1/SLC5A1, coupled with the basolateral Na^+-independent, high-affinity GLUT1/SLC2A1, reabsorb the remaining low concentration of glucose in the late part of the proximal tubule.

Maturation of Glucose Transport

The immature renal tubule in animals (315, 316) and humans (277, 317, 318) is characterized by decreased ability to reabsorb glucose. Tubular reabsorption of glucose relates directly to postnatal age and glycosuria occurs commonly in infants less than 30 weeks' gestational age (317–319). There are few data on the development of renal glucose transport mechanisms. The fetal kidneys of various animal species (315, 320, 321) have been shown to reabsorb glucose. In the fetal rat kidney (320), glucose reabsorption appeared to be Na^+ dependent and phlorizin inhibitable. A decreased initial rate uptake of -methyl-D-glucoside was found in isolated renal tubules from neonatal rat (322) and dog (316). BBMV studies (323) demonstrated a concentrative, Na^+-dependent, electrogenic and phlorizine-sensitive glucose transport in the fetal rabbit kidney. The fetal glucose transport mechanism, however, had a significantly lower capacity than the adult glucose transport system. Experiments exploring the expression of SGLT1 and SGLT2 mRNAs in embryonic rat kidneys (296) revealed that the two Na^+-glucose cotransporters appeared early in gestation and that they were developmentally regulated. Evidence suggests that the increase in SGLT1 mRNA accompanying cell differentiation in the pig kidney cell line LLC-PK1 is regulated by PKA (324) and PKC (325).

Little is known about the maturation of the facilitative glucose transporters in the kidney. A study (326) examining the developmental pattern of these transporters in the rat kidney showed that renal GLUT1 and GLUT5 gene expression was unchanged throughout development, whereas GLUT2 was most abundant before weaning. The latter finding may be related to the fact that the kidney alone seems to be responsible for gluconeogenesis before expression of gluconeogenic enzymes by the liver.

Further studies are needed to explore the activity, expression, and distribution of various glucose transporters during kidney development and to elucidate the molecular mechanisms underlying the maturation of renal tubular glucose transport.

Glycosuria

Hereditary renal glycosuria is an abnormality in which variable amounts of glucose are excreted in the urine at normal concentrations of blood glucose (327). The renal defect is specific for glucose and there is no increase in the urinary excretion of other sugars. Renal glycosuria is a benign condition without symptoms or physical consequences except during pregnancy or prolonged starvation, when dehydration and ketosis may develop (327). The metabolism, storage, and use of carbohydrates as well as insulin secretion are normal. The condition exists from infancy throughout adult life, and diagnosis usually is done on routine urine analysis. The distinction between renal glycosuria and diabetes mellitus is made with a fasting blood glucose level and a glucose tolerance test.

The genetic pattern in renal glycosuria is autosomal recessive, although glycosuria in some heterozygotes has led some investigators to postulate a dominant inheritance (327, 328). Renal glycosuria is not associated with impaired D-glucose transport in the intestinal epithelium (329). The underlying pathogenic mechanism appears to be an isolated, selective defect in proximal tubular glucose transport.

Renal glycosuria is a heterogenous condition. Analysis of renal titration curves for glucose reabsorption reveals two types of renal glycosuria (274, 327) (*Fig. 37-7*). In type A, or classic renal glycosuria, minimal glucose threshold (F_{minG}) and maximum rate of glucose reabsorption (Tm_G) are reduced. In type B, F_{minG} is reduced, while Tm_G is normal but has an increased splay. It has been suggested that the type A mutation reflects reduction in the capacity of the glucose transport system, which might arise from a uniform defect in all nephrons, and type B reflects a decrease in the affinity of the transport system, which might also be a consequence of nephron heterogeneity (329, 330). A third type of glycosuria, termed type O, was described by Oemar et al. (331). In this rare condition, tubular reabsorption of glucose is virtually absent, and all glucose filtered is excreted in the urine.

In 2002, the SGLT2 gene, SLC5A2, was first established as the mutated gene in hereditary isolated glycosuria (332) (*Fig. 37-9*). Subsequent studies have confirmed this finding (333–337). To date, close to 30 mutations have been identified in patients with hereditary renal glycosuria. These include missense, nonsense and frame shift mutations.

Of note, some SLC5A2 mutations may result in renal glycosuria accompanied by generalized aminoaciduria (336). Renal glucose wasting associated with generalized aminoaciduria is also a feature of maturity-onset diabetes of the young type 3 (MODY 3) caused by a mutation in the hepatocyte nuclear factor – 1 alpha (HNF-1α) gene (338). HNF-1α acts as a regulator of both transcription of SLC5A2 ((339, 340) and expression of collectrin, a mediator of amino acid transport (341) (see Hartnup Disease). Hence, aberrant HNF-1α may constitute the link between the glycosuria and the aminoaciduria observed both in some cases of hereditary renal glucosuria and in MODY 3.

It is important to consider the relationships between renal glycosuria, a benign condition, and intestinal glucose-galactose malabsorption, a potentially lethal disease. Glucose-galactose malabsorption, an autosomal-recessive disease, is characterized in homozygotes by a neonatal onset of severe watery diarrhea that results in death unless glucose and galactose are removed from the diet (327). Studies using jejunal biopsy specimens from affected patients have demonstrated a defect in intestinal Na^+-dependent glucose transport (342). In 1991, molecular genetic studies in two sisters afflicted with glucose-galactose malabsorption have revealed a missense mutation that causes a change in residue 28 from aspartate to asparagine in the intestinal brush-border SGLT1 Na^+-glucose cotransporter (343). This made glucose-galactose malabsorption the first reported disease that is caused by a mutation in a membrane transport protein. To date, more than 40 mutations have been identified in patients with glucose-galactose malabsorption (284, 327). The mutant proteins, when expressed in *Xenopus* oocytes cause a marked reduction in Na^+-glucose transport activity (327), which, in most cases is due to missorting of the protein in the cell (284).

Patients with glucose-galactose malabsorption who have been studied show a mild defect in renal tubular reabsorption of glucose, with normal Tm for glucose but decreased minimal threshold (F_{minG}) (327, 342). In contrast, patients with renal glycosuria show no defect in intestinal D-glucose absorption. This has indicated that the SGLT1 Na^+-glucose cotransporter affected in glucose-galactose malabsorption is shared between the intestine and the kidney, as also suggested by the molecular studies of Pajor et al. (293) and Lee et al. (289) (see earlier). It has been evident that the glucose transporter impaired in glycosuria is not shared.

The accumulating clinical, physiologic, and molecular data on renal glucose transport have led to the following model of the pathogenesis of hereditary renal glycosuria (272, 274) (*Fig. 37-9*). A defect in the low-affinity/high-capacity, 1 Na^+:1 glucose cotransporter (SGLT2/SLC5A2) of the early proximal tubule, which reabsorbs most renal tubular glucose, would produce type A or type O, classic renal glycosuria but has no effect on glucose absorption in the intestine. By contrast, SGLT1/SLC5A1, the high-affinity/low-capacity, 2 Na^+:1 glucose cotransporter of the late proximal tubule (which also carries galactose) mediates residual glucose reabsorption in the renal tubule and, when defective as in glucose-galactose malabsorption, causes only mild type B renal glycosuria.

Mutations in the gene for GLUT2 (SLC2A2), the basolateral membrane – bound, facilitative glucose transporter of the proximal convoluted tubule, are also associated with glycosuria in the Fanconi-Bickel syndrome (344–346) (*Fig. 37-9*). This autosomal recessive disorder is characterized by hepatorenal glycogen accumulation, fasting hypoglycemia, impaired utilization of glucose and galactose. Fanconi syndrome, rickets and markedly stunted growth. The renal loss of glucose is

Figure 37-9

Schematic model for the distribution (luminal or basolateral) of cloned glucose transporters in renal tubular epithelium. Orientation permits net reabsorption from lumen to interstitium. Depicted are hereditary glycosurias caused by defects in these transporters. See text for details.
