due to the transport defect for monosaccharides across the renal basolateral membrane. To date, more than 30 different mutations in SLC2A2 have been detected in patients with Fanconi-Bickel syndrome (347). Knockout mice lacking the GLUT2 gene exhibit extreme glycosuria (348). Therapy of patients with Fanconi Bickel syndrome is symptomatic and includes stabilization of glucose homeostasis and replacement of renal solute losses (346).

38 Tubular Disorders of Electrolyte Regulation

Olivier Devuyst · Martin Konrad · Xavier Jeunemaitre · Maria-Christina Zennaro

In this section, we will discuss the inherited disorders associated with defective tubular handling of NaCl, causing secondary aldosteronism and hypokalemia (Bartter-like syndromes), abnormal handling of calcium and magnesium, the states of low-renin hypertension with hypokalemia, and the two forms of pseudohypoaldosteronism (type I and type II). We will not address other types of inherited tubulopathies, such as renal Fanconi syndrome, diabetes insipidus, or renal tubular acidosis, which are detailed elsewhere.

Bartter-Like Syndromes

Introduction

In 1962, F. Bartter and co-workers described two African American patients with a new syndrome, characterized by hypokalemic metabolic alkalosis, renal K^+ wasting, hypertrophy and hyperplasia of the juxtaglomerular apparatus, and normotensive hyperaldosteronism (1). The disorder also featured increased urinary excretion of prostaglandins, high plasma renin activity, and a relative vascular resistance to the pressor effects of exogenous angiotensin II (1). For decades, many similar cases and several phenotypic variants have been progressively identified and included in a group of hypokalemic salt-losing tubulopathies, referred to as Bartter-like syndromes (2). All these disorders are recessively inherited and associated with hypokalemia and hypochloremic metabolic alkalosis due to stimulation of the renin-angiotensin-aldosterone system (RAAS). However, they markedly differ in terms of age of onset, severity of symptoms, presence of urinary concentrating defect, other electrolyte abnormalities (including hypomagnesemia), and magnitude of urinary calcium excretion. Over the years, it became apparent that these tubulopathies affect salt handling in distinct nephron segments, based on the analogy between patient's symptoms and the effects of loop and thiazide diuretics affecting the thick ascending limb (TAL) and the distal convoluted tubule (DCT), respectively.

In the normal nephron, the TAL reabsorbs approximately 25% of the filtered NaCl load. The apical Na^+–K^+–$2Cl^-$ cotransporter NKCC2 mediates the uptake of Na^+, K^+ and Cl^- from the lumen into the epithelial cells, driven by the electrochemical gradient for Na^+ established by the basolateral Na^+-K^+-ATPase. The K^+ channel ROMK recycles K^+ across the luminal membrane, whereas the ClC-Ka and ClC-Kb Cl^- channels coupled to their beta-subunit barttin are responsible for the basolateral exit of Cl^- (*Fig. 38-1*). These concerted transport processes are crucial for the vectorial NaCl transport in the TAL, and thus the urinary concentrating ability, and for generating the lumen-positive electrical charge that drives the paracellular reabsorption of Na^+, Ca^{2+} and Mg^{2+} in this segment (3). The importance of NKCC2 in the TAL transport is evidenced by the effects of loop diuretics, which, as pharmacologic NKCC2 inhibitors, induce a strong increase in urinary water, salt, and calcium excretion. The DCT is responsible for the reabsorption of 5–10% of the filtered NaCl (4). Driven by the activity of the basolateral Na^+-K^+-ATPase, Na^+ enters the DCT cells via the thiazide-sensitive Na^+-Cl^- cotransporter, NCCT (or TSC, for thiazide-sensitive cotransporter). Because it is coupled to Na^+, Cl^- moves into the cell against its electrochemical gradient and then passively exits through the ClC-Kb channel in the basolateral membrane. The DCT cells are also involved in K^+ secretion, through the K^+ channel ROMK and a K^+-Cl^- cotransporter located in the apical membrane, and the transcellular reabsorption of Ca_2^+ and Mg_2^+, via the TRPV5/6 and TRPM6 channels, respectively, which belong to the transient receptor potential (TRP) channel family (5). Thiazide diuretics, which specifically bind and inhibit NCCT, induce a milder diuretic response than loop diuretics, typically associated with magnesium wasting and hypocalciuria.

Based on clinical manifestations, the Bartter-like syndromes were grouped into two major groups: the antenatal Bartter syndrome (aBS) (also named hyperprostaglandin-E syndrome (HPS)), which can be associated or not with sensorineural deafness (SND); and the classic Bartter and Gitelman syndromes (cBS and GS, respectively). Despite

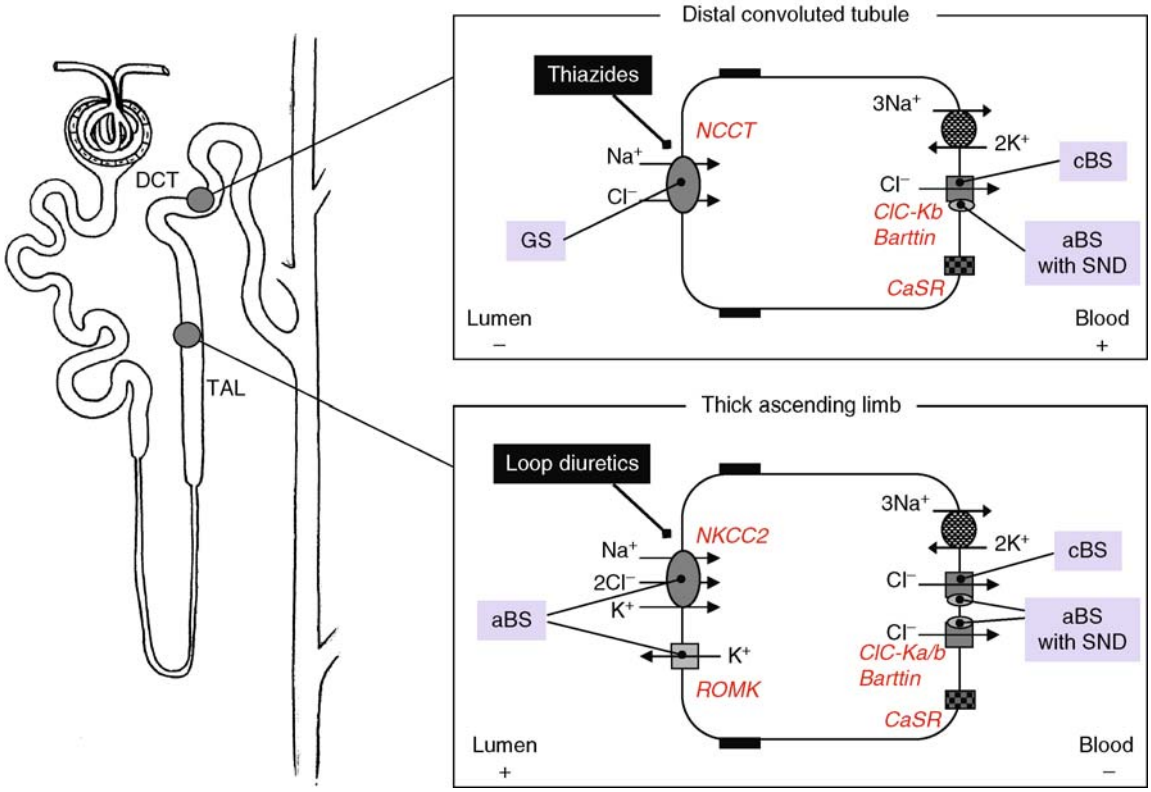
Figure 38-1

Molecular basis of Bartter-like syndromes. Approximately 25% of the filtered NaCl is reabsorbed in the thick ascending limb (TAL) via the apical Na^+–K^+–$2Cl^-$ cotransporter NKCC2 (inhibited by loop diuretics), organized in parallel with the apical K^+ channel ROMK to ensure K^+ recycling and the lumen-positive voltage. The Na^+–K^+-ATPase and the Cl^- channels ClC–Ka and ClC–Kb associated with the regulatory beta-subunit Barttin mediate the exit of Na^+ and Cl^- ions from the cells. The thiazide-sensitive Na^+–Cl^- cotransporter NCCT mediates 5–10% of the NaCl reabsorption in the distal convoluted tubule (DCT). Loss of function mutations in *SLC12A1* (coding for NKCC2) and *KCNJ1* (coding for ROMK) cause antenatal Bartter syndrome (aBS), whereas inactivating mutations of *BSND* encoding the beta-subunit barttin cause antenatal Bartter syndrome with sensorineural deafness (aBS with SND) and mutations in *CLCNKB* (ClC-Kb) cause classic Bartter syndrome (cBS). Inactivating mutations in *SLC12A3* (coding for NCCT) are associated with Gitelman syndrome (GS). It must be noted that a few patients with autosomal dominant hypocalcemia due to severe gain-of-function mutations of the CASR may present a salt-losing, Bartter-like tubulopathy.



some overlapping features, the aBS group included disorders affecting the TAL, with furosemide-like manifestations, whereas the second group—and GS in particular—was related to a defect in the DCT, with thiazide-like manifestations (2). From 1996, a series of seminal studies by Lifton and colleagues identified loss-of-function mutations in transporters and channels responsible for these inherited tubulopathies. The aBS was associated to inactivating mutations in the genes encoding the apical NKCC2 (6) or ROMK (7), whereas inactivating mutations in barttin, a regulatory beta-subunit of the basolateral ClC-Ka and ClC-Kb channels, were detected in aBS with SND (8). On the other hand, inactivating mutations of ClC-Kb, which is located both in the TAL and DCT, were associated with the cBS (9), whereas GS was found to be associated with mutations of NCCT (10) (*Fig. 38-1*).

A classification of these salt-losing tubulopathies, based on the clinical, physiological, and molecular insights discussed above, provides a basis to understand the distinct phenotypes of these disorders (*Table 38-1*). When discussing such patients, the clinical diagnosis of the BS subtype, based on relatively simple clinical criteria, should

Table 38-1

Inherited Bartter-like salt-losing tubulopathies

Disorder	OMIM #	Inheritance	Gene locus	Gene	Protein	Affected tubular segment
Antenatal Bartter syndrome (aBS), Hyperprostaglandin-E syndrome (HPS), Type I Bartter syndrome[a]	601678	AR	15q15-q21.1	*SLC12A1*	Na^+–K^+–$2Cl^-$ cotransporter NKCC2	TAL
Antenatal Bartter syndrome (aBS), Hyperprostaglandin-E syndrome (HPS), Type II Bartter syndrome[a]	241200	AR	11q24	*KCNJ1*	K^+ channel ROMK (Kir1.1)	TAL + CCD
Antenatal Bartter syndrome with sensorineural deafness (aBS with SND)[b], Type IV Bartter syndrome[a]	602522	AR	1p31	*BSND*	Barttin, beta-subunit of ClC-Ka/b	TAL + DCT
Classic Bartter syndrome (cBS) Type III Bartter syndrome[a]	607364	AR	1p36	*CLCNKB*	Cl^- channel ClC-Kb	TAL + DCT
Gitelman syndrome (GS)	263800	AR	16q13	*SLC12A3*	Na^+-Cl^- cotransporter NCCT	DCT

TAL thick ascending limb; *CCD* cortical collecting duct; *DCT* distal convoluted tubule

[a]This classification is based on the chronological order of gene discovery

[b]A digenic disorder with inactivating mutations of *CLCNKA* and *CLCNKB* has been associated with the aBS with SND phenotype

be completed whenever possible by the genotyping information since there is no direct genotype-phenotype correlation in these diseases (2, 11).

Antenatal Bartter Syndrome

Genetics

Antenatal Bartter syndrome (aBS, OMIM #601678, #241200) is a rare, life-threatening disorder characterized by massive polyuria that manifests *in utero* with the development of polyhydramnios and premature delivery in almost all cases. Affected neonates rapidly develop salt wasting, hypokalemic metabolic alkalosis, and profound polyuria (12–14). The disorder is accompanied by markedly elevated urinary PGE_2 excretion, and treatment with PG synthesis inhibitors effectively reduces clinical and biochemical manifestations, explaining why aBS is also designed as hyperprostaglandin-E syndrome (HPS) (15). As patients with aBS/HPS fail to respond to loop diuretics such as furosemide, a defective NaCl reabsorption in the TAL was suspected (16). By combining a candidate gene approach with linkage analysis, Simon et al. demonstrated that aBS/HPS is either due to mutations in NKCC2 (type I BS) or in ROMK (type II BS) (6, 7) (*Fig. 38-1*). The two forms of aBS are clinically and biochemically hardly distinguishable (17).

Type I BS is due to mutations in the *SLC12A1* gene located on 15q15-q21.1 and containing 26 exons (6, 14, 18). The *SLC12A1* gene codes for the bumetanide-sensitive NKCC2, a 121 kD protein with 12 putative membrane-spanning domains. NKCC2 is expressed in the apical membrane of epithelial cells lining the TAL and in the macula densa (19). Loop diuretics bind to portions of transmembrane domains 11 and 12, whereas portions of domains 2, 4, and 7 are involved in ion transport (20). At least 30 mutations, essentially missense or frameshift, have been described thus far (21). The 5 initial kindreds (6), and others reported subsequently (14, 18) were consanguineous, but compound heterozygotes and patients harboring only one heterozygous mutation have been reported (14, 18, 21, 22). Although a founder mutant allele (W625X) was reported in a cohort of Costa Rican patients (22), the aBS mutations are evenly distributed throughout the *SLC12A1* gene (21). Of note, alternative splicing of the NKCC2 pre-mRNA results in the formation of three full-length isoforms of NKCC2, which differ in their variable exon 4, their localization along the TAL, and their transport characteristics (23). Accordingly, one could speculate that mutations affecting low-capacity/high-affinity isoform might result in a milder phenotype (14).

Type II BS has been linked to mutations in the *KCNJ1* gene that is located on chromosome 11q24 and contains 5 exons (7). The *KCNJ1* gene encodes ROMK (also known as Kir1.1), an ATP-sensitive, inwardly-rectifying renal K^+ channel that is critical for K^+ recycling in the TAL and K^+ secretion in the distal nephron (24). ROMK channels are assembled from four subunits, each consisting of two transmembrane domains flanking a conserved loop that contribute to the pore and selectivity filter, and cytoplasmic N and C termini that contain regulatory and oligomerization domains (25). ROMK exists in three N-terminal splice variations that all behave as rectifying K^+ channels gated by intracellular pH (24). Through the recycling of reabsorbed K^+ back to the lumen, ROMK is believed to be a regulator of NKCC2 cotransporter activity. Therefore, loss of function in ROMK, as well as in NKCC2, disrupts NaCl reabsorption in the TAL. At least 40 mutations in *KCNJ1* that coseggregate with aBS have been reported, including missense, nonsense, frameshift and deletions (7, 17, 26–30). The first mutations were reported in exon 5, common to all ROMK isoforms (7, 17), but homozygous deletions in exons 1 and 2 have also been reported (26, 29).

Clinical Manifestations

Typical features of aBS type I (NKCC2) and type II (ROMK) include polyhydramnios (within the second trimester of gestation), premature delivery (around 32 weeks), severe polyuria, life-threatening episodes of dehydration, hypercalciuria, leading to nephrocalcinosis within the first months of life, and activation of the RAAS (*Table 38-2*). The polyuria can be massive (>20 mL/kg/h) despite adequate fluid replacement. Magnesium wasting is not common in aBS (31), although hypomagnesemia was evident in half of the Costa Rican patients (32). Failure to thrive and growth retardation are invariably observed (13, 32, 33). A peculiar facies, characterized by a triangularly shaped face, prominent forehead, large eyes, protruding ears and drooping mouth, has been reported but could reflect dystrophic premature babies (22, 32). Systemic manifestations including fever of unknown origin, diarrhea, vomiting, generalized convulsions, which have been attributed to enhanced systemic overproduction of PGE, as well as recurrent urinary tract infection may occur (31, 34). Osteopenia is common in aBS (13, 35), associated with high urinary excretion of bone resorption markers (36). Increased urinary PGE2 excretion is usually detected, although not invariably (2, 13). Hypophosphatemia with decreased tubular phosphate reabsorption has been described, possibly related to tubular damage and hypokalemic nephropathy (33, 36). High Cl^- and aldosterone concentrations in the amniotic fluid have been reported (13).

Although rare, phenotype variability among NKCC2-deficient patients has been reported, including absence of hypokalemia and/or metabolic alkalosis during the first years of life and persistent metabolic acidosis or hypernatremia (18). The Costa Rican cohort harboring the W625X founder allele showed a somewhat milder phenotype with a median age of diagnosis at 10 months of life, and no necessity of indomethacin treatment in most patients (22, 32). A late-onset presentation (age 13 and 15 years) with mild polyuria and borderline hypercalciuria has been reported in two brothers compound heterozygotes for NKCC2 mutations (37).

While renal function is generally well preserved in aBS (18, 32), progressive renal failure leading to ESRD has been reported (32, 38, 39). The potential mechanisms that could lead to kidney damage in aBS include consequences of early neonatal events and dehydration episodes, hypokalemic nephropathy, nephrocalcinosis, and nephrotoxicity of NSAID (38, 40, 41). Renal biopsies of children with aBS revealed a marked hypertrophy and hyperplasia of the juxtaglomerular apparatus, with stimulation of the renin-angiotensin system (42, 43). This feature is not specific for aBS and may be observed in all Bartter-like syndromes. Reinalter et al. (41) showed inflammatory infiltrates, with areas of interstitial fibrosis, focal tubular atrophy with thickening of basement membranes and degenerated tubular epithelia, and focal segmental mesangial matrix increase and hypercellularity in renal biopsies obtained in 10 aBS/HPS patients. Of interest, patients harboring ROMK mutations had only minimal histological lesions as compared with NKCC2 patients and cBS patients (41).

Because NKCC2 and ROMK are functionally coupled in the apical membrane of the TAL, patients with a defective ROMK have a very similar clinical picture than NKCC2 deficiency, with polyhydramnios, premature delivery, severe neonatal polyuria with isosthenuria, and hypercalciuria with secondary nephrocalcinosis (2, 31). However, there is an important difference in that ROMK-deficient patients show a transient hyperkalemia during the first days of life, correlated with gestational age (31, 44). The association of such hyperkalemia with hyponatremia and hyperreninemic hyperaldosteronism may erroneously suggest the diagnosis of pseudohypoaldosteronism type 1 (PHA1) (44). Renal K^+ wasting in these cases may not be apparent until 3–6 weeks postnatally, leading to modest hypokalemia in most patients. Typically,

Table 38-2

Clinical and biochemical features of Bartter-like syndromes

Feature	aBS (*SLC12A1*) Type I BS	aBS (*KCNJ1*) Type II BS	aBS with SND (*BSND*) Type IV BS	cBS (*CLCNKB*) Type III BS	GS (*SLC12A3*)
Age of onset	Antenatal	Antenatal	Antenatal	Variable	Childhood, adolescence
Maternal polyhydramnios	Present	Present	Present	Rare	Absent
Prematurity	Present	Present	Present	Rare	Absent
Polyuria	Present	Present	Present	Occasional	Absent
Failure to thrive	Present	Present	Present	Common	Absent
Growth retardation	Present	Present	Present	Common	Occasional
Spasm/tetany/ muscle weakness	Absent	Absent	Absent	Occasional	Present
Nephrocalcinosis	Present	Present	Absent	Rare	Absent
Sensorineural deafness	Absent	Absent	Present	Absent[a]	Absent

Hypokalemic metabolic alkalosis	Present	Present (transient neonatal hyperkalemia)	Present	Present	Present
Plasma Mg^{2+}	Normal	Normal	Normal or low	Normal or low	Low
Urinary Ca^{2+} excretion	High	High	Moderate (transient) or normal	Usually normal	Low
Urinary NaCl excretion	High	High	Very high	Variable increase	Mild increase
Maximal urine osmolality	Hyposthenuria	Hyposthenuria	Iso-/hyposthenuria	Usually normal	Normal
High renin/ aldosteronism	Present	Present	Present	Present	Present
Urinary PGE2 excretion	High	High	High	Slightly elevated	Usually normal

PGE2 prostaglandin E2

[a]SND is present in case of digenic disorder with inactivating mutations of *CLCNKA* and *CLCNKB*

hypokalemia in ROMK-deficient patients is less severe than that observed in NKCC2-patients (29, 31).

Recently, Ji and Lifton reported that heterozygote carriers of inactivating mutations in NKCC2 and ROMK in the general population had significantly lower systolic and diastolic blood pressure, and a significant reduction in the risk of developing hypertension (45). Furthermore, Tobin et al. (46) showed that polymorphisms in *KCNJ1* were associated with blood pressure values in a cohort of 2,037 adults after adjusting for age, sex, and familial correlations. Taken together, these studies suggest that the transporters involved in NaCl handing in the TAL may exert a profound influence on blood pressure regulation (47).

Differential Diagnosis

Antenatal BS should always be suspected in face of polyhydramnios due to fetal polyuria. As discussed above, patients with type II aBS due to ROMK deficiency may show a transient hyperkalemia, which can mimick PHA1. However, PHA1 is characterized by permanent hyperkalemia with metabolic acidosis, whereas type II aBS patients

typically have metabolic alkalosis, as well as hypercalciuria and nephrocalcinosis. In some patients with aBS, the urinary concentrating defect is so severe that it can lead to hypernatremia, resembling nephrogenic diabetes insipidus (18). Some patients with aBS may lack metabolic alkalosis during the first year of life, or even present a transient metabolic acidosis with defective urinary acidification (48). This association, which probably results from medullary nephrocalcinosis, can mimick incomplete distal renal tubular acidosis (18). Other causes of pseudo-Bartter syndromes will be discussed in the section on cBS.

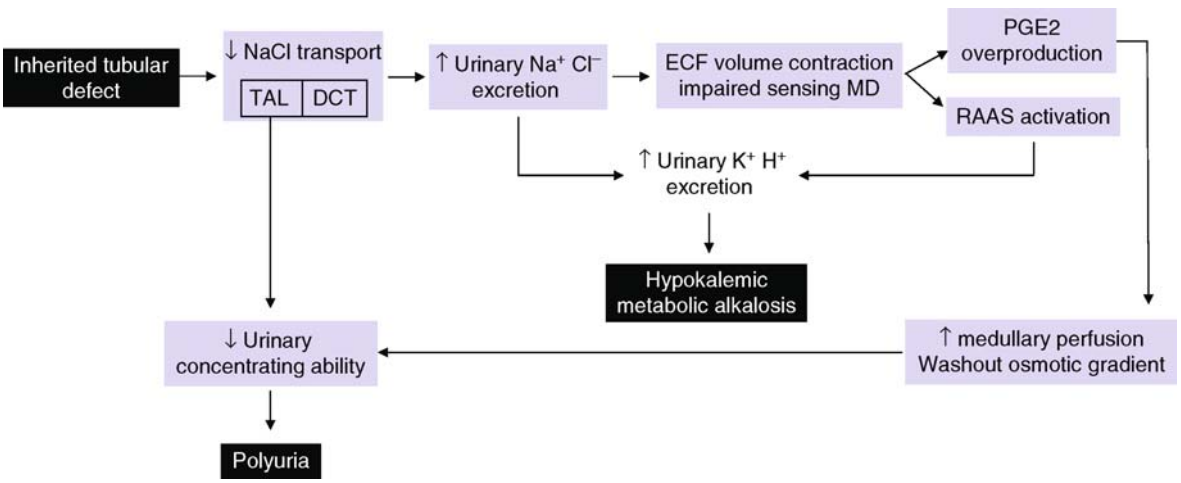
Pathophysiology

Functional investigations of pathogenic NKCC2 mutations in *Xenopus laevis* oocytes revealed a low expression of normally routed but functionally impaired transporters (49). A partial intrinsic transport defect was demonstrated in a peculiar mutant (F177Y), which may account for the attenuated phenotype of the affected patients (37). Similar functional studies provided insights into the role of ROMK in aBS. Two C-terminal mutations located nearby or inside the putative protein kinase A (PKA) phosphorylation site of ROMK showed a decreased open probability of the channel (50). Several missense mutations located in the intracellular N- and C-termini were shown to encode functional channels, but with altered pH gating (28). Starremans et al. investigated eight ROMK mutants and showed that loss-of-function may result from defective cellular routing to the plasma membrane, or impaired channel function (30). Peters et al. (51) identified defective membrane trafficking in 14/20 naturally occurring ROMK mutations, and showed that two early inframe stop mutations could be rescued by aminoglycosides, resulting in full-length ROMK and correct trafficking to the plasma membrane.

The functional data obtained in vitro suggest that loss-of-function mutations in NKCC2 and ROMK disrupt NaCl transport in the TAL, leading to salt wasting, volume contraction, and stimulation of the RAAS. In turn, the distal reabsorption of Na^+ via the epithelial Na^+ channel ENaC leads to increased urinary excretion of K^+ and H^+, causing hypokalemic metabolic alkalosis (*Fig. 38-2*). These changes are already observed prenatally, with polyhydramnios, high Cl^- concentrations and increased aldosterone levels in the amniotic fluid (52, 53). Chronic volume contraction, elevated levels of angiotensin II, and intracellular Cl^- depletion stimulate PGE2 production, which further inhibits NaCl transport in the TAL and contributes to the washout of the osmotic gradient through enhanced medullary perfusion (2). The inhibition of NKCC2 in the macula densa could impair the luminal Cl^- sensing of these cells, which may disrupt the tubuloglomerular feedback and further activate renin release from juxtaglomerular cells (54). It also appears that cyclooxygenase-2 (COX-2) is induced in the macula densa of children with aBS (55), which could further contribute to hyperreninemia (56). The early neonatal hyperkalemia harbored by some ROMK-deficient patients is explained by the involvement of ROMK in K^+ secretion in the cortical collecting duct, with subsequent

Figure 38-2

Physiopathology of hypokalemic metabolic alkalosis and polyuria in Bartter syndrome. See text for details.



activation of an alternative pathway for K^+ secretion in the CCD explaining the transient nature of this feature (44).

The impaired Cl^- transport in the TAL affects the lumen-positive electrical potential, causing persistent hypercalciuria and early-onset nephrocalcinosis in aBS. Renal Mg^{2+} wasting and overt hypomagnesemia do not reliably segregate with aBS, consistent with the observation that chronic furosemide treatment is not generally associated with hypomagnesemia (57). Possibly, the loop of Henle or more distal segments may adapt and compensate more efficiently for Mg^{2+} than Ca^{2+} in this syndrome. In the TAL, this adaptation might involve tight jnction structures (claudin16/claudin19), whereas increased PGE2 synthesis may contribute to increased Mg^{2+} reabsorption in the DCT (58). It has been suggested that a bone resorption process and a PGE2-mediated increase in calcitriol may contribute to hypercalciuria in aBS (35, 59). Recently, Schurman et al. (60) suggested that elevated levels of angiotensin II may stimulate the synthesis of basic-fibroblast growth factor (b-FGF), with a resulting increase in bone resorption via a prostaglandin-dependent mechanism.

NKCC2 knockout (KO) mice show massive perinatal fluid wasting and dehydration, leading to renal failure and death prior to weaning (61). Treatment of the NKCC2 KO mice with indomethacin from day 1 allowed 10% mice to survive until adulthood, despite polyuria, hydronephrosis, hypokalemia, and hyperalciuria. Similarly, the ROMK KO mice (62) manifest early death associated with polyuria, polydipsia, and impaired urinary concentrating ability. Approximately 5% of these mice survive the perinatal period, but show renal failure, hypernatremia and metabolic acidosis. Micropuncture analysis revealed that the absorption of NaCl in the TAL was reduced, with severe impairment of the tubuloglomerular feedback. Another strain of ROMK-null mouse with a BS-like phenotype showed increased survival to adulthood, due to compensatory mechanisms mostly active in the DCT (63). Recently, Lu et al. used CFTR-deficient mouse models to demonstrate that this Cl^- channel may regulate the ATP sensitivity of ROMK in the TAL, which could explain why patients with cystic fibrosis are prone to develop the pseudo-Bartter features of hypokalemic metabolic alkalosis (64).

Treatment

The initial treatment of preterm infants or neonates with aBS should focus on the correction of dehydration and electrolyte disorders, which often requires continuous saline infusion in a neonatal intensive care unit. Elevated levels of urinary PGE2 provided a rationale for NSAID, and indomethacin has been widely used (2, 13, 31, 33, 48). Typically, administration of indomethacin starting 4–6 weeks after birth, when massive urinary electrolyte losses have been controlled and hypokalemic metabolic alkalosis is established, corrects both the systemic and biochemical manifestations of aBS (31). Indomethacin (at doses ranging from 0.5 to 2.5 mg/kg/day) reduces polyuria, improves hypokalemia, normalizes plasma renin levels, and reduces hypercalciuria (13, 31, 33, 34, 48). However, the potential benefit of indomethacin administration in premature babies and neonates should be weighted against risks of severe gastrointestinal complications, such as ulcers, perforation and necrotizing enterocolitis (13, 33, 65). In particular, administration of indomethacin in newborn infants with defective ROMK may be complicated by oliguric renal failure and severe hyperkalemia. At any time, the ROMK-deficient patients are particularly sensitive to indomethacin, with doses well below 1 mg/kg/day sufficient to maintain normal plasma K^+ levels (66). Similarly, the potential benefit of prenatal treatment with indomethacin (66) should be weighed against the lack of evidence for hyperprostaglandinism in the fetus (13), and the negative effects of NSAID on the ductus arteriosus and the development of the kidney (65). Kleta et al. pointed that selective and nonselective cyclooxygenase inhibitors can be used for treatment (66). As an alternative to indomethacin, the COX-2 selective inhibitor rofecoxib ameliorated clinical and biological manifestations in aBS patients, with significant suppression of PGE2 and correction of hyperreninemia (56, 67). However, a case of reversible acute renal failure associated with rofecoxib in an 18-month-old girl with aBS has been reported (68).

Importantly, it should be remembered that HPS is secondary to volume depletion (13), and that the appropriate compensation of fluid and salt wasting remains the essential priority. Additional K^+ supplementation is required, more often for NKCC2-deficient than ROMK-deficient patients (2, 31). In some cases, a K^+-sparing diuretic (usually, spironolactone) is necessary to increase serum K^+ levels (13). Treatment with angiotensin converting enzyme (ACE) inhibitors has been reported effective in a few cases (33, 69) but should be used with caution as these drugs could block the distal compensatory Na^+ reabsorption. Thiazides should not be used to reduce hypercalciuria, since they interfere with compensatory mechanisms in the DCT and further aggravate dehydration.

The appropriate management of aBS with correction of fluid and electrolyte disorders, indomethacin and K^+ supplements results in catch-up growth and normal

pubertal and intellectual development (13, 33). However, most patients show a persistent deficiency in height and weight (32, 41). Correction of hypercalciuria is usually partial, with progression of nephrocalcinosis and a slow decrease in renal function evidenced in some cases (13, 33, 38, 48). Chaudhuri et al. (39) reported a case of severe aBS in whom pre-emptive nephrectomy followed by a living-related donor renal transplantation resulted in correction of metabolic abnormalities and excellent graft function.

Antenatal Bartter Syndrome with Sensorineural Deafness

Genetics

In 1995, Landau et al. (70) described a subtype of aBS/HPS associated with sensorineural deafness (SND) in 5 affected subjects from an inbred Bedouin kindred. These patients had a particularly severe salt wasting and fluid loss, with poor response to indomethacin and, most often, progressive renal failure (70, 71). By studying the large original kindred, Brennan et al. mapped the disease-causing gene to chromosome 1p31 (72). In 2001, Birkenhager et al. (8) identified a novel gene, *BSND*, within the critical interval, and detected inactivating mutations in affected individuals. This subtype of aBS was named aBS with SND, or type IV BS (OMIM #602522). The original mutations included a splicing mutant, a deletion of two exons, three missense mutations affecting a conserved residue close to the first putative membrane domain, and one mutation resulting in the loss of the start codon (8). The *BSND* gene consists of 4 exons. It encodes barttin, a 320 amino-acids protein that contains two putative transmembrane domains and is expressed in the thin limb and thick ascending limb of the loop of Henle and the DCT in the kidney (*Fig. 38-1*), and in the stria vascularis surrounding the cochlear duct in the inner ear (8, 73).

Clinical Manifestations

Typically, patients harboring mutations in *BSND* show the most severe form of aBS, with maternal polyhydramnios beginning at week 25 of gestation, severe prematurity, life-threatening neonatal episodes of dehydration, polyria with hypo- or isosthenuria, and increased urinary PGE2 excretion (2, 74) (*Table 38-2*). All patients are deaf and show a severe growth defect, with delayed motor development (71). They present multiple episodes of fever, vomiting, and bacterial infections. Jeck et al. (71) reported progressive renal failure in all patients, attributable to glomerular sclerosis and tubular atrophy. However, Shalev et al. reported that early renal failure is not a uniform finding (74). In contrast with patients harboring mutations in NKCC2 and ROMK, barttin-deficient patients exhibit only moderate and transient hypercalciuria and do not show nephrocalcinosis (2, 74). This could be due to defective NaCl transport in both the TAL and DCT, with divergent effects on urinary calcium excretion somehow similar to a combined action of a loop diuretic with a thiazide. Accordingly, barttin-deficient patients may show a severe Mg^{2+} wasting, caused by a defect in both the paracellular (TAL) and transcellular (DCT) pathways of Mg^{2+} reabsorption (2). Of note, a lack of diuretic response to furosemide and to hydrochlorothiazide was evidenced in one barttin-deficient patient, supporting a defect in both TAL and DCT (75).

Recent reports have suggested some degree of phenotype variability among patients with *BSND* mutations. Miyamura et al. (76) reported a patient harboring the loss-of-function G47R mutation of *BSND* who presented at age 28 years, with congenital deafness but without polyhydramnios, premature labor, or severe salt wasting in the neonatal period. In contrast, five patients from two unrelated Spanish families harboring the same G47R mutation presented with polyhydramnios, premature birth and salt loss (77). Kitana et al. (78) reported a patient harboring two mutations in *BSND* (Q32X and G47R) who presented with relatively mild perinatal clinical features but developed end-stage renal failure at age 15 years, requiring renal transplantation. The functional evaluation of the G210S mutation of *BSND* revealed only a very mild disturbance in current-voltage relationship (79), possibly accounting for a milder phenotype (74). Renal biopsies obtained in patient with *BSND* mutation showed variable features including hyperplasia of the juxtaglomerular apparatus, mild mesangial hypercellularity, mild to severe tubulointerstitial fibrosis, areas of tubular atrophy, and sclerosed glomeruli (71, 74).

Pathophysiology

Functional expression studies revealed that barttin is an essential beta-subunit for the Cl^- channels ClC-Ka and ClC-Kb, by stimulating Cl^- currents and enhancing surface expression of these channels (73). ClC-Ka and ClC-Kb are two members of the CLC gene family that are located on the basolateral membrane of the cells lining the thin ascending limb (ClC-Ka only), TAL and DCT, and the intercalated cells of the collecting duct. ClC-Ka

and ClC-Kb are also expressed in the inner ear, where they colocalize precisely with barttin in specialized, K^+-secreting cells of the stria vascularis and the vestibular organ (73). The co-expression of barttin with ClC-Ka/b channels is crucial for NaCl reabsorption in the TAL/DCT (*Fig. 38-1*) and K^+ recycling in the inner ear. Disease-causing mutations in barttin disrupt the Cl^- exit from the TAL and DCT, causing the severe salt-losing tubulopathy. Furthermore, the defective barttin-ClC-Ka/b complex impairs the basolateral recycling of Cl^- in the stria vascularis, decreasing the secretion of K^+ into the endolymph and causing SND (73, 80). The role of barttin as an essential beta-subunit for ClC-Ka and ClC-Kb has been substantiated by two recents reports of patients showing a typical aBS with SND phenotype indistinguishable from barttin-deficient patients, in association with a digenic disease caused by loss-of-function mutations in both *CLCNKB* and *CLCNKA* genes (81, 82).

Treatment

Barttin-deficient patients are managed primarily with intravenous fluids in neonatal intensive care units. In contrast with other forms of aBS, and despite high levels of urinary PGE2, the effect of indomethacin on growth and correction of electrolyte disorders is rather poor (71, 74). Hypokalemic metabolic alkalosis persists despite high doses of NaCl and KCl supplementation (71). Zaffanello et al. (75) reported that combined therapy with indomethacin and captopril was needed to discontinue intravenous fluids and improve weight gain in a single patient. A pre-emptive nephrectomy for refractory electrolyte and fluid losses and persistent failure to thrive, followed by peritoneal dialysis and succesful renal transplantation has been reported in a 1-year-old child with type IV BS (39).

Classic Bartter Syndrome

Genetics

Classic Bartter syndrome (cBS, or type III BS, OMIM #607364) usually presents during infancy or early childhood, with a phenotype similar to the original description given by Bartter et al. (1), i.e., without the prenatal onset and the nephrocalcinosis seen in the aBS variant. The cBS variant is caused by mutations in the *CLCNKB* gene located on 1p36 (9, 11). The gene, which contains 19 exons, encodes the basolaterally located renal chloride channel ClC-Kb, which mediates Cl^- efflux from epithelial cells lining the TAL and DCT (9, 80) (*Fig. 38-1*). There is a high rate of deletions encompassing a part of or the entire *CLCNKB* gene (9, 11, 83). It is hypothesized that the close vicinity of the almost identical *CLCNKA* and *CLCNKB* genes, which are separated by only 11 kb, predisposes to a high rate of rearrangements, for example, by unequal crossing over as demonstrated in two kindreds (9, 11). In addition, missense, nonsense, small insertions/deletions, frameshift and splice-site mutations have also been reported (http://www.hgmd.cf.ac.uk). A founder mutation (A204T) affecting a highly conserved residue has been reported at the homozygous state in ten patients from nine unrelated, non-consanguinous families in Spain (84). As expected for a recessively transmitted disorder, a significant number of subjects originates from consanguineous kindred (9, 11).

Pathophysiology

As mentioned earlier (see section on barttin), ClC-Kb is a plasma membrane channel that belongs to the CLC family of chloride channels/exchangers (80). ClC-Kb and the closely related ClC-Ka isoform are located on the basolateral membrane of the cells lining the thin ascending limb (ClC-Ka only), TAL and DCT cells, as well as in the intercalated cells of the collecting duct (*Fig. 38-1*). They both require the beta-subunit barttin to facilitate their insertion in the plasma membrane and to generate Cl^- currents (73, 79). Disease-causing missense mutations of ClC-Kb result in significant reductions or the loss of ClC-Kb/barttin currents (73). Thus, inactivating mutations in ClC-Kb affect the basolateral exit of Cl^-, which in turn reduces the reabsorption of NaCl in the TAL and DCT. The phenotypic variability of type III BS, which ranges from aBS/HPS in some cases to typical GS in others, may thus be explained by the wide distribution of ClC-Kb (11, 31). Alternative pathways for Cl^- exit could partially compensate for ClC-Kb inactivation in the kidney (11, 85). Importantly, none of the type III BS patients with ClC-Kb mutations is deaf, because the function of ClC-Kb/barttin channels in the inner ear can be replaced by ClC-Ka/barttin. Only the disruption of the common β subunit barttin (73) or the combined loss of ClC-Ka and ClC-Kb (81, 82) results in a Cl^--recycling defect that lowers K^+ secretion in the stria vascularis to a pathogenic level.

To date, there is no mouse model with targeted deletion of ClC-Kb. Mice lacking ClC-K1 (corresponding to ClC-Ka in humans) show a phenotype of nephrogenic diabetes insipidus, with no modification in the fractional

excetion of Na^+ and Cl^-, and no hypokalemic alkalosis (86). These features are caused by the loss of the Cl^- transport across the thin ascending limb, which is essential for generating a hypertonic interstitium (86). No corresponding human disease linked to loss-of-function mutations of *CLCNKA* has been described. A recent study supported the potential role of *CLCNKA* as a susceptibility gene for salt-sensitivity (87).

Clinical Manifestations

Patients harboring mutations of ClC-Kb present a broad spectrum of clinical features (*Table 38-2*) that range from the aBS/HPS phenotype, with polyhydramnios, isosthenuria, and hypercalciuria, over the classic BS phenotype, with less impaired concentrating ability and normal urinary calcium excretion, to a GS-like phenotype with hypocalciuria and hypomagnesemia (2, 11, 31, 84). Most patients have episodes of hypokalemic alkalosis and dehydration complicated with muscular hypotonia and lethargy during the first years of life. They are also characterized by increased urinary excretion of PGE2 (2, 11, 31). The median duration of pregnancy was 38 weeks in the series of Jeck et al. (2), and failure to thrive is common (31, 84). The diagnosis of Bartter syndrome is usually made during the first year of life, but prenatal (with history of mild maternal polyhydramnios) and late-onset cases are also reported. Most patients with classic BS show failure to thrive and growth retardation (36, 88, 89). Like in the antenatal variants, osteopenia with increased markers of bone resorption can be observed (36).

The electrolyte abnormalities are usually severe at presentation, with low plasma Cl^- and severe hypokalemic alkalosis. Increased plasma renin levels, with high or inappropriately normal (with respect to the hypokalemia) aldosterone levels are typically observed (11, 31). Polyuria is not uniformly found in classic BS. Iso/hyposthenuria was only evidenced in approximately one-third of patients, whereas some achieved urinary osmolality above 700 mOsm/kg (2). The persistance of such a concentrating ability suggests that patients lacking ClC-Kb have a residual TAL function. This is further supported by the fact that only ~ 20% of patients had sustained hypercalciuria (31). Nephrocalcinosis was reported in 4/36 affected children (11), but was not detected in three other series (84, 88, 89). The patients may show a mild hypophosphatemia, which could be related to tubular damage and hypokalemic nephropathy (33, 36). Isolated cases present with manifestations of renal Fanconi syndrome or distal renal tubular acidosis (84). About half of the patients lacking ClC-Kb have hypomagnesemia (11). Several patients harboring mutations in *CLCNKB* show overlapping features of cBS (presentation within the first year of life with episodes of dehydration) and GS (hypomagnesemia with hypocalciuria) (11, 85, 90, 91). Sun et al. (92) reported a patient with cBS who had bilateral sclerochoroidal calcification attributed to persistent hypomagnesemia for 26 years despite magnesium supplementation.

If the full phenotypic spectrum of the Bartter-like syndromes can result from mutations in *CLCNKB*, a significant clinical heterogeneity is observed among patients harboring the same mutation, and even between siblings (84). No correlations between a particular phenotype and *CLCNKB* genotype have been documented yet (11, 85). It has been suggested that ethnic differences may participate in the phenotype variability (2). Indeed, the two original patients described by Bartter were of African Americans origin (1), and early reports suggested that the course of BS may be more severe in African Americans (93). More recently, Schurman et al. (89) reported significant phenotype variability in the neonatal period in a series of 5 unrelated African American children with a homozygous deletion of the entire *CLCKNB*.

A vascular hyporeactivity to the infusion of angiotensin II was originally described by Bartter et al. (1). This feature is not consistently observed, probably because vascular hyporeactivity improves after correction of volume depletion or treatment with NSAID. Extensive studies (reviewed in 94) showed that this hyporeactivity could be due to various modifications in the angiotensin II-signaling, including downregulation of the alpha subunit of the heterotrimeric Gq protein, decreased intracellular Ca^{2+} and blunted protein kinase C activation, downregulation of the RhoA/Rho kinase pathway, and upregulation of endothelial NO synthase. In turn, these modifications may affect the upregulation of NAD(P)H oxidase and prevent the release of free radicals – offering increased protection against cardiovascular remodeling in these patients (94). Stoff et al. (95) evidenced a defect in platelet aggregation in four subjects with Bartter syndrome, but not in other hypokalmic patients. The platelet abnormality was exacerbated by restriction of dietary sodium and lessened by the administration of PG inhibitors. A circulating metabolite of prostacyclin, 6ketoPGE1 may be responsible for the defect (96).

Bartter syndrome is not classically associated with proteinuria, and renal biopsies consistently show hyperplasia of the juxtaglomerular apparatus, with minimal or no glomerular or tubular abnormalities (1). However, a few cases of cBS with proteinuria have been reported. Sardani et al. (97) described a 4-year-old African American child

with a homozygous deletion in *CLCNKB* and mild mesangial proliferative glomerulonephritis consistent with C1q nephropathy. The recent follow-up studies of Bettinelli et al. (88) revealed mild-to-moderate glomerular proteinuria in 6/13 ClC-Kb-deficient patients. It was associated with decreased GFR in four patients and microhematuria in two. Renal biopsy in two patients revealed diffuse or moderate mesangial hypertrophy (88). In addition, a few cases of clinical Bartter syndrome with unknown genetic defect presented with focal segmental glomerulosclerosis (FSGS) and renal failure (98, 99). One of the patients described by Bartter developed renal failure, with evidence of advanced nephrosclerosis, interstitial fibrosis, tubular atrophy, and glomerular hyalinization (100). Causes of renal failure in BS include complication of renal salt-wasting (including long-standing hypokalemia, hypovolemic episodes or nephrocalcinosis), chronic activation of the RAAS with ensuing stimulation of TGF-beta and/or TNF-alpha, and toxicity of NSAID (38, 97, 99). Renal dysfunction was temporally associated with NSAID therapy in two cBS patients, with biopsy-proven interstitial nephritis and resolution after NSAID withdrawal (38). However, the pathogenic role of NSAID in causing renal damage in Bartter syndrome has been questioned by the nature and topology of the histological lesions, the fact that renal lesions were identified in some patients before initiation of AINS, and the lack of progression of tubulointerstitial lesions over more than a decade under NSAID treatment (41, 101). Of note, renal cysts have been identified in patients with classic BS (33, 102), potentially linked to renal K^+ wasting and secondary aldosteronism (103).

Recently, Jeck et al. identified the common T481S variant in *CLCNKB*, which showed significantly increased currents when expressed in oocytes (104) and was associated with essential hypertension in a German cohort (105). The relevance of these findings has been discussed (106), and linkage of the T481S variant to high blood pressure was not confirmed in a Japanese cohort (107).

Differential Diagnosis, Unusual Associations, Pseudo-Bartter Syndromes

The differential diagnosis of cBS includes the surreptitious use of loop diuretics, laxative abuse (108), which are both unusual in children (109), and chronic vomiting (110). Measurement of urinary Cl^- and urine screen for diuretics are usually useful to diagnose these patients (111, 112).

The association of hypokalemic metabolic alkalosis with hyperreninemic secondary aldosteronism is also found in other familial disorders affecting the kidneys or the gastrointestinal tract, or can be acquired. Generalized dysfunction of the proximal tubule (renal Fanconi syndrome), for instance due to cystinosis (113), or Kearns-Sayre syndrome, a mitochondrial cytopathy caused by large deletions in mitochondrial DNA leading to cytochrome c oxidase deficiency (114), can be associated with biochemical features resembling BS. A case of familial renal dysplasia with hypokalemic alkalosis has been reported (115). Patients with cystic fibrosis are prone to develop episodes of hyponatraemic, hypochloraemic dehydration with metabolic alkalosis (116, 117). As mentioned earlier, the Cl^- channel CFTR, which is mutated in cystic fibrosis, may regulate the function of ROMK in the TAL (64). Gastrointestinal malformations which are associated with Cl^- deficiency (118), or Hirschprung disease (119) can also lead to pseudo-Bartter syndrome. Administration of protaglandins in neonates with a ductus-dependent congenital cardiopathy (120), aminoglycosides (121, 122) or combined chemotherapy (123) can also induce the biochemical features of BS. Bartter syndrome has also been reported in association with autoimmune diseases, for isntance with Sjögren syndrome (124, 125). Güllner et al. (126) described a syndrome of familial hypokalemic alkalosis in a sibship presenting with hyperreninemia, aldosteronism, high urinary prostaglandin E2 excretion, normal BP, and resistance to angiotensin II. At variance with BS, the patients had hypouricemia, indicative of proximal tubule dysfunction, and the fractional chloride reabsorption in the TAL was normal. The renal biopsy showed an extreme hypertrophy of the PT basement membranes, whereas the juxtaglomerular apparatus were of normal appearance. The molecular basis of this familial tubulopathy remains unknown. Finally, the association of BS with a partially empty sella detected by MRI of the brain has been reported in both adult and pediatric patients (127, 128).

Treatment

Patients with cBS are typically treated with PG synthetase inhibitors and escalating doses of KCl, complemented with K^+-sparing diuretics (most often, spironolactone) and NaCl in some of them (41, 88, 89). Indomethacin is the most frequently used drug, usually started within the first 4 years of life at doses ranging from 1 to 2.5 mg/kg/day. Doses above 3 mg/kg/day are considered nephrotoxic. Indomethacin is well tolerated, but one should remain cautious for gastrointestinal complications (33) or alteration of renal function (38, 88). Selective COX2 inhibitors, such as rofecoxib have been used instead of

indomethacin (33) and are currently evaluated on a larger scale. Potassium supplementation (usually KCl, 1–3 mmol/kg/day) is mandatory in cBS, as hypokalemia is often severe at presentation and is not fully corrected by indomethacin (89). If KCl alone fails to correct hypokalemia, then addition of spironolactone (1–1.5 mg/kg/day) is recommended. The use of ACE-inhibitors, which have been used for treating hypokalemia in adults with BS (129), should be cautious given the risk of hypotension. Magnesium supplementation should be added when hypomagnesemia is present, but the correction is typically difficult (31). Some patients with cBS require gastrostomy tube placement and enteral feeding (89).

The long-term efficacy of the standard treatment with indomethacin and KCl supplementation has been established in cBS. Most biochemical features improve with therapy, although K^+ levels are typically difficult to normalize in most patients despite NSAID, KCl and spironolactone. Treatment also results in improved height and weight, but catch-up growth is inadequate and there is persistent height retardation (33, 41, 88, 89). Recently, growth hormone deficiency has been demonstrated in some patients, with a positive effect of recombinant human hormone treatment (88). As discussed above, some cases of cBS are complicated by chronic renal failure. A few cases of living-related kidney transplantation have been reported, with improvement of biochemical and hormonal abnormalities after transplantation (98, 101, 130).

Peri-operative management of patients with cBS requires a particular care for volume repletion and correction of electrolyte abnormalities during anesthesia, and the continuation of anti-prostanglandin therapy to prevent the defective platelet aggregation (131, 132).

Gitelman Syndrome

Genetics

Gitelman syndrome (GS) (OMIM #263800) is generally considered as a milder disorder than BS and, with a prevalence of ~ 1 per 40,000, arguably the most frequent inherited tubulopathy detected in adults (40). The syndrome was first described in 1966 by Gitelman and co-workers as a familial disorder in which patients presented with hypokalemic alkalosis and a peculiar susceptibility to carpopedal spasm and tetany due to hypomagnesemia (133). For more than 20 years, GS was assimilated with BS. In 1992 Bettinelli and co-workers concluded that GS could be distinguished from BS, based on low urinary Ca^{2+} excretion (molar urinary calcium/creatinine ratio less than or equal to 0.20) (134). Also, BS patients were more often born after pregnancies complicated by polyhydramnios or premature delivery and had short stature, polyuria, polydipsia and tendency to dehydration during infancy and childhood, whereas GS patients presented tetanic episodes or short stature at school age (134). The dissociation of renal Ca^{2+} and Mg^{2+} handling in GS, together with the subnormal response of these patients to thiazides (135, 136), pointed to a primary defect in the DCT.

In 1996, Simon and colleagues demonstrated that presumable loss of function mutations in the *SLC12A3* gene were responsible for GS (10). The *SLC12A3* gene is located on 16q13 and comprises 26 exons. It encodes the thiazide-sensitive Na^+-Cl^- cotransporter (NCCT), a 1,021 amino-acids integral membrane protein expressed in the apical membrane of cells lining the DCT (*Fig. 38-1*). NCCT belongs to the nine-member family of electroneural cation-chloride coupled cotransporters (*SLC12*) that also includes the Na^+-K^+-$2Cl^-$ and the K^+-Cl^- cotransporters (137). NCCT contains a central hydrophobic region comprising 12 putative transmembrane (TM) domains flanked by a short N-terminal and a long C-terminal hydrophilic intracellular termini (138). A model suggests that the affinity-modifying residues for Cl^- are located within TM 1–7 and for thiazides between TM 8–12 and that both segments are implicated in defining Na^+ affinity of NCCT (139).

Gitelman syndrome is transmitted as an autosomal recessive trait, and the majority of patients are compound heterozygous for different mutations in *SLC12A3*. To date, more than 110 mutations scattered through *SLC12A3* have been identified in GS patients (http://www.hgmd.cf.ac.uk). Most (~ 75%) are missense mutations substituting conserved amino acid residues, whereas nonsense, frameshift and splice-site defects, and gene rearrangements are less frequent. A significant number of GS patients, up to 25% in some series, is found to carry only a single mutation in *SLC12A3*, instead of being compound heterozygous or homozygous (140–142). Because GS is recessively inherited, it is likely that there is a failure to identify the second mutation in regulatory fragments, 5′ or 3′ untranslated regions, or deeper intronic sequences of *SLC12A3*, or that there are large genomic rearrangements. As discussed above, mutations in *CLCNKB* have been detected in a few patients presenting simultaneous features of cBS and GS (85, 90, 91). The distribution of ClC-Kb in both the TAL and DCT, and potential compensation by other Cl^- transporters, may probably explain these overlaping syndromes (2). In any case, GS is indeed genetically heterogeneous, raising the possibility of a concurrent heterozygous mutation in a

gene other than *SLC12A3*. In addition to *CLCNKB*, other genes participating in the complex handling of Na^+, Ca^{2+} and Mg^{2+} in DCT, or its regulation, are potential candidates (143).

Pathophysiology

The functional effects of mutants NCCT were tested using *X. laevis* oocytes (142, 144–146). Functional analyses revealed that some mutant NCCT proteins were synthesized but not properly glycosylated, targeted for degradation, and not delivered to the plasma membrane (144). Another class of *SLC12A3* mutations results in normal glycosylated proteins partly impaired in their routing and insertion, that perform normal function once they reach the plasma membrane (145, 146). Some NCCT mutants affect the intrinsic activity of the cotransporter, with normal glycosylation and plasma membrane insertion (142). Finally, splicing mutations of *SLC12A3* result in truncated transcripts that trigger nonsense-mediated decay (NMD), a mRNA surveillance pathway that allows cells to degrade mRNA that contains premature translation stop codons (142). Taken together, these results imply that GS may arise from impaired protein synthesis (splicing mutants); defective processing; defective protein insertion of functional mutants; and defective intrinsic activity of the mutant NCCT in the DCT cells (142).

Schultheis and colleagues generated a mouse model with a null mutation in the *Slc12a3* gene on a mixed background (147). The NCCT null mice showed hypocalciuria and hypomagnesemia at baseline but, in marked contrast to GS patients, no hypokalemic metabolic alkalosis. The NCCT-deficient mice had no signs of hypovolemia on a standard Na^+ diet, but they showed a lower blood pressure than wild-type when fed a Na^+-depleted diet for 2 weeks suggesting a subtle hypovolemia compensated at baseline. Subsequent studies performed on a homogeneous C57BL/6 strain showed that NCCT null mice had a mild compensated alkalosis with increased levels of plasma aldosterone (148) and an increased sensitivity to develop hypokalemia when exposed to dietary K^+ reduction (149). More recently, Belge and co-workers showed that mice lacking parvalbumin, a cytosolic Ca^{2+}-binding protein that is selectively expressed in the DCT, had a phenotype resembling GS, with volume contraction, aldosteronism and renal K^+ loss at baseline, impaired response to hydrochlorothiazide, and higher bone mineral density (150). They demonstrated that these modifications were due to modifications in intracellular Ca^{2+} signaling and decreased expression of NCCT in the DCT (150).

Studies of inactivating *SLC12A3* mutations and mouse models indicate that the GS phenotype results from dysfunction of NCCT. The loss of NCCT in the DCT leads to salt wasting, volume contraction, stimulation of the RAAS, and increased excretion of K^+ and H^+ in the collecting duct resulting in hypokalemic metabolic alkalosis. By contrast, the pathogenesis of hypocalciuria and hypomagnesemia remains debated. Two hypotheses prevail respecting hypocalciuria. First, the volume contraction causes a compensatory increase in proximal Na^+ reabsorption, driving passive Ca^{2+} transport in the PT (151). Second, the epithelial cells of the DCT hyperpolarize, due to lower intracellular Cl^- activity, which opens the apical voltage dependent Ca^{2+} channels (TRPV5), resulting in increased Ca^{2+} influx and reabsorption (152). Such hyperpolarization could also stimulate the basolateral Na^+/Ca^{2+} exchanger, further increasing Ca^{2+} reabsorption (153). Studies performed in chronic hydrochlorothiazide-treated mice (154) favor the first hypothesis, as micropuncture experiments demonstrated increased reabsorption of Na^+ and Ca^{2+} in the proximal tubule, whereas Ca^{2+} reabsorption in the distal convolution was unaffected. Furthermore, micropuncture experiments performed in NCCT-deficient mice revealed an enhanced fractional reabsorption of Na^+ and Ca^{2+} upstream of the DCT to compensate the transport defect in that segment (148).

Hypomagnesemia is an essential feature of GS. Several mechanisms, including K^+ depletion, increased passive Mg^{2+} secretion, or defective active Mg^{2+} transport in the DCT, have been proposed to explain the Mg^{2+} wasting in GS (4, 155). The recent identification of TRPM6 as a Mg^{2+} permeable channel in the DCT and its involvement in the pathogenesis of autosomal recessive hypomagnesemia (*see below*), suggested that this channel constitutes the apical entry step in active renal Mg^{2+} reabsorption (156). Indeed, chronic thiazide administration increased Mg^{2+} excretion and reduced renal expression levels of TRPM6 in mice. In addition, TRPM6 expression was also drastically decreased in mice lacking NCCT (154). These results suggest that the pathogenesis of hypomagnesemia in chronic thiazide treatment as well as GS could involve TRPM6 downregulation. Structural variations in the epithelial cells lining DCT, with decreased absorptive surface area for Mg^{2+}, may also play a role (147, 157).

Clinical Manifestations

Classically, GS was considered as a benign variant of Bartter-like syndromes, usually detected during adolescence or adulthood. Since the disorder originates from

the DCT, the salt and water losses in GS patients are less pronounced than in aBS or cBS because urinary concentrating ability should not be affected (*Table 38-2*). The GS patients are often asymptomatic or presenting with mild symptoms such as weakness, fatigue, salt craving, thirst, nocturia, constipation, or cramps. They may also consult for growth retardation and short stature, reflecting an alteration in the growth hormone-insulin-like growth factor I axis or pleiotropic effects resulting from magnesium depletion (158). Typical manifestations include muscle weakness, carpopedal spasms, or tetanic episodes triggered by hypomagnesemia (57, 159). Blood pressure is reduced, particularly for patients with severe hypokalemia and hypomagnesemia (160). Since Mg^{2+} ions increase the solubility of calcium pyrophosphate crystals and are important for the activity of pyrophosphatases, hypomagnesemia may promote the formation of calcium pyrophosphate crystals in joints and sclera, leading to chondrocalcinosis (161) and sclerochoroidal calcifications (162). Patients with GS have higher bone mineral density, similar to chronic thiazide treatment, which likely arises from increased renal Ca^{2+} reabsorption and a decreased rate of bone remodeling (163). Potassium and Mg^{2+} depletion prolong the duration of the action potential in cardiomyocytes, resulting in prolonged QT interval in $\sim$ 50% of the patients, which could lead to an increased risk for ventricular arrythmias (164, 165). Cases of GS patient who presented with long runs of ventricular tachycardia (166) or ventricular fibrillation with favorable outcome after cardioversion and continuous supplementation (167) have been reported. Pregnancies in GS appear to have a favorable outcome, provided continuous K^+ and Mg^{2+} supplementation and monitoring for oligohydramnios (168). A summary of the manifestations associated with GS and their frequency is shown in *Table 38-3*.

The classical biochemical features of GS include hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria. The presence of both hypomagnesemia (< 0.75 mM) and hypocalciuria (molar urinary calcium/creatinine ratio < 0.2) is highly predictive for the diagnosis of GS (134). The criteria for hypocalciuria in infants or children with GS have recently been precised (169). However, there are inter- and intra-individual variations in the extent of hypocalciuria, and hypomagnesemia may be absent in some GS patients (2, 31, 170). In addition, the combination of hypocalciuria and hypomagnesemia is also detected in rare cases of cBS (90). Although the urinary PGE_2 excretion is classically normal in GS, increased values can also be detected in some patients (2).

No specific findings are observed at renal biopsy, apart from occasional hypertrophy of the juxta-glomerular apparatus and markedly reduced expression of NCCT by immunohistochemistry (171). Hanevold et al. (172) reported a case of focal segmental glomerulosclerosis and C1q nephropathy in an African American child with GS who subsequently developed nephrotic range proteinuria.

Phenotype Variability and Potential Severity of GS

The view that GS is a benign condition has been challenged by reports emphasizing the phenotype variability and the

Table 38-3
Clinical manifestations associated with Gitelman syndrome

Most common (>50% of patients)	Prominent (20 to 50% of patients)	Occasional (Less than 20%)	Rare (Case reports)
Salt carving	Fainting	Early onset (before age 6)	Seizure
Cramps, muscle weakness, pain	Polyuria	Failure to thrive	Ventricular tachycardia
Fatigue	Arthralgia	Growth retardation	Rhabdomyolysis
Dizziness	Chondrocalcinosis	Vertigo, ataxia	Blurred vision
Nocturia	Prolonged corrected QT interval	Carpopedal spasm, tetany	Pseudotumor cerebri
Thirst, polydipsia	Febrile episodes	Vomiting	Sclerochoroidal calcifications
Paresthesia, numbness		Constipation	
Palpitations		Enuresis	
Low blood pressure		Paralysis	

potential severity of the disease. A detailed evaluation of 50 adult GS patients with identified *SLC12A3* mutations revealed that GS was associated with a significant reduction in the quality of life – similar to that associated with congestive heart failure or diabetes (173). Manifestations such as early onset (before age 6 years), growth retardation, invalidating chondrocalcinosis, tetany, rhabdomyolysis, seizures, and ventricular arrhythmia have been described, although in a limited number of cases (31, 142, 158, 166, 173). Based on the large number of patients harboring *SLC12A3* mutations, the phenotype of GS is highly heterogeneous in terms of age at presentation, nature/severity of biochemical abnormalities, and nature/severity of the clinical manifestations (*Table 38-3*). The phenotype variability has been documented not only between patients carrying different *SLC12A3* mutations, but also for a common underlying mutation (174) and between affected family members (142, 175).

The mechanisms that could account for intrafamilial variability include gender (affected brothers are apparently more severely affected than their sisters carrying the same mutation), modifier genes (affecting the regulation or activity of NCCT), and environmental factors (dietary intake of NaCl, Ca^{2+}, or Mg^{2+}) (2, 142, 175, 176). Compensatory mechanisms operating in other nephron segments should also be considered, as evidenced in mice with defective NCCT (148, 150, 154). Finally, considering that most of patients with GS are compound heterozygous harboring various mutant *SLC12A3* alleles, the phenotype variability could be related to the nature and/or position of the underlying mutation(s). This hypothesis has been substantiated by the recent studies of Riveira-Munoz et al. (142) which showed that a specific combination of mutations was preferentially associated with a severe presentation of GS.

Blood Pressure in GS: Effect of the Carrier State

In 2001, Cruz et al. investigated a large Amish kindred to show that patients with GS had significantly lower age- and gender-adjusted diastolic and systolic blood pressure, a higher urinary Na^+ excretion, and a higher salt intake than their wild-type relatives (160). Additional support for the role of NCCT in blood pressure regulation was provided by the report that transplantation of a GS kidney into a non-Gitelman hypertensive recipient resulted in the correction of hypertension in the latter (177). Considering that the frequency of heterozygote carriers of *SLC12A3* mutations is approximately 1%, the question was thus raised whether single loss-of-function mutations in *SLC12A3* may affect blood pressure regulation in the general population (47). Recently, Lifton and colleagues screened 3,125 adult subjects from the Framingham Heart Study for mutations in *SLC12A3* (and by extension *SLC12A1*, and *KCNJ1*, responsible for aBS) and identified 30 different mutations (15 in *SLC12A3*, 10 in *SLC12A1*, and 5 in *KCNJ1*) in 49 subjects (45). Of these mutations, ten were biochemically proven loss of function (seven in NCCT alone) and 20 were inferred from the conservation and rarity criteria. Examination of long-term BP revealed that 80% of the mutation carriers were below the mean systolic BP values of the entire cohort. The mean BP reduction in carriers was similar to values obtained with chronic thiazide treatment (45). Thus, rare functional variants of three genes involved in Bartter-like syndromes, including GS, have a significant impact in the heritability of BP variation.

Differential Diagnosis

The differential diagnosis of GS includes other Bartter-like syndromes (*Table 38-1*), and particularly cBS due to mutations in *CLCNKB* (2, 170), as well as diuretic or laxative abuse, and chronic vomiting. As mentioned above, the clinical history and biochemical features, even hypocalciuria and hypomagnesemia, may not be fully reliable to distinguish GS from cBS. Although implementation of genetic testing should be promoted, such testing in the context the BS and GS bears a significant cost, considering the number of exons to be screened, the lack of hot-spots, and the large number of mutations described. Recently, Colussi et al. evaluated the response to a simple thiazide test in the diagnosis of GS (170). They monitored the chloride fractional clearance during the 3 h following the administration of hydrochlorothiazide (HCTZ, 1 mg/kg or 50 mg in adults) orally. More than 90% (38/41) of patients with GS showed a blunted response ($<2.3\%$) to HCTZ, a feature that was never observed in seven patients with BS (five with aBS and two with cBS) and three patients with diuretic abuse or vomiting. Thus, the HCTZ test offers a high sensitivity and specificity for the diagnosis of GS (170). However, it should not be recommended to diagnose aBS, in view of the specific clinical history and the potential danger of diuretic treatment in these patients. Whether this test has the power to distinguish between the overlapping features of GS and cBS due to *CLCNKB* mutations is also uncertain (178).

Gitelman syndrome-like manifestations including hypokalemic metabolic alkalosis with hypomagnesemia and

hypocalciuria, have been reported as a rare complication of the use of cisplatin (179). Although the mechanism remains uncertain, cisplatin is known to induce focal tubular necrosis lesions in the DCT (180). Autoimmune disorders cause acquired renal tubular disorders, potentially due to autoantibodies against tubular components (181). Typical features of acquired GS have been reported in association with various autoimmune disorders including iritis and arthritis (182), sialoadenitis (125), and Sjögren syndrome (183). Of note, there was no improvement of renal K^+ wasting after corticosteroid treatment in one such case (183).

Treatment

Magnesium and potassium supplementations are the main treatments in patients with GS. Magnesium supplementation should be considered first, since Mg^{2+} repletion will facilitate K^+ repletion and reduce the risk of tetany and other complications related to hypomagnesemia (159, 184). All types of magnesium salts are effective, but their bioavailability is variable. Magnesium chloride, magnesium lactate and magnesium aspartate show higher bioavailability (159). $MgCl_2$ is recommended since it will also correct the urinary loss of Cl^-. The dose of magnesium must be adjusted individually in 3–4 daily administrations, with diarrhea being the limiting factor. In addition to magnesium, high doses of oral KCl supplements (up to 10 mg/kg/day in children) may be required (185). Importantly, Mg^{2+} and K^+ supplementation results in a catchup growth (142, 158). Spironolactone or amiloride can be useful, both to increase serum K^+ levels in patients resistant to KCl supplements and to treat Mg^{2+} depletion that is worsened by elevated aldosterone levels (186). Both drugs should be started cautiously to avoid hypotension. Patients should not be refrained from their usual salt craving, particularly if they practice a regular physical activity. Prostaglandin inhibitors are less indicated in GS than in aBS, since urinary PGE_2 levels are usually normal. Liaw et al. reported an improvement in growth response following high-dose indometacin, but complicated by gastrointestinal haemorrhage (187). Refractory hypokalemia has also been treated with the specific COX-2 inhibitor Rofecoxib (188). Considering the occurrence of prolonged QT interval in up to half GS patients (164, 165), QT-prolonging medications should be used with caution.

Although GS adversely affects the quality of life (160), we lack informations about the long-term outcome of these patients. Renal function and growth appear to be normal, provided lifelong supplementation (189). Progression to renal failure is extremely rare in GS: only two GS patients who developed end-stage renal disease have been reported (190, 191).

Disorders of the Calcium-Sensing Receptor

The extracellular Ca^{2+}-sensing receptor (CaSR) is a G protein-coupled receptor belonging to the metabotropic glutamate receptor subfamily that was identified in 1993 by Brown, Hebert, and colleagues (192). The human *CASR* gene is located on chromosome 3q21 with a coding region of 3,234 bp and 6 exons (193). The CaSR is a ~120 kD protein forming homodimers through interactions of cysteine residues in the extracellular domain (194). The CaSR is predominantly expressed in the apical membrane of the parathyroid hormone (PTH)-secreting cells in the parathyroids and, in the kidney, in the apical membrane of PT cells and principal cells of the medullary CD and on the basolateral membrane of cells lining the TAL and DCT (195). The CaSR regulates the PTH secretion and modulates the renal tubular reabsorption of Ca^{2+} and Mg^{2+} in response to ionized serum Ca^{2+} and Mg^{2+} concentrations (195, 196).

The CaSR responds to physiologically relevant, millimolar concentrations of extracellular $Ca^{2+}[Ca^{2+}_o]$, with a half-maximal response (EC50) of 3 mM. It also shows a distinct affinity for various multivalent cations in vitro, including Mg^{2+} (EC50, 10 mM) (192). Activation of the CaSR mediates different, cell-specific signal transduction pathways (195). In bovine parathyroid cells, high levels of $[Ca^{2+}_o]$ activate phospholipase C (PLC) via a member of the Gq family, followed by the breakdown of phosphatidylinositol 4,5-bisphosphate with formation of 1,2-sn-diacylglycerol and of inositol 1,4,5-trisphosphate (IP3). The accumulation of IP3 leads to the release of intracellular pools of Ca^{2+} causing inhibition of PTH secretion through mechanisms that remain to be fully defined (195). Microperfusion studies in rat revealed that elevation of peritubular $[Ca^{2+}_o]$ and $[Mg^{2+}_o]$ markedly reduces the fractional absorption of Ca^{2+}, Mg^{2+}, and Na^+ in the TAL (197). As discussed above (see section on BS), the reabsorption of Ca^{2+} and Mg^{2+} in the TAL occurs mainly through a paracellular pathway driven by a lumen-positive, transepithelial potential generated by the combined activity of NKCC2 and ROMK (*Fig. 38-1*). High $[Ca^{2+}_o]$ in the TAL decreases hormone-dependent cAMP accumulation, reflecting a direct inhibition of the CaSR-dependent Galpha-adenylylate cyclase (AC) activity (195). In turn, the

reduced cAMP levels decrease NaCl transport, hence Ca^{2+} and Mg^{2+} reabsorption. In addition, Ca^{2+}-induced activation of the CaSR leads to production of arachidonic acid and its metabolites which inhibit the activity of ROMK and NKCC2 activity, further reducing Ca^{2+} and Mg^{2+} transport (198).

Additional evidence of the role of the CaSR in regulating tubular reabsorption of Ca^{2+} and Mg^{2+} was provided by the identification of different types of mutations in the *CASR* gene (199). Loss-of-function CaSR mutations result in familial hypocalciuric hypercalcaemia (FHH) and neonatal severe primary hyperparathyroidism (NSHPT) (200, 201), whereas gain-of-function CaSR mutations result in autosomal dominant hypocalcemia (ADH) (202, 203), which can be associated with a Bartter-like syndrome (204, 205) (*Table 38-4*; *Fig. 38-3*). The prevalence of FHH is up to one in 16,000, ADH one in 70,000, whereas NSHPT is very rare (206).

Familial Hypocalciuric Hypercalcemia, Neonatal Severe Primary Hyperparathyroidism

In 1972, Foley et al. described *familial hypocalciuric hypercalcemia (FHH)*, also named *familial benign hypercalcemia (FBH)*, (OMIM #145980), an autosomal dominant disorder characterized by a mild-to-moderate hypercalcemia, with mild hypermagnesemia, inappropriately normal or mildly elevated serum PTH levels, and hypocalciuria (207). Although patients with FHH are usually asymptomatic, complications such as chondrocalcinosis, acute pancreatitis and gallstones may occur with age (208, 209). A simple diagnostic test is a calcium over creatinine clearance ratio (CCCR) <0.01 (210). The finding of hypercalcemia in first-degree relatives supports the diagnosis, particularly when found in children under age 10 years.

Calcium infusion studies in FHH patients revealed a higher-than-usual set point for the release of PTH, suggesting an alteration in Ca^{2+} sensing (211). Genetic linkage studies mapped the gene for FHH to the region of chromosome 3 where the CaSR gene was located, and mutational analyses of the *CASR* gene revealed unique heterozygous mutations in approximately 90% of the FHH kindreds examined (199, 212, 213). Isolated cases of FHH with a de novo mutation in *CASR* have also been reported (214, 215). Many *CASR* mutations cluster in aspartate and glutamate-rich regions of the extracellular domain of the receptor, which may act as cationic binding sites (199). Expression studies confirmed that FHH-causing mutations induce a rightward shift of the set point for the Ca^{2+}-dependent responses, corresponding to a loss-of-function (201, 203). The defective extracellular CaSR likely leads to inappropriate absorption

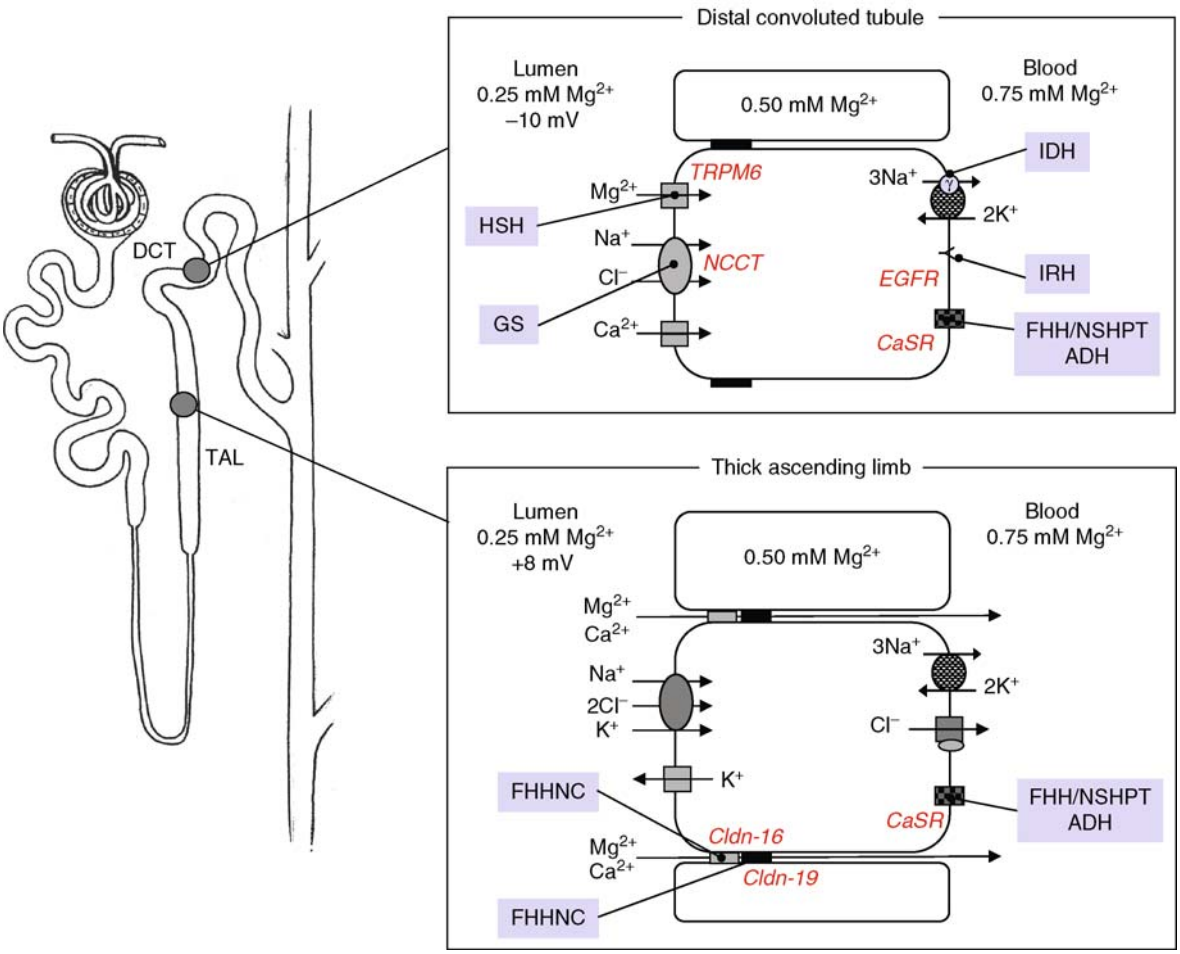
Table 38-4

Inherited disorders of the extracellular Ca^{2+}-sensing receptor

Disorder	OMIM #	Inheritance	Type of mutation	Age at onset	Serum Ca^{2+}	Serum Mg^{2+}	Serum PTH	Urine Ca^{2+}	Urine Mg^{2+}	Complications
Familial hypocalciuric hypercalcemia (FHH), Familial benign hypercalcemia (FBH)	145980	AD	Loss-of-function	Childhood	↑	N – ↑	N – ↑	↓	N – ↓	Pancreatitis, chondrocalcinosis, gallstones
Neonatal severe primary hyperparathyroidism (NSHPT)	239200	AR	Loss-of-function	Neonatal	↑↑	↑	↑↑	↓↓	↓	Life-threatening condition, failure to thrive, osteopenia, fractures
Autosomal dominant hypocalcemia (ADH), Autosomal dominant hypoparathyroidism	146200	AD	Gain-of-function	Infancy	↓	↓	↓	↑	↑ – ↑↑	Nephrocalcinosis and renal stones under vitamin D treatment, Bartter-like syndrome with the most severe activating mutations

Figure 38-3

Inherited disorders of magnesium reabsorption in the loop of Henle and distal convoluted tubule. In the thick ascending limb (TAL) of Henle's loop, Mg^{2+} is reabsorbed through a paracellular pathway, driven by the lumen-positive transcellular voltage generated by the transcellular reabsorption of NaCl. Mutations in the *CLDN16* and *CLDN19* genes that encode the tight junction proteins, claudin-16 and claudin-19 cause familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC). In the distal convoluted tubule (DCT), Mg^{2+} is actively reabsorbed via the transcellular pathway involving an apical entry step through a Mg^{2+}-permeable ion channel (TRPM6) and a basolateral exit, presumably mediated by a Na^+–coupled exchange mechanism. The molecular identity of the basolateral exchange is unknown. Basolateral EGF stimulates the basolateral EGF receptor EGFR, which then increases the activity of TRPM6. Mutations of *SLC12A3* coding for NCCT are responsible for Gitelman syndrome (GS). Mutations in the apical TRPM6 channel (*TRPM6*) cause hypomagnesemia with secondary hypocalcemia (HSH), whereas mutations in the gamma-subunit of the Na^+-K^+-ATPase (*FXYD2*) cause isolated dominant hypomagnesemia (IDH) and mutations in the *EGF* gene coding for the epidermal growth factor EGF cause isolated recessive hypomagnesemia (IRH). Loss-of-function mutations in the *CASR* gene (CaSR) are associated with familial hypocalciuric hypercalcemia (FHH) and neonatal severe primary hyperparathyroidism (NSHPT), whereas activating mutations of the CaSR cause autosomal dominant hypocalcemia (ADH).



of Ca^{2+} and Mg^{2+} in the TAL (198) and Mg^{2+} transport in the DCT (196). Renal excretion of Ca^{2+} and Mg^{2+} is reduced, which leads to hypercalcemia and sometimes hypermagnesemia (216).

FHH is genetically heterogeneous, since no *CASR* mutation can be detected in ~ 10% of the probands. Two additional loci have been mapped on chromosome 19p13.3 and chromosome 19q13 (199). It must be noted

that patients with autoimmune manifestations may present circulating antibodies to the extracellular domain of the CaSR, which may interfere with the normal activation of the receptor by extracellular Ca^{2+}, leading to acquired FHH with hypocalciuria and hypercalcemia (217).

Neonatal severe primary hyperparathyroidism (NSHPT) (OMIM #239200) is a life-threatening, severe hyperparathyroidism characterized by hypercalcaemia, failure to thrive, osteopenia, multiple fractures, and rib cage deformities developing soon after birth (218). NSHPT is usually caused by homozygous *CASR* mutations in children born to consanguineous FBH parents (201, 202). Of note, a marked phenotypic heterogeneity has been observed amongst four members of a kindred harboring the homozygous (Q164X) mutation of *CASR* (219). Patients with sporadic NSHPT have been reported to be associated with de novo heterozygous inactivating mutations of *CASR* (199, 212). At least 60 mutations of the *CASR* gene, mostly missense, have been reported in FHH and NSHPT kindreds (http://www.hgmd.cf.ac.uk).

Ho et al. generated a CaSR knock-out mouse and showed that the heterozygous mice have modest elevations of serum calcium, magnesium and parathyroid hormone levels as well as hypocalciuria, thus mimicking FHH, whereas homozygous null mice show markedly elevated serum calcium and parathyroid hormone levels, parathyroid hyperplasia, bone abnormalities, retarded growth and premature death like humans with NSHPT (220). In order to remove the confounding effects of elevated PTH and assess the independent function of CaSR, double-homozygous mice lacking CaSR and Gcm2 were generated (221). Gcm2 is the mouse homologue of the *Drosophila* gcm (glial cell missing) gene which is specifically expressed in developing parathyroids, and its genetic ablation in mouse leads to a lack of parathyroid glands (222). The Gcm2 deficiency rescued the lethality of CaSR deficiency in this model. Furthermore, the lack of severe hyperparathyroidism prevented rickets and osteomalacia, but it did not rescue the hypocalciuria – indicating that hypocalciuria in FHH and NSHPT is mediated by the lack of CaSR in the kidney (221).

When treating FHH and NSHPT, one should consider that these disorders represent the mildest and severest variants of hyperparathyroidism, respectively. In most kindreds with FHH, the lifelong hypercalcemia is very mild, causing no specific symptoms, and requiring no treatment. In contrast, the severe hypercalcemia and hyperparathyroidism associated with NSHPT remains challenging and requires specific measures. The acute management of hypercalcemia classically relies on saline perfusion and careful use of loop diuretics. Pamidronate, a biphosphonate drug that could halt the bone resorption process mediated by uncontrolled hyperparathyroidism, has been successfully used in NSHPT patients to control severe hypercalcemia prior to parathyroidectomy (219). Radical subtotal parathyroidectomy is often the treatment of choice in NSHPT (223). Parathyroidectomy may also be appropriate in kindreds with FHH in which there is unusually severe hypercalcemia, particularly with musculoskeletal and neurobehavioral manifestations, or frankly elevated PTH levels (224). Calcimimetic CaSR activators, which potentiate the activation of the CaSR by extracellular Ca^{2+}, reset the Ca^{2+}-regulated PTH release in primary and secondary hyperparathyroidism toward normal. These drugs may be of interest in FHH and NSHPT, in which they could increase the sensitivity of the CaSR to extracellular Ca^{2+}, thereby reducing PTH secretion and serum calcium concentration (225). Such an effect has been documented in a single FHH patient due to a de novo inactivating mutation of the CaSR, in which a maintenance treatment with the calcimimetic drug Cinacalcet HCl resulted in a rapid decrease in PTH secretion and a sustained normalization of serum calcium (215).

Autosomal Dominant Hypocalcemia

Activating mutations of the *CASR* gene were first described in families affected with autosomal dominant hypocalcemia (ADH, also named autosomal dominant hypoparathyroidism, or autosomal dominant hypocalcemia with hypercalciuria, ADHH) (OMIM #146200) (202, 203). Affected individuals present with hypocalcemia, hypercalciuria, and polyuria, and about 50% of these patients have hypomagnesemia. The serum phosphate concentrations in patients with ADH are either elevated or in the upper-normal range (199, 203). Hypocalcemia in ADH is generally mild to moderate, and patients may present carpopedal spasms and/or seizures. Elevated urinary calcium may lead to nephrolithiasis despite increased magnesium excretion (57).

More than 20 different mutations of the *CASR* gene, mostly missense, have been identified in ADH patients. About half of these mutations are in the extracellular domain of the CaSR (199). Expression studies confirmed that these activating mutations induce a leftward shift in the dose-response curve of the mutant CaSR, corresponding to enhanced sensitivity for extracellular Ca^{2+} and Mg^{2+} (203). This results in inappropriately low serum PTH and decreased reabsorption of Ca^{2+} and Mg^{2+} in the TAL and DCT, leading to Ca^{2+} and Mg^{2+} wasting. The impaired reabsorption of Ca^{2+} and Mg^{2+} in the TAL is thought to

be due to a reduction of the paracellular permeability and/or to a decreased lumen-positive transepithelial voltage due to defective transcellular NaCl reabsorption (195). Hormone-stimulated Mg^{2+} reabsorption is also inhibited in the DCT, which probably contributes to the renal magnesium loss (155).

In treating ADH patients with an activating CaSR mutation, it is important to avoid vitamin D which can dramatically increase urinary calcium excretion, leading to nephrocalcinosis, nephrolithiasis, and even irreversible reduction of renal function in some patients (199, 203). Therefore, the treatment of hypocalcemia in ADH with vitamin D and calcium supplementation should be restricted to clearly symptomatic patients (57). Addition of hydrochlorothiazide may reduce urinary calcium excretion and maintain serum calcium concentrations near the lower limit of normal, allowing the reduction of vitamin D treatment (226).

It was shown recently that patients with ADH due to activating *CASR* mutations may have a clinical course complicated with a Bartter-like syndrome, i.e., development of a salt-losing tubulopathy associated with urinary concentrating defect and hypokalemic metabolic alkalosis (204, 205). All three patients described thus far had hypomagnesemia. Heterologous expression of the mutant CaSR revealed that the underlying mutations (L125P, C131W, A843E) are among the most severe gain-of-function *CASR* mutations, characterized by a leftward shift in the dose-response curve for the receptor and also a much lower EC50 than patients with ADH (204, 205). These mutations appear to be fully activated under normal serum Ca^{2+} concentrations and induce a significant salt-losing phenotype by inhibiting the reabsorption of NaCl in the TAL (*Fig. 38-1*). Accordingly, this subset of ADH patients presenting a Bartter-like syndrome was qualified as "Type 5 Bartter-like syndrome." The inclusion of these cases among the Bartter-like syndromes is debated, and it must be pointed that the Bartter-like phenotype may be very mild, as recently reported for another ADH-causing mutation (227).

Disorders of Magnesium Metabolism

Introduction

Magnesium is an important intracellular cation. As a cofactor, it is involved in energy metabolism and protein and nucleic acid synthesis. It is also critical for the modulation of membrane transporters and in signal transduction. Under physiologic conditions, serum Mg^{2+} levels are maintained at almost constant values. Mg^{2+} homeostasis depends on a balanced intestinal absorption and renal excretion. Mg^{2+} deficiency can result from reduced dietary intake, intestinal malabsorption or renal loss. The control of body Mg^{2+} homeostasis primarily resides in the kidney tubules.

The dietary intake of Mg^{2+} may vary substantially. The principal site of Mg^{2+} absorption is the small intestine, where Mg^{2+} absorption occurs via two different pathways: a saturable active transcellular transport and a nonsaturable paracellular passive transport (228, 229). In the kidney, approximately 80% of total serum Mg^{2+} is filtered in the glomeruli, of which more than 95% is reabsorbed along the nephron. Tubular Mg^{2+} reabsorption differs in quantity and kinetics depending on the different nephron segments. In the adult kidney, approximately 15–20% is reabsorbed in the PT, whereas the premature kidney of the newborn is able to reabsorb up to 70% of the filtered Mg^{2+} in this nephron segment (230). From early childhood on, roughly 70% of Mg^{2+} is reabsorbed in the cortical TAL of the loop of Henle. Transport in this segment is passive and paracellular, mediated by claudin-16 and claudin-19. The driving force for reabsorption against an unfavorable concentration gradient is the lumen-positive transepithelial voltage (*Fig. 38-3*). Only 5–10% of the filtered Mg^{2+} is reabsorbed in the DCT. However, in this part of the nephron the fine adjustment of renal excretion is accomplished. In the DCT, Mg^{2+} transport is an active transcellular process (*Fig. 38-3*). Physiologic studies indicate that apical entry into DCT cells is mediated by the specific and regulated Mg^{2+} channel TRPM6. The mechanism of basolateral transport into the interstitium is unknown. Here, Mg^{2+} has to be extruded against an unfavorable electrochemical gradient. Most physiologic studies favor a Na^{+}-dependent exchange mechanism (231). Mg^{2+} entry into DCT cells appears to be the rate-limiting step and the site of regulation. For details of Mg^{2+} transport in the distal tubule see Dai et al. (155). In the collecting duct, there is no significant Mg^{2+} uptake. Finally, 3–5% of the filtered Mg^{2+} is excreted in the urine.

Magnesium depletion is usually secondary to another disease process or to a therapeutic agent (e.g., loop diuretics, thiazides, aminoglycosides, cisplatine, calcineurin inhibitors). During infancy and childhood, a substantial proportion of patients receiving medical attention for signs of hypomagnesemia are affected by inherited renal disorders associated with Mg^{2+} wasting. In these disorders hypomagnesemia may either be a leading symptom or may be part of a complex phenotype resulting from tubular dysfunction, as will be detailed below. Recent advances

in molecular genetics of hereditary hypomagnesemia substantiated the role of a variety of genes and their encoded proteins in human epithelial Mg^{2+} transport, and helped to characterize different clinical subtypes of hereditary Mg^{2+}-wasting (Table 38-5). A careful clinical and biochemical assessment allows to distinguish the different disease entities in most cases, even when there is a considerable overlap in the phenotypic characteristics (Table 38-6).

Gitelman Syndrome

This primary salt-wasting disorder complicated by urinary Mg^{2+} wasting and hypomagnesemia is discussed in detail above.

Isolated Dominant Hypomagnesemia

Isolated dominant hypomagnesemia (IDH, OMIM #154020) results from a mutation in the *FXYD2* gene on chromosome 11q23 which encodes a γ-subunit of the Na^+-K^+-ATPase (232). Only two IDH families have been described so far (233, 234). In both families, the index patients presented with seizures during childhood (at 7 and 13 years) with serum Mg^{2+} levels of approximately 0.4 mmol/L. One patient was treated for seizures of unknown origin with antiepileptic drugs until serum Mg^{2+} levels were evaluated during adolescence. At that time mental retardation was evident. Serum Mg^{2+} measurements performed in members of both families revealed low serum Mg^{2+} levels (around 0.5 mmol/L) in numerous apparently healthy individuals. A ^{28}Mg-retention study in one of the patients indicated a primary renal defect (233). The intestinal absorption of Mg^{2+} was preserved and even stimulated in compensation for the increased renal losses. Urinary Mg^{2+} measurements in affected family members revealed significant renal Mg^{2+} loss (around 5 mmol per day) despite profound hypomagnesemia. Urinary Ca^{2+} excretion rates were low in all hypomagnesemic individuals, a finding reminiscent of patients presenting with GS. However, in contrast to GS patients, no other biochemical abnormalities were reported, especially no hypokalemic alkalosis. In the two families, hypomagnesemia was inherited as an autosomal dominant trait. A genome-wide linkage study could map IDH to chromosome 11q23 (235). Detailed haplotype analysis demonstrated a common

Table 38-5
Inherited disorders of renal magnesium handling

Disorder	OMIM #	Inheritance	Gene locus	Gene	Protein
Gitelman syndrome	263800	AR	16q13	*SLC12A3*	NCCT, Na^+-Cl^- cotransporter
Isolated dominant hypomagnesemia	154020	AD	11q23	*FXYD2*	γ-subunit of the Na^+-K^+-ATPase
Isolated recessive hypomagnesemia	611718	AR	4q25	*EGF*	Pro-EGF, epidermal growth factor
Autosomal dominant hypocalcemia, Autosomal dominant hypoparathyroidism	146200	AD	3q21	*CASR*	CaSR, Ca^{2+}/Mg^{2+}sensing receptor
Familial hypocalciuric hypercalcemia, Familial benign hypercalcemia	145980	AD	3q21	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Neonatal severe primary hyperparathyroidism	239200	AR	3q21	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Familial hypomagnesemia with hypercalciuria/ nephrocalcinosis	248250	AR	3q28	*CLDN16*	Claudin-16 (paracellin-1), tight junction protein
Familial hypomagnesemia with hypercalciuria/ nephrocalcinosis and severe ocular involvement	248190	AR	1p34	*CLDN19*	Claudin-19, tight junction protein

[a]frequent complication during therapy with Ca^{2+} and vitamin D

haplotype segregating in the two families suggesting a common ancestor. Subsequent mutation analysis of the *FXYD2* gene demonstrated the identical mutation G41R in all affected individuals of both family branches (232).

The protein encoded by *FXYD2* is a member of a small single transmembrane protein family which share the common amino acid motif F-X-Y-D. FXYD proteins modulate the function of the ubiquitous Na^+-K^+-ATPase, a dimeric enzyme invariably consisting of one α- and one β-subunit. FXYD proteins constitute a third or γ-subunit that represents a tissue-specific regulator of the Na^+-K^+-ATPase. Two members of this family, FXYD2 and FXYD4, are highly expressed along the nephron displaying an alternating expression pattern (236). The FXYD2 γ-subunit comprises two isoforms (named γ-α and γ-β) that are differentially expressed in the kidney. The γ-α isoform is present predominantly in the proximal tubule and expression of the γ-β isoform predominates in the distal nephron, especially in the DCT and connecting tubule (237). The FXYD2 γ-subunit increases the apparent affinity of Na^+-K^+-ATPase for ATP while decreasing its Na^+ affinity (237). Thus, it might provide a mechanism for balancing energy utilization and maintaining appropriate salt gradients.

Expression studies of the mutant G41R-γ-subunit revealed a dominant-negative effect leading to a retention of the γ-subunit in the Golgi complex. The mechanism of a dominant negative effect is supported by the observation that individuals with a large heterozygous deletion of chromosome 11q including the *FXYD2* gene exhibit normal serum Mg^{2+} levels (234). Urinary Mg^{2+} wasting together with the expression pattern of the *FXYD2* gene indicate defective transcellular Mg^{2+} reabsorption in the DCT in IDH patients. The exact mechanism causing increased urinary Mg^{2+} excretion has yet to be determined. Meij and colleagues have suggested that diminished intracellular K^+ might depolarize the apical membrane resulting in a decreased Mg^{2+} uptake (232). Alternatively, an increase in intracellular Na^+ could impair basolateral Mg^{2+} transport which is presumably achieved by a Na^+-coupled exchange mechanism. Another explanation is that the γ-subunit is not only involved in Na^+-K^+-ATPase function but also an essential component of a yet unidentified ATP-dependent transport system specific for Mg^{2+}. Similar to Ca^{2+}, both, a specific Mg^{2+}-ATPase and a Na^+-coupled exchanger might exist. Further studies are needed to clarify this issue.

An interesting feature of IDH is the finding of hypocalciuria which is primarily observed in GS. Unfortunately, only one large family with IDH has been described and an animal model for IDH is still lacking. Mice lacking the γ-subunit (*Fxyd2*) do not demonstrate significant abnormalities in Mg^{2+} conservation or balance (238). One could speculate that, like in GS, a defect in Na^+-K^+-ATPase

function and energy metabolism might lead to an apoptotic breakdown of the early DCT responsible for Mg^{2+} reabsorption, while later parts of the distal nephron remain intact. In IDH, there is no evidence for renal salt wasting and no stimulation of the RAAS. The finding of hypocalciuria without apparent volume depletion apparently contradicts recent experimental data which favor an increase in proximal tubular Ca^{2+} reabsorption due to volume depletion in GS (154).

Isolated Recessive Hypomagnesemia

Geven and colleagues reported a form of isolated recessive hypomagnesemia (IRH, OMIM #611718) in a consanguineous family (239). Two affected girls presented with generalized seizures during infancy. Possibly related to late diagnosis, both patients also exhibited neurodevelopmental deficits. Clinical and laboratory workup at 4 and 8 years of age, respectively, revealed serum Mg^{2+} levels around 0.5–0.6 mmol/L with no other associated electrolyte abnormalities. A ^{28}Mg-retention study in one patient pointed to a primary renal defect while intestinal Mg^{2+} uptake was preserved (239). Both patients exhibited renal Mg^{2+} excretion of 3–6 mmol per day despite hypomagnesemia confirming renal Mg^{2+} wasting. In contrast to IDH, renal Ca^{2+} excretion rates in IRH are within the normal range.

The molecular defect for IRH was identified by Groenestege et al. who demonstrated a homozygous P1070L mutation in both affected siblings in the *EGF* gene encoding the epidermal growth factor EGF (240). The EGF protein is expressed in the DCT, and its binding to the receptor EGFR is essential for the function of the TRPM6 channel. The mutation is located in the cytosolic C-terminal terminus within a sorting motif (PXXP) which is necessary for the trafficking of EGF to the basolateral membrane. Expression studies demonstrated that mutant pro-EGF retains EGF secretion to the apical membrane but does not reach the EGF receptor in the basolateral membrane, resulting in dysfunction of TRPM6 (240). Even if IRH seems to be an extremely rare disease phenotype, the identification of EGF mutations is important because this is the first autocrine/paracrine magnesiotropic hormone known at the molecular level.

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC, OMIM #248250) is an autosomal recessive tubular disorder. Since its first description by Michelis et al. in 1972 (241), numerous kindreds have been reported, allowing a comprehensive characterization of the clinical spectrum of this disorder and discrimination from other Mg^{2+} losing tubular diseases (242–246). As a consequence of excessive renal Mg^{2+} and Ca^{2+} wasting, patients develop the characteristic triad of hypomagnesemia, hypercalciuria and nephrocalcinosis that gave the disease its name. Most FHHNC patients present during early childhood with recurrent urinary tract infections, polyuria/polydispsia, nephrolithiasis, and/or failure to thrive. Clinical signs of severe hypomagnesemia are less common. Extrarenal manifestations, especially ocular involvement (including severe myopia, nystagmus, or chorioretinitis) have been reported (244–246). Additional laboratory findings include elevated serum PTH levels before the onset of chronic renal failure, incomplete distal tubular acidosis, hypocitraturia, and hyperuricemia, which are present in most patients (247). The clinical course of FHHNC patients is often complicated by the development of renal failure during the first two decades of life, and about one third of patients develop ESRD during adolescence. Due to a reduction in filtered Mg^{2+} that limits urinary Mg^{2+} excretion, hypomagnesemia may completely disappear with the decline of GFR.

Beside continuous Mg^{2+} supplementation, therapy aims to reduce Ca^{2+} excretion by using thiazides to prevent the progression of nephrocalcinosis and stone formation. The degree of renal calcification has been correlated with progression of chronic renal failure (245). In a short term study, thiazides have been demonstrated to effectively reduce urinary calcium excretion in FHHNC patients (248). However, these therapeutic strategies have not been shown yet to significantly influence the progression of renal failure. Supportive therapy is important for protecting kidney function and should include provision of sufficient fluids and whenever possible, the prevention and/or effective therapy of urinary tract infections. Renal transplantation does not result in recurrence of the disease because the primary defect resides in the kidney.

By positional cloning, Simon et al. identified a new gene on 3q27 (*CLDN16*, formerly *PCLN1*), which is mutated in patients with FHHNC (249). *CLDN16* codes for claudin-16, a member of the claudin family. More than 20 claudins identified so far comprise a family of ~22 kD proteins with four transmembrane segments, two extracellular domains, and intracellular N- and C-termini. Claudins are important components of tight junctions. The individual composition of tight junction strands with different claudins confers the characteristic properties of

different epithelia for paracellular permeability and/or transepithelial resistance. In this context, a crucial role has been attributed to the first extracellular domain of the claudin protein which is extremely variable in number and position of charged amino acid residues. Most mutations reported so far in FHHNC are simple missense mutations affecting the transmembrane domains and the extracellular loops with a particular clustering in the first extracellular loop containing the putative ion selectivity filter. Within this domain, patients originating from Germany and Eastern European countries exhibit a common mutation (L151F) due to a founder effect (247). As this mutation is present in approximately 50% of mutant alleles, molecular diagnosis is greatly facilitated in patients originating from these countries.

Family analysis revealed that carriers of heterozygous *CLDN16* mutations may also present with clinical symptoms. Two independent studies describe a high incidence of hypercalciuria, nephrolithiasis and/or nephrocalcinosis in first degree relatives of FHHNC patients (245, 247). A subsequent study also reported a tendency towards mild hypomagnesemia in family members with heterozygous *CLDN16* mutations (250). Thus, one might speculate that *CLDN16* mutations could be involved in idiopathic hypercalciuric stone formation.

A homozygous *CLDN16* mutation (T303R) affecting the C-terminal PDZ domain has been identified in two families with isolated hypercalciuria and nephrocalcinosis without disturbances in renal Mg^{2+} handling (251). Interestingly, the hypercalciuria disappeared during follow-up and urinary Ca^{2+} levels reached normal values beyond puberty. Transient transfection of Madine Darby canine kidney (MDCK) cells with the *CLDN16* (T303R) mutant revealed a mistargeting into lysosomes whereas wildtype claudin-16 was correctly localized to tight junctions. It still remains to be determined why this type of misrouting is associated with transient isolated hypercalciuria without increased Mg^{2+} excretion.

The exact physiological role of claudin-16 is still not fully understood. From the FHHNC disease phenotype, it was concluded that claudin-16 might regulate the paracellular transport of Mg^{2+} and Ca^{2+} ions by contributing to a selective paracellular conductance by building a pore permitting paracellular fluxes of Mg^{2+} and Ca^{2+} down their electrochemical gradients (249, 252). However, recent functional studies in porcine renal tubule epithelial kidney cells (LLC-PK1) cells could show that the expression of claudin-16 selectively and significantly increased the permeability of Na^{+} with a far less-pronounced change of Mg^{2+} flux. From these observations, it was hypothesized that in the TAL claudin-16 probably contributes to the generation of the lumen-positive potential (allowing the passive reabsorption of divalent cations) rather than to the formation of a paracellular channel selective for Ca^{2+} and Mg^{2+} (253).

As mentioned above, many FHHNC patients develop chronic renal failure associated with progressive tubulointerstitial nephritis. The pathophysiology of this phenomenon, which is not usually observed in other tubular disorders is unclear. Traditionally, renal failure in FHHNC has been attributed to the concomitant hypercalciuria and nephrocalcinosis, but a true correlation has not been established. Therefore, it has been speculated that claudin-16 is not only involved in paracellular electrolyte reabsorption but also in tubular cell proliferation and differentiation (254). This hypothesis is supported by the bovine *CLDN16* knockout phenotype, which exhibit early onset renal failure due to interstitial nephritis with diffuse zonal fibrosis (255, 256). Tubular epithelial cells were reported as "immature" with loss of polarization and attachment to the basement membrane. A close association between fibrosis and abnormal tubules was noted, and the term "renal tubular dysplasia" was used to emphasize that the lesions develop first in the epithelial cells of the renal tubules (257). These cattle have large homozygous deletions whereas human FHHNC mutations are mainly missense mutations affecting the extracellular loops of claudin-16. From these observations it appears that the site and extent of the mutation determines the phenotypic manifestation ranging from isolated alterations in channel conductance to an alteration in cell proliferation and differentiation. This hypothesis is consistent with the results of a large retrospective study in which the clinical course of FHNNC in more than 70 patients was compared to the functional analysis of the underlying *CLDN16* mutations (258). This study could demonstrate that patients carrying complete loss of function mutations on both alleles are younger at disease onset and have a much more rapid decline of GFR than those patients with at least one mutant allele which displays residual function (258).

FHHNC is genetically heterogenous, since mutations in another tight junction gene encoding claudin-19 have also been demonstrated to cause this disease (259). The identification of *CLDN19* mutations could explain the variable ocular phenotype, because *CLDN19* defects seem to be invariably associated with severe ocular abnormalities (including severe myopia, nystagmus, or macular coloboma) (244–246). The latter association has been named FHHNC with severe ocular involvement (OMIM #248190). In contrast, only a small subset of FHHNC patients with *CLDN16* defects display severe myopia whereas nystagmus or colobomata have not been described (247).

The renal phenotype is very similar between these two FHHNC subtypes. Expression studies revealed that claudin-16 and claudin-19 perfectly colocalize at tight junctions of the TAL (259). It could further be demonstrated that claudin-16 and claudin-19 functionally interact, which could increase the cation selectivity of tight junctions above that of claudin-16 alone (260). This is most likely due to anion-blocking properties of claudin-19 preventing back diffusion of Cl^- anions to the tubular lumen.

Hypomagnesemia with Secondary Hypocalcemia

Hypomagnesemia with secondary hypocalcemia (HSH, OMIM #602014) is a rare autosomal recessive disorder first described in 1968 (261). It manifests in early infancy with generalized seizures or other symptoms of increased neuromuscular excitability. Delayed diagnosis or noncompliance with treatment can be fatal or result in permanent neurological damage. Biochemical abnormalities include extremely low serum Mg^{2+} (about 0.2 mmol/L) and low serum Ca^{2+} levels. The mechanism leading to hypocalcemia is still not completely understood. Severe hypomagnesemia results in an impaired synthesis and/or release of PTH (262). Consistently, PTH levels in HSH patients were found to be inappropriately low. The hypocalcemia observed in HSH does not respond to therapy with Ca^{2+} or vitamin D. Relief of clinical symptoms, normocalcemia, and normalization of PTH levels can only be achieved by administration of high doses of Mg^{2+} (263). Transport studies in HSH patients indicated a primary defect in intestinal Mg^{2+} absorption (264). However, in some patients an additional renal leak for Mg^{2+} was suspected (265).

A gene locus (*HOMG1*) for HSH had been mapped to chromosome 9q22 in 1997 (266). Later, two independent groups identified *TRPM6* at this locus and reported loss of function mutations, mainly truncating mutations, as the underlying cause of HSH (156, 267). Subsequently, additional HSH mutations in *TRPM6* have been identified (268, 269). *TRPM6* encodes a member of the transient receptor potential (TRP) family of cation channels. The TRPM6 protein is homologous to TRPM7, a Ca^{2+} and Mg^{2+} permeable ion channel regulated by Mg-ATP (270). TRPM6 is expressed along the entire small intestine and colon but also in the kidney in distal tubule cells. Immunofluorescence studies localized TRPM6 to the apical membrane of the DCT (271) confirming that renal Mg^{2+} wasting could play a role in the pathogenesis of HSH (272). This was also supported by intravenous Mg^{2+} loading tests in HSH patients, which disclosed a considerable renal Mg^{2+} leak (267).

TRPM6 is closely related to TRPM7 and represents the second TRP protein being fused to a C-terminal α-kinase domain. The *TRPM6* gene encodes a large protein with 2,022 amino acid residues. *TRPM6*-mRNA shows a more restricted expression pattern than TRPM7 with highest levels along the intestine and the DCT of the kidney (156). Immunohistochemistry shows a complete colocalization with the Na^+-Cl^- cotransporter NCCT (also serving as a DCT marker) but also with parvalbumin and calbindin-D_{28K}, two cytosolic proteins that putatively act as intracellular (Ca^{2+} and) Mg^{2+} buffers (271). As yet, the biophysical characterization of TRPM6 remains controversial. Voets et al. could demonstrate striking parallels between TRPM6 and TRPM7 with respect to gating mechanisms and ion selectivity profiles, since TRPM6 was shown to be regulated by intracellular Mg^{2+} levels, and to be permeable for Mg^{2+} and Ca^{2+} (271). Permeation characteristics with currents almost exclusively carried by divalent cations with a higher affinity for Mg^{2+} than Ca^{2+} support the role of TRPM6 as the apical Mg^{2+} influx pathway. Furthermore, TRPM6 -analogous to TRPM7- exhibits a marked sensitivity to intracellular Mg^{2+}. Thus one might speculate about an inhibition of TRPM6-mediated Mg^{2+} uptake by rising intracellular Mg^{2+} concentrations, as a possible mechanism for regulation of intestinal and renal Mg^{2+} (re-)absorption. This inhibition might in part be mediated by intracellular Mg-ATP as shown for TRPM7 (270). Chubanov et al. reported that TRPM6 is only present at the cell surface when associating with TRPM7 (273). Furthermore, FRET (fluorescence resonance energy transfer) analyses showed a specific direct protein-protein interaction between both proteins. Electrophysiological data in a *Xenopus* oocyte expression system indicated that coexpression of TRPM6 results in a significant amplification of TRPM7-induced currents (273). Schmitz et al. (274) demonstrated that TRPM6 and TRPM7 are not functionally redundant and that both proteins can influence each other's biological activity. In particular, TRPM6 can phosphorylate TRPM7 and TRPM6 might modulate TRPM7 function in a Mg^{2+}-dependant manner (274).

TRPM6 has been shown to be regulated by the first magnesiotropic hormone identified so far, namely the epithelial growth factor (EGF) which is expressed in the DCT. In a cell culture model, Groenstege et al. could show that EGF increases the activity of TRPM6 expressing cells (240). This is in line with the clinical observation that cancer patients treated with cetuximab, a monoclonal antibody directed against the EGF receptor, develop

hypomagnesemia secondary to increased Mg^{2+}-wasting. These findings suggest that EGF acts in an autocrine or a paracrine manner to stimulate TRPM6 activity leading to increased reabsorption of Mg^{2+} in the DCT. TRPM6 is also regulated by changes in body magnesium content, with hypomagnesemia resulting in the upregulation of TRPM6 expression not only in the DCT but also in the gastrointestinal tract (275). Similarly, 17-beta-Estradiol induces an upregulation of TRPM6, as shown in ovariectomized rats (275). From a clinical point of view it is important to note that the well-known hypomagnesemia in patients receiving calcineurin inhibitors (cyclosporin A, FK506) is at least in part mediated by downregulation of TRPM6 (276, 277).

Mitochondrial Hypomagnesemia

A mutation in the mitochondrial-coded isoleucine tRNA gene, $tRNA^{Ile}$ or MTTI, related to hypomagnesemia has been discovered in a large Caucasian kindred (278). An extensive clinical evaluation of this family was prompted after the discovery of hypomagnesemia in the index patient, leading to the characterization of mitochondrial hypomagnesemia (OMIM #500005). Indeed, pedigree analysis was compatible with mitochondrial inheritance as the phenotype was exclusively transmitted by affected females. The phenotype includes hypomagnesemia, hypercholesterolemia, and hypertension. Of the adults on the maternal lineage, the majority of offspring exhibited at least one of the mentioned symptoms, approximately half of the individuals showed a combination of two or more symptoms, and around 1/6 had all three features. Serum Mg^{2+} levels of family members on the maternal lineage varied greatly from ~0.3 to ~1.0 mmol/L with approximately 50% of individuals being hypomagnesemic. The hypomagnesemic individuals (serum Mg^{2+} <0.9 mmol/L) showed higher fractional excretions (median around 7.5%) than their normomagnesemic relatives (median around 3%) clearly pointing to renal Mg^{2+} wasting as causative for hypomagnesemia. Interestingly, hypomagnesemia was accompanied by decreased urinary Ca^{2+} levels, a finding pointing to the DCT as the affected tubular segment.

The mitochondrial mutation observed in the affected family involves the $tRNA^{Ile}$ gene *MTTI*. The observed nucleotide exchange occurs at the T-nucleotide directly adjacent to the anticodon triplet. This position is highly conserved among species and critical for codon-anticodon recognition. The functional consequences of the tRNA defect for mitochondrial function remain to be elucidated in detail. As ATP consumption along the tubule is highest in the DCT, the authors speculate about an impaired energy metabolism of DCT cells as a consequence of the mitochondrial defect which in turn could lead to disturbed transcellular Mg^{2+} reabsorption (278). Further studies in these patients might help to better understand the mechanism of distal tubular Mg^{2+} wasting in this disease.

Management of Hypomagnesemia/ Magnesium Deficiency

The main goal of Mg^{2+} substitution in hypomagnesemic patients is the relief of clinical symptoms. In most cases, especially in primary Mg^{2+} wasting diseases, normal levels cannot be achieved by oral substitution without considerable gastrointestinal side effects. The route of administration depends on the severity of clinical symptoms. Acute intravenous infusions should be reserved for patients with severe symptoms, i.e., with cerebral seizures (279). Especially in children, painful intramuscular injections should be avoided. In infants and children, the starting dose is 20–50 mg Mg^{2+} sulfate (0.1–0.2 mmol Mg^{2+}) per kilogram body weight. Mg^{2+} sulfate should be given slowly intravenously (over 20 min). The maximum dose for adults is 2 g of Mg^{2+} sulfate. Single doses can be repeated every 6–8 h or followed by continous infusion of 100–200 mg Mg^{2+} sulfate (0.4–0.8 mmol Mg^{2+}) per kilogram body weight per day (280). During Mg^{2+} infusion, close monitoring of cardiorespiratory function is important and Ca^{2+} gluconate should be available as an antidote. The assessment of renal function is also mandatory.

Asymptomatic hypomagnesemia or chronic Mg^{2+} deficiency should be treated with oral Mg^{2+} substitution. In children, 10–20 mg Mg^{2+} (0.4–0.8 mmol) per kg body weight given three to four times a day has been recommended to correct hypomagnesemia (281). Of note, the solubility, intestinal absorption, and side effects considerably differ depending on the Mg^{2+} salt used for oral therapy. The bioavailability and pharmacokinetics of different Mg^{2+} salts have been reviewed recently (282). With respect to solubility, intestinal absorption and bioavailability, organic Mg^{2+} salts (e.g., citrate or aspartate) appear most suitable for oral substitution. Moreover, the laxative effect of organic Mg^{2+} salts seems to be less pronounced compared to inorganic salts.

The use of certain diuretics has been proposed for the reduction of renal Mg^{2+} excretion. Both, K^+-sparing diuretics and aldosterone antagonists, exert Mg^{2+}-sparing effects (283, 284). Their beneficial effect on renal Mg^{2+} excretion, serum Mg^{2+} levels and clinical symptoms is well documented in hereditary Mg^{2+}-wasting diseases (186, 285).

Low Renin Hypertension with Hypokaliemia

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA, OMIM #103900), also called dexamethasone-suppressible hyperaldosteronism (DSH) or familial hyperaldosteronism type I (FH-I) is a rare but fascinating disease. It was first individualized by Sutherland and coworkers in 1966 (286) and since then has been reported in less than 100 unrelated cases (287, 288).

Clinical Features

Individuals with GRA are usually hypertensive in the youth and demonstrate rapidly a severe form of hypertension, despite the fact that few families with a moderate phenotype have been described (289). Since the disease is transmitted as an autosomal dominant trait with a high penetrance, there is often a strong family history of hypertension and/or stroke. Indeed, analysis of affected kindreds has shown a high prevalence of hemorrhagic stroke and ruptured intracranial aneurysms, usually before the age of 40 years (290). The biological profile of affected subjects suggests a primary aldosteronism but GRA patients can be normokaliemic. A specific feature of the disease is the aldosterone hyperresponsiveness to maneuvers stimulating or inhibiting the cortisol hypopituitary axis (291). Acute or chronic administration of ACTH induces a strong increase in plasma aldosterone level, whereas it has little or small effect on patients with other forms of primary aldosteronism. Conversely, aldosterone is suppressed by the administration of glucocorticoids, the acute dexamethasone suppression test being recognized as a diagnostic test for the pathology (292, 293). The second specific feature is the abundant urinary excretion of 18-hydroxycortisol and 18-oxocortisol (294). However, dosages of these steroids require sophisticated methods and antibodies and are not performed routinely.

Genetics

In 1992, Lifton and colleagues (295) showed that GRA was linked to an abnormal aldosterone synthase gene. They studied a large affected kindred and found a gene duplication arising from an unequal crossing over, resulting in a fusion of the 11β-hydroxylase (CYP11B1) promoter with the coding sequence of aldosterone synthase. In all families reported so far, the chimaeric gene derives from unequal homologous recombination between intron 1 and intron 4 of the *CYP11B1* and *CYP11B2* genes, respectively. This recombination takes always place upstream of exon 5, since this exon contains two residues that differ between the two homologous enzymes (296) and that are critical to confer the aldosterone synthase specificity. Thus, it encodes a protein that can hydroxylate cortisol (the steroid substrate present in the zona fasciculata) in the 18-position. This gene is under the control of the 11 β-hydroxylase gene regulatory region, which expression is under ACTH control and can be down-regulated by exogenous glucocorticoid administration (297). Therefore, aldosterone hypersecretion seems to mainly derive from the zona fasciculata. The genetic screening for this condition is easy to perform and is based on Southern-blotting or on a long-range PCR looking for the existence of an hybrid gene containing the 5′ part of the CYP11B1 gene and the 3′ part of the CYP11B2 gene (298). Even if the condition is rare, clinicians should not hesitate to prescribe this genetic test since it is 100% sensitive and specific in reference laboratories and since a positive finding strongly influences the medical care of the patient and possibly his family. An early-onset of hypertension (before 30 years of age) associated to biological features compatible with an hyperaldosteronism and a positive familial history of early hypertension and/or stroke, should encourage to perform this genetic test.

Therapy

Taking into account this mechanism, the treatment of GRA is based on the administration of dexamethasone at low doses (0.5 mg/day), which only partially suppresses ACTH but lowers the possible side effects from long-term exogenous glucocorticoid treatment. A complementary treatment based on amiloride or spironolactone at low dose as well other classical antihypertensive agents is often required (299).

Other Forms of Familial Aldosteronism

GRA is probably very rare. In our experience, we only detected six unrelated cases amongst 700 patients with primary aldosteronism (X. Jeunemaitre, unpublished data).

Gordon and Stowasser described another form of familial primary aldosteronism, called type II (FH-II). It was initially detected in few families with about one-third

of the affected patients presenting an aldosterone-producing tumor (300). The clinical and biological characteristics of these patients do not differ from those with usual primary aldosteronism, except that the trait seems inherited according to an autosomal dominant transmission with partial penetrance (301). The screening of the entire genome in a large family with FH-II showed linkage with chromosome 7p22 (302). In addition to two Australian kindreds, two other Italian families with FH-II were found to be linked to this locus (303), but no causal gene has been identified yet.

Very recently, a new familial form of aldosteronism has been reported in one single family (304) that could be due to a new gene regulating adrenal steroid biosynthesis. A father and his two daughters had very early (by the age of 7) and severe hypertension with hyperaldosteronism. Very high levels of 18-oxocortisol and 18-hydroxycortisol were not influenced by dexamethasone and GRA was excluded.

Liddle Syndrome

In 1963, Liddle and colleagues described a family with hypertension and an abnormality of Na^+ reabsorption at the level of the renal distal tubule which simulated primary aldosteronism but had negligible basal and stimulated aldosterone secretion (305) (OMIM #177200). Although blood pressure and hypokaliemia were not influenced by spironolactone treatment, triamterene, a specific inhibitor of the distal renal epithelial Na^+ channel, corrected these abnormalities. The authors proposed that the primary abnormality was a constitutive activation of the epithelial Na^+ channel. Some 30 years later, this hypothesis was reinvestigated in the originally described pedigree. The index case developed renal failure and renal transplantation corrected the aldosterone and renin responses to salt restriction. These features demonstrated the involvement of the kidney in the disease (306), making the epithelial amiloride-sensitive Na^+ channel (ENaC) located in the cortical CD an attractive candidate gene for Liddle syndrome.

Genetics

Analyzing the original Liddle's pedigree, Shimkets et al. (307) showed complete linkage of the gene encoding the β subunit of ENaC, located at chromosome 16p13-12. In this pedigree and in other unrelated kindreds, a premature stop codon, a frameshift mutation and other deleterious mutations were found, all located in the last exon of the *SCNN1B* gene encoding for the intracellular carboxy-terminal domain of the β subunit. These mutations were showed to be gain of function mutations, with an increased amiloride-sensitive Na^+ current after transfection of the corresponding mutant subunits together with α and γ wild-type subunits. In a Portuguese family affected with this syndrome, we found a 32 base pair deletion leading to a premature termination of the carboxy-end of the same subunit (308). Measurement of transnasal potential difference, as an alternative to transepithelial transport in the kidney, showed the presence of an increased amiloride-sensitive conductance in the three affected boys but not in their unaffected sister (309). Other point mutations affecting the same region of the *SCNN1G* gene coding for the γ subunit of ENaC have also been found to cause Liddle's syndrome (310). No mutation of αENaC has been associated with Liddle syndrome, yet.

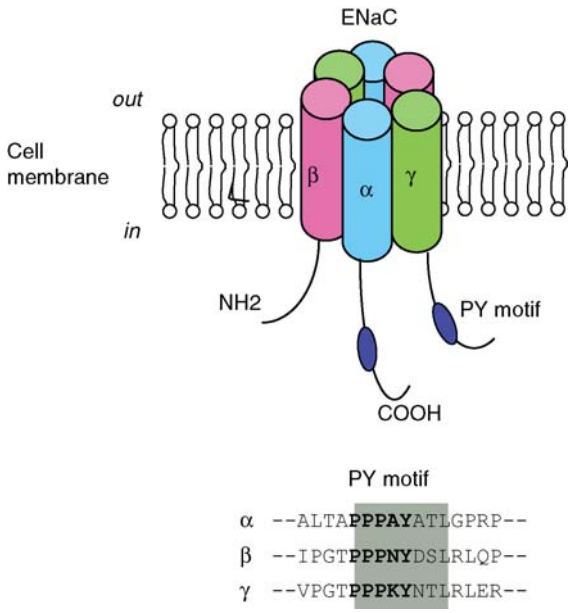
Pathophysiology

ENaC is constituted of at least three homologous subunits, α, β and γ which act together to confer its low Na^+ conductance, and its high selectivity for Na^+ and amiloride (311). The stochiometry of the channel can be deduced from the crystal structure of a chicken acid-sensing ion channel which belongs to the same family (312). It is an heterotrimeric protein composed of one α, β and γ subunit (*Fig. 38-4*). Each subunit is composed of short amino and carboxy termini, two transmembrane helices, and a multidomain extracellular region. ENaC is located in the apical membrane of epithelial cells and plays a major role in the reabsorption of Na^+ ions, especially in kidney, colon and lung. In the kidney, it is mainly expressed in the distal part of the DCT and in the cortical CD. It is finely tuned by changes in salt regimen, thus allowing appropriate changes in Na^+ reabsorption (313).

Comprehensive studies have shown that the mechanism by which the truncation of the C terminus of the β and γ subunits alters the ENaC function corresponds to an alteration of a conserved motif (PPxxY) in the C-terminus of all three subunits of ENaC (314, 315). Normally, a specific interaction between this PY motif and cytosolic proteins (Nedd4 isoforms 1 and 2, and other related WW proteins) leads to ubiquitylation and then degradation of part of the newly synthetized subunits (316). Thus, cell surface expression of ENaC is in part controlled via ubiquitylation which it itself regulated by aldosterone-induced proteins and glucocorticoid induced

Figure 38-4

Membrane topology of the epithelial Na^+ channel ENaC. The proposed model is a heterotrimeric structure by one α subunit, one β subunit, and one γ subunit. Each subunit is formed by two transmembrane domains, a large extracellular loop and cytoplasmic amino – and carboxy termini. The C-terminus contains a PY motif with at least three proline and a tyrosine residues (PPPXYXXL), highly conserved between the α, β, and γ subunits and between species. This motif is essential for the interaction with intracytoplasmic proteins (among them Nedd4–2) and the regulation of the number of channels at the plasma membrane.



kinase 1 (317). Both truncation or punctual mutation of the C-terminal PY motif increased surface expression of the mutant proteins and thus increased the number of Na^+ channels in the apical membrane (318), favoring renal Na^+ absorption and hypertension. This results in expanded plasma volume which in turns inhibits the renin aldosterone secretion. The fact that only one heterozygous mutation of either the β or γ ENaC subunit is sufficient to lead to the pathology is probably due in part to the multimeric arrangement of the channel.

It has been suggested that polymorphisms at each *SCNN1A*, *SCNN1B* and *SCNN1G* genes could be related to essential hypertension (319). However, the in vitro demonstration of their functionality has proven to be difficult (320). A special emphasis has been put on the Thr574Met polymorphism at the βENaC which frequency is higher (around 8%) in the African populations. A higher frequency of the 574Met allele has been suspected in black hypertensives living in London compared to normotensives (321), this allele being associated with lower plasma renin values, and possibly with an enhanced sensitivity to amiloride (322). Other polymorphisms at the γENaC have also been associated to essential hypertension (323, 324).

Diagnosis

Recognition of Liddle syndrome is important because it is potentially cured by the administration of amiloride. It is a form of pseudoaldosteronism, i.e., hypertension associated with hypokalemia, metabolic alkalosis, and suppression of plasma renin but with very low levels of aldosterone in plasma and/or urine. As a consequence of the high penetrance of this genetic defect and its autosomal dominant transmission, one can usually find the presence of hypertensive individuals in successive generations. As well, affected individuals are diagnosed at a relatively young age, most often between the age of 10 and 30 years (325). These features are clearly different from the more severe and recessively transmitted apparent mineralocorticoid excess (see below). It resembles to the very rare (only one family described) form of hypertension secondary to activated mineralocorticoid receptor, both forms being not sensitive to spironolactone (see also below). In any case the peculiar sensitivity to amiloride and the possibility of genetic testing allow a sure and rapid diagnosis. The genetic screening is based on the sequence analysis of the last exon 13 of the *SCNN1B* and *SCNN1G* genes.

Therapy

It is interesting to consider that a specific drug therapy for Liddle syndrome was developed in 1967 as a K^+-sparing diuretic (326), a long time before ENaC was cloned and was demonstrated to be responsible for the disease. Due to its very potent inhibiting properties on ENaC, amiloride is very effective in Liddle syndrome at doses comprised between 10 and 20 mg/day (327). Surprisingly for such a chronic and often severe condition, a change in blood pressure and in the biological profile can be observed as soon as after 2–4 weeks of treatment (308). In our experience, chronic therapy with amiloride alone is

sufficient to control blood pressure. Spironolactone has no effect which is expected since renin and alosterone are completely suppressed.

Early-Onset Hypertension Secondary to a Gain of Function Mutation in the Mineralocorticoid Receptor

One unique case of a new monogenic form of hypertension, that could be called pseudoaldosteronism type II, has been reported by Geller and colleagues (328). It is characterized by an early-onset and severe form of hypertension, associated with low plasma levels of renin and aldosterone, with severe exacerbation in pregnancy (OMIM #605115). It is caused by an activating missense mutation (Ser810Leu) of the *MR* (or *NR3C2*) gene that encodes the mineralocorticoid receptor. This mutation is located within the hormone binding domain and results in a constitutive mineralocorticoid receptor activity and in an alteration of the receptor specificity. The receptor becomes abnormally activated by progesterone and other steroids lacking 21-hydroxyl groups which act normally as antagonists. Thus, spironolactone acts an angonist on the mutated receptor instead of an antagonist and could be detrimental. In the family described by Geller and coworkers, all women bearing the mutation had severe pregnancy-induced hypertension with hypoaldosteronism which was caused by the massive increased production of progesterone during pregnancy (328). These original findings open the possibility of discovering other cases of similar type of mutations in pregnancy-induced hypertension. However, several groups including ours (unpublished) failed to find such activating mutation in large series of pre-eclamptic women.

Apparent Mineralocorticoid Excess

The syndrome of apparent mineralocorticoid excess (AME) is a rare autosomal recessive form of hypertension (OMIM #218030). It was first described by New (329) and Ulick (330) in two subjects: one was a 3-year-old Native American girl and the other one was a boy from Middle Eastern who had suffered a stroke at age 7 and was severely hypertensive. For both of them, clinical and biochemical evaluation failed to reveal overproduction of aldosterone or any other known steroid, establishing a new syndrome. AME is usually diagnosed within the first years of life and is characterized by polyuria and polydipsia, a failure to thrive, a severe hypertension associated with hyporeninism and hypoaldosteronism, a profound hypokalemia with alkalosis and most often nephrocalcinosis (331). The syndrome is rare, since less than 100 cases have been reported in the last 30 years. The clinical and biochemical characteristics of AME, mimicking a very strong hyperaldosteronism, together with the frequent consanguinity between parents make the diagnosis relatively easy. A few patients with a mild form of AME, also called AME type 2 (OMIM # 207765), have also been reported, with less caricatural hypertension and only mild abnormalities of cortisol metabolism. It was first described by Ulick (332) and later in an extensive consanguineous Sardinian pedigree in whom Li et al. found a novel homozygous mutation in the *HSD11B2* gene (333). Affected homozygous individuals were >30 years of age and had both mineralocorticoid hypertension and evidence of impaired metabolism of cortisol to cortisone, whereas heterozygous subjects were phenotypically normal with only subtle biochemical defects.

Pathophysiology and Genetics

The 11-beta-hydroxysteroid dehydrogenase is a microsomal enzyme complex responsible for the interconversion of cortisol and cortisone. Whereas the type I isoform (HSD11B1) is capable to have both the dehydrogenase and reductase activities, the type II isoform (HSD11B2) has only the 11-beta-dehydrogenase activity and thus only catalyzes the cortisol to cortisone reaction (334). Edwards and colleagues (335) showed that the HSD11B2 isoform is highly concentrated in aldosterone-responsive tissues – particularly in the distal nephron -, and actually protects the mineralocorticoid receptor from a stimulation by the cortisol which plasma concentration is about 100-fold higher than aldosterone. Because of the defect in the HSD11B2 isoform, AME patients are characterized by high values of the cortisol/cortisone ratio in plasma (F/E) and urine (THF/THE), and by arterial hypertension, mimicking a primary aldosteronism (336).

The group of White first showed that AME is due to mutations in the *HSD11B2* gene that encodes the HSD11B2 isoform (337). They screened the five exons of *HSD11B2* in nine affected individuals and found missense and frameshift mutations which markedly affected enzymatic activity in vitro and were associated with increased urinary (THF/THE) ratios, the more severe mutations resulting in the higher precursor/product ratios. Subsequently, other loss-of-function mutations have been found in affected patients being either homozygous for the mutation – especially in consanguineous families – or

composite heterozygous (331, 338–340). HSD11B2-null mice provide a good model for the pathology (341). They show signs of hypertension, hypotonic polyuria, hypokalemia and hypochloremia, a phenotype directly comparable to AME patients. They confirm the crucial importance of the HSD11B2 isoform in metabolizing cortisol to cortisone in the renal tubule, thus protecting the mineralocorticoid receptor from the influence of cortisol.

Differential Diagnosis

Consumption of natural licorice can mimick an AME in adults but is exceptionally observed in children. Indeed, it requires either a sustained and chronic or a high acute exposure to cause this adverse effect. The mechanism behind this effect is the fact that licorice contains glycyrrhetinic acid and glycyrrhizic acid, the latter being a potent inhibitor of HSD11B2 (342). These molecules are mostly excreted in the bile together with their metabolites, with very little excretion in urine, explaining the need of an important and chronic consumption to lead to a mineralocorticoid form of hypertension. Carbenoxolone, an antiulcer drug, is also a competitive inhibitor of HSD11B2, and cause sodium retention and hypertension (343).

Treatment

Two main strategies can be used to treat AME. The first is the blockade of the mineralocorticoid receptor by spironolactone, thus acting as a competitive antagonist of the endogeneous cortisol. Daily doses of spironolactone between 2 and 10 mg/kg are usually sufficient to correct hypertension and increase natriuresis and renin levels (331). The addition of thiazides can help to normalize blood pressure and lower hypercalciuria and nephrocalcinosis. The second, complementary strategy consists in administering exogenous corticoids to block ACTH and suppress the endogeneous secretion of cortisol. This strategy has shown its efficiency on blood pressure, renin and aldosterone but has little effect on urinary concentrations of the metabolites of cortisol, cortisone and corticosterone (344). Interestingly, a 31-years-old women with AME was cured by renal transplantation while receiving also dexamethasone. The curative effect of renal transplantation on the cortisol/cortisone ratio confirmed that AME as a renal disorder and that the transplanted kidney had functional HSD11B2 activity (345). In addition to these two strategies, the use of non-specific antihypertensive agents such as calcium antagonists is often required in AME, due to the severity of hypertension (346).

Pseudohypoaldosteronism Type II, Gordon Syndrome

Pseudohypoaldosteronism type II (PHA2) (OMIM #145260), also known as Gordon syndrome, or familial hyperkalemic hypertension, is an autosomal dominant form of volume-dependent hypertension characterized by hyperkaliemia and hyperchloremic acidosis despite normal renal function (347). Since the first description of the disease by Paver and Pauline in 1964 (348), about 100 other cases and families have been reported. Gordon and colleagues reported their first case in 1970 and helped to demonstrate the existence of a unifying syndrome (347). The original case was a 15-year-old boy with severe hypertension (180/120 mmHg) and very high potassium levels (7.0–8.2 mmol/L). Detailed analyses showed that the kidney was probably involved but that the renal tubule reacted normally to an acid load and to carbonic anhydrase inhibitor. Sensitivity to thiazide diuretics was reported a few years later in unrelated affected subjects (349). A high variability in the age at diagnosis, which may range from the first few weeks of life until late in adulthood, has been reported in sporadic and familial cases. Usually, the biochemical abnormalities precede the increase in blood pressure which seems to depend primarily on age in affected individuals (350). This phenotypic variability, associated with sensitivity to thiazides — which are widely used in hypertension — may have led to an underestimation of PHA2 frequency.

The low renin levels in PHA2 are thought to be the consequence of volume expansion whereas plasma aldosterone levels are variable depending on the opposite influences of low renin and high potassium levels. At least two arguments suggest a primary renal tubular defect along the DCT: affected patients are highly sensitive to thiazide diuretics (349) and the clinical and biochemical features of PHA2 are the mirror image of Gitelman syndrome in which inactivating mutations in NCCT have been demonstrated (see above). However, the pathophysiology of PHA2I is certainly more complex as it has been associated in some cases with defective proximal reabsorption, impaired chloride reabsorption, and altered sensitivity to mineralocorticoids (351).

Genetics

The first genome scan was reported by Lifton's group (352). Using eight affected but limited families, they identified two loci on chromosome 1 (1q31-q42) and chromosome 17 (17q21-q22), respectively named PHA2A and PHA2B

(*Fig. 38-5*). The selection and genetic analysis of a large French pedigree led us to identify a third chromosomal region on chromosome 12p13, called PHA2C (353). Exclusion of linkage for these 3 chromosomal regions in two additional affected pedigrees suggests further genetic heterogeneity (354). Thus, it is expected that molecular genetics of this syndrome will lead to a variety of molecular defects, revealing the role of either several new components of the same pathway, or direct or indirect partners of the sodium-chloride cotransporter.

The two genes, *WNK1* and *WNK4*, corresponding to the PHA2B and PHA2C loci were identified in 2001 (355) (*Fig. 38-6*). Both genes are members of a particular family of serine-threonine kinases, called With No Lysine (WNK) kinase (356). Disease-causing mutations in the *WNK1* gene are large deletions in the first intron which lead to increased gene expression of the kidney isoform. Mutations in the *WNK4* gene are missense mutations clustering in a highly conserved domain among this type of kinases. Altogether, these findings implicate these kinases in a previously unrecognized signaling pathway likely to be involved in the control of Na^+ reabsorption in the distal nephron and blood pressure regulation (357).

Pathophysiology

The mechanism of PHA2 has been debated for many years. The two main suggested mechanisms – excessive Na^+ reabsorption via the thiazide-sensitive cotransporter NCCT in the DCT, or a "chloride shunt" that would favor Na^+ reabsorption via ENaC (351) – have been revisited according to the recent identification of *WNK1* and *WNK4* genes as causing the disease (358).

WNK4 seems to be a major player in regulating Na^+, K^+, and Cl^- reabsorption in the distal nephron by regulating regulation of a number of renal ion transporters and channels. In vitro experiments showed that it inhibits NCC activity in *Xenopus* oocytes by decreasing its surface expression and that mutated WNK4 has lost this ability to regulate NCCT (359). It could also inhibit the activity of the renal apical K^+ channel ROMK, the basolateral isoform of the Na^+-K^+-$2Cl^-$ cotransporter (NKCC1), the apical $Cl^-/HCO3^-$ exchanger CFEX and TRPV4 (360), again by decreasing their surface expression. Finally, WNK4 was shown to stimulate the paracellular Cl^- transport, via phosphorylation of members of the claudin family that encode tight junction proteins. Transgenic

Figure 38-5

Genetic heterogeneity of Pseudohypoaldosteronism type II. Three loci have been identified on chromosome 1 (PHA2-A), chromosome 17 (PHA2-B) and latest on chromosome 12 (PHA2-C). Genes corresponding to two of these loci have been identified, *WNK4* for the PHA2-B and *WNK1* for the PHA2-C locus, respectively. Further genetic heterogeneity exists since several affected families do not show linkage at these loci (for details see text).

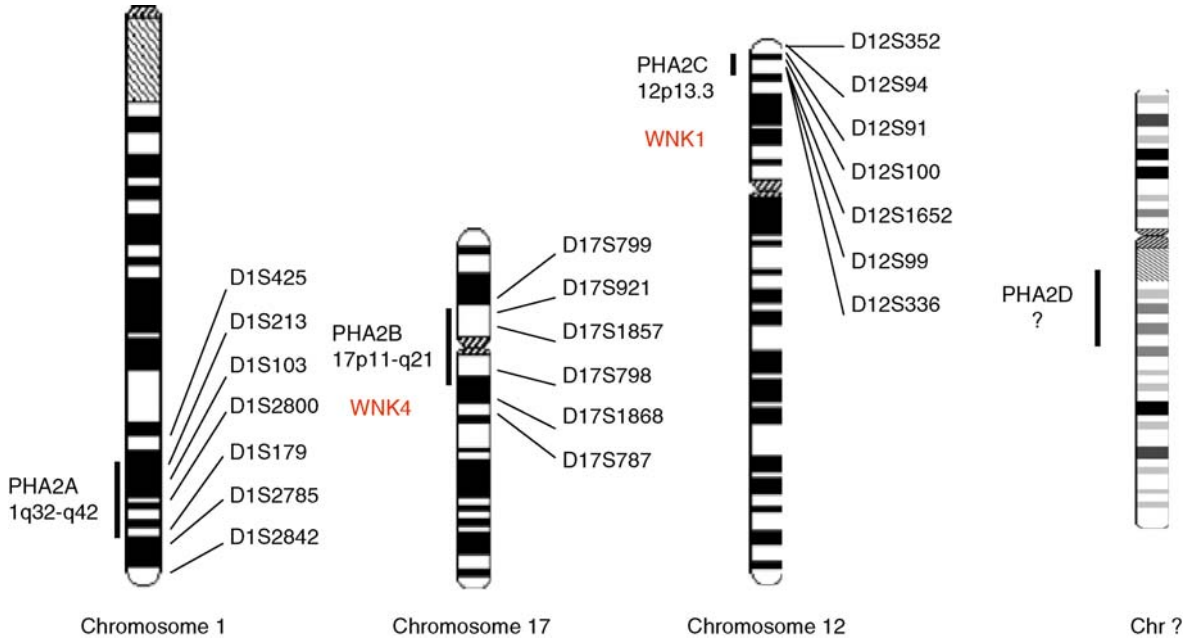


Figure 38-6

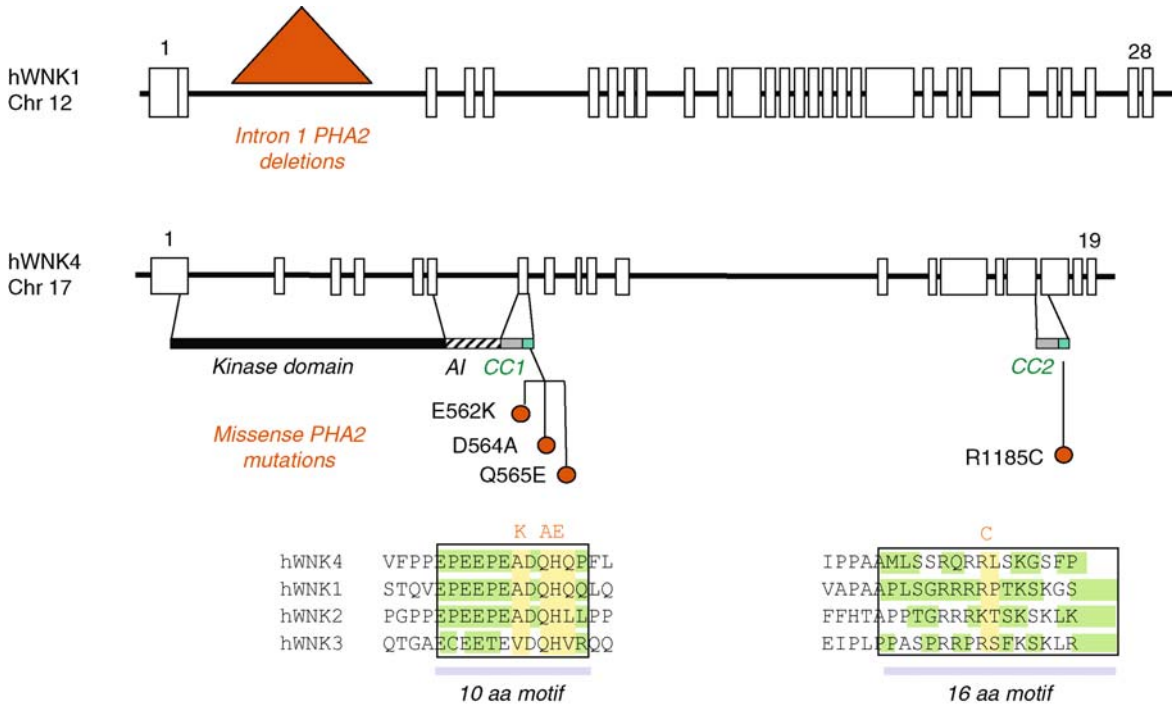
WNK1 and WNK4 mutations in pseudohypoaldosteronism type II. PHA2 causing mutations at the *WNK1* gene correspond to large (41 and 22 Kb) deletions in the intron 1. As a consequence of the suppression of important regulatory elements, the expression of the L-WNK1 and KS-WNK1 are increased in the renal tubule. PHA2 causing mutations at the *WNK4* gene correspond to missense mutations located into two conserved negatively and positively charged regions downstream the two coiled-coil domains.



mouse models showed that the main effect of the *WNK4* PHA2 mutations is an increased NCCT activity associated to a marked hyperplasia of the DCT (361, 362). Thus, WNK4 could be a determinant of the choice faced by the kidney between maximal NaCl reabsorption and K^+ secretion in response to aldosterone secretion and this determination could be mediated mainly by modulating NCCT activity.

The role of WNK1 is more complex to analyze since multiple isoforms are produced from the *WNK1* gene due to the existence of three promoters, two polyadenylation sites and several alternatively spliced exons (363). The short kidney-specific isoform (KS-WNK1) lacks any kinase activity and is produced at a high level, exclusively in the DCT. The full-length (long) isoform (L-WNK1) is produced ubiquitously and at a low level all along the nephron. In vitro, L-WNK1 and KS-WNK1 have been shown to interact together and with other partners such as WNK4, the Serum Glucocorticod Kinase SGK1 and ENaC. Several studies in vitro have shown that WNK1 may act as an osmotic sensor in various cells (364). It is supposed that the ratio between L- and KS-WNK1 is probably important in the distal nephron, adding a supplementary level of fine regulation of the ionic transport (358).

It is not clear yet whether the two genetic defects on *WNK1* and *WNK4* give a similar phenotype in terms of biochemical and clinical severity, because of the very low number of families detected up to now. The only biochemical difference that has been shown concerns calcium excretion. PHA2 families with *WNK4* mutation have been reported as having hypercalciuria whereas normocalciuria was observed in the only *WNK1*-linked PHA2 family analysed for this parameter (350). In the WNK4 pedigree analysed by Farfel'group (365), affected members had hypercalciuria with normomagnesemia and decreased bone mineral density. No susceptibility to kidney stones was observed. Transgenic mice overexpressing a mutant WNK4 also display increased blood pressure, hyperkalemia, hypercalciuria together with marked

hyperplasia of the DCT (362). The effet on the calcium balance could be due to the interaction between WNK4 and TRPV4 which are coexpressed in the distal nephron (366).

Therapy

Low salt regimen can be in part effective in PHA2 as also evidenced in other forms of volume-dependent hypertension (367). Low-salt diet can be sufficient, especially in childhood, since blood pressure might be normal and chronic hyperkaliemia is usually well tolerated. Thiazides diuretics are the treatment of choice since they interfere with the mechanism of the disease. Low doses of hydrochlorothiazide (i.e., 12.5–25 mg daily) are very efficient to correct both biochemical abnormalities and blood pressure in a few weeks. Thiazide diuretics also correct the hypercalciuria that is observed in WNK4-linked PHA2 (365). Furosemide is also effective but less logical since it increases hypercalciuria and could enhance the risk of nephrolithiasis. From our experience, there is no loss of efficiency of thiazides along the years. However, their potential metabolic side effects constitute a rationale to develop new antihypertensive agents controlling the WNK pathway.

Pseudohypoaldosteronism Type I

Pseudohypoaldosteronism type I (PHA1) (OMIM#177735, OMIM #264350) is a rare form of mineralocorticoid resistance characterized by neonatal renal salt wasting, failure to thrive and dehydration. It is associated with hyponatriemia, hyperkalemia and metabolic acidosis, despite extremely high values of plasma renin and aldosterone (368). It was first reported by Cheek and Perry, who described a male infant with severe salt wasting in the absence of any renal or adrenal defect (369). There exist two different clinical forms of PHA1: (1) a renal form, in which mineralocorticoid resistance is restricted to the kidney, and (2) a generalized form, where mineralocorticoid resistance is systemic and salt loss occurs in multiple organs (370) (*Table 38-7*).

Clinical and Biochemical Features

Renal PHA1. Renal PHA1 (also called autosomal dominant PHA1) (371) is a mild and most frequent form of the disease. Clinical expression is variable: in general, patients show a neonatal salt losing syndrome, with weight loss, failure to thrive, vomiting and dehydration. Biological findings are hyponatremia, hyperkalemia and inappropriately high urinary Na^+ excretion, with occasional hypercalciuria. Urinary K^+ excretion is low, with reduced fractional K^+ excretion and transtubular K^+ gradient (372, 373). The diagnosis is confirmed in the presence of high plasma and urinary aldosterone and high plasma renin levels. Symptoms of renal PHA1 usually improve in early childhood. The mechanisms which restore Na^+ homeostasis in these patients are not clear; most likely, kidney maturation, access to dietary salt, compensatory increase in proximal Na^+ reabsorption as well as the up-regulation of the mineralocorticoid axis all play a role to compensate for the distal salt loss. Indeed, high plasma aldosterone levels persist into adulthood, while plasma renin activity decreases into normal range (370, 374, 375).

Generalized PHA1. In contrast to the renal form, patients affected by generalized PHA1 (also called autosomal recessive PHA1) (371) present with severe salt wasting from kidney, colon, sweat and salivary glands (376). In addition to severe dehydration, vomiting and failure to thrive, the clinical picture may be complicated by cardiac dysrhythmias, collapse, shock or cardiac arrest (374). Severe hyperkalemia and high aldosterone and plasma renin levels orient the diagnosis that can be completed by a positive salivary or sweat test. The prognosis of this form of PHA1 is poor: no remission has been reported and patients suffer from recurrent, life-threatening episodes of salt loss. In addition to the renal phenotype, frequent respiratory tract illnesses have been observed, evoking cystic fibrosis, that are caused by an increase in the volume of airway surface liquid (377). Also, an eczematoid rush of the skin is frequent in these patients, due to the severe salt loss from sweat glands (374, 378, and unpublished observations).

Transient pseudohypoaldosteronism has been observed in infants less than 7 months of age suffering from urinary tract malformations or urinary tract infections (379–381). In these patients, medical or surgical care of the primary disease restores the normal response to aldosterone. The possibility that a transient tubular mineralocorticoid resistance can arise in infants with urinary tract malformations or urinary tract infections strongly supports an indication for renal ultrasonograpy and urine cultures in all children presenting with salt wasting and hyperkalemia (379). Secondary PHA1 may also develop in the adult following resection of the ileum and colon (382) or after renal transplantation (383).

Table 38-7

Distinctive clinical and biological features of renal and generalized PHA1

Feature	Renal PHA1	Generalized PHA1
OMIM #	177735	264350
Inheritance	AD	AR
Age of onset	Neonatal	Neonatal
Phenotype	Mild	Severe
Failure to thrive	Present	Present
Vomiting	Present	Present
Dehydration episodes	Mild	Severe
Cardiac dysrhythmias, collapse, shock or cardiac arrest	No	Sometimes
Respiratory tract illnesses	No	Frequent
Eczematoid rush of the skin	No	Sometimes
Hyperkalemic metabolic acidosis	Present	Present
Serum Na^+	↓	↓
Serum K^+	↑	↑
Urinary Na^+ excretion	↑	↑
Urinary Ka^+ excretion	↓	↓
Plasma aldosterone	↑	↑
Plasma renin	↑	↑
Urinary aldosterone	↑	↑
Sweat Na^+	N	↑
Salivary Na^+	N	↑
Type of mutation	Loss-of-function	Loss-of-function
Gene locus	4q31.1	12p13, 16p13-p12, 16p13-p12
Genes	*NR3C2*	*SCNN1A*, *SCNN1B*, *SCNN1G*
Proteins	MR, mineralocorticoid receptor	α, β, γ Subunits of the epithelial Na^+ channel ENaC

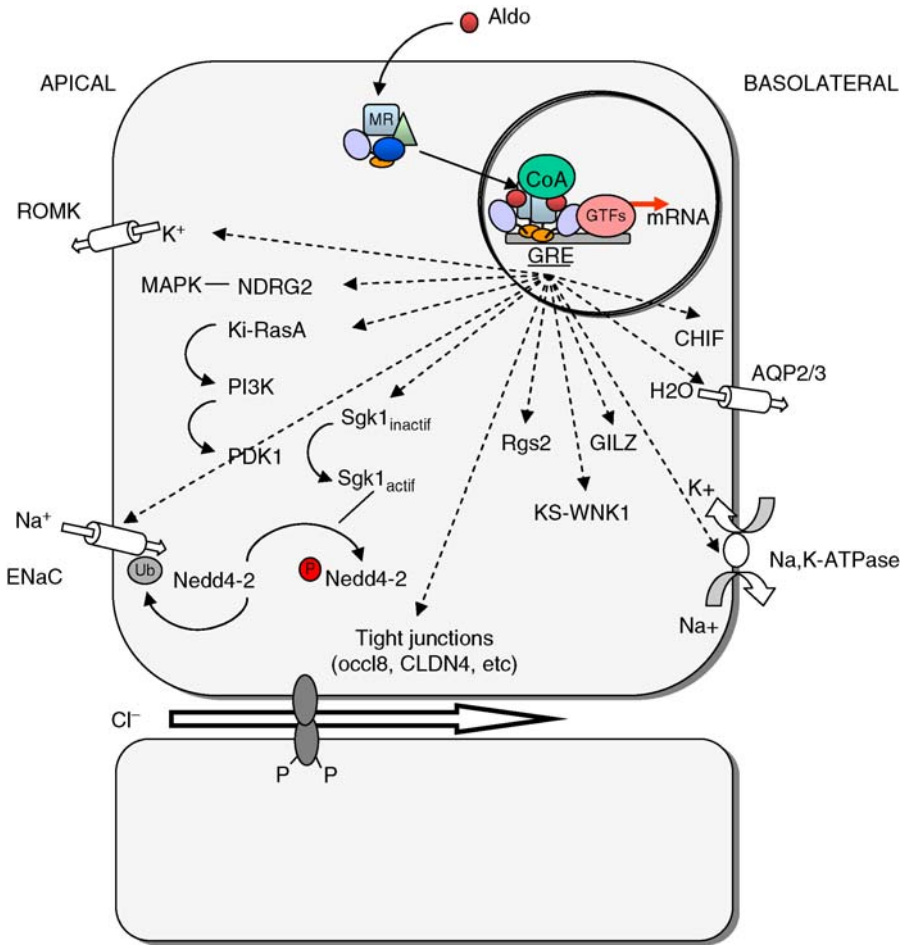
Pathophysiology and Genetics

Since the first description of PHA1, a defect of the tubular response to aldosterone had been suggested as the underlying cause. The mineralocorticoid receptor (MR) classically mediates aldosterone effects on electrolyte balance and blood pressure by regulating trans-epithelial sodium transport through tight epithelia (*Fig. 38-7*). The MR belongs to the nuclear receptor superfamily and acts as a ligand-activated transcription factor regulating expression of a coordinate set of genes involved in the physiologic response to aldosterone, including ENaC (384, 385). Armanini et al. confirmed the hypothesis of an abnormal MR-aldosterone axis by showing that ^{3}H-aldosterone binding was absent or very low in mononuclear leukocytes of affected patients (386). In a detailed study of 8 families, a dual pattern of inheritance was observed that correlated with receptor binding abnormalities. In some families an autosomal recessive inheritance was observed, and binding studies and aldosterone levels were normal in both parents. In contrast, some families presented with an autosomal dominant inheritance, and low receptor number and elevated plasma aldosterone were always found in one of the parents (387).

Subsequently it was shown that the two clinical forms of PHA1 are caused by different genetic defects. Inactivating mutations in the *MR* (or *NR3C2*) gene coding for the MR are found in renal PHA1 (368, 388, 389). Patients are

Figure 38-7

Molecular basis of pseudohypoaldosteronism type I. Aldosterone binds to its intracellular receptor, the mineralocorticoid receptor (MR). Hormone binding induces dissociation of MR-associated proteins and translocation of the aldosterone-receptor complex into the nucleus, where it binds to specific DNA sequences in regulatory regions of hormone-responsive genes. These genes code for proteins involved in transepithelial sodium transport (the epithelial sodium channel, ENaC; the sodium-potassium pump Na,K-ATPase), for regulatory proteins (serum- and glucocorticoid- regulated kinase 1 (sgk1), channel-inducing factor (CHIF), the proto-oncogene K-Ras2, N-myc down-regulated gene 2 (NDRG2)) and others. Aldo, Aldosterone; apical and basolateral indicate the two poles of the epithelial cell.



always heterozygous for the mutations, which occur at high frequency both in patients with familial autosomal dominant PHA1 and patients with a sporadic renal presentation (390). In the latter group, only one third are de novo mutations, implying that carriers develop clinically evident disease only in a small proportion of kindreds. Although the exact causes for the variable phenotypic expression of renal PHA1 are unknown, possible reasons include the occurrence of events that trigger neonatal salt loss, such as intercurrent volume-depleting events or infections. Also, naturally occurring hypomorphic or hyperfunctioning alleles of other genes, coding for proteins involved in distal sodium reabsorption, may aggravate or attenuate the phenotype.

The severe and generalized, recessive form of PHA1 is due to mutations in the genes coding for the α, β and γ subunits of the sodium channel ENaC, *SCNN1A*, *SCNN1B*, and *SCNN1G*, respectively. Deleterious mutations have been found in affected patients being either homozygous – in consanguineous families – or composite heterozygous (385, 391–393). They include missense and nonsense mutations, deletions, insertions and splice site

junction mutations leading to abnormal mRNA splicing. Mutations appear in all ENaC subunits, but are more frequent in the α subunit, consistent with its determinant role in channel function. None of these mutations occur in the cytoplasmic C-terminus of ENaC subunits, where mutations result in a hyperfunctioning channel and a clinical phenotype, Liddle's syndrome, which is a mirror image of PHA1.

The pathogenic mechanism of PHA1 in patients with heterozygous MR mutations depends on the mutation. Although haploinsufficiency is sufficient to cause autosomal dominant PHA1 (371, 394), mutated receptors may also exert dominant negative effects on the wild type receptor (394), since the MR regulates transcription by binding as receptor dimer to regulatory regions of target genes. In this case, effects of mutated receptors are strongly promoter-dependent and may differentially affect MR function in a gene-specific manner (395). In generalized PHA1, inactivating mutations affect one of the subunits of the amiloride-sensitive sodium channel ENaC. Absence of amiloride-sensitive Na^+ transport across airway epithelia has been evidenced in a neonate with generalized PHA1 by measuring transepithelial voltage across the nasal epithelium (396). The mutations causing generalized PHA1 are distributed all along the sequence of ENaC subunits. It is conceivable that nonsense, frameshift mutations, as well as mutations leading to abnormal splicing, cause a channel decrease or a loss of function. Missense mutations are found in critically important domains of the protein and affect functions like intracellular trafficking of the channel, channel gating, or the ion-selectivity filter (385).

Treatment and Prognosis

Treatment of PHA1 consists in the replacement of salt loss and rehydration, as well as correction of hyperkalemia and acidosis in the acute phase of the disease. Since the main differential diagnosis is congenital adrenal hyperplasia or isolated deficiency in aldosterone synthase (CMOI and CMOII) (397, 398), replacement therapy with fludrocortisone and hydrocortisone may be undertaken while confirming the diagnosis by hormonal measurements. Early postnatal hyperkalemia may sometimes complicate aBS, due to mutation in the potassium channel ROMK (44). Its association with hyponatremia and hyperreninemic hyperaldosteronism may erroneously suggest the diagnosis of PHA1. However, hyperkalemia appears usually very early and normalizes by the end of the first postnatal week, whereas PHA1 is characterized by permanent hyperkalemia. Other distinctive features of aBS patients are metabolic alkalosis as well as hypercalciuria and nephrocalcinosis. Also maternal hydramnios, present in aBS, is a rare event in generalized PHA1.

After the acute period, treatment consists in salt supplementation. The doses vary depending on the severity of the disease. In renal PHA1, 3–20 mEq/kg/day of NaCl, given as NaCl and $NaHCO_3^-$, are sufficient to compensate for the salt loss and are followed by rapid clinical and biochemical improvement. The expansion of extracellular volume results in increased tubular flow and Na^+ delivery to the distal nephron, stimulating K^+ secretion. Nevertheless, ion exchange resins are often included to the treatment to normalize plasma K^+ levels. The amount of Na^+ required is deduced from the normalization of plasma K^+ concentration and plasma renin. Since renal PHA1 improves with age, treatment can be discontinued after a variable period of time in most patients, generally around age 18–24 months. Older children are generally asymptomatic on a normal salt intake and show a normal growth and psycho-motor development.

In contrast to renal PHA1, generalized PHA1 represents a therapeutic challenge. No evidence-based treatment has been described, and therapeutic intervention is patient-specific. Generally, high doses of sodium (between 20 and 50 mEq/kg/day) are used, together with ion exchange resins and dietary manipulations to reduce K^+ levels. Corticoid treatment is sometimes associated and seems to provide some additional benefit. Administration of indomethacin may be useful in occasional patients (399). Symptomatic treatment is necessary for the respiratory tract illnesses and to correct the skin phenotype. Only few cases of generalized PHA1 followed up for several years or into adulthood have been described: treatment is necessary throughout life, consisting of salt supplementation (8–20 g NaCl/day) and ion exchange resins (374, 375).

39 Renal Tubular Acidosis

Raymond Quigley

Introduction

Renal tubular acidosis (RTA) is *a condition in which there is a defect in renal excretion of hydrogen ion, or reabsorption of bicarbonate, or both, which occurs in the absence of or out of proportion to an impairment in the glomerular filtration rate* (1). Thus, RTA is distinguished from the renal acidosis that develops as a result of advanced chronic kidney disease (2–4). Albright originally described the disease as "renal acidosis resulting from tubular insufficiency without glomerular insufficiency" to emphasize this distinction (5). The term was reduced to "renal tubular acidosis" by Pines and Mudge in their studies published in 1951 (6). These renal tubular abnormalities can occur as an inherited disease or can result from other disorders or toxins that affect the renal tubules.

Historical Development of Classification of RTA

The historical development of renal tubular acidosis parallels the historical development of our understanding of renal physiology. As with many complex diseases, investigations into disease processes improve our understanding of normal physiology and, in turn, the advances in basic physiologic research shed light on pathophysiology and mechanisms of diseases. This is apparent in the historical development of renal tubular acidosis which began in the early twentieth century and is now extending into the molecular biologic era as medicine enters the twenty-first century. In addition, some of the confusion with the classification scheme of RTA stems from its historical development.

At the British Pediatric Association meeting in 1935, Lightwood described six infants out of an autopsy series of 850 that had "calcium infarction" of the kidneys (7). This would later be recognized as the first report of infants with nephrocalcinosis from renal tubular acidosis. Butler et al. described a series of four infants with similar findings in 1936 (8). In addition to nephrocalcinosis, these infants were also found to have hyperchloremia and acidosis, suggesting that there was a relationship between the biochemical findings and nephrocalcinosis. It was not clear from these first reports if the biochemical findings were the cause of the calcium deposits in the kidneys or were the result of damage to the renal tubules from the calcinosis.

The first description of the potential pathophysiologic explanation for these findings was put forward by Albright, et al. in 1946 (5). In this classic description of various forms of osteomalacia, the authors also outlined the treatment of these patients with a solution of citric acid and sodium citrate that was advocated by Dr Shohl. Albright described this form of acidosis as "renal acidosis resulting from tubular insufficiency without glomerular insufficiency" to distinguish this form of acidosis from the acidosis that occurs in renal failure.

The entity of "infantile renal acidosis" was then described by Lightwood in 1953 in a series of 35 infants (9). This was a larger series of infants than his first description and they had similar clinical histories and biochemical findings as the series by Butler (8). The first description of an adult with similar findings was made in 1945 by Baines, et al. (10).

During the 1940s and 1950s, a number of cases of renal tubular acidosis were described and led to investigations of the renal acidification defect (4, 11). The primary feature in these patients was the inability to lower their urine pH despite having mild to moderate acidosis. This became the defining characteristic of this disease as reported in a series of studies by Elkinton (12, 13). In the classic report by Pines and Mudge, the term "renal tubular acidosis" was used to replace the previously more cumbersome term of "renal acidosis resulting from tubular insufficiency without glomerular insufficiency" (6). This new term was emphasized in an editorial review by Elkinton and has remained the term for this disease ever since (12). Thus, at the end of the 1950s, renal tubular acidosis was thought to be a disease process that limited the ability of the kidneys to lower the urine pH, despite the fact that the patient had mild to moderate acidosis.

Although the concept of glomerular filtration had been well established in the early twentieth century, the measurement of the rate of glomerular filtration in humans had not been performed. This was accomplished

© Springer-Verlag Berlin Heidelberg 2009

by the pioneering work of Homer Smith. He was one of the first to conceive of the idea of a renal excretion system in which there was a high glomerular filtration rate which required tubular reabsorption of solutes (14). The fact that the glomerular filtration rate was very high and was followed by tubular modifications of the urine had profound effects on the ideas of bicarbonate handling and acid secretion.

The disorder of renal tubular acidosis was initially thought to be due to the inability of the kidney to maintain the steep pH gradient in the distal nephron segment. The idea that this disorder could arise from the inability of the proximal tubule to recover the filtered bicarbonate was first suggested in 1949 by Stapleton (15). He reported a patient that had significant amounts of bicarbonate in the urine at low concentrations of serum bicarbonate. This idea was further advanced by Soriano in a report of two patients that demonstrated an abnormally low threshold for bicarbonate excretion (16, 17). Based on their findings in these patients, Soriano and Edelmann proposed classifying patients with RTA as having either distal or proximal tubule defects. This was the initial description of the need for a classification scheme for this disease, suggesting that there could be multiple causes for this disease process.

The dichotomy of proximal and distal RTA was firmly established in the classic review by Rodriguez-Soriano and Edelmann which summarized the understanding of the pathophysiology at that time (1). The nomenclature of type I and type II RTA was established by the end of the 1960s in a review by Morris (18). In this review, distal RTA was referred to as type I (or classic) and proximal RTA as type II. The author also described a type III RTA as those patients that displayed features consistent with both forms of RTA. In 1972, McSherry, et al. described several patients that displayed characteristics of classic type I RTA but in addition had a reduced threshold for bicarbonate reabsorption. These patients seemed to fit the description of type III RTA. Subsequently, the reabsorption of bicarbonate in these patients normalized so that they were thought to have classic type I RTA with a developmental immaturity of the proximal tubule. Since that time, type III RTA has been essentially dropped from the classification scheme of RTA. It is interesting to note that the review by Genarri and Cohen did not mention type III RTA (19).

In the middle of the twentieth century, the discovery of aldosterone revolutionized our understanding of the physiology of sodium and potassium metabolism (20). Subsequently, it was found that patients with aldosterone deficiency had a form of RTA that resembled that of distal RTA, but the patients had hyperkalemia and not hypokalemia (21, 22). This form of RTA was then referred to as type IV RTA. More recently, other defects in distal nephron transporters have also been characterized and resemble the findings of type IV RTA. Although they are not true aldosterone deficient syndromes, they also are described as type IV RTA since these patients also have hyperkalemia. To add to the confusion, a review published in 1986 classified RTAs as type I (distal), type II (proximal) and type III (aldosterone deficient RTA) (23).

In recent years, there have been suggestions to clarify the classification of RTAs in a scheme that is based more on the pathophysiologic mechanism of the disease (24, 25). While this might eventually be the preferred nomenclature, most practicing nephrologists continue to use the historical classification. The other schemes will be discussed as part of the pathophysiology of RTA.

Over the past century, advances in renal physiology, acid-base chemistry, and molecular genetics have greatly improved our understanding of the various forms of renal tubular acidosis. Currently, the diagnosis and classification of the various types of renal tubular acidosis continue to rely on biochemical measurements of blood and urine. During the twenty-first century, however, the diagnosis of renal tubular acidosis may eventually be made by a molecular genetic approach and not by extensive biochemical testing.

Physiology of Acid Secretion

The kidney is the primary organ for long term acid base regulation. Thus, an understanding of the normal renal excretion of acid is necessary to understand the defects present in patients with RTA.

The typical Western diet generates approximately 1 mmol of H^+ per kilogram of body weight in adults (26). In addition, children generate acid from the production of hydroxyapatite in growing bone and thus generate a total of approximately 2–3 mmol of H^+ per kilogram of body weight (27–29). The acid generated from the diet and bone growth necessitates the excretion of acid by the kidneys.

The amount of acid excreted by the kidneys is referred to as Net Acid Excretion (NAE) and is expressed quantitatively as:

$$NAE = \left(U_{NH_4^+} + U_{TA} - U_{HCO_3}\right) \times V,$$

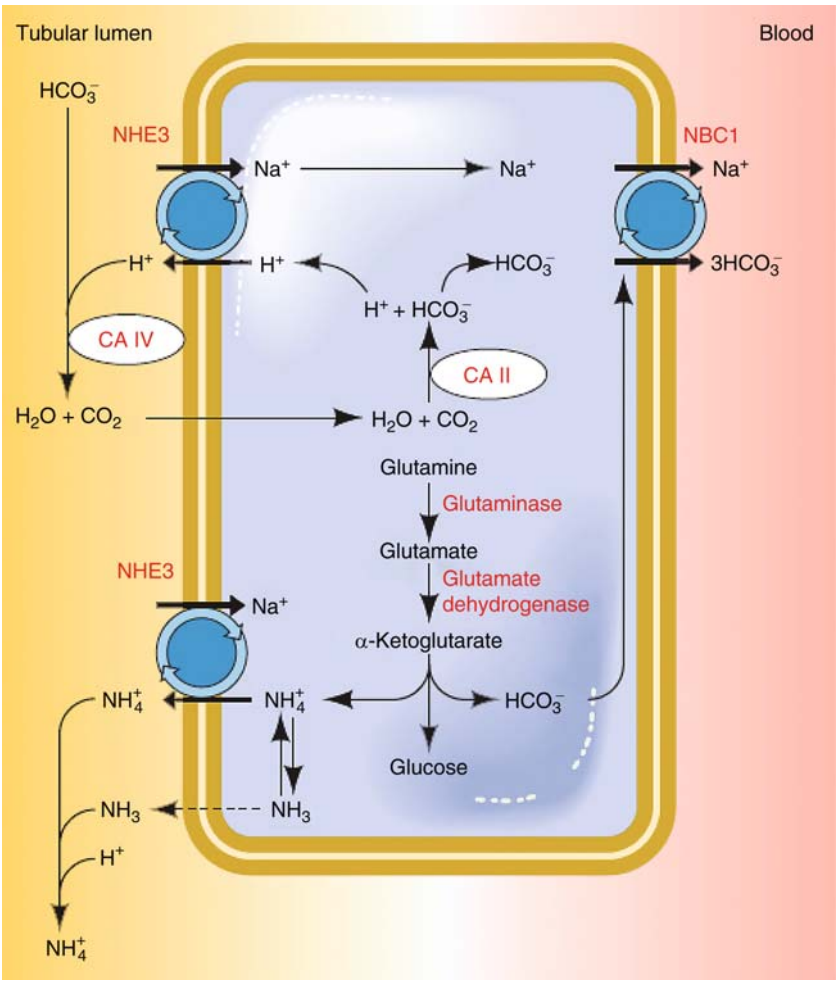
where V is the urine flow rate, $U_{NH_4^+}$ is the urine ammonium concentration, U_{TA} is the urine titratable acid concentration and U_{HCO_3} is the urine bicarbonate

concentration. Thus, the components of acid secretion can be thought of as bicarbonate reclamation to prevent bicarbonate loss, ammonium excretion and titratable acid excretion. The processes for maintaining acid base balance are quite complex, but the basic concepts will be reviewed so that the pathophysiologic changes in RTA can be described.

The kidneys are responsible for the excretion of nitrogenous waste products, principally urea, that are generated from our diet. In mammalian kidneys, urea is excreted primarily by filtration which requires having a high filtration rate so this can be accomplished. The average adult will filter about 150–180 L of blood per day. Because bicarbonate is freely filtered in the glomerulus, a large amount of bicarbonate (about 4,000 mEq per day in an adult) must be reabsorbed by the tubules each day to prevent loss of base. The bulk of the filtered bicarbonate is reabsorbed in the proximal tubule by mechanisms that are illustrated in *Fig. 39-1*. A number of proteins, both transporters and enzymes, work in

Figure 39-1

Model of bicarbonate reabsorption by a proximal tubule cell. The Na-K-ATPase located in the basolateral membrane generates and maintains the low intracellular sodium concentration. Protons are excreted into the tubule lumen by the sodium-proton exchanger (NHE3) where they combine with bicarbonate to form carbonic acid. In the presence of carbonic anhydrase IV (CAIV) the carbonic acid is hydrolyzed to water and carbon dioxide which enter the cell and recombine to form carbonic acid by the action of intracellular carbonic acid II (CAII). The carbonic acid ionizes into a proton which is then excreted into the lumen and bicarbonate which is transported by the sodium-bicarbonate symporter (NBC1) into the blood stream (reprinted with permission from (30)).



concert to reclaim approximately 80% of the filtered bicarbonate in this tubule segment (31–33).

The initial step in the reabsorption of bicarbonate is the secretion of protons into the tubular lumen. About two thirds of the proton secretory rate is provided by the sodium-proton antiporter (34–36). The isoform that is present on the luminal membrane of the proximal tubule has been termed NHE3 (sodium hydrogen exchanger 3). The energy for proton secretion by the antiporter is derived from the low intracellular sodium concentration that is maintained by the basolaterally located sodium-potassium ATPase. There is evidence that approximately one third of the proton secretory rate is provided by a proton ATPase located in the luminal membrane (36, 37). This transporter derives its energy directly from ATP.

Once the hydrogen ion is in the lumen of the proximal tubule, it combines with bicarbonate to form carbonic acid which will then form carbon dioxide and water as shown in the following equation:

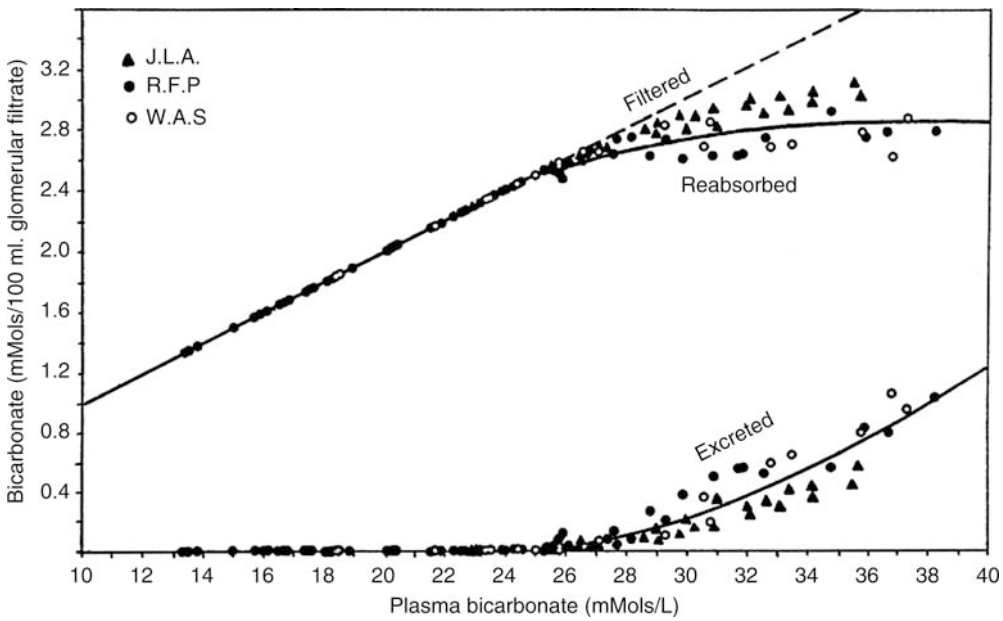
$$H^+ + HCO_3^- \longleftrightarrow H_2CO_3 \xleftrightarrow{\text{carbonic anhydrase}} H_2O + CO_2$$

The enzyme, carbonic anhydrase, is critical for catalyzing this process (38–40). One isoform of this enzyme (carbonic anhydrase IV) is located in the brush border membrane of the proximal tubule and serves to catalyze the forward reaction while another isoform of the enzyme (carbonic anhydrase II) is located inside the tubule cell for catalyzing the reverse reaction (38). Thus, carbon dioxide and water can move rapidly into the proximal tubule cell and recombine to form carbonic acid which will ionize to form bicarbonate and a hydrogen ion. The hydrogen ion is then available for secretion into the tubule lumen while the bicarbonate ion is then transported through the basolateral membrane by the sodium-bicarbonate cotransporter, NBC (41–43).

The overall process for reabsorbing bicarbonate in the proximal tubule is saturable (44). This is illustrated in *Fig. 39-2*. When the serum bicarbonate concentration is within the normal range, the filtered load of bicarbonate can be almost completely reabsorbed. If the serum bicarbonate concentration begins to rise, the filtered load of bicarbonate will then exceed the reabsorption rate of the kidney and bicarbonate will then be excreted into the urine. This has been studied in humans who were administered bicarbonate to determine the point at which bicarbonate would appear in the urine (44). The data from these experiments form a titration curve (see *Fig. 39-2*). The normal serum concentration of bicarbonate is thus determined by the threshold at which bicarbonate is excreted.

Figure 39-2

Bicarbonate titration curves for normal humans. At low concentrations of serum bicarbonate, all of the filtered load can be reabsorbed. The process of bicarbonate reabsorption is saturable, so once the delivered bicarbonate rate exceeds the transport maximum, bicarbonate will be excreted in the urine (reprinted with permission from (45)).



An additional task in maintaining acid base balance for the proximal tubule is the generation of ammonia to serve as a buffer to efficiently excrete the bulk of the acid that is generated from our diet. It has long been recognized that the excretion of ammonium is critical to the overall excretion of acid by the kidneys (46). This is primarily due to ammonium's ability to buffer hydrogen ions. To excrete 100 mmol of unbuffered H^+ at a pH of 4.0 ($[H^+] = 10^{-4}$ mol/L) would require a volume of 1,000 L of urine. The reaction of ammonia and H^+ to form ammonium has a pKa of approximately 9.0 (47). Thus, at a pH of 7.0, 99% of all the ammonia in the urine is in the form of ammonium ion and is excreted as ammonium chloride, limiting the amount of free hydrogen ions in the urine. Thus, the ammonium excretion rate is a quantitatively more important factor for the excretion of acid than the urine pH.

This can also create confusion in the assessment of a patient's ability to excrete acid. The equation that defines net acid excretion (see above) does not include information about the urine pH. Since the pKa of the ammonia/ammonium equilibrium is nine, if the patient is excreting a large amount of protons as ammonium, the pH will tend to rise even though the amount of acid being excreted has increased.

The tubular handling of ammonia and ammonium is complex (48–50). Briefly, ammonia is generated in the proximal tubule by the metabolism of glutamine and is secreted into the tubule lumen by the sodium-proton exchanger as the ammonium ion (see *Fig. 39-1*). The diffusion of ammonia gas across the proximal tubule apical membrane accounts for a small fraction of the total excretion of ammonia. The ammonium ions are then reabsorbed into the interstitium by the thick ascending limb of Henle to be secreted again by the collecting ducts (50, 51). The generation of ammonia by the proximal tubule can be upregulated in the presence of acidosis by 5- to 10-fold over baseline in adults (46, 52, 53). The ability of the neonatal kidney to upregulate ammonium excretion is somewhat limited and can prolong the recovery phase of acidosis in infants. The upregulation of ammonium production and secretion serves as the principal means of correcting acidosis that is due to non-renal causes. As will be seen below, the inability of the kidney to secrete acid as ammonium is a key feature of RTA.

The thick ascending limb of Henle is responsible for continued reabsorption of bicarbonate as well as ammonium (54, 55). The transporters involved include the sodium-hydrogen exchanger (NHE3), the sodium-potassium-2 chloride cotransporter, NKCC2 and the sodium-potassium ATPase (54). The thick ascending limb of Henle reabsorbs approximately 10% of the filtered bicarbonate.

The distal nephron is responsible for the secretion of protons which are then buffered by ammonia and titratable acid. The cell type in the collecting duct that is responsible for this is the alpha intercalated cell that is depicted in *Fig. 39-3*. The luminal membrane has a proton ATPase that utilizes ATP directly to secrete protons into the lumen of the tubule (56–59). This generates a bicarbonate ion that is then excreted through the basolateral membrane by the anion exchanger AE1 in exchange for a chloride ion (60, 61). The chloride can then exit the cell by the potassium chloride cotransporter (KCC) or the chloride channel, CLC-Kb (62, 63). Carbonic anhydrase II is critical for the formation of the carbonic acid in the cell that ionizes into the proton and bicarbonate ion (39).

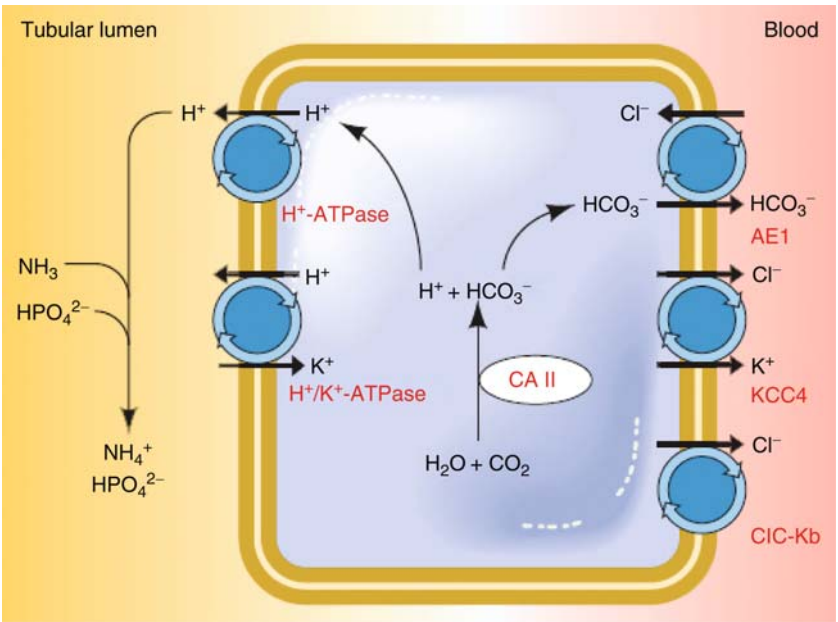
The principal cells of the collecting duct are responsible for the reabsorption of sodium and the secretion of potassium and thus do not directly secrete protons into the tubular fluid. However, these processes influence the rate of acid secretion indirectly by affecting the electrical potential difference across the epithelium. Thus, disease processes or drugs that have a primary effect on sodium or potassium transport in the collecting duct can eventually lead to acid base disturbances.

As discussed above, the proximal tubule generates ammonia that is eventually excreted as ammonium as a mechanism for acid excretion. The other major buffers in the urine are referred to as titratable acids and include phosphate, sulfate and many other anions. Of the many buffers available, the quantitatively most significant is phosphate. Phosphate exists in the blood as several different ionic species (H_3PO_4, $H_2PO_4^{-1}$, HPO_4^{-2} and PO_4^{-3}) with $H_2PO_4^{-1}$ and HPO_4^{-2} being the most abundant at physiologic pHs. The pK for the equilibrium between $H_2PO_4^{-1}$ and HPO_4^{-2} is 6.8, thus at a normal blood pH of 7.4, the ratio of $H_2PO_4^{-1}$: HPO_4^{-2} is approximately 4:1. As the urine passes through the collecting duct where the pH is lower, HPO_4^{-2} can accept protons and be converted to $H_2PO_4^{-1}$ and will aid in the buffering of excreted acid.

In addition to bicarbonate reabsorption and ammonia generation, the proximal tubule reabsorbs almost the entire filtered load of glucose and amino acids as well as approximately 85% of the filtered load of phosphate. These processes are coupled to the apical membrane sodium electrochemical gradient and are thus driven by the low intracellular sodium concentration and the negative electric potential inside the cell. Diseases that affect

Figure 39-3

Model of acid excretion in an alpha-intercalated cell in the distal nephrons. Protons are excreted into the tubule lumen by the proton-ATPase and are buffered by ammonia or titratable acid (mostly phosphate). Inside the cell, carbonic anhydrase II (CAII) provides the protons and bicarbonate through the hydration of carbon dioxide to form carbonic acid. Bicarbonate is excreted into the blood stream by action of the chloride bicarbonate exchanger (AE1) on the basolateral membrane. Chloride homeostasis is maintained by the potassium-chloride cotransporter (KCC4) and the chloride channel (ClC-Kb) (reprinted with permission from (30)).



the ability of the proximal tubule cell to maintain this gradient result in a condition known as the Fanconi syndrome (64). This is a form of proximal tubule dysfunction that includes proximal RTA, glucosuria, amino aciduria and phosphaturia. As will be discussed below, most forms of proximal RTA are associated with the Fanconi syndrome.

Proximal Renal Tubular Acidosis (Type II RTA)

Pathophysiology

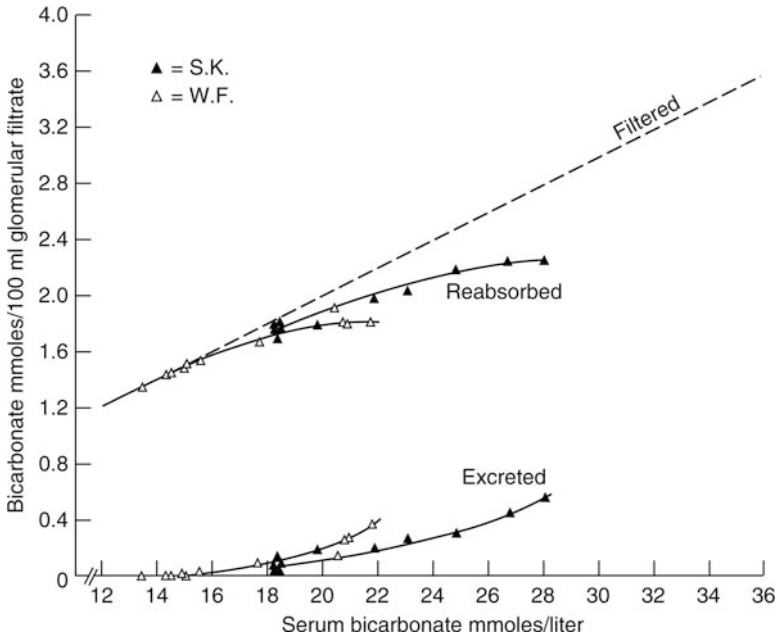
As discussed above, the transport of bicarbonate in the proximal tubule is a saturable process. Thus, the transport of bicarbonate exhibits the typical titration curve which has a threshold for bicarbonate reabsorption as illustrated in *Fig. 39-2* (44). This threshold for the reabsorption of bicarbonate is the main factor determining the serum bicarbonate concentration. If the serum bicarbonate concentration rises above the threshold, the filtered load will exceed the transport maximum for reabsorption and bicarbonate will be excreted. This will bring the serum concentration down until it matches the threshold and then all of the filtered bicarbonate is again reabsorbed.

The hallmark of proximal RTA is a reduced threshold for the reabsorption of bicarbonate as illustrated in *Fig. 39-4* and thus, these patients will have a low serum bicarbonate concentration (17, 66). When the serum bicarbonate concentration increases and approaches the normal range, patients with proximal RTA will develop bicarbonaturia. Their bicarbonate titration curve is similar to that of normal patients, but it is shifted to the left (see *Fig. 39-4*). It is important to note that the threshold for bicarbonate excretion is generally in the 14–18 mEq/L range and remains stable (1, 17).

This reduction in the capacity for reabsorption of bicarbonate makes the treatment of patients with proximal RTA difficult. Most patients require well over 6 mEq/kg/day of bicarbonate therapy to make an improvement in their serum bicarbonate concentration (67, 68).

Figure 39-4

Bicarbonate titration curves for patients with proximal renal tubular acidosis. Patients with proximal RTA have a reduced threshold for bicarbonate reabsorption and will thus excrete significant amounts of bicarbonate in their urine at lower serum bicarbonate concentrations. Thus, their titration curves are shifted to the left (reprinted with permission from (65)).



As the patient is treated with bicarbonate and the serum bicarbonate rises, bicarbonate excretion will increase dramatically with little increase in the serum bicarbonate concentration. In addition, the distal delivery of the non-reabsorbable anion will obligate the excretion of sodium and potassium. This leads to volume depletion and an increase in the serum aldosterone concentration (69). The combination of the increased distal delivery of sodium and the elevated aldosterone concentration leads to a marked excretion of potassium. Thus, many patients with proximal RTA become hypokalemic during the treatment of the disease.

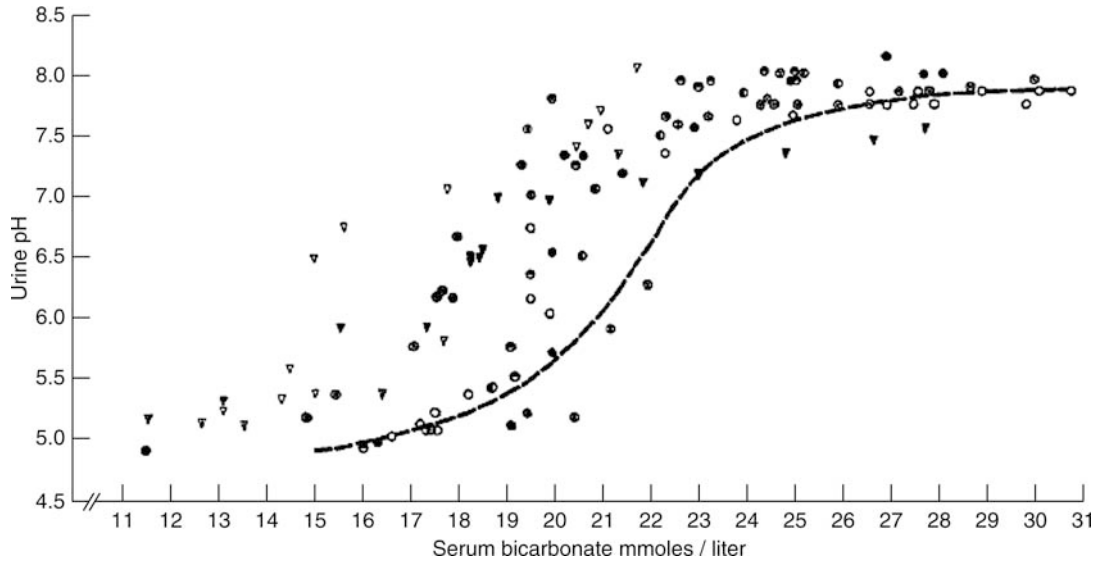
Although the treatment of these patients can be difficult, their overall acid base balance is generally good. In patients with proximal RTA, when the serum bicarbonate remains at or below the threshold for bicarbonate excretion, the patient can reclaim the filtered load of bicarbonate and will remain in relative acid base balance (16, 17, 67). This is due to the fact that the patient's distal nephron remains intact and is able to excrete the acid generated from their diet and will help prevent the patient from developing a large base deficit. This is reflected in the fact that their urine pH can decrease to less than five (*Fig. 39-5*) (1). Thus, while most patients with proximal RTA have a low serum bicarbonate, it will remain constant because the patient remains in acid base balance.

The acid base balance of patients with pure proximal RTA has been extensively studied (67, 68). At baseline, the patients were found to be in acid base balance with normal ammonium and titratable acid excretion and did not develop a base deficit. When challenged with an ammonium chloride load, they were able to increase the excretion of acid in the form of ammonia as well as titratable acid (67).

While the excretion of ammonium increased in this study, it is unclear if patients with proximal RTA have the same capacity to increase ammonia excretion as normal individuals. Because the proximal tubule is the site of ammoniagenesis, there could conceivably be a defect in the ammonia generation rate. When these patients were loaded with ammonium chloride, their excretion of acid was increased; however, the ratio of ammonia excretion to titratable acid excretion remained constant (16, 17, 67). This brought into question their ability to increase ammonia excretion in the face of an acid load and thus would probably not be able to recover from acidosis as well as a normal patient would. It was also thought that the

Figure 39-5

Urine pH of patients with proximal RTA. When patients with proximal RTA become acidotic, their serum bicarbonate concentration falls below the threshold for excretion. Because their distal nephron is intact, they can lower their urinary pH to values less than 6.0 (reprinted with permission from (70)).



level of ammonium excretion could be considered low for the chronic acidotic state (67).

A more recent study has indicated that while patients with proximal RTA are in balance at baseline, when their acidosis worsens, they cannot fully compensate (71). In this study, patients with proximal RTA were loaded with ammonium chloride for 3 days. Previous studies had been performed with an acute ammonium chloride load. The chronic loading demonstrated that the patients with proximal RTA indeed had an inability to increase their ammonium excretion as compared to the normal control subjects (71). Interestingly, the patients with proximal RTA were able to lower their urine pH to a value below the control subjects' urine pH (4.66 vs. 5.00). This was thought to be due to the fact that the normal subjects had higher amounts of ammonium in their urine to buffer the protons.

The mechanism for the ability to maintain acid base balance is due in part to an increase in titratable acid excretion (67). Because of their intact distal nephrons, these patients can also lower their urine pH to the 4.5–5 range. However, this usually occurs at very low serum pH values and is depicted in *Fig. 39-5* (1).

Calcium excretion rates in patients with proximal RTA were found to be within the normal range, indicating that there was no loss of calcium from their bones (67, 68). There was also no evidence of rickets or osteomalacia in these patients with isolated proximal RTA (67).

Fanconi Syndrome (See also Chapter 42)

As discussed above, the proximal tubule is also responsible for the reabsorption of glucose, amino acids and phosphate by sodium dependent transport systems. Many of the processes that interfere with the reclamation of bicarbonate are due to a defect in maintaining a low intracellular concentration of sodium and will thus affect the reabsorption of all of these solutes. This condition is known as the Fanconi syndrome which can be thought of as a global dysfunction of the proximal tubule (64). Thus, proximal RTA can be divided into isolated proximal RTA, which is relatively rare, and Fanconi syndrome, which is actually a more common cause of proximal RTA. This will be an important point in the clinical presentation and work up of these patients.

In addition to the problems with bicarbonate wasting, patients with Fanconi syndrome have additional pathophysiologic changes. The original definition of Fanconi syndrome consisted of skeletal findings secondary to hypophosphatemia (i.e., rickets), generalized

aminoaciduria and glucosuria (64). Later, it was found that the tubular reabsorption of bicarbonate was impaired and the definition then included proximal RTA (1). Recent reports indicate that severe osteomalacia can develop in adult patients with Fanconi syndrome (72, 73). Hypokalemia also develops in most patients with this disorder (30).

There are numerous diseases that present with Fanconi syndrome, but they appear to have a final common pathway for the proximal tubule dysfunction. A number of studies have indicated that depletion of the intracellular ATP store is responsible for the loss of the transmembrane sodium gradient (74, 75). This then leads to the inability to secrete protons and reabsorb glucose, phosphate and amino acids.

Etiology

As with most clinical disease processes, isolated proximal RTA and Fanconi syndrome can occur as an inherited defect or as an acquired disease. We will first discuss the congenital causes of this syndrome, and then review the acquired causes.

Congenital Isolated Proximal RTA

As mentioned above, isolated proximal RTA is rare (76). The initial descriptions of isolated proximal RTA were of infants that had a transient form of the disease (1, 68, 77). This form was found predominately in males and appeared to improve after several years of life. Patients presented with failure to grow and repeated bouts of vomiting and dehydration. This form follows a sporadic inheritance pattern and has no known cause.

There is a well described kindred of patients from Puerto Rico that have isolated proximal RTA that follows an autosomal dominant pattern of inheritance (67). To date, there are no reports of a gene defect in this family. Interestingly, the patients are more severely affected as infants, but tend to have less of a problem when they are older. This suggests that either the defect is attributable to a developmental transporter or to compensation with age by other transport processes in the more distal nephron segments. Children in these families have moderate acidosis and do not grow at normal rates unless they receive treatment (67). As discussed above, treatment with alkali therapy does not fully correct their acidosis because of the increased excretion of the administered base, but treatment will allow them to grow at near normal rates.

In recent years, another family with isolated proximal RTA that has an autosomal dominant inheritance pattern has been reported (78). The clinical features of this family were very similar to the previous report (67). A candidate gene approach was taken in an attempt to determine the genetic defect in this family. Extensive sequencing was done on many of the genes known to be involved in the proximal tubule reabsorption of bicarbonate; carbonic anhydrase II and IV as well as carbonic anhydrase XIV; NBC1; NHE2, NHE3 and NHE8 as well as the sodium proton exchanger regulatory proteins NHRF1 and NHRF2; and the chloride bicarbonate exchanger, SLC26A6. However, no defects were found. The authors concluded that either additional proteins are involved in the regulation of bicarbonate reabsorption or that there might have been defects in transcription factors that could regulate the expression of these genes (78).

A rare cause of isolated proximal RTA is a mutation in the sodium bicarbonate cotransporter, NBC1, which is inherited in an autosomal recessive pattern (79–81). The initial patients described were two brothers that had proximal RTA as well as eye and dental abnormalities (82). Since then, only a few other patients have been described with these features (82, 83). These patients were found to have a defect in the sodium bicarbonate cotransporter, NBC1, that is responsible for transporting bicarbonate out of the proximal tubule cell and into the blood stream (80, 83–85). Although these cases are very rare causes of isolated proximal RTA, they have demonstrated the critical function of NBC1 in the proximal tubule reabsorption of bicarbonate.

The sodium bicarbonate cotransporter, NBC1, is in the class of transporters that are critical in the membrane transport of bicarbonate known as SCLA4 (60, 61, 86–88). This class also includes the chloride bicarbonate exchanger that will be discussed in the section on distal RTA. The sodium coupled bicarbonate transporter in the proximal tubule cotransporter is designated SCLA4A4 (NBC1) and is also found in other tissues such as the eyes as well as the heart (80). This kidney specific isoform is determined by alternate splicing of the gene. Defects in this transporter result in proximal RTA due to the inhibition of bicarbonate transport in the proximal tubule. Because of the distribution of the protein in the eye, patients also develop ocular defects (80). Recently it was found that the defect might be in trafficking of the protein and not the actual function of the protein (89).

Defects in carbonic anhydrase cause dysfunction of the proximal tubule, but because of its distribution in the distal nephron, these defects cause combined proximal

and distal RTA (43, 90). These will be discussed in detail below in the section on Type III RTA.

The sodium hydrogen exchangers have been considered candidate genes for the cause of isolated proximal RTA, however, to date there have been no defects found in these genes. To determine the role of these exchangers in overall acid base balance, knockout mouse models have been generated. The primary sodium hydrogen exchanger in the apical membrane of the proximal tubule is NHE3 (34). Mice that have had NHE3 knocked out have a modest metabolic acidosis (91). They have an elevated serum aldosterone level as well as upregulation of colonic sodium transporters indicating that these animals have evidence of volume contraction (91). Perfusion of the proximal tubules in vitro shows a reduced ability to acidify the urine (92). As discussed above, a recent study in patients with isolated proximal RTA failed to detect a defect in any known gene for bicarbonate transport including NHE3 (78).

Another mouse model of proximal RTA was developed recently (93). The TASK K + channel is located in the proximal tubule and appears to regulate bicarbonate transport. When this channel was knocked out, the animals developed acidosis which was due to renal bicarbonate wasting (93).

Congenital Fanconi Syndrome

There are a number of genetic defects that result in Fanconi syndrome. These are listed in *Table 39-1* and will be described briefly.

The most common cause of congenital Fanconi syndrome is cystinosis which is an autosomal recessive disorder (94, 95). This disease results from a defect in the gene CTNS which encodes for the lysosomal membrane transporter, cystinosin (96, 97). Lysosomes are organelles responsible for degradation of proteins within the cell. Cystinosin is responsible for the transport of cystine out of the lysosome so that the organelle can continue to function. In the disease cystinosis, cystine accumulates within the lysosome of the cells throughout the body (95). It is not clear how this leads to the Fanconi syndrome, but it appears to be related to depletion of intracellular ATP (74, 75).

The other diseases that result in the Fanconi syndrome are much rarer. One in particular is worth mentioning because it is thought to be the cause of the syndrome first described by Fanconi (98–102). This is a defect in the facilitative glucose transporter GLUT2. This transporter is responsible for transporting glucose out of the proximal tubule cell and into the blood stream. Thus, a mutation in this protein would lead to accumulation of glucose within the proximal tubule. It is unclear how this would cause the Fanconi syndrome, but could be due to the consumption of intracellular phosphate by the accumulated glucose.

Table 39-1
Inherited causes of Fanconi syndrome

Disease	Gene defect	OMIM
Cystinosis	Cystinosin (CTNS)	219,800
Tyrosinemia	Fumarylacetoacetase	276,700
Fanconi-Bickel syndrome	Glut 2	138,160
Hereditary fructose intolerance	Fructose-1-phosphate aldolase	229,600
Dent's disease	ClCN5	300,009
Lowes syndrome	Phosphatidylinositol 4,5-bisphosphate 5-phosphatase deficiency (OCRL1)	309,000
Galactosemia	Galactose-1-phosphate uridylyltransferase	230,400
Wilson's disease	ATPase, Cu^{2+}-transporting, beta polypeptide	277,900

Hereditary fructose intolerance is of interest because this served as a useful model for the study of Fanconi syndrome (103, 104). The cause of the Fanconi syndrome in this disorder is thought to be due to the depletion of intracellular phosphate that occurs when the cell is presented with a load of fructose. Patients with this disorder tend to have normal renal function and no acid-base disturbance when they remain on a fructose restricted diet.

The oculo-cerebro-renal syndrome of Lowe is due to a mutation in the OCRL1 gene which encodes for the enzyme, phosphatidylinositol 4,5-bisphosphate 5-phosphatase (105). This causes an accumulation of phosphatidylinositol 4,5-bisphosphate in the cells which presumably leads to the Fanconi syndrome because it interferes with actin polymerization (106). The syndrome is inherited in an X-linked pattern.

Dent disease is caused by mutations in the chloride channel encoded by the gene, CLCN5 (107–110). The original term for this disorder was X-linked hypercalciuric nephrolithiasis. The chloride channel that the gene encodes for is found in intracellular organelles and appears to be critical for maintaining pH gradients. It is not clear how this defect results in the Fanconi syndrome.

Other diseases that lead to the Fanconi syndrome include galactosemia and tyrosinemia (111–114). These disease processes can also be controlled by diet. Rarely, other forms of glycogen storage disease can result in the Fanconi syndrome (115–117). Mitochondrial defects can also rarely be associated with the Fanconi syndrome (118–121).

Recently, mutations in the transcription factor HNF1 alpha have been associated with dysfunction of the proximal tubule (122). In addition, these defects result in maturity onset diabetes of the young type 3 (MODY3) (123). This syndrome has been reproduced in a mouse model (124). Thus, it appears that this transcription factor is a key regulator of glucose metabolism and could impact the function of the proximal tubule.

Acquired Isolated Proximal RTA

Most diseases and toxins that affect the proximal tubule result in the Fanconi syndrome, thus it is rare for isolated proximal RTA to be acquired. The primary cause of isolated proximal RTA is inhibition of carbonic anhydrase (CA) (125). Acetazolamide is given to treat pseudotumor cerebri and some forms of glaucoma. One side effect of this treatment is the development of proximal RTA. Indeed, this is often used as a marker of treatment adequacy. A number of other medicines can also cause CA inhibition, e.g., hydrochlorothiazide and topiramate (126–129).

Acquired Fanconi Syndrome

There are many toxins and medications including heavy metals that are now known to affect the proximal tubule and result in the Fanconi syndrome (130–133). In particular, a number of well documented cases of Fanconi have been reported with valproic acid (134, 135). These appear to be reversible processes, but the time of resolution can be significant. Chinese herbs containing aristolochic acid have also been associated with Fanconi syndrome (136, 137). Other agents that have been associated with Fanconi syndrome include aminoglycosides, ifosfamide, the antiviral agent tenofovir and salicylate (138–145).

Disease processes that cause the Fanconi syndrome are either immune mediated diseases or paraproteinemia syndromes. For example, Sjogren's disease will typically cause distal RTA but has been reported to cause Fanconi syndrome (146). The classic paraproteinemia that results in Fanconi syndrome is multiple myeloma (147–149).

Other conditions that are associated with Fanconi syndrome include vitamin D deficiency (150, 151). The mechanism of action for this process is not well understood. In addition, proximal RTA has been reported in pregnancy and with paroxysmal nocturnal hemaglobinuria (152, 153).

Distal Renal Tubular Acidosis (Type 1 RTA)

Pathophysiology

The hallmark of distal RTA is the inability to lower the urine pH maximally in the face of moderate to severe systemic acidosis (1). This is clearly shown in *Fig. 39-5* where the urine pH is graphed against the serum bicarbonate concentration. As can be seen in the normal individuals, the urine pH decreases to a value of approximately 4.5–5.0, but the patients with distal RTA fail to reduce their urine pH below 6.5. While this feature has been known for many years and was the initial defining characteristic of RTA, the causes of this dysfunction have only recently been elucidated (*Fig. 39-6*).

The primary function of the distal nephron in acid base homeostasis is excretion of the acid generated by the metabolism of our diet. As described earlier, the typical western diet generates approximately 1 mmol of acid per kilogram of body weight (26). Children have an additional 1–2 mmol of acid per kilogram body weight that is generated from the formation of hydroxyapatite in growing bone. Thus, the distal nephron in the growing child has the task of excreting between 1 and 3 mmol of acid per kilogram (27–29). If the distal nephron is not capable of performing this function, the patient will use the existing buffers in the body to buffer this acid. Most of the pathophysiologic consequences of distal RTA are due to accumulation of acid. Even though the proximal tubule is functioning normally to reabsorb the filtered load of bicarbonate, the patient will continue to accumulate acid and develop an ever increasing base deficit.

After the bicarbonate buffers in the extracellular fluid space are depleted, the bones begin to serve as the buffer source for the accumulated acid. Hydroxyapatite can be dissolved to liberate hydroxyl ions to help in the neutralization of the acid. Studies in patients with distal RTA have shown that they are in negative calcium balance due to the reabsorption of bone (1). This will lead to nehrocalcinosis and nephrolithiasis.

Another contributing factor to the development of nephrocalcinosis is the fact that citrate reabsorption in the

Figure 39-6

Urine pH of patients with distal RTA. Because patients with distal RTA cannot excrete hydrogen ions against a gradient in the distal nephron, they are unable to significantly lower their urine pH, even when they become very acidotic (reprinted with permission from (70)).

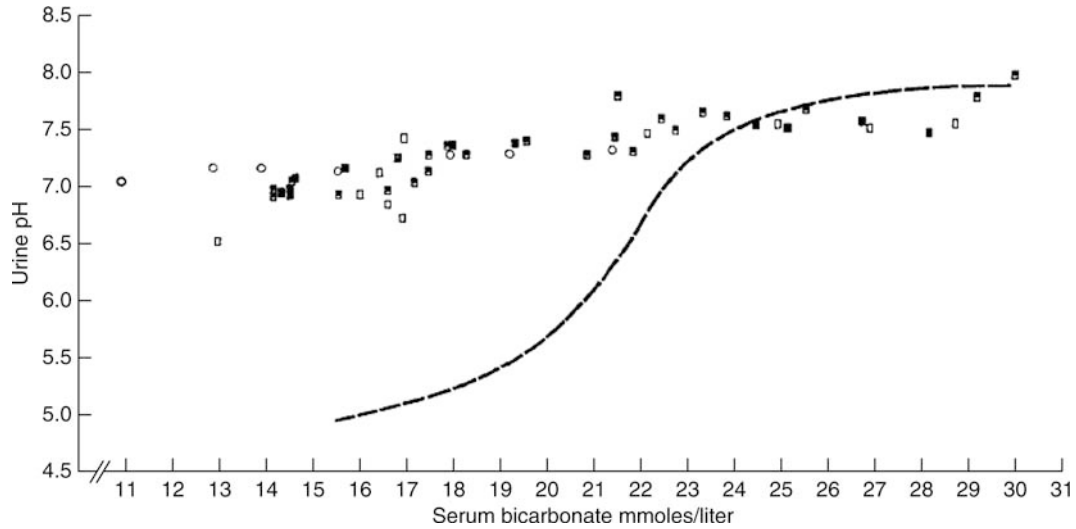


Figure 39-7

Nephrocalcinosis in a patient with distal RTA (reprinted with permission from (156)).

proximal tubule will be increased to help provide for base equivalents (154, 155). The resulting hypocitraturia will contribute to the development of nehrocalcinosis and nephrolithiasis. This can be used to help differentiate distal RTA from proximal RTA as seen in *Fig. 39-7* (157). In growing bones, the acid base disturbance will lead to rickets whereas in the older patient, they will develop osteomalacia. The description of this was provided by Albright (5).

Nephrocalcinosis has also been associated with increased production of red cells (158, 159). It is not clear what the mechanism is in these patients. Erythrocytosis has been observed in some patients with distal RTA, presumably as a result of the nephrocalcinosis (158, 159).

The proximal tubule provides ammonia that is delivered to the distal nephrons to serve as a buffer. Recently, it has been appreciated that the rate of ammonium excretion in patients with distal RTA is less than that of normal subjects (24, 25, 160). This is presumably due to the fact that ammonia that is not converted to ammonium ion by the secretion of protons can then diffuse back into the blood stream and is subsequently not excreted. There have been a number of reports of patients with distal RTA that have hyperammonemia at the time of presentation when they are extremely acidotic (161–163). They do not have liver dysfunction but they have an inability to excrete the ammonia generated in the proximal tubule.

This phenomenon has lead some investigators to postulate that the excretion of ammonium be used as a new classification scheme of RTA (160). While this could result in a more physiologic scheme for the classification of RTA, this is probably not practical at the present time. The measurement of ammonium in the urine is not a routine laboratory test. Methods for estimating ammonium excretion will be discussed in the section on clinical aspects.

Another pathophysiologic finding in patients with classical distal RTA is hypokalemia (164, 165). The exact mechanism for this is not entirely clear but is at least partially due to elevated aldosterone concentrations in these patients (45). Careful studies have indicated that the aldosterone concentration is routinely elevated in patients with distal RTA. A few patients had aldosterone concentrations in the normal range, but were inappropriately normal for the degree of hypokalemia. It was thought that the patients were mildly volume depleted because of mild proximal tubule dysfunction. The hypokalemia can be severe and cause muscle paralysis (166). This has occasionally been the presenting sign of RTA (167).

Etiology

Congenital

Congenital forms of distal RTA are divided into autosomal dominant (type Ia) and autosomal recessive with (type Ib) and without (type Ic) hearing loss. The molecular basis for these forms of inherited distal RTA have become clear over the past few years and have greatly improved our understanding of the molecular basis of renal acid base metabolism.

Autosomal dominant distal RTA is caused by mutations in the anion exchanger (AE1) that is located in the basolateral membrane of the alpha intercalated cells of the collecting duct. This exchanger is responsible for the basolateral exit of bicarbonate into the blood stream. Thus, if the protein is not functioning, acid secretion into the tubule lumen will be limited.

The biology of AE1 has proven to be very interesting (60, 168, 169). The exchanger is also located in the red cell membrane where it was first discovered and was termed "band 3 protein" (169). While it serves to function in the red blood cell as an anion exchanger, it also binds to other membrane proteins and contributes to the stability of the red cell membrane. Thus, defects in AE1 have been associated with hereditary spherocytosis and south-east Asian ovalocytosis (SAO) (168). In general, patients with these disorders do not have RTA.

The mutations in AE1 that result in autosomal dominant distal RTA are located in a different area of the molecule than the mutations causing the red cell membrane defects (170, 171). Patients with autosomal dominant distal RTA tend to develop a less severe form of RTA than patients with the autosomal recessive forms (172, 173). Most of the patients do not have red cell membrane defects. However, there have been recently described patients with both RTA and SAO. These patients were found to be compound heterozygotes for mutations that cause the two different disorders or they were homozygous for a mutation that could cause both RTA and SAO (174–176).

The autosomal recessive distal RTA with hearing loss (type Ib) was found to be due to mutations in a subunit (ATP6V1B1) of the proton pump located on the apical membrane of the alpha intercalated cell of the collecting duct (177). This led to the discovery of the proton pump location in the inner ear (178, 179). The proton pump is a key transporter in the secretion of hydrogen ions (56–59). It is a complex molecule with multiple subunits that are specific to the location in the body.

Subsequent to the initial discovery, a number of other mutations have been discovered that are responsible for autosomal recessive distal RTA with hearing loss (70, 180). Most recently, a large family with this form of RTA and hearing loss had been reported (181). The defect has been recently determined to be a truncating mutation of the ATP6V1B1 which prevented the subunit from organizing with the rest of the proton pump for complete function (182).

As families were characterized for mutations in the proton pump, it was clear that some of the families did not have hearing loss and did not have defects in the ATP6V1B1 subunit. This led to the designation of autosomal recessive distal RTA without hearing loss (type Ic). Defects in a separate subunit (ATP6N1B) were found to be the cause in the initial families studied (183). Subsequently, a number of patients developed hearing loss later in life. These patients were found to have a defect in subunits that were found in the inner ear (180).

Mouse models of distal RTA have also been developed. A mouse model that lacks AE1 (slc4a1) has been produced and found to have many of the same features as the human disease (184). The importance of the potassium chloride transporter KCC4 for function of the alpha intercalated cells was shown in a knock out model (62). These mice had features of distal RTA. A mouse that lacked the transcription factor Foxi1 was shown to have distal RTA (185). This transcription factor is evidently important in the development of the alpha intercalated cells. There are no known human mutations in this factor, but the mouse model raises the possibility of this being another gene to consider in human disease.

Acquired

The most common cause of acquired distal RTA is immunologic destruction of the alpha intercalated cells. This occurs most frequently with Sjogren's syndrome (186, 187). Distal RTA in Sjogren's has been reported to occur in about one third of the patients and after a duration of 10 years (187, 188). It can also occur in patients with systemic lupus erythematosis and has been reported in a patient with Graves' disease (189–192). Distal RTA has also been reported in renal transplant patients, however it is not clear if this is immune mediated or secondary to the medications (193).

A number of medications have been found to cause distal RTA. The classic example is amphotericin (194). This model has been used to study the pathogenesis of RTA in the laboratory (195, 196). The primary defect in acid secretion due to amphotericin appears to be an increase in the permeability of the collecting duct cells to hydrogen ions. This would then prevent the formation of the gradient that is necessary to secrete protons into the urine. While these results helped explain the pathophysiology of the backleak and is important clinically, this probably does not apply to patients with inherited defects that result in distal RTA.

Other medications that are known to cause distal RTA include lithium, foscarnet and melphalan (197–199). The mechanisms for these effects are not clear.

Acquired distal RTA can also result from the treatment of hypophosphatemic rickets (200). This is probably a result of the nephrocalcinosis that develops form the high dose of vitamin D these patients receive. Examination of patients with idiopathic hypercalciuria also demonstrated some defects in renal acidification (201).

An interesting association of distal RTA and ingestion of vanadate has been proposed as a mechanism for the high endemic rate of RTA in northeastern Thailand (202). These patients develop severe hypokalemia and it is thought that this could be due to inhibition of the H-K-ATPase by vanadate. There is a high level of vanadate in the soil in this area and experiments with rats have shown that administration of vanadate can lead to renal tubular acidosis (203).

Glue sniffing has been listed as a cause of distal RTA; however careful examination of a patient with acidosis form glue sniffing suggests a different cause of the acidosis (204). The toluene in the glue is rapidly metabolized to hippuric acid which is promptly excreted by the kidneys. When measurements were made of ammonium excretion rates, they were found to be normal. Thus, the conclusion is that while there might be some renal tubule damage from the glue sniffing, the bulk of the acidosis results from hippuric acid production. The prompt excretion of the hippurate prevents the development of an increase in the anion gap (204).

Type III Renal Tubular Acidosis

Type III RTA refers to a form of renal tubular acidosis that has features of both proximal RTA and distal RTA. During the middle of the twentieth century, a number of patients were found to have features of both forms of RTA and the third type of RTA was suggested. It was subsequently found that these patients had distal RTA with a transient form of proximal RTA. Thus, the term fell out of favor and had not been used.

More recently, a form of RTA that occurs with some forms of osteopetrosis has been characterized that seems to meet the criteria for the designation of Type III RTA. This association was originally described in 1972 (205). Subsequently, the defect was found to be a mutation in the gene for carbonic anhydrase II (43, 90). After the initial finding of the genetic defect, a number of other patients have been described with similar clinical findings

(156, 206, 207). These patients have other extrarenal findings such as cerebral calcifications as well as the bone problems associated with osteopetrosis (207). It should be pointed out that osteopetrosis can be caused by a defect in a number of different genes that affect the osteoclast (208). Thus, the finding of osteopetrosis does not imply that the patient will have a defect in carbonic anhydrase II and will develop RTA. The form of osteopetrosis associated with the carbonic anhydrase deficiency is the syndrome known as Guibaud-Vainsel syndrome or marble brain disease (208).

Type IV Renal Tubular Acidosis

The effects of aldosterone on electrolyte balance have been extensively studied since the discovery of aldosterone in the 1950s (20). The initial findings demonstrated dramatic effects of aldosterone on sodium reabsorption and potassium secretion. In the latter half of the twentieth century it became clear that aldosterone also had effects on acid base balance. With the recent advances in molecular biology, the mechanisms involved in the genetic causes of type IV RTA have been elucidated.

Type IV RTA was initially used to describe patients that developed acidosis from aldosterone deficiency. This could occur as an inherited defect, such as congenital adrenal hyperplasia, or could be acquired as in Addison's disease. The principal feature that distinguished type IV RTA from classic type I RTA was the finding of hyperkalemia. Patients with type IV RTA are hyperkalemic while many of the patients presenting with classic type I RTA were hypokalemic. This led investigators to believe that the cause of this form of RTA was aldosterone deficiency. Later it became apparent that many of the patients were not aldosterone deficient, but had a decreased responsiveness of the renal tubules to aldosterone and hence developed hyperkalemic RTA. Currently the term type IV RTA is applied to all forms of hyperkalemic RTA, regardless of the serum aldosterone concentration.

Pathophysiology

The primary effect of aldosterone on the collecting duct is to stimulate sodium reabsorption and potassium secretion in the principle cells (209). This results in an enhancement of the lumen negative electrical potential which can then help promote proton secretion. Aldosterone also has direct effects on the alpha intercalated cells to promote proton secretion by upregulating expression of the proton ATPase as well as carbonic anhydrase (209). The effect of aldosterone on ammonia excretion is not clear. There is evidence that aldosterone deficiency could directly inhibit the production of ammonia while other studies indicate that the effect could be secondary to hyperkalemia (210–212). Ammonia secretion in patients with aldosterone deficiency was low and was shown to increase after administration of mineralocorticoid; however, it was still not clear if the effect could be secondary to changes in potassium concentration.

Patients that are aldosterone deficient or resistant to the actions of aldosterone have increased excretion of sodium which leads to volume depletion and potentially a decrease in the glomerular filtration rate (213, 214). Thus, many of the symptoms of this process are secondary to the volume depletion.

The acidosis in most patients with type IV RTA is not as severe as in other forms of RTA (213). Thus, the main clinical problem with most of these patients is the hyperkalemia. Treatment often relies on restricting the intake of potassium but will ultimately depend on the cause of the RTA.

Etiology

As discussed above, type IV RTA can result from a deficiency of aldosterone or from a resistance of the renal tubules to the actions of aldosterone.

Aldosterone Deficiency

Aldosterone deficiency can be the result of a global dysfunction of the adrenal gland, referred to as Addison's syndrome, or it can be the result of isolated aldosterone or mineralocorticoid deficiency. The most common inherited form of mineralocorticoid deficiency is congenital adrenal hyperplasia (CAH) which is due to 21-hydroxylase deficiency (65, 215). Other infants can present with isolated aldosterone synthase deficiency which is not as severe a disease process since the glucocorticoid pathway remains intact (216).

Aldosterone Resistance

There are a number of inherited and acquired conditions that result in resistance of the tubules to the action of aldosterone. The pathway for aldosterone action includes the mineralocorticoid receptor and the epithelial sodium

channel (ENaC). Defects in both of these components results in type IV RTA. Because of the renal tubular resistance to aldosterone, aldosterone concentrations in the blood are quite elevated. Thus, this is referred to as pseudohypoaldosteronism (PHA).

Defects in the mineralocorticoid receptor lead to an autosomal dominant form of PHA (217). This form is the least severe of the PHAs and patients tend to improve as they get older. This is presumably due to compensation by other pathways to reabsorb sodium and secrete potassium and hydrogen ions.

An autosomal recessive form of PHA is due to defects in ENaC (218). Patients with this form can be severely affected since the final pathway for sodium regulation in the collecting duct involves ENaC. In addition, they have severe pulmonary problems at birth because ENaC is present in the lungs and is a key factor in the reabsorption of fluid from the lung space after birth.

Both of these forms of PHA lead to salt loss and volume depletion. Patients tend to be hypotensive and dehydrated. Additionally, plasma concentrations of renin and aldosterone are quite elevated because of the volume depletion.

A form of PHA that occurs in patients that are hypertensive was originally thought to be due to a "chloride shunt" in the collecting duct and was referred to as PHA type 2 or Gordon's syndrome (219). These patients are characterized by having hyperkalemia and acidosis, but have a low concentration of renin and aldosterone in their plasma. This led investigators to hypothesize that the paracellular pathway in the collecting duct was allowing chloride to be reabsorbed at a higher rate than was needed (220). This would cause the electrical potential difference in the tubule to decrease and would thus decrease the excretion of potassium and protons.

Recent discoveries have shown that PHA type 2 is due to defects in WNKs (with no lysine kinases) (221). Specifically, there are families with the syndrome that have mutations in WNK1 and some with mutations in WNK4. The biology of the WNKs has turned out to be very complicated and is beyond the scope of this chapter. However, they seem to be key players in the regulation of potassium and blood pressure.

Acquired

Addison's disease can be an autoimmune disease or can be the result of damage to the adrenal gland from infection or infarction. Treatment involves replacing the adrenal hormones as needed as well as treating the underlying infection. In adult patients, diabetes is a leading cause of type IV RTA as a result of hyporeninemic hypoaldosteronism (222). There are other disease processes that also lead to a decrease in production of renin which would then lead to a decrease in aldosterone secretion. If the patient has type IV RTA from acquired hypoaldosteronism, treatment with mineralocorticoids will correct the defect (223).

Tubular resistance to aldosterone can occur as a result of a number of different processes. Autoimmune diseases can lead to interstitial nephritis that decreases the tubule responsiveness to aldosterone (224). Patients with systemic lupus erythematosis classically develop type 1 RTA, but have been reported to present with type IV RTA (192). Infections such as acute pyelonephritis can also cause a resistance to aldosterone action.

Probably the most common cause of acquired type IV RTA in the pediatric age range is obstruction of the urinary tract. The mechanism by which obstruction causes resistance of the tubule to aldosterone is not clear, but this is commonly seen in patients with posterior urethral valve or with prune belly syndrome.

Type IV RTA can also been seen in patients with a renal transplant (225). This could be due to either an immune mediated mechanism or it could be related to medications used for the treatment of rejection. In particular, calcineurin inhibitors are known to cause a type IV RTA (193, 226).

Other medications that are known to interfere with the action of aldosterone include angiotensin converting enzyme inhibitors (ACE inhibitors), heparin, prostaglandin inhibitors (NSAIDs) and a number of potassium sparing diuretics. These would include amiloride which blocks the epithelial sodium channel and spirinolactone which blocks the mineralocorticoid receptor.

Clinical Aspects of Renal Tubular Acidosis

The diagnosis of renal tubular acidosis represents a challenge to the clinician for a number of reasons. Depending on the severity of the disease presentation, the patient could present with findings consistent with proximal and distal RTA. The patients are also many times quite volume depleted at presentation and it is not clear how much this impacts the serum chemistries. In addition, patients with infections can be septic and in shock. Thus, the complete evaluation of a patient for renal tubular acidosis might have to occur after the acute illness has subsided.

As with any complex disease, the diagnosis of RTA begins with clinical suspicion. If the disease is not being considered in the differential diagnosis, then a definitive diagnosis will not be made. There have been a number of recent reviews that outline practical guidelines for the diagnosis and management of RTA (227–230). This section of the chapter will focus on the reasoning behind the laboratory testing that is recommended for the work up of patients with suspected RTA.

The inherited forms of renal tubular acidosis present almost uniformly with failure to grow and repeated episodes of vomiting and dehydration (1, 68). It should be emphasized that most of these patients are very ill appearing at the time of presentation. The patient with failure to grow that otherwise appears healthy ahs a much lower probability of having RTA. A recent study examined patients referred for failure to thrive that had serum chemistries indicating the possibility of RTA (231). Simply performing a venous blood gas analysis in the patients demonstrated the absence of acidosis.

The first step in the evaluation of patients with an acidosis is to determine the serum anion gap (232–234). Patients with RTA are characterized by having a normal anion gap. This is also referred to as a hyperchloremic metabolic acidosis. Interpretation of the anion gap can occasionally be misleading. Other factors can affect the anion gap such as serum protein concentrations, calcium and other anions such as phosphate (233). Thus, the determination of a normal anion gap acidosis can only be correctly made when these factors are taken into account.

Although renal tubular acidosis should be suspected in these patients with metabolic acidosis with a normal anion gap, there are other disorders to consider in the differential diagnosis such as gastrointestinal loss of bicarbonate. The workup of these patients is therefore designed to differentiate whether the acidosis is of renal or extrarenal origin. Thus, it is necessary to examine the response of the kidney to the metabolic acidosis. As discussed above, the normal renal response to metabolic acidosis is to increase ammonium chloride excretion as a way to enhance hydrogen ion excretion to correct the acidosis. Unfortunately, measuring ammonium in the urine is not a routine function in most hospital laboratories. Over time, several approaches have been taken to estimate the urinary excretion of ammonium to determine if the kidney is responding normally (235–239).

The measurement of the urine pH can be helpful but also can be misleading in the diagnosis of RTA (240). Where it tends to be helpful is in determining whether or not there is bicarbonate in the urine (see *Fig. 39-8*).

The simplest test that was devised is to measure the urine sodium, potassium and chloride concentrations and calculate the urinary anion gap using the following equation:

$$Urinary\ anion\ gap = U_{Na} + U_K - U_{Cl},$$

where U_{Na} is the urinary sodium concentration, U_K the urinary potassium concentration and U_{Cl} the urinary chloride concentration. This approach is based on the fact that the unmeasured cations and anions are constant and that ammonium would be the primary cation other than sodium and potassium that would be excreted with chloride. The amount of ammonium in the urine when the anion gap is zero turned out to be 80 mmol/L. The other assumptions in this approach are that there is no appreciable bicarbonate in the urine and the patient is not receiving medications that are excreted in the urine in ionic form such as penicillins. If the urine pH is less than seven, the urinary bicarbonate will be less than 10 mmol/L (see *Fig. 39-8*). This simple approach has been verified in normal controls as well as patients with RTA and gastrointestinal causes of acidosis (235, 237).

Modifications to the urinary anion gap calculation have been made to expand its application to conditions that could yield misleading results. If patients are excreting other anions, ammonium would be excreted with the unmeasured anion instead of chloride. Thus, the urinary anion gap would underestimate the amount of ammonium in the urine. The osmolal gap was developed to take this into account (238). The osmolal gap is calculated by the following equation:

$$Urine\ osmolal\ gap = measured\ urine\ osmolality - calculated\ osmolality.$$

The calculated osmolality is determined by the following equation:

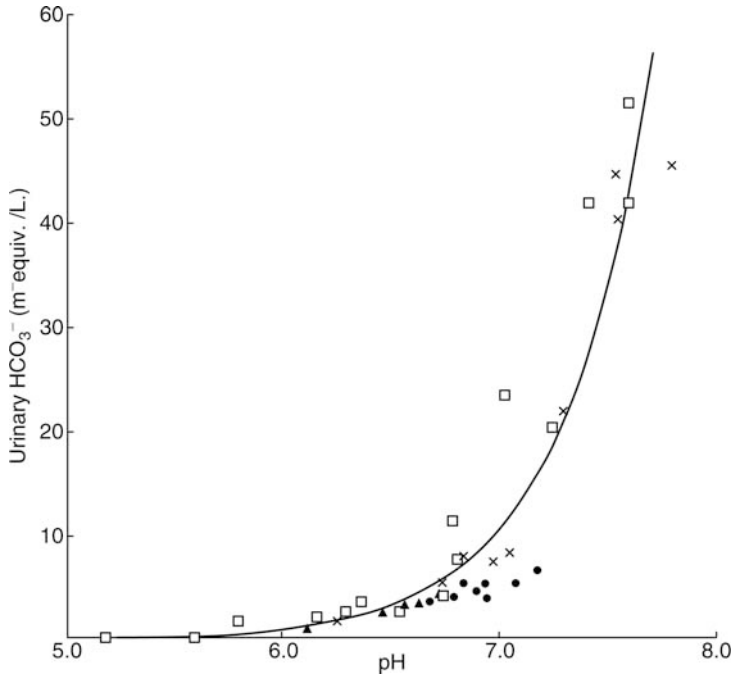
$$\text{Calculated osmolality} = \text{Na} + \text{K} + \text{HCO}_3 + \text{urea nitrogen}/2.4 + \text{glucose}/18.$$

This was shown to correctly account for the unmeasured anions in patients with ketoacidosis (238). An additional modification was then developed because of the difficulty in measuring the urine bicarbonate concentration. This method replaces the urine bicarbonate measurement by multiplying the sum of the sodium and potassium concentrations by two (236).

The above approaches are designed to estimate the amount of ammonium in the urine. Normal controls have about 80 mmol/L of ammonium in the urine (237). What makes the test work well in the evaluation of acidosis is

Figure 39-8

Urinary bicarbonate concentration as a function of urinary pH. As can be seen, once the urine pH becomes less than 6.5, the concentration of bicarbonate is less than 10 mEq/L. This might have an impact in determining the urinary anion gap (reprinted with permission from (241)).



the fact that normal individuals will have an increase in their ammonium excretion but the patients with RTA will not. A recent study examined the correlation of these techniques with actual measurement of urinary ammonium (242). This study concluded that the correlation many times was not good and that direct measurement of the urinary ammonium would be a better method. Another problem with this approach is that neonates were found to have a poor correlation between urinary anion gap and urinary ammonium concentration (243).

Another approach to examine the urine for proton secretory rate is to measure the urine and blood pCO_2 during bicarbonate loading (244–246). The idea is to take advantage of the low level of carbonic anhydrase activity in the distal nephron. When the patient is loaded with bicarbonate, the delivery to the proximal tubule will exceed the transport maximum and significant amounts of bicarbonate will be delivered to the distal nephron. If the patient has a normal proton secretory rate, hydrogen ions will be secreted into the tubule lumen. Although there is CA II in the distal nephron, the rate of reaction is slow enough that the carbon dioxide will be excreted in the urine and not reabsorbed. Under these conditions, normal individuals will have a urinary pCO_2 of greater than 70 mm Hg or a blood-urine pCO_2 of greater than 30 mm Hg. Patients with a defect in hydrogen ion secretion will have a urinary pCO_2 of less than 70 mm Hg or a blood-urine pCO_2 of less than 30 mm Hg. This method has been shown to be useful in neonates as well as adults (246).

Other tests might be indicated if the results of the above remain indeterminate. Traditionally, the patient's ability to acidify the urine is tested using acute or chronic loading with ammonium chloride (228). Because of the unpalatable nature of the ammonium loading, urinary acidification can be evaluated using a combination of a mineralocorticoid and furosemide (247).

Differentiating Proximal and Distal RTA

Once it has been determined that the patient has RTA, it is necessary to determine if it is a proximal or distal defect. Usually this can be determined by the associated findings in the patient. As outlined above, most patients with proximal RTA have the Fanconi syndrome. Thus, it is

very helpful to evaluate the urine for glucosuria and phosphaturia. If these are normal but the patient is suspected of having a proximal tubule defect, it might be necessary to perform a bicarbonate titration to find the threshold for bicarbonate excretion (228). The serum potassium concentration will also help determine if the patient has a type IV RTA.

Another useful determination is a renal sonogram or X-ray to determine if the patient has nephrocalcinosis (see *Fig. 39-7*). Patients with distal RTA have hypocitraturia and therefore are much more likely to have nephrocalcinosis and form renal stones. Patients with proximal RTA are in relative acid base balance so that they have normal amounts of citrate in their urine and they do not excrete large amounts of calcium.

Treatment

The treatment of RTA will of course be determined by the type and cause of RTA. Fanconi syndrome due to cystinosis should be treated with cysteamine (241, 248, 249). This will prevent further damage to the renal tubular cells by preventing the accumulation of cystine. However, these patients continue to have Fanconi syndrome and require large amounts of alkali therapy as well as phosphate and vitamin D.

The sporadic forms of proximal RTA are also difficult to correct completely, but mild improvements in their acid base status allows them to grow normally (67). These patients tend to improve with age and will need less alkali as the grow.

The treatment of distal RTA is somewhat more straight forward. The amount of alkali needed to correct the acidosis and maintain normal acid base balance is much less than that needed in patients with proximal RTA. The dosage of alkali necessary has been recently studied. Using potassium citrate, investigators have found that 3–4 mEq/kg/day was necessary to normalize the urinary citrate excretion (250, 251). A previous study had also indicated that the dosage of alkali needed to be higher in younger children and decreased to about 3 mEq/kg/day after the age of 6 years (69).

The importance of continued therapy in these children has been a recent concern (252). It appears that subclinical acidosis could have long term effects on the bone, resulting in osteoporosis. The loss of calcium from the bones would also lead to nephrocalcinosis and renal stone formation.

40 Nephrogenic Diabetes Insipidus

Nine V. A. M. Knoers · Elena N. Levtchenko

History

First familial cases with diabetes insipidus were described by McIlraith in 1892, however, he did not distinguish between renal and neurohormonal forms of the disorder (1). The renal type of diabetes insipidus was appreciated as a separate entity more than 50 years ago, when it was described independently by two investigators: Forssman (2) in Sweden and Waring et al. (3) in the United States. In 1947, Williams and Henry (4) noticed that injection of antidiuretic hormone (ADH) in doses sufficient to induce systemic side effects could not correct the renal concentrating defect. They coined the term *nephrogenic diabetes insipidus*. Subsequent studies revealed active hormone in the serum and urine of affected persons and lent further support to the theory of renal unresponsiveness to vasopressin. Nephrogenic diabetes insipidus is synonymous with the terms *vasopressin-* or *ADH-resistant diabetes insipidus* and *diabetes insipidus renalis*.

Definition and Clinical Manifestations

Congenital nephrogenic diabetes insipidus (NDI) is a rare inherited disorder, characterized by insensitivity of the distal nephron to the antidiuretic effects of the neurohypophyseal hormone arginine vasopressin (AVP). As a consequence, the kidney loses its ability to concentrate urine, which may lead to severe dehydration and electrolyte imbalance (hypernatremia and hyperchloremia). Patients with NDI have normal birth weight and pregnancies are not complicated by polyhydramnios. Urine concentrating defect in NDI is present from birth, and manifestations of the disorder generally emerge within the first weeks of life. With breast milk feedings, infants usually thrive and do not develop signs of dehydration. This is because human milk has a low salt and protein content, and therefore a low renal osmolar load. With cows' milk formula feedings, the osmolar load to the kidney increases, resulting in an increased demand for free water. This is not provided by oral feeding and, therefore hypernatremic dehydration appears. Irritability, poor feeding, and poor weight gain are usually the initial symptoms (5). Patients are eager to suck but may vomit during or shortly after the feeding. Dehydration is evidenced by dryness of the skin, loss of normal skin turgor, recessed eyeballs, increased periorbital folding, depression of the anterior fontanelle, and a scaphoid abdomen. Intermittent high fever is a common complication of the dehydrated state, particularly in very young children. Body temperature can be normalized by rehydration. Seizures can occur but are rare and most often seen during therapy, particularly if rehydration proceeds too rapidly. Constipation is a common symptom in children with NDI. Nocturia and nocturnal enuresis are common complaints later in childhood.

Untreated, most patients fail to grow normally. In a retrospective study of 30 male NDI patients, most children grew below the 50th percentile, most of them having standard deviation (SD) scores lower than −1 (6). Some well-treated patients, however, may achieve normal adult height. Catch-up growth occurs at least in some patients after normalization of water and electrolyte balance, especially in those with adherence to treatment. Bone age is generally not delayed (7). Weight for height SD scores are initially low, followed by global normalization at school age (6). Initial feeding problems and the ingestion of large amounts of low-caloric fluid resulting in a decreased appetite may play roles in failure to thrive seen in NDI (8, 9). Furthermore, it is possible that repeated episodes of dehydration have some as yet undetermined negative effects on growth.

Mental retardation has long been considered an important complication of untreated NDI and assumed to be a sequel of recurrent episodes of severe brain dehydration and cerebral edema caused by overzealous attempts at rehydration (10–12). Additional evidence underscoring the assumption that NDI has adverse effects on the cerebrum is provided by several reports describing intracranial calcifications in NDI patients (13, 14). Such lesions are generally considered to be the result of hemorrhage or necrosis. Most of the reported patients with cerebral calcifications were mentally retarded. Nowadays mental retardation is rare due to earlier recognition and treatment of NDI. Exact estimates of the current frequency of mental retardation under modern treatment are unknown,

but in the largest psychometric study ever reported only 2 of the 17 male NDI patients (aged 3–30 years) tested had a total intelligence quotient more than 2 SD below the norm. Fourteen patients had an intelligence score within or above the normal range and one patient had a general index score between −1 and −2 SD. (15)

The psychological development of NDI patients is influenced by a persistent desire for drinking and the need for frequent voiding, which compete with playing and learning. Therefore many NDI patients are characterized by hyperactivity, distractibility, short attention span, and restlessness. In the psychometric study mentioned earlier, the criteria for attention deficit hyperactivity disorder were met in 8 of 17 tested NDI patients (15).

Persistent polyuria can result in the development of megacystis, trabeculated bladder wall, hydroureter, and hydronephrosis (6, 16, 17). Large capacity hypotonic bladder dysfunction might require clean intermittent catheterization (17). Patients should be trained to void regularly in order to assure that maximal urinary bladder capacity remains within normal range. Both patient's groups with AVPR2 and AQP2 mutations can develop urinary tract dilatation and bladder dysfunction (16, 18).

Diagnostic Procedures

The observation of polyuria in a dehydrated infant, together with the finding of a high serum sodium concentration, provides presumptive evidence for a renal concentrating defect. To confirm the concentrating defect and to distinguish the renal form of diabetes insipidus from the central form, a vasopressin test is performed with 1-desamino-8-D-arginine vasopressin (DDAVP), a synthetic analogue of the natural arginine vasopressin that produces a high and prolonged antidiuretic effect. In the test, DDAVP (10 µg for infants, 20 μg for children) is administered intranasally. Urine is collected during the subsequent 5.5 h. The first collected portion of the urine should be discarded. The maximal urine osmolality in any collected aliquot is chosen as a measure of the concentrating capacity (19). After DDAVP administration, NDI patients are unable to increase urinary osmolality, which remains below 200 mOsm/kg H_2O (normal $\geq$807 mOsm/kg H_2O) and cannot reduce urine volume or free-water clearance.

Plasma vasopressin levels are normal or only slightly increased in affected children. Other laboratory findings have been described, which mainly result from chronic dehydration. Serum sodium concentration is generally elevated and may be above 170 mmol/L. There is also an increase in serum chloride concentration and retention of urea and creatinine. All values are normalized by adequate rehydration. In addition, reduced glomerular filtration rate (GFR) and renal blood flow return to normal when a normal hydration state has been achieved.

The primary congenital form of NDI has to be differentiated from central diabetes insipidus (due to lack of AVP) and from the secondary or acquired forms, which are much more common. In our experience, the urinary osmolality obtained after DDAVP administration in secondary disorders is always higher than in NDI. Several secondary causes, some of which will be discussed later, are listed in *Table 40-1*.

Cellular Physiology of Arginine Vasopressin's Antidiuretic Action in the Distal Nephron

The physiologic action of vasopressin on the renal collecting duct has been one of the most intensively studied processes in the kidney. Arginine vasopressin (AVP, ADH) is synthesized on the ribosomes of the magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus as a large biologically-inactive bound form. Within storage granules, the hormone is cleaved into the biologically active form and transported down the neuronal axons to the posterior pituitary and stored there. Following appropriate stimuli, AVP is secreted from the posterior pituitary into the circulation as biologically active hormone. AVP release is primarily regulated by changes in

plasma osmolality (by >2%), but can also occur in response to nonosmotic stimuli. These nonosmotic stimuli are generally related to changes in either total blood volume or the distribution of extracellular fluid. In addition, physical pain, emotional stress, and certain drugs (e.g., nicotine) influence the release of AVP. In its effector organ, the kidney, AVP binds to vasopressin type-2 (V_2) receptors on the basolateral membrane of the principal inner medullary collecting duct cells and of the arcade cells (*Fig. 40-1*). The arcades are long, highly branched renal tubule segments that connect distal convoluted tubules of several deep and midcortical nephrons to the origin of cortical collecting ducts. V_2 receptor occupancy results, via the intermediacy of a stimulatory G-protein (G_s), in activation of adenylate cyclase and an increase in intracellular cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). The elevated cAMP levels stimulate protein kinase A (PKA), which in turn initiates a redistribution of aquaporin-2 (AQP2) water channels from intracellular vesicles to the apical plasma membrane, rendering this membrane water permeable.

The increase in apical membrane permeability allows water to flow from the tubule lumen to the hypertonic medullary interstitium, via AQP2 in the apical membrane and via AQP3 and AQP4, constitutive water channels in the basolateral membrane (*Fig. 40-1*). This then leads to the formation of concentrated urine. Upon fluid intake, AVP release into the blood decreases, AQP2 is redistributed into intracellular vesicles, and water reabsorption is reduced. Katsura et al. have shown that the AVP-regulated recycling of AQP2 can occur at least six times with the same molecules (20).

In recent years, our knowledge of the AQP2 dynamics in the cell has increased significantly. We will describe the

most important regulators here. For further details the reader is referred to several excellent reviews on this subject (21–23).

Phosphorylation of a PKA-consensus site in AQP2, the serine at position 256 in the cytoplasmic carboxy terminus, is absolutely essential for AQP2 delivery to the apical membrane (24, 25). In addition, it has been shown that anchoring of PKA to PKA-anchoring proteins (AKAPs) which ensures targeting of PKA to AQP2- bearing vesicles, is another prerequisite for AVP-mediated AQP2 translocation. (26). AQP2 is expressed at the apical membrane as a homotetramer and studies using oocytes as a model system indicated that for plasma membrane localization 3 out of 4 monomers in an AQP2 tetramer need to be phosphorylated. (27).

PKA is the main kinase for AQP2 phosphorylation, but other kinases may potentially participate in the regulation of AQP2 trafficking. Besides PKA sites, putative phosphorylation sites for PKG, PKC, and casein kinase II are also present in the AQP2 sequence.

There is evidence that a cGMP-dependent pathway can induce AQP2 apical accumulation. Thus, Bouley et al. have shown that nitric oxide and atrial natriuretic factor stimulate the insertion of AQP2 in renal epithelial cells via a c-GMP dependent pathway (28).

Intracellular calcium mobilization also has an important role in vasopressin-mediated AQP-2 trafficking. Vasopressin binding to the V_2 receptor was demonstrated to trigger a rapid increase of intracellular calcium, which in turn stimulates apical exocytosis of AQP2 and increase of osmotic water permeability across the collecting duct (29). A recent study indicated that Epac (Exchange Protein directly Activated by cAMP) rather than PKA is the signaling cascade that transmits the vasopressin signal to calcium mobilization (30).

Reorganization of the actin cytoskeleton is an another important mechanism in the translocation of AQP2-containing vesicles to the apical membrane. The actin cytoskeleton most likely provides a network that anchors the AQP2-bearing vesicles in the unstimulated cell. Vasopressin has been shown to depolymerize apical F-actin in rat inner medullary collecting duct, resulting in the fusion of AQP2-carrying vesicles with the apical membrane (31), indicating that reorganization of the apical actin network may be critical in promoting the trafficking of AQP2-bearing vesicles. Both forskolin and okadaic acid stimulate AQP2 translocation by inducing a reorganization of the apical actin network (32). Furthermore, RhoA inhibition through PKA-mediated phosphorylation of RhoA is shown to be a key event for actin dynamics inducing AQP2 translocation (33).

The molecular machinery for the docking and fusion of AQP2-containing vesicles with the apical membrane is similar to the process of synaptic vesicle fusion with the presynaptic membrane and involves vesicle (v) SNAREs (soluble NSF attachment protein receptors) and target membrane (t) SNAREs. Thus, in subcellular fractions from rat kidney, enriched for AQP2-containing vesicles, the v-SNARE synaptobrevin (VAMP-2) was found, as well as the fusion mediating protein SNAP23 (34–37). A proteomic analysis of AQP2-bearing vesicles also indicated the presence of a series of SNAREs, confirming their importance in AQP2 trafficking (38).

During the endocytotic process, AQP2 accumulates in clathrin-coated pits and is internalized via a clathrin-mediated process (39–41). Thus, AQP2 on the apical membrane is dependent on the balance between exocytosis and endocytosis, and inhibition of endocytosis is another way to increase the water permeability of collecting ducts. Prostaglandin E_2 stimulated removal of AQP2 from the surface of the cells when added after vasopressin treatment, but did not alter the phosphorylated state of AQP2 in MDCK cells, indicating that dephosphorylation of AQP2 may not be necessary for its subsequent internalization (42).

AQP2 on the plasma membrane is retrieved to early endosomes through phosphatiylinositol 3-kinase-dependent mechanism, and then is transferred to Rab11-positive storage vesicles (43). AQP2 in the storage vesicles reappears on the apical membrane upon vasopressin stimulation and the importance of Rab11 in such an AQP2-specific recycling was confirmed by a knockdown study using siRNA (44).

Evidence is emerging for ubiquitination as a signal for endocytosis and subsequent transport to multivesicular bodies (MVB) or proteasomes (45). AVP removal induces a short-chain ubiquitination of AQP2 at amino-acid 270 (Lysine = K), and the K270R (R = arginine) mutant was endocytosed with a much slower rate (46).

Long-term adaptation to circulating AVP- levels, for instance in a dehydrated state, is accomplished by increasing the expression of AQP2 mRNA and protein. Transcriptional regulation of the AQP2 gene seems to be the main action of AVP and is mediated by phosphorylation of a cAMP-response element-binding protein (CREB) and binding of the phosphorylated cAMP-response-element-binding protein to the cAMP-response element in the promoter region of the AQP2 gene (47).

Genetics

Three different inheritance patterns of NDI have been recognized. In most cases (about 90%) NDI is transmitted

as an X-linked recessive trait (MIM304800). In these families, female carriers who are usually unaffected transmit the disease to sons, who display the complete clinical picture (2, 4, 48). In 1988, the major NDI locus was mapped to the distal region of the long arm of the X-chromosome (Xq28) (49), and in 1992 mutations in the V_2 receptor gene were shown to underlie X-linked NDI (50–52). In a minority of families (about 10%), the transmission and phenotypic characteristics of NDI are not compatible with an X-linked trait. In these families, females display the complete clinical picture of NDI and are clinically undistinguishable from affected male family members (53–55). In addition, linkage analysis in these families has excluded linkage between NDI and polymorphic DNA markers from the Xq28 region. Family pedigrees suggested the existence of both an autosomal recessive (MIM 222,000) and an autosomal dominant form (MIM 125,800) of NDI. It was subsequently demonstrated that both autosomal forms of NDI are caused by mutations in the AVP-sensitive aquaporin-2 water channel (56, 57). The prevalence of NDI is not exactly known, but the disease is assumed to be rare. The most recent estimate of the prevalence of NDI in Quebec, Canada is 8.8:1,000,000 males (58). In the Dutch population of about 16 million, 40 different families are known.

X-Linked Nephrogenic Diabetes Insipidus: Mutations in the Vasopressin V_2 Receptor Gene

The vasopressin type-2 receptor had long been considered a prime candidate for the defective step in the AVP-mediated response in X-linked NDI. The reason for this belief was the observation that in patients with X-linked NDI, not only the antidiuretic but also the vasodilatory coagulation and fibrinolytic responses to the V_2 receptor-specific agonist DDAVP were lacking (59). This finding suggested a general V_2 receptor defect in these patients. Independent support for the V_2 receptor being involved in X-linked NDI was provided by the finding that a gene conferring V_2-like binding activity colocalized with the NDI locus in the subterminal region of the X-chromosome long arm (Xq28) (60). Soon after the identification of the human V_2 receptor gene and complementary DNA (cDNA) in 1992 (41), the role of the V_2 receptor in the pathogenesis of NDI was finally proven by the demonstration of mutations in the encoding gene in affected individuals (50–52; reviews in 12, 62, 63). The V_2 receptor gene (AVPR2; Genbank association number L22206) is relatively small and consists of three exons separated by two short intervening sequences (introns). The mRNA has been found exclusively in the kidney, specifically in the cortical and medullary collecting ducts. The cDNA encodes a receptor protein of 371 amino acids, has a predicted molecular mass of approximately 41 kDa and shares the general structure of a G protein-coupled receptor consisting of seven hydrophobic transmembrane helices, connected by extracellular and intracellular loops. The receptor contains one unique consensus sequence site for N-linked glycosylation in the extracellular aminoterminus (64) and phosphorylation sites for G-protein-coupled receptor kinases (GRK) represented by a serine cluster in the carboxy-terminus (65, 66). The amino-terminal part of the protein including the first transmembrane domain and the positively-charged first intracellular loop are important for proper insertion and orientation in the membrane (67). A conserved glutamate-dileucine motif in the intracellular carboxy-terminal part of the receptor is essential for receptor transport from the endoplasmic reticulum (ER) to the Golgi-apparatus (68). Two conserved adjacent cysteines in the C-terminus are palmitoylated, thereby anchoring the carboxy-tail to the plasma membrane and controlling the tertiary structure of this region of the receptor (69).

To date, more than 190 distinct putative disease-causing mutations in the V_2 receptor gene have been detected in families with X-linked NDI (see: http://www.medcor.mcgill.ca/nephros). The mutations are not clustered in one domain of the V_2 receptor but are scattered throughout the protein, except for the part coding for the N- and C-terminal tails of the receptor. Approximately 50% of the mutations are missense mutations. Nucleotide deletions and insertions causing frame-shifts (27%), nonsense mutations (12%), large deletions (5%), in-frame deletions or insertions (4%), and splice site mutations (2%) account for the remainder of mutations (12, 62). Several mutations are recurrent as evidenced by the fact that these mutations were found on different haplotypes in ancestrally independent families. The most frequent of these recurrent mutations (D85N, V88M, R113W, R137H, S167L, R181C, and R202C) occur at potential mutational hotspots.

The molecular mechanism underlying the renal insensitivity for AVP differs between mutants. As upcoming pharmacological treatments for NDI likely depend on the underlying mechanism, GPCR mutations in general and V_2R mutations in particular have been divided in five different classes according to their cellular fate (70, 71).

Class I comprises all mutations that lead to improperly processed or unstable mRNA, like promoter alterations, exon skipping or aberrant splicing. This class also holds

frame shift and non-sense mutations, which result in truncated proteins like V_2R-Q119X, -W293X and -R337X and -C358X.

Class II mutations are missense or insertions/deletions of 1 or more nucleotide triplets, resulting in fully translated proteins. Due to the mutation, however, mutant receptors are misfolded and retained in the endoplasmic reticulum (ER), as the ER is the organelle that has the cellular quality control over proper folding and maturation of synthesized proteins. Misfolded proteins are subsequently mostly targeted for proteasomal degradation (72). Intracellular entrapment of missense V_2R mutants and their rapid degradation likely represents the most important cause of NDI, as more than 50% of the mutations in V2R are missense mutations and cellular expression revealed that most of these result in ER-retained proteins. The extent of ER retention, however, may differ between mutants, and may represent differences in their folding state. Hermosilla et al. recently reported that of eight V_2R mutants that are retained, only three were strictly kept in the ER, whereas the five other mutants were transported to the ER-Golgi intermediate compartment, followed by retrograde transport to the ER (73).

Class III comprises similar mutations as of class II, but the resulting mutants are not considered misfolded by the ER and can continue their itinerary to the plasma membrane. However, these mutations disturb binding of the stimulatory Gs protein, leading to a reduced activation of adenylate cyclase and thus formation of cAMP.

Class IV mutations also result in full-length receptors expressed at the cell surface, but here the mutation interferes with, or reduces, AVP binding. These mutations especially involve residues thought to be in or close to the AVP binding pocket, of which V_2R-ΔR202 is a clear example (74).

Finally, class V mutations allow normal protein synthesis and maturation, but they cause misrouting to different organelles in the cell. The NDI R137H mutation, located in the well conserved DRY/H motif of GPCRs, is a member of this class, as V_2R-R137H is constitutively internalized from the plasma membrane, and therefore only briefly available to bind AVP (75, 76).

Sometimes, mutants do not exert a full phenotype of a particular class and then often also show features of another class. For example, some V_2R missense mutants are partially ER-retained (class II), but are also partially expressed in the plasma membrane, where they might show a reduced G protein coupling (class III) or AVP binding (class IV). As such, it provides an explanation for the observed small anti-diuretic response to high doses of dDAVP in NDI patients harbouring such mutations (77).

Genotype-Phenotype Correlations in X-Linked NDI?

Almost all mutations in the V_2 receptor gene result in a uniform clinical NDI phenotype with polyuric manifestations in the first weeks of life and poor growth. There are, however, a few exceptions to this rule. Several mutations (D85N, G201D, P322S, S329R) are associated with a milder form of NDI, characterized by a later manifestation, not at birth but later in childhood, and without growth retardation (74, 78). Functional studies of some of these mutations by in vitro expression systems have confirmed the partial phenotype of the NDI. P322S is the most remarkable of these three mutations, since another mutation substituting proline 322, namely P322H, is associated with a severe phenotype. By in vitro expression of both P322H and P322S in COS-7 cells, Ala et al. (74), have shown that the P322H mutant had totally lost the ability to stimulate the Gs/adenylate-cyclase system whereas the P322S mutant was able to stimulate adenylate-cyclase, albeit less than the wild-type receptor. Thus, the in vitro experiments closely correspond to the clinical phenotype. On the basis of three-dimensional modeling of the P322H and P322S mutant receptors, a plausible hypothesis to explain the molecular basis for the mild phenotype of the P322S has been proposed. Based on this modeling it is suggested that complete loss of function of the P322H receptor could be due, in part, to hydrogen bond formation between the His322 side chain and the carboxyl group of Asp85, which does not occur in the P322S receptor (74).

Recently, a family was reported in which the R137H mutation was associated with severe NDI in the proband but with very mild NDI in his affected brother (79). Genetic and/or environmental modifying factors are likely to account for this intrafamilial phenotype variability.

The Autosomal-Recessive and Autosomal Dominant Forms of Nephrogenic Diabetes Insipidus: Mutations in the Aquaporin-2 Water Channel

Both the autosomal recessive and the autosomal dominant types of NDI are caused by mutations in the AQP2 water channel gene (Genbank accession number z29491). The human AQP2 gene is a small gene consisting of 4 exons, comprising 5 kb genomic DNA. The 1.5 kb mRNA encodes a protein of 271 amino-acids which has a predicted molecular weight of 29 kDa (80). AQP2

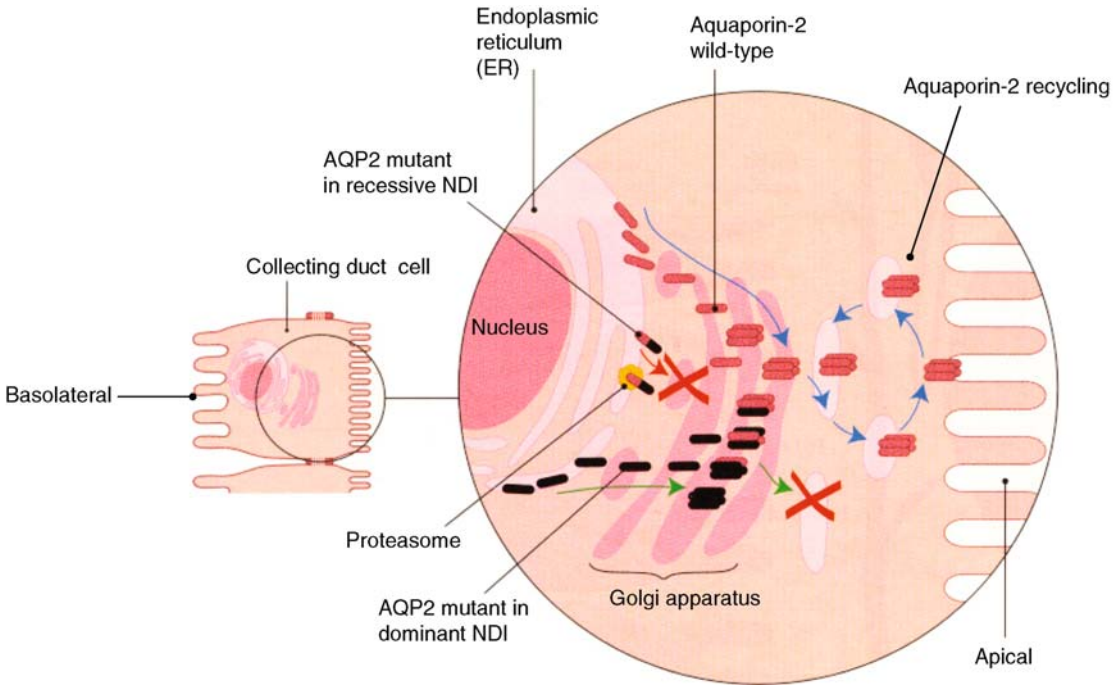
belongs to a family of membrane integral proteins, aquaporins, which function as selective water transporters throughout the plant and animal kingdom. In mammals, 13 different aquaporins have been identified to date, eight of which (aquaporins 1–4, 6–8, and 11) are highly expressed in the kidney. Like other aquaporins, AQP2 is assembled in the membrane as a homotetramer in which each 29 kDa monomer, consisting of six membrane spanning α-helical domains and intracellular N- and C-termini, is a functional water channel. The six transmembrane domains are connected by five loops (A through E). In the hourglass hypothesis, loops B and E are assumed to fold back into the membrane and to interact via their highly conserved motifs asparagine-proline-alanine (NPA boxes) to form the water pore (81). Structural characterization of AQP2 crystals by atomic force and electron crystallography revealed that this was indeed the case (82). AQP2 is exclusively localized in the apical membrane and a subapical compartment of collecting duct cells. It is upregulated by dehydration or AVP, indicating that it is the AVP-regulated water channel.

To date, 40 putative disease-causing mutations in AQP2 have been identified in families with autosomal recessive NDI (reviews in 62, 63, and 83–86). Most are missense mutations, but in addition some nonsense mutations, small deletions, and splice-site mutations have been detected. About one-half of these mutations are found in the B and E loops of the protein where it is likely that they will destroy the pore function of the protein. Expression studies in *Xenopus leavis* oocytes have revealed that all but one AQP2 missense mutations that cause recessive NDI are class II mutations. Thus, these mutations lead to misfolding of the mutant protein and retention in the endoplasmic reticulum (ER) (84, 87, 88; *Fig. 40-2*). At high expression levels in oocytes and Chinese hamster (CHO) cells, six of these AQP2 mutants (A147T, T126M, G64R, L22V, A47V and T125M) confer water permeability (84, 87, 89, 90). This indicates that at high expression levels these AQP2 mutant proteins escape from the ER and are routed to the plasma membrane, where they are functional. Recently one AQP2 missense mutation, P262L, located in the AQP2 C-terminal tail, a region until then believed to result in dominant NDI, surprisingly was found to be involved in recessive NDI (91). In cell biological experiments it was shown that the P262L mutant is a functional water channel that forms hetero-oligomers with wt-AQP2s. These wtAQP2/AQP2-P262L are located in the apical membrane, indicating that the apical sorting of wild type AQP2 is dominant over the mis-sorting signal of AQP2-P262L. This is different from dominant NDI, because in this form mutants retain wtAQP2 in intracellular locations (see below). The recessive inheritance in the two patients encountered (patients were heterozygous for a R187C or A190T mutation on one allele, combined with a P262L mutation on the other allele) can be explained as follows: AQP2-R187C and AQP2-A190T are retained in the ER and do not interact with AQP2-P262L. AQP2-P262L folds properly and assembles in homotetramers, but will be retained mainly in intracellular vesicles. The consequent lack of sufficient AQP2 proteins in the apical membrane of the patients'collecting duct cells explains their NDI phenotype. In the parents coding for wt-AQP2 and AQP2-R187C or AQP2-A190T, wt AQP2 will not interact with either mutant but will form homotetrameric complexes, of which the insertion into the apical membrane will be regulated properly by vasopressin and will give a healthy phenotype. In the parents coding for wt-AQP2 and AQP2-P262L both proteins likely assemble into heterotetramers. The dominancy of wt-AQP2 sorting on the localization of AQP2-P262L will result in proper AVP-regulated trafficking of the heterotetremic complexes to the apical membrane and will also give a healthy phenotype (91).

At present eight families have been described with autosomal dominant NDI, initially uncovered due to father -to -son transmission of the disease. In these families subsequent sequencing of the AQP2 gene revealed putative disease-causing mutations of one AQP2 allele. The identified mutations in AQP2 comprise deletions, insertions and missense mutations (review in 83). All mutations causing dominant NDI are located in coding region of the C-terminal tail of AQP2, which is not part of the pore-forming segment, but, as shown by the role of phosphorylation of S256 in AQP2, has an important role in AQP2 trafficking. Indeed, all mutants AQP2 proteins found in dominant NDI appeared to be folded functional water channels that were sorted to other subcellular locations in the cell than wt-AQP2. Because none of these mutants was misfolded, they were, in contrast to AQP2 mutants in recessive NDI, able to interact and form heterotetramers with wt-AQP2. Due to this wt-mutant interaction and the dominancy of the mis-sorting signals in the mutant protein, the wt-mutant complexes are also mis-sorted. For instance, expression studies in polarized cell lines have revealed that the dominant AQP2- E258K mutant is routed to the Golgi-complex or late endosomes/lysosomes (57; *Fig. 40-2*). In co-expression studies with wild-type AQP2, a dominant-negative effect was observed, caused by impaired routing of wild-type AQP2 to the plasma membrane after hetero-oligomerization with the E258K mutant. (92). Mistargeting to the basolateral membrane has been reported for the AQP2-721delG, AQP2-763-772del, AQP2-812-818del, and AQP2-779-780insA

Figure 40-2

Schematic representation of the postulated mechanisms in a collecting duct cell to explain recessive and dominant forms of NDI causes by AQP2 mutations. Normal AQP2 proteins are transported from the endoplasmic reticulum (ER) via the Golgi apparatus to the luminal side of the cell. In case of a recessive NDI mutation AQP2 is retained in the ER due to misfolding and subsequently broken down by proteasomes. In case of a dominant NDI mutation there is a change in the transport signal of the AQP2 protein and consequent misrouting to i.e., the Golgi network or late endosomes/lysosomes (adapted from 134).



mutants (93, 94). The AQP2-727delG mutant was shown to interfere with the routing of wild-type AQP2 to the apical membrane by its mistargeting to the basolateral membrane en late endosomes/lysosomes (94).

Differential Diagnosis Between the X-Linked and the Autosomal Forms of NDI

With a few exceptions, no differences in clinical symptoms between X-linked and autosomal-recessive forms of NDI can be observed, nor in the time of onset of the disease. Only in a minority of patients with the X-linked form of NDI, namely those individuals carrying V_2R mutations with partial insensititvity to AVP, the disease onset is not directly after birth but later in childhood. In general the initial symptoms in most autosomal-dominant cases also appear later in childhood.

Male patients with X-linked NDI can de discriminated from patients with autosomal recessive NDI on the basis of their extrarenal reaction to administration of the synthetic V_2 -vasopressin analogue 1-desamino-8-D-arginine vasopressin (DDAVP). Patients with autosomal-recessive NDI show a decrease in blood pressure, accelerated heart rate and an increases in von Willebrand factor, factor VIII, and tissue-type plasminogen activator levels, whereas in all studies patients with X-linked NDI these extra-renal responses are absent as a result of an extrarenal mutant V_2R (95). In female patients, the interpretation of this intravenous DDAVP test is more complicated. Although absence of the extrarenal responses to intravenous administration of DDAVP in females clearly points to the presence of a V_2R defect, a normal response cannot be interpreted as indicative of a defect beyond the V_2R, and thus an AQP2 defect. For instance, a symptomatic female patient described by Moses et al., who was shown to be hetereozygous for a V_2R mutation, showed a twofold increase in factor VIII activity after administration of DDAVP. (96). The discrepancy between the renal and extrarenal response to DDAVP in these female V_2R

mutation carriers might be explained by variability in the pattern of X-inactivation between different tissues.

Nephrogenic Diabetes Insipidus in Females

Several families have been described in which females show classical clinical and laboratory features of NDI. After the identification of AQP2 mutations as a cause for autosomal-recessive NDI, and in some cases for autosomal-dominant NDI, a satisfying explanation for the complete manifestation of the disease in some females had been found. However, several families have been reported in which symptomatic females do not have an AQP2 defect, but are heterozygous for a V_2 receptor defect (97–99). In some of these women maximal urinary osmolality after DDAVP administration does not exceed 200 mOsmol/L. Of interest, in some of the reported families, asymptomatic female family members shared the same V_2 receptor mutation with the manifesting females (97, 100). The most likely explanation for the existence of different phenotypes in carriers of a V_2 receptor mutation, varying from no symptoms to complete manifestation of the disorder, is skewed X-inactivation. This hypothesis was underlined by studies investigating the X-inactivation patterns in peripheral blood leukocytes of female carriers via the detection of a methylated trinucleotide repeat in the human androgen receptor gene (101). In asymptomatic females random X-inactivation was found, while in most female carriers who showed clinical NDI symptoms, skewed X-inactivation patterns occurring preferentially to normal X alleles were recognized. In a few females with overt clinical NDI, however, random X-inactivation was identified.

In conclusion, clinical NDI phenotypes may correlate with the X-inactivation patterns in females with heterozygote V_2R mutations. In some female carriers, however, the clinical phenotype cannot be predicted by evaluation of X-inactivation patterns in peripheral blood cells, probably due to the fact that X-inactivation ratios within an individual may vary between different tissues.

Acquired Nephrogenic Diabetes Insipidus

Although the hereditary forms of NDI are relatively rare, a wide range of pathologic conditions and drug treatments can lead to acquired NDI (*Table 40-1*). In our experience, the urine osmolality obtained after dDAVP administration in these acquired disorders is always higher than in congenital NDI. All these disorders have been shown to coincide with decreased AQP2 expression in the collecting duct and in its apical membrane. (102–108). For instance, prolonged treatment with lithium, the drug of choice for treating bipolar disorders and prescribed to 1 in 1,000 of the population, leads to AQP2- downregulation and development of NDI. It has been shown that lithium-NDI is associated with decreased mRNA levels, likely through reduced AQP2 transcription, with attenuated apical targeting of AQP2 in rats (102, 109), and with decreased urine AQP2 excretion in humans (110). The onset of lithium-induced AQP2 downregulation and NDI development occurs independent from the activity of principal cell adenylyl cyclase activity (111). Since lithium enters the cells via epithelial sodium channel (ENaC), lithium-induced NDI can be modified by the administration of ENaC channel blocker amiloride. In rats treated with lithium it was demonstrated that amiloride restored urinary concentrating mechanisms via upregulation of AQP2, AQP3 and urea transporter UT-A1 expression and an increase of renal medullary osmolarity (112).

Treatment

Symptomatic treatment of NDI is aimed to achieve normovolemia by replacing urinary water losses and reducing urinary volume. Adequate supply of fluid to prevent dehydration is the most important component of the therapy. For reducing urine output a low-solute diet is applied to diminish the renal osmolar load and decrease obligatory water excretion (113). Initially, a diet low in sodium (1 mmol/kg per day) as well as protein (2 g/kg per day) was recommended. However, severe limitations of dietary protein may introduce serious nutritional deficiencies. Therefore, it is preferable to prescribe dietary restriction of sodium only.

Diuretics such as hydrochlorothiazide (2–4 mg/kg per 24 h) were the first class of drugs shown to be effective in lowering the urine volume in NDI (114). When combined with a reduction of salt intake, hydrochlorothiazide reduces urine volume by 20–50% of baseline values. However, thiazide-induced hypokalemia may cause further impairment or urine concentrating ability in patients with NDI. Another possible risk associated with hypokalemia is cardiac arrhythmia. Simultaneous administration of potassium salt is therefore advised in most cases. Very low daily sodium intake in combination with thiazide diuretics should be avoided to prevent the development of hyponatremia.

There is ample evidence that the combined administration of hydrochlorothiazide with either a prostaglandin-synthesis inhibitor such as indomethacin (2 mg/kg per 24 h), or the potassium-sparing diuretic amiloride, is much more effective in reducing urine volume than the thiazide-diuretic alone (115–119). Prolonged use of prostaglandin-synthesis inhibitors, however, is often complicated by gastrointestinal and hematopoietic side effects. Gastrointestinal complaints and complications include anorexia, nausea, vomiting, abdominal pain, ulceration, perforation, and hemorrhage. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely, aplastic anemia. In addition, renal dysfunction has been described during indomethacin therapy, most often consisting of a slight reduction in GFR.

In patients, who are not tolerating indomethacin, selective inhibitors of cyclooxygenase-2 (COX-2) might be helpful (120). Caution in using indomethacin and selective COX-2 inhibitors in NDI is warranted as their administration can potentially lead to the acute deterioration of renal function in dehydrated patients.

Amiloride counterbalances the potassium loss from prolonged use of thiazides and thus prevents hypokalemia. Since amiloride appears to have only minor long-term side effects, the combination of hydrochlorothiazide (2–4 mg/kg/24 h) with amiloride (0.3 mg/kg/24 h) is the first choice of treatment. Our personal experience of more than 17 years with the amiloride-hydrochlorothiazide combination, however, indicates that amiloride is less well tolerated in young children below the age of 4–6 years because of persistent nausea. Therefore we advise the temporary use of the combination of indomethacin-hydrochlorothiaizde in these young children.

For a long time the following mechanism for the antidiuretic effect of thiazides in NDI has been proposed: thiazides reduce sodium reabsorption in the distal tubule by inhibition of the NaCl co-transporter (NCC). This subsequently results in increased sodium excretion, extracellular volume contraction, decreased glomerular filtration rate, and increased proximal sodium and water reabsorption. Consequently, less water and sodium reach the collecting tubules and less water is excreted (121, 122). This hypothesis, however, has been challenged by Magaldi, who reported new insights into the possible mechanism of action, based on microperfusion studies in rat inner medullary collecting duct (IMCD) (123, 124). In these studies it was shown that in the absence of vasopressin, hydrochlorothiazide, when added to the luminal side, increased osmotic and diffusional water permeabilities, thus, decreasing water excretion. When prostaglandins were added, the effect of thiazides decreased. This finding may offer one explanation why indomethacin potentiates the effect of thiazides in NDI (124). Antidiuretic effect of thiazides is associated with an increase in AQP2 expression in collecting duct cells (125). Long-term side effects of chronic thiazide administration such as hyperuricemia, alterations in serum lipid spectrum and glucose intolerance should be monitored.

Based on the fact that the majority of V_2R mutations found in X-linked NDI and all AQP2 mutations found in autosomal recessive NDI are retained within the endoplasmic reticulum (*class II* mutations), a treatment aimed at restoring the plasma membrane routing of ER-retained, but otherwise functional V_2R or AQP2 mutants, becomes an interesting potential. Indeed, Morello et al. have shown in vitro that selective, nonpeptide cell-permeant V_2R-antagonists increased cell-surface expression and rescued the function of V_2R mutants by promoting their maturation and targeting to the plasma membrane (126). Thus, these V_2R antagonists function as pharmacological chaperones.

A recent study in MDCK cells showed that four nonpeptide V_2R antagonists induced receptor maturation and rescued the basolateral membrane expression of eight from nine V_2R mutants. At clinically relevant concentrations only high affinity antagonists (OPC31260 and OPC41061) induced functional rescue in vitro (127). Long-term efficiency and extra-renal side affects of these compounds in vivo should be further evaluated.

Another study demonstrated that V1a receptor antagonist SR49059, having moderate affinity for VR2, had beneficial effect on urine volume and osmolality in five patients with X-linked NDI harboring three different AVPR2 mutations (128). However, the clinical development of this drug was interrupted because of the possible interference with P450 metabolic pathway. Similarly to V_2R mutants, it has been shown that treatment of cells, expressing ER-retarded AQP2 mutants with chemical chaperones, such as glycerol, facilitated the translocation of these mutants to the plasma membrane (90). Another potential therapeutic strategy for treating autosomal NDI could be an activation of cGMP signaling pathway (129), or inhibition of AQP2 endocytosis (130). Both approaches would induce AVP independent apical AQP2 accumulation.

Although in vitro studies have suggested that in future gene-therapy for NDI may become technically feasible (131), there are questions as to whether gene-therapy would be the treatment of choice for this disorder, and even if so, it will certainly take a long time before the therapeutic potential of this form of therapy can be assessed. Therefore, developments of gene-transfer vectors

and gene-delivery techniques and analysis of gene-therapy safety need to be pursued and facilitated in order to determine the feasibility of gene-therapy in renal diseases, such as NDI. In this respect, the developed transgenic mice carrying a functionally inactive V_2R receptor protein (132) and the renal collecting duct-selective conditional AQP2 knock-out mice (133) are of important value.

41 Cystinosis

William A. Gahl

Introduction

Overview

Nephropathic cystinosis (1–3) deserves a special place in the annals of clinical medicine as the first treatable lysosomal storage disease. The pathophysiology itself, based upon the formation of cystine crystals within the lysosomes of cells, is remarkable. The presence of cystine crystals provides a clue to the basic defect in cystinosis, i.e., failure to transport of cystine out of lysosomes (4–6). This created a new area of biomedical investigation, explained the lysosome's function in salvaging small molecules for reutilization by the cell, and revealed a new category of lysosomal storage disorders due to transport defects rather than enzyme deficiencies. Even more striking, a rational therapy of cystine depletion (i.e., cysteamine) emerged (7–9), transforming nephropathic cystinosis from a universally fatal disease to a treatable chronic disorder with a decent quality of life. Today, physicians can even observe the gradual dissolution of cystine crystals by cysteamine eyedrops bathing the corneas of patients' eyes (10–12).

History

Cystinosis was first described by Abderhalden in 1903 (13), when understanding of its renal disease remained rudimentary. Fanconi, de Toni and Dubre recognized the renal tubular defect of cystinosis in the 1930s (3), and this complication retains the appellation Fanconi syndrome today. Generalized aminoaciduria was noted as a concomitant of nephropathic cystinosis in the late 1940s (14), and cystine storage within cellular lysosomes was proven in the late 1960s (15). By 1982, the basic defect of impaired lysosomal membrane transport of cystine was reported (4–6), and therapy with the cystine depleting aminothiol cysteamine was shown to be safe and effective by 1987 (8). Over the past two decades, numerous non-renal complications of cystinosis have been described, and oral cysteamine therapy has been shown to prevent virtually all of them (16, 17).

The Basic Defect

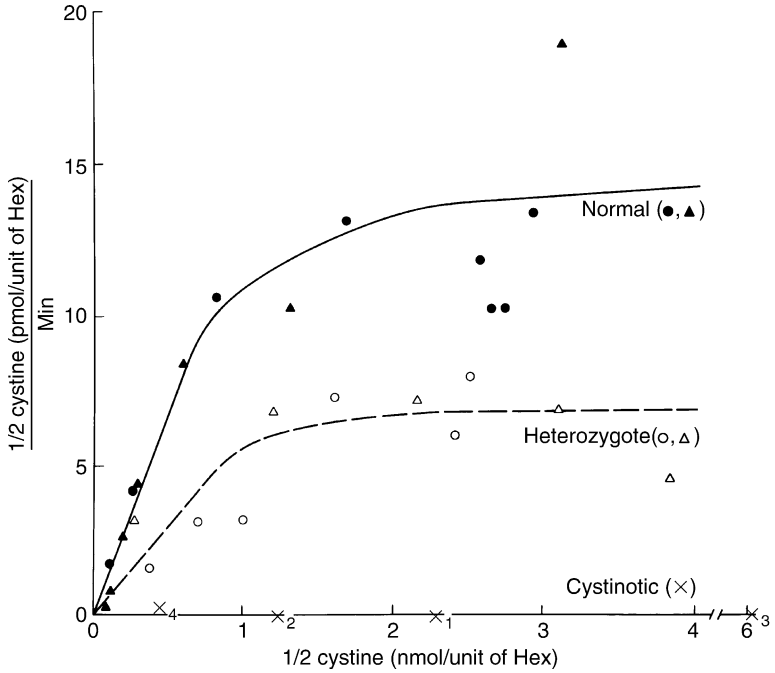
Cystine has a molecular weight of 240 daltons and consists of two molecules of cysteine ($HS\text{-}CH_2\text{-}CH(NH3^+)COO^-$) joined by a disulfide bond. The equilibrium between cystine and cysteine depends upon their redox potentials and the pH of the milieu; if a high enough concentration of cystine obtains, it may fall out of solution because of its poor solubility in aqueous, i.e., less than 2 mM (18). Cysteine, which is very soluble, is produced by the hydrolysis of proteins; this occurs within lysosomes by the action of acidic hydrolases. Cysteine is then oxidized to cystine within lysosomes, where it accumulates if the cell is cystinotic (15, 19). For decades, scientists investigated the cause of lysosomal cystine accumulation in cystinosis (3).

One possibility was a defective enzyme responsible for the reduction of cystine to cysteine, or for catalyzing disulfide interchange reactions between cystine and other free thiols. This hypothesis was examined, but no deficiency in a cystine-catabolizing enzyme was found (20). Another possibility was that, in cystinosis, cystine could not exit lysosomes because a transporting system present in normal lysosomal membranes was defective in cystinosis. Indeed, normal polymorphonuclear leucocytes were able to clear themselves (i.e., their lysosomes) of cystine, but cystinotic cells could not (21). Studies of isolated granular fractions, i.e., lysosomes, gave similar results (5). In fact, normal, cystine-loaded lysosomes could transport cystine in either direction across their membranes, while cystinotic lysosomes could neither take up nor release cystine (4, 22). Cystine transport in neutrophil lysosomes was subsequently shown to be ligand specific, stereospecific, and ATP-dependent (6, 22). It displayed classical saturation kinetics (*Fig. 41-1*) and counter-transport. Similar findings were observed in cultured lymphoblasts (6). In composite, these discoveries proved that the process of lysosomal cystine transport is carrier-mediated and deficient in cystinosis. Indeed, heterozygotes for cystinosis displayed half the maximum velocity of cystine transport (23), consistent with having half the normal number of cystine carriers (*Fig. 41-1*).

© Springer-Verlag Berlin Heidelberg 2009

Figure 41-1

Lysosomal cystine transport in leucocyte granular fractions. Normal lysosomes were loaded with cystine by exposure of whole leucocytes to cystine dimethylester, which is hydrolyzed to cystine within the acidic lysosome. Cystinotic lysosomes contain endogenously produced cystine. The abscissa gives the level of cystine loading per unit of hexosaminidase, i.e., per lysosome. The ordinate gives the rate of cystine egress in picomoles per minute per unit of hexosaminidase. Normal lysosomal cystine egress exhibits saturation kinetics, while cystinotic lysosomes show virtually no cystine egress. Heterozygotes for cystinosis, with half the number of lysosomal cystine transporters, display half the normal maximal velocity of cystine egress. Reprinted from (4).



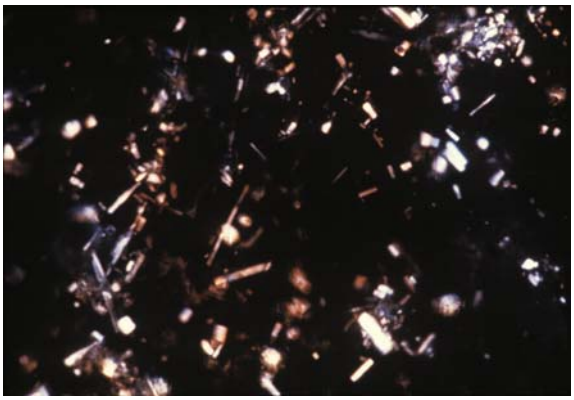
The later discovery of the cystinosis gene, *CTNS*, and studies of its gene product, cystinosin, demonstrated that this protein does indeed transport cystine, in a process driven by the hydrogen ion gradient across the lysosomal membrane (24, 25).

Pathology

Patients who have not received significant cystine-depleting therapy exhibit specific pathological features. As a consequence of excessive cellular cystine storage (to 10–1,000 times normal levels), patients with cystinosis develop microscopic crystals of cystine, apparent within lysosomes by electron microscopy (19). Subcellular fractionation using sucrose density gradients (15) verified the lysosomal location of cystine. Tissues containing cystine crystals include the cornea, conjunctiva, liver, spleen, kidneys, intestines, rectal mucosa, pancreas, testes, lymph nodes, bone marrow, macrophages, thyroid, muscle, and choroid plexus (3, 26). Crystals form in macrophages but not in cultured fibroblasts or lymphoblasts. The crystals are generally hexagonal or rectangular, and appear birefringent under polarizing light (*Fig. 41-2*). To preserve crystals during histological processing, tissues should be fixed in absolute alcohol rather than in aqueous solutions.

Tissue damage accompanies the intracellular cystine accumulation of cystinosis, with the greatest effects seen in the kidney. Renal tubules show a characteristic narrowing called a "swan-neck deformity" (27), followed by interstitial nephritis and endothelial glomerular proliferation, necrosis and hyalinization. Crystals are occasionally seen within glomeruli. In the eye, the retina exhibits patchy hypopigmentation (28); crystals appear occasionally in the iris and rarely in the retina (29). In older patients, the thyroid and testes appear fibrotic. Muscle histopathology involves a late vacuolar myopathy with

Figure 41-2
Birefringent cystine crystals in cystinosis tissue under light microscopy. Note rectangular and needle-like shapes. Some crystals are undergoing dissolution due to the aqueous fixative. (See color plate 24)



variation in fiber size, atrophy of type I fibers, and ring fibers (30, 31). In the liver, a nodular regeneration can occur in adults (32).

The pathogenesis of tissue damage in cystinosis is thought to involve cell death, followed by replacement with fibrous tissue. Crystal enlargement could disrupt lysosomal integrity, releasing hydrolytic enzymes that might destroy the cell. However, there has been no direct evidence for this. There are data supporting a more ordered loss of cells through the process of *apoptosis,* which is putatively triggered by cystine accumulation (33).

Genetics

Cystinosis is an autosomal recessive disorder, and heterozygotes are always clinically normal. The disease occurs with an incidence of approximately one in 100,000–200,000 live births, although there are genetic clusters of cystinosis, including one with a frequency of 1 in 26,000 in Brittany (34) and another among French Canadians. Within the United States population, one in 150–200 individuals carry a cystinosis (i.e., *CTNS*) mutation. This number provides the basis for appropriate genetic counseling for individuals, who are at risk for having a child with cystinosis because a family member has been diagnosed.

Approximately 500–600 cystinosis patients reside in the United States, and approximately half of them have undergone renal transplantation. It is estimated that 20–40 children with cystinosis are born annually in the United States. Our NIH patient cohort includes individuals from all over the world, including Mexico, Brazil, India, Iran, Egypt, Australia, and a variety of European countries. The pan-ethnic distribution of the disease, along with the scarcity of reports of cystinosis in underdeveloped countries, suggests that there are large numbers of undiagnosed patients with disease around the world. In general, cystinosis breeds true within families; siblings manifest very similar clinical phenotypes.

The *CTNS* Gene

The cystinosis gene was mapped to chromosome 17p13 in 1995 (35) and identified in 1998 (24). It contains 12 exons within 23 kb of genomic DNA, and codes for a 367-amino acid protein, cystinosin, with 7 transmembrane domains. The function of cystinosin as a cystine transporter has been confirmed (25). More than 60 different *CTNS* mutations have been reported, including deletions, insertions, and nonsense, missense and splice site mutations (1, 36, 37). The promoter (38), leader sequence, transmembrane regions, and non-transmembrane regions are affected by different mutations. The most common mutation is a 57,257 deletion removing the first 10 exons of *CTNS* (39, 40). This deletion arose in Germany ~500 A.D. and is present in the homozygous or heterozygous state in more than half of the cystinosis patients of European descent (36). Homozygosity for this deletion is associated with a slightly greater frequency of non-renal complications of cystinosis in adulthood (17). Otherwise, there is only a mild correlation of genotype and phenotype within nephropathic cystinosis patients. Two other founder mutations, W138X and G339R, have been reported among French Canadians (41) and Amish Mennonites of southwestern Ontario (42), respectively.

Cystinosis Variants

Traditionally, cystinosis has been divided into three subtypes (3). Infantile nephropathic cystinosis is the classic disease, described below and comprising 95% of cases. Affected individuals have two severe *CTNS* mutations. Patients with intermediate (formerly juvenile or adolescent) cystinosis have milder disease, with diagnosis in adolescence or early adulthood; they eventually develop renal failure. Intermediate patients number fewer than 20 reported cases, and carry one severe and one mild *CTNS* mutation (43). Patients with ocular (formerly adult or benign) cystinosis never exhibit renal failure or

retinal hypopigmentation, but have cystine crystals in their bone marrow and corneas (3). They do have measurable residual cystine-transporting capacity in their polymorphonuclear leucocytes' lysosomes (44). The only clinical manifestation of ocular cystinosis is photophobia, and patients are generally diagnosed incidentally on eye examination that includes the use of a slit lamp. There exist approximately 20 ocular cystinosis patients, who have either one mild and one severe or two mild *CTNS* mutations (45). Several ocular cystinosis patients from different families have at least one allele with a 928 G > A mutation in *CTNS*. The distinction among the three types of cystinosis is artificial, since a continuum of disease severity, rather than discrete categories, exists.

A $Ctns^{-/-}$ mouse accumulates cystine in its tissues, but does not manifest renal disease (46).

Early Clinical Manifestations

As for patients with other lysosomal storage disorders, individuals with cystinosis appear entirely normal at birth. Nevertheless, the disease eventually affects nearly every tissue of the body, with variable times of onset. The signs and symptoms can be described as early and late findings, demarcated roughly by adolescence. The earliest manifestations of cystinosis involve complications of renal Fanconi syndrome and growth retardation.

Renal Tubular Fanconi Syndrome

Cystinosis, the most common identifiable cause of renal Fanconi syndrome in childhood, is also one of the most treatable causes. It should be considered first when renal tubular solute wasting is recognized. In cystinosis, Fanconi syndrome is not present at birth but generally appears at 6–12 months of age, with variable severity. Undoubtedly, some infants die of the dehydration and electrolyte imbalance associated with the Fanconi syndrome, without the benefit of a diagnosis.

The Fanconi syndrome of cystinosis (Table 41-1) is primarily a proximal tubular defect. It includes failure to reabsorb water, bicarbonate (acidosis), electrolytes (hypokalemia and occasional hyponatremia), minerals (phosphaturia, hypocalcaemia, and hypomagnesaemia), amino acids, carnitine, glucose, and small molecular weight proteins (less than 50,000 daltons). Clinical manifestations include polyuria, dehydration (sometimes with consequent fevers) and polydipsia, ranging from 2 to 3 L/day in small children, up to 5–6 L/day in older children (47). Urine osmolality can be 200–300 mOsm/L. Large volumes of fluid intake fill the stomach and reduce appetite.

Table 41-1
Characteristics of renal tubular Fanconi syndrome in cystinosis

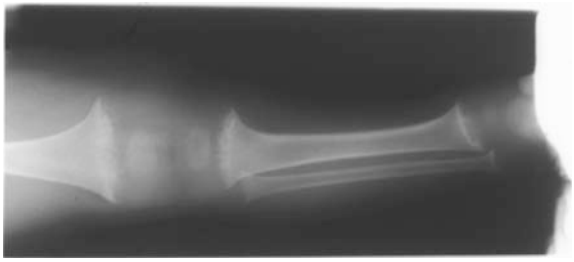
Polyuria
Polydipsia
Dehydration (fever)
Proteinuria
Glucosuria
Aminoaciduria
Acidosis
Hypokalemia
Hyponatremia (salt craving)
Hypophosphatemia
Hypocalcemia
Hypomagnesemia
Hypocarnitinemia
Increase serum alkaline phosphatase
Rickets
Tetany
Growth failure

Acidosis typically lowers the serum carbon dioxide level to below 20 mEq/L, and chronically untreated children can have levels below 5 mEq/L. Serum potassium concentrations below 2.0 mEq/L are not rare, and values below 3 mEq/L are common. Phosphate wasting causes hypophosphatemic rickets, with low serum phosphate and elevated heat-labile alkaline phosphatase levels (2,000–3,000 U/L in florid cases). Children may fail to walk because of the pain involved, and they exhibit tender, swollen wrists and ankles due to metaphyseal widening. In severe cases, frontal bossing, a rachitic rosary, and genu valgum develop. Osteoporosis and epiphyseal fraying are visible on radiographs (*Fig. 41-3*). The combination of hyperphosphaturia and hypercalciuria often results in medullary nephrocalcinosis (48). Hypocalcaemia can cause painful episodes of tetany, especially 20–30 min after a dose of an alkalinizing medication that lowers circulating concentrations of ionized calcium. Magnesium is lost commensurately with calcium, and serum magnesium levels are often low.

The poor health of infants and small children with cystinosis makes them irritable and picky eaters. Carnitine

Figure 41-3

Rickets in a 16-month-old boy with nephropathic cystinosis. Note widening of the metaphysis, fraying of the epiphysis, and osteoporosis.



is only ~70% reabsorbed in cystinosis (normal, 97%), leading to chronically low levels of free carnitine, typically 11 μM (normal, ~40 μM) (49). Since carnitine is essential for fatty acid transport into mitochondria, carnitine deficiency may contribute to poor muscle development, although this has not been proven. The aminoaciduria of cystinosis can be quantified using the Fanconi Syndrome Index (FSI), a measurement of the daily urinary excretion of 21 specific amino acids, expressed per kg of body weight (50). For children with cystinosis, the FSI is always above normal (94 ± 45 μmole/kg/day), and is often ~1 mmol/kg/day. Urine organic acids have been reported elevated in children with cystinosis, but without apparent clinical consequences (3).

The Fanconi syndrome of cystinosis can mislead physicians in several ways. The combination of polyuria and glucosuria has led to the incorrect diagnosis of diabetes mellitus, which can be readily dismissed by the finding of a normal serum glucose. Other patients have carried the diagnosis of diabetes insipidus or Bartter's syndrome for years before being correctly ascertained as having cystinosis (2, 3). The tubular proteinuria of cystinosis can reach nephrotic levels; some children excrete 3–4 g of protein per day. This can be taken to reflect glomerular damage, which may be present to a certain extent, but the bulk of the protein is generally of low molecular weight, reflecting tubular dysfunction. Urine protein electrophoresis can distinguish tubular from glomerular proteinuria. Finally, as cystinosis patients approach renal failure, their reduced filtration function creates the expectation that oliguria, hyperkalemia, and hyperphosphatemia will occur. In cystinosis, however, the tubular defect consistently overrides the glomerular damage. Patients with creatinine clearances less than 30 ml/min/1.73m^2 can still have urine volumes of 3 L and, if not supplemented, profound dehydration, hypokalemia and phosphate wasting.

Glomerular Damage

Cystinosis accounts for ~5% of chronic renal failure in children (51). By the time a typical cystinosis infant is diagnosed at approximately 1 year of age, significant renal glomerular damage has already occurred. A reasonable estimate would place the creatinine clearance at the time of diagnosis at approximately 70% of normal, and this level of function slowly but inexorably decreases. By age 10, most children with cystinosis have reached renal failure and require transplantation or dialysis. In a European study of 205 cystinosis children, the mean age for end-stage renal disease was 9.2 years (52). However, rates of decline are somewhat variable, with milder patients maintaining function until age 12, and severely affected children losing function by age 6. The substantial reserve of human kidneys means that serum creatinine seldom rises above normal until 5 years of age, especially if growth retardation creates a reduced creatinine load on the kidneys. However, measurement of glomerular filtration rate using a 24-urine collection and calculation of creatinine clearance generally reveals a significant deficit at the time of diagnosis even at a year of age.

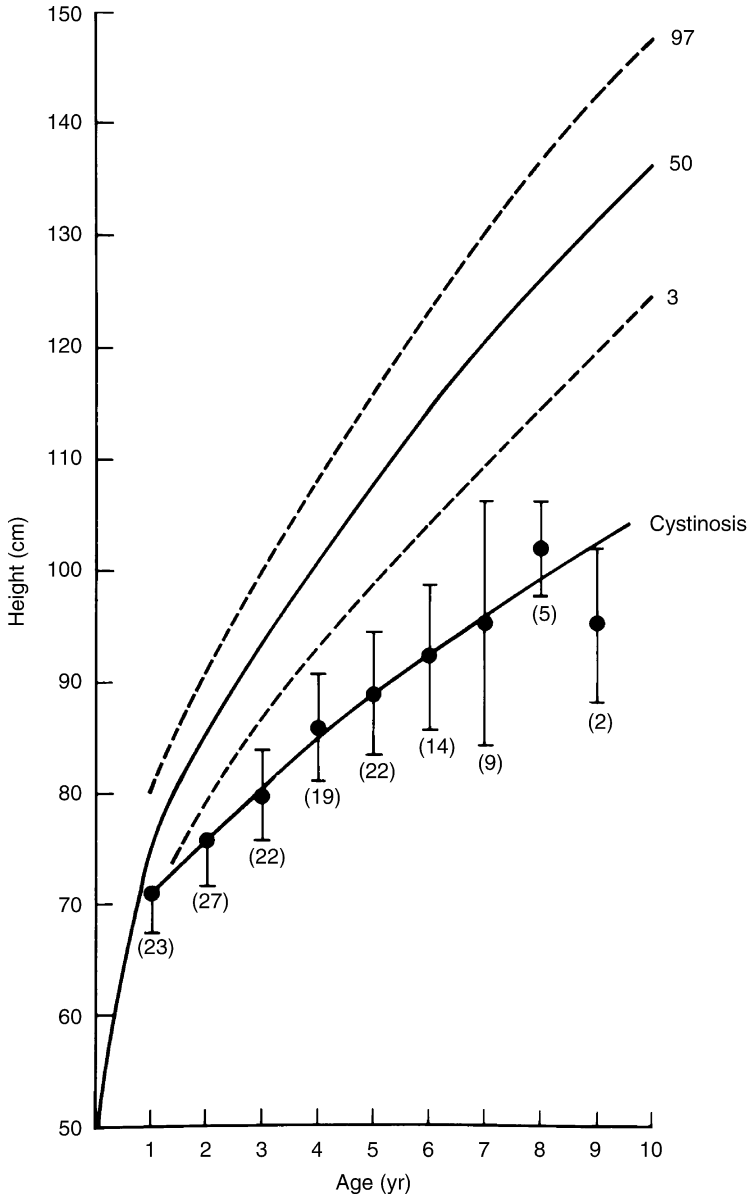
The uremia of cystinosis resembles that of other renal disorders, except that the growth retardation and anemia may be somewhat exaggerated. Hypertension can accompany chronic renal failure or arise in the post-transplant period, but cystinosis itself does not predispose to this complication.

Growth Impairment

Newborns with cystinosis are normal in height, weight, and head circumference. While head circumference is maintained, height and weight percentiles generally fall by 6–12 months of age; this is often the first indication of the diagnosis. By 1 year of age, the average infant with cystinosis has a height at the third percentile (8). Without treatment, growth continues at 50–60% of the normal rate. By age 8, the average untreated child with cystinosis has the height of a 4-year old (*Fig. 41-4*). In the past, some poorly treated, post-transplant adults achieved less than 4 ft in height. Weight usually follows height, but with greater variability. The normal head circumference,

Figure 41-4

Natural history of growth in children with cystinosis. Mean values for cystinosis children are superimposed upon a normal growth chart. On average, a child with cystinosis falls from normal height to the third percentile at 1 year of age, and continues to grow slowly so that the height age is 4 years when the chronological age is 8 years. Reprinted from (8).



combined with reduced height and weight, give the impression of macrocephaly, but this is relative, not absolute.

In patients not receiving growth hormone, bone age usually lags behind chronological age by 1–3 years. Children with retarded bone ages retain growth potential past the usual age of epiphyseal closure, but height is never gained past age 20, regardless of the bone age.

The cause of impaired growth has not been definitively determined. Growth hormone is normal (53), although patients respond to supraphysiologic doses of growth hormone (54). Hypophosphatemia, acidosis, poor nutrition, and cystine storage in the bone may contribute to poor growth in cystinosis. However, with adequate nutrition, replacement of renal losses, and

cystine depleting therapy, a normal growth rate can be achieved. (See below.)

Ocular Involvement

A patchy retinal depigmentation has been described early in infancy in cystinosis (28), but the primary ophthalmic manifestation of cystinosis is photophobia. This occurs due to corneal crystals that first appear in the anterior third of the cornea. Corneal crystals are always present by 16 months of age on slit lamp examination (12). Prior to then, the crystals may not be apparent. The number of crystals increases with age, reaching a maximum discernible density by ~8 years of age. An atlas of corneal crystal density at different ages has been published (12). Crystal density among ocular cystinosis patients appears less than that of patients with classical disease.

Children with cystinosis complain of sensitivity to light at variable ages, but usually not until 5–10 years of age. They squint to the point that, without treatment, they can eventually develop blepharospasm refractory to all modes of therapy. Often, patients wear dark glasses outside and turn down the lights inside. Occasionally, a child with cystinosis may experience a corneal ulceration as a crystal breaks through the corneal epithelium. This complication occurs much more frequently in adolescence and adulthood, when haziness of the cornea also appears.

Hypothyroidism

In the natural history of cystinosis, approximately half of patients are hypothyroid by age 10 (55) and 90% by age 30 (56). Thyroxine and free T4 are low and TSH is high, pointing to primary hypothyroidism, although partial pituitary resistance has also been reported (57). In cystinosis, the thyroid tissue appears fibrotic with occasional crystals present.

Cognition and Psychological Aspects

Children with cystinosis learn normally and have low normal full-scale IQs (58, 59). However, recent evidence indicates isolated deficits in visual processing and tactile recognition (60, 61). Short-term visual memory can be impaired (62), and several children have exhibited behavioral and social problems (58, 63), undoubtedly related in part to their chronic disease, renal failure, and growth retardation.

Other Clinical Findings

Cystinosis children are notoriously poor eaters, with understandable craving for salty foods such as pickles, ketchup and potato chips (47). In addition, many children exhibit a pica for hot foods such as jalapeno peppers and tabasco sauce, without an obvious explanation. Young children and infants exhibit an increased tendency toward vomiting, worse in the morning and on an empty stomach. Some of this may be related to medications, but there appears an intrinsic element as well. The nausea and vomiting often decrease with age, and generally cease by 7–8 years of age. Rarely, a patient may suffer from gastrointestinal immotility and have projectile vomiting upon eating or drinking slight amounts of food or water.

One-third to one-half of cystinosis children 10–18 years of age have mild hepatomegaly on physical examination (55), with no identifiable cause. One 9-year-old boy had hepatic veno-occlusive disease and underwent a liver transplantation (64). Patients from lightly pigmented backgrounds sometimes appear less pigmented than other family members. This may reflect dysfunction of melanosomes, which are lysosome-related organelles, or formation of excessive cysteinyl-dopaquinone, the precursor of pheomelanin, a blond-red pigment. Alternatively, the blond pigmentation characteristic of cystinosis may reflect the high frequency of Germanic and Nordic heritage among cystinosis patients. African American and hispanic patients have pigmentation indistinguishable from that of their siblings. Most cystinosis patients manifest decreased sweat production, causing flushing, heat avoidance and occasional hyperthermia (65). In addition, tear and saliva production is often reduced in cystinosis.

Enuresis in children with cystinosis may reflect the large volume of urine produced daily. Patients combat infections in a normal fashion, although gastroenteritis in children with Fanconi syndrome will cause dehydration much more rapidly than in normal individuals.

Idiopathic intracranial hypertension, or pseudotumor cerebri, has been reported in several patients and has been attributed, in part, to cystinosis itself (66). It has caused blindness in at least two children with cystinosis.

Laboratory Abnormalities

In addition to laboratory aberrations related to the Fanconi syndrome, children with cystinosis frequently exhibit mild microscopic hematuria, an elevated sedimentation rate, increased platelet counts, and anemia that is excessive for the degree of renal failure (3). Cholesterol levels

are usually elevated, with each of the lipoprotein fractions proportionally increased. The hypercholesterolemia persists after renal transplantation (16, 17).

Diagnosis

Because a safe and efficacious treatment exists for cystinosis, physicians should be anxious to make this diagnosis and should maintain a high index of suspicion. Unfortunately, the average age of diagnosis for cystinosis remains just over 1 year (3), and even today several patients escape detection for years, despite manifesting typical signs and symptoms.

Postnatal Diagnosis

A family history of cystinosis will naturally point to this disease in a child with suggestive findings. Even without a previously affected sibling, though, evidence of renal tubular Fanconi syndrome (polyuria, polydipsia, proteinuria, glucosuria, acidosis, dehydration, electrolyte imbalance, salt craving, and tetany) should prompt investigation of cystinosis. Other signs include poor growth, failure to walk at an appropriate age, and other evidence of rickets. The presence of typical corneal crystals on slit lamp examination by an experienced ophthalmologist will make the diagnosis. Such crystals are usually not apparent within the first several months of life, but a few crystals are always present by 16 months of age (12).

Elevated intracellular free (nonprotein) cystine concentrations also permit definitive diagnosis. Cystinosis patients have high concentrations of cystine in a variety of cell types, but polymorphonuclear leucocytes are the preferred cells in which to assay cystine (1–3). While cystinotic lymphocytes have three to fivefold normal cystine concentrations, neutrophils have 50–100 times the normal levels, i.e., 3–23 nmol half-cystine/mg protein (normal, <0.2) (67). Units of half cystine are employed by convention, because early assays did not distinguish cystine from cysteine. Patients with intermediate cystinosis generally have values at the lower end of the cystinotic range, and ocular cystinosis patients have values of 1–5 nmol half-cystine/mg protein (3). Heterozygous values are less than 1 nmol half-cystine/mg protein.

Several methods of cystine analysis have been employed. Ion exchange chromatography, used for amino acid analysis, can be insensitive if a very small amount of cell protein is available. The cystine binding protein assay is sensitive and specific (68), but is being supplanted by tandem mass spectrometric analysis. In general, approximately 3–10 ml of heparinized blood is used to isolate polymorphonuclear leukocyte-rich white cells, using dextran sedimentation and hypotonic lysis of erythrocytes. Red cell contamination will increase the protein denominator and underestimate the cystine concentration. Similarly, lymphocyte contamination will lower the value of cystine/mg protein. Keeping blood at room temperature for long durations (e.g., a day) can cause the cystine to leach out of leucocytes, giving spuriously low values. Relatively little sensitivity is needed to simply make a diagnosis of cystinosis, but high sensitivity is necessary when following cystine depleting treatment. (See below.)

In the past, biopsies of kidney, bone marrow, rectal mucosa, or conjunctiva were performed, seeking the presence of crystals to make or confirm the diagnosis of cystinosis (3). This outmoded method of diagnosis is not indicated.

CTNS mutation analysis can confirm the diagnosis of nephropathic cystinosis, and a multiplex PCR methodology is available for the common 57,257-bp deletion (40). However, molecular methods play little or no role in postnatal diagnosis of cystinosis. Currently, newborn screening for cystinosis does not exist.

Prenatal Diagnosis

When one child has been diagnosed with cystinosis, the disorder can be identified in subsequent pregnancies by several methods. At 8–10 weeks of gestation, chorionic villus samples can be directly assayed for cystine, as long as enough tissue (5 mg wet weight) is available (69). At 14–16 weeks' gestation, amniotic fluid cells can be cultured for approximately 4 weeks to obtain enough cells to measure the cystine content (70). Measurement of cystine in a placenta will make the diagnosis at birth (71). In addition, any of these cell sources can be used for molecular diagnosis, as long as both mutations have been previously identified in the affected sibling.

Heterozygote Detection

Carrier (heterozygote) detection based upon leukocyte cystine measurement is problematic. While carrier levels can be as high as 1 nmol half cystine/mg protein, they can also be within the normal range (<0.2). Hence, carrier status can be ruled in but sometimes cannot be ruled out. If both *CTNS* mutations are known in a proband, the

carrier status of other family members can be ascertained using molecular diagnostic techniques.

Differential Diagnosis

As noted above, the polyuria/hypokalemia/glucosuria associated with renal Fanconi syndrome can lead to the mistaken diagnosis of nephrogenic diabetes insipidus, Bartter syndrome, or diabetes mellitus. Once true Fanconi syndrome is diagnosed, cystinosis should be considered first, but the differential includes tyrosinemia type I, Wilson disease, Oculocerebrorenal Syndrome of Lowe, glucose-6-phosphatase deficiency, fructosemia, galactosemia, and heavy metal toxicity. The vitamin D-resistant, hypophosphatemic rickets of cystinosis has been mistaken for vitamin D deficiency. We know of patients who have carried the diagnosis of glomerulosclerosis or simply renal insufficiency until crystals were discovered upon removal of the native kidneys at transplant. Conversely, cystinosis was mistakenly diagnosed in a patient with idiopathic nephrocalcinosis but without intracellular cystine storage.

Cystinosis, in which free cystine accumulates within the lysosomes of cells, should not be confused with cystinuria, in which cystine, arginine, ornithine and lysine fail to be properly reabsorbed by renal tubular cells (72). In cystinuria, massively elevated urinary cystine concentrations result in renal stone formation, often beginning in adolescence. In cystinosis, generalized aminoaciduria occurs because of the Fanconi syndrome, but there is no particular elevation in urinary cystine, and no diathesis toward renal stone formation.

Therapy

Treatment of nephropathic cystinosis can be divided into symptomatic modalities for particular organ complications and cystine-depleting therapy directed specifically at reducing the cystine content of all cells of the body.

Replacement of Renal Losses

Renal tubular Fanconi syndrome results in wasting of small molecules, which need to be replaced. First, there must be free access to water (and bathroom privileges); dehydration can destroy glomeruli and hasten renal failure. At the same time, electrolytes must be supplied. Sodium should not be restricted, and affected children should be permitted to indulge their natural cravings for salty foods. Potassium generally needs to be supplemented, either as the chloride, gluconate or citrate salts. Oral doses can reach several times the normal daily maintenance requirements; excess potassium will be excreted. We are often unable to keep the serum potassium above 3.0 mEq/L, and remain content with that concentration. For alkalinization, solutions containing 2 mEq/ml of citrate can be administered. These include Polycitra (1 mEq/ml of sodium and 1 MEq/ml of potassium), Polycitra K (2 mEq/ml potassium), and Bicitra (2 mEq/ml sodium). A typical child's dose is 5–10 mL q6h, and we are satisfied to achieve a serum carbon dioxide of $\geq$20 mEq/l, especially in infants (47).

Phosphate is provided as Neutraphos or Neutraphos-K, one-half to one packet q6h. Vitamin D, as calcitriol, fosters gastrointestinal absorption of the phosphate, although patients are not naturally deficient in vitamin D. With adequate phosphate replacement, the rickets should resolve in 3–6 months, although osteoporosis may persist on radiography. Some children require calcium to prevent tetany. If so, the calcium administration must be separated from phosphate ingestion by at least an hour to prevent precipitation of calcium phosphate in the gut. An occasional patient requires magnesium supplementation, and many patients receive oral carnitine.

Doses of replacement medications are often greater than necessary at first, and requirements do not change significantly with growth. However, one consideration is that, after the adolescent growth spurt, phosphate supplementation could be reduced to minimize the occurrence or progression of nephrocalcinosis (48).

Physicians should be aware of the huge amounts of fluid and electrolytes required to replace cystinosis children who are dehydrated due to gastroenteritis. Amounts needed for a 10 kg infant who is 10% dehydrated include 1 L/day for maintenance, 1 L for replacement, and perhaps 2.5 L for ongoing, constitutive losses. At 4,500 mL/day, the intravenous line must run at nearly 200 mL/h, a rate which will challenge most pediatricians and 23 gauge i.v. catheters.

Another special case warrants mention. As cystinosis patients approach renal glomerular failure, they are expected to become oliguric, hyperkalemic and hyperphosphatemic. In fact, however, tubular losses mitigate against these conditions, as renal wasting persists despite a low glomerular filtration rate. Hence, when a uremic child with cystinosis develops gastroenteritis, large amounts of fluids and electrolytes, especially potassium, are still required.

Other Symptomatic Treatments

The poor eating habits, nausea, vomiting, and early satiety due to excessive fluid ingestion all contribute to poor nutrition, especially around the time of diagnosis. Nutritional consultations can prove critically important to ensure, for example, that ingested fluids contain calories whenever possible. Once mineral, electrolyte, and acid-base balance are established, children can begin to eat normally. Most children eat well by 6–10 years of age and do not require feeding tubes. An occasional child requires gastric tube access for medications or calories, but maintenance of the masticatory process is critical. When tube feeding bypasses the swallowing mechanism early, completely, and chronically, the swallowing reflex may have to be re-learned later.

Some nephrologists prescribe acetylcholinesterase inhibitors to reduce proteinuria, based upon the benefit of this therapy in maintaining renal function in diabetic nephropathy. The efficacy of this practice with respect to glomerular function has not been investigated in cystinosis. Some cystinosis patients, especially those in Europe, receive indomethacin to reduce urine volume (3). This medication causes a transient increase in serum creatinine, reversible upon cessation of the drug. Indomethacin administration is generally reserved for patients with huge urine volumes.

In the past, most patients with cystinosis required thyroid hormone replacement, but treatment with cystine-depleting therapy has reduced the number of patients who need L-thyroxine supplementation (56). Some children benefit from judicious use of anti-emetics, which are most often taken just before the breakfast meal. The impairment of sweating predisposes to heat prostration, so children should avoid prolonged periods (i.e., greater than 20 min) in the sun. Exercise helps to maintain muscle strength in the face of nutritional challenges. Occasionally, patients with severe rickets or renal osteodystrophy require corrective orthopedic surgery such as an osteotomy.

Although cystinosis patients possess normal amounts of growth hormone, they still benefit from growth hormone supplementation under the care of an endocrinologist (54). After the diagnosis of cystinosis, children should be stabilized, supplemented for their renal losses, and placed on an adequate dose of the cystine-depleting agent, cysteamine. (See below.) This regimen can achieve a normal growth rate within 6–12 months of initiation, although it will not usually allow for catch-up growth. Hence, if children remain below the third percentile for height a year after their medications have been adequately received, growth hormone should be considered. Initiating cysteamine and growth hormone therapy at the same time will not allow for attribution of benefit to either intervention. Some physicians think that the optimal time for growth hormone treatment is between 4 and 10 years of age. Growth hormone therapy is often truncated once a child reaches the 10th–25th percentile for height; after this milestone is reached, children are expected to continue to grow along their centiles without growth hormone, as long as their other medications remain adequate. The added growth of children receiving growth hormone increases creatinine production and its load on the kidney. Consequently, serum creatinine can rise even though renal function remains unaltered by the supplemental growth hormone.

Renal Replacement Therapy

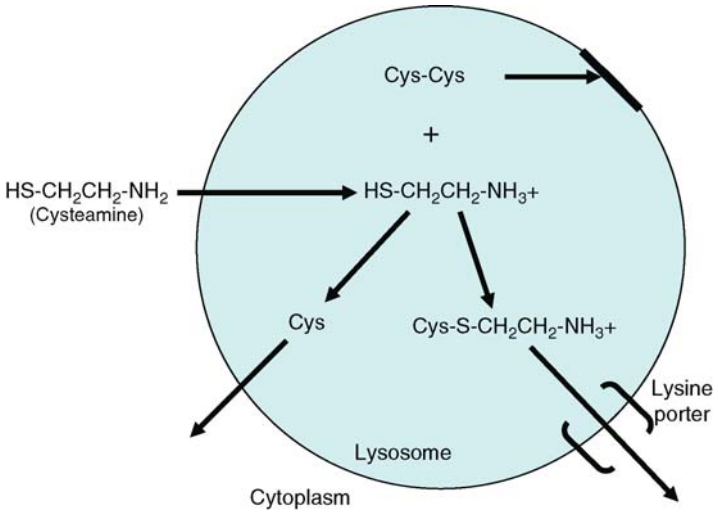
Either hemodialysis or peritoneal dialysis serves as a temporizing measure once a cystinosis patient approaches renal failure. The loss of renal function occurs slowly but inexorably, so that end-stage renal disease can be anticipated, as for other renal disorders, by plotting reciprocal serum creatinine against age. Prolonged dialysis carries significant risks; we have seen a patient who underwent peritoneal dialysis for approximately 10 years and had widespread calcification of his abdominal cavity.

Cystinosis patients respond very well to kidney transplantation, and no particular findings distinguish cystinosis patients from other candidates for renal replacement therapy. A living donor is preferred, and current anti-rejection therapy has obviated the requirement for a related donor. Carriers of a *CTNS* mutation, e.g., parents of an affected child, are suitable donors because no symptoms ever occur in heterozygotes for cystinosis; kidney function, in particular, is normal. When a living donor is available, families and physicians should consider a pre-emptive transplant. Even cadaver allografts, however, perform extremely well. Some transplants into cystinosis patients have lasted 25 years. Cystinosis does not recur in the transplanted kidney, because the lysosomal cystine transport defect is intrinsic to the host cell. Nevertheless, a graft biopsy can sometimes contain cystine crystals due to infiltration of the donor kidney by host macrophages (3).

Cystinosis patients receive standard anti-rejection therapy, which sometimes involves a steroid-free regimen. Current practice involves retention of host kidneys. When this occurs, especially in pre-emptive transplants when some renal function remains, blood flow to the host

Figure 41-5

Mechanism of action of cysteamine. The free thiol enters the lysosome and reacts with cystine (Cys-Cys), which cannot exit the cystinotic lysosome. The two products, cysteine and cysteine-cysteamine mixed disulfide, can readily leave the cystinotic lysosome; the mixed disulfide leaves through the lysine transporter. This process lowers lysosomal cystine levels by over 90%.



kidneys may result in persistent Fanconi syndrome post-transplant. Polyuria may occasionally be problematic, and potassium supplementation may be needed after renal transplantation.

After a renal allograft, cystinosis patients virtually always improve in activity, appetite, and feeling of well being. Patients grow significantly after receiving a transplant, at rates that depend upon chronological age and bone age.

Oral Cysteamine Therapy

Many putative cystine-depleting regimens have proven unsuccessful in cystinosis patients, including restriction of sulfur-containing amino acids, and the administration of ascorbic acid, dithiothreitol, and penicillamine (3, 47). One specific radioprotective agent, however, has proven efficacious. In 1976, the aminothiol cysteamine, or beta-mercaptoethylamine (7), was shown to deplete cystinotic fibroblasts in vitro, and polymorphonuclear leucocytes in vivo, of cystine. Cysteamine passes through the plasma and lysosomal membranes into the lysosome, where the acidic environment puts a charge on the amine group and traps the molecule. Within the lysosome, cysteamine interacts with cystine in a disulfide interchange reaction to produce cysteine and cysteine-cysteamine mixed disulfide, both of which readily exit the lysosome without requiring a functional cystine transporter (*Fig. 41-5*). In fact, cysteine leaves via its own carrier, and the mixed disulfide leaves via a lysine carrier (73), since it structurally resembles lysine. Once outside the lysosome, cysteine participates in normal cytoplasmic reactions and can be eliminated from cells and eventually excreted as sulfate.

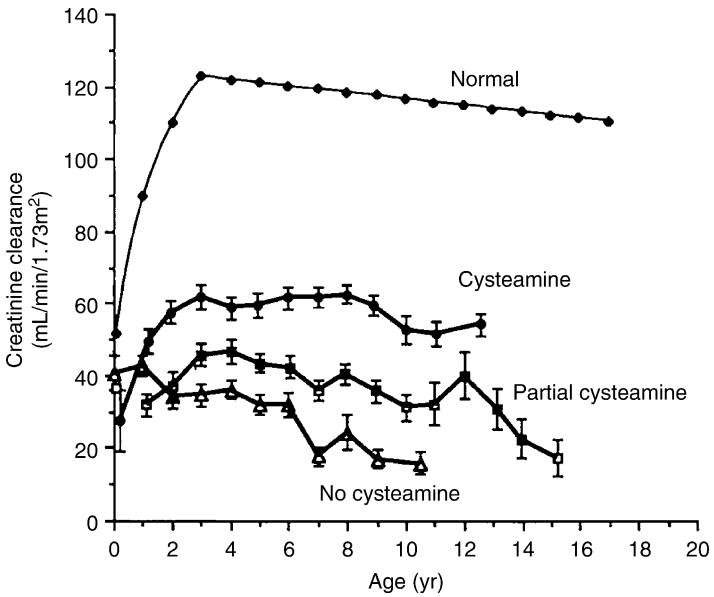
When taken orally, cysteamine removes up to 95% of leukocyte cystine within an hour of ingestion. Parenchymal cells are thought to respond in a similar fashion, although the extent and time course of depletion remains unknown for other tissues.

A clinical trial of oral cysteamine therapy was initiated in 1978, after a randomized, placebo-controlled trial of ascorbic acid failed to demonstrate efficacy in preserving renal function (74). The cysteamine trial was open-label, and 93 treated patients were compared to the 55 historical control patients of the ascorbic acid protocol (8). By the end of the study in 1985, the cysteamine-treated group had significantly better renal function than the untreated group (38.5 vs. 29.7 ml/min/1.73 m^2) despite being 1.4 years older, on average. Growth velocity was also better in the cysteamine-treated group. Based on this report, oral cysteamine became the treatment of choice for pre-transplant patients with nephropathic cystinosis.

Subsequent studies, including a seminal intent-to-treat analysis in 1993 (9), verified the safety and efficacy of chronic oral cysteamine therapy. In the 1993 study, 17 patients treated early and well (before 2 years of age,

Figure 41-6

Cysteamine preserves renal glomerular function in cystinosis and allows for growth of kidneys in the first 3 years of life. Creatinine clearance, based upon 24-h urine collections, was used as a measure of glomerular filtration rate. The normal curve indicates rapid growth of renal function early in life as the kidneys enlarge. The other curves were constructed using values from children with cystinosis. The "No Cysteamine" curve reflects the natural history of cystinosis, i.e., a monotonic decline in creatinine clearance leading to end-stage renal disease at 10 years of age. The "Cysteamine" curve represents mean values for 17 children treated early and well with oral cysteamine. Renal growth and acquisition of increased renal function were preserved. The "Partial Cysteamine" curve was for patients treated less well, and the results fall between those in the other two groups. Reprinted from (9).



achieving leukocyte cystines less than 2 nmol half-cystine/mg protein, and treated for a mean duration of 7.1 years) had a mean creatinine clearance of 57 ± 20 ml/min/1.73 m^2 at a mean age of 8.3 years. Of 27 children with no cysteamine treatment, 16 had gone to renal failure with a mean creatinine clearance of 8.0 ± 4.5 ml/min/1.73 m^2 at a mean age of 8.3 years. Children with poor treatment had outcomes between these extremes (*Fig. 41-6*). In this retrospective study, oral cysteamine not only slowed the deterioration of glomerular function, it also allowed for normal kidney growth in the first 3 years of life. Consequently, early initiation of cysteamine was deemed critical; every month of treatment in the first 2 years of life telescopes into 14 months of preservation of renal function later in life. The optimally treated patients also grew at a normal rate, parallel to normal height curves, while remaining below the third percentile on average (75). Cysteamine bitartrate was approved as Cystagon^R by the Food and Drug Administration on 15 August, 1994 for preservation of renal function and enhancement of growth in cystinosis patients.

Cysteamine is given at a dose of 60–90 mg/kg/day or 1.3–1.95 g/m^2/day, in divided doses every 6 h. Blood levels peak at 1 h and fall off over the next few hours. A high blood level must be achieved, since a large portion of the free thiol will bind to circulating proteins, preventing entry into parenchymal cells. Hence, the full recommended dose should be taken within a few minutes, and a dose should be repeated once if vomiting occurs within 15 min of ingestion. When initiating cysteamine therapy, dosing should begin at approximately one-fourth the target dose, with incremental increases every ~3–7 days. Doses are titrated to maintain leukocyte cystine levels less than 1 nmol half-cystine/mg protein. However, since a value of 0.2 is preferable to a value of 0.9, some patients receive the maximum tolerated dose, as long as it is below 90 mg/kg/day. The recommended adult dose of oral cysteamine is 500 mg q6h, although some patients receive as much as 750 mg q6h.

One child with intestinal immotility received cysteamine intravenously, through a central line, for years (76). The blood levels achieved with this regimen resembled those of other children given similar doses orally.

There was hope that early initiation of cysteamine therapy could allow patients with cystinosis to avoid the need for renal transplantation entirely (9). However, a significant amount of glomerular damage is often present by the time of diagnosis, and cystine depletion may not completely stop the progressive loss of renal function. Hence, even our early-treated, compliant patients reach end-stage renal disease by their late teens or early twenties. Furthermore, although cysteamine therapy can occasionally be associated with improved renal tubular function (77), the Fanconi syndrome of cystinosis is generally irreversible and refractory to cystine-depleting therapy. In patients receiving oral cysteamine beginning prior to 2 months of age because an affected sibling allowed early diagnosis, the Fanconi syndrome was delayed and attenuated but not entirely prevented.

In approximately 10–15% of patients, the side effects of cysteamine prevent this treatment (8), and in another fraction of patients the adverse effects limit either dosage or compliance. Because cysteamine is a free thiol, it smells like rotten eggs, and this odor sometimes emanates from the skin. Cysteamine also tastes terrible and can cause nausea and vomiting. Breath fresheners and a variety of over-the-counter remedies are variably effective in combating the smell. Anti-emetics can be useful for the nausea and vomiting. Some children and adults clearly do better than others taking oral cysteamine, and for children, parental persistence and diligence is critical for compliance. Several adolescents and young adults, upon achieving a measure of independence or upon leaving home, have eschewed cysteamine as a medication and have lost their kidneys within approximately 6 months.

Three decades ago, one uremic patient receiving oral cysteamine at high doses experienced a seizure, another had reversible neutropenia, and another experienced an apparent drug rash (78). These and other side effects are distinctly unusual and appear related to excessive dosing, sometimes initiated by families or patients themselves. We have noted lethargy or somnolence in two patients on very high doses of cysteamine. In addition, apparent vascular fragility, noted especially on the elbows, has been observed, largely among children on very high doses of cysteamine. To date, this later complication has been seen only among European patients. The free thiol group of cysteamine has the potential to interact with disulfides or other free thiols, including cysteine residues on circulating proteins (79).

Alternative methods of cysteamine delivery have been employed. On a molar basis, phosphocysteamine has efficacy equal to that of cysteamine in terms of leukocyte cystine depletion (80). Cystamine, the disulfide of cysteamine, is considered effective as well. A delayed release preparation of cysteamine is under development (81), with the hope that twice daily dosing can replace q6h dosing.

Cystinosis patients who are pregnant should be aware that the teratogenic potential of cysteamine has not been assessed in humans. It is recommended that females planning pregnancy discontinue cysteamine at the time of conception, throughout their pregnancies, and while nursing. Since all pregnant females to date have been post-transplant, adherence to this advice has not had repercussions on the patients' renal function. This issue will become acute and problematic as more young women reach child-bearing age with their native kidneys, which require constant cysteamine therapy for maintenance of function. Because cysteamine is not known to be safe in pregnancy, it has not been used for in utero treatment.

Chronic oral cysteamine treatment has been shown to deplete muscle and liver of cystine (82). The inference that other tissues became similarly depleted is bolstered by evidence that treated patients escape the need for thyroid hormone replacement (56). Recent evidence indicates that long-term oral cysteamine can prevent most, if not all, of the late complications of cystinosis (17) (see below).

Patients diagnosed with ocular cystinosis may, in fact, have a mild form of nephropathic cystinosis, and may eventually develop renal glomerular dysfunction. Hence, such individuals should be monitored for any decrement in renal function and, if it occurs, consideration should be given to instituting cysteamine therapy, depending upon the age of the patient and the rate of deterioration.

Cysteamine Eyedrops

Oral cyteamine fails to reach the avascular cornea, so cystine crystals continue to accumulate there despite Cystagon^{R} treatment. Delivery of cysteamine directly to the cornea, through cysteamine eyedrops, has enormously salutary effects. In general, within approximately 3 weeks, patients' eyes feel better, and the photophobia is at least partially relieved (10). The eyedrops, containing 0.55% cysteamine hydrochloride in sterile normal saline plus 0.01% benzalkonium chloride as preservative, can dissolve corneal crystals within 1–3 years when given 8–10 times per day (*Fig. 41-7*). The beneficial effects of cysteamine eyedrops can occur at any age (12), and older patients can observe a clarification of the haziness in their corneas. The eyedrops, which can sting to various degrees in different patients, remain an investigational

Figure 41-7

Corneal cystine crystals and the effects of cysteamine eyedrops. Slit lamp examination of a 21-year-old cystinosis patient showing the cornea packed with crystals. (a) Same cornea 3 years later, nearly devoid of crystals subsequent to application of topical cysteamine therapy. (b) An adult post-transplant patient with cystinosis treated her right eye with cysteamine eyedrops, and the cornea became clarified. Her untreated left eye remained hazy, filled with cystine crystals.

drug, but this issue is being addressed. The disulfide cystamine is not as effective as the free thiol cysteamine in dissolving corneal cystine crystals (83). Some partial relief of corneal discomfort can be achieved by over-the-counter eyedrops not containing cysteamine, probably by virtue of their lubricating ability.

Other Therapeutic Considerations

Families must recognize that oral cysteamine therapy is life-saving, and counseling in this regard should be part of the therapeutic plan. By the time children with cystinosis enter school, they have interacted closely with health professionals for years and may appear sophisticated. However, they are still children who need limits as well as understanding. Conversely, some adults with cystinosis are small in stature, but should be treated as adults.

Cystinosis in Adults

The success of renal transplantation has created a population of adult patients with nephropathic cystinosis, and this situation has revealed the consequences of prolonged cystine accumulation (16, 17). Eventually, cystinosis damages or destroys nearly every tissue and organ of the body, with variable frequencies (*Table 41-2*). This multisystemic involvement presents a significant

Table 41-2

Frequency of complications in 100 adults with cystinosis*

Finding	Frequency (%)
Hypothyroidism	75
Male hypogonadism	74
Pulmonary dysfunction	69
Swallowing abnormality	60
Myopathy	50
Retinopathy	32
Vascular calcifications	31
Diabetes mellitus	24
Cerebral calcifications	22

*92 patients had received a renal allograft

Figure 41-8

Myopathic hands of an adult with cystinosis, untreated with oral cysteamine. Note muscle wasting and claw-hand posture of flexion.

challenge to the effective transitioning of patients from pediatrics to internal medicine.

The following is a description of the natural history of late cystinosis, without cystine depleting therapy.

Growth and Appearance

Untreated or poorly treated adult cystinosis patients (males and females) average 144 cm in height (~13 cm below the mean third centile for males and females) and 45 kg in weight (~5 kg below the third centile for males and females) (16, 17). Head circumference is normal. Because nearly all transplanted adults are receiving prednisone, they have the facial and body stigmata of steroid use, including a pudgy, aged visage and, occasionally, verrucal warts on the hands.

Myopathy

A large proportion of untreated adults with nephropathic cystinosis exhibit a distal vacuolar myopathy, beginning in the hands with loss of the interosseous muscles and the thenar and hypothenar eminences, and progressing to the arms, legs, shoulders, neck, and chest (30, 31). This complication does not occur before adolescence, and is attributable to cystine accumulation within muscle tissue, not to carnitine deficiency, which resolves with renal transplantation. Affected patients hold their fingers in partial flexion, giving the appearance of a claw hand (*Fig. 41-8*); they have difficulty opening jars. Without cysteamine treatment, the muscle weakness and atrophy progress inexorably to include the head and neck, causing poor tongue and lip strength and hypophonic speech. Nerve conduction velocities are normal, and electromyography shows a myopathic pattern (84).

Eventually, swallowing difficulty supervenes in most myopathic patients. Symptoms include slow eating, choking, pain on swallowing, and heartburn (85). The impairment results from deterioration of swallowing muscles rather than from nerve involvement, and it poses a significant risk of aspiration. The first patient ascertained with the myopathy of cystinosis died of aspiration (30). The swallowing problem involves pooling in the valleculae and pyriform sinuses and, rarely, a double bolus. Other issues of oromotor dysfunction include a hyperactive gag reflex, hoarse voice, and inability to elevate the palate and move the jaw normally.

Another concomitant of severe myopathy in cystinosis is impaired lung function, due to weakness of the thoracic musculature rather than parenchymal lung damage (86). Pulmonary function tests are often significantly reduced, with volumes approximating 50% of predicted for size and age. Early rickets might also confer a conical shape to the chest cavity, potentially reducing maximum achievable volumes.

Pancreatic Involvement

A significant number of post-transplant cystinosis patients have insulin-dependent diabetes mellitus (87), presumably due in part to destruction of pancreatic beta cells. The frequency and severity of diabetes in cystinosis cannot be attributed entirely to the effects of steroids given to prevent

rejection of renal allografts. Rarely, pancreatic exocrine insufficiency has occurred in cystinosis, as evidenced by steatorrhea that is ameliorated by institution of pancreatic enzyme supplementation (88).

Hypogonadism

In the natural history of cystinosis, puberty is delayed by approximately 1–3 years, and some males never completely develop secondary sexual characteristics, including muscular development, facial hair, and a deep voice. Adult males with untreated cystinosis have low levels of testosterone and elevated levels of luteinizing hormone and follicle stimulating hormone, reflecting damage to testicular function (89). Sperm counts, measured in three individuals, were zero in all of them. No male patient has been reported to sire a child.

Females have no apparent impairment of ovulatory function and have normal sex hormone levels. Several post-transplant patients have given birth to entirely normal children (90). Of course, having an allograft by itself makes a pregnancy high-risk.

Central Nervous System Involvement

Brain cystine levels were originally considered normal in cystinosis, and the brain was thought to be spared. This notion was discarded, however, as patients survived to adulthood by virtue of renal replacement therapy. In fact, many adults with cystinosis have cerebral atrophy and periventricular and basal ganglia calcifications on CT scans (91). These findings have not correlated directly or immediately with functional deficits. Serious involvement of the central nervous system rarely occurs, but destruction of the parenchyma, with bradykinesia, inability to walk, and loss of speech and short term memory have been reported (92). In addition, cerebrovascular accidents have occurred, most likely as complications of uremia, dialysis, or transplantation.

Ocular Findings

Untreated, the corneas of cystinosis patients continue to accumulate crystals, and can develop a vision-impairing band keratopathy. Chronic photophobia can result in irreversible blepharospasm and posterior synechiae (scar tissue binding the iris to the posterior lens), impairing accommodation and causing angle closure glaucoma (29). Loss of retinal pigment epithelium can damage the rods and cones, initially impairing night and color vision and eventually reducing visual acuity. The retinopathy can be confirmed by electroretinography (93). An estimated 3–5% of cystinosis adults who have not received oral cysteamine therapy have retinal blindness.

Other Complications

Vascular calcifications occur with increased frequency among all individuals who have received dialysis, but the prevalence among cystinosis patients appears greater than expected (94). Involved vessels include the internal carotids, coronary arteries, aortic arch, and abdominal aorta. One 25-year-old man required stent placement for occluded coronary arteries (94).

Two young men with cystinosis died of severe liver dysfunction with portal hypertension; the pathologic diagnosis was nodular regenerating hyperplasia (32).

Death

In a study of 100 adults age 18–45 years seen at the NIH Clinical Center between 1985 and 2006, 33 had died at an average age of 28.5 years (17). The most common causes of death were sepsis, uremia, and respiratory complications. A few patients died of intestinal perforations. The oldest possible living patient was born in 1958, since he would reach renal failure (age 10) at the time of the first renal replacement therapy for cystinosis, i.e., 1968.

Occupations

The physical impairments of cystinosis adults not treated with cysteamine (i.e., growth retardation, muscle weakness, reduced vision) restrict most patients to sedentary occupations. Similarly, preservation of intellectual capacity directs patients toward professions involving computers, music, health care, and teaching. The physical normalcy that accompanies good cystine-depleting therapy will broaden the spectrum of jobs held by cystinosis patients in the future.

Treatment of Adults

Symptomatic Therapy

The various late complications of cystinosis require specific, symptomatic treatments. Up to 90% of adult patients who never received oral cysteamine require

L-thyroxine replacement by 30 years of age (56). Some males with hypogonadism receive testosterone injections every 2–4 weeks; this enhances secondary sexual characteristics as well as libido. The diabetes mellitus of long-standing cystinosis often requires insulin therapy.

Lost muscle mass cannot be recovered, but maximum retention of muscle can be achieved by consistent exercising. For patients with swallowing difficulty, specialists recommend maneuvers to reduce the risk of aspiration. Decreased chest expansion, causing reduced lung volumes, prompts yearly administration of the influenza vaccine as prophylaxis against pneumonia. For severe hand weakness, tendon transplantation has improved function in selected individuals.

Cystine Depleting Therapy

Virtually all the late, non-renal complications of nephropathic cystinosis are preventable with chronic oral cysteamine therapy. Of 100 adult patients seen at the NIH, the 39 who received cysteamine for at least 8 years had better growth, later onset of renal failure, fewer deaths, lower cholesterol levels, and fewer overall complications of the disease (17). Diabetes mellitus, myopathy, pulmonary dysfunction, hypothyroidism and death increased in frequency as the number of years *without* cysteamine increased; these complications decreased in frequency as the number of years *with* cysteamine increased. Other studies showed that the frequencies of retinopathy (93), swallowing difficulty (95), and vascular calcifications (94) were reduced by chronic oral cysteamine therapy. All these findings make Cystagon^{R} the treatment of choice in post-transplant as well as pre-transplant cystinosis patients. In addition, topical cysteamine eyedrops can dissolve corneal cystine crystals in the fourth decade of life as well as in the first decade.

Cystinosis Advocacy Groups

Patient advocacy groups include the Cystinosis Research Network (www.cystinosis.org/), the Cystinosis Foundation (www.cystinosisfoundation.org/), and the Cystinosis Research Foundation (www.natalieswish.org/).

Summary

Nephropathic cystinosis serves as a model for lysosomal storage diseases due to membrane transport defects, which currently include only sialic acid storage disorders (96) and cobalamin F disease (97). The discovery of the defect in cystinosis revealed that small molecules (amino acids, sugars, minerals, and nucleotides), produced by lysosomal hydrolysis of macromolecules, are salvaged by the cell. Cystinosis is the first treatable lysosomal storage disease and, as the most common cause of Fanconi syndrome in childhood, must be the first disease considered when tubular wasting is ascertained. Recent evidence of preservation of non-renal organs by oral cysteamine treatment reinforces the need for diligent, life-long cystine-depleting therapy. The overall success of this treatment should prompt renewed pursuit of a method for newborn screening. When gene therapy can be safely delivered to the many tissues involved in cystinosis, that treatment modality may supplant small molecule therapy. Until then, we consider ourselves blessed with an incredibly effective, albeit imperfect, method of treatment for what used to be a universally fatal malady.

42 Fanconi Syndrome

Takashi Igarashi

Fanconi syndrome (FS) is a generalized dysfunction of the renal proximal tubules leading to excessive urinary wasting of amino acids, glucose, phosphate, uric acid, bicarbonate, and other solutes. The patients develop failure to thrive, polyuria, polydipsia, dehydration, and rickets in children, and osteoporosis and osteomalacia in adults. The patients also manifest renal salt wasting, hypokalemia, metabolic acidosis, hypercalciuria, and low-molecular-weight (LMW) proteinuria. De Toni, Debré, and Fanconi described children with renal rickets and glucosuria in the 1930s (1, 2, 3). FS is named after Guido Fanconi, a Swiss pediatrician or it is called as de Toni-Debré-Fanconi syndrome.

Pathophysiology

The renal proximal tubules reabsorb almost all of the physiologically filtered load of proteins including of albumin, LMW proteins, amino acids, glucose, bicarbonate, sodium, chloride, phosphate, and uric acid. The transport processes in the proximal tubule can be characterized broadly as megalin/cubilin-mediated endocytic pathways and sodium (Na^+) gradient-dependent transport systems.

The proximal tubule cells have extensive luminal receptors and endocytic apparatus such as megalin and cubilin that are critical for the reabsorption and degradation of proteins that traverse the glomerular filtration barrier (4) (*Fig. 42-1*) as well as for the extensive recycling of many functionally important membrane proteins (5). Numerous filtered proteins including albumin, LMW proteins, polypeptide hormones, vitamin-binding proteins, and polybasic drugs such as aminoglycosides from glomerulus are bound to megalin and cubilin in the luminal membrane of proximal tubules. Then, the protein-receptor complex is incorporated into the endosome. The ligand and receptor are disassociated in the endosome; the receptor is recycled back to the luminal membrane and the reabsorbed proteins go into lysosome for further processing (*Fig. 42-2*). This disassociation is dependent on acidification of the endosome by increased concentration of H^+ and Cl^- due to the function of H^+-ATPase (proton pump) and ClC-5 chloride channel. An abnormal endocytosis pathway may affect the recycling of transport proteins (megalin and cubilin), the back to the luminal membrane, and the expression of megalin and cubilin in the luminal membrane, leading to decreased solute reabsorption. Perturbation of endosomal acidification in proximal tubule cells leads to diminished reabsorption and increased urinary wasting of albumin, LMW proteins, electrolytes, and solutes. Cadmium inhibits H^+-ATPase and mitochondria, which results in a Fanconi-like syndrome (6). Folimycin, a H^+-ATPase inhibitor, abolishes albumin uptake by proximal tubules (7). Moreover, a defect of ClC-5 chloride channel in patients with Dent disease manifests Fanconi syndrome (8). Acidification defect in the endosome in Dent disease leads to recycling from intracellular endosome into luminal membrane resulting in megalin deficiency in the luminal membrane of the proximal tubule. Analysis of normal human urine samples identified megalin as a physiologically excreted protein. The presence of megalin in normal human urine is due to shedding from the proximal tubule cells into the lumen. Patients with Dent disease demonstrate an almost complete absence of urinary megalin (9). This megalin-shedding deficiency in the urine is also observed in patients with Lowe syndrome (9).

Reabsorption of filtered solutes including glucose, phosphate, amino acids, and bicarbonate by proximal tubule cells is accomplished by transport system at the brush border membrane that are directly or indirectly coupled to Na^+ movement, by energy production and transport from the mitochondria, and by the Na^+, K^+-ATPase at the basolateral membrane. The Na^+, K^+-ATPase lowers intracellular Na^+ concentration and provides the electrochemical gradient that allows Na^+-coupled solute entry into the cell. Disturbances in energy generation could impair net transepithelial transport in the proximal tubule. Energy is necessary for the operation of Na^+, K^+-ATPase and other membrane carriers that are involved with solute reabsorption of amino acid, glucose, phosphate, uric acid, and bicarbonate. Although the weight of bilateral kidneys is less than 1% of total body weight, kidneys consume about 10% of the total energy consumed by the whole body in a static condition. Moreover, most of the energy is consumed in the proximal tubule cells to operate multiple

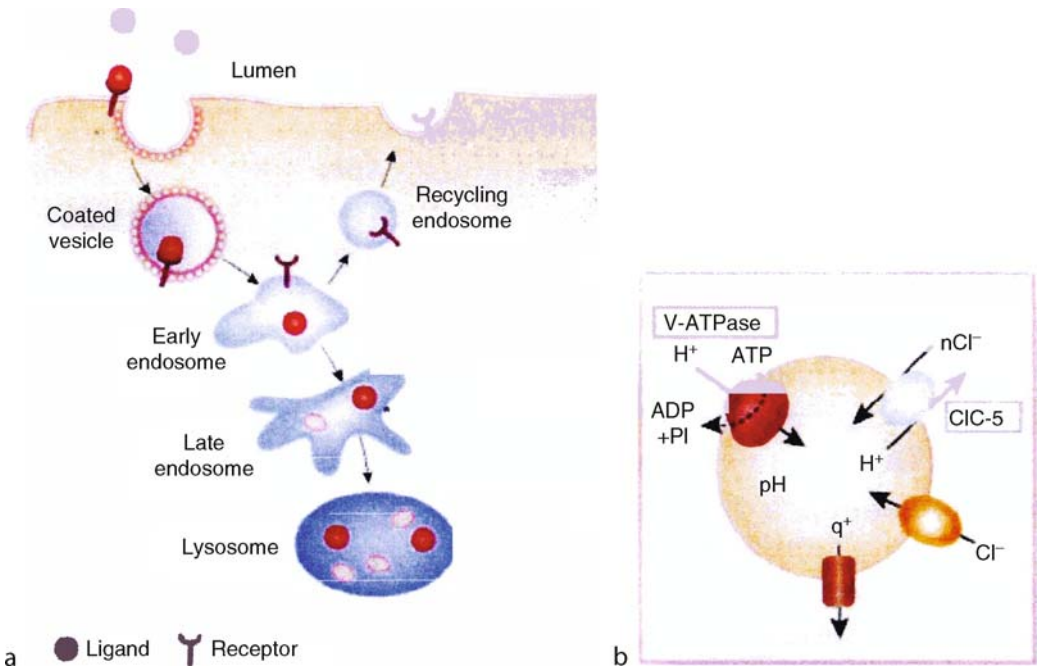
membrane and intracellular transporter proteins. A defect in energy generation in the proximal tubule cells produces multiple transport anomalies of the proximal tubule that characterize the FS. The ATP production is severely compromised in cystine-loaded tubule in cystinosis (10). Thiol-containing enzymes are critical for renal energy metabolism. Cystine inhibits in vivo and in vitro the thiol-containing enzyme activity resulting in multiple renal transport anomalies (11). The mitochondrial respiratory chain has a major role in ATP production during aerobic respiration. Genetic defects of enzyme complexes of the oxidative phosphorylation system or toxic substances including of drugs in the proximal tubule cells can produce mitochondrial respiratory chain defect leading to multiple renal transport anomalies (12, 13). In contrast, isolated dysfunction of transporter proteins in proximal tubule cells results in the selective wasting of amino acids, glucose, phosphate, bicarbonate, or uric

Figure 42-2

Schematic model of endocytosis in the proximal tubule cells. Albumin and low molecular weight proteins are filtered into the primary urine and endocytosed by proximal tubule cells via the megalin-cubilin receptor pathway. (a) The receptor-ligand complexes progress along the endocytic pathway. The endosomes undergo a progressive, ATP-dependent acidification that results in the dissociation of the receptor-ligand complexes, with megalin and cubilin being recycled in the luminal membrane, whereas the ligand is directed to lysosomes for degradation. (b) Vesicular acidification is mediated by the vacuolar H^+-ATPase, which requires a net Cl^- conductance to functions as an electrogenic nCl^-/H^+ exchanger, which is predicted to facilitate acidification and to play a role in keeping high vesicular Cl^- concentration. (Devuyst O, Pirson Y. Genetics of hypercalciuric stone forming disease. *Kidney Int* 2007:72:1065–1092).



acids. However, glucosuria and aminoaciduria are seen in some patients with defective isolated proteins. They are familial renal glucosuria resulting from the mutations in the kidney-specific low affinity/high capacity Na^+/glucose cotransporter gene (*SLC5A2*) and maturity-onset diabetes of young age type 3 (MODY3) resulting from the mutations in hepatocyte nuclear factor-1 alpha gene that acts as a regulator of transcription for *SLC5A2* (14, 15). Generalized aminoaciduria seen in these patients is considered as a consequence of the impairment in tubular glucose reabsorption, whereas the precise mechanism is not known.

Signs and Symptoms

Growth Retardation (Failure to Thrive)

Growth retardation (failure to thrive) is a common feature of FS in children (16). Patients with FS present severe growth failure at the time of diagnosis that persists into adult life. The pathomechanism of growth failure in FS is complex. Malnutrition, hypokalemia, hypophosphatemia, and metabolic acidosis can lead to growth retardation in patients with FS (17). Potassium deficiency induces growth retardation through reduced circulating levels of growth hormone (GH) and insulin-like growth factor I (IGF-I) (18, 19). Hypokalemia can induce appetite decrease leading to malnutrition and extracellular volume contraction. Metabolic acidosis inhibits growth hormone secretion, the expression of IGF-I and GH receptor (20). Hypophosphatemia is related to severe bone changes leading to rickets and growth retardation in children with FS (21). In patients with adult onset FS, osteomalacia is thought to result from hypophosphatemia due to renal phosphate loss and relative 1,25-dihydroxyvitamin D3 deficiency (22, 23). Metabolic acidosis impairs the conversion of 25-vitamin D3 to 1,25-dihydroxy vitamin D3. The patients present bone and joint pain in the hips,

shoulders, and trunk and difficulty of walking due to multiple bone fracture. Hypomineralization of dentin structure and immature formation of craniofacial bones are seen in patients with FS (24). Specific forms of FS are associated with endocytotosis pathway dysfunction; disruption of megalin-mediated uptake vitamin D-binding protein/25-vitamin D3 complex produces metabolic bone disease in affected individuals (25).

Earlier diagnosis and efficient correction of acidosis and electrolyte balances by supportive therapy can contribute to improve growth and final height in patients with FS (17, 21). However, supportive therapy is frequently unable to prevent further loss of relative height in patients with FS, especially those with cystinosis.

Polyuria, Polydipsia, and Dehydration

Polyuria, polydipsia, and dehydration are frequently seen in patients with FS. Polyuria is secondary to the osmotic diuresis from the excessive urinary solute losses and urine concentration defect in the collecting ducts due to chronic hypokalemia. Recurrent acute fever due to dehydration is a frequent manifestation in infants with FS. In the most common type of cystinosis, Fanconi syndrome occurs at 6–12 months of age. Recurrent febrile episodes are often the first sign of FS in infantile patients with cystinosis (26).

Generalized Aminoaciduria (Generalized Hyperaminoaciduria)

Molecular weight (MW) of 20 different amino acids is small; the largest amino acid is tryptophan [MW = 204 D (daltons)]. Amino acids are not bound to proteins in the plasma. Thus, amino acids are freely filtered from glomerulus. Then, 95–99% of filtered load of amino acids are reabsorbed in the proximal tubules. More than one transporter in the proximal tubule cells absorbs amino acids. Fractional excretion of amino acid is usually less than 3% in the controls except for neonate or premature babies. However, only histidine has a fractional excretion of 5% in the controls.

$$\text{Fractional excretion of amino acid } (\%) = [(\text{Uaa}/\text{Paa})/(\text{Ucr}/\text{Pcr})] \times 100$$

(aa; amino acid, cr; creatinine, U; urine, P; plasma)

Therefore, the excretion more than 5% of the filtered load of amino acid is termed aminoaciduria or hyperaminoaciduria. Every amino acid is highly excreted in patients with FS, and this phenomenon is called as *generalized aminoaciduria*.

Glucosuria

Filtered load of glucose (D-glucose, MW = 180 D) is almost completely absorbed by a sodium-coupled active transport located in the brush border membrane of the proximal tubule in the normal condition. Glucose reabsorption involves a couple of transporters at the luminal and basolateral membranes of the proximal tubules. The driving force for glucose reabsorption is provided by Na^+, K^+-ATPase in the plasma membrane. Thus, very small amount of glucose are present in the urine in the normal condition. Glucosuria is a common manifestation in FS. It is derived from impaired reabsorption of glucose when serum glucose is normal. Renal threshold of glucose is reduced in FS. Glucosuria is one of the originally described clinical features of FS (1, 2, 3). 0.5–20 g of glucose a day is lost in the urine in patients with FS.

Hypophosphatemia

Most of the patients with FS manifest a low tubular reabsorption of phosphate (percent tubular reabsorption of phosphate: %TRP, >80–85% in the control) and decreased serum phosphate. Rickets and osteomalacia are produced by the increased urinary wasting of phosphate as well as by impaired 1α-hydroxylation of 25-hydroxy vitamin D3 by proximal tubule cells (27).

$$\%\text{TRP} = [1-(\text{Up}/\text{Sp})/(\text{Ucr}/\text{Scr})] \times 100$$

(p; phosphate, cr; creatinine, U; urine, S; serum)

The maximal threshold of phosphate (TmP/GFR) is a very sensitive indicator that reflects the reabsorption of phosphate in the renal tubules.

$$\text{TmP}/\text{GFR} = \text{TRP} \times \text{Sp}$$

(GFR; glomerular filtration rate, p; phosphate, S; serum)

The Tm/GFR is usually very low (2.3–4.3 in the control) in patients with FS. Rickets manifests bowing deformity of the lower limbs, distal femur, the ulna, and the radius.

Phosphate handling in the kidney is affected by a couple of factors including parathyroid hormone (PTH) and vitamin D. PTH level is normal or elevated in patients with FS. Serum 1, 25-dihydroxy vitamin D3 is variable in patients with FS (28, 29).

Metabolic Acidosis

More than 85% of filtered load of bicarbonate ($HCO3^-$) is reabsorbed by the proximal tubule cells. This is accomplished by the coordinated function of luminal membrane Na^+/H^+ exchanger, luminal membrane carbonic anhydrase IV and XIV, and basolateral membrane $Na^+/HCO3^-$ cotransporter (30). Hyperchloremic metabolic acidosis is a common feature of FS resulting from defective bicarbonate reabsorption in the proximal tubules. Anion gap is normal. More than 30% of filtered load of $HCO3^-$ is not reabsorbed in patients with FS, and they manifest low plasma $HCO3^-$ levels between 12–18 mEq L^{-1}. Fractional excretion of $HCO3^-$ ($FEHCO3^-$) under the alkali treatment to increase plasma $HCO3^-$ to the normal ranges is >15% in patients with FS.

$$\text{Fractional excretion of } HCO_{3^-}\% = [(UHCO_{3^-}/PHCO_{3^-})/(Ucr/Pcr)] \times 100$$

($HCO3^-$; bicarbonate, cr; creatinine, U; urine, P; plasma)

Acidification in the distal tubule is usually normal or impaired in association with chronic hypokalemia or toxic effect on distal tubules due to the original disorder in patients with FS.

Sodium and Potassium Losses

60–80% of filtered load of Na^+ is reabsorbed in the proximal tubules in the normal condition. Renal Na^+ reabsorption in the proximal tubules decreased in patients with FS. It leads to hyponatremia, hypotension, and dehydration. Hypokalemia is a secondary phenomenon. Increased delivery of Na^+ into the distal tubules and activation of the renin-angiotensin system secondary to hypovolemia cause potassium (K^+) wasting in the distal tubules. Severe hypokalemia can cause sudden death.

Hypercalciuria

Hypercalciuria is a common finding in patients with FS due to several original diseases. Defective endocytosis of parathyroid hormone (PTH) in patients with Dent disease resulting in its persistence in the lumen of the proximal tubule stimulates 25-hyroxyvitamin D3 1-hydroxylase to produce more 1,25-dihydroxyvitamin D3, raising serum levels of this vitamin. 25-hydroxyvitamin D3 is presented to 25-hydroxyvitamin D3 1-hydroxylase in the form of a complex with the vitamin D3-binding protein. As this complex is lost in the urine as a result of defective endocytosis leading to LMW proteinuria, the precursor 25-hydroxyvitamin D3 could be in short supply. The overall outcome of increased 1, 25-dihydroxyvitamin D3 levels may depend on the delicate balance between these processes. The slightly elevated serum levels of 1, 25-dihydroxyvitamin D3 in patients with FS can lead to increased intestinal Ca^{2+} reabsorption which will lead to hypercalciuria (*absorptive hypercalciuria*) (29). Hypercalciuria is rarely associated with nephrolithiasis in FS, possibly because of the polyuria and alkalized urine. However, patients with Dent disease manifest hypercalciuria and nephrolithiasis.

Hyperuricosuria (Uricosuria)

Uric acid (urate) is the end product of purine metabolism in humans. Because of its small molecular size (MW = 126 D), uric acid is freely filtered from the glomerulus. Then, 90–95% of filtered load of uric acid is eventually reabsorbed in the proximal tubules. A four-component hypothesis has been proposed to explain the renal uric acid transport mechanism; it includes glomerular filtration, presecretory reabsorption, secretion, and postsecretory reabsorption (31). Hyperuricosuria is often present in FS, leading to secondary hypouricemia (<2 mg dL^{-1}) (32). A voltage-sensitive uric acid pathway and uric acid exchangers are located at both luminal and basolateral membranes of proximal tubule cells (33). Uric acid-anion exchanger (URAT1) that reabsorbs uric acid from the lumen of the proximal tubules in the luminal membrane of proximal tubules regulates serum uric acid levels. This uric acid-anion exchanger can be disturbed in patients with FS. Defective URAT1 is a predominant cause of the patients with renal hypouricemia who manifest acute renal failure after exercise (34, 35). Hexose transporter gene (*SLC2A9*) is identified as a cause of gout and hyperuricemia (36). This transporter transports both fructose and uric acid. *SLC2A9* produces two isoforms by alternative splicing; the long isoform is expressed in basolateral membrane of proximal tubular cells and the short isoform is expressed in apical membrane of proximal tubular cells. This hexose transporter can be affected in patients with FS. Uric acid is a selective antioxidant, capable especially of reaction with hydroxyradicals and hypochlorous acid, itself being converted to innocuous products such as allantoin, allantoate, glyoxylate, urea, and oxalate (37).

Proteinuria (LMW Proteinuria)

The proximal tubules have a high capacity for uptake of filtered proteins from the glomerulus. The cut off molecular weight for filtration of plasma proteins is assumed to be in the range of 65 KD (kilodaltons) that corresponds to the molecular weight of serum albumin. However, small amount of larger weight proteins including gammaglobulin are filtered from glomerulus in the normal condition. Albumin and LMW proteins (MW<45,000 D) filtered in the glomerulus are considered to be the major source of urinary albumin and LMW proteins. Filtration of albumin and LMW proteins are followed by tubular reabsorption, and thus the resulting albuminuria and LMW proteinuria reflect the combined contribution of these two processes. Dysfunction of both these processes may result in increased urinary excretion of albumin and LMW proteins, and both glomerular injury and tubular impairment have been implicated in the initial events leading to proteinuria. In FS, proteinuria is predominantly caused by the dysfunction of reabsorption in the proximal tubules. Adolescent patients with FS due to Dent disease or Lowe syndrome excrete greatly increased amounts of proteins (1,740 ± 660 mg/day) and peptide (446 ± 145 mg/day). LMW proteins ranging from 2 to 5 KD were present in 12.9 ± 3.9-fold excess in FS compared with normal urine (38). The micropuncture technique in dogs revealed that the filtered load of albumin was 50μg m^{-2} suggesting that a filtered load of albumin is 9 g/day in normal humans (39). However, urinary excretion of protein is less than 0.1–0.15 g/day in the normal condition. Numerous filtered proteins including albumin and LMW proteins from glomerulus are bound to megalin and cubilin in the luminal membrane of proximal tubules. Then, the protein-receptor complex is incorporated into the endosome. The ligand and receptor are disassociated in the endosome; the receptor is recycled back to the luminal membrane and the reabsorbed proteins go into lysosome for further processing. Megalin is a 600 KD glycoprotein and a member of the low-density lipoprotein receptor family. Megalin is expressed in the proximal tubule brush-border and luminal endocytic apparatus. Megalin binds to a number of structurally very different proteins. It contains a large amino-terminal, extracellular domain, a single transmembrane domain and a short carboxy-terminal cytoplasmic tail (*Fig. 42-1*). Cubilin is a multiligand, endocytic receptor. It is a 460 KD protein with little structural homology to known, endocytic receptor (*Fig. 42-1*). Cubilin is expressed in the proximal tubule brush-border and luminal endocytic apparatus. Megalin involved in albumin reabsorption directly as a receptor for albumin, and/or indirectly by affecting the expression and/or endocytic function of cubilin (40, 41). Megalin's expression was decreased in patients with Dent disease. Acidification defect due to endosomal defective ClC-5 in patients with Dent disease disturbs the recycling from intracellular endosome into luminal membrane of the proximal tubule resulting in megalin and cubilin deficiency in the luminal membrane of the proximal tubule.

Etiologies

The causes of FS are divided into three main categories; hereditary, acquired, and exogenous substances (*Table 42-1*). Most of the hereditary FS occurs as one of the manifestations of congenital metabolic disorders or as sporadic or familial disorders. Acquired forms are derived from immunological reactions, nephrotic syndrome or accumulated abnormal proteins. Exogenous substances are composed of drugs, chemical compounds, and heavy metals.

Hereditary Fanconi Syndrome

Dent Disease

Dent disease is an X-linked proximal tubulopathy characterized by LMW protinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, and eventual end stage renal failure. Hypophosphatemic rickets and metabolic acidosis are sometimes seen (42, 43). Almost all of the patients are males. Adult patients with Dent disease manifest FS. However, children with Dent disease often manifest LMW proteinuria and one or two of the manifestations due to proximal tubular dysfunction and this is called partial FS (44). They usually fall into end stage renal failure by the age of 40s. However, this is highly variable, and one third of patients with Dent disease will not develop end stage renal failure. Patients with Dent disease never manifest extrarenal manifestations, except for rickets, which may itself be a consequence of phosphaturia. School children with Dent disease manifest proteinuria. A lot of school children with Dent disease are detected as proteinuria by school urine mass screening program in Japan, and it was called as idiopathic low molecular weight proteinuria (45, 46). Carrier females are often manifest less severe LMW proteinuria and hypercalciuria, depending on X-chromosome inactivation, but they rarely develop clinically significant problems.

Table 42-1
Causes of Fanconi syndrome

Hereditary
• Dent disease
• Lowe syndrome
• Mitochondriopathies
• Cystinosis
• Galactosemia
• Hereditary fructose intolerance
• Glycogen storage disease type I (von Gierke disease)
• Fanconi-Bickel syndrome
• Tyrosinemia
• Wilson disease
• Idiopathic Fanconi syndrome
Acquired
• Nephrotic syndrome
• Myeloma
• Sjögren syndrome
• Renal transplantation
• Acute tubulointerstitial nephritis with uveitis (TINU) syndrome
• Autoimmune interstitial nephritis and membranous nephropathy
• Anorexia nervosa
• Untreated condition of distal renal tubular acidosis
Exogenous substances
• Drugs
• Chemical compounds
• Heavy metals

Dent disease is associated with inactivating mutations in *CLCN5* gene, which encodes 746 amino acids renal specific chloride channel-5 (ClC-5) (8, 47–49). ClC-5 belongs to the family of voltage-dependent chloride channels, which function as homodimeric proteins. ClC-5 is co-expressed with the vacuolar H^+-ATPase and plays a key role in endosomal acidification that is a crucial function in the receptor-mediated endocytic pathway (50). More than 80 distinct *CLCN5* mutations are reported in patients with Dent disease. They are nonsense, missense, frameshift, splice-site, insertional, and deletional mutations, which result in total or partial loss of function. There are no genotype-phenotype correlations as various mutations are associated with different clinical phenotypes, even within the same family.

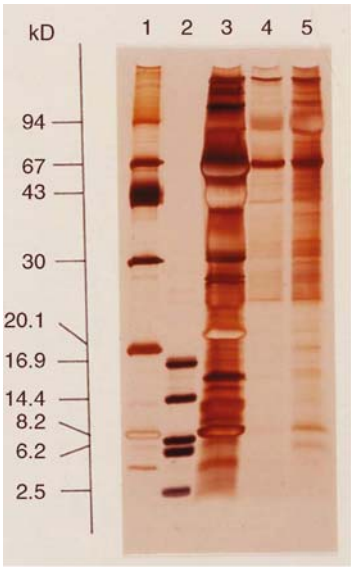
Numerous filtered proteins are bound to megalin and cubilin in the luminal membrane of proximal tubules, and the protein-receptor complex is incorporated into the endosome. The ligand and receptor are disassociated in the endosome; the receptor is recycled back to the luminal membrane and the reabsorbed proteins go into lysosome for further processing. This disassociation is dependent on acidification of the lumen of endosome by increased concentration of H^+ and Cl^- due to the function of H^+-ATPase and ClC-5 chloride channel. An abnormal endocytosis pathway due to ClC-5 dysfunction disturbs the recycling of megalin and cubilin, the back to the luminal membrane, and the expression of megalin and cubilin in the luminal membrane of proximal tubules, leading to LMW proteinuria, hypercalciuria, hyperphosphaturia, and nephrolithiasis. Proper acidification is also important for protein degradation in the endosome. Immunohistochemical analysis of proximal tubule cells in patients with Dent disease revealed an inverted polarity of the H^+-ATPase, with redistribution to basolateral regions, suggesting that the loss of ClC-5 channel alters the function of components that co-distribute and physically interact with it (51).

Total urine protein ranges from 0.5–2.5 g a day, but may reach 4 g or higher in patients with Dent disease (45, 52). More than 60% of the filtered proteins are LMW proteins with molecular weight less than 45 KD (*Fig. 42-3*). Nephrotic syndrome does not occur. LMW proteinuria is the most consistent and one of the earliest presenting abnormalities. Urinary beta 2-microglobulin, a LMW protein (MW = 11.6 KD), is excreted in amounts 100–300 times the upper limit of the normal. Albumin is also excreted in the urine. The pattern of proteins representing the increased excretion of several LMW proteins as well as albumin (MW = 65 KD) is termed as *tubular proteinuria* (52, 53). The terms of LMW proteinuria and tubular proteinuria have usually been used interchangeably (53).

Patients with Dent disease manifest hypercalciuria in the range of 4–10 mg kg^{-1} of body weight a day in children and 4–6 mg kg^{-1} of body weight a day in adults (54). Nephrocalcinosis is also found in children (*Fig. 42-4*). Defective endocytosis of parathyroid hormone (PTH) in patients with Dent disease resulting in its persistence in the lumen of the proximal tubule stimulates 25-hydroxyvitamin D3 1-hydroxylase to produce more 1,25-dihydroxyvitamin D3 resulting in the increased serum levels of this vitamin. 25-hydroxyvitamin D3 is presented to 25-hydroxyvitamin D3 1-hydroxylase in the form of a complex with the vitamin D3-binding protein. As this complex is lost in the urine as a result of defective endocytosis leading to LMW proteinuria, the precursor

Figure 42-3

Electrophoresis of urine from the family members of Dent disease on the polyacrylamide gel and stained by sliver representing LMW proteinuria. Lanes 1 and 2, molecular markers; Lane 3, 12-year-old boy with Dent disease; Lane 4, his mother; Lane 5, his father.



25-hydroxyvitamin D3 could be in short supply. The overall outcome of increased 1, 25-dihydroxyvitamin D3 levels may depend on the delicate balance between these processes. The slightly elevated serum levels of 1, 25-dihydroxyvitamin D3 in patients with Dent disease can lead to increased intestinal Ca^{2+} reabsorption resulting in hypercalciuria (*absorptive hypercalciuria*). In fact, 70% of the patients with *CLCN5* mutations manifest hypercalciuria, even though some of these do exhibit nephrocalcinosis (55). This may be explained by the *CLCN5* knock-out mice model; ClC-5 disruption promotes calcium crystal agglomeration, as well as a redistribution of the crystal-binding molecule annexin A2, in collecting duct epithelial cells (56).

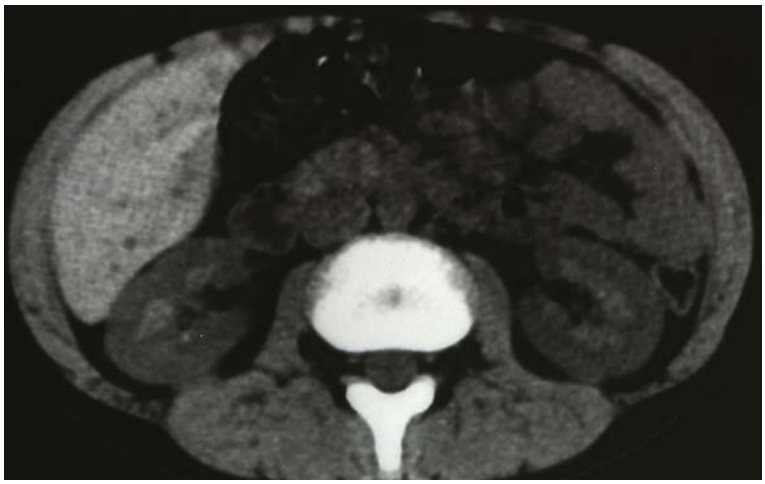
The onset of renal insufficiency and progression to end-stage renal failure are quite variable. Significant decrease of glomerular filtration rate is seen in children with Dent disease, and the patients fall into end-stage renal failure by the end of the age of 40s. Renal biopsy demonstrates normal or focal global glomerulosclerosis with tubular atrophy, tubular dilatation, and interstitial infiltration of monocytes. Medullary nephrocalcinosis is a significant feature in patients with Dent disease. Patients less than 5 years of age manifest medullary nephrocalcinosis. The precise mechanism of progressive renal failure is not known in patients with Dent disease. Nephrocalcinosis can be a candidate to disturb the glomerular filtration rate. High urinary concentrations of potentially bioactive proteins including insulin, insulin like growth factor-1 (IGF-1), and the chemokine monocyte chemoattractant protein-1 (MCP-1) may contribute to interstitial fibrosis that will lead to progressive renal failure in patients with Dent disease (57). Generalized proximal tubule dysfunction is associated with increased cell proliferation, dedifferentiation, and oxidative stress resulting in interstitial fibrosis and eventual renal failure (58). Patients and carrier females often manifest nephrolithiasis, and renal stone is calcium phosphate stone that is also seen in patients with distal renal tubular acidosis.

Dent disease is genetically heterogeneous. Mutations in the *OCRL1* gene are identified in a subset of patients with the Dent disease phenotype (59). Unlike patients with typical Lowe syndrome, typical facial features, mental retardation, metabolic acidosis, and ocular abnormalities are usually absent in patients with Dent disease who have *OCRL1* mutation. The phosphoinositol 4,5-bisphosphate phosphatase (PIP_2 5-phosphatase) activity is markedly reduced in skin fibroblasts cultured from patients with Dent disease due to *OCRL1* mutations, and protein expression, measured by Western blotting, is reduced or absent. PIP_2 5-phosphatase participates the trafficking and recycling of endosome in the proximal tubules. Defective PIP_2 5-phosphatase activity can lead to endosomal dysfunction leading to LMW proteinuria. Unlike the patients with typical Lowe syndrome, none of patients have metabolic acidosis. These observations and findings suggest that *OCRL1* mutations can cause the isolated renal phenotype of Dent disease and affected individuals lack the cataracts, typical facial features, renal tubular acidosis, and neurologic abnormalities that are characteristic to Lowe syndrome. It is difficult to explain that *OCRL1* mutations can cause the isolated renal phenotype of Dent disease. However, it is possible that another phosphatase, *INPP5B*, which shares amino acid homology with *OCRL1*, can compensate phosphatase activity in patients with Dent disease due to *OCRL1* mutations.

There are no specific interventions at present that will change the natural course of renal manifestations and progressive renal failure in patients with Dent disease. Hypercalciuria is corrected by thiazide diuretics therapy in doses similar to effective doses for idiopathic hypercalciuria, presumably by stimulating the reabsorption of calcium in the distal convoluted tubule, where ClC-5 channel is not expressed (60). However, this is not a long-term study which provides the evidence that it is

Figure 42-4

Abdominal CT demonstrating bilateral medullary nephrocalcinosis in a 12-year-old boy with Dent disease.



effective to prevent or delay the progression of end stage renal failure. In animal experiment using *clcn5* (mouse chloride channel 5 gene) knock-out mice, high citrate diets can delay the progression of nephrocalcinosis and end stage renal failure (61, 62). Treatment with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) may delay progression of end stage renal failure (63).

Lowe Syndrome

The oculocerebrorenal syndrome of Lowe (OCRL) is a rare X-linked disorder that is characterized by a complex phenotype that involves major abnormalities of the eyes (particularly congenital cataracts), central nervous system abnormality and FS (64). Cataracts are recognized in all the male patients. Lens opacities are present in all carriers of females by slit-lamp examination and this is a reliable screen for carriers (65). Other ocular abnormalities include glaucoma, microphthalmos, and corneal keloid formation. Visual acuity is frequently disturbed. Central nervous system abnormalities include infantile hypotonia (floppy infant), areflexia, and mental retardation. The patients manifest mild ventriculomegaly and cysts in the periventricular regions in the brain. Status epilepticus is sometimes recognized. FS is a major clinical feature and occurs in the 1st year of life, but the severity and age of onset vary. The patients manifest LMW proteinuria, glucosuria, aminoaciduria, hyperphosphaturia, hypercalciuria, hypophosphatemic rickets, hypercholoremic metabolic acidosis, and progressive renal insufficiency (66). Renal insufficiency progresses at variable rate among patients, and it progresses to end-stage renal failure by 30s or 40s.

Like in patients with Dent disease, megalin is nearly absent from the urine in patients with Lowe syndrome suggesting of the decreased expression of megalin in the luminal membrane of the proximal tubule cells. Thus, urinary excretion of retinol-binding protein and the lysosomal enzyme N-acetyl-glucosaminidase are significantly increased in young boys with OCRL (67).

The gene (*OCRL1*) that is responsible for OCRL encodes a 105 KD Golgi protein with phosphoinositol 4,5-bisphosphate phosphatase (PIP_2 5-phosphatase) activity (68). PIP_2 5-phosphatase is mainly a lipid phosphatase that may control cellular levels of a critical metabolite, phosphatidylinositol 4,5-bisphosphate, and is involved in the inositol phosphatase signaling pathway (69). PIP_2 5-phosphatase is present in cultured skin fibroblast and it is not present in peripheral blood cells. PIP_2 5-phosphatase activity is markedly reduced in fibroblasts from patients with Lowe syndrome (70). However, this biochemical test for carrier diagnosis is not reliable; lyonization produces a highly variable pattern of tissue expression in females.

Deficiency of PIP_2 5-phosphatase leads to cellular accumulation of its substrate PIP_2. PIP_2 accumulates in lysosomal membrane (71). PIP_2 is involved in signal transduction, vesicle trafficking and actin polymerization. Absence of PIP_2 5-phosphatase activity leads to a reduction in the number and length of actin stress fibers, a tendency of actin fibers to depolymerize when provoked,

and an abnormal distribution of two actin-binding protein gelsolin and alpha-actinin. This disruption of actin function has significant effects on epithelial function through disrupting cell–cell contacts such as tight junctions or adherent junctions or by altering membrane trafficking such as transport proteins (72). Trans-Golgi dysfunction or altered actin polymerization can explain FS in patients with Lowe syndrome. PIP_2 5-phosphatase is localized to endosome and Golgi membranes along with clathrin, giantin, the mannose 6-phosphate receptor, transferrin, and the early endosomal antigen 1 marker. PIP_2 5-phosphatase interacts with clathrin terminal domain and the clathrin adaptor protein AP-2. This suggests a role for PIP_2 5-phosphatase in endosomal receptor trafficking and sorting (73, 74). OCRL1 is present throughout the early endocytic pathway, including in endocytic clathirin-coated pits, and demonstrate a connection between OCRL1 and adaptor molecules implicated in the endocytic trafficking of receptor in the kidney (75).

OCRL1 has a C-terminal RhoGAP domain. *OCRL1* encodes a PIP_2 5-phosphatase activity that binds to Rac GTPase. Activated Rac GTPase stably associates with the *OCRL1* RhoGAP domain. In this sense, the protein encoded in *OCRL1* can play a bifunctional role. Loss of *OCRL1* RhoGAP domain and the resulting alteration in Rho pathways may contribute to mental retardation in Lowe syndrome, as observed in other forms of X-linked mental retardation (76).

OCRL1 mutations can cause the isolated renal phenotype of Dent disease and affected individuals lack the cataracts, typical facial features, renal tubular acidosis, and neurologic abnormalities that are characteristic to Lowe syndrome. It is difficult to explain that *OCRL1* mutations can cause the isolated renal phenotype of Dent disease. However, another phosphatase, *INPP5B*, which shares amino acid homology with *OCRL1,* can compensate phosphatase activity in patients with Dent disease due to *OCRL* mutations.

More than 70 *OCRL1* mutations have been described in patients with Lowe syndrome; nearly all are clustered in exons 10–23, especially exon 15, and almost none are found in exons 1–9 (70).

Treatment is supportive and includes taking care of ocular manifestations, anticonvulsants, speech therapy, and dental complications. The eye abnormalities usually require therapy early in life. Bicarbonate therapy is usually necessary at a dose of 2–3 mmol kg^{-1} of body weight a day every 6–8 h. Sodium or potassium phosphate can be given in amounts of 1–4 g a day for phosphate depletion and if unsuccessful, vitamin D can be given.

Mitochondriopathies

The mitochondria (mt) have a major role in fatty acid oxidation, tricarboxylic acid cycle, urea cycle, and ATP production through the process of oxidative phosphorylation. Oxidative phosphorylation occurs at the level of the respiratory chain in the inner membrane of the mt (77). The respiratory chain comprises five components (*Fig. 42-5*). Complex I (NADH-coenzyme Q reductase) carries reducing equivalents from NADH to coenzyme Q and consists of different polypeptides, seven of which are encoded by mitochondrial DNA (mtDNA). Complex II (succinate-coenzyme Q reductase) carries reducing equivalents from $FADH_2$ to coenzyme Q and contains five polypeptides that are all encoded only by mtDNA. Complex III (reduced coenzyme Q-cytochrome c reductase) carries reducing equivalents from coenzyme Q to cytochrome c and contains 11 subunits, one of which is encoded by mtDNA. Complex IV (cytochrome c oxidase) transfers reducing equivalents from cytochrome c to oxygen. This complex is composed of cytochromes a and a3, and 13 protein subunits, three of which are encoded by mtDNA. The fifth complex is ATP synthetase.

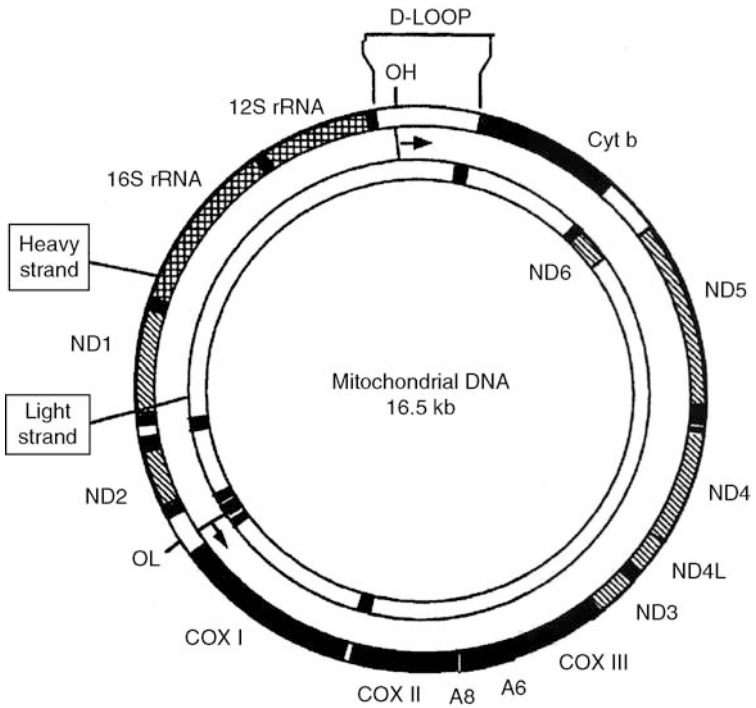
Oxidative phosphorylation consists of oxidative reactions that lead to oxygen consumption and phosphorylation of ADP to ATP. Each mt have its own 2–10 mtDNA. MtDNA genome is a 16.5 kb circular double stranded DNA with an asymmetrical base composition. The heavy strand contains more guanine residues while the light strand contains more cytosine residues. The mtDNA contains 37 genes; 13 encode for polypeptides of the respiratory chain, 2 for the ribosomal RNAs and 22 for transfer RNAs (78). Mitochondrial injury is due to congenital insults or may be the result of secondary events. Genetic defects of one or several polypeptide enzyme complexes of the oxidative phosphorylation system in the mt DNA or nuclear DNA which encodes structural or functional mitochondrial proteins can give rise to mitochondriopathies (mitochondrial cytopathies, mitochondrial diseases) (79).

Mitochondriopathies are multi-systemic disease and may begin at any age. Affected organs are diverse including central nervous system, muscle, liver, heart, kidney, gut, endocrine system, bone marrow, ear, eye, and skin (*Table 42-2*). They display extreme heterogeneity, and make unpredictable the extent and manifestations of disease presentation (80). With the course of the disease, the numbers of organs involved are increased.

The screening for mitochondriopathies includes the determination of plasma lactate, pyruvate, keton bodies and their ratios in fasted and fed patients, polarographic, and spectrometric studies to evaluate the different

Figure 42-5

Map of mitochondria genome. Regions encoding cytochrome b (ctb b), various subunits of NADH-coenzyme Q reductase (ND), cytochrome c oxidase (COX), ATPase, and ribosomal RNAs (rRNA) are indicated (Niaudet P, Rötig A. The kidney in mitochondrial cytopathies. *Kidney Int* 1997;51:1000–1007).



enzymatic complexes of the respiratory chain, muscle histologic studies, and genetic analysis (4).

Renal disease may be the first sign of mitochondriopathies, or it may appear simultaneously with neurological and neuromuscular signs (81). FS is particularly frequent in newborns, infants, and young children (82–84), whereas tubulointerstitial nephropathy is more frequent in children and young adults (85, 86), and can be associated with hereditary focal segmental glomerulosclerosis due to the mitochondrial transfer RNA gene mutation (87–89) and collapsing glomerulopathy due to the mutations in the gene *COQ2* encoding the parahydroxybenzoate-polyprenyl-transferase enzyme of the CoQ10 synthesis pathway (CoQ2 nephropathy) and in the gene *PDSS2* encoding for decaprenyl diphosphate synthase (90, 91).

Most patients with FS due to mitochondriopathies manifest moderate FS including failure to thrive, dehydration, aminoaciduria, glucosuria, proteinuria, LMW proteinuria, phoshaturia, uricosuria, hypercalciuria, and bicarbonaturia. Many patients manifest FS by the age of 2 years. Extra-renal manifestations including neurological symptoms, myopathy, hepatic dysfunction, clinical features of Pearson syndrome, partial adrenal insufficiency, cardiac involvement, diabetes mellitus, deafness, and ophthalmoplegia often manifest in the patients (12, 92, 93). Patients who manifested proximal tubular acidosis with hypercalciuria or Bartter syndrome were described (94, 95). Some patients manifest progressive renal failure (96). Histological analysis reveals tubular dilatations, tubular atrophy and cytoplasmic vacuolization of the tubules. Bizarre giant mitochondria are frequently observed (97).

No satisfactory treatment is presently available to alter the course of mitochondriopathies. The treatment is mainly symptomatic: supplements of sodium bicarbonate, potassium, vitamin D3, phosphate, and water are necessary. Carnitine is given in case of secondary carnitine deficiency. It includes avoidance of drugs that interfere with the respiratory chain such as valproate and barbiturates, or that inhibit mitochondrial protein synthesis such as tetracyclines and chloramphenicol. Dietary recommendations include a high lipid and low carbohydrate diet in patients with complex I deficiency. Hypercaloric diet and parenteral nutrition should be avoided in these patients.

Table 42-2
Clinical symptoms in patients with mitochondriopathies

Affected organs	Symptoms
Central nervous system	Apnea, lethargy, hypotonia, coma, pshycomotor retardation, cerebellar ataxia, stroke-like episodes, myoclonus, seizures, dementia, spasticity, headache, hemiparesis
Muscle	Myopathy, poor head control, limb weakness, myalgia, exercise intolerance
Liver	Hepatomegaly, liver dysfunction
Heart	Cardiomyopathy, arrhythmia
Kidney	Fanconi syndrome, tubulointerstitial nephropathy, nephrotic syndrome (focal segmental glomerulosclerosis, collapsing nephropathy), renal failure
Gut	Vomiting, diarrhea, villous atrophy, cholonic pseudoobstruction, pancreatic dysfunction
Endocrine	Diabetes mellitus, growth hormone deficiency, hypoparathyroidism, hypothyroidism, adrenal insufficiency
Bone marrow	Sideroblastic anemia, neutorpenia, thrombocytopenia
Ear	Hearing loss
Eye	Progressive extrarenal ophthalmoplegia, pigmentary retinal degeneration, ptosis, diplogia, cataract
Skin	Mottled pigmentation, trichothiodystrophy

Cystinosis

Cystinosis is reviewed in detail in Chapter 41 of this textbook, and therefore only a short description is included here. Cystinosis is an autosomal recessive lysosomal storage disorder characterized by an accumulation of cystine, the disulfide of the amino acid cysteine, in the systemic organs, notably kidney, cornea, bone marrow, thyroid, lymph nodes, liver, and spleen (98). Renal manifestations dominate the clinical presentation and course in infantile cystinosis. Cystinosis is the most common familial form of the FS in Western countries. Many patients, particularly in North America, have blonde or reddish-blonde hair. Other organs frequently affected include the cornea and thyroid, causing painful photophobia and hypothyroidism respectively.

Various clinical forms of the disease exist and are based on age at onset and severity of the symptoms (*Table 42-3*). The most severe form, infantile cystinosis, is manifested by failure to thrive, polyuria, polydypsia, dehydration, fluid and electrolyte loss, aminoaciduria, glucosuria, phosphaturia, renal tubular acidosis between 6 and 12 months of age. Some of the patients may develop vitamin D-resistant rickets due to phosphaturia and manifest severe growth failure. Renal function is generally normal at presentation. However, subsequent glomerular impairment leads to focal segmental glomerulosclerosis and eventually to end stage renal failure by 10 years of age without treatment (99). Patients with infantile cystinosis manifest FS, including hyperchloremic metabolic acidosis, aminoaciduria, hypokalemia, hypophosphatemia, glucosuria, and phosphaturia. There have been several patients of nephropathic cystinosis presenting with features of secondary Bartter syndrome (hypokalemia, hyperchloremic metabolic alkalosis, hyperreninemia, and hyperaldosteronism), suggesting abnormalities of Na^+ and Cl^- reabsorption (100, 101). Patients with cystinosis often manifest medullary nephrocalcinosis (102).

Renal histopathologic changes in infantile cystinosis include severe lesions of proximal tubules; typical alterations to the glomerular podocytes, which become multinucleated giant cells; and the presence of cystine crystals, mostly in interstitial cells and podocytes (103). The proximal tubule is the first clinical target of the disease, but cystine crystals are rarely found in the tubular cells of patients with cystinosis. Cystine crystal deposition in the cornea leads to photophobia. Continuous widespread cystine accumulation eventually leads to rickets and retinal, endocrinologic (hypothyroidism and impaired glucose tolerance), hepatic, gastrointestinal, muscular, and neurological abnormalities.

Two less severe and less common form of cystinosis are juvenile (or late-onset) and ocular cystinosis. Patients with juvenile cystinosis manifest glomerular impairment between 12 and 15 years of age but do not suffer from severe tubulopathy or growth failure. Progression to end stage renal failure is slow and occurs at

Table 42-3

[a]may be transient and coexist with common manifestations

variable ages (104). Patients with ocular cystinosis do not involve kidney.

Infantile cystinosis is caused by mutations of the *CNTS* gene encoding cystinosin, a lysosomal transport protein, leading to complete abolition of cystine transport (105). Cystinosin has 367 amino acids and seven transmembrane domains. Cystine transport is dependent on the pH gradient, and the transport of cystine out of the lysosome is driven by the high H^+ content within the lysosomal lumen that is produced by the activity of the H^+-ATPase. A range of mutations in *CNTS* gene has been described, but a single mutation, a 57-kb intragenic deletion, accounts for as many as three quarters of all European cases (105). The adolescent and ocular forms have one severe and one mild *CTNS* mutation, leading to reduced transport activity. The sparing of the kidney in patients with ocular cystinosis reflects tissue-specific expression of splicing factors, or the increased endogenous level of *CTNS* mRNA normally seen in the kidney (106). Individuals who are heterozygous for severe *CTNS* mutations reveal elevated levels of leukocyte cystine but are completely asymptomatic.

The pathophysiology of tubular cystine transport defects in patients with cystinosis is poorly understood, reflecting of an animal model for the disease. Knock-out mice model lacking cystinosin gene do not manifest signs of FS, despite accumulation of lysosomal cystine in the proximal tubules (107). Cystine-loaded proximal tubular cells demonstrate loss of free phosphate and defective ATP production and inhibition of Na^+-dependent transporters (108). ATP depletion can reduce proximal tubular Na^+, K^+-ATPase activity leading to increased Na^+ delivery into the distal tubules and Bartter syndrome (101). A cell culture demonstrated that cells accumulated with intracellular cystine undergo apoptosis at a rate two- to four-fold higher than controls (109). Another works suggests that increased oxidative stress and altered redox status in proximal tubule cells cultured from the urine of patients with cystinosis are associated with proximal tubule dysfunction (110).

The diagnosis of cystinosis is confirmed by demonstrating elevated cystine levels in peripheral leukocytes (97). Corneal crystals detected by slit-lamp examination are diagnostic in childhood cystinosis because these crystals are not seen in patients with other hereditary FS. However, this finding is not sensitive for early diagnosis. The renal pathologic findings in infantile cystinosis consist of a chronic tubulointerstitial nephropathy, with characteristic multinucleated podocytes and intracellular crystalline inclusions in interstitial histiocytes (111). Although numerous multinucleated podocytes are the most characteristic pathologic findings, they are not found in the sclerotic glomeruli and detected only in low frequency (<4%). The cystine crystals are birefringent under polarized light in only alcohol-fixed tissue or in unfixed frozen tissue, because they are water-soluble and not retained in the tissue after routine histologic preparation with aqueous solutions (112).

The management and treatment for infantile cystinosis involve supportive therapy to maintain fluid balance and replace electrolyte losses at initial presentation. Early diagnosis and oral cysteamine, a cystine-depleting agent, can delay the progression of end stage renal failure and other organ involvement. Oral cysteamine therapy given at doses of 60–90 mg kg^{-1} of body weight (or between 1.3 and 1.95 g m^{-2}) a day divided every 6 h generally achieves approximately 90% depletion of cellular cystine, as measured in circulating leukocytes (<1.0 nmol half-cystine/mg protein) (113). The dosage recommended for adults is 500 mg every 6 h, but higher dosages are often required to achieve satisfactory cystine depletion. On the basis of its beneficial effects in maintaining thyroid function and depleting muscle of cystine, oral cysteamine

therapy should continue in patients after renal transplantation to help preserve other organs. Administration of 0.55% cysteamine eye-drops, given 6–12 times a day, can dissolve corneal cystine crystals and lessen visual symptoms (114). Other therapies to supply potassium, alkalinizing agents including citrate or bicarbonate, phosphate, and vitamin D3 are required. When the growth velocity has not improved and the patient remains below the 3rd percentile for height after one year of therapy, growth hormone therapy may be considered.

Galactosemia

Galactosemia is an autosomal recessive disease of galactose metabolism. Nursing infants must move large amounts of galactose through Leloir pathway in order to utilize the carbon skeletons for energy (*Fig. 42-6*). Galactose is the preferred carbon source in mammalian neonates, since it is incorporated into glycogen more efficiently than is glucose (115).

The most frequent form is classic galactosemia that is due to the deficient activity of galactose-1-phosphate uridyl-transferase (GALT) encoded by *GALT1* (116). GALT catalyzes the reaction of galactose-1-phosphate (gal-1-p) plus uridine diphosphate glucose to uridine diphosphate galactose plus glucose-phosphate. Uridine diphophate galactose can be further metabolized to either glucose or CO_2 and H_2O via glycolysis. Milk is a major source of galactose. Accumulated gal-1-p due to defective GALT and exposure to galactose lead to acute deterioration of multiple organ systems, including liver, kidney, ovary, brain, and eye. Affected infant patients manifest vomiting, diarrhea, failure to thrive, developmental delay, liver dysfunction, coagulopathy, renal tubular dysfunction, cerebral edema, vitreous hemorrhage, and *Escherichia coli* sepsis. They sometimes manifest jaundice and unconjugated hyperbilirubinemia and may have severe hemolysis. Liver damage leads to hepatomegaly and cirrhosis that is potentially lethal. Neonatal screening program includes galactosemia, anticipating that early detection and intervention would prevent long-term complications such as mental retardation, premature ovarian failure, and speech delay. Although a galactose-restricted diet prevents the neonatal death, many well-treated patients continue to develop debilitating complications (117, 118). Clinically evident speech delay and cerebellar signs are more frequent than other findings. Premature ovarian failure is nearly universal in females with galactosemia. The predominant manifestation due to kidney damage is FS including hyperaminoaciduria, LMW proteinuria, hyperphosphaturia, and bicarbonaturia (118). Patients placed on a galactose-restricted diet are never truly free of galactose insult, as a significant amount of galactose is found in non-dairy foodstuffs such as vegetables and fruits (119, 120). More importantly, galctose moieties can be produced endogenously from UDP-glucose via the UDP-4-galactose epimerase reaction, and natural turnover of glycoproteins/glycolipid; the rate of endogenous galactose synthesis ranges from 0.53–1.05 mg kg^{-1} of body weight a day (121, 122). Once the lactose is formed intracellularly, it will be converted to gal-1-p by GALT. The less common form of galactosemia is a deficiency of galactose kinase (GALK), which forms gal-1-p from galactose. These patients do not manifest either the acute toxicity syndrome or chronic complications seen in patients with classic galactosemia. They manifest cataracts. Since GALK-deficient patients do not accumulate gal-1-p in their tissues, gal-1-p is considered to play a significant role in the pathogenesis of classic galactosemia (123, 124). GALT deficiency results in accumulation of toxic galactose leading to the unfolded proteins, altered calcium homeostasis and subsequently endoplasmic reticulum (ER) stress (125). ER stress caused by GALT-deficiency might contribute to accelerated apoptosis seen in the granulose cells maturing follicles in galactosemic females, leading to premature ovarian failure (126). Formation of galactitol from galactose by aldose reductase has been proposed as a pathogenetic mechanism and is at least responsible for cataract formation.

The diagnosis is suggested by galactose or galactose 1-phosphate in serum, or in the urine. The diagnosis is confirmed by demonstrating deficient GALT activity in red blood cells, fibroblasts, leukocytes, or hepatocytes.

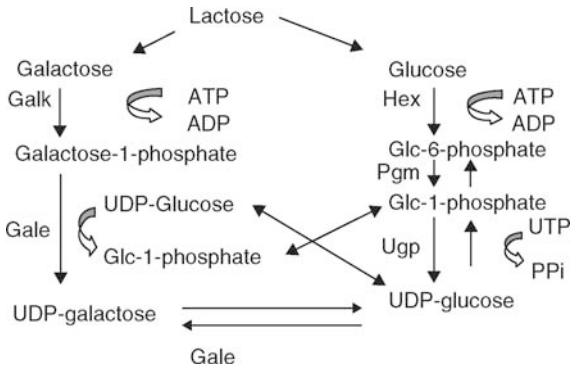
Treatment of this disorder is elimination of galactose from the diet. Acute symptoms and signs resolve within a few days after starting the diet therapy. However, developmental delay, speech disturbance, ovarian dysfunction, and growth retardation are common outcomes in this disorder (127).

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder caused by a deficiency of aldolase B, an enzyme of liver, intestine, and renal cortex catalyzing the metabolism of fructose of exogenous origin (128). Frequency of HFI is estimated at 1 in 20,000 live births. Aldolase B catalyses the specific and reversible cleavage of

Figure 42-6

Composite diagram of the Leloir pathway and uridine diphosphate (UDP)-glucose pyrophosphorylase pathway. *Galk*, galactokinase; *galt*, galactose-1-phosphate uridyltransferase; *Gale*, UDP-galactose 4-epimerase; *Hex*, hexokinase; Pgm, phosphoglucomutase; *Ugp*, UDP-glucose pyrophosphorylase (Leslie ND. Insights into pathogenesis of galatosemia. *Annu Rev Nutr* 2003;23:59–80).



fructose-1,6-bisphophate (FBP) and fructose-1-phosphate (F1P) into dihydroxyacetone phosphate and D-glyceraldehyde-3-phophate, or D-glyceraldehyde, respectively. Aldolase B is equally active with FBP and F1P, whereas aldolase A and aldolase C, the other two vertebrate isozymes, are more active with FBP than with F1P. Aldolase B is encoded in Aldolase B gene *(ALDOB)* mapped to chromosome 9q21.3–q22.2 (129, 130). Missense and nonsense mutations, large and small gene deletions and mutations in the splicing region have been identified in *ALDOB* of HFI patients (131).

Affected individuals manifest symptomatic hypoglycemia, vomiting and life-threatening episodes shortly after the intake of fructose or related sugars including sucrose and sorbitol (132). Prolonged ingestion leads to failure to thrive, hepatomegaly, jaundice, hepatic cirrhosis, and nephrocalcinosis, and may lead to convulsions, coma, and death from severe liver and kidney failure. Symptoms of HFI appear during infancy when infants with HFI are fed a formula or foods including fruits, vegetables, and sweetened cereals that contain sucrose. Patients with HFI may develop a protective aversion to sweets and fruits, which is a reason that diagnosis is frequently missed, and which also explains that reliable prevalence numbers for different populations do not exist.

HFI is associated with proximal tubule dysfunction leading to aminoaciduria, bicarbonaturia, phosphaturia, and lactic acidosis. These manifestations appear rapidly after the ingestion of fructose (133, 134). The development of lactic acidosis adds significantly to the metabolic acidosis (135). Chronic fructose ingestion leads to nephrocalcinosis and impaired distal tubular function. In contrast, resolution of proximal tubule dysfunction can take days or weeks with strict restriction of fructose and sucrose (136).

Aldolase B coexists abundantly in endocytosis zones of the proximal tubule cells with H^+-ATPase (137). Nonfunctional aldolase B impairs the coupling of H^+-ATPase to glycolysis and endosomal acidification that will lead to FS.

Diagnosis includes the metabolic response to an intravenous fructose load or an enzymatic assay of liver or intestinal biopsy samples. However, both of them are bothering and invasive (138). Fructose breath hydrogen test is one of the standard procedures for the diagnosis. However, it can develop life-threatening adverse effects during the test (139). Molecular analysis is available for the diagnosis.

Strict avoidance of foods or drugs containing fructose, sucrose, and sorbitol is the predominant treatment.

Glycogen Storage Disease Type I (von Gierke Disease)

Glycogen storage disease type I (GSD-I) is a group of autosomal recessive disorders with an incidence of 1 in 100,000. There are two major subtypes. Glycogen storage disease type Ia (GSD-Ia, von Gierke disease) is common and is caused by s deficiency in glucose-6-phosphatase-alpha (G6Pase-alpha), a key enzyme in glucose homeostasis that catalyzes the hydrolysis of glucose-6-phosphate (G6P) to glucose and phosphate in the terminal step of gluconeogenesis and glycogenolysis (140). G6Pase-alpha is a hydrophobic endoplasmic reticulum-associated transmembrane protein. Glycogen storage disease type Ib (GSD-Ib) is caused by a deficiency of microsomal glucose-6-phosphatase transporter (G6PT). G6PT translocates G6P from cytoplasm to the lumen of the endoplasmic reticulum. Therefore, G6PT and G6Pase-alpha work in concert to maintain glucose homeostasis. Whereas G6Pase is exclusively expressed in gluconeogenic cells, G6PT is ubiquitously expressed and its deficiency generally causes a more severe phenotype.

Patients with GSD-Ia manifest a phenotype of disturbed glucose homeostasis characterized by fast life-threatening hypoglycemia, hepatomegaly, nephromegaly, hypercholesterolemia, hypertriglyceridemia, hyperuricemia, lactic acidemia, neutrophilia, and growth retardation (141, 142). Infants with GSD-Ia typically present with

seizures and hepatomegaly at 6–8 months of age. Approximately 75% of adolescent and adult patients develop hepatocellular adenoma (HCA), which can lead to considerable morbidity and mortality (143). The incidence of HCA to hepatocellular carcinoma is recently increasing because the patients can live longer than before (144). The presence of GSD-Ia and GSD-Ib are associated with reduced quality of life, independent functioning, and elevated levels of internalizing distress, and parental stress relative to healthy peers.

Renal complications include renal enlargement, gout nephropathy, renal stones, nephrocalcinosis, Fanconi-like syndrome, and chronic renal disease leading to renal insufficiency (145). Hepatomegaly is a common finding in GSD-Ia. Hyperuricemia and uric acid stone in GSD-Ia are explained by a combination of increased synthesis of purine and a competitive inhibition of renal tubular excretion of uric acid (urate) by lactate (146). Proximal tubular dysfunction has been observed in patients with GSD-Ia. Patients manifest proximal renal tubular acidosis due to loss of bicarbonate in the urine, hyperphosphaturia, generalized aminoaciduria and increased excretion of beta 2-microglobulin which are ameliorated by intensive diet therapy (147, 148). This finding suggests that good metabolic control can prevent proximal tubular dysfunction. Chronic renal disease is a long-term complication. Renal biopsies reveal interstitial fibrosis, tubular atrophy, and focal segmental glomerulosclerosis with marked glomerular basement membrane (GBM) thickening and lamellation in patients with GSD-Ia (149–151). Glycogen granules are present in the areas of abnormal GBM. The glycogen content in the mesangium and in the epithelial, mesangial and endothelial cells is increased. Recent treatment has significantly alleviated the metabolic abnormalities and delayed the clinical manifestation of chronic renal disease and renal insufficiency in patients with GSD-Ia. However, glomerular hyperfiltration, hypercalciuria, hypocitraturia that worsens with age, and urinary albumin excretion still occur in metabolically compensated patients with GSD-Ia (152, 153). Although the molecular mechanism responsible for chronic renal disease is still poorly understood, activation of the angiotensin system is suggested to have an important role for the disease progression (154). The expression of TGF-beta 1 in kidney tissue is increased in a patient with GSD-Ia manifesting proteinuria, interstitial fibrosis, and tubular atrophy (155).

The objective of treatment is to maintain normoglycemia to avoid metabolic complications and lactic acidosis. Normoglycemia is accomplished at night with nasogastric feeding of glucose or with orally administered uncooked cornstarch (156). A single dose (1.75–2.5 g kg^{-1} of body weight) of uncooked cornstarch will maintain serum glucose concentration higher than 3.9 mmol L^{-1} for 7 h in most young adults (157, 158).

Liver transplantation is indicated in the patients when medical treatment fails to control the metabolic problems or when HCA or hepatocellular carcinoma develops. Living-donor liver transplantation is a viable option to restore normal metabolic balance and keeping normal renal function (159). Hepatocyte transplantation can be a potential therapeutic intervention to prevent hypoglycemia despite the discontinuation of cornstarch meals (160).

Fanconi-Bickel Syndrome

Fanconi-Bickel syndrome (FBS) is an autosomal recessive disorder characterized by failure to thrive, "doll-like" face, hepatomegaly, nephromegaly, and severe rickets. Patients with FBS manifest glycogen accumulation in hepatocytes and proximal tubular cells, fasting hypoglycemia, galactose intolerance, and FS including glucosuria, aminoaciduria, hyperuricosuria, hyperphosphaturia, proteinuria, and sodium and potassium wastage (161, 162). Some patients manifest cataracts in neonatal period (163). Overall prognosis of FGS is considered as favorable (164). However, some patients manifest neonatal diabetes mellitus and galactosemia and die of hepatic failure during infancy (165).

FBS is caused by the mutations in facilitative glucose transporter gene (*SLC2A2*, also referred to as *GLUT2*) expressed in liver, kidney, intestine, and pancreatic islet cells (166). Over 60 mutations in *SLC2A2* were reported (167). This facilitative glucose transporter is expressed in hepatocytes, pancreatic beta cells, and renal and intestinal epithelial cells and is important for the exchange of glucose between these cell types and the bloodstream (168). Renal histology reveals an increase in mesangial cellularity, glomerulosclerosia, and patchy swelling of epithelial foot process and irregularly thickened lamina rara interna in the glumeruli, and vacuolization of epithelial nuclei in the proximal tubule cells suggesting the presence of glycogen in a 7 year-old patient with FBS (169).

The therapy for FBS is directed at the renal solute losses including sodium bicarbonate and potassium-sodium phosphate; treatment of rickets including active vitamin D3; and frequent feeding including night-time supplementation to prevent ketosis. Uncooked cornstarch has been shown to lessen hypoglycemia and improved growth (170). Galactose–free milk is also used for infant patients (165, 171).

Tyrosinemia I

Hereditary tyrosinemia type I (TI) is an autosomal recessive disorder of an amino acid metabolism. TI is due to the defect in the fumarylacetoacetate hydrolase (FAH) gene (172, 173). FAH is the last enzyme in the tyrosine catabolic pathway.

Patients with TI display a variety of clinical symptoms, such as liver damage from infancy that advances to cirrhosis, reduced coagulation factors, hypoglycemia, high plasma concentrations of methionine, phenylalanine, and aminolevulinic acid, high risk of hepatocellular carcinoma, and tubular and glomerular renal dysfunction (174).

Progressive renal damage begins from early infancy in severe form. Chronic liver damage with a high incidence of hepatoma (hepatocellular carcinoma) is characteristic in milder form (175). Even a patient without clinical manifestations of TI can manifest hepatoma during childhood (176). Accumulated fumarylacetoacetate in the patients with TI is pathogenic for hepatoma. Patients with milder form of TI are at risk for acute exacerbation of liver dysfunction. A common presentation mode is the "acute hepatic crisis" in which ascites, jaundice, and gastrointestinal bleeding are precipitated by an acute event such as an infection. Acute hepatic crises usually resolve spontaneously but on occasion progress to complete liver failure and encephalopathy. Acute, painful peripheral neuropathy may appear and can lead to transient paralysis. Autonomic dysfunction with hypertension and tachycardia can be associated with this acute neuropathy (177). Plasma tyrosine and methionine levels usually are elevated in untreated patients. The presence of succinylacetone in plasma and urine is diagnostic of TI. A rapid ultra performance liquid chromatography tandem mass spectrometric method is used for mass screening of tyrosinemia (178).

FS and developmental hypophosphatemic rickets are features of the kidney involvement. Generalized aminoaciduria, renal tubular acidosis, and mild proteinuria are also often seen, whereas glucosuria is less common because plasma glucose levels are low. Kidney enlargement is common, and nephrocalcinosis can be seen (179). FS leads to carnitine deficiency (180). Glomerulosclerosis and impaired GFR may be seen with time.

Disturbances in tyrosine metabolism lead to increased levels of succinylacetone and succinylacetoacetate. However, the mechanisms causing liver failure, cirrhosis, renal tubular dysfunction, and hepatocarcinoma are still unknown. Apoptosis of hepatocytes and renal tubular epithelial cells are characteristic features of this disease and the apoptotic signal in this disease seems to be initiated by fumarylacetoacetate (181, 182). Accumulated maleylacetoacetate and fumarylacetoacetate in affected tissues can react with free sulfhydryl groups and reduce intracellular levels of glutathione. They may be capable of acting as alkylating agents. Maleylacetoacetate and fumarylacetoacetate are not detectable in plasma or urine but are converted to succinylacetoacetate. Succinylacetone, a metabolite of succinylacetoacetate, is structurally similar to maleic acid, which is known to induce FS and may be the cause of tubular dysfunction of HI. Experimentally, succinylacetone administration to rats leads to FS (183, 184).

Treatment with a low-phenylalanine and low-tyrosine diet dramatically improves the renal tubular dysfunction (185). However, this treatment cannot necessarily improve the hepatic involvement. Moreover, there is a risk of inducing deficiencies of phenylalanine or tyrosine. The formation of pathogenic fumarylacetoacetae is prevented by 2- (2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC). NTBC is used for the patients with TI during the first 6 months of life in addition to a diet low in tyrosine and phenylalanine. NTPC clearly improves the vital prognosis and quality of life in the patients (186). However, some patients with NTBC treatment develop hepatoma. A rise of alpha-fetoprotein (AFP), a slow AFP decrease, and never normalizing levels of AFP are important predictors of hepatoma development (187). Liver transplantation has been used for patients with liver failure and to prevent the development of hepatoma (174). Liver transplantation leads to rapid correction of FS (188).

Wilson Disease

Wilson disease (WD, progressive hepatolenticular degeneration) is an autosomal recessive inborn error of copper (Cu) metabolism that affects numerous organ systems (189). Biliary excretion of Cu and incorporation into ceruloplasmin is impaired, leading to liver damage, neuronal degeneration, and impairment of other organs from accumulation of Cu in patients with WD.

The majority of patients with WD presents with either predominantly hepatic or neuropsychiatric symptoms, and with either clinically asymptomatic or symptomatic liver involvement. Approximately 40% of patients presents with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities. Symptoms rarely occur before 6 years of age. Hepatic involvement includes acute hepatitis, fulminant hepatic failure, or progressive chronic liver disease in the form of either chronic

active hepatitis or cirrhosis of the macronodular type. Neuropsychiatric involvements are variable. The most common initial presentation is bulbar symptoms characterized by difficulties with speech and swallowing, and drooling. They frequently manifest dysarthria and coordination defects of voluntary movements accompanied by involuntary movements. One third of the patients with WD manifest psychiatric disturbances. The remaining patients with WD may present with symptoms including hemolytic anemia, bone fracture, arrhythmias, FS, hyperpigmentation, Kayser-Fleisher ring, cataract, and gynecological problems that are attributable to the involvement of the organs.

WD is caused by a mutation in the gene *ATP7B* that encodes a P-type Cu transporting ATPase beta polypeptide enzyme (ATP7B) (190). This ATPase is targeted to the mitochondria, suggesting that its role in Cu dependent processes takes place in this organelle. The disease frequency is estimated to be between 1 in 5,000 and 1 in 30,000, and the carrier frequency is approximately 1 in 90 (191).

Cu is absorbed by the intestinal cells and stored with metallothionein in a non-toxic form. The Cu is later delivered into the circulation by a Cu transporter 15,000 amino acid protein, Cu-transporting P-type ATPase 1 (ATP7A), which is located on the membrane of enterocytes (› *Fig. 42-7*) (192). It is then transported to the liver tagged with albumin, from where it is accepted by hepatocytes. The ATOX1 chaperone protein directs Cu to its binding targets in the hepatocytes. Some of Cu bounds to metallothionein for storage, and the remainders are excreted into ATP7B-regulated biliary canaliculi. ATP7B also mediates the transfer of Cu to apoceruloplasmin to form a six-Cu binding protein, ceruloplasmin (193). Ceruloplasmin is released into the blood, carries 90% of the Cu present in the plasma, and acts as a source for peripheral organs. Mutations of the *ATP7A* gene result in the storage of Cu in enterocytes, preventing entry of Cu into the circulation and thus causing a complete Cu deficiency (Menkes kinky hair disease) (192).

Mutations in *ATP7B* gene lead to a reduction in the conversion of apoceruloplasmin into ceruloplasmin, which is usually present at low levels in the patients of WD. A failure to excrete Cu into the biliary canaliculi leads to toxic effect to hepatocytes. Excess Cu damages mitochondria, which produce oxidative damage to the cells and allows spillage of Cu into the blood, thereby overloading other tissues including the brain, kidney, and red blood cells, initiating toxic effects.

Excessive accumulation of Cu in the kidney leads to renal tubular dysfunction in patients with WD. Patients show most features of FS before the onset of hepatic failure and is characterized by intermittent glucosuria, aminoaciduria, hyperphosphaturia, hyperuricosuria, and proteinuria (194–196). Patients can manifest rickets or osteomalacia. hypercalciuria, urolithiasis, nephrocalcinosis, decreased urine concentrating ability and distal renal tubular acidosis are reported (197). Glomerular function decreases as the disease progresses, but death from extrarenal causes occurs before the onset of renal failure.

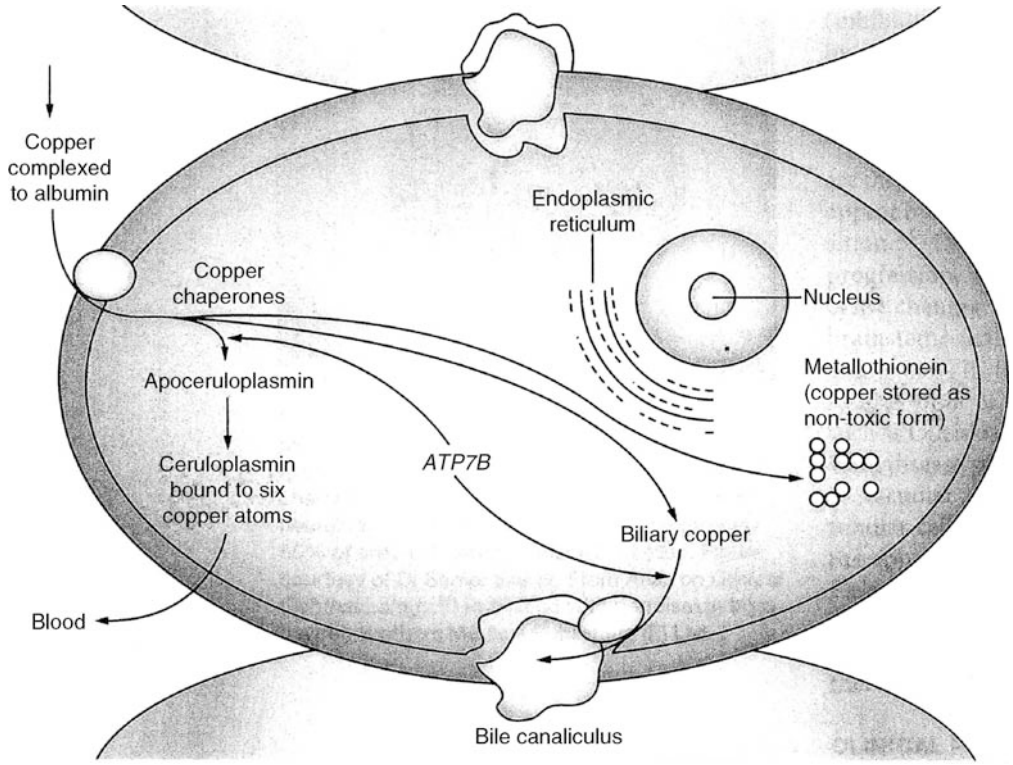
Histological analysis of the patients with WD revealed no alteration on light microscopy or only flattened proximal tubule cells without recognizable brush border (198). Electron microscopy disclosed loss of the brush borders, electron dense deposit in the subapical region of tubular cytoplasm probably representing metalloproteins, and cavitation of the mitochondria with disruption of the normal cristae pattern (199).

All subjects presenting with symptomatic or asymptomatic liver disease with no apparent causes or with extrapyramidal features along with a past or family history of similar hepatic or neurological illnesses in other siblings should be screened for WD (200). Measurement of the serum ceruloplasmin is valuable for diagnosis. Any value below 200 mg L^{-1} is abnormal, and reduced levels are seen in up to 95% of the patients with WD. An estimation of 24 h urinary Cu excretion is another reliable test for the diagnosis of WD. Normal excretion is between 20 and 50 μg a day, and Cu excretion is increased to in excess of 100 μg a day in patients with WD. Serum free Cu is a measure of nonceruloplasmin toxic Cu in the blood, and normal value range from 1.3 to 1.9 μmol L^{-1} (8–12 μg dL^{-1}) in parallel with the increased urinary Cu excretion, because of saturation of the hepatic storage of Cu. A hepatic biopsy and a measurement of its Cu content are helpful for diagnosis. 80% of the patients manifest increased hepatic Cu (>250 μg/g of dry tissue weight). Genetic analysis of *ATP7B* gene is a helpful confirmation of WD. Brain MRI is a very sensitive method for revealing abnormalities in patients with WD. Generalized brain atrophy and hyper-intensity in the basal ganglia, white matter, thalamus, or brainstem are common findings in the patients. Patients exhibit characteristic features on MRI; "face of the giant panda" is seen in the midbrain and "face of the miniature panda" is seen in the tegmentum region of the pons in T2-weighted images (201, 202).

WD has a fatal outcome if not treated appropriately and in a timely manner. The aim of treatment for WD is to remove the toxic deposit of Cu from the body to produce a negative Cu balance, and to prevent its reaccumulation (190, 203). Successful therapy is measured in terms of a restoration of normal levels of free serum Cu and its excretion in the urine. The average daily diet

Figure 42-7

Schematic representation of cooper metabolism within a liver cell. *ATP7b*, causative gene for Wilson disease. (Das SK, Ray K. Wilson's disease: an update. *Nat Clin Pract Neurol* 2006;2:482–493).



contains 2–4 mg of Cu, and 0.8 mg is normally lost into the feces. Patients should avoid Cu-rich foods including chocolate, nuts, shellfish, mushrooms, and liver. D-penicillamine therapy (20 mg kg^{-1} of body weight a day) has been the most commonly used chelating agent that may reverses multiple tissue dysfunction including FS. However, use of D-penicillamine has been questioned, because of reported side effects. The side effects from D-penicillamine can occur both early and late in the treatment period. Early side effects include a hypersensitivity reaction characterized by fever, skin rash, and lymphadenopathy. Delayed side effects including Goodpasture's syndrome, polymyositis, systemic lupus erythematosus, and bone marrow suppression are caused by immunological reactions. Trientine is another effective chelating agent (750–2,000 mg a day for adults). Ammonium tetrathiomolybdate (2–3 mg kg^{-1} of body weight a day in six doses along with meals and in the interval between meals) is a potent agent in removing Cu from the body and may be the drug of choice for patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with D-penicillamine therapy. Zinc acetate or sulfate induces intestinal metallothionein and helps in the prevention of Cu absorption from the gut (3–5 mg kg^{-1} of body weight a day in three divided doses before meals). D-penicillamine should be taken 2 h after meals to avoid any interaction with the zinc. Zinc acetate or zinc sulfate has been used successfully in asymptomatic or presymptomatic affected family with WD, and is equally as effective as D-penicillamine in a group of patients predominantly with neurological disease (204, 205). The use of trientine, tetrathiomolybdate, and zinc has been advocated, although results of long-term trials are awaited. The best therapeutic approach remains controversial and there is no universally accepted regimen. Liver transplantation is effective for the patients with progressive live failure or acute liver failure. Liver transplantation is also indicated for patients with WD in whom medical therapy is ineffective. Symptomatic patients with WD require lifelong treatment, because an interruption to therapy or inadequate treatment can lead to fatalities within 9 months to 3 years (189, 203).

Idiopathic Fanconi Syndrome

Although the significant numbers of genetic causes for the disorders leading to FS are identified, there exist patients with idiopathic FS. Idiopathic FS should be diagnosed when all other known causes have been excludes. Idiopathic FS can be inherited as an autosomal dominant (206–211), autosomal recessive (212, 213), and X-linked form (214). However, most of the familial forms are autosomal dominant inheritance.

Children with idiopathic FS manifest failure to thrive, frequent bouts of dehydration, and rickets. They often have other features of FS, including polyuria, polydipsia, hypokalemia, hypophosphatemia, proximal renal tubular acidosis, aminoaciduria, glucosuria, and proteinuria. Glomerular filtration rate is usually normal during childhood. However, some develop chronic renal insufficiency or chronic renal failure 10–30 years after the onset of symptoms (208, 209, 213). Nephrocalcinosis and *genu vulgum* (knock knee) are seen in some patients (213). Bone pain, bone fracture, and scoliosis due to osteomalacia can become serious complications in adult patients with idiopathic FS (*Fig. 42-8*).

Renal histology reveals chronic tubulointerstitial fibrosis. The interstitium demonstrates patchy fibrosis associated wit tubular atrophy and focal collections of mononuclear inflammatory cells. Occasional cystically dilated tubules are seen containing eosinophilic proteinaceous material that stains positive for PAS (213).

Treatment for idiopathic FS remains symptomatic. Careful follow-up of these patients is necessary to prevent recurrent bouts of dehydration, electrolyte imbalance, and metabolic bone diseases. Glomerular function and nephrocalcinosis must be checked regularly. Renal transplantation has been done in a few patients who had end-stage renal failure (209).

Figure 42-8

Plain X-ray showing scoliosis and osteopenia in a 35-year-old female with idiopathic Fanconi syndrome.

Acquired Fanconi Syndrome

Nephrotic syndrome is associated with FS (215). The renal pathology is focal segmental glomerulosclerosis. Although the true pathogenesis is not clarified, mitochondriopathies can manifest FS, focal segmental glomerulosclerosis leading to nephrotic syndrome, and both (79–84).

Immunological or hematological disorders are associated with dysproteinuria leading to FS. They are multiple myeloma, Sjögren syndrome, and amyloidosis. Almost all of the patients with theses diseases are adults. In early stages of myeloma, light chain nephrotoxicity often presents with proximal tubular functional abnormalities leading to FS. Proximal tubule dysfunction is the most common mode of renal involvement and it can manifest in a variety of ways. Endocytosis in the proximal tubules is overloaded and cell stress responses that include phosphorylation of MAPKs, prominently, p38 MAPK, and nuclear transcription factors NF-kappa B, AP-1 are activated resulting in production of inflammatory and proinflammatory cytokines, TNF-alpha, interleukin-6, 8 and monocyte chemo-attractant protein-1 (216). These proximal tubule alterations often progress to a severe tubulointerstitial nephritis and end stage renal failure.

Sjögren syndrome is an autoimmune connective tissue disorder that affects exocrine glands. Renal involvement of Sjögren syndrome is mainly manifested as tubular disorders; 70% of the patients manifest distal renal tubular acidosis (217). Urinary concentration defect, proteinuria and LMW proteinuria are often seen in the patients. Only 4% of the patients manifest FS (217). Patients with FS and Sjögren syndrome manifest osteomalacia including bony deformities of rib cage, bilateral humeral shaft fractures, and marked cortical bone thinning (218). Characteristic histological feature of Sjögren syndrome is chronic interstitial nephritis, with diffuse or focal plasmacytoid lymphocytic infiltration. In the late stage of the disease, tubulointerstitial fibrosis is severe. Corticosteroid or/and immunosuppressant therapy can improve the prognosis.

FS has appeared rarely after renal transplantation (219). Acute tubular necrosis, chronic rejection reaction, and nephrotoxic drugs can induce the progression of FS in the patients.

Acute tubulointerstitial nephritis with uveitis (TINU) syndrome is an immunological disease that leads to tubulointerstitital nephritis and anterior uveitis (220). Patients with TINU syndrome manifest asthenia, malaise, weight loss, nocturia, and thirst. Patients also manifest incomplete or complete FS including proteinuria, LMW proteinuria, glucosuria, aminoaciduria, bicarbonaturia, phosphaturia, and uricosuria due to proximal tubule dysfunction and acute renal failure (221). Urine concentration is decreased in the patients. Corticosteroid therapy can improve renal and eye manifestations.

Autoimmune interstitial nephritis and membranous nephropathy is a distinct disorder. The patients manifest failure to thrive, multiple renal tubular disorders including FS and proteinuria (222, 223). Renal biopsy revealed interstitial nephritis with lymphocytic infiltration and fibrosis, and membranous nephropathy. In advanced stage, focal segmental glomerulosclerosis and tubular atrophy develop. Immunofluorescence analysis shows linear staining of IgG along the glomerular capillaries and the tubular basement membrane. These renal lesions result from an autoimmune response to the 58-kD tubular basement membrane autoantibody (224). This disorder is genetically related to HLA B7 serotype (224).

A patient with anorexia nervosa is described to manifest reversible FS like condition including glucosuria, phophaturia, and uricosuria, although the precise pathogenesis is not known (225). These manifestations subside with nutritional recovery.

Untreated patients with distal renal tubular acidosis manifest LMW proteinuria, generalized aminoaciduria, phosphaturia, uricosuria, and hypercalciuria (226, 227). These proximal tubular abnormalities are transient and disappear by the alkali and potassium therapy. Although the precise pathogenic mechanisms underling the development of proximal tubular dysfunction remains unclear, decreased pH in the cytoplasm of the proximal tubule cells resulting from the intracytoplasmic accumulation of H^+ due to luminal membrane H^+-ATPase dysfunction can disturb trafficking of endosome.

Exogenous Factors

Drugs

Numerous drugs and herbs are implicated in the pathogenesis of FS. Drugs and herbs are usually filtered from the glomerulus and reabsorbed in the proximal tubules. They include outdated tetracycline (228), aminoglycosides (229, 230), salicylate (231), valproic acid (232, 233), and Chinese herbs (234, 235). Aminoglycoside antibiotics reduce glucose reabsorption in kidney tissue by reducing mRNA, protein expression, and function of the Na^+-dependent glucose transporter, which is located in the luminal membrane of the proximal tubule (236). Covalent binding of salicylate or its metabolites to mitochondria in proximal tubule cells alters the function of mitochondria (231). Valproic acid produces the defects of mitochondrial respiratory chain and lysosomal enzyme activity in the proximal tubule cells leading to multiple renal transport abnormalities (13, 237). Chinese herbs containing aristolochic acids cause proximal tubular injury, and this is called as aristolochic acid-related nephropathy.

A number of cancer chemotherapy agents are associated with renal glomerular and tubular dysfunctions including FS. The nephrotoxicity of cancer chemotherapy agents is dose dependent and often irreversible. Ifosfamide is an alkylating agent widely used in the treatment of various solid tumors. Chloroacetaldehyde (CAA), one of the main metabolites of ifosfamide, contributes to inhibit endocytosis in the proximal tubule cells (238). CAA decreases total glutathione and ATP levels in the proximal tubule cells. CAA also inhibits endosomal H^+-ATPase activity, which disturbs intracellular vesicle trafficking (239). Patients receiving ifosfamide who have received prior cisplatin are at significantly higher risk of developing FS than are those who have received no prior nephrotoxic therapy (240). When the patients manifest FS, renal sonography reveals hyperechogenicity of the parenchyma with good corticomedullar differentiation (241). Taurine can protect against ifosfamide-induced renal dysfunction without compromising its anti-tumor activity (242). Cisplatin also reduces glucose reabsorption in kidney tissue by reducing mRNA, protein expression, and function of the Na^+-dependent glucose transporter (243). Cisplatin inhibits various types of amino acid transporters in the proximal tubule cells leading to a generalized aminoaciduria (243).

Imanitib mesylate is a specific tyrosine kinase inhibitor that is the first line therapy for patients with chronic myeloid leukemia. This agent induces partial FS including phosphaturia and uricosuria with mild renal failure. Combined blockade of both platelet-derived growth factor receptor and c-Kit receptor tyrosine kinase in proximal tubules causes partial FS (244).

Nucleotide reverse transcriptase inhibitors that are used as anti-human immunodeficiency virus (HIV) agents including adefovir, cidofovir, and tenofovir induce

FS, nephrogenic diabetes insipidus, and acute renal failure (245–248). Adefovir and cidofovir interact with organic anion transporters (OAT); these drugs enter into proximal tubule cells by activated OAT located in the basolateral membrane. However, their efflux into the tubular lumen is decreased by inactivated multidrug-resistance-protein 2 (MRP 2) located in the luminal membrane. Thus, these drugs are accumulated in the proximal tubule cells leading to mitochondrial damage and tubular toxicity. Cytotoxicity of adefovir and cidofovir is proportional to cellular OAT expression (246). Histologic and ultrastructural examination reveals tubular degenerative changes of proximal tubules with swollen and dysmorphic mitochondria. In tubular cells, respiratory chain components encoded by mitochondrial DNA (cytochrome oxidase subunit I) are selectively deficient in renal tubular cells, and mitochondrial DNA is quantitatively reduced (249). In contrast to adefovir and cidofovir, renal toxicity of tenofovir is much less frequent. Tenofovir has little mitochondrial toxicity and it does not interact with OAT (250). Therefore, the precise mechanisms of nephrotoxicity by tenofovir remain unknown.

Chemical Compounds

Paraquat, a non-selective herbicide, and colloidal bismus subcitrate cause FS (251, 252). Large amount of these compounds are usually ingested in a suicide attempt. Patients manifest FS and acute renal failure. Treatment with the chelating agent sodium-2,3-dimercapto-1-propanesulfonate in combination with hemodialysis is highly effective in reducing the serum bismus level. Methyl-3-chromone (diachrome) (253), 6-mercaptopurine (254), and toluene also lead to FS (255).

Heavy Metals

Heavy metals such as lead, cadmium, mercury, chromium, and platinum are a major environmental and occupational hazard. They are very toxic at very low doses. The kidney is the first target organ of heavy metal toxicity. The extent of renal damage by heavy metals depends on the nature, dose, route, and duration of exposure. Both acute and chronic intoxication have been demonstrated to cause nephropathies, with various levels of severity ranging from tubular dysfunctions like acquired FS to severe renal failure (256). Lead poisoning leads to FS, predominantly in children (257). As lead is non-biodegradable with a very long biological half-life, aminoaciduria and glycosuria persist up to 13 years after childhood severe lead poisoning (258).

Cadmium intoxication leads to FS after a long exposure (259). The industrial waste contaminating cadmium in the Jinzu River basin in Toyama prefecture in Japan produced a lot of patients with *Itai-Itai* (*ouch-ouch*) disease that is compatible to FS with severe osteomalacia. Patients complained severe bone pains that are derived from advanced non-traumatic multiple bone fractures. Cadmium produces free radicals that alter mitochondrial activity or induce mitochondrial gene deletion in the proximal tubules (260, 261). Cadmium inhibits H^+-ATPase, which results in a Fanconi-like syndrome (6).

Therapy

Identification of the underling cause for FS is a first step and is critical to direct specific therapy. Avoidance of offending nutrients in galactosemia, HFI, and tyrosinemia and avoidance of Cu-rich foods in WD are therapeutically critical. Specific treatments with Cu-chelating agents including D-penicillamine, trientine, and ammonium tetrathiomolybdate, and zinc are effective for WD. Imuunosuppressive drugs are used for immunologically induced disorders including Sjögren syndrome, TINU syndrome and autoimmune interstitial nephritis and membranous nephropathy. These treatments can completely resolve FS.

When specific therapy does not exist, therapy is directed at the biochemical abnormalities secondary to renal solute and fluid losses and the metabolic bone diseases. Proximal renal tubular acidosis usually requires large amount of alkali (2–15 mEq kg^{-1} of body weight a day) divided into four to six daily doses. High dose of alkali can produce volume expansion, further bicarbonate wasting and potassium loss in the patients with FS. 1–3 mg kg^{-1} of body weight a day of hydrochlorothiazide can reduce the dose of alkali by preventing the volume expansion. Administration of potassium salt of citrate, bicarbonate, or acetate fulfills the dual purpose of treating acidosis and preventing hypokalemia. Sodium wasting and dehydration are treated with combination of sodium bicarbonate, citrate, and chloride, depending on the degree of acidosis. Ensuring adequate fluid and electrolyte intake is essential, especially in the case of infants or gastrointestinal diseases. Early intervention with intravenous replacement therapy is required for the patients with FS who manifest vomiting and diarrhea.

Hypophosphatemia and impaired renal vitamin D3 metabolism in patients with FS lead to rickets and other metabolic bone diseases. 1–3 g of phosphate supplementation

is necessary as neutral phosphate (the mixture of sodium phosphate dibasic 1.94 g and potassium phosphate monobasic 0.34 g contains 0.5 g of phosphate) divided into four to six daily doses. Supplementation of 1,25-dihydroxyvitamin D3 or dihydrotachysterol is effective to treat or prevent rickets and osteomalacia. Vitamin D3 therapy improves the hypophosphatemia and lessens the risk of hyperparathyroidism. Hypercalcemia and hypercalciuria are toxic side effects of vitamin D3 therapy. An adequate amount of physical activity, as well as appropriate diet with calcium, phosphate, and vitamin D3, is necessary to prevent bone deformations, non-traumatic fractures leading to bone pain, deterioration of motor development and disability (262).

Aminoaciduria, glucosuria, proteinuria, LMW proteinuria, and uricosuria usually do not induce clinical symptoms and do not require specific treatments.

Growth failure is a major complication in FS. Despite correction of electrolyte abnormalities, some patients manifest severe growth retardation, especially those with cystinosis and Fanconi-Bickel syndrome. A patient with FS was reported to have growth hormone deficiency (263). Supplemental growth hormone has been used successfully in a few patients with FS.

43 Primary Hyperoxaluria

Pierre Cochat · Sonia Fargue · Jérôme Harambat

Introduction

Hyperoxaluria may be either a secondary or a primary disease. Two distinct autosomal recessive inherited enzyme defects of glyoxylate metabolism have been related to type 1 and type 2 primary hyperoxalurias (PH), i.e., alanine: glyoxylate aminotransferase (AGT) and glyoxylate reductase/hydroxypyruvate reductase (GRHPR), respectively; in addition non-PH1 non-PH2 patients have been reported. Among all PH patients, type 1 accounts for 77%, type 2 for 9% and non-type 1 non-type 2 for 14% (1).

PH1 is one of the most challenging issues for both adult and pediatric nephrologists worldwide. The diagnostic accuracy has improved during the recent years and can be based on reasonable recommendations. However, due to its rarity and variable phenotype, therapeutic guidelines come, not only from evidence based information, but also expert opinion and experience.

Primary Hyperoxaluria Type 1

Pathophysiology

PH1 (MIM 259900) is an autosomal recessive disorder (~1: 100,000 live births per year in Europe), caused by the functional defect of the liver-specific peroxisomal, pyridoxal phosphate-dependent enzyme AGT (EC 2.6.1.44) leading to oxalate overproduction (*Fig. 43-1*) (2). The disease occurs because AGT activity is insufficient or because AGT is mistargeted to mitochondria which may explain enzymatic heterogeneity. Since calcium oxalate (CaOx) is insoluble in urine, PH1 usually presents with symptoms referable to oxalate deposition in the urinary tract. The median age at initial symptoms is 5–6 years and end-stage renal disease (ESRD) is reached between 25 and 40 years of age in half of patients (2, 3). Indeed it is responsible for less than 0.5% of ESRD in children in Europe *versus* ~10% in Kuwait and ~13% in Tunisia (4, 5), due to genetic make-up and a higher rate of consanguineous marriages. Along with progressive decline of glomerular filtration rate (GFR) due to renal parenchymal involvement, continued overproduction of oxalate by the liver along with reduced oxalate excretion by the kidneys leads to a critical saturation point for plasma oxalate (Pox) so that oxalate deposition occurs in many organs, leading to systemic involvement (named 'oxalosis') and bone is the major compartment of the insoluble oxalate pool. Calcium salts of glycolate are soluble and do not result in any pathology (6).

The infantile form often presents as a life-threatening condition because of rapid progression to ESRD due to both early oxalate load and immature GFR: one-half of affected infants experience ESRD at the time of diagnosis and 80% develop ESRD by the age of 3 years (7, 8).

Recent reviews have focused either on molecular pathophysiology of the disease or on current therapeutic approaches (9, 10). Therefore, clear recommendations may be now made for patients and their families.

Diagnosis

Because of the rarity of the disease and because of an insufficient knowledge of inherited urolithiasis by physicians, there is an average 5-year time interval from initial symptoms to diagnosis of PH1 (2, 3). The combination of both clinical and sonographic signs is a strong argument for PH1, i.e., the association of renal calculi, nephrocalcinosis and renal impairment; in addition family history may bring additional information (1).

PH1, in general, has five presentations: (1) an infantile form with early nephrocalcinosis and kidney failure; (2) recurrent urolithiasis and progressive renal failure leading to a diagnosis of PH1 in childhood or adolescence, (3) a late-onset form with occasional stone passage in adulthood, (4) diagnosis suggested and confirmed only by post-transplantation recurrence and, (5) pre-symptomatic subjects with a family history of PH1 (9).

Crystalluria and infrared spectroscopy are of major interest for identification and quantitative analysis of crystals and stones, showing CaOx monohydrate crystals (type Ic whewellite) with a crystal number $>200/mm^3$ in case of heavy hyperoxaluria (*Fig. 43-2*) (11).

In patients with normal or significant residual GFR, concomitant hyperoxaluria (urine oxalate >1 mmol/1.73 m^2

Figure 43-2

Infrared spectrophotometry showing monohydrated calcium oxalate.

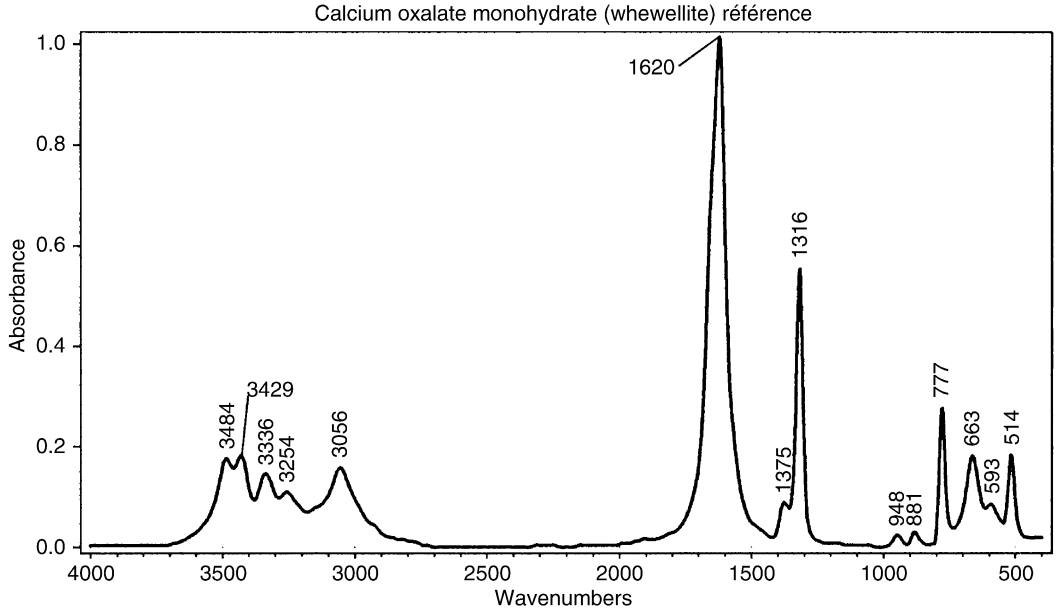

Table 43-1

Approximate cost of specific diagnostic tests and therapeutic procedures in France (in euros, 2007)

Diagnosis	
Crystalluria	27 €
Urine oxalate	135 €
Urine glycolate	135 €
Plasma oxalate	56 €
DNA sequencing	621 €
Prenatal diagnosis (known mutation)	135–270 €
AGT activity on liver tissue	324 €
Conservative treatment	
K/Na citrate	0.05 €/g
Vitamine B6	3 €/day
Transplantation (surgery + first postoperative stay)	
Kidney transplantation	42,685 €
Liver transplantation	86,895 €
Combined liver + kidney transplantation	137,204 €

BSA per day, normal <0.5) and hyperglycoluria (urine glycolate >0.5 mmol/1.73 m^2) are indicative of PH1, but some patients do not present with hyperglycoluria (*Table 43-1*). In ESRD patients, plasma oxalate (±glycolate): creatinine ratio and oxalate (±glycolate) measurement in dialysate might be helpful for screening in children (12). Normal values (mmol/mol) of plasma oxalate: creatinine ratio are <300 for age <2 years, <130 for age 2–5 years, <70 for age 5–15, and <40 for age >16 years [cited in 13]; however such ratios need to be confirmed by complete urine collection (*Table 43-1*). Urinary oxalate excretion is falsely low in patients with deceased GFR because of oxalate retention and systemic deposition as calcium oxalate (13).

In patients with well-defined phenotype, genotyping can be further proposed in order to screen the most common mutations according to local background (*Table 43-1*). Independent of diagnostic value, mutation analysis may provide information on potential pyridoxine responsiveness, on complex enzyme phenotype, and sometimes inform clinical prognosis (14).

In the presence of atypical presentation, a definitive diagnosis requires AGT activity measurement in liver tissue (*Table 43-1*). However, despite controversial information about the relationship between AGT catalytic activity and the severity of the disease (15), liver biopsy is not mandatory if genotype is already known.

Oxalate Burden

When GFR falls to below 30–50 mL/min per 1.73 m^2, continued overproduction of oxalate by the liver along with reduced oxalate excretion by the kidneys leads to a critical saturation point for Pox (Pox >30–50 µmol/L) so that oxalate deposition occurs in many organs. Therefore the presence of any kind of extrarenal involvement is a mark of systemic involvement and therefore may be assessed as a marker of oxalate burden.

Bone is the major compartment of the insoluble oxalate pool and the bone oxalate content is higher (15–910 µmol oxalate/g bony tissue) than among ESRD patients without PH1 (2–9 µmol/g) (16). CaOx crystals first accumulate in the metaphyseal area and form dense suprametaphyseal bands on x-ray. Later on, oxalate osteopathy leads to pain, erythropoetin-resistant anemia, and spontaneous fractures (*Figs. 43-3* and *43-4*).

Along with the skeleton, systemic involvement includes many organs because of progressive vascular lesions: heart, nerves, joints, skin, soft tissues, retina (*Fig. 43-5*) and other visceral lesions. Systemic involvement is responsible for poor quality of life leading to both disability and severe complications. Indeed PH1 is one of the most life-threatening hereditary renal diseases, mainly in developing countries where the mortality rate may reach 100% in the absence of adequate treatment (9).

Molecular Approach

Mutation Analysis

Human liver AGT cDNA and genomic DNA have been cloned and sequenced; the normal *AGXT* gene is a single copy gene which is located on chromosome 2q37.3 (11 exons spanning ~10 kb); the protein contains 392 amino acids and has a molecular mass of 43 kDa (14). More than 60 mutations (mainly point missense or nonsense mutations) and polymorphisms have been identified so far and it has been shown that selective exon sequencing can allow a definitive diagnosis in half patients within 2 weeks (6, 17). Some mutations are more frequent (*Table 43-2*) and play a role either in enzyme trafficking or in clinical/biochemical phenotype: Gly82Glu leads to loss of AGT catalytic activity due to inhibition of cofactor (pyridoxal phosphate) binding; Ile244Thr to aggregation and accelerated degradation of AGT; Gly41Arg to AGT intraperoxisomal aggregation as well as accelerated degradation; Gly170Arg to peroxisome-to-mitochondrion trafficking defect, sometimes with significant AGT catalytic activity; Gly170Arg and Phe152Ile to pyridoxine responsiveness; and in some patients homozygous for the 33insC mutation to ESRD during infancy (6, 15, 18–26). Ile244Thr and Gly170Arg mutations are the most common in European and North-American patients (~40% of mutant alleles) and interact with the common Pro11-Leu polymorphism (frequency = 50% in PH1 vs. 15–20% in normal subjects) which plays an important role in phenotype determination (6, 20, 26).

DNA analysis among different ethnic groups has revealed the presence of specific mutations, founder effects and phenotype-genotype correlations among North-African, Spanish, Canary Island, Japanese, Turkish, and Pakistani populations as well as in Arabs in Israel (26–29).

Prenatal Diagnosis

Mutation analysis is based on the sequencing of the 11 exons from the index case and gene segregation is checked in both parents. Prenatal diagnosis can be performed from DNA obtained from crude chorionic villi or amniocytes, on the basis of a restricted analysis of exons including the familial mutation (*Table 43-1*). Such a procedure allows the identification of normal, affected and carrier fetuses.

Table 43-2

Percentage of the most common mutations identified from 200 alleles studied in Lyon, France (9)

Ile244Thr	18.5%	North Africa: 35/37 alleles
Gly170Arg	14.5%	Western Europe: 26/29 alleles
33insC	7.0%	Various countries
Arg122X	5.0%	Middle East: 10/10 alleles
Met195Arg	4.0%	Various countries
Others	49.0%	Various countries

Therapy: General Supportive Principles

Conservative measures should be started as soon as the diagnosis has been made and even suspected. The aims are to increase urinary solubility of CaOx and to decrease oxalate production. The risk of stone formation is increased when urine oxalate exceeds 0.4 mmol/L, especially if urine calcium is plentiful.

Treatment should be initiated with high fluid intake (2–3 L/m^2 per day) aiming at urine dilution by day and night, that may require tube feeding in young children but often fails due to the high non-compliance rate with this difficult management regimen at the time of adolescence. CaOx crystallization inhibitors, such as citrate (potassium or sodium citrate, 100–150 mg/kg per day in 3–4 divided doses, *Table 43-1*) or neutral phosphate (30), are mandatory in order to decrease calcium absorption and therefore calciuria, and to decrease growth and agglomeration of CaOx crystals. Diuretics require careful management: frusemide will increase urine output with the risk of an increased calciuria whereas the diuretic effect of thiazides is less marked but is associated with an appreciable decrease of calcium excretion. Restriction of dietary oxalate intake (spinach, rhubarb, chocolate, tea, etc.) has limited influence on the disease as oxalate of dietary origin contributes very little to hyperoxaluria in PH. Calcium restriction is not recommended, because less calcium would then bind oxalate and form insoluble CaOx complexes in the gut. Ascorbic acid supplementation is not recommended as it is a precursor of oxalate.

The main purpose of therapy is to lower both Pox and plasma CaOx saturation. The effects of conservative measures can be assessed by serial determinations of crystalluria score and CaOx supersaturation software (31).

Pyridoxine is metabolized in the body to pyridoxal phosphate, the main cofactor of AGT. Pyridoxine sensitivity (i.e., >30% reduction of urinary oxalate excretion) is found in 10–30% of PH1 patients, so that it must be tested early at a daily dose of 5–10 mg/kg according to urinary oxalate (*Table 43-1*) (6, 25, 30). Response to pyridoxine may therefore help to preclude or delay the progression to ESRD (31); the patients most likely to respond are those with homozygous Gly170Arg or Phe152Ile mutation, who also experience preserved renal function over time under adequate treatment (25, 26). In case of isolated kidney transplantation in such pyridoxine sensitive patient, pyridoxine should not be discontinued at the time of surgery.

In summary, an aggressive supportive management should be started as soon as the diagnosis of PH1 has been considered that may significantly improve renal survival provided compliance is optimal.

Urologic Therapy

The treatment of stones should avoid open and percutaneous surgery because additional peri-operative renal insults will exacerbate progressive renal injury. The use of extracorporeal shock wave lithotripsy is an available option in selected patients but the presence of nephrocalcinosis may be responsible for parenchymal damage. In patients with repeated renal colic, stone removal can be attained by ureteroscopy and a ureteral JJ stent may be helpful for pain control and protection of renal damage. Management of stones in patients with PH is challenging and important in the long term care of these patients, so that referral to urologists experienced in this field is recommended.

Bilateral nephrectomy may be proposed to at-risk patients while on renal replacement therapy in order to limit the risk of further infection, obstruction and passage of stones.

Failure of Dialysis

Conventional dialysis is unsuitable for patients who have reached ESRD because it cannot overcome the continuous excess production of oxalate in spite of its small molecular mass (COOH-COOH: 1 mmol = 90 mg). Indeed the difference between oxalate generation (4–7 mmol/1.73 m^2 per day) and conventional dialysis removal (1–2 mmol/1.73 m^2 per day) shows that tissue accretion rate is uncontrolled (32). Conventional long-term HD is therefore associated with unacceptable quality of life and is a life threatening option.

In such patients, predialysis Pox usually ranges between 100 and 200 µmol/L (N < 7 µmol/L), which is significantly higher than in non-PH1 HD patients (40–50 µmol/L); calculated CaOx saturation (βCaOx, N ≤ 1 relative unit) is also higher in PH1 (~4.5 relative

units) compared to non-PH1 HD patients (~1.5 relative units) (33). Predialysis Pox is reduced by ~60% following HD (and βCaOx remains more than 1), but returns to 80% of the predialysis levels within 24 h and 95% within 48 h; indeed HD only removes the small fraction of total body oxalate and is followed by a rebound coming from the slow turnover compartment. Therefore daily hemodialysis (HD, >5 h per session) would be the preferred option but it cannot be universally applied and ongoing CaOx tissue deposition continues (34). The challenge is therefore to keep pre-dialysis Pox below 50 μmol/L in order to limit the progression of systemic oxalosis. Peritoneal dialysis (PD) by itself is unable to clear enough oxalate but, in some patients (e.g., children with an aggressive infantile form of oxalosis), combined PD and HD will enhance overall clearance and help in preventing the rebound in Pox after HD (35). On the same pathophysiological bases, HD may be required in selected condition in transplant patients (see below).

In summary, there are limited indications for dialysis in children with PH1: (1) if diagnosis of PH1 has not been established, (2) in small children with infantile oxalosis waiting for organ transplantation, (3) in preparation for kidney transplant, whether before of after liver transplantation, in order to deplete oxalate from the body, (4) following isolated kidney or combined liver-kidney transplantation with any delay in achieving optimal renal function, as a temporary adjunct in the case of high oxalate burden, or with transient loss of transplant function, (5) very exceptionally in older patients if the only alternative is no dialysis, (6) in developing countries, HD (or even less satisfactory, PD) may be indicated as only a preference to absolute withdrawal of all therapy.

Organ Transplantation

Ideally, any kind of transplantation should be a preemptive procedure (*Table 43-1*). Further assessment of oxalate burden needs therefore to be predicted by monitoring sequential GFR, Pox, CaOx saturation and systemic involvement (bone mineral density, bone histology) (9, 36). In addition, recent genotype-phenotype correlations regarding the degree of response to pyridoxine and the presence of Gly170Arg mutation may influence further therapeutic options (25, 26).

Kidney Transplantation

Kidney transplantation allows significant removal of soluble Pox (35). However, because the biochemical defect is in the liver, overproduction of oxalate and subsequent deposition in tissues continues unabated. The high rate of urinary oxalate excretion originates from both ongoing oxalate production from the native liver and oxalate deposits in tissues. Due to oxalate accumulation in the graft, isolated elective kidney transplantation is no longer recommended in ESRD, because frequently recurrence leads to poor graft survival and patient quality of life (37). Again, testing pyridoxine sensitivity is a major issue since it may allow to consider isolated kidney transplantation in selected responsive patients, a condition which is found in patients with the Gly170Arg mutation (25, 26). However most of them should not require renal replacement therapy if diagnosis is made on time and the favorable long term outcome of isolated kidney transplantation together with pyridoxine in these patients remains to be demonstrated. Isolated kidney transplantation may be also regarded as a temporary solution in some developing countries before managing the patient in a specialized center for further combined liver-kidney procedure (*Table 43-1*).

Rationale for Liver Transplantation

Since the liver is the only organ responsible for glyoxylate detoxification by AGT, the excessive production of oxalate will continue as long as the native liver is left in place. Therefore any form of enzyme replacement will succeed only when the deficient host liver has been removed. Liver transplantation is a form of gene therapy as well as enzyme replacement therapy as it will supply the missing enzyme in the correct organ (liver), cell (hepatocyte) and intracellular compartment (peroxisome) (27). The ultimate goal of organ replacement is to change a positive whole-body accretion rate into a negative one by reducing endogenous oxalate synthesis and providing good oxalate clearance *via* either native or transplanted kidney. However the current reason for enzyme replacement (liver transplantation) is only to decrease oxalate, not to cure the disease.

Combined Liver-kidney Transplantation

In Europe, 6–7 combined liver-kidney transplantations per year have been reported, i.e., 61% of all combined liver-kidney transplantations in children (38); the results are encouraging, as patient survival approximates 80% at 5 years and 69% at 10 years (39). Comparable results have

been reported from the United States Renal Data System, with a 76% death-censored graft survival at 8 years post transplantation (37). Such a strategy can be successfully proposed to infants with PH1 (8). In addition, despite the potential risks for the grafted kidney due to oxalate release from the body stores, kidney survival is about 95% three years post-transplantation and the GFR ranges between 40 and 60 mL/min per 1.73 m^2 after 5–10 years.

However the strategy of combined liver-kidney transplantation may be influenced by the stage of the disease (*Table 43-1*). Indeed simultaneous liver and kidney transplantation is logical in patients with a GFR below 40 mL/min per 1.73 m^2 but a metachronous procedure (liver transplantation, then dialysis until sufficient oxalate clearance from the body, followed by kidney transplantation) may be proposed to ESRD patients, mainly infants with a long waiting time (9, 40).

Preemptive Liver Transplantation

Preemptive isolated liver transplantation might be the first-choice treatment in selected patients before advanced chronic renal failure has occurred, i.e., at a GFR between 60 and 40 mL/min/1.73 m^2 (41, 42). Such a strategy has a strong rationale but raises ethical controversies especially when the GFR is superior to 60 mL/min per 1.73m^2. Indeed PH1 is the only peroxisomal disease without psychomotor delay due to cerebral involvement and the conservative management of PH1 patients has significantly improved during the last 10 years; this may influence the role of preemptive liver transplantation in such patients. Several patients have received an isolated liver transplant without uniformly accepted guidelines, since the course of the disease is unpredictable and a sustained improvement in kidney function can follow a transient phase of rapid decrease in native GFR (41, 42).

Post-transplantation Reversal of Renal and Extrarenal Involvement

After combined liver-kidney transplantation, urinary glycolate immediately returns to normal and Pox returns to normal before urine oxalate does. Indeed oxaluria can remain elevated as long as several years due to the slow resolubilization of systemic CaOx deposition. Therefore there is still a risk of recurrent nephrocalcinosis or renal calculi that might jeopardize graft function.

Thus, independent of the transplantation strategy, the kidney must be protected against the damage that can be induced by heavy oxalate load suddenly released from tissues. Forced fluid intake (3–5 L/1.73 m^2 per day) supported by the use of crystallization inhibitors is the most important approach. Pox, crystalluria and CaOx saturation are helpful tools in renal management after combined liver-kidney transplantation (43). The benefit of daily high-efficiency post-transplant HD is still debated and should be limited to patients with significant systemic involvement; it will provide a rapid drop in Pox and therefore reduce the exposure of the transplanted organs to high Pox, but it may also increase the risk of CaOx supersaturation due to reduction in urine volume in the case of inappropriate fluid removal. However it is obvious that post-transplant HD is mandatory in patients with acute tubular necrosis or delayed graft function.

Combined transplantation should be planned when the GFR ranges between 15 and 40 mL/min per 1.73 m^2 because, at this level, oxalate retention increases rapidly (40). In ESRD patients, vigorous HD should be started and urgent liver-kidney transplantation should be performed. Even at these late stages, damaged organs, such as the skeleton or the heart, do benefit from enzyme replacement, which results in an appreciable improvement in quality of life.

Donors for Combined Liver-kidney Transplantation

The transplantation strategy may be based either on immunological bases (i.e., using the same donor for both organs) or on biochemical rationale (i.e., using a two-step procedure according to oxalate body store) (*Table 43-3*) (9). Indeed most publication currently report on the use of cadaver donors but a living related donor may be considered under certain conditions (44).

In summary, there are different approaches to transplantation strategy which may be influenced by the local allocation system. The largest experience has been obtained with a one-step combined liver-kidney transplantation leading to acceptable results. The option of a two-step procedure should be kept in mind according to local experience and when the prospective waiting time is long enough to jeopardize both patient quality of life and survival.

Future Trends

The absence of intestinal oxalate-degrading bacterium *Oxalobacter formigenes* has been found to be associated

Table 43-3

Suggestions for transplantation strategies in pyridoxine resistant PH1 patients according to residual GFR, systemic involvement and local facilities (9)

GFR (mL/min per 1.73 m^2)	Estimated oxalate load	Proposed Tx strategy	Comments
60–40	±	Preemptive CAD L-Tx?	Hazardous (hepatectomy, immunosuppression) Limited experience Ethical issues
<40	+	Preemptive simultaneous (CAD) LK-Tx	Post-Tx HD only if ATN/DFG Exposure to immunosuppression
ESRD	++	Simultaneous Tx procedure	Renal risk Post-Tx HD often required
		2-step Tx procedure: (1) L-Tx, (2) HD proposed to clear, oxalate, (3) K-Tx	DD: needs 2 different donors - loss of immunological benefit LD: immunological benefit – increased risk for the donor

ATN, acute tubular necrosis, *DD* decreased donor, *DFG* delayed graft function, *ESRD* end-stage renal disease, *HD* hemodialysis, *K* kidney, *L* liver, *LD* living donor, *Tx* transplantation

with hyperoxaluria (45), so that a colonization of the gut by direct administration of the bacteria in capsule form may decrease oxalate absorption and might even extract oxalate from the circulation.

The administration of pyridoxamine - which is able to chelate the precursors of oxalate (e.g., glycolate) - to experiment animals has provided encouraging results (46).

At the moment, the only therapeutic option for PH1 patients who are unresponsive to pyridoxine is liver transplantation which is still a palliative measure so that future research would focus on molecular approaches. Different AGT crystal structures have been obtained for polymorphic variants, and aminoacid changes found in these crystals may affect AGT conformation and stability (6). A better understanding of such changes will allow designing pharmacological agents (chemical chaperones) that may stabilize AGT, thus providing a potential treatment for some PH1 patients with missense mutations (such as the most common mutation-polymorphism combinations, i.e., Gly170Arg + Pro11Leu and Ile244Thr + Pro11Leu) without the need for organ transplantation and even gene therapy (6, 10).

However gene therapy has been advocated and recent experience in AGT transfection into hepatocytes has provided encouraging results *in vitro* (47). Many years of research will be required before considering its potential use in humans because of the large number of hepatocytes to be transduced with the normal AGT gene expressed in the liver as a whole (6).

Non-Type 1 Primary Hyperoxaluria

In patients with overt hyperoxaluria, the pattern of urinary metabolites is indicative but no longer diagnosis of PH. In patients with a clinical picture of PH1, 10–30% have normal AGT activity, that may lead to a diagnosis of PH2 or of another disorder causing hyperoxaluria. Enzyme activity measurement in a single needle liver biopsy can confirm or exclude PH1 and PH2.

Primary Hyperoxaluria Type 2 (PH2)

PH2 (MIM 260000) is another rare inherited defect of oxalate metabolism causing raised urine oxalate and L-glycerate (*Fig. 43-1*).

Metabolic Derangement

PH2 is caused by a complete -or nearly complete- absence of the cytosolic/mitochondrial enzyme with glyoxylate/hydroxypyruvate reductase (GR/HPR, EC 1.1.1.26), and D-glycerate dehydrogenase (GD) activities (*Fig. 43-1*) (48–50). Analysis of liver and lymphocyte samples from patients with PH2 showed that GR activity was either very low or undetectable while GD activity was reduced in liver but within the normal range in lymphocytes (51).

Genetics

There is evidence for autosomal recessive transmission and the gene encoding the enzyme glyoxylate reductase/hydroxypyruvate reductase (*GRHPR*) has been located on chromosome 9q11 (52). More than 12 insertions, deletions, or splice site mutations have been identified (6, 50).

Clinical Presentation

PH2 has been documented in less than 40 published patients but there are probably some unreported cases (48, 53). Median age at onset of first symptoms is 1–2 years, and the classical presentation is urolithiasis, including hematuria and obstruction. However stone-forming activity is lower than in PH1 so that nephrocalcinosis and urinary tract infection are less frequent (31). Glomerular filtration rate is usually maintained during childhood and systemic involvement is therefore exceptional (53).

Diagnostic Test

In the presence of hyperoxaluria without hyperglycoluria, a diagnosis of PH2 should be considered, especially when AGT activity is normal. However, hyperoxaluria in PH2 tends to be less pronounced than in PH1. The biochemical hallmark is the increased urinary excretion of L-glycerate (13, 54) but the definitive diagnosis requires measurement of GR activity in a liver biopsy (55) as some PH2 patients have normal L-glycericaciduria (56).

Treatment and Prognosis

The overall long term prognosis is better than for PH1. ESRD occurs in 12% of patients, between 23 and 50 years of age (53). As in PH1, supportive treatment includes high fluid intake, crystallization inhibitors and prevention of complications; there is no rationale to use pyridoxine (6). Kidney transplantation has been performed in some ESRD patients, often leading to recurrence (nephrocalcinosis) including hyperoxaluria and L-glycerate excretion (53, 57, 58). The concept of liver transplantation has therefore been suggested since GR/HPR is present in the liver at higher levels than found in other tissues, but more data are needed because its distribution is the body is more widespread than that of AGT (6). Gene therapy may be expected to work but there is no current available data on this approach. In addition, prospects for using chemical chaperones are rather limited in PH2 since most GR/HPR mutations are not open to stability modification.

Non-type 1 Non-type 2 Primary Hyperoxaluria

Few reports have shown a possible association of PH (1) without AGT nor GR/HPR deficiency, (2) with hyperglycoluria in the absence of AGT deficiency (21). Such unclassified hyperoxalurias suggest the possibility of additional type(s) of PH; hepatic glycolate oxidase (GO) is a candidate enzyme for a third form of inherited hyperoxaluria.

Conclusion

Patients with hyperoxaluria should be referred for diagnosis and management to centers with interest and experience in the conditions and access to the appropriate biochemical and molecular biological facilities. Indeed major advances in biochemistry, enzymology, genetics and management have been achieved during recent years. The understanding of genotype-phenotype relationship and underlying metabolic defects of PH is in progress. The ongoing analysis of transplant strategies from multicenter database will improve individual enzyme replacement and subsequent patient survival and quality of life.

44 Tubulointerstitial Nephritis

Uri S. Alon

Introduction

Involvement of the tubulointerstitial compartment in renal diseases can be either primary or even more commonly secondary to glomerular, vascular or structural disease (*Table 44-1*). However, even in the latter disorders the magnitude of involvement and damage to the tubulointerstitium can have a significant effect on the outcome of the primary disease (1, 2). This chapter addresses primary tubulointerstitial nephritis (TIN) which is a syndrome with a wide clinical spectrum. TIN is characterized histologically by inflammation and damage of tubulointerstitial structures, with relative sparing of glomerular and vascular elements (3, 4). Acute TIN is typically associated with marked tubulointerstitial inflammation, varying degrees of edema and tubular epithelial cell damage, and mononuclear cell infiltration (5). In contrast, chronic TIN is characterized by tubular epithelial cell damage and atrophy, with tubulointerstitial fibrosis (5). Although there are important clinical and pathophysiologic distinctions between acute and chronic TIN, they are best viewed as manifestations of a continuum of renal injury (6, 7). Acute TIN is often reversible, however, progression to chronic renal disease can occur (8–10).

Structure and Function of the Tubulointerstitial Compartment

The tubulointerstitial compartment comprises about 80% of the renal parenchyma with the majority of its volume contributed by the tubules (11). The interstitium is comprised of matrix and cells. Two main types of cells have been identified: (1) type I interstitial cells are fibroblast-like cells which are capable of producing and degrading extracellular matrix. An inner medullary subgroup of type I cells produce prostaglandins; (2) type II interstitial cells include dendritic antigen-presenting cells located mainly in the cortex, and monocyte-derived macrophages capable of plagocytosis found in all renal zones (12, 13). The matrix is composed of a fibrillar net of basement membrane and interstitial collagens, glycoproteins and proteoglycans as well as interstitial fluid (13). The interstitium provides structural support for the nephrons and capillaries and plays an important role in the transport of solutes. It is also the site where cytokines and hormones such as prostaglandins and erythropoietin are produced. The roles of the tubules in maintaining kidney function and homeostasis of fluid, electrolytes, minerals and acid-base balance are described in Chapters ZZZ (ED-those which refer to tubular structure and Fx). Damage to different segments of tubules will result in metabolic abnormalities related to the specific functions of the affected segments.

Pathophysiology

Tubulointerstitial lesions in all forms of TIN are predominantly characterized by T-cell lymphocytic infiltrates, suggesting immune-mediated mechanisms of renal injury (6, 14). Such mechanisms are likely important in both initiating tubular injury and amplifying damage induced by both immune and nonimmune causes. Studies from experimental models of tubulointerstitial disease indicate that activation of both cell-mediated and humoral immune pathways induce renal injury (15, 16).

Cell-Mediated Immunity

Historically, abnormalities in cell mediated immune responses have been implicated as the major pathophysiologic mechanisms of TIN. Analysis of infiltrating mononuclear cells in human TIN of various etiologies identified the majority as T lymphocytes (17–19). T-cell lymphocytic ($CD4^+$ and $CD8^+$) interstitial infiltrates generally occur in the absence of antibody deposition (5). Immunohistochemical studies conducted on biopsies obtained in drug-induced TIN also indicate the importance of cell-cell interactions in intrarenal inflammation, as there is increased interstitial expression of cellular adhesion molecules. In human forms of acute TIN, increased expression of LFA-1 and VLA-4 cell-surface receptors, as well as their respective ligands, ICAM-1 and VCAM-1, is seen in areas of mononuclear cell infiltration (20). Further support of cell-mediated events in human disease is based on

c. Reflux nephropathy

observations of in vivo and in vitro activation of lymphocytes isolated from affected patients following repeat exposure to specific inciting agents of TIN (21, 22). In view of these observations, the role of cell-mediated events in TIN has been extensively studied in murine models of anti-TBM disease and spontaneous TIN (16, 23, 24). In both of these models, the effector T cell (T_e) lymphocytes that differentiate in diseased animals are $CD8^+$ renal tubular antigen-specific T cells. Nephritogenic $CD8^+$ T_e cells induce renal injury in genetically susceptible animals, and can adoptively transfer renal disease to naive hosts (15, 16, 23, 24).

Cell-mediated responses are initiated by T-cell recognition of relevant antigen presented in the context of appropriate major histocompatibility complex (MHC) molecules. Class I MHC molecules primarily direct $CD8^+$ T cell responses, and class II MHC determinants direct $CD4^+$ T cell responses (25). In vitro studies show that resident renal cells, such as renal tubular epithelial cells, glomerular epithelial cells, and mesangial cells, have the potential to present a variety of antigens (26, 27). Correlation of in vitro antigen-presenting activity to disease activity in vivo, however, has not been established (28). It is noteworthy that renal tubular epithelial cells express class II MHC determinants in inflammatory renal disease and in culture, when stimulated by proinflammatory cytokines such as IFN- and TNF (29, 30). Moreover, class II MHC expression on renal tubular epithelial cells induces in vitro proliferation of antigen-specific T-cell clones and hybridomas and promotes autoimmune renal disease in vivo. These findings suggest that induced class II MHC expression on renal tubular epithelial cells promotes autoimmune injury by facilitating presentation of a self (tubular) antigen by nonlymphoid cells (28). The cause for antigen expression by the tubular cells is unknown. Tubular epithelial cells normally do not express costimulatory molecules such as CD80 and CD86, which likely limits their ability to present antigen under physiologic conditions (31). Genetic susceptibility may play a factor in antigen expression and consequent immune response (16). Other mechanisms, such as drugs or infectious agents, may serve as inciting antigens of cell-mediated responses targeting the kidney (32, 33). In addition, degenerate recognition of peptide antigens by autoreactive T cells in autoimmune disease has been reported (32, 34). The potential relevance of such molecular mimicry in autoimmune T-cell activation to renal immune responses, however, awaits further investigation. There is a large body of research implicating the interaction between effector and suppressor T-cells in the inflammatory process in the renal interstitium. However, a definitive role for such interaction in the pathogenesis of TIN is still unclear (9, 11).

Antibody-Mediated Immunity

Occasionally antibody-mediated TIN can be seen. When antibodies are present by immunofluoresence, they are usually associated with the tubulointerstitial cells, along the basement membrane or as immune complexes. Anti-TBM staining often occurs as part of anti-GBM disease, but can also be a primary phenomenon resembling experimental anti-TBM disease. Anti-TBM antibodies can be seen in drug-induced TIN, and also in renal transplants due to the presence of foreign antigens in the transplanted kidney (35, 36).

Primary immune deposit-mediated TIN is rare. It seems that in such instances the complexes are formed in situ, as circulating complexes would be entrapped in the glomeruli. Indeed, in many of the cases in which immune complexes are detected in the interstitium, they are also observed in the glomeruli. Examples include SLE, IgA nephropathy and membranous nephropathy. The presence of interstitial immune complexes might still require cellular immune response genes for the development of a complete inflammatory reaction. Most studied experimentally is anti-TBM disease. Other animal models

for experimental antibody and immune complex mediated TIN include the Heymann nephritis antigen complex in brush border abnormalities (37) and reaction to Tamm-Horsfall protein (38).

Local and Extrarenal Antigens

Antigens presented to the immune system may be derived from resident cells or arrive at the tubulointerstitial compartment from extrarenal origin. As mentioned previously, resident cells of the tubulointerstitial component and in particular tubular epithelial cells have the potential to present antigens. In addition, local antigens may be related to Tamm-Horsfall protein or, uromodulin, which is a glycoprotein secreted by the cells of the ascending loop of Henle. This glycoprotein can precipitate immune deposits at the base of tubular cells and lymphatic drainage of the ascending limb, and result in binding of neutrophils to the cell-surface (39, 40). In experimental Heymann nephritis, antibodies reacting to the tubular brush border have been detected, at times associated with interstitial infiltration (41, 42). Most extensively studied is the antigen in anti-tubular basement membrane (anti-TBM) disease, named 3M-1 (43, 44). It has been detected both in humans and rodents, showing extensive polymorphic expression (45, 46).

Extrarenal antigens may present to the interstitium as isolated antigens or as part of an immune complex. Antigens arriving at the tissue like those originally derived from drugs like penicillin, cephalosporin and phentoin combine with antibodies and inflammatory cells which initiate interstitial disease. Another mechanism by which external antigens initiate an immune response is by mimicking of epitopes. For instance some antibodies to *Escherichia* coli cross-react with Tamm-Horsfall protein (47). A similar mechanism may be responsible for TIN which follows certain viral illnesses (48, 49). It has also been hypothesized that non-infectious, shared epitopes, may instigate the immune process, (i.e., anti-DNA antibodies) (50, 51).

Circulating immune deposits which settle in the interstitium can cause TIN. This might be the case in SLE, IgA nephropathy and possibly some cases of chronic idiopathic human tubulointerstitial nephritis (52, 53). Experimentally, a model of chronic serum sickness disease in the rabbit results in immune deposits in the interstitium (54).

Cytokines and Amplification of Injury

Events resulting from infiltration of T-cells, and deposition of specific antibodies or immune complexes which augment inflammation and injury are part of the "amplification process." These processes include the release of cytokines and proteases from T cells; the attraction and activation of nonspecific immune effector cells including eosinophyls and macrophages (which themselves release various effector products); and the activation of the complement cascade (19, 55). Interestingly the presence of complement in TIN is infrequent. When present, it is usually associated with deposition of IgG and immune complexes (54–57) or IgE and eosinophils (54, 57, 58). Even more important seems to be the activation of the alternative passway by ammonia, in the absence of antibodies (59). This process may be instrumental in progressive local injury in non-immune mediated TIN. It may also indicate the importance of correction of metabolic acidosis in the prevention of progressive renal damage by diminishing ammonia production. It is possible that both resident epithelial cells and infiltrating cells further amplify damage by expressing chemokines. This sub-class of structurally related cytokines selectively promote the chemotaxis, adhesion and activation of leukocytes (60). Following ureteric obstruction in the mouse, the most potent recruiter of macrophages is monocyte chemoattractent peptide – 1 (MCP-1), which is expressed in tubular epithelium (61). The chemokines induce their effect by binding to specific cell-surface receptors on target cells. Various types of leukocytes are activated by differential chemokines-receptor binding patterns. The pharmocologic blockage of chemokines and their receptors may have a potential in controlling the inflammatory response (62). In humans with ureteropelvic junction obstruction, urinary MCP-1 is increased, and decreases after surgical alleviation of the obstruction (63).

Fibrogenesis and Atrophy

Interstitial fibrosis is the final common injury pathway for a variety of glomerular and tubular disorders, particularly when associated with massive glomerular proteinuria or the presence of inflammatory cells in the tubulointerstitial component (64, 65). It seems that both processes induce local cytokines which transform and activate several types of resident cells in the tubulointerstitial compartment to produce new or modified extracellular matrix (66). Some of the activated cells probably change phenotype (67–69). It is unclear why what is usually a self-limited wound repair process continues unabated. It is possible that failure of homeostatic regulatory mechanisms is responsible for the continuous inflammatory process of chronic TIN.

Tubulointerstitial scars are primarily composed of collagen type I and III, fibronectin and tenascin (70, 71). Early in the development of a scar, the fibrotic tissue may contain monocytes, tubular cells and fibroblasts (65). It appears that local monocytes release cytokines, affecting the activity of their neighboring fibroblasts. The phenotypic expression of the fibroblast and hence the renal glycoprotein synthesized by it may be related to the type of cytokines stimulating the cell (72). Among the strongest morphogenic cytokines driving TIN fibrosis is angiotensin II (73).

The source of the fibroblasts in the tubulointerstitium is yet unknown. There are several lines of evidence to suggest that they may arise from transformation of resident cells like the tubular epithelium through the mechanism of epithelial-mesenchymal transformation (74–76). The transformation is probably activated by immune-mediated mechanisms and various cytokines which result in changes in the basement membrane of the tubular epithelial cell. Once transformed to a mesenchymal cell it acquires motility and becomes responsive to growth factor stimuli (77). Several local chemoattractants stimulate the migration of the newly formed fibroblasts. These chemoattractants are released by macrophages or the fibroblasts themselves (78, 79). The latter, mainly by secreting TGF-β amplify the process (80). Once fibroblasts migrate to their new location they begin to deposit fibronectin matrix which serves as a skeleton for the deposition of other glycoproteins. Concomitantly with the transformation process, the effect of cytokines on tubular cell can result in their atrophy by disturbing their basement membrane synthesis. Additional damage to the tubular cell can be caused by T cell clones with cytotoxic activity resulting in tubular cell destruction and atrophy. Thus tubular atrophy and interstitial fibrosis often coexist.

Acute Tubulointerstitial Nephritis

Epidemiology

Acute TIN accounts for 10–25% of reported cases of acute renal failure (ARF) in adults (3) and up to 7% of children with ARF (81). However, in both children and adults acute TIN may be underreported because many patients with ARF recover spontaneously after removal of the suspected offending agent, and definitive diagnosis based on a renal biopsy is not routinely established (7). Lower reported incidences of acute TIN in children than in adults may reflect more common use of nephrotoxic pharmacologic agents and greater prevalence of preexisting renal abnormalities in older patients.

Clinical, Laboratory and Radiologic Features

The clinical manifestations of TIN are variable and many of them are seen in both acute and chronic TIN (*Table 44-2*). The severity of renal impairment ranges from asymptomatic urinary abnormalities to mild azotemia, and to non-oliguric and oliguric ARF (82). The nonspecific nature of the clinical findings in TIN emphasizes the need for a renal biopsy to make a definitive diagnosis in questionable cases (4, 83). In one series of 13 children with biopsy proven acute TIN, only 6 were suspected of having the diagnosis before the procedure (84). However, in a child suspected to have acute TIN, if improvement in kidney function is noticed after withholding the suspected offending agents and starting treatment, there is no need for a biopsy.

Systemic manifestations of a hypersensitivity reaction, such as fever, rash, and arthralgias, are variable findings. Although these symptoms are more likely to occur in drug-induced acute TIN (81, 85), in a series of nine adults with acute TIN caused by medications, components of this classic triad comprised the presenting symptoms in only about half of the patients (86). In a more recent study on 128 adults with TIN, in which 70% were due to drugs, the triad of rash, fever and eosinophilia was seen in about 10% (87). The rash may be maculopapular, morbilliform, or urticarial, and often it is fleeting (86–90). Arthralgia is seldom a prominent feature (86). Acute TIN associated with infection may present with extrarenal manifestations of disease, such as fever and sore throat (84). Nonspecific constitutional symptoms of fatigue, anorexia, weight loss, nausea and vomiting, and flank pain with macroscopic hematuria may occur (88, 90). Hypertension and edema are seldom noted, except in specific drug-induced lesions, such as the nephrotic syndrome associated with nonsteroidal anti-inflammatory drugs (NSAIDs) (91) or in TIN secondary to glomerular disease (8, 82).

Acute and chronic TIN have quite similar laboratory findings (7). Renal tubular epithelial cell damage is the predominant finding in all forms of TIN, and biochemical abnormalities observed in patients with TIN may reflect injury to specific nephron segments involved in the inflammatory process (*Table 44-3*) (92). In general cortical damage may affect mainly the proximal and distal tubules whereas medullary lesions may affect mainly the loop of Henle and the collecting duct. Proximal tubule injury results in Fanconi syndrome with impaired urinary reabsorption of glucose, bicarbonate, phosphorus, amino acids, and uric acid (93). Damage to the loop of Henle may result in magnesium and sodium losses. Distal tubular lesions result in renal tubular acidosis, impaired

potassium excretion, and sodium wasting (94). Biochemical abnormalities in TIN are an elevated serum creatinine concentration with hyperchloremic metabolic acidosis (3, 84). If proximal tubular involvement is prominent, serum phosphorus, bicarbonate, uric acid, and potassium concentrations may be decreased. Whereas oliguria can occur, many patients have nonoliguric renal failure, and others a urine concentrating defect. The urine microscopic examination may show active or relatively bland changes.

Relevant serologic studies in the investigation of TIN are listed in *Table 44-4*. Normochromic, normocytic anemia is often associated with TIN (81, 92). Hemolytic anemia has also been reported in acute TIN induced by allopurinol, penicillins, and rifampin (4, 92). Leukocytosis may occur, and some but not all patients with drug-induced TIN have peripheral eosinophilia (85, 90, 95). Drug induced liver damage will be reflected in elevated hepatic enzymes (95, 96). Elevated serum IgE titers have been reported in up to 50% of biopsy-proven cases and is suggestive, but not diagnostic, of drug-induced TIN (82, 86). Anti-DNA antibodies, antinuclear antibodies, and complement levels are normal in most forms of TIN, unless associated with a systemic autoimmune disorder (3, 88). Circulating anti-TBM antibodies are detected on rare occasions (89).

Urinary abnormalities vary considerably (*Table 44-4*). Microscopic hematuria is commonly detected and macroscopic hematuria and sterile pyuria also occur (81, 90). Mild to moderate proteinuria (less than 1 g/day) is detected in most patients with TIN (84). Nephrotic range proteinuria is not characteristic of TIN but has been associated with acute TIN induced by certain medications including NSAIDs, lithium, ampicillin, and rifampin (5, 97). Urinary sediment analysis shows granular, hyaline, and white blood cell casts (5). Red blood cell casts are rarely seen in acute TIN (84). Eosinophiluria, defined as greater than 1% of urinary leukocytes stained positively with Hansel's or Wright's stain, is suggestive of acute TIN and has been reported in 50–90% of patients with drug-induced acute TIN (86, 98). However, eosinophiluria can be seen in many inflammatory renal diseases (99). In a study of 51 patients, eosinophiluria had a sensitivity of 40% and specificity of 72%, with a positive

Table 44-3

Patterns of renal tubular dysfunction in tubulointerstitial nephritis

Nephron site	Functional defect	Clinical manifestation
Proximal tubule	Decreased HCO_3, PO_4, amino acids, uric acid, and glucose reabsorption	Fanconi syndrome, hyperchloremic metabolic acidosis, polyuria, hypokalemia
Loop of Henle	Defective NaCl reabsorption, decreased calcium and magnesium reabsorption	Polyuria (polydipsia), salt wasting, calcium, potassium and magnesium losses
Distal tubule	Defective NaCl reabsorption and potassium and hydrogen ion secretion	Hyperkalemia, hyperchloremic metabolic acidosis, sodium and potassium losses
Collecting tubule	Defective water reabsorption	Nephrogenic diabetes insipidus

predictive value for TIN of only 38% (99). In a more recent study the use of Hansel's stain was much superior to Wright's stain in detecting eosinophiluria and differentiating between acute interstitial nephritis and acute tubular necrosis (100).

Renal ultrasound examination usually demonstrates normal or enlarged kidneys, depending on the relative proportions of tubulointerstitial inflammation and edema (3, 81). Gallium citrate scanning may be useful in distinguishing acute TIN from other common causes of ARF (86). However, increased uptake on gallium scan is a relatively nonspecific finding and may be seen in cases of allograft rejection, acute pyelonephritis, and severe minimal change nephrotic syndrome (3). A definitive diagnosis of TIN can be made only by renal biopsy (3, 4).

Pathology

Typical light microscopy findings in acute TIN consist of tubulointerstitial mononuclear cell infiltration and edema, with varying abnormalities in renal tubular epithelial cells (*Fig. 44-1*) (82, 83). In general, vessels and glomerular structures are unaffected (82, 86). Mild mesangial hypercellularity or periglomerular inflammation and fibrosis occasionally are seen (84). Cellular infiltrates, primarily of T-lymphocytes, often are patchy and are variably distributed throughout the kidney (5, 86, 87). Monocytes, macrophages, and plasma cells are also commonly noted in affected areas (84, 88). Eosinophils are most commonly seen with drug-induced acute TIN and can comprise up to 10% of the infiltrate (89). Interstitial granulomas occasionally are seen, particularly in drug-induced or infection-related acute TIN (101, 102). Complement and immunoglobulin deposition are not characteristic of acute TIN (5, 103, 104) but have been noted in children with acute TIN because of systemic lupus erythematosus (SLE), syphilis, hepatitis B, shunt nephritis, and some drug-induced lesions (105).

Tubular epithelial cell damage varies from minimal histologic changes to frank necrosis (85, 103). Most often there is flattening of renal tubular cells with atrophy, degeneration, and loss of the brush border in proximal convoluted tubules (5, 8). Renal tubules are commonly dilated, with splitting or fracturing of the basolateral membrane. The tubule lumens may contain desquamated cells or blood (8, 84). In some instances, infiltrating lymphocytes are observed between tubular epithelial cells (86). Electron microscopy typically reveals striking renal tubular epithelial cell mitochondrial damage, cytoplasmic vacuoles, and significantly dilated rough endoplasmic reticulum (83, 84, 86).

Etiology

The causes of acute TIN can be grouped into four broad categories: medications, infections, immunologic diseases, or idiopathic processes (*Table 44-5*). As described in the pathology section of this chapter, all forms of acute TIN have similar pathologic features. Unique features of distinct forms of acute TIN are described in more detail.

Medications

Medications, rather than infection, are now the leading cause of acute TIN in children (8, 87). An ever increasing list of medications are implicated as causes of acute TIN (*Table 44-6*). However, establishing a clear link between a medication and acute TIN may be difficult, because many case reports of drug-induced acute TIN are in patients who have received several medications simultaneously. In other

instances it might be indeed a combination of medications causing the TIN (106). The major categories of drugs consistently associated with acute TIN in both children and adults include: antibiotics, NSAIDs, anticonvulsants, and diuretics (85, 86, 90). Although symptoms of acute TIN caused by a specific drug can occur within hours or months after starting a medication, they are usually seen 2–3 weeks after starting therapy (4). Antimicrobials and NSAID are the most common drugs causing acute ATN in children (85, 90). The incidence of acute TIN caused by methicillin, which is no longer used, was 16% (90). The incidence of acute TIN with currently available penicillins is significantly less than that previously observed with methicillin. Systemic manifestations of hypersensitivity with fever, rash, and eosinophilia in the setting of ARF can occur in up to 30% of patients with penicillin-induced acute TIN (4). By contrast, these hypersensitivity manifestations are not typically associated with NSAID-induced acute TIN (91). NSAID-induced TIN may be associated with minimal change nephrotic syndrome (97). Although NSAID-induced acute TIN in children occurs less often than in adults, the increasing availability of over-the-counter NSAIDs preparations for children may result in an increase in cases in that age group. Proton-pump inhibitors have recently become another common cause of acute TIN (107).

A category growing in significance is renal damage, including TIN, secondary to dietary supplements (108).

[a]Common cause in children

Drug-induced acute TIN is an idiosyncratic reaction, and as such, it is difficult to predict which patients will be affected. No specific risk factors have been consistently identified. Acute TIN has been reported with various routes of administration including oral, intravenous, intramuscular, and rectal (85, 90, 103, 109). Duration and the dosage of therapy also do not correlate well with the development of disease, although several reports suggest that acute TIN is more common with high-dose therapy (7, 90).

The association of drug-induced acute TIN with fever, rash, and eosinophilia suggests an underlying allergic reaction to administered drugs. Reports of accelerated, recurrent TIN on drug rechallenge also implicate drug hypersensitivity (109, 110). Administration of structurally similar medications may induce cross-reactivity as evidenced by recurrent acute TIN after cephalosporin administration in individuals with previous penicillin-induced TIN (90).

Drug induced acute interstitial nephritis was found to be a cause for graft dysfunction in kidney transplant recipients. Early diagnosis and treatment prevented permanent damage (111).

Infections

In the preantibiotic era, infection, especially Streptococcal, was the predominant cause of acute TIN in children. Councilman's initial postmortem findings of TIN involved 42 children who succumbed to scarlet fever (112). With the development of effective antimicrobial therapy, the incidence of streptococcus-associated acute TIN has decreased. Other infectious organisms have become important causes of acute TIN. These include unusual bacteria such as *Rickettsia* species, *Yersinia*, and mycoplasma. Viruses, such as adenovirus and human immunodeficiency virus (HIV), and parasites are also causes of acute TIN (*Table 44-7*) (5, 113–115). Naturally HIV infection/AIDS may serve as background for other infectious or drug induced TIN (116). Infections may induce acute TIN by two distinct processes. Organisms may directly invade the renal parenchyma, producing local renal infection and inflammation. This form of acute TIN may respond to treatment of the underlying infection. Alternatively, organisms may induce "reactive" intrarenal inflammation without evidence of renal infection. The latter mechanism is implicated by the observation that group A streptococcal infections can cause acute TIN in children, even with appropriate antibiotic therapy (84). Mechanisms for the renal inflammatory reaction in the absence of renal infection are not clearly elucidated but are presumed to be immunologically mediated (84).

Immunologic Diseases

Immunologic diseases elicit acute TIN in two distinct settings (*Table 44-5*). TIN occurs with either a primary glomerular lesion or, less commonly, as an isolated primary TIN. SLE is the most important cause of acute TIN seen in association with glomerulonephritis in children. Tubulointerstitial immune deposits may be present in up to 60% of SLE patients who are biopsied and correlate with both severity of interstitial inflammation and degree of functional renal impairment (117, 118). As is the case with other glomerular diseases, severe tubulointerstitial involvement with fibrosis is a poor prognostic indicator for renal function (105). Acute TIN occasionally is seen in children with membranous nephropathy, postinfectious glomerulonephritis, and shunt nephritis (105). IgA nephropathy was found to be associated with significant TIN in 37% of 51 patients (119). At follow-up, patients with renal tubular deposits had significantly worse renal function than those with isolated glomerular findings (119). Immunologic diseases that present with isolated tubulointerstitial involvement are tubulointerstitial nephritis with uveitis (TINU) syndrome, allograft rejection,

and rarely, SLE (120–122). Allograft rejection is discussed in detail in Chapter ZZZ.

TINU syndrome was first described in 1975 in a report of two adolescent girls that developed ARF with eosinophilic TIN associated with anterior uveitis and bone marrow granulomas (123). Subsequent reports have highlighted the significant adolescent female predominance (120). The pathogenesis of this syndrome remains unclear and preliminary evidence suggests roles for both humoral and cell-mediated immune mechanisms. Circulating or deposited immune complexes were detected in up to 60% of patients (124, 125). A significant number of patients, however, have no evidence of tubulointerstitial immune deposits on renal biopsy. Analysis of the lymphocytic infiltrates on biopsies of patients with TINU demonstrated a predominance of activated memory T helper cells, thus providing further evidence for cell-mediated events (120). A genetic predisposition is suggested by the occurrence of TINU in identical twins within the same year (126). In other cases, prior infection, use of certain drugs or the presence of an autoimmune disorder have been implicated (127, 128). Among others TINU has been described in association with granulomatous hepatitis (129), hyperthyroidism (130) and Epstein-Barr virus infection (131). Patients usually have anorexia, fever, weight loss, abdominal pain and polyuria. Eye tenderness may not be evident at presentation, as uveitis could occur at any time with respect to the onset of renal disease (132). Laboratory abnormalities include an elevated erythrocyte sedimentation rate, increased serum IgG levels, azotemia, and nonhemolytic anemia. Urinary abnormalities include proteinuria, glucosuria, and sterile pyuria. In most cases the interstitial nephritis resolves completely, either spontaneously or after steroid therapy. In a study on 21 children with acute TIN, TINU patients required a longer period of time for the renal function to recover in comparison with other etiologies (133). The uveitis often requires multiple steroid courses and other immunosuppressives like methotrexate, azathioprine and cyclosporin A, and may relapse (105, 134).

Idiopathic

Idiopathic cases of acute TIN are uncommon in childhood. In a series of 12 children with biopsy-proven acute TIN, only 1 had idiopathic disease (8). These cases are diagnosed by exclusion of the previously described entities and usually are not associated with hypersensitivity symptoms of fever, rash, or eosinophilia (3).

Treatment and Prognosis

The initial treatment of acute TIN is primarily supportive, with dialysis therapy as indicated (3, 4). It is important to

immediately discontinue all possible offending medications which in many patients might be multiple. When replacing the suspected medications, it is important to select medications that are not potentially cross-reactive (e.g., a cephalosporin to replace a -lactam penicillin) or other potentially nephrotoxic agents (90). In infection-related acute TIN, specific treatment of the underlying infection is indicated (84).

The use of corticosteroid therapy for acute TIN remains controversial (7, 135). Anecdotal case reports and uncontrolled trials with small numbers of patients suggest a therapeutic benefit (9, 81, 84). However, prospective controlled studies of corticosteroids or other cytotoxic agents in acute TIN are lacking, and it is possible that many reported patients would have recovered merely from the withdrawal of the inciting agent. Various steroid treatment regimens for acute TIN have been reported, primarily in the adult literature (86, 136). Some children have been treated with daily prednisone at a dosage of 2 mg/kg per day, which is tapered rapidly over 2–4 weeks (84). Pulse methylprednisolone followed by high-dose daily or alternate-day prednisone has also been used in adults (136). It was found recently to be significantly more effective if introduced early in the course of the disease (137). In idiopathic cases and those in which removal of the offending agent do not result in improvement we use a similar protocol of pulse methylprednisolone followed by daily oral prednisone of 2 mg/kg (maximum dose 80 mg) for 4 weeks, then changed to alternate day treatment and tapered over a period of several months depending on the response.

In patients who are steroid-dependent or steroid-resistant, several case reports and small series reported successful use of cyclosporine and mycophenilate (138, 139). It seems that especially the latter may have a room in treating patients who cannot tolerate steroids or are steroid-dependent or steroid-resistant (139). Whether the treatment with mycophenilate can be further potentiated by co-administration of low dose steroids requires further investigation. It seems likely that in coming years, new family of medications targeted at specific sites of the immunologic and injury mechanisms, currently under development, will be ready for clinical application

(140, 141). Their use will be complemented by the identifications of new markers better delineating the nature of kidney injury and response to treatment (142).

Prognosis for recovery of renal function in children with acute TIN is excellent (8, 81, 84, 90). Most affected patients recover renal function completely within weeks to months of onset of ARF. The mean renal recovery time of 13 children with acute TIN from various causes was 69.5 ±34.7 days (84). All patients had normal serum creatinine and urinalysis at follow-up examination 11/2 to 10 years after presentation. Of note, the clinical or histologic severity of disease at presentation did not correlate with rate of recovery of renal function. Another study of 7 children with acute TIN, 42% of whom required dialysis, reported a renal recovery rate of 86% (81). In two studies of adults with acute TIN, poor prognostic factors included the severity of the interstitial inflammation on renal biopsy and the duration of acute renal failure (143, 144).

Chronic Interstitial Nephritis

Epidemiology

Chronic TIN in children occurs primarily in the setting of obstructive uropathy, vesicoureteral reflux, and inherited conditions (3, 9). Obstructive uropathy together with reflux nephropathy account for almost 30% of all children who develop chronic renal insufficiency (145, 146). Primary chronic TIN from other causes accounts for only 2–4% of children with chronic renal failure, and chronic TIN plays a role in some patients with transplant nephropathy (146). In a few families chronic TIN has been described in association with cholestatic liver disease (95, 96) and in others with mitochondrial abnormalities (147, 148).

Clinical, Laboratory and Radiologic Features

Chronic TIN tends to progress more slowly than other forms of chronic renal diseases, and therefore, affected individuals often have no clinical evidence of disease until late in the course of renal insufficiency (3). Many patients have nonspecific constitutional symptoms characteristic of chronic renal failure, with weight loss, growth retardation, fatigue, anorexia, vomiting, and occasionally polyuria and polydipsia (149). Hypertension may also occur (150). Patients with the syndrome of chronic TIN associated with cholestatic liver disease may also have symptoms of hepatic dysfunction, such as pruritis and scleral icterus (151). Naturally in children with chronic TIN a major manifestation may include growth failure.

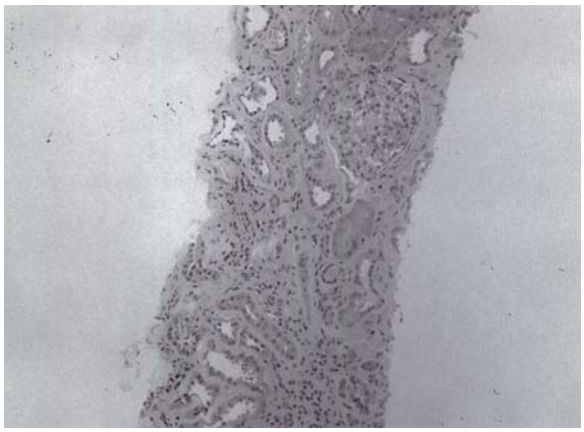
The clinical, laboratory and radiologic findings in chronic TIN are in essence similar to those observed in acute TIN. However, as in other cases of chronic kidney failure, the deterioration in kidney function is insidious and the medical history might extend back to a longer period. In contrast to some patients with acute TIN, patients with chronic TIN do not have oliguria; on the contrary some may be polyuric. In advanced cases, renal ultrasonography shows small and hyperchogenic kidneys. Skeletal radiographs may show renal osteodystrophy and in the case of Fraconi syndrome rickets and osteomalacia.

Pathology

Histologic findings in chronic TIN are characterized by tubulointerstitial fibrosis with a lymphocytic infiltrate, as well as tubular atrophy and thickening of the tubular basement membrane (3, 152). When renal damage is associated with high intratubular pressure, as occurs with vesicoureteral reflux and urinary tract obstruction, dilated renal tubules are particularly evident (83). In primary chronic TIN, glomeruli are often normal until late in the course of disease, when periglomerular fibrosis and global sclerosis are seen (*Fig. 44-2*) (151, 152).

Figure 44-2

Chronic TIN. Light microscopy of idiopathic chronic TIN in a 12-year-old boy. Renal cortex showing moderate interstitial fibrosis, tubular atrophy and tortuosity. The interstitium is infiltrated by scattered mononuclear cells. A preserved glomerulus with periglomerular fibrosis is seen.



Etiology

The causes of chronic TIN are summarized in Table 44-8. Of note, acute TIN from any cause can progress to chronic TIN if the disease process is not abated by removal of the inciting agent or steroid therapy. Secondary chronic TIN associated with primary glomerular or vascular disorders, especially focal segmental glomerulosclerosis and hemolytic uremic syndrome, is a common histologic finding in patients with progressive renal disease (153).

Chronic TIN in children most commonly is due to obstructive uropathy or high grade vesicoureteral reflux, especially when associated with urinary tract infections (146). Urinary tract obstruction of only a few weeks' duration may result in irreversible renal damage (7). Isolated vesicoureteral reflux, without obstruction, might also be associated with chronic TIN in children. Interstitial damage and progressive fibrosis in these disorders may result from renal immune responses that amplify tubulointerstitial injury initially induced by high urinary tract pressures at time starting in utero. Persistent and progressive renal inflammation and damage can occur, however, despite relief of the obstruction or surgical correction of the vesicoureteral reflux, mostly seen nowadays in severe prenatal obstructive and reflux nephropathy (147, 154, 155).

Treatment and Prognosis

There is currently no known effective therapy for chronic TIN. Naturally, when an offending agent is detected it should be removed. However, even in such cases the damage may be irreversible and its progression self perpetuating. Some experimental data indicate the potential for pharmacotherapy in stopping or slowing the inflammatory, apoptotic and fibrotic mechanisms by blocking their stimulating signals and activity. For instance, in the mouse model of unilateral obstruction, injury to the kidneys starts with increased angiotensin II production, which activates TGF-β in a cascade leading to tubulointerstitial inflammation and fibrosis (61). The use of ACE inhibitors in this model diminished transformation of renal cells to interstitial myofibroblasts and decreased migration of inflammatory cells into the interstitium. It is possible that the addition of aldosterone receptor blocker to the ACE inhibitor augments its beneficiary effect (156).

In a study in the mouse model of unilateral ureteral obstruction, injection of exogenous hepatocyte growth factor blocked myofibroblast activation and dramatically prevented interstitial fibrosis (157). The study suggested

that blockage of the transition of tubular epithelial cells to myofibroblasts may provide a novel therapeutic approach in halting fibrosis. In another study on the same animal model administration of bone morphometric protein-7 (BMP-7) prevented tubulointerstitial fibrosis and inhibited tubular atrophy by prevention of apoptosis. The exact mechanism of action by which BMP-7 provides renoprotective effect is yet unknown (61). Several studies have demonstrated the potential of 3-hydroxy-3-methylglutaryl CoA (HMGCoA) reductase inhibitors, like simvastatin and fluvastatin, in ameliorating interstitial fibrosis in animal models (158, 159). Other studies examined the effect of blocking TGF-β and its mediators in tissue fibrosis, like connective tissue growth factor (160). A different direction of investigation is focused on the potential protective effect of nitric oxide in chronic TIN (63, 161, 162).

At the moment, patients with chronic TIN are treated with supportive therapy. Whether the use of ACE inhibitors or HMGCoA reductase inhibitors in human chronic TIN is effective as is in some glomerular diseases associated with proteinuria has yet to be proven.

The prognosis for normalization of renal function in chronic TIN is less favorable than in acute disease. In specific forms of chronic TIN, such as juvenile nephronophthisis, progression to end-stage renal disease is almost inevitable (149, 150). By contrast, patients with chronic TIN in the setting of obstructive uropathy have a more variable clinical course (147, 154).

Systemic Disease

45 Vasculitis

Seza Ozen

Vasculitis is the inflammation in a blood vessel wall. This inflammation leads to narrowing or aneurysm of the vessel resulting in protean manifestations in the tissue that it nourishes. Kidney is one of the target organs frequently affected in vasculitis. The vasculitis syndromes have certain predilections for the size of the vessel and the organ they affect. A number of attempts have been made to classify the vasculitis syndromes based on these features. The nomenclature criteria suggested by the Chapel Hill Consensus Conference has been the most widely accepted (1). However, these criteria are mainly definition criteria. The American College of Rheumatology has suggested classification criteria for each vasculitis (2–4). However, these are strictly based on adult experience. Thus, in 2006 a group of pediatric rheumatologists and nephrologists published the working classification for childhood vasculitides (5) (*Table 45-1*) and classification criteria for the common childhood vasculitides (5). One should remember that all the mentioned criteria are classification criteria and the diagnosis of these diseases depend on the judicious assessment of the patient.

The most common vasculitides of children are Henoch Schonlein purpura (HSP) and Kawasaki Disease (KD), depending on the geographic area. HSP is reviewed in a separate chapter.

Kawasaki Disease (KD)

Definition and classification: KD is a vasculitis that affects the skin and mucosa as well. KD is characterized by a special preference for the coronary vessels. According to the Chapel Hill nomenclature criteria, KD is defined as arteritis involving large, medium-sized and small arteries and associated with mucocutaneous lymph node syndrome (1). KD is classified according to the presence of fever of at least 5 days duration plus four of the following five features (5–7):

Changes in peripheral extremities (edema and/or erythema of the hands and feet and subsequent periungual desquamation) or desquamation of the perineal area (*Fig. 45-1*).
Polymorphous exanthema mainly truncal,
Bilateral nonpurulent conjunctival injection,
Changes of lips and oral cavity: injection of oral and pharyngeal mucosa and
Cervical lymphadenopathy, usually unilateral.

As is the case in many vasculitides, KD is an abnormal immune response to environmental or infectious trigger (s), in a certain individual who is predisposed by virtue of their genetic constitution. Superantigens have been frequently implicated as the causative agents. This has been supported by the skewing of the T cell receptor Vβ repertoire (8). The fact that KD mainly affects the young children may be because of timing of the exposure of the environmental agent in a naïve immune pathway.

Clinical features: The clinical features of the disease are those included in the diagnostic criteria (7). Renal involvement is not common. However, pyuria and urethritis are frequent (8). Since this is a vasculitis affecting medium size arteries, it is perhaps not surprising that renal artery has been involved in a significant portion of historic biopsies (9). With improving imaging techniques, there have been reports of renal artery aneurysms in patients with KD albeit rare. Thus angiographic evaluation of other mid size arteries should be done as deemed necessary. Renal parenchymal involvement and acute renal failure have been reported only in rare case reports; one with a biopsy showing acute interstitial nephritis (10).

In the laboratory work-up, a complete blood count is mandatory. Thrombocyte counts are elevated at the second week of the disease; however, in the early phase of the disease they may be abnormally low (8). Acute phase reactants are high. Every child suspected of having KD should have an echocardiography for the search of coronary artery involvement.

Treatment: The treatment of KD consists of intravenous immunoglobulin (IVIG) administered at a dose of 2 g/kg along with salicylates at a dose of 60–80 mg/kg/d (7, 8). Steroids may be indicated in patients resistant to IVIG.

KD is the top cause of acquired heart disease in the western world (7). Thus, early recognition of the disease and administration of IVIG in the first 10 days of initiation is crucial. Aspirin should be given for 6 weeks

or until the ESR and thrombocyte counts are normal and lifelong for those who have any cardiac involvement.

Childhood Polyarteritis (PAN)

The Chapel Hill Nomenclature criteria (CHCC) defines polyarteritis in two separate groups (1): Classic PAN is defined by the CHCC as the necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles capillaries or venules. The same group has defined microscopic polyarteritis or polyangiitis (MPA) as necrotizing vasculitis, with few or no immune deposits, affecting small vessels (i.e., capillaries, venules or arterioles). Necrotizing arteritis involving small and medium sized arteries may be present. Necrotizing glomerulonephritis is very common and pulmonary capillaritis often occurs (1).

The consensus conference held with pediatric rheumatologists and nephrologists have revised the ACR and other existing pediatric criteria of polyarteritis nodosa (PAN) (*Table 45-2*) (5). Childhood PAN differs from microscopic polyangiitis through the absence of necrotizing glomerulonephritis and ANCA. In childhood PAN, kidney involvement occurs through necrotizing arteritis of the renal vascular bed whereas, as mentioned above, the presence of necrotizing glomerulonephritis classifies the child as MPA (11). In a large adult series, Agard et al. reported that the initial manifestations of both classic PAN and MPA were very similar except for gastrointestinal involvement and peripheral neuropathy being more frequent in PAN (12).

Childhood PAN also differs from adult PAN with the possible involvement of small size arteries as well (13). Furthermore the HBsAg associated PAN is very rare in children.

The new suggested criteria of childhood PAN include the demonstration of necrotizing arteritis in small-medium size arteries or aneurysms in mid-size arteries by imaging techniques (5).

Pathogenesis: As in KD, infections are implicated as a triggering agent in a predisposed host. In fact, a number of reports point to the role of streptococci in childhood PAN (13). In animal models, polyarteritis-like vascular lesions have been induced by infectious agents (14). On the other hand, other forms of PAN have more specific pathogenesis: HBs Ag-related classic PAN is an immune complex disease. MPA is a disease related to MPO-ANCA where the role of ANCA is vascular and capillary injury is similar to that suggested for WG (see below).

Table 45-2

Classification criteria for childhood PAN (reference 5)

A systemic illness characterized by a biopsy showing small and mid-size artery necrotizing vasculitis OR *Angiographic abnormalities* (aneurysms or occlusions)*
In the presence of at least two out of the following seven criteria
1. Skin involvement (livedo reticularis, tender subcutaneous nodules, other vasculitic lesions)
2. Myalgia or muscle tenderness
3. Systemic hypertension, relative to childhood normative data
4. Mononeuropathy or polyneuropathy
5. Abnormal urine analysis and/or impaired renal function
6. Testicular pain or tenderness
7. Signs or symptoms suggesting vasculitis of any other major organ system (gastrointestinal, cardiac, pulmonary, or central nervous system)

Clinical features: PAN often presents with general findings and wide range of systemic symptoms. In an effort to define the characteristics of childhood PAN throughout the world, we have recruited 110 patients from 21 pediatric centers from over the world (13). The mean age of the patients was 9.05 ± 3.57 years with a range of 1 to 16 years. There were an equal number of girls and boys (13). These features were similar to those reported in small series and were different from the adult data. The average ages of patients were 9.3 and 7.5 years in two series both including infants (15,16). Children almost always have general symptoms such as malaise, fever and/or weight loss. A number of patients do not have typical presentations of microscopic or classic PAN, but have inflammation in varying sized arteries of skin, musculoskeletal, and other organ systems (15,17).

Kidney involvement presents with systemic vasculitis along with an ischemic kidney involvement ranging from hypertension to tubulointerstitial nephritis or glomerular features. In previous small series before the Chapel Hill criteria were introduced, renal involvement was present in 65–80% (18,19). In the aforementioned multinational study, renal involvement was present in a significant proportion of the patients. The participating pediatricians classified 57.2% of their patients to have a systemic PAN disease, 30% as cutaneous PAN and 8.1% as microscopic PAN or polyangiitis (13). The clinical features of the childhood PAN are clearly reflected in this large series of childhood patients. Vessel size was not segregated in the classification of these patients. The disease often has an insidious onset with constitutional symptoms, typical skin lesions, abdominal pain and musculoskeletal complaints (13).

Renal involvement in childhood PAN may present as hypertension reflecting the necrotizing vasculitis of the renal artery. In fact, in the series of 110 children with PAN, 43% of the patients with systemic form of the disease had hypertension. Eighteen had abnormalities in the urinalysis whereas seven (11.1%) had impaired renal function during the course of their diseases. As to other organ systems involved, one-third had CNS involvement. Pulmonary and cardiac disease was reported in 11% and 14%, respectively (13).

Diagnosis was reached by angiographies in 52.5% of the patients, whereas it was through biopsies from various sites of involvement in the rest (13). The biopsies demonstrated the typical pauci-immune necrotizing arteritis.

In the last decade, a number of childhood series have been reported (15). Five patients with PAN and six patients with MPA have been reported from India (20). General symptoms, musculoskeletal complaints, peripheral neuropathy and skin lesions dominated the clinical picture. All the patients with PAN were HBsAg and ANCA negative and had normal urinalysis findings. In contrast, all patients with MPA demonstrated an active urine sediment and 83.3% were pANCA positive (20). Among the series of 7 patients reported by Peco-Antic et al., 29% presented with acute renal failure and three had deterioration of renal function (21).

Complete blood count may reveal anemia, leukocytosis and thrombocytosis. The work-up should include urinalysis, monitoring renal function, acute phase reactants to reflect disease activity and study of ANCA. It should be remembered that ANCA is often negative in childhood PAN although there may be nonspecific indirect immunofluorescence staining (13). Acute phase reactants are often elevated. Imaging for mid-size arteries is required for the patient for a search of aneurysm in a patient who presents with hypertension or ischemic abdominal pain. In a childhood series, children with medium or large vessel aneurysms or those with renal perfusion defects on angiography had a higher likelihood of having renal impairment (5, 16). In a review of the angiograms in PAN patients, Brogan et al. have concluded that the most reliable non- aneurysmal findings were of perfusion defects, presence of collateral arteries, lack of crossing of peripheral renal arteries, and delayed emptying of small arteries (16). In patients without hypertension, renal involvement is unlikely and mesenteric or hepatic arteritis may be the cause of abdominal pain and ischemia.

Treatment: Childhood PAN is a severe vasculitis that necessitates efficient treatment. Corticosteroids are the basis of treatment. Treatment of the systemic disease is similar to that of ANCA-related vasculitides. The pediatric literature reveals that additional immunosuppressive treatment is often used for these children. However, we need long-term and multicenter studies to define the need of additional immunosuppressive treatment and the length of steroid therapy in patients with limited disease.

Microscopic Polyangiitis

If the child with vasculitis presents with a rapidly progressive glomerulonephritis, then one needs to consider necrotizing glomerulonephritis (*capillaritis*) which is associated with ANCA (1) (see above). During the aforementioned conference of pediatricians, the presence of antineutrophil cytoplasmic antibody (ANCA) directed against the MPO antigen shown by ELISA and/or strong perinuclear staining pattern by indirect immunoflourescence (IIF) has been added to the previous definition of CHCC (5).

Pathogenesis: Both in vitro and in vivo experimental data support the pathogenic role of ANCA in MPA (22). In fact, a recent mice model has introduced direct role of the injury by anti-MPO: anti-MPO IgG led to focal necrotizing and crescentic GN with a paucity of glomerular immune deposition which mimics the human disease (23). On the other hand, we still need further data on the factors that are effective in the production of ANCA at the first place and the genetic factors involved.

Clinical and laboratory features: The presence of histopathologically proven necrotizing glomerulonephritis along with a positive MPO-ANCA titer in the absence of granulomatous lesions and upper respiratory tract involvement leads to a diagnosis of MPA (5). In the largest adult series of 85 MPA patients, 78.8% had renal symptoms and 47 had renal insufficiency (24). Childhood cases have been reported as small series. Hattori et al. (25) have reviewed 34 ANCA-seropositive Japanese pediatric patients with biopsy-proven pauci-immune necrotizing crescentic glomerulonephritis and 21 were classified as microscopic polyangiitis. The authors concluded that the disease was similar to that of adults except for female predominance (25). Patients who subsequently developed end-stage renal disease (n = 9) had significantly higher average peak serum creatinine levels and more chronic pathologic lesions at diagnosis compared with patients with favorable renal outcome (25).

In a pediatric series reported by Peco-Antic et al., 57% of patients had pulmonary-renal syndrome and two had acute renal failure progressing to ESRD (21). Another one developed chronic renal failure (42.8%). In another series of 6 pediatric patients from India, 50% presented with pulmonary renal syndrome (20). We reported a series of 25 patients with PAN, 10 of whom were classified as small vessel necrotizing arteritis (microscopic PAN) (15). Six developed renal failure and three of them had pulmonary-renal syndrome. All had high MPO-ANCA levels. Six had renal biopsies showing pauci-immune, necrotizing crescentic glomerulonephritis. Four of them (40%) progressed to chronic renal insufficiency (15). All the 19 MPA patients and 1 WG from China presented with hematuria and proteinuria and 80% had acute renal failure. Eighty five percent had various multiorgan involvement (26).

Laboratory investigations: An immuno-fluorescence testing for ANCA often reveals a p-ANCA pattern. Further ELISA testing should also be ordered which typically will show a high titer of MPO-ANCA (5, 22, 24). Urinalysis will reflect the glomerular disease with proteinuria, hematuria and an active urine sediment with casts. Renal function tests were impaired in 30–60% of the pediatric patients reported in the pediatric series (15, 20, 21). A chest X-ray is required in all patients. In patients with X-ray abnormalities, more sophisticated techniques such as CT are needed to define the extent of the lung disease.

Kidney biopsy is indicated in children with kidney involvement. The renal biopsy will typically reveal a pauci-immune necrotizing glomerulonephritis (*Fig. 45-2*). Immunofluorescence shows no specific staining and few if any electron dense deposits are present on electron microscopy (17, 24).

Differential diagnosis includes other ANCA-associated vasculitides such as Wegener Granulomatosis and Churg Strauss syndrome, lupus nephritis, severe cases of Henoch Schonlein nephritis, and coagulation disorders.

Treatment and Prognosis: The prognosis of ANCA-related vasculitides in children, MPA and WG, have substantially improved with the new treatment modalities in adult patients (27).

Treatment can be divided into two parts as induction and maintenance:

For induction treatment, corticosteroids and cyclophosphamide are widely accepted. Daily oral corticosteroids (1–2 mg/kg/d) and cyclophosphamide (2 mg/kg/d p.o. or monthly IV pulses 0.75gr/sqm) may be initiated as induction therapy. Whether cyclophosphamide is to be given via an oral or IV route is still a matter of debate. Although we wait for the results of the CYCLOPS trial, there is probably no significant difference between the two modalities. In patients with severe disease, intravenous methylprednisolone for 3 days is also suggested.

Figure 45-2

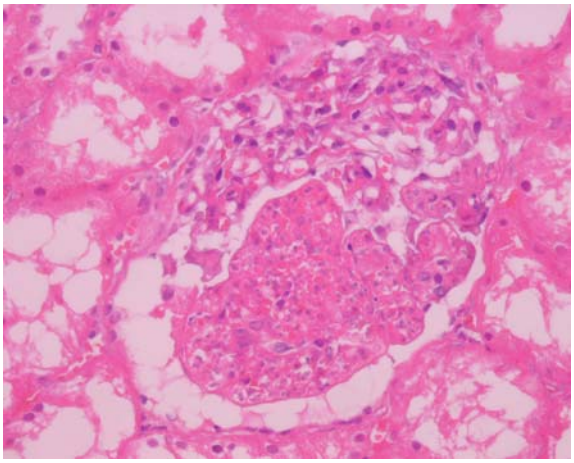

Figure 45-3
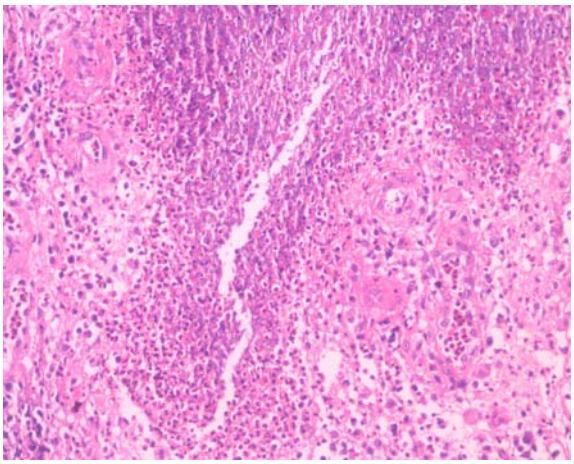
Maxillar sinus biopsy revealing a vessel wall showing evidence of vascular necrosis with transmural vasculitis and granulomatous inflammation with multinuclear giant cells around the vessel (HE, original magnification: ×200). (With the courtesy of Dr D Orhan, Hacettepe University). (See color plate 29)



For maintenance treatment, the steroid dose is tapered following clinical and laboratory response but not before 4 weeks to 1 mg/kg/d and the dose is decreased by 10 mg every 2 weeks to reach a minimum dose of 10 mg/d and subsequently every other day. This dose is continued for a year after clinical remission. For maintenance regimen, total cyclophosphamide dose has always been a concern for pediatricians. The CYCAZAREM study has shown that the replacement of cyclophosphamide with azathioprine at 3 months is also effective for disease control (27). Methotrexate has also been shown to be an alternative for maintenance treatment (28). A number of adult series have suggested the continuation of oral cyclophosphamide after remission.

Plasmapheresis, in addition to immunosuppressive treatment, may be used for life-threatening disease. The MEPEX study has shown that plasmapheresis is advantageous over pulse steroids in patients with renal failure (29).

The prognosis in children seems to be better than that reported in adults. In the childhood multinational series of 110 patients, there was only one (1.1%) death and two (2.2%) end-stage renal disease (ESRD) (13). In the adult series, the morbidity and mortality rate are significant.

Wegener Granulomatosis

WG is defined as a granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels. Necrotizing glomerulonephritis is common (1). WG is a vasculitides with major kidney involvement like microscopic polyangiitis. According to the criteria revised for childhood, three of the following six should be present to classify a child as having WG (5):

granulomatous inflammation on biopsy (*Fig. 45-3*),
abnormal urinalysis,
nasal-sinus inflammation,
subglottic, tracheal or endobronchial stenosis,
an abnormal chest x-ray or CT and
PR3 ANCA or C-ANCA staining.

Pathogenesis: The etiology of WG remains unknown; however, the endothelium itself is the target for initial injury. Recent studies suggest a direct involvement of ANCA in the pathogenesis of the disease and that inflammatory cells primed with ANCA are cytotoxic to the endothelial cell (22, 30). It has been shown that In vitro ANCA induces endothelial injury through the activation of neutrophils and the reactive oxygen molecules, proteases and cytokines that they release. In WG, ANCA is "active" against the proteinase 3 (PR3) on neutrophils. In vitro ANCA can further activate neutrophils to release reactive oxygen species, which in conjunction with neutrophils can damage and start the inflammation of endothelial cells (30). However, interestingly the mice model defined with MPO-ANCA was not been able to be repeated in PR3-deficient mice (22).

There are a number of hypothesis about why ANCA is produced in the first place (31). There have been a number of genetic associations with the disease including HLA antigens, a region on chromosome 6p21.3 (31). The polymorphisms of the natural inhibitor of PR3, alpha-1-antitrypsin was also studied as a susceptibility factor for the disease: heterozygosity for alpha1-antitrypsin deficiency has been associated with an increased risk and morbidity of WG (32). As to environmental factors, respiratory infections especially staphylococcal infections may have a triggering role during onset and relapses (32). The reader is referred to an excellent review on the existing hypotheses on the etiology of ANCA-associated vasculitis (31).

Clinical and laboratory Features: Data from small pediatric series reflect that 90% of children with Wegener granulomatosis present with symptoms related to the upper and lower respiratory tract vasculitis (33–35). This consists of sinusitis, epistaxis and nasal inflammation. Lower-airway inflammation will manifest as cough, dyspnea and hemoptysis and 30% will have abnormalities in the chest X-ray (33–35). In a recent series, upper airway involvement occurred in 21 patients at presentation and 24 during follow-up (35). Twenty patients had initial pulmonary involvement, most commonly nodules (44%) and pulmonary hemorrhage (44%). Four patients (16%) had venous thrombotic events. (35).

Kidney involvement occurs in 10 to 100% of affected children (33–35). In patients with kidney involvement, the findings range from proteinuria and/or hematuria to impairment of renal function. According to a recent series of 25 children, glomerulonephritis was present in 22 patients at presentation; Only one of 11 patients who presented with or developed renal impairment had normalization of serum creatinine (35). Necrotizing glomerulonephritis is one of the most serious manifestations in WG: a significant proportion of patients develop renal insufficiency (32).

Other clinical findings may include blurred vision, eye pain, conjunctivitis, episcleritis, persistent otitis media (33–35). CNS involvement may occur and present as cranial nerve palsies, seizures or neuropathies (32). Skin lesions include purpuric maculas, nodules, ulcerations and gangrene. Musculoskeletal complaints may be present. Cardiac involvement is very rare (32). Gastrointestinal involvement may occasionally be present in the form of nonspecific pain, nausea and vomiting (32, 33).

ANCA are present (1, 5). A cytoplasmic pattern on immunofluorescent staining of ANCA (c-ANCA) is present in 70–90% of patients with active WG (32, 35). ELISA tests detecting PR3-ANCA (Proteinase 3) will confirm this specificity in a high proportion of the patients.

White blood count and acute phase reactants are elevated (32). RF may be positive in low titers. Urinalysis is essential and will show hematuria, proteinuria casts when there is kidney involvement. Chest X-ray and pulmonary function tests are indicated for the assessment of lung disease (5, 35). The chest X-ray may show nodular infiltrates and nodules. Further assessment with a chest CT may be required.

Biopsies of airways show the characteristic granulomatous inflammation with necrotizing vasculitis and patchy necrosis (*Fig. 45-3*). Kidney biopsy shows pauci-immune focal necrotizing crescentic glomerulonephritis (1, 32–35). In about half of the cases, renal vasculitis can also be seen. Unlike the biopsy of lung or sinuses, the renal biopsy rarely shows a granuloma.

Differential diagnosis is similar to MPA. In addition, other granulomatous diseases such as sarcoidosis, lymphomatoid granulomatosis and tuberculosis are also included in the differential diagnosis of a child with WG.

Treatment and Outcome: Treatment of WG and microscopic polyangiitis is similar (36). In fact, most of the adult studies published by the EUVAS (European Vasculitis Study group) include MPA and WG patients together (27, 28).

Etanercept which is an TNF receptor blocker, has not been shown to be effective in WG in a prospective and randomized trial (37). Rituximab, an anti-CD20 monoclonal antibody, has been shown to be effective in small series (36).

Relapses are frequent as in the adults. Stegmayr et al. have found that relapses occurred after a median of 28 months (4–120) (34).

In WG, treatment with trimethoprim sulfamethoxazole is justified by the reports showing its prevention of relapses (32, 36). The overall data support the strong prognostic impact of renal function at diagnosis and of renal relapses during follow-up.

Churg Strauss Syndrome (CSS)

CSS is defined by the CHCC as a systemic necrotizing vasculitis with hypereosinophilia and extravascular granulomas along with asthma (1). The classification criteria have been developed by the ACR (38). CSS is very rare in childhood; the literature consists of case reports only.

The disease presents with long history of asthma. As indicated in the ACR criteria, the children are expected

to have features of eosinophilia, a history of allergy, peripheral nervous system involvement, or sinus involvement. Skin involvement and vasculitis is similar to that of PAN. However, this pauci-immune small vessel vasculitis is distinguished form WG and MPA by the presence of granulomatous inflammation and asthma along with hypereosinophilia. Among adult patients, about 20% develop renal involvement in the form of glomerulonephritis and renal insufficiency (39).

The laboratory work-up is similar to MPA or WG. This is one of the ANCA-associated vasculitides. Typically, a p-ANCA pattern is expected. Specific laboratory tests are required for the ACR criteria and differential diagnosis.

Treatment is similar to that of other ANCA-associated vasculitides (28).

Takayasu Arteritis (TA)

Takayasu arteritis is defined as a granulomatous inflammation of the aorta and its main branches (1, 2). Although this has not been confirmed, children seem to have a higher incidence of renal artery stenosis. This led to the inclusion of hypertension as a criterion to the new childhood criteria. According to the revised classification of TA for childhood, *angiographic abnormalities* (conventional, CT or MR) of aorta or its main branches is a mandatory criterion and at least one of the following four should be present (5):

1. Decreased peripheral artery pulse(s) and/or claudication of extremities
2. Bruits over aorta and/or its major branches
3. Blood pressure difference >10 mmHg
4. Hypertension (related to childhood normative data)

The exact etiology and pathogenesis are unknown. Inflammation of the vasa vasorum and myointimal proliferation of the involved large arteries is a marked feature of the disease (40).

Clinical and laboratory features: General symptoms may occur. End-organ ischemic features ensue according to the involved vessel site. Relevant symptoms may be claudication, abdominal pain, headache, syncope, stroke, and renal hypertension due to renal artery involvement (2). Hypertension is the most common renal manifestation. In a report of 10/25 kidney specimens for autopsies, 10 (40%) were classified as diffuse mesangial proliferative glomerulonephritis and 4 (16%) as other associated glomerulopathies (41).

In adults, the disease is divided into prepulseless phase and a pulseless phase. The prepulseless disease is not always evident in children. Aorta and the large arteries on both sides of the diaphragm may be involved. Symptoms depend on the anatomical location of the artery and on the type of lesion (stenotic, occlusive or aneurysmal).

Laboratory findings frequently include elevated ESR and CRP (42). Autoantibodies to nuclear antigens and ANCA are negative. The diagnosis depends on imaging techniques that demonstrate stenosis, and/or aneurysmal changes and/or aortitis in the aorta and its main branches. An MR-angiography or CT- angiography may provide the evidence of TA. In fact these latter technologies also provide information for the thickening of the vessel wall which reflects the inflammation. Recent reports highlight the value of PET-scan in the diagnosis of this disease. However, PET-scan is expensive and should be reserved for rare instances where differential diagnosis of fibromuscular dysplasia pose a problem.

Treatment and prognosis: Corticosteroids constitute the main treatment as other vasculitides. Concomitant use of methotrexate provides a higher remission rate and lower dose of maintenance steroid (40, 42). Cyclophosphamide may be required for patients with severe or resistant disease (42). Anti-TNF treatment also appears to be promising in selected cases (40). For patients who require revascularization intervention, both surgical and endovascular procedures can be performed, with low morbidity and mortality (40). The prognosis has improved with lower relapse rates. However, the evaluation of disease activity is a major problem in the management and follow-up. Any sign of vascular ischemia, a rising ESR, and new angiographic abnormalities should suggest a relapse of the disease and patients should be managed accordingly.

Behcet Disease

Behcet disease is classified according to the criteria used for adults where the presence of oral ulcers is a mandatory criterion. Two other criteria are needed: genital ulcers, skin findings, eye involvement and a positive pathergy test (43).

Behcet disease is rare in childhood (42). However, it has certain characteristics that would be of interest. Behcet disease is the only vasculitis that affects vessels of all sizes and both arteries and veins – except SLE. Behcet disease is a vasculitis that affects the mucosal membranes and the skin just as KD. The epidemiology suggests a certain spread through the ancient "silk road." BD has wide range of renal involvement (44). The common types of glomerular lesions among the reported cases

are crescentic GN, proliferative GN, and immunoglobulin A (IgA) nephritis (44). Aneurysms may be located throughout the renal artery, from the orifice of the main artery to intrarenal microaneurysms.

Treatment depends on the organ system involved and frequently requires immunosuppressive treatment.

In conclusion, kidney is an organ that is frequently involved in vasculitides. It has a major impact on the morbidity of the disease. Careful assessment and effective management of these patients are essential.

46 Henoch-Schoenlein Purpura

Rosanna Coppo · Alessandro Amore

History and Diagnostic Criteria

Heberden was the first to report, the beginning of 1800, the observation of one child presenting with petechial hemorrhages on lower limbs, joint, and abdominal pain, bloody stools and gross hematuria (1). The syndrome was named after the description by Schoenlein of the clinical entity characterized by purpura and joint pain (2) and by Henoch of the frequent association of gastrointestinal symptoms and kidney involvement (3). Henoch-Schoenlein purpura (HSP) is a small vessel vasculitis with multiorgan involvement including skin, gastro-intestinal tract, joints, and kidneys with variable clinical expression (4, 5). The past ambiguous definitions of hypersensitivity angiitis, anaphylactoid purpura or streptococcal rheumatic peliosis indicate the frequent clinical relationship between HSP and either allergy or infections.

The 1994 Consensus Conference on Nomenclature of Systemic defined HSP as a small vessels vasculitis (involving capillaries, arterioles, venules) with immunoglobulin (Ig) A (IgA)-dominant immune deposits, typically involving skin, gut, and glomeruli and associated with arthralgias or arthritis (6). The European League against Rheumatism/Pediatric Rheumatology European Society (EULAR/PReS) endorsed consensus criteria for the classification of childhood vasculitis proposes as classification criteria for HSP the presence of palpable purpura (mandatory criterion) and at least one of the following features: diffuse abdominal pain; any biopsy showing predominant IgA deposits; arthritis or arthralgia; renal involvement (any hematuria and/or proteinuria) (7).

The differential diagnosis, which is sometimes difficult in adults, is thought to be easy in children as many pediatricians consider that purpura without thrombocytopenia is sufficient to allow the diagnosis of HSP. However, skin biopsy confirms the suspect in only half of children (8), showing granulocytes in the walls of small arterioles or venules (leukocytoclastic vasculitis) and IgA vascular deposits.

Pathogenesis

The finding of IgA deposited in the vessel wall, as well as in the glomerular mesangial area, allows a clear-cut distinction of HSP and other systemic vasculitides or collagen diseases with similar multiorgan involvement.

IgA is found in serum and mostly in external secretions, playing a major role in mucosal immunity. Two distinct subclasses of IgA exist, IgA1 and IgA2, differing with the insertion of 19 aminoacids, peculiar to IgA1 and deleted in IgA2 subclass in the hinge region connecting the CH1 and CH2 domains, at the junction between the Fab and the Fc portions of the IgA1 molecule (9). Either subclass is synthesized by plasma cells as a 155 kD protein consisting of two α heavy chains and two κ or λ light chains, or as dimers or polymers of the basic 4-chain Ig structure, with molecular weights multiple of 155 kD. Dimers are joined by a J chain and can be transported from the basolateral to the luminal surface of secretory epithelium via a specialized glycoprotein receptor, the secretory component. In humans, serum IgA is predominantly monomeric, of the IgA1 subclass, and is derived from plasmocytes within the bone marrow and spleen. Mucosal-derived plasmocytes produce predominantly dimeric IgA containing J-chain (10) of both IgA1 and IgA2 subclasses. Glomerular deposits in HSP as well an in primary IgAN are made of polymeric IgA1, leaving open the possibility of either bone-marrow or mucosal origin, by a somehow disturbed synthetic pathway (11).

HSP, as well as primary IgAN, can be triggered by mucosal infections. Since IgA is the prominent Ig in mucosal secretions acting as a defense against viral and bacterial agents, several authors have tried to identify the eliciting antigen(s). HSP could be secondary to an immune response to antigen/s because eluted mesangial IgA cross-react with the mesangial area of other biopsy samples from different HPS patients (12). The concept of HSP as an antigen-dependent process was further emphasized by the experimental observation that most closely reproduces HSP: systemic vasculitis and nephritis can be

© Springer-Verlag Berlin Heidelberg 2009

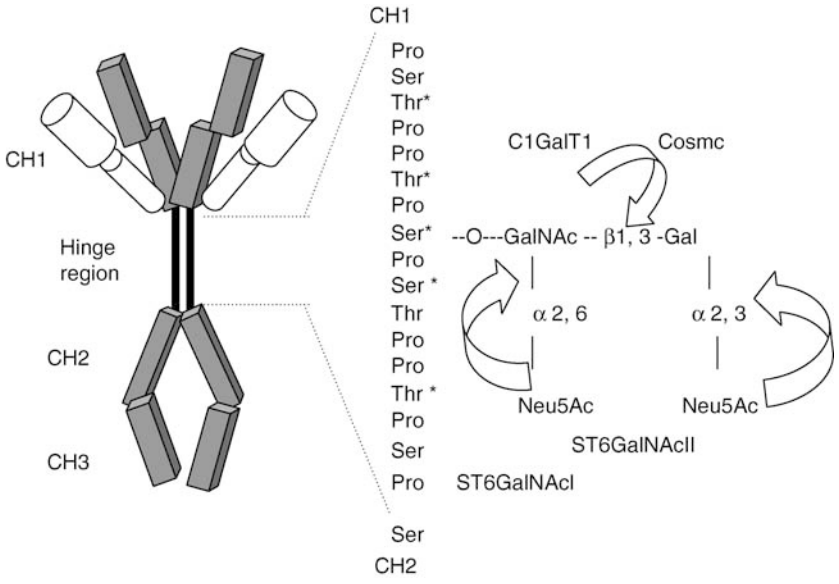
induced by injecting animals with a complement-activating carbohydrate antigen (13, 14). Food antigens or infectious organisms have been suspected (15–17), but the possibility of a single eliciting antigen remains unproved (18, 19), and environmental antigens rather play the role of triggering factors.

The accumulation of IgA immune complexes (IgAICs) within glomeruli has been considered the major pathogenic mechanism for HSP nephritis as for idiopathic IgAN. High levels of IgAICs have been detected during clinically active phases of purpuric rashes or HSP nephritis (20–23). However, IgAICs are not detected in all patients with renal involvement, suggesting the involvement of other pathogenic mechanisms. In HSP patients and particularly in those with nephritis, circulating IgA molecules react with α-galactosyl residues (23), fibronectin (24),gluten-derived molecules (19), mesangial matrix glycoproteins (25), or endothelial cells (26). Hence, it was postulated that these interactions were not true antigen-antibody reactions but rather related to the affinity of circulating IgA to various molecules, mostly glycoproteins.

Attention has been focused on the carbohydrate moieties of IgA, particularly IgA1, which is the predominant subclass deposited in both primary IgAN and HSP nephritis. IgA1 is highly glycosylated (9) (*Fig. 46-1*). In addition to the *N*-linked oligosaccharides typically present in the carboxyl terminal portion of all classes of Ig heavy chain, IgA1 contains 5 short *O*-linked oligosaccharide chains composed of *N*-acetylgalactosamine (GalNAc), galactose (Gal) and sialic acid (Neu5Ac). These oligosaccharides are coupled to serine and/or threonine residues which lie in the aminoacid insertion typical of IgA1 in the hinge region (9). The core 1 structure, Gal β1–3 bound to 3GalNAcα1-R, is synthesized from GalNAcα1-R by the action of core 1 β1,3-galactosyltransferase (core 1β3-Gal-T) and its chaperone, the core 1 β3-Gal-T (Cosmc). Sialyltransferases ST6GalNAcI and ST6GalNAcII bind the Neu5Ac residues to GalNAc in α2–6 and to Gal in α 2–3 respectively (9). The gene encoding the core galactosyltransferase is C1GALT1 is mapped on chromosome 7p14-p13, and the gene encoding for the specific chaperone Cosmc, C1GALT1C1, is mapped on chromosome Xq2 (27). Aberrant IgA1 glycosylation with defective sialylation and galactosylation and increased exposure of GalNAc residues has been detected in patients with HSP as well as in primary IgAN (28–31). A defective activity of core β3-Gal-T in B-cells has been postulated as for primary IgAN (32), but results are still inconclusive. A down-regulation of Cosmc expression in B lymphocyte of patients with IgAN has been recently

Figure 46-1

Human IgA1 contains five short *O*-linked oligosaccharide chains composed of *N*-Acetylgalactosamine (Gal NAc), Galactose (Gal) and Neuraminic Acid (Neu5Ac). These oligosaccharides are coupled to serine (Ser) and/or threonine (Thr) residues which lie in the aminoacid insertion typical of IgA1 in the hinge region connecting the CH1 and CH2 domains. The core 1 structure, Gal β1–3 bound to GalNAc, is synthesized by the β1,3-galactosyltransferase (C1GalT1) and its specific molecular chaperone (Cosmc). Sialyltransferases ST6GalNAcI and ST6GalNAcII bind the Neu5Ac residues to the core chain.



reported (33), however variants of C1GALT1 gene, rather than C1GALT1C1 have been found to be associated with the genetic susceptibility to IgAN (34). An imbalance in lymphocyte function, with a prevalence of T-helper 2 over T-helper 1 T cell subsets, can lead to altered IgA glycosylation in mice (35).

In vitro, desialylated or degalactosylated IgA molecules show a high tendency for self-aggregation, resulting in the formation of macromolecules with a molecular weight similar to IgAICs (36). Moreover, aberrantly glycosylated IgA1 trigger the synthesis of autoreactive IgA with formation of mixed IgA1/IgG ICs (37). Hence aberrantly glycosylated IgA1 can circulate in monomeric form or participate in the formation of self-aggregates or true IgA1ICs. Whether present in IgA1ICs or in self-aggregates, such aberrantly glycosylated IgA1 likely escapes clearance by hepatic receptors for asialoglycoproteins (38) because of the lack of Gal and possibly because of the size of the aggregate, which excludes them from the space of Disse. Abnormally glycosylated IgA1 may deposit in the glomerular mesangium more readily than normal IgA1 by virtue of enhanced inter-carbohydrate (lectin-like) reactivity with the fibronectin, laminin, and collagen within the mesangial matrix (25).

An enhanced interaction of aberrantly glycosylated IgA1with the transferrin receptor (TfR) and Fcα receptors on mesangial cells results in cellular activation and phlogistic mediator synthesis (39). We demonstrated an increased expression of integrin adhesion molecules (40), and of the inducible form of nitric oxide synthase (41) in mesangial cells after incubation with desialylated/degalactosylated IgA or IgA1 isolated from patients with IgAN. The resultant increase in the production of intraglomerular nitric oxide may lead to peroxidative damage, apoptosis, and sclerosis. This effect can be further enhanced by the concomitant depressed expression of vascular endothelial growth factor induced by aberrantly glycosylated IgA1 on mesangial cells, leading to an impaired repair process (42). Aggregates of IgA also stimulate the synthesis of a variety of cytokines (e.g., interleukin-6, platelet-derived growth factor, interleukin-1, tumor necrosis factor α, transforming factor β), vasoactive factors (e.g., prostaglandins, thromboxane, leukotrienes, endothelin, platelet-aggregating factor, nitric oxide) or chemokines (monocyte chemotactic protein-1, interleukin-8) by mesangial cells.

Complement activation may have a role in the pathogenesis of HSP nephritis. It is of interest that aberrantly glycosylated IgA can activate complement more efficiently than normal IgA (43, 44). In children with active HSP, CH50, and properdin levels are often reduced with increase in levels of C3d (21, 45), even though serum levels of C3 and C54 are within the normal range. This suggest a complement activation, possibly via the alternative pathway, balanced by enhanced factor synthesis, thus masking the consumption.

Antineutrophil cytoplasmic antibodies (ANCA) of the IgA isotype (IgA-ANCA) have been found in adults with HSP, but other reports failed to confirm these findings (46, 47). We demonstrated that IgA molecules from children and adults with HSP nephritis show an increased binding to sonicated neutrophil extracts and to purified myeloperoxidase but not to serine protease-3 (29). Of interest, this reactivity was never observed in sera of patients with primary IgAN, even though they have aberrantly glycosylated IgA1. This binding is affected by electrical charge and carbohydrate interactions, suggesting a lectin-like binding of aberrantly glycosylated IgA1 to ANCA antigens, rather than a true antigen-antibody reaction. Myeloperoxidase may be released in excess during phlogistic processes, leading to circulating IgA1-ANCA complexes, which, in the presence of increased levels of eosinophilic cationic proteins (48) as well as other phlogistic mediators, may favor vascular deposition of IgA1. Plasma IgE levels are increased in HSP and are significantly higher than in IgAN (49), which might be consequent to a prevalence of T-helper 2 lymphocytes. The vascular affinity of circulating IgA-containing immune material leads to purpura and systemic vasculitis.

Signs of increased oxidative stress can be detected in children with HSP, likely a result of a systemic immune system activation (50). Increased number of B cells synthesizing IgA and abnormalities of T-suppressor activity have been observed during the acute phase (51). In patients with HSP nephritis a reduction in Fcγ, C3b, and Fn receptor function of mononuclear phagocytes has been reported (52). These abnormalities were transient, probably secondary to saturation of receptors more than a primary event.

Several reports indicate that HLA Class II gene polymorphisms can to be a risk factor for HSP. A positive association with DRB1*01 and DRB1*11 (64% vs. 48% in the controls) as well as a negative association with HLA-DRB1*07 was first reported by our group in an Italian cohort (53) and confirmed in another study (54). An increase in DQA1*0301 (55) was found in Japanese children. An increased frequency of homozygous C4A or C4B null phenotype was observed in whites (56) and in Japanese patients (55). No association of angiotensin-converting enzyme genes polymorphism and manifestations or progression of HSP nephritis was found (57). The risk of developing severe gastrointestinal complications is

negatively associated with polymorphism of the intercellular adhesion molecule 1 (ICAM-1) and it has been suggested that it might also reduce the risk of renal involvement (58).

Clinical Data

Epidemiology

HSP is the most frequent vasculitis in childhood. Its annual incidence is approximately 14 cases of 100,000 children (59). In a recent Dutch epidemiology study the incidence was 6.1 cases of 10,000 children (8) whereas the incidence in United Kingdom was 22.1 in another study (60). HSP is frequent in the first decade of life; however it rarely affects children younger than 2 years of age. The median age at onset is 4–5 years (61). The sex ratio shows a male preponderance (male to female ratio, 1.4–1.7:1). Renal involvement is most frequent between 6 and 10 years of age (62–64). The geographic distribution of HSP is similar to that of IgAN. HSP is common in Europe [particularly in France, Italy, Spain, UK, and Finland] and Asia (e.g., Japan, Singapore, and China), whereas it is less common in North America and Africa (65, 66). The disease may be favored by racial factors, as HSP rarely affects blacks and American Indians (67).

Factors Triggering Henoch-Schonlein Purpura

The disease may be triggered by an infectious disease (62). *Streptococcus β, Yersina, Mycoplasma, Toxoplasma, varicella*, measles, rubella, adenovirus, HIV, and several other agents have been recorded among the triggering factors but without direct evidence of causality (66). There is a peak incidence of HSP in winter in North Europe and in June in Italy (68). Some epidemic clusters and familial cases of HSP have been reported (69).

The role of allergic reactions has been questioned, as well as the role of vaccinations (e.g., against smallpox or influenza), drugs (e.g., including ciprofloxacin, vancomycin, minocycline, carbamazepine), or other allergens (66).

Systemic Manifestations

HSP syndrome is characterized by a multiorgan involvement (61, 64, 67).

Skin

The characteristic skin lesions consist of slightly raised "palpable" purpuric macules that do not disappear on pressure with normal platelet count. They mostly begin with erythematous macules, some of which evolve into slightly raised urticarial papules, which soon become purpuric and eventually take a fawn color as they fade. Individual petechiae often become confluent in large patches. The purpuric rash often has a symmetrical distribution over the extensor surfaces of the lower limbs and forearms and the buttock sides (*Fig. 46-2*). The purpura is mostly present in the ankle area and in the milder cases it can be present only there. It also affects pressure areas (e.g., belt and pants) and occasionally involves earlobes, nose, and genitalia. Sometimes the rash is accompanied by fever and general malaise, with a clinical picture of infectious purpura or allergic reaction.

At microscopic examination of skin biopsy, leukocytoclastic vasculitis of dermal vessels is observed with IgA deposits in the vascular wall.

Purpura is concomitant with renal involvement in two-thirds of the cases. In 25% of children purpura precedes and in 10% follows the urinary abnormalities by 3–12 months (64). The purpura lasts for a few days but often relapses. Subsequent flare-ups of purpura occur 25% of children with severe renal disease (70, 71). Relapses of purpura may be accompanied by macroscopic hematuria and a transient increase in proteinuria, although the extent and duration of purpuric rash are not correlated with the severity of the renal lesions.

Figure 46-2

Purpuric rash of Henoch-Schoenlein purpura over the sides of the buttocks.

Gastrointestinal Tract

Gastrointestinal symptoms are reported in 50–70% of patients (4), more frequently in children than in adults (64). The most typical manifestation is diffuse abdominal pain, increasing after meals, referred to as *bowel angina*. Vomiting, hematemesis, and hematochezia or melena is frequent (5). Major abdominal complications, like intussusception, intestinal infarction, and bowel perforation are rare events. The pain is often severe and mimics an acute surgical emergency. There is a range of endoscopic findings including gastritis, duodenitis, ulceration, and purpura, mostly involving the second portion of the duodenum. Intestinal biopsies show IgA deposition and leukocytoclastic vasculitis in the submucosal vessels. Steroid therapy may be useful in relieving bowel-wall edema and pain, however most children improve spontaneously.

Joints

Transient arthralgia is reported in 50–70% of cases (4). They mostly involves lower limb articulations, ankles, and knees, with a picture of oligoarticular synovitis, A periarticular edema may be present. The articular involvement does not lead to joint erosions, deformities or functional limitations.

Kidney

The selection of HSP patients strongly affects the data concerning the prevalence of renal involvement (4, 59–65). Variations in the prevalence of renal involvement among different series may also depend on the methods of detection of nephritis and it may increase if serial urinalyses are performed. In unselected cohorts of children, the prevalence of the renal involvement during the course of HSP is approximately 33%, ranging form 20–55% (63). When serial urinalyses are performed for one year, the percentage of renal involvement among children with HSP increases progressively, (71). The urinary abnormalities detected in unselected cohorts of children with HSP include hematuria and various degrees of proteinuria, up to nephrotic-ranges (*Fig. 46-3*).

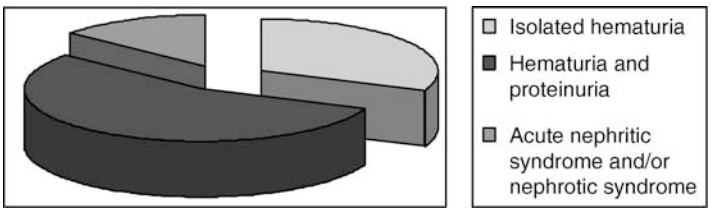
In cohorts of children with severe renal disease, as in the cohort of the Italian register of renal biopsies in children (72), the prevalence of glomerulonephritis related to HSP is 11.6% of all renal diseases. These figures are similar to French series, where HSP was detected in 10 to 15% of cases (73).

The pre selection of children investigated also affects the clinical picture. General pediatricians often report a systemic disease with modest and transient urinary abnormalities (73), whereas in pediatric nephrology departments the renal disease is more severe (74, 75).

The manifestations of glomerulonephritis secondary to HSP include isolated microscopic or macroscopic hematuria, mild or heavy proteinuria with or without nephrotic syndrome, renal failure, and hypertension (63). The more frequent clinical presentation of HSP nephritis in non selected pediatric series is an isolated microscopic hematuria (73, 76). In 80% of cases, it is detected within 4 weeks after the onset of the disease. It is often transient, detectable only by routine urinalysis during the acute phase, followed by a complete recovery. In some patients, proteinuria of variable amounts is present. Nephrotic syndrome is more common in referral centers but is rare in unselected series. Renal function is normal in most children but may be impaired in children with severe nephritic syndrome It is most often a moderate renal failure, which rarely requires dialysis. Hypertension is rare at onset and has been reported in children with minimal urinary abnormalities.

Figure 46-3

Clinical presentation of children with nephritis of Henoch-Schoenlein purpura. Cumulative data from 666 children (76, 77, 87, 88, 92, 93).



Other Non Renal Manifestations

HSP can be complicated by a cerebral vasculitic process, resulting in convulsions, encephalopathy, chorea or blindness (74).

Other rare manifestations include hemorrhage in the calf or subcutaneously, pulmonary-renal syndrome, cardiopulmonary syndrome, pancreatitis (77), adrenal bleeding or testicular involvement mimicking torsion (66).

The vasculitic process can affect the ureter (78). In these cases it is generally associated with loin pain. The ureteral lesion of necrotizing vasculitis may evolve into sclerotic lesions and progress to stenosis, requiring correction (78, 79). An early diagnosis by repeated ultrasound can limit can the consequences of this complication (80).

Laboratory Data

In HSP, as in the idiopathic IgAN, serum IgA levels are increased, in up to 70% of patients, but the increase is often limited to the acute initial phase, returning to normal levels when the children enter remission. The subclass mostly increased is polymeric IgA1 (66). IgA1 with aberrant glycosylation and increased exposure of GalNAc residues can be detected particularly during acute phases as well as IgA1ICs (28–31) and IgA/fibronectin aggregates (24). IgA antibodies to endogenous or exogenous antigens have been reported, including IgA rheumatoid factor (81). High levels of IgA reacting with sonicated neutrophil extracts (IgA-ANCA) and with purified cytoplasmatic antigens (myeloperoxidase) have also been detected in children with HSP nephritis (29, 46).

Platelet count is in the normal range and the activity of the clotting factors is normal. Conversely abnormalities and low levels of fibrin-stabilizing factor (factor XIII) have been reported (82) as well as increased von Willebrand factor plasma levels (83), in acute phases of HSP, indicating an endothelial damage that favors fibrin deposition and crescent formation.

Recent investigations are focused on a renal damage pattern found in urine of patients with IgA-associated glomerulonephritis by capillary electrophoresis (84) as well as increased podocyturia (85) but these new biomarkers need further validation.

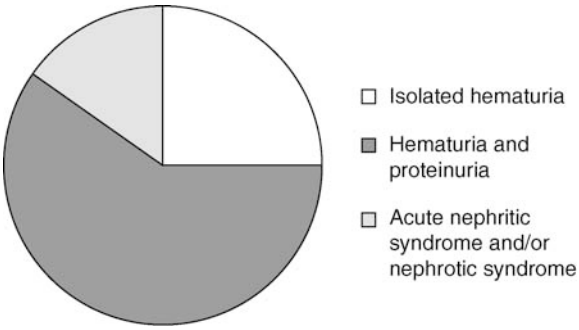
Pathology

Light Microscopy Features

HSP nephritis is characterized by mesangial damage with different degrees of hypercellularity (*Fig. 46-4*), ranging from isolated mesangial proliferation to focal and segmental proliferation and severe crescentic glomerulonephritis.

Figure 46-4

Renal biopsy specimen from a patient with nephritis of Schoenlein-Henoch purpura showing expansion of the mesangial matrix and increase in mesangial cellularity (PAS × 250).



Light microscopic examination shows a wide range in terms of the type and severity of glomerular involvement from one patient to another and also within the same biopsy, from glomerulus to glomerulus (86–88). Classifications of HSP nephritis are mostly based on the severity of the proliferative lesions (4, 67, 87). Adhesions of the tuft to Bowman's capsule can be found in coincidence with segmental proliferative lesions, often with splitting and duplication of glomerular basement membranes. In rare cases the severe mesangial proliferation is associated with mesangial interposition in which cells and matrix migrate into the capillary walls, between the basement membrane and endothelial cytoplasm, mimicking a membranoproliferative glomerulonephritis. Polymorphonuclear cells may infiltrate the glomerular tufts, sometimes as severely as in acute post-streptococcal glomerulonephritis. Segmental necrosis of the glomerulus is often present at onset. It is not rare to detect intracapillary glomerular thrombi.

It is common to find crescent formation varying in size from a limited segment to circumferential crescents. At onset, crescents are cellular, then evolve into fibrous crescents, generating segmental scars or global sclerosis. The most common histological feature is a predominance of small crescents. In children with severe renal symptoms, extra-capillary proliferation is detected in more than half of the cases (65, 89). In these cases, crescents often involve less than 50% of glomeruli. Some biopsies show periglomerular inflammatory infiltrates, mostly associated with crescents (15% of the children) (71).

Histologic classes of HSP nephritis can be distinguished according to the presence or absence and the extension of extra capillary proliferation, and degree of the endocapillary lesions (*Table 46-1*) (67). The six classes include minimal or moderate glomerular lesions and absence of crescents (Class I or II), various extent of extra-capillary cellular proliferation (in less than 50% of glomeruli, in 50–75% or in more than 75%, Class III, IV, and V respectively). Class VI includes pseudo-membranoproliferative glomerulonephritis.

The distribution of histologic changes in 270 children (65, 89, 90), showed in half of the cases endocapillary focal or diffuse proliferation with crescents involving less than 50% of glomeruli. Severe extracapillary proliferation involving more than 50% of glomeruli was limited to approximately 25% of the cases (*Fig. 46-5*).

Hyalin changes or accumulation of fibrinoid material, or necrosis with inflammatory infiltration and clear findings of vasculitis are present in approximately 10% of children. Blood vessels may show medial hypertrophy and intimal fibroelastosis. Necrosis of the capillary tuft has been reported in 8% of children, coincident with extra-capillary proliferation. The renal biopsies form children with HSP nephritis frequently show degenerative tubular alterations with flattening, vacuolization, desquamation, and focal loss of the brush-border microvilli, in the cortex (67). Tubular cylinders and blood casts are detected in 30% of patients.

Immunohistochemistry

Mesangial IgA granular deposits are the hallmark of the disease which, in contrast with the frequent focal and segmental proliferative changes, is always diffuse as in primary IgAN (*Fig. 46-6*). IgA1 is the dominant subclass with equal distribution of light chains. The J chain is detectable, indicating that IgA in deposits is dimeric, but the secretory tract is absent. Extensive sub-endothelial deposits are associated with the most severe histologic forms with endocapillary proliferation or crescents.

C3 is codeposited in 75–85% of the cases similarly to idiopathic IgAN. The membrane attack complex C5–C9 and the alternative complement pathway components are always detected. Early classical pathway complement components C1q and C4 are present only rarely and stain with low intensity (67). IgG and IgM codeposits are present in the 40% of the cases. Fibrin or fibrinogen deposits are found in 60–70% of patients, both in mesangial and in parietal areas, often coincident with mesangial proliferation, suggesting a role of the clotting cascade activation. Glomerular fibrin-related deposits are much more frequently present in HSP nephritis than in IgAN (65) and are often related to active phases with extracapillary proliferation. Deposits of IgA and C3 can be found in arterioles or cortical peritubular capillaries in children with severe glomerular changes.

Electron Microscopy

Electron-dense deposits are detectable in a setting of mesangial matrix expansion and variable degree of cellular hyperplasia (67). The deposits, initially paramesangial and small, become larger and of non uniform

Table 46-1

Classification of Henoch Schoenlein nephritis lesions according to Emancipator (67)

Class I:	Minimal glomerular lesions and absence of crescents
Class II:	No crescents IIa: Pure mesangial proliferation IIb: Focal-segmental endo-capillary proliferation IIc: Diffuse endo-capillary proliferation
Class III:	Presence of extra-capillary cellular proliferation in less than 50% of glomeruli IIIa: In association with focal and segmental endo-capillary proliferation IIIb: With diffuse endo-capillary proliferation
Class IV:	Florid extra-capillary proliferation in 50–75% of glomeruli IVa: In association with focal and segmental endo-capillary proliferation IVb: With diffuse endo-capillary proliferation
Class V:	Extra-capillary proliferation in more than 75% of glomeruli Va: In association with focal and segmental endo-capillary proliferation Vb: With diffuse endo-capillary proliferation
Class VI:	Pseudo-membranoproliferative glomerulonephritis

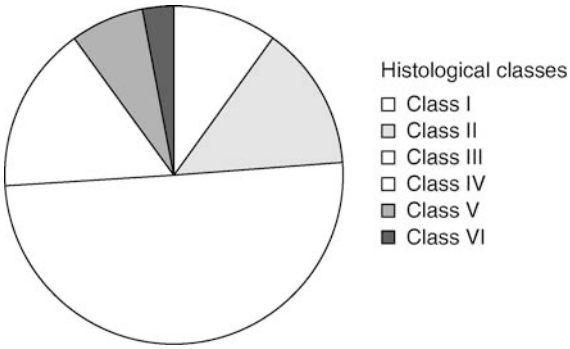
Immunopathology of Henoch-Schoenlein nephritis: Mesangial deposits of IgA (anti IgA × 250).



density, in strict connection with the mesangial matrix. Most deposits have a mesangial localization with parietal extension (in 60% of the cases), are purely mesangial only in 30% of cases. The parietal, paramesangial electron-dense material is generally subendothelial, more rarely subepithelial. Sometimes, electron-dense deposits, "hump" like with "garland" shape or fluffy aspects, are detectable. In other cases, the deposits show with a "woolly" aspect in the external rara lamina, placed in the periphery of the capillary loops and delimited by a thick layer of new basement membrane. As a possible consequence of the membrane reactivity to immune deposits, the presence of parietal deposits modifies the capillary basal membrane profile because of the widening of the rara internal and external lamina, with neo-formed layers.

Follow-Up Renal Biopsies

Studies of serial biopsies in children with HSP showed a good correlation between the histologic changes, clinical data – particularly at follow-up – and outcome (91). When patients undergo clinical resolution, mesangial proliferation disappears, and small crescents regress while others evolve into segmental synechiae. IgA deposits substantially decrease and sometimes completely disappear. Conversely, when repeat biopsies are performed in patients with persistently active or progressing nephritis, the proliferation continues to be severe, and evolution into fibrotic lesions is detected. The importance of careful clinical monitoring during the follow-up of children with HSP nephritis must be stressed also on the basis of the good correlation between clinical and histological data reported by this study.

Non Renal Lesions

The typical lesion of HSP, either in skin, gut or in kidney vessels is leukocytoclastic vasculitis with fragmentation of leukocyte nuclei in and around arterioles, capillaries, and venules, surrounded by infiltrating neutrophils and monocyte cells in the presence of nuclear residues (nuclear dust) in the wall of arterioles. Fibrinoid deposits and arteriolar and venular necrosis can be found. Deposits of IgA and C3 are present in the dermal capillaries in purpuric lesions and uninvolved skin and are considered a valid diagnostic criterion, with 100% specificity in combination with leukocytoclastic vasculitis. IgG and IgM can be codeposited in approximately 20% of the cases, whereas C1q and C4 are absent. Similar deposits have been reported in superficial derma capillaries of IgAN patients. In dermatitis herpetiformis, IgA deposits are found as well, but they are located on the top of the derma papilla. In systemic lupus erythematosous, the dermal-epidermal junction is mostly positive for IgG, C1q, and C4. The diagnosis may be difficult in the rare cases in which skin

eruption entirely consists of urticaria lesions without purpura. Hypersentitivity vasculitis is sometimes overlapping, but the dermal IgA vascular deposits are specific for HSP lesions.

Correlations between Clinical and Pathologic Data

In the Italian HSP series of 74 children (64, 70), patients with minimal proteinuria had higher prevalence of histologic lesions without crescents (classes I and II) (92%). In cases with significant proteinuria, more severe renal lesions were frequently found. Extracapillary proliferation was often found in children with nephrotic proteinuria (33% of class III and IV). Gross hematuria at presentation was associated with crescent formations in the 22% of the children. The clinical feature mostly predictive for severe histologic lesions was the onset with renal function impairment, as 62% of children with severe acute nephritic syndrome and severe kidney function impairment, had crescents, and other authors reported similar findings (86).

Clinical Course and Prognosis

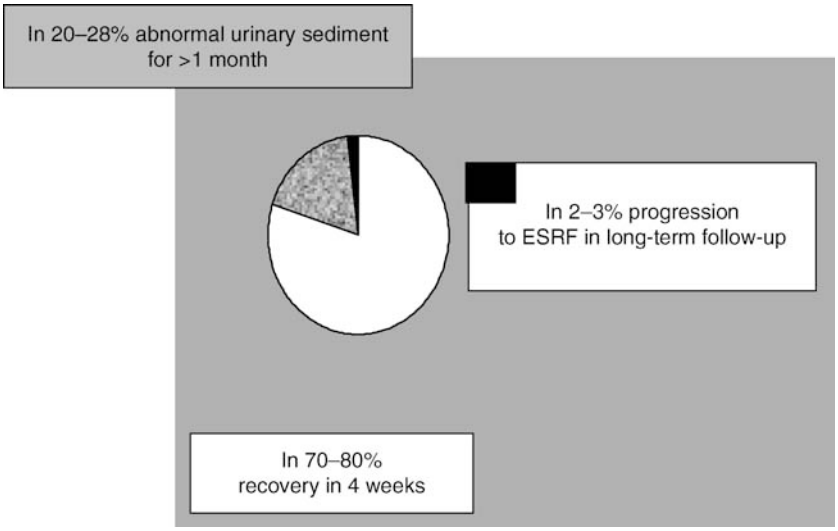
HSP nephritis accounts for 5.1% of children with end-stage renal failure (ESRF) in Europe (4, 68).

The clinical course and long-term outcome vary according to the cohorts examined, particularly when unselected cohorts are compared with children followed by pediatric nephrology units. In unselected series, HSP is a mild disease, with renal involvement in a minority of cases, mostly presenting with isolated hematuria or minimal proteinuria and with long-term concerning no more than 1% of patients (91). Reports of series of children admitted into general pediatric hospitals indicate a prevalence of urinary sediment abnormalities in 20–54% of the cases, which disappear within four weeks in 70–80% of the cases, or last for more than one month in 20–28% of the cases (81, 87, 88, 92, 93) (*Fig. 46-7*). With a follow-up of more than 10 years, a progression to ESRF is observed in approximately 2–3% of the children with initial signs of renal involvement (94).

The remission rates reported by tertiary reference centers are below 50%, with poor outcome in 10–25% of children (75, 95). In cohorts of children with a severe disease, long-term prognosis is poorer, as 15–30% of them progress to renal failure with wide variability depending on the duration of follow-up (63). In a long-term follow-up study, a late progression was observed after 25 years in 25% of children, not only in cases with persistently active renal disease, but also in others having experienced clinical improvement after the acute phase (75). These authors reported persistent urinary abnormalities in 15% of children with a nephrotic onset or persistent heavy proteinuria, 40% of those

Figure 46-7

In children admitted into general pediatric hospitals, the urinary sediment abnormalities disappear within four weeks in 70–80% of the cases, last for more than one month in 20–28% of the cases. Progression over long-term follow-up is observed in 2–3% of the children (81, 87, 88, 92–94).



with a nephritic presentation and 50% of those with mixed nephritic-nephrotic syndrome at onset. Some of these patients ended in ESRF. It is clear that renal function may deteriorate during the follow-up even in patients who apparently completely recovered two years after onset (75), perhaps due to sequences of glomerular hypertension. Even in some cases who had a second renal biopsy years after the initial vasculitis episode and no urinary abnormalities, IgA mesangial deposits were detected, indicating a protracted silent renal disease (96).

In the Italian multicenter study (70, 89) after 1–20 (mean 6.7) years, one-third of the 83 children who had had a renal biopsy were in remission (*Fig. 46-7*). In 40% of the cases only minimal or moderate proteinuria was left. Chronic renal failure or doubling of baseline creatinine occurred in 14.5% of children and 7.2% reached ESRF needing dialysis after 4.5–12.0 years (89). When comparing children and adults with a HSP nephritis severe enough to warrant renal biopsy, the outcomes are similar over the first years (70). However, over longer follow-up the final outcome results worse in adults, as renal survival at 10 years was 90% in children and 75% in adults (relative risk 3.5) when considering dialysis as the end-point, and 86% and 67% respectively (relative risk 14.9) when considering doubling of baseline creatinine as the end-point (89). Physiological long-term function decline in old subject should also be considered.

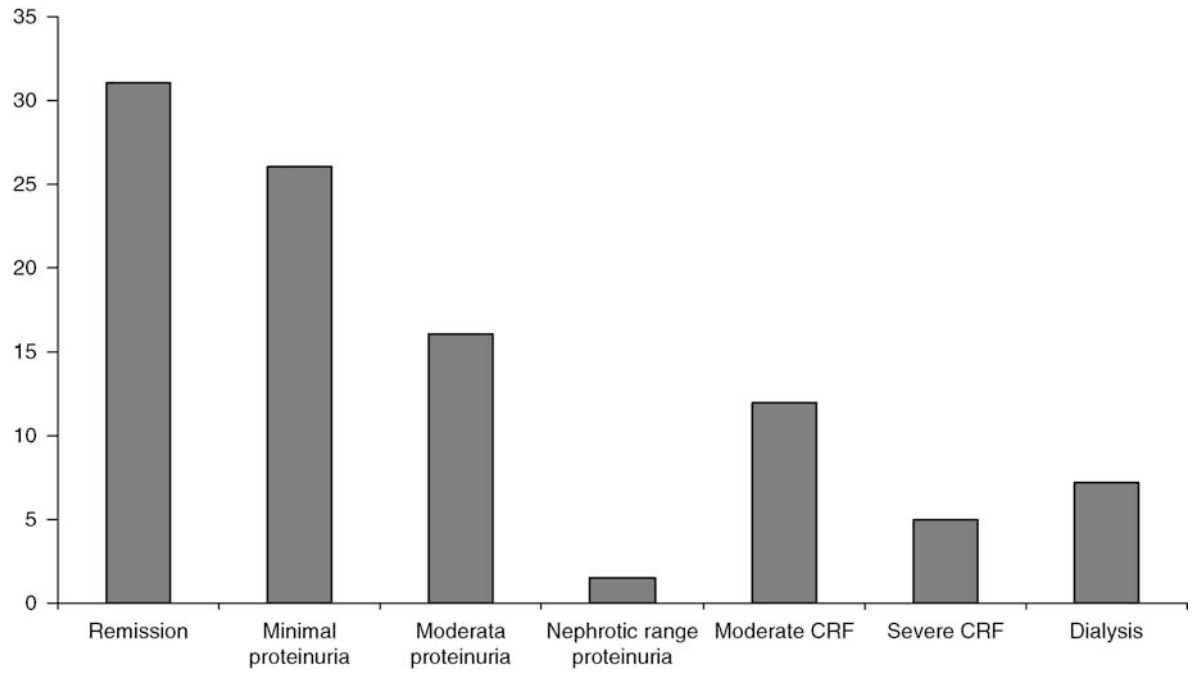
Children at Risk for Progression

It is of paramount importance to identify children with potentially progressive renal disease. As reported above, the clinical presentation is, in general terms, indicative of the long-term outcome (76). In some reports, nephrotic syndrome or renal insufficiency at onset were risk factors (44%) for renal failure after two decades of follow-up (75) (*Fig. 46-8*).

Conversely, in the Italian cohort (70, 89), no significant prognostic factor was found at presentation, including renal function impairment at onset or hypertension. Mild proteinuria or, at the opposite, nephrotic-range levels, were respectively associated with high frequency of remission or functional deterioration. However, children with mild proteinuria also frequently displayed severe histologic lesions, with extracapillary proliferation and nephrotic and nonnephrotic children had similar outcomes. The variable found at multivariate analysis to be

Figure 46-8

Long-term renal outcome of patients with Henoch-Schoenlein nephritis. Mean 5-year follow-up of 57 children with severe Henoch-Schoenlein nephritis, warranting renal biopsy (From the Italian Group of Renal Immunopathology (70)). Moderate CFR: chronic renal failure with <90 to >60% glomerular filtration rate. Severe CRF: chronic renal failure with <60 to >30% glomerular filtration rate. (Adapted from reference (70).



strongly predictive for both progression to doubling of creatinine and dialysis, was mean proteinuria values during follow-up (89).

The percentage of glomeruli involved by extracapillary proliferation, the extent of Bowman's space occupied by individual crescents, the fresh/fibrous crescents ratio are important risk factors (74). There is a close relationship between the extent of crescents and long-term sequela in patients with Class IV and V, with extensive glomerular involvement by crescents in more than 50% and more than 75% of glomeruli, respectively. In a Japanese series, 33% of Class IV and 83% of Class V, ended in ESRF (97). The predictive value of mild extracapillary proliferation is low when crescents involved less than 50% of glomeruli, because many of these cases recover, and also some children without crescents experience an unfavorable outcome (98). According to multivariate analysis, the presence of crescents on renal biopsy (classes III–V) was not an independent risk factor for progression to doubling of serum creatinine or to dialysis, when compared to the survival of patients without crescents at renal biopsy (Class I and II) (89).

Renal Transplantation in Children with HSP Nephritis

Recurrence of IgA mesangial deposits is frequent after renal transplantation, even though the recurrence of clinical symptoms of HSP is unusual. In adults, the actuarial risk for histologic or immunofluorescent recurrence is 35% at 5 years, with graft loss in 11% (99, 100). In most patients, no clinical manifestations or minimal hematuria accompany histologic recurrence in grafted kidneys (101). Recurrence is not prevented by triple therapy, including cyclosporine and is was more frequent in rapidly progressive cases. Delaying transplantation of one year after the last systemic signs was not effective in decreasing the rate of recurrence. The recurrence rate appears to be increased in good HLA match (99) and recipients of living-related grafts, suggesting a role for genetic factors. This is controversial, however, and the issue of whether using living donors for renal transplantation in HSP is still debated (102, 103).

Therapy

Mild cases do not require treatment, provided urine monitoring is ensured to detect modifications in the clinical follow-up, mostly during the first 2–3 months after the purpuric rash. The abdominal pain is generally controlled by small doses of steroids which favor a rapid resolution. Patients with recurring necrotizing purpura or severe abdominal pain have been successfully treated by intravenous Ig infusion (104).

Because in most cases the purpuric rash precedes by days or weeks the detection of urinary abnormalities, attempts have been made to prevent the development of the nephropathy by giving prednisone (1–2.5 mg/Kg/day for 1–3 weeks). A beneficial effect was not observed in retrospective studies, which compared treated versus untreated patients. However, the treatment was often reserved to the more active cases, thus introducing a selection bias which may have influenced the outcome (105–107). Conversely, a prospective trial (albeit not strictly randomized) suggested a protective effect of two weeks small doses of prednisone (108). The prevention consisted in avoiding the appearance of microscopic hematuria, which is not associated with a high risk for progression to renal failure. A recent systematic review of reported outcomes of children with HSP who were treated at diagnosis with corticosteroids compared with those with supportive care only, concluded that corticosteroid, given early in the course of illness seem to produce consistent benefits for major HSP outcomes, including the resolution of abdominal pain, the need of surgical intervention and the odds of developing persistent renal disease (109).

Once the nephritis is developed, it is possible either to treat or to wait for a spontaneous remission. Based on observations dating decades ago, oral corticosteroids were believed to be ineffective for treating HSP nephritis. Indeed, retrospective analyses failed to demonstrate any benefit of prednisone in children with HSP nephritis (110). However, again a selection bias favoring treatment of more severe cases was likely, because the severity of the disease was a major determinant in the decision to treat. More recently, a one year treatment with oral prednisone and azathioprine in patients with moderately severe renal involvement gave positive results in comparison with historical untreated cases (95, 111). However, as the historical group included particularly severe cases, no recommendation for treatment of moderately severe HSP nephritis is presently possible (112). One small series of children suggested that the addition of azathioprine to steroids may ameliorate histopathological features and the clinical course of severe HSP nephritis (113).

Tonsillectomy has been proposed for HSP nephritis, as for primary IgAN, with the aim of limiting the mucosal immune response. The overall analysis does not support

the recommendation for this intervention to treat HSP nephritis (114).

Nephrotic range proteinuria and crescents in >50% of glomeruli were mostly associated with poor outcome. There is a need for an efficient treatment for children with severe endocapillary and extracapillary proliferation and clinical presentation of nephrotic or nephritic syndrome with impaired renal function. In severe forms of HSP nephritis, long-term immunosuppressive therapy, based on daily steroids and cyclophosphamide for 8–12 weeks followed by azathioprine and a reducing regimen of alternate-day steroids for 8–12 months, did not avoid progression to ESRF in 15% of the cases and persistent renal abnormalities on long-term follow-up (115). An aggressive therapeutic regimen resulted in a favorable clinical outcome in 11/12 children with 60–90% glomeruli with crescent formations. This regimen consisted in a triple therapy of 3-methylprednisolone pulses followed by a 6-month course of prednisone, dipyridamole, and cyclophosphamide for 3 months (116). More than 60% of these patients experienced a complete remission. Similar positive results have been reported using high dose steroids in association with oral cyclophosphamide (117).

A larger French series confirmed that methylprednisone pulses, followed by a 3-month course of oral prednisone and, in some patients, with a 2-month course of oral cyclophosphamide, resulted in clinical recovery in 71% of children with nephrotic syndrome or crescentic involvement in greater than 50% of the glomeruli, versus 40% in a historical group of untreated children (118). Similarly, in children with greater than 50% of glomeruli involved with crescents, good results were reported with oral prednisone for 4 months in association with 2 months of cyclophosphamide and 4 months of heparin or warfarin (119). A combination of prednisone, azathioprine or cyclophosphamide also gave positive results (120), as well as methylprednisolone and urokinase pulse therapy combined with cyclophosphamide in severe histologic forms (121).

Our group (122), and more recently others (123–125), successfully treated children with rapidly progressive HSP nephritis with plasma exchanges, corticosteroids, and cytotoxic drugs. In our series, even though some cases experienced a complete remission, most had subsequent renal relapses and, in spite of a new cycle of plasma exchanges, renal function did not improve, and patients progressed to ESRF. The progression was delayed by 1–4 years. In the Japanese series, 60% of the treated patients had a complete remission of renal disease after 10 years (123). A German series showed that aggressive treatment, including PE may delay the rate of progression in the majority of patients with severe crescentic HSP nephritis, but the treatment was unable to definitely prevent the progression to ESFR (126). Of interest, the report of a difficult case of recurrent HSP nephritis in renal allograft, successfully treated with PE (127).

The analysis of uncontrolled studies with a combination of corticosteroids (either intravenous pulses or oral), immunosuppressive drugs (cyclophosphamide or azathioprine), sometimes in association with anticoagulation (warfarin or dipyridamole) in children with nephrotic-range proteinuria, or major extracapillary proliferation on biopsy, allows us to conclude that aggressive therapeutic regimens are effective in decreasing the rapidity of progression to chronic renal failure. However, these treatments should be started early during the course of the disease before the crescents become fibrotic. At this late stage, the treatments are ineffective.

Cyclosporine A in association with steroids in cases with nephrotic-range proteinuria is effective in reducing proteinuria, and improving the activity index at control renal biopsy, however the risk of nephrotoxicity should be considered (128).

In patients with heavy proteinuria, favorable results with decrease in proteinuria and improvement of histological index of renal activity have been reported using intravenous Ig infusions (129, 130). However, a rebound was noticed shortly after the therapeutic cycles, which somehow banished the positive results obtained (129). On the contrary, Ig infusion may be useful in cases with severe recurrent purpuric rash and mild urinary symptoms. Nephrotoxicity can be a serious rare complication of i. v. Ig therapy, mostly associated with sucrose-containing preparations in volume-depleted subjects (131). New treatments, like leukocytapheresis have been successfully tried for the treatment of refractory HSP resistant to both prednisolone and i. v. Ig therapy (132).

Relationship between Henoch-Schoenlein Purpura and primary Immunoglobulin A Nephropathy

The main reason for which a relationship between HSP and IgA nephropathy has been suggested is that these two conditions are indistinguishable by renal histopathology. Furthermore, other features are in favor of an unifying concept. Occasional patients with IgA nephropathy have extrarenal symptoms. A few patients may present with IgA nephropathy and develop a purpuric rash months or years later. Some patients with HSP may

develop episodes of macroscopic hematuria suggestive of IgA nephropathy, in the following years. The occurrence of both diseases in the same family is not uncommon (133). In a French nation survey on 40 families with two or more members affected by primary IgAN, five had members presenting with complete HSP syndrome, confirming a possible genetic link between the two diseases (134). Most patients with HSP nephritis who undergo renal transplantation have a recurrence of IgA deposits in the graft in the absence of extrarenal symptoms, as do patients with IgA nephropaty. Last, a male preponderance is seen in both diseases, and the high prevalence of both conditions is observed in the same geographic areas (e.g., Europe, Asia).

HSP and primary IgAN share similar disturbances in the IgA system. Both diseases present with high levels of serum IgA, as well as high levels of circulating IgA-ICs, IgA1-IC, and IgA-fibronectin aggregates, as discussed above, even though the levels in acute phases of HSP are generally higher than in primary IgAN (20, 22). Both diseases have aberrantly glycosylated IgA1 in circulation (28–31). The present hypothesis of the factors which condition the development of HSP nephritis rather than primary IgAN, stresses the role of complement and coagulation pathways activation, with involvement of eosinophilic reactivity possibly due to different IgA1 glycosylation properties. However, this remains an unproved hypothesis.

47 Systemic Lupus Erythematosus

Patrick Niaudet · Rémi Salomon

Introduction

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease characterized by highly diverse clinical manifestations and the presence in the serum of a variety of autoantibodies reacting with different cell components. The skin, joints, lungs, heart, kidneys, nervous system, and other organs are involved. The role of autoantibodies in the pathogenesis of the disease is subject to debate. Certain autoantibodies, such as those reacting with cell surface determinants or circulating proteins, are directly responsible for specific clinical manifestations of the disease. The clinical course of the disease is characterized by flares, periods of chronic disease and periods of remissions.

The American Association of Rheumatology (AAR) developed diagnostic criteria of SLE (1, 2) to established with certainty the diagnosis of SLE and distinguishing it from other rheumatic diseases (*Table 47-1*). When four of these criteria are present, the sensitivity for the diagnosis of SLE is 95% and the specificity is 96%. Some patients with the disease may not satisfy initially the criteria but may develop other manifestations later and then have the full criteria for the diagnosis of SLE. For example, some patients may have isolated nephritis, such as membranous nephropathy, without serological evidence of SLE at first.

The prevalence of SLE is approximately 40 in 100,000 in Europe and North America (3). SLE is three times more frequent in Afro-Americans than in Caucasians but is exceptional in blacks from Africa (4, 5). In a survey of pediatric lupus in the United Kingdom, the relative risk was 6.7 in Asian populations and 6.1 in black populations compared with the white population (6). In more than 80% of cases, SLE affects females after puberty. In children, the prevalence is 1 in 100,000 with girls more frequently affected than boys. The female:male ratio increases from 2:1 in prebubertal children to 4.5:1 in adolescents and 8:1 in adults (7). In children, most cases of lupus occur after age five, with a peak incidence in late childhood and adolescence (8). Twenty percent of SLE cases begin in childhood.

The presentation of the disease in children varies both in terms of the gravity of symptoms and the diversity of clinical manifestations. However, the disease is often more acute and severe, affecting multiple organs in children compared to adults (9–12). In addition to organ damage, SLE has a major detrimental impact on growth and psychological development. It is important to promote a multidisciplinary approach to SLE to assure better individual treatment of patients.

Pathogenesis

The etiology of the SLE remains unknown despite the progress that has been made during the recent years in understanding the pathogenic mechanisms of the disease. SLE is characterized by the development of autoantibodies directed against a variety of self components and, contrary to other autoimmune diseases, there are no stigma of organ-specific autoimmunity.

Genetic factors – The evidence for a genetic susceptibility to SLE in humans is based on familial aggregation. The prevalence of SLE is estimated to be 2.6–3.5% in first-degree relatives of SLE probands compared with 0.3–0.4% in relatives of match controls. Moreover, an increase in concordance rate is observed in monozygotic twins (24–56%) compared to dizygotic twins (2–5%). The risk of developing the disease in siblings of SLE patients is 10–40 times higher than that in the general population. An analysis of 125 lupus multiplex families including at least two cases recruited through a French national survey demonstrated in most cases a non-Mendelian inheritance suggesting a complex multifactorial inheritance pattern with several genes interacting together in a single individual (13). Recent technological advances have allowed rapid analysis of the whole genome in patients with complex disease and matched controls. Several genomewide association studies in large international cohorts of patients have identified genetic variants in susceptibility genes that confer a significant risk of SLE. This approach gives some new insights in the comprehension of the disease mechanisms and open avenues for therapeutic intervention. In these lines, it has been demonstrated that the genes encoding the interferon regulatory factor

© Springer-Verlag Berlin Heidelberg 2009

5 (IRF5) (14), the protein tyrosine phosphatase type 22 (PTPN22) (15) as well as the B-cell-specific tyrosine kinase (BLK) (16) are implicated in the pathogenesis as some variants in these genes are significantly associated with the disease.

As lupus is a multifactorial disease with a multigenic inheritance, one can assume that many more polymorphisms with subtle functional impact have a role in inducing the full-blown disease in conjunction with environmental factors.

Studies in various mouse models suggest that lupus may be mediated by a multitude of genetic abnormalities that impact on specific checkpoints, starting with a loss of immunologic tolerance to nuclear antigens, leading to a pathogenic autoimmunity and organ targeting. While the genes involved in these perturbations are still unknown, recent findings have provided insights into specific clue elements implicated in these pathways. Several studies suggest that increased liberation or disturbed clearance of nuclear DNA–protein complexes after cell death may initiate the disease. Dnase1 deficient mice generated by gene targeting exhibit a phenotype very similar to classical human SLE (17). Moreover, mutations responsible for a loss of function of this enzyme have been found in patients with SLE (17). *Table 47-2* shows the different genes for which variants have been shown to be associated with SLE in humans and in mice (17–28).Variation in gene copy number is increasingly recognized as a source of genomic variability. Loss of the rat-specific *Fcγr3* related gene is responsible for macrophage overactivity and glomerulonephritis in Wistar Kyoto rats. (29). In human, a strong association between *FCγR3B* copy number and risk of systemic lupus erythematosus, microscopic polyangeitis and Wegener's granumalomatosis in two independent cohorts from the UK and France has been demonstrated (30).

Table 47-1

The 1982 revised ARA criteria for classification of systemic lupus erythematosus

Malar rash
Discoid rash
Photosensitivity
Oral ulcers
Arthritis
Serositis (pleuritis or pericarditis)
Proteinuria >0.5 g/day or red casts
Psychosis or seizures
Hemolytic anemia or leucopenia (<4,000/mm^3) or lymphopenia (<1,500/mm^3) or thombopenia (<100,000/mm^3)
Antinuclear antibodies
Anti-dsDNA antibodies or anti-Sm antibodies or false positive TPI/VDRL or positive LE cell test

Table 47-2

Mouse and human genes that cause lupus*

Categories	Mouse with null mutation	Patients with SLE	References
Regulatory machinery			
Activation threshold of lymphocytes			
PD-1	Autoimmune cardiomyopathy	A polymorphism in intron 1 is more frequent in patients than in control (12 vs. 5%)	16, 18
Lyn	Autoreactive antibodies and severe glomerulonephritis	Lyn in significantly decreased in B-cells at the mRNA and protein levels	19, 20
Deletion of autoreactive T-cells			
P21	Anti-dsDNA, glomerulonephritis	Reduced expression of p21 in lymphocytes	21, 22
Scavenger machinery			
C1q	High autoantibodies titers, 25% had glomerulonephritis with great numbers glomerular apoptotic bodies	C1q deficiency is strongly associated with SLE	23, 24
DNAse1	Antinuclear autoimmunity and glomerulonephritis	Heterozygous nonsense mutation and decreased Dnase1 activity in serum of patients	17, 25
Serum amyloid P (SAP)	Antinuclear autoimmunity and severe glomerulonephritis	Low levels of SAP-DNA complexes in serum of patients	26, 27

*This list is not exhaustive

Environmental and infectious factors – Based on twin concordance studies, additional factors appear to be necessary to induce the disease, indicating a multifactorial origin for SLE. Environmental, hormonal, toxic and infectious factors have been suspected. The fact that seroconversion against EBV was observed in 99% of children with SLE as compared to only 70% of their controls is consistent with but does not in itself establishes EBV as a causative factor in SLE (31). Antibodies to 60 Kda RO (a ribonucleoprotein complex) are the earliest autoantibodies detected in the preclinical period as individual progress towards clinical disease (32). The initial autoantigenic 60 Kda RO crossreacts with a peptide from the latent viral protein Epstein-Barr virus nuclear antigen-1 (EBNA-1). Moreover, mice immunized with either the first epitope of 60 KdA or cross-reactive EBNA-1 epitope acquire clinical symptoms of lupus including renal dysfunction (33). These data suggest that autoimmunity may arise through molecular mimicry between EBNA- and some lupus autoantigens.

Photosensitivity is a common feature of SLE since specific lupus lesions occur on sun-exposed areas and the disease is aggravated by sun exposure in 40–70% of patients. The current theory is that UV light induces apoptosis of keratinocytes, which develop small surface blebs containing lupus autoantigens such as the Ro particle (34). Similarly drugs such as chlorpromazine (35) or environmental toxics such as silica dust have been shown capable of inducing apoptosis.

Hormonal factors – The female predominance in SLE is particularly strong during childbearing ages, suggesting that hormonal differences may contribute to the increased risk of the disease (36, 37). Reduced androgen levels, increased estradiol and prolactin levels have been reported in SLE patients. Moreover, studies in mouse models have shown disease exacerbation by estrogen and prolactin and improvement by androgens. However, a population-based study of 240 female SLE patients found little evidence that estrogen- or prolactin-related exposures are associated with an increased risk of lupus (38).

Role of T and B lymphocytes – In SLE, autoantibodies, immune complexes and autoreactive T cells may cause tissue damage. While an absence of autoreactive T-cells deletion in central lymphoid organs in SLE is still controversial, a loss of self-tolerance in the periphery appears to be critical in the pathogenesis of SLE (39). In normal mature B cells the immunoglobulin FcγRIIB receptor opposes signals for proliferation that are generated when B cell receptor binds antigen. FcγRIIB deficiency coupled with failure to eliminate immature self-reactive B cells in the lupus-prone mice B6.Sle1z, allows self-reactive B cells to escape clonal anergy that normally control the production of autoantibodies (40). The partial restoration of inhibitory Fc receptor (FcγRIIB) levels on B cells is sufficient to restore tolerance and prevent autoimmunity (41).

Regulatory T-cells (Tregs) are a specialized subpopulation of T lymphocytes that act to inhibit the autoreactive lymphocytes. Tregs have been shown to have a reduced ability to suppress the proliferation of helper T-cells in patients with active lupus compared to patients with inactive lupus (42). Self-antigen can trigger autoimmunity by several ways. The level of autoantigens may be increased by an impaired clearance of immune complexes or of apoptotic cells. Defects in the complement system or lymphocyte Fc receptor alterations may enhance the level of available autoantigen (43–45). Perturbations of the cytokine network could activate antigen-presenting cells (APC) and thereby reduce the signaling threshold of self-reactive peripheral T or B cells to a given concentration of autoantigen (46). Alterations in these different regulatory pathways have been described in lupus-prone natural and knockout mouse models (*Table 42-2*). Moreover, polymorphisms or mutations of several genes implicated in these processes have been reported in lupus patients.

The production of autoantibodies against components of the cell nucleus is a hallmark of SLE, the most prominent being those against double-stranded DNA (dsDNA) and histones. There is growing evidence that the nucleosome, the fundamental unit of chromatin composed of histones and dsDNA is a major autoantigen that drives a T-cell-dependent autoimmune response. Its implication in the pathogenesis of SLE seems to be closely related to an abnormal regulation of apoptosis and an impaired clearance of apoptotic products. High levels of these products and particularly of nucleosomes have been observed in lupus patients in comparison to controls (47).

Dendritic cells are key regulators of the immune system. These professional antigen-presenting cells induce the activation of naïve T-cells and stimulate growth and proliferation of B-cells. It has been shown that SLE patient's serum induces monocytes to differentiate into dendritic cells able to capture dying allogeneic cells and to present their antigens to autologous CD4+ T cells leading to their proliferation. Furthermore this capacity to induce dendritic cell differentiation is correlated with disease activity (48) and is abolished by blocking interferon-γ suggesting that this cytokine is the major mediator of monocyte to dentritic cell differentiation. The dendritic cells might capture apoptotic cells and nucleosomes, present in SLE patient's blood. Subsequent presentation of autoantigens to CD4+ T cells could then initiate the expansion of autoreactive T cells, followed by differentiation of autoantibody-producing B cells.

Complement deficiency – Activation of the complement system is implicated in the defense against microbes and in the adaptive immune response and inflammation. The complement system plays a paradoxical role in the development and expression of SLE. While the activation of complement is involved in tissue damage as illustrated by several studies in mice, inherited deficiencies of components of the classical pathway are strongly associated with the development of SLE. Lupus develops in many patients with complete deficiencies in C1q (90%) and C4 (75%) suggesting that these molecules have a protective role against the development of the disease (49). The protective role of C1q has been confirmed by the observation of severe lupus nephritis in C1q deficient mice. The complement system is involved in the clearance of apoptotic cells notably through the binding of the C1q and mannan-binding lectins molecules to the apoptotic cells and the subsequent complement activation (50).

Clinical Manifestations

SLE is often acute in onset and manifests with general symptoms of fever and fatigue associated with cutaneous and articular symptoms (11, 51). Such a cluster of symptoms is suggestive of SLE. In a French multicenter study, it was found that the most common initial manifestations were hematologic (72%), cutaneous (70%), musculoskeletal (64%), renal (50%), and fever (58%). Thirty-two percent of children had atypical symptoms, mainly including abdominal involvement in 26 patients (52). In some cases, SLE begins with an isolated symptom such as a hemolytic anemia, a nephritic syndrome with hematuria, chorea, or pericarditis. The performance of systematic serologic tests permits the linkage of these manifestations to SLE (53).

General symptoms, particularly weight loss, anorexia, and asthenia, are virtually constant in SLE. Episodic fever is frequent during acute phase of the disease or during infection. Pulmonary or urinary tract infections are frequent during the course of SLE. Opportunistic infections may be life threatening. A number of factors may favor a relapse of the disease, including exposure to ultraviolet light (54), infection (55), stress (56), surgery or pregnancy.

Joints and muscles – Arthralgia is the most common manifestation, observed in 80% of cases during the evolution of the disease (57). Both large and small articulations, especially the hands, are affected, causing moderate pain and articular swelling. The damage of periarticular tissues is often more pronounced than synovial damage, particularly in the form of tendinitis. Arthritis is very rarely deforming and synovial fluid contains relatively few cells, essentially mononuclear. Myalgia is less frequent. Avascular osteonecrosis which often affects femoral heads may occur in the absence of treatment with corticosteroids. This complication can be asymptomatic at first or accompanied by pain. In early stages, X-ray results are often normal while MRI reveals necrotic lesions.

Skin – The most classic skin lesion is the "butterfly" rash over the cheeks and nose, present in a third of cases. It often appears after sun exposure (58). Maculopapulus eruptions on the upper portion of the trunk as well as cutaneous zones exposed to light are more common. Papular and squamous lesions on the trunk, face, and palms of the hands can be observed in less severe, strictly cutaneous forms of the disease, often linked to the presence of anti-Ro antibodies. Raynaud's phenomena of the extremities causes painful white marble-like lesions, leg ulcers, and peri-ungual or finger-pad erythema. Urticarian eruptions and pigmentation anomalies are sometimes observed. Cutaneous photosensitivity is noted, especially in white patients. Mucosal lesions, particularly in the form of oral ulcerations, are common. Alopecia is observed in some children, especially those with active forms of the disease.

Lungs – Pulmonary involvement occurs in more than 50% of children (59). Pleuritis, observed in 40% of children, is often asymptomatic. It may be revealed by thoracic pain. Pleural liquid, more or less abundant, is an exudate, containing an excessive number of neutrophils and lymphocytes. The levels of C3 and C4 are diminished while the level of antinuclear antibodies is elevated. Anomalies in diaphragm function have been reported, responsible for dyspnea. Pulmonary damage may manifest as an acute pneumonitis with thoracic pain, dyspnoea, and fever (60). Poorly defined opacities can be observed on X-ray. Histologically, lymphoplasmocytic infiltrates may be present. Chronic fibrosing alveolitis have been described. Pulmonary arterial hypertension is a rare but severe problem, which may be secondary to repeated pulmonary embolism (61). Pulmonary hemorrhage during acute phase of the disease or during infections may be life threatening.

Heart – Pericarditis is frequent and is often diagnosed on echocardiography. Myocarditis with congestive heart failure is rare. Endocarditis of Liebman-Sachs which often affects the mitral valve and is associated with antiphospholipid (APL) antibodies is rare (62, 63).

Nervous system – Neuropsychiatric symptoms are present in 30–45% of children with SLE (64–66). These symptoms can either be a direct result of SLE or secondary to arterial hypertension, renal insufficiency, infectious

complication, hemostasis abnormalities, or various treatments, particularly corticosteroids (67). Mood disorders or behavior disturbances are often difficult to interpret in this chronic disease. Headache is the most frequent neurological manifestation of SLE and is often accompanied by localized or generalized seizures (68). Symptoms suggestive of a cerebral tumor have been described. Chorea is frequent in children, sometimes in association with APL antibodies. Cranial nerve palsies have been described, particularly ptoses and hemiparesis. Psychiatric symptoms consist of difficulties with attention or memory, disorientation, behavioral problems, depressive syndrome, or psychotic states with hallucinations and delirium (69–71). These symptoms can occur in an acute, transitory manner, during a flare of the disease, or can be more prolonged. They are often linked to ischemic cerebral vascular lesions that can be visualized by magnetic resonance imaging (72). Damage to the large arteries is rare. The role of antineuronal antibodies that are found in half of patients in the pathophysiology of the lesions is uncertain. Thrombotic phenomena secondary to the APL antibodies may play a role in the pathogenesis of neurological manifestations (73, 74). Behavioral problems, with a decrease in academic achievements, are often noted in children with SLE. These problems could be linked to the disease itself, to the treatment with corticosteroids, or the psychological response to a serious chronic illness. If these problems are secondary to SLE, the symptoms can respond favorably to an increase in corticotsteroid doses.

Eye – Both the retina and the cornea can be affected. Keratoconjunctivitis sicca is the most common ocular manifestation. The retinal lesions consist of white, cottony exudative lesions of the optic nerve, papillary edema, or thrombosis of the central retinal artery, causing blindness (75).

Hematopoietic system – Hematological manifestations are common in SLE (76). Inflammatory cervical or diffuse adenopathies occur in children with SLE. Anemia, observed in more than half of cases, is usually normochromic and normocytic and its degree reflects the activity of the disease. Hemolytic anemia is present in less than 10% of cases, accompanied by reticulocytosis, a positive Coombs test, an increase in free bilirubin levels and a decrease in haptoglobin levels. Aplastic anemia has been reported and responds to treatment with corticosteroids. Leukopenia, noted in more than 50% of cases, is in part responsible for an increased sensitivity to infections. Neutropenia may be linked to medullary suppression, hypersplenism, or antineutrophil antibodies. Lymphopenia affects both T and B lymphocytes. Thrombopenia, noted in 10–25% of cases, is accompanied by an increase in megacarycotyes in the marrow, indicating peripheral destruction of platelets. The acute, severe forms of thrombocytopenia are often observed during an acute phase of the disease and are responsive to treatment with corticosteroids, while more chronic forms are less symptomatic and less responsive.

Antiphospholipid antibodies – APL antibodies may be directed against epitopes on oxidized phospholipids complexed with a glycoprotein, β2-glycoprotein I, or against the glycoprotein itself. The principal APL antibodies include anticardiolipin antibodies, β2-glycoprotein-I antibodies and the lupus anticoagulant (77). These antibodies are responsible for thrombosis in vivo while they prolong phospholipid-dependent coagulation tests in vitro (78). Patients with SLE have a high incidence of antiphospholipid antibodies with a consequent high risk of thrombosis (79).

A patient with the APL syndrome must meet at least one of the two clinical criteria (e.g., vascular thrombosis or complications of pregnancy) and at least one of two laboratory criteria (e.g., anticardiolipin antibodies or lupus anticoagulant antibodies). Patients with APL antibodies develop thrombotic arterial or venous accidents, thrombocytopenia, and the experience of repeated abortions. Primary APL syndrome occurs in patients without clinical evidence of another autoimmune disease, whereas secondary APL syndrome occurs in association with autoimmune or other diseases (80). The prevalence of APL antibodies is 1–5% among apparently healthy subjects in the young and increases with age. Among patients with SLE, the prevalence of APL is much higher, ranging from 12 to 30% for anticardiolipin antibodies and 15 to 34% for lupus anticoagulant antibodies (81).The APL syndrome may develop in 50–70% of patients with SLE and APL antibodies within 20 years of the initial diagnosis.

Patients with primary and secondary APL syndrome have similar clinical consequences of APL antibodies (82). The clinical hallmark of the APL syndrome is the presence of vascular thrombosis. Venous thromboses are more frequent than arterial thrombosis. Involvement of the small vessels, particularly in the kidneys can mimics the hemolytic-uremic syndrome and the thrombotic thrombocytopenic purpura. The APL syndrome may also occur as a more chronic process, resulting in progressive loss of organ function (83).

In a cross-sectional cohort study in 59 consecutive SLE patients, thirteen thrombotic events occurred in 10 of the 59 patients (17%). There was a direct relationship between the presence of a lupus anticoagulant and a thrombotic event (84). Similar findings were reported in a retrospective study in 36 children with lupus nephritis.

No difference in the incidence of APL positivity was detected between the eight children who experienced thrombotic complications and those who did not (85).

Altered fibrinolysis secondary to an increase of the inhibitor of the plasminogen activator and a decrease of protein S have also been described in patients with SLE. Other more rare circulating anticoagulants have been observed. They are true in vivo anticoagulants, including antifactor VIII, antifactor XI, or antifactor XII.

Endocrine glands – An autoimmune thyroiditis, with antithyroglogulin and antimicrosome antibodies may be responsible for symptoms of hypothyroidism and less often symptoms of hyperthyroidism. A study found a high frequency of antithyroid antibodies in children with SLE (86). Diabetes mellitus is often secondary to high doses of corticosteroids but it may be secondary to SLE with the presence of antiinsulin receptor antibodies. Hormonal contraception may promote lupus activity and thromboses, particularly in patients with antiphospholipid antibodies. Therefore, it is important that appropriate contraception is adapted when necessary and patients must be informed of the risks of future pregnancy, which would need specialized monitoring (87).

Gastrointestinal manifestations – Gastrointestinal manifestations are often secondary to the side effects of treatments. Gastritis and peptic ulcers may be secondary to the use of nonsteroidal antiinflammatory agents or corticosteroids. Oral ulcers are frequent during the course of SLE and patients may complain from dysphagia. Esophageal reflux or ulceration may occur. Abdominal pain is a frequent complain in patients with SLE. It may be related to serositis, peritonitis, intestinal vasculitis, intra-abdominal thrombosis, small intestinal bacterial overgrowth or pancreatitis (88). Vascular lesions can cause intestinal ischemia and/or perforations. Clinical manifestations linked to these gastrointestinal lesions can be masked by corticosteroids. Pancreatitis may be directly related to SLE or secondary to corticosteroid therapy.

Hepatomegalia is frequent but rarely accompanied by significant liver dysfunction. The presence of liver abnormalities with antinuclear antibodies is more likely to be due to chronic active hepatitis, also called "lupoid hepatitis," than to SLE.

Renal Disease in SLE

Pathogenesis of Lupus Nephritis

Genetic or acquired susceptibility factors are probably associated with the onset of renal disease. Numerous mouse models have improved our understanding of the pathogenesis of lupus nephritis.

Nucleosome play a central role in the pathogenesis of SLE. There is growing evidence that increased apoptosis and impaired clearance of apoptotic cells facilitate the emergence of anti-DNA antibodies and immune complexes. Nucleosomes are also important for triggering tissue lesions, including glomerular lesions. They are at least two mechanisms that explain how autoantibodies mediate tissue damage: (a) deposition of preformed immune complexes in the kidney or *in situ* formation of these complexes via the interaction between nucleosome already deposited in the glomerulus and anti-dsDNA antibodies, (b) cross-reactivity of antibodies with glomerular basement membrane components. The recent demonstration by means of electron microscopy in mice and humans that anti-dsDNA antibodies colocalize with extracellular chromatin in glomerular-membrane associated electron-dense structures supports the first hypothesis (89, 90). α-actinin has been identified as a cross-reactive target bound by nephritogenic anti-dsDNA in a lupus mouse model (91). α-actinin is an actin-bundling protein expressed in podocytes, monocytes, capillaries and larger vessels. Mutations of the gene encoding the isoform α-actinin-4 have been identified in familial focal and segmental glomerulosclerosis. α-actinin may also be a target for anti-dsDNA in human.

Inherited deficiencies of the early components of the complement classical pathway are the strongest susceptibility genes for the development of SLE in humans. C1q deficient mice have been generated by homologous recombination (19). The presence of multiple apoptotic bodies in the altered glomeruli suggests a critical role for C1q in the clearance of apoptotic cells. This finding is consistent with the report that C1q binds to apoptotic keratinocyte (92). Apoptotic cells are thought to be a major source of the autoantigens of the SLE, and impairment of their removal by complement may explain the link between hereditary complement deficiency and the development of SLE.

Another study on lupus-prone New Zealand black and New Zealand white mouse has shown that the γ chain of the T-lymphocyte receptor is mandatory to initiate the inflammatory cascade in the kidney. Indeed, when the NZB/NZW mice were backcrossed with FCγR deficient mice, glomeruli were not affected despite the deposition of immune complexes and C3 (93). In humans, decreased binding affinity of the FcγRIIIA-158F allele may result in ineffective clearance of antigen–antibody complexes, resulting in an increased susceptibility to immune-complex-mediated nephritis (94). Of interest,

another polymorphism in the gene coding for the FcγRIIIA receptor represents a significant risk factor for SLE but has no clear effect on susceptibility for lupus nephritis (95). A study of inflammatory markers after remission in NZB/NZW mice indicates that activated macrophages type II have a central role in the genesis of lupus nephritis (96).

Clinical Findings

Clinical symptoms of renal involvement are noted in 40–80% of patients, appearing most often during the first years (7). Renal involvement is variable, with some patients showing minimal urinary anomalies and other having nephritic syndrome with rapidly progressive renal failure. Proteinuria is the most frequent symptom. Proteinuria is frequently abundant accompanied by a nephrotic syndrome responsible for edema. Microscopic hematuria is frequently associated to proteinuria but is rarely seen in isolation. The urinary sediment contains granular and red cells casts. Patients with severe nephritis are often hypertensive and have a reduced renal function. Up to 50% of children with lupus nephritis have a decreased glomerular filtration rate. Signs of renal tubular dysfunction may be observed and are related to the presence of immune deposits along the tubular basement membranes and to interstitial cellular infiltrates. Increased excretion of ß2 microglobulin is frequently found. Renal tubular acidosis with hyperkalemia has been reported.

Histologic Classification

Most authors believe that the presence of urinary abnormalities or renal function impairment is an indication for renal biopsy, especially to guide the initial treatment (97). There is no close correlation between symptoms and the class of glomerular lesions (focal or diffuse proliferative nephritis with varying degrees of severity or membranous nephritis). The type of histological lesions is most important to decide the best therapy. A renal biopsy may also be indicated in a patient with glomerular disease without extra-renal manifestations of SLE. It is more difficult to decide whether to perform a renal biopsy in patients with no clinical evidence of renal disease. Although the clinical signs of renal damage are present in only 40–75% of patients, renal biopsy studies show nearly universal histologic changes. The majority of clinically asymptomatic patients show moderate histological damage most often mesangial deposits and mild mesangial proliferation but some may have more severe histological lesions such as focal and segmental glomerulonephritis or very rarely diffuse proliferative glomerulonephritis (silent lupus nephritis).

Histological anomalies are present in 90% of patients and immune deposits are almost always found on immunofluorescence examination or by electron microscopy. There is a wide diversity of glomerular damage in SLE. Moreover, tubulointerstitial and vascular lesions can be observed in addition to glomerular lesions. The first World Health Organization (WHO) classification proposed by Pirani and Pollack in 1974 was based primarily on the histological changes observed by light microscopy. It was modified in 1982 by the ISKDC (International Study of Kidney Disease in Children). A revised classification based on glomerular lesions has recently been proposed with the objectives to standardize definitions, emphasize clinically relevant lesions and facilitate reproducible reporting (98–100) (*Table 47-3*). The main

Table 47-3

International society of nephrology/renal pathology society (ISN/RPS) classification of lupus nephritis

Class I – Minimal mesangial lupus nephritis
Normal by light microscopy but mesangial deposits by immunofluorescence
Class II – Mesangial proliferative lupus nephritis
Mesangial hypercellularity and mesangial deposits by immunofluorecence
Class III – Focal lupus nephritis
Class III (A): with active lesions
Class III (B): with active and chronic, sclerosing lesions
Class III (C): with chronic, sclerosing lesions
Class IV – Diffuse lupus nephritis
Class IV-S (A): diffuse segmental proliferative lupus nephritis with active lesions
Class IV-G (A): diffuse global proliferative lupus nephritis with active lesions
Class IV-S (A/C): diffuse segmental proliferative and sclerosing lupus nephritis
Class IV-S (C): diffuse segmental sclerosing lupus nephritis
Class IV-G (C): diffuse global sclerosing lupus nephritis
Class V – Membranous lupus nephritis
Global or segmental subepithelial immune deposits
Class V lupus nephritis In combination with class III or class IV
Class V with sclerosing lesions
Class VI – Advanced sclerosing lupus nephritis
>90% sclerosed glomeruli without active lesions

changes concern the elimination of the subcategories membranous lupus nephritis which are close to class III or class IV lupus nephritis and the introduction of a subclassification of class IV lupus nephritis with segmental (IV-s) or global (IV-g) distribution of the lesions. An adequate renal specimen, containing at least ten glomeruli, must be obtained for light microscopy analysis. Immunofluorecence examination is also mandatory. Electron microscopy may aid the classification but is not necessary for diagnosing lupus nephritis. Furthermore, renal biopsies have permitted clinicopathologic correlations with the natural outcome of the disease. Of importance, the histologic categories guide therapeutic decisions (101, 102).

Class I is defined as minimal mesangial lupus nephritis with normal glomeruli by light microscopy but mesangial immune deposits by immunofluorescence (*Fig. 47-1*).

Class II is defined as mesangial proliferative lupus nephritis with mesangial hypercellularity and mesangial immune deposits. Immunofluorescence and electron microscopy examination show mesangial deposits whereas the glomerular walls are normal. Urine examination can be normal or reveal microscopic hematuria and moderate proteinuria. The prognosis is excellent except in cases of transformation to a more severe form (103).

Class III is defined as focal lupus nephritis involving less than 50% of glomeruli. The affected glomeruli show segmental lesions of endocapillary proliferation or inactive segmental scars. Necrotic lesions and cellular crescents may be present. Immunofluorescence examination reveals subendothelial deposits along the glomerular capillary walls with focal or diffuse mesangial immune deposits. Tubulointerstitial or vascular lesions are often present in addition to glomerular lesions. When less than 20% of glomeruli are affected by small segmental lesions, patients usually have mild renal symptoms with low-grade proteinuria without nephrotic syndrome and normal GFR. The long-term prognosis is favorable with probably less than 5% risk of progression to end stage renal failure after 5 years (104). Conversely, when cellular proliferation, necrosis and large subendothelial deposits involve more than 40% of the glomeruli, the clinical symptoms are more severe with active urine sediment, nephrotic syndrome, hypertension and moderate renal insufficiency in some patients. The prognosis is the same as for diffuse lupus nephritis (101, 104).

Class IV is defined by diffuse lupus nephritis involving more than 50% of glomeruli, The lesions may be segmental, affecting less than 50% of the glomerular tuft, or global, affecting more than 50% of the glomerular tuft. Therefore, this class may be subdivided in diffuse segmental lupus nephritis (IV-s) and diffuse global lupus nephritis (IV-g). In diffuse segmental lupus nephritis more than 50% of the glomeruli show segmental lesions of endocapillary proliferation with or without necrosis and with or without segmental scars. In diffuse global lupus nephritis more than 50% of the glomeruli show global and diffuse endocapillary proliferative lesions with often extracapillary proliferation.

In addition, active lesions are often seen such as necrotic lesions, karyorrhexys, hematoxylic bodies, leukocytic infiltrates, wire-loops and hyaline thrombi. The proportion of glomeruli with epithelial crescents is an important pronostic factor. Tubulointerstitial lesions with mononuclear cell infiltrates are common. Immunofluorescence and electron microscopy show diffuse mesangial and more or less extensive subendothelial immune deposits. Deposits are also found frequently along the tubular basement membranes and the capillary walls. The clinical symptoms are often severe: hematuria with casts, nephrotic syndrome, hypertension and moderate or severe renal insufficiency. Patients with class IV nephritis are at high risk of progression to end stage renal disease if adequate therapy is not undertaken.

Class V is defined as membranous lupus nephritis, characterized by a thickening of the glomeruli capillary walls and the presence of global or segmental continuous subepithelial immune deposits separated by "spikes," In pure class V, there is little or no cellular proliferation. Compared to the idiopathic form of membranous nephropathy, mesangial deposits are almost constant. In some patients, mesangial hypercellularity and subendothelial deposits are present, in which case class V is associated with lesions of class II, class III or class IV lupus nephritis. Membranous nephritis may precede other manifestations of lupus. Moderate proteinuria is accompanied in 50% of patients by hematuria. Nephrotic syndrome often develops. Moderate renal failure and hypertension are observed in 25% of patients.

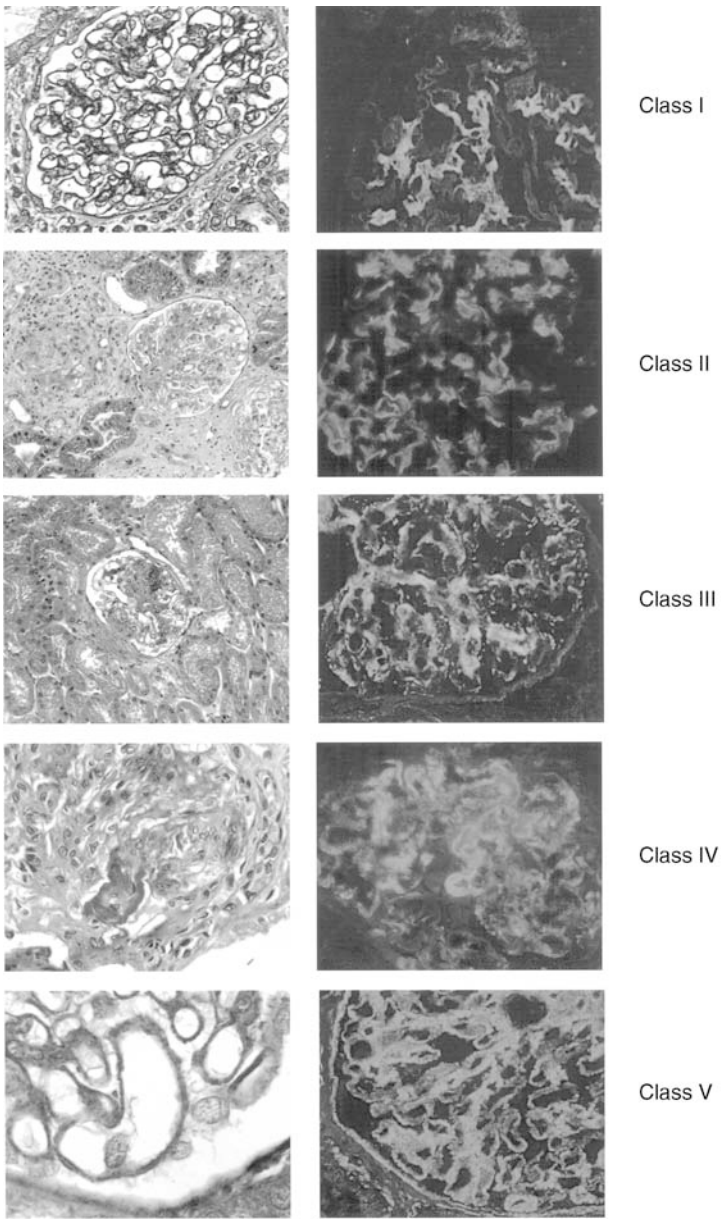
Class VI corresponds to an advanced stage of lupus nephritis where most glomeruli are sclerotic but without evidence of active glomerular lesions.

In addition to glomerular lesions, tubulointertitial and vascular changes are often observed including inflammatory vasculitis, vascular thrombosis, interstitial inflammation, interstitial fibrosis and tubular changes.

By immunofluorescence, the composition of deposits is remarkable no matter where they are located. In these deposits, IgG is dominant, mostly IgG1 and IgG3. IgA and IgM are also present, as well as early complement components, C4 and C1q along with C3. Such positivity for all three Ig classes and C3, C4 and C1q is called *full house* and is highly suggestive of lupus nephritis. Fibrin deposits are also found, particularly in class IV biopsies.

Figure 47-1

Class I: Normal glomerulus by light microscopy (right-hand side) but mesangial immune deposits by immunofluorescence study (left-hand side). Class II: Purely mesangial hypercellularity and mesangial matrix expansion in glomerulus by light microscopy with mesangial immune deposits by immunofluorescence study. Class III: Segmental endo- and extracapillary proliferation involving $<$ 50% of all glomeruli by light microscopy with mesangial and some subendothelial immune deposits by immunofluorescence study. Class IV: Global endo- and extracapillary proliferation and subendothelial deposits by light microscopy and numerous immune deposits by immunofluorescence study. Class V: Membranous glomerulonephritis with subepithelial deposits by light microscopy, clearly defined by immunofluorescence study. (Courtesy of Dr Laure-Hélène Noël) (See color plate 30)



Activity and Chronicity Indexes

Pirani et al. and Morel-Maroger et al. introduced the concept of histological signs of activity and chronicity (105). Later, Austin et al. introduced the activity and the chronicity indices, which may help to define to prognosis (106). Active histological lesions include cellular crescents, endocapillary proliferation, fibrinoid necrosis, karyorrhexis, thrombi, wire-loops with subendothelial immune deposits, glomerular leucocyte infiltration and interstitial mononuclear cell infiltration (*Table 47-4*). These active lesions are each graded 0–3 (with both necrosis and cellular crescents graded 0–6) to give an activity index graded 0–24. Active lesions are potentially reversible with the treatment. Glomerular capillary wall necrosis is associated with poor outcome when these lesions affect a high percentage of glomeruli (107). Extramembranous deposits are not considered as active lesions. Conversely, irreversible lesions, including glomerular sclerosis, fibrous crescents, tubular fibrosis and interstitial fibrosis, permit the definition of chronicity index. These lesions do not respond to treatment. If the activity and the chronicity indices are important to decide the best therapy for individual patients, their prognostic significance is still debated. The NIH group found that an activity index >12/24 or an elevated chronicity index were indicative of a poor renal prognosis (106). A chronicity index less than 2 was associated with a 10-year renal survival rate of 100% whereas when the chronicity index was comprised between 2 and 4 the renal survival rate was only 70%. The renal survival rate at 10 years was only 35% in patients with a chronicity index greater than 4. However, a study including unselected patients with lupus nephritis found that activity and chronicity indices did not accurately predict renal outcome (108).

Table 47-4
Active and chronic histological renal lesions

Active lesions

Glomerular sclerosis (segmental or global)
Fibrous crescents
Fibrous adhesions
Extramembranous deposits
Tubulo-interstitial
Interstitial fibrosis
Tubular atrophy

Repeat Renal Biopsies

Repeat biopsies have shown that transformations from one class to another are possible, either via aggravation or amelioration of the histological lesions. A class II nephritis can transform into class III nephritis or class IV nephritis. These, in turn, are susceptible to improvement under treatment. In contrast, transformation is rare in cases of class V nephritis. Hill et al. reported that a repeat renal biopsy at 6 months carries pronostic significance (109). Repeat renal biopsies allow for the evaluation of the efficacy of treatment and are useful in considering therapeutic changes, particularly in cases of worsening clinical symptoms (proteinuria, renal insufficiency). In some cases, clinical aggravation may be secondary to sclerotic lesions, for which treatment is ineffective. Sclerotic lesions are especially seen in patients who have had insufficient treatment for an active nephropathy. In other cases, deterioration may be related to active histological lesions, which require a more aggressive treatment. Also, deterioration of renal function may be secondary to nephrotoxic treatments such as non steroidal antiinflammatory drugs, cyclosporine or antibiotics rather than SLE itself. Therefore, a repeat renal biopsy may be indicated in case of persistent nephrotic syndrome or persistent active urine sediment despite adequate therapy, recurrent proteinuria and/or hematuria after remission or an increase in serum creatinine without clear explanation.

Prognostic Factors in Patients with Severe Lupus Nephritis

Several studies have analyzed the factors that are associated with a higher risk of progression. Extensive crescent

formation and necrotizing glomerular lesions are associated with an adverse outcome (110–115). In addition to these histological signs of severity, other factors may be of prognostic significance, including age, gender, race, hypertension, initial serum creatinine concentration, the delay between onset of renal disease and treatment, the occurrence of exacerbations of the nephropathy, the response to therapy after the first year (106, 110, 116–120).

An analysis of these prognostic factors is important in order to propose the most effective and safest therapy for individual patients. Several studies have shown that lupus nephritis has a worse prognosis in men compared to women. Renal survival in black Americans with diffuse lupus nephritis is poorer as compared to white patients (121). Renal survival rate in black patients was 58% at 5 years compared to 95% of white patients who retained renal function following pulse cyclophosphamide therapy. Several possible reasons for the significance of race in the poorer prognosis in lupus nephritis have been proposed and include socioeconomic factors, different HLA phenotypes and inherited susceptibility for progression to renal failure.

In a study of 86 patients with severe class III or class IV lupus nephritis who were treated with prednisone and oral cyclophosphamide, an elevation of serum creatinine was the only initial feature predictive of progression to renal failure (122). Of interest, the same authors found that the subsequent clinical course in response to therapy supplemented prognosis based on initial serum creatinine. The risk of progression to renal failure was higher in those patients who did not show resolution of renal abnormalities within 48 weeks of follow-up. Patients with normal initial serum creatinine and patients with resolution of initial serum creatinine elevations had a similar and much lower risk of progression to renal failure. Other authors have also reported the poor prognostic significance of elevated serum creatinine at presentation (106, 110, 116, 123, 124). However, these findings were not confirmed in several studies with longer periods of follow-up (101, 115, 120, 125).

In a cohort of 87 patients, the duration of renal disease prior to renal biopsy and initiation of therapy was a statistically significant predictor for renal failure or death due to renal disease (126). The most likely explanation for these findings is that early treatment of renal disease is associated with better outcome. There was a significant increase in serum creatinine, in urinary protein excretion and in activity and chronicity indexes on renal biopsy in those patients in whom the treatment was delayed. Lim et al. found that chronicity index, male sex and initial renal insufficiency were prognostic factors for class IV lupus nephritis (127). Similarly, a retrospective study of 43 patients with severe lupus nephritis who were treated with IV cyclophosphamide found that increased serum creatinine and a high degree of interstitial fibrosis on renal biopsy before treatment were associated with a worse renal prognosis (118).

Moroni et al. studied the prognostic significance of renal flares defined as a rapid increase of serum creatinine and/or in proteinuria in a retrospective study of 70 patients with lupus nephritis (120). Patients with renal flares had a higher probability of having a persistent doubling of serum creatinine compared to those who had no renal flares. The relative risk of having a persistent doubling of serum creatinine was 27 times higher in patients with rapid increases in serum creatinine. This outcome was more frequent in patients who did not respond rapidly to therapy. These data support the need for aggressive treatment of lupus nephritis exacerbations. In a study of 189 patients, Mok et al. found that the occurrence of nephritic flares was the only predictor of creatinine doubling (128). Moroni et al. found that the risk of relapse was related to the duration of initial treatment and the duration of remission before withdrawal of therapy (129). The mean duration of treatment in the group of patients who did not relapse was 57 vs. 30 months in patients who relapsed after cessation of therapy. In a retrospective study of 35 patients with lupus nephritis who were followed for up to 10 years, Barber et al. found that female gender, older age, higher nonrenal SLEDAI scores at the time of diagnosis were predictive of sustained remission (130).

A retrospective study of 93 African Americans, 100 Hispanics, and 20 Caucasians identified predictors of outcome. At baseline, mean blood pressure and serum creatinine were higher in African Americans compared to Hispanics and Caucasians. Class IV lupus nephritis was seen more often in African Americans and Hispanics compared to Caucasians. Renal deterioration or death occurred more frequently in African Americans and Hispanics than in Caucasians indicating that these populations have a more aggressive disease and a worse outcome (131). Similarly, Korbet et al. in a study of 86 patients with severe lupus nephritis reported a more aggressive renal disease resulting in worse outcomes in black patients compared with white patients (132).

Several reports have claimed a poorer prognosis of lupus nephritis in children as compared to adults. However, in a series of 80 patients with onset of disease under the age of 20 years, Cameron et al. reported a renal survival rate of 85% at 5 years and 82% at 10 years (133). Platt et al., in a series of 70 patients, found rates of 85% and 81% (8). Several reports have identified the risk factors for renal failure in children with lupus nephritis.

In a retrospective study of 167 children, persistent hypertension, anemia, increased serum creatinine concentration at the time of biopsy, low titer of CH50 were associated with a higher risk of renal failure (134). In this study, the overall renal and patient 5-year survival rates were 87.7 and 91.1% respectively. McCurdy et al. reported on a group of 71 children of whom 22% progressed to end stage renal failure (124). They also found that persistent hypertension, anemia, abnormalities of the urineanalysis and elevated serum creatinine levels were significantly associated with progression to renal failure. Class IV nephritis, active and chronic lesions were also associated with progression to renal failure. Emre et al. found that the prognosis of lupus nephritis in children is primarily dependent on the histopathological lesions. Moreover, the severity of the clinical renal disease at admission and the presence of persistent hypertension are the main poor prognostic factors (135). Baqi et al. analyzed the risk factors for renal failure in 56 children with lupus nephritis (117). Univariate analysis revealed that with an elevated serum creatinine level, a decreased C3 complement level, hypertension and class IV lupus nephritis were associated with the rate of progression to renal failure. Multivariate analysis showed that progression to renal failure was independently associated with class IV lupus nephritis, hypertension at presentation and low C3 complement level in association with elevated serum creatinine levels. These three reports as well as other studies in adults found that hypertension was a significant risk factor for renal failure. Therefore, children with hypertension should be treated appropriately with antihypertensive drugs, as control of blood pressure may be as important as antiinflammatory treatment.

Prognostic Factors in Patients with Membranous Lupus Nephritis

Patients with class V lupus nephritis, without mesangial hypercellularity have a good prognosis with a 5-year renal survival close to 85% (136–138). Conversely, Sloan et al. found that when membranous nephropathy was associated with segmental endocapillary proliferation and/or necrosis in less than 50% of glomeruli, the 5-year renal survival was 72% and only 49% when more than 50% of glomeruli were affected (137). Therefore, associated glomerular inflammation and/or necrosis are important prognostic factors in membranous lupus nephritis. Elevation of initial serum creatinine or worsening renal function and severe nephrotic syndrome are also risk factors for poor renal outcome.

Laboratory Investigations

SLE is characterized by a large variety of autoantibodies of which certain, such as anti-DNA antibodies, are found almost exclusively in patients suffering from this disease (139). These autoantibodies, associated with the corresponding antigen, form immune complexes which activate the classic complement pathway. Immune complexes can be detected in the circulation or are deposited in different tissues where they are detectable by immunofluorescence techniques.

The detection of antinuclear antibodies (ANA) by indirect immunofluorescence is a simple and sensitive test in which the serum is incubated with tissue section of a suspension of cells such as polynuclear cells. ANA are present in significant titer in 95% of patients and the diagnosis of SLE is unlikely in their absence (140). The pattern of fluorescence gives an indication on the specificity of the antibodies. A homogenous or diffuse aspect of fluorescence is related to the presence of anti desoxyribonucleoprotein antibodies and is strongly associated with SLE. The same antibodies are responsible for the formation of Hargraves cells (LE cells). Following the reaction of the antibodies with the nucleus of leukocytes, the chromatin pattern is altered and the DNA forms a large mass with the antibodies and the complement that is then ingested by a phagocyte. A peripheral aspect of the fluorescence points to the presence of antinative DNA antibodies, characteristic of active SLE. A speckled aspect of the fluorescence is related to the presence of antibodies reacting with various nuclear antigens, such as anti-Sm or anti-RNP antibodies. Such a pattern of fluorescence may be observed in SLE or mixed connective tissue disease but is more frequently associated with scleroderma. The nucleolar pattern is observed in only 25% of patients with SLE.

The presence of ANA is not unique to SLE as one finds them in other rheumatologic disorders such as chronic juvenile arthritis, scleroderma or mixed connective tissue disease, autoimmune hepatitis, thyroiditis, or after taking certain medications. ANA titers should be determined, as if low levels are found in around 2% of the general population, high levels are highly suggestive of SLE. A small proportion of patients with SLE does not have ANA and over half of them have anti-SSA antibodies. Anti-SSA antibodies are not detected by indirect immunofluorescence tests, which explains negative results. Clinically, these patients have photosensitivity, arthralgia, and serous effusions.

Antinative, double stranded, DNA antibodies are relatively specific for SLE (97%) and therefore very useful for diagnosis (141–143). They can be detected in the serum by measuring their capacity to bind radiolabeled native

DNA (Farr test) or by an immunoenzymatic technique. Anti-DNA antibodies can also be detected by indirect immunofluorescence on the microorganism Crithidia Luciliae, which have a kinetoplast in their cytoplasm containing native DNA. The Farr assay detects high affinity antibodies whereas the immunoenzymatic technique detects both high and low affinity antibodies. The Farr assay correlates with disease activity especially with proliferative nephritis (144). Moreover, the Farr assay gives estimation on the level of antibodies, which is used to monitor disease activity. Normal or stable levels are positively correlated to a stability of the disease, while an increase often precedes the reappearance or aggravation of clinical manifestations of the disease. The ELISA is of interest for screening diagnosis. The antibody titer correlates well with disease activity but moderately well with the activity of nephritis.

The Smith (Sm) antigen is a nuclear nonhistone protein (145). Anti-Sm antibodies are specific to SLE but are only found in 30% of cases and are often associated to a less severe form of the disease (146). Antiribonucleoprotein antibodies, present in 35% of SLE cases, are not specific for SLE. These antibodies bind to proteins containing U1-RNA (147). Antierythrocyte antibodies, detected by the Coombs test can be responsible for severe hemolytic anemia. Antiplatelet antibodies are often present, sometimes causing thrombopenia. Antilymphocyte antibodies, directed against T lymphocytes, may play a role in the pathogenesis of the disease. Siegert et al. found a correlation between the levels of anti-C1q antibodies and the occurrence of nephritis, the titers of anti-DNA antibodies and hypocomplementemia (148). The increase of anti-C1q titers was correlated with the development of class IV lupus nephritis. Thus, the serial measurements of these antibodies may be useful to predict relapses of nephritis. Because C1q is found in glomerular immune deposits, C1q may act as a planted antigen for anti-C1q antibodies, thus increasing the inflammatory reaction (149).

APL antibodies, including anticardiolipin and the lupus anticoagulant, may be found in SLE and are responsible for an increased risk of thrombotic complications.

Many of these autoantibodies can be responsible for the formation of immune complexes, either in the serum or localized in tissues. Circulating immune complexes can be detected by several tests but these tests are not useful in the diagnosis or the monitoring of SLE as many other conditions can be accompanied by circulating immune complexes. Immune complexes deposited in the tissues are detected by direct immunofluorescence techniques. Deposits are very frequently found in the kidneys. Skin biopsy may show immunoglobulin, principally IgG, and complement fraction deposits at the dermo-epidermic junction. These fine-grained deposits principally contain IgG. This is the lupus band test that is highly suggestive of SLE (150).

Hypocomplementemia is observed in 75% of cases at presentation, particularly in patients with nephritis. Decreased levels of CH50, C1q and C4 are related to the activation of the classical pathway of the complement system. A permanent low C4 level may also be secondary null C4 alleles. A deficiency of other complement factors may be observed. Levels of C4, C1q and C3 are used to monitor disease activity in conjunction with anti-DNA antibodies. In most patients with nephritis, flares are preceded by a decrease of these complement components. Concentrations of properdin and factor B are also depressed due to the activation of the alternative pathway.

Regular testing of biological parameters (blood cell count, erythrocyte sedimentation rate, serum albumin, proteinuria, urinary sediment, GFR, anti-DNA antibodies, CH50, C4 et C3) every 3–6 months is important during the evolution of the disease. This testing allows for the detection of hematological or renal involvement as well as a serological evidence of disease activity prior to the appearance of clinical manifestations (151).

Drug-Induced Lupus

Several drugs, particularly those which are metabolized by acetylation in the liver, such as procainamide or hydralazine, can induce a lupus like syndrome, (152, 153). The syndrome is more likely to develop in slow acetylers, which have a genetically determined deficit in hepatic *N*-acetyltransferase (154).

One characteristics of drug-induced lupus is the presence of antihistone antibodies, which are found in 95% of patients. Other autoantibodies, such as anti-DNA antibodies are rarely found in those with drug-induced lupus. These autoantibodies are formed against a complex between DNA and a histone dimer of H2A and H2B. Of interest, although the drugs responsible for drug-induced lupus are quite heterogeneous, all of these antibodies are directed against the same epitope (155). With hydralazine, the complex is composed of H1 and H3-H4 and DNA.

Procainamide, hydralazine and penicillamine, isoniazid, interferon-alpha, methyldopa, chlorpromazine, diltiazem are all likely causes of lupus. Anticonvulsants (e.g., phenytoin, mephenytoin, trimethadione, ethosuximide), quinidine, antithyroid drugs, antimicrobial agents (sulfonamides, rifampin) may possibly induce lupus.

Clinical manifestations associated with drug-induced lupus include fever, cutaneous rash, arthralgia and serositis, while renal, hematologic or neurological symptoms are rare. Anti-DNA antibodies are often absent, and the level of complement fractions normal.

The differentiation between SLE and lupus syndrome secondary to a medication is not always clear. The principal criterion is the spontaneous recovery from the syndrome within 6 months after withdrawal of the suspected medication.

Neonatal Lupus

Neonatal lupus occurs in 1–2% of children born to mothers with lupus and is due to passively transferred autoantibodies. The main complication is a complete and irreversible atrioventricular block secondary to anti-SSA (Ro) and anti-SSB antibodies, which interferes directly with the development of the conduction system (156). Some infants require insertion of a pacemaker. The incidence of congenital heart block in children from mothers with anti-SSA (Ro) antibodies ranges from 0.2 to 7.5% (157).

Other newborns, particularly girls, present with erythematous rash that often develops after exposure to ultraviolet light. The rash regress totally after 6 months. Other manifestations may include anemia, moderate leukopenia and thrombocytopenia, or hepatomegalia with cytolysis (158).

Treatment of Lupus Nephritis

Therapeutic options for patients with lupus nephritis vary depending on the histological lesions observed on renal biopsy.

Therapy of Patients with Mild Renal Lesions

Patients with class II lupus nephritis do not need specific therapy, as there is little probability of progression (103). Nevertheless, careful follow-up of the patient is necessary, as transformation to a more severe renal disease is possible.

Therapy of Patients with Class III Lupus Nephritis

Patients with class II lupus nephritis and less than 20% of the glomeruli affected by small segmental lesions have a favorable long-term outcome. In this setting, there is no indication for specific therapy, which may however be required for extra-renal symptoms. Conversely, when cellular proliferation and necrosis involve more than 40% of the glomeruli, the course of the disease is close to that of class IV lupus nephritis and the same aggressive therapy is needed (101, 108).

Therapy of Patients with Class IV Lupus Nephritis

The therapeutic regimen of class IV lupus nephritis have changed over the years (159). Although there are a large number of reports on this topic, there are only few randomized studies, which deal with limited numbers of patients, and more importantly many of them do not indicate the long-term outcome after 10 years of follow-up. The optimal therapy for patients with class IV lupus nephritis remains a challenge but it has been shown that aggressive immunosuppressive therapies have improved the prognosis. Most nephrologists agree that initial therapy should be intensive in order to achieve complete remission which is associated with a better long term outcome. Indeed, in a study involving 86 patients with severe lupus nephritis, patients who achieved remission had a 94% renal survival rate at 5 and 10 years compared to 46 and 31% renal survival rate at 5 and 10 years in patients who did not achieve complete remission (160). The aim of the treatment is also to prevent renal flares and avoid deterioration of renal function. Indeed, renal flares are associated with a worse prognosis (128, 161). Finally the optimal therapy should be associated with limited side effects.

Induction Therapy

Pulse Methylprednisolone

Patients with class IV lupus nephritis are treated with prednisone 1–2 mg/kg/day for several months. However, high doses of oral prednisone alone not only give poor results on the long term but also are often associated with serious side effects. Many authors have proposed to initiate therapy with three intravenous methylprednisolone pulses, which have potent and rapid antiinflammatory and immunosuppressive effects (162–164). Following methylprednisolone pulses, extra-renal symptoms disappear rapidly and serum creatinine returns more rapidly to normal. The NIH protocole gives monthly methylprednisolone pulses in addition to IV cyclophosphamide.

Following methylprednisolone pulses, oral prednisone is started but the optimal initial dose is not well defined. Similarly, there is no consensus on how the dosage should be decreased.

Cyclophosphamide: High-dose vs. Low-dose

Induction therapy with cytotoxic drugs and corticosteroids was shown to be superior to corticosteroids alone in preventing the progression to renal failure with a follow-up of 5 years (165, 166). The "standard" therapeutic regimen combines cyclophosphamide and corticosteroids. The NIH trials showed that this association was the best option to preserve long-term renal function. The first trial showed that patients receiving IV or oral cyclophophamide with glucocorticoids had a better renal survival than those receiving glucocorticoids alone (165, 167). In the second NIH trial, a long course IV cyclophospphamide over 30 months was compared to a short course over 6 months and to IV methylprednisolone pulses The probability of doubling serum creatinine after 5 years of follow-up was higher in patients treated with methylprednisolone pulses compared to those receiving IV cyclophosphamide (48 vs. 25%). The probability of nephritis flares was significantly higher in patients receiving cyclophosphamide pulses for 6 months compared to those receiving the long-course cyclophosphamide regimen (55 vs. 10% after 5 years) (168). In the third NIH trial, patients receiving both IV cyclophosphamide and IV methylprednisolone had a higher rate of remission compared to those receiving IV methylprednisolone alone and a reduced risk of long-term deterioration of renal function (169). However, these therapeutic regimen did not decrease overall mortality (170) and were associated with significant side effects, including a high rate of amenorrhea, infections and possibly neoplasias (171).

The Lupus Nephritis Collaborative Study treated patients with severe lupus nephritis with oral prednisone at a starting dose of 60–80 mg/day and oral cyclophosphamide for only 8 weeks, a shorter and therefore less toxic course of cyclophosphamide than the NIH protocoles (122). Exacerbations were treated using increased doses of corticosteroids. Only 16% of the 31 patients who had normal serum creatinine concentration at the start of the treatment had a rise of serum creatinine at latest follow-up and only two of them (6.5%) progressed to renal failure. Conversely, 16 of the 55 patients (29%) with elevated initial serum creatinine levels progressed to renal failure during the follow-up period. These patients may have benefited from a more aggressive regimen. Patients with severe lupus nephritis and normal initial serum creatinine may thus achieve excellent outcome without cyclophosphamide pulses, although the duration of follow-up in this study was rather short.

The possibility to control the disease with lower doses of IV cyclophosphamide was also investigated in Europe considering that lupus nephritis might be less severe in Caucasians and that lower doses may result in fewer side-effects. The Euro-Lupus nephritis trial included 90 adult patients with diffuse proliferative lupus nephritis and compared the efficacy and the toxicity of a high-dose IV cyclophosphamide regimen (6 monthly pulses and two quarterly pulses) and a low-dose IV cyclophosphamide regimen (6 fortnightly pulses at a fixed dose of 500 mg) (172). In both arms, azathioprine was given as maintenance therapy for at least 30 months. The rate of renal remission was not statistically different in both groups but adverse side-effects were less frequent in the low-dose group. With a mean follow-up of 97 months, the cumulative probability of doubling serum creatinine or reaching end stage renal failure was not different in both groups (173). The best predictor of good long-term renal outcome was an initial favorable response (174).

In children with active lupus nephritis, the data on the efficacy of cyclophosphamide pulses remain scant (175). Lehman et al. treated 16 children with cyclophosphamide monthly for 6 months and then every 3 months (176). They reported significant improvement at 1 year in urine protein excretion, hemoglogin levels, C3 and C4 and creatinine clearance despite a significant reduction in prednisone dosage. Baqi et al. compared the results of two treatment modalities in children with class II and class IV lupus nephritis: high-dose pulse methylprednisolone for 10 days, followed by oral prednisone (20 patients) or IV cyclophosphamide given monthly for 6 months and every 3 months for a period of 3 years with oral prednisone (30 patients) (117). The authors did not find any difference in outcome between the two treatment modalities.

Azathioprine

The Dutch Working group on SLE compared IV cyclophosphamide monthly for 6 months and every 3 months for a total of 7 doses and azathioprine for 2 years with methylprednisolone pulses (three series of 3 pulses within 6 weeks). After 2 years, all patients received azathioprine with prednisone. Although there were no differences between the two groups in the rate of complete and partial

remissions during the first 2 years, a higher proportion of patients in the azathioprine group experienced relapses with a mean follow-up of 5.7 years (177).

Mycophenolate Mofetil

Following the observations of the improvement of nephritis in murine lupus with the use of mycophenolate mofetil (MMF) (178, 179), several uncontrolled studies in adults and in children confirmed the potential benefits of this drug in lupus nephritis (180–183). The first controlled trial involving 42 patients with class IV lupus nephritis compared prednisolone and MMF given for 12 months with prednisolone and oral cyclophosphamide given for 6 months, followed by prednisolone and azathioprine for 6 months. After 1 year, both groups showed similar rates of complete or partial remissions, relapses and treatment discontinuations (184). Adverse effects of treatment were more frequent in the group of patients receiving cyclophosphamide. In a trial involving 44 patients with class IV lupus nephritis, Ong et al. reported a remission rate of 26% in the MMF group compared to 12% in the IV cyclophosphamide group but the difference was not significant due to the small number of patients (185). Ginzler et al. compared MMF and IV cyclophosphamide given as induction therapy for 6 months in 140 patients (186). Complete remissions were significantly more frequent in the MMF group (23%) compared to the IV cyclophosphamide group (6%) ($p = 0.005$). Severe infections and death in two patients only occurred in the cyclophosphamide group. A metanalysis performed in 2007 evaluated the outcome of 268 patients and concluded that MMF compared with cyclophosphamide reduces the risk for failure to induce remission during induction therapy and may reduce the risk for death or end-stage renal disease (187). The authors conclude that MMF may be considered as a first-line induction therapy for the treatment of lupus nephritis in patients without severe renal dysfunction. It is not known whether MMF would be as efficient in patients with more severe renal dysfunction.

Plasma exchanges have been proposed with the aim of removing immune complexes that may be involved in the pathogenesis of lupus nephritis. A randomized controlled trial compared a standard therapy with prednisone and oral cyclophosphamide to the same treatment with plasma exchanges, three times a week for 4 weeks in 86 patients with severe lupus nephritis (188). The mean follow-up was 136 weeks. There were no differences between both groups in term of patient survival, renal survival, clinical activity of the disease and complications. However, it does not mean that plasma exchanges are not of help in individual patients (189, 190).

Maintenance Therapy

The maintenance therapy is aimed to maintain remission, prevent relapses and reduce the risk of progression to renal failure. The optimal drug and the optimal duration for maintenance therapy are still debated.

Contreras et al. performed a prospective controlled trial in 59 patients with class IV lupus nephritis comparing three maintenance regimen (oral MMF, oral azathioprine and quarterly pulse cyclophosphamide) following the same induction therapy in all patients (4–7 monthly cyclophosphamide pulses plus prednisone) (191, 192). With a mean follow-up of 30 months of maintenance therapy, there were five deaths (four in the IV cyclophosphamide group and one in the MMF group) and five patients progressed to end stage renal failure (three in the IV cyclophosphamide group and one in each of the two other groups). Event-free survival (based on a composite end point of death and renal failure) was therefore significantly better in the MMF and the azathioprine groups compared to the IV cyclophosphamide group. Moreover, the relapse rate was lower in the MMF group compared to the IV cyclophosphamide group.

Another study from Italy compared cyclosporine and azathioprine in 69 patients who had first received methylprednisolone pulses and oral prednisone plus oral cyclophosphamide for 3 months. At 4 year follow-up, there were no difference in the change in creatinine clearance, in the reduction in proteinuria or the occurrence of flares between the two groups.

The results of two ongoing controlled studies, Maintain and ALMS, should answer wether MMF is superior to azathioprine for maintenance therapy.

The optimal duration of maintenance therapy is not known and there is no study comparing different durations of treatment. Some authors maintain the treatment for 18–24 months while others propose a longer duration up to 5–8 years (177, 193).

Treatment of Relapses

Relapse of the disease may be defined by a worsening of renal symptoms once patients have achieved remission. Some patients may present with active urinary sediment often accompanied by increasing serum creatinine and proteinuria (194). The presence of red cell and/or white

cell casts is a strong predictor of a renal relapse. An elevation in the titer of anti-DNA antibodies and a decrease in the complement levels (C4 and C3) are often associated with renal "flare." These serological parameters should be checked regularly, as their changes precede clinical relapse (144, 195). These patients should be closely monitored but should not be treated solely for changes in serologic activity. In cases with worsening of renal symptoms, repeat renal biopsy may also be of help before deciding a change in the therapy. Patients who show active lesions on repeat renal biopsy may need aggressive treatment. Other patients with increased serum creatinine may have extensive tubulointerstitial lesions without active glomerular lesions, which represent a nonimmunologic progression of the renal disease and do not respond to therapy. Other patients treated initially for diffuse proliferative glomerulonephritis and who responded well to therapy may have an increased proteinuria several months later. A repeat renal biopsy is useful in this situation as it may show active lesions or pure membranous nephropathy which require different therapeutic decisions. Therefore, a repeat renal biopsy is often needed in patients with renal relapses in order to decide the best therapy and avoid unnecessary aggressive treatments. Some authors treat renal exacerbations with methylprednisolone pulses followed by oral prednisone with tapering doses (196).

Treatment of Patients with Membranous Nephropathy

Patients with pure membranous nephropathy, mild proteinuria and normal renal function have a good prognosis and there is general agreement that no immunosuppressive treatment is needed (136, 137). The treatment of patients with nephrotic syndrome is controversial. These patients are at risk of thrombotic complications. A NIH trial including 41 patients led to the conclusion that patients treated with either cyclophosphamide or cyclosporine had higher remission rates (46 vs. 13%) and lower rates of persistent nephrotic syndrome (19 vs. 60%) compared with patients treated with prednisone alone. There was a trend to more relapses with cyclosporine compared to cyclophosphamide (197).

Moroni et al. performed a trial where patients were randomly assigned to receive either a 6 month regimen consisting of corticosteroids (3 methylprednisolone pulses followed by oral prednisone 0.5 mg/kg/day during months 1, 3 and 5) and chlorambucil (0.2 mg/kg/day during months 2, 4 and 6) or a symptomatic treatment (198). The probability of surviving without developing renal failure at 10 years was 92% in the treated group vs. 60% in the control group. Complete or partial remissions were significantly more frequent in the treated group. Radhakrishnan et al. treated 10 nephrotic patients with cyclosporine for periods up to 43 months (199). Proteinuria decreased to less than 1 g/day in 6 patients and between 1 and 2 g/day in two. Repeat renal biopsies in five patients showed a decrease in the histological activity index but a rise in the chronicity index. Serum creatinine levels were not significantly increased at the end of the study. In addition to immunosuppressive treatment, aggressive renoprotective therapies are recommended with ACE inhibitors and/or angiotensin II receptor blockers which often are accompanied by a reduction in proteinuria (200).

Patients with a worsening of renal function should have a repeat renal biopsy, as membranous nephropathy may be associated with proliferative glomerulonephritis. In this setting, patients should be treated with the same regimen as that used for diffuse proliferative glomerulonephritis

Other Therapeutic Approaches

Rituximab

Rituximab, a chimeric mouse/human monoclonal antibody which recognizes B lymphocytes, is being increasingly used in autoimmune diseases. Rituximab induces a prolonged depletion of peripheral blood CD20 positive cells but has no effect on plasma cells. In SLE there are arguments for the role of B lymphocytes in the pathogenesis of the disease. Indeed, B lymphocytes not only produce autoantibodies but may also act as antigen-presenting cells and recruit clones of autoreactive T lymphocytes. Interestingly, Sfikakis et al. studied prospectively peripheral blood lymphocytes markers in ten patients with severe lupus nephritis who received rituximab. The expression of the costimulatory molecule CD-40 ligand on CD4+ T lymphocytes was significantly decreased as well as the expression of several markers of T lymphocyte activation (201). These changes were correlated with the clinical efficacy of rituximab. Vigna-Perez et al. found a significant increase of regulatory T cells (TREG) and an increase in the apoptotic T cells in patients with lupus nephritis following rituximab therapy. There are several reports suggesting that rituximab may have a beneficial role in patients with severe active lupus nephritis resistant to standard treatments. Overall, the rate of clinical remission is about 80% (202–207).

However, as most patients receive rituximab in combination with other immunosuppressants, including in several studies IV cyclophosphamide, it is difficult, in the absence of controlled studies to ascertain the benefit of rituximab. In a study of seven patients with proliferative lupus nephritis, Gunnarsson et al. observed an improvement of histopathologic class of nephritis on repeat renal biopsies in the majority of patients with a decrease in the activity index and a decrease in the number of T and B lymphoctes in the interstitium in 50% of the patients (208). Willems et al. reported a series of 11 children including eight with renal involvement (209). A complete renal remission was observed in two children, a partial remission in four while rituximab had no effect in two patients. Serious adverse events occurred in five of the 11 children including septicemia in two and severe hematologic toxicity in four. Thrombocytopenia and severe neutropenia occurred 1–3 days after rituximab infusion in two patients and resolved within 10 days.

Intravenous immunoglobulins have been reported to be effective in individual patients, including patients with proliferative lupus nephritis (210, 211). A recent meta-analysis found a response rate ranging from 33 to 100% and controlled trials are warranted (212).

Several biological agents have recently been studied in SLE. LJP-394, which consists of four-linked oligonucleotides, binds to anti-DNA producing B lymphocytes. Although LJP-394 has been shown to decrease anti-DNA titers (213), the clinical benefit has not been proven (214).

Anti-CD40 ligand monoclonal antibodies improve renal disease in murine lupus (215). However, studies in human were abandoned because of thrombotic complications (216).

CTLA4Ig, abatacept, is a fusion protein between CTLA4 (the human cytotoxic T-lymphocyte associated antigen) and the constant region of IgG1 heavy chain. CTLA4Ig binds to CD80 and CD86 on antigen-presenting cells, blocking the engagement of CD28 on T cells and preventing T-cell activation (217). CTLA4Ig treatment prevents onset of SLE in several murine models (218) and reduces anti-dsDNA antibodies, increases C3 concentrations, and decreases hematuria in patients with proliferative lupus nephritis (219).

Prognosis and Complications

Until 30 years ago, the prognosis of patients with lupus nephritis was very poor. Better management of lupus has improved the prognosis with a 10-year survival rate exceeding 80% (220). The disease is often marked by flares and periods of remission. The prognosis of SLE must also take into consideration iatrogenic complications since they are often linked with flares of the disease, particularly infections, vascular complications, osteonecrosis, or thrombosis.

Infectious complications are a significant cause of death during the course of SLE (220–222). These are favored by leukopenia and the reduction of the phagocytic functions, functional asplenia, hypocomplementemia, and, more important, by treatment with corticosteroids and immunosuppressive agents (223–225). Some authors have recommended systematic preventive antibiotherapy and antipneumococcal vaccination. Sepsis may be difficult to distinguish from a relapse of lupus. Herpes zoster is very common among the viral complications (8, 226). Early treatment with acyclovir avoids dissemination.

Accelerated atherosclerosis is now recognized as a frequent cause of morbidity and mortality in young adults with lupus and the process may start during childhood (226–231). Myocardial infarction has been reported in very young patients (232). The pathogenesis is probably multifactorial and includes inflammatory vascular disease, APL antibodies, hypertension, lipid abnormalities associated with the nephrotic syndrome or renal insufficiency, and corticosteroids (233–238). The prevalence of coronary-artery calcification is elevated and the age at onset is reduced compared to control subjects (239).

Thrombosis is another common complication of SLE (240). The risk factors include antiphospholipid antibodies, decreased levels of plasminogen activator, decreased levels of protein S and, in some patients, the additional risks related to the nephrotic syndrome (84, 241–246). Arterial thromboses are observed in lupus patients with APL antibodies and often involve cerebral arteries (247). Venous thrombosis are more common (248). Pulmonary embolism is frequent and may be complicated by pulmonary hypertension.

End stage renal failure occurs in 10–20% of patients with severe renal disease after a mean period of 5 years (7, 249, 250). While lupus nephritis progresses to renal insufficiency, the activity of SLE often diminishes in terms of other clinical manifestations and biological symptoms (251). Dialysis can be started and these patients do as well as nonlupus patients with end stage renal disease. Some patients, however, have a rapid course to renal failure, maintaining clinical and serological signs of activity. Therapeutic decisions are difficult as aggressive treatments may allow a recovery of renal function and discontinuation of dialysis. On the other hand, these patients are at higher risk of iatrogenic complications, particularly infection, which may be life-threatening (252, 253). Clinical and biological symptoms of the disease most often

improve in patients on chronic dialysis, thus allowing stopping of corticosteroids and immunosuppressive therapy. However, clinical manifestations can persist or even appear at this stage.

Renal transplantation is the treatment of choice for those who progress to renal failure. The outcome after renal transplantation in these patients is similar to that of patients with other diseases in adults (254–258) as well as in children (259). The risk for thrombotic complications is greater in patients with SLE, particularly those with APL-antibodies (260). However, it is advisable to wait before proposing transplantation until the clinical and serological activity of lupus has decreased. Moreover, a period without corticosteroids and immunosuppressive agents may be beneficial to the child. After renal transplantation, the activity of the disease declines and recurrence on the graft is unusual. The very low rate of recurrence of the disease after transplantation is a strong argument against a direct role of circulating immune complexes in the pathogenesis of the nephropathy. An analysis of patient and graft outcomes in patients with lupus nephritis was conducted by UNOS. The study concludes that patients with lupus have outcomes comparable to nonlupus transplant recipients (258).

Ischemic thrombosis of the bone is a rare complication of lupus in children. Several factors may be involved including the presence of APL antibodies and corticosteroid therapy. It may affect any bone but the femoral head and the femoral condyle are more commonly involved (261). Bone mineral density measurements may show osteoporosis and a study found an inverse correlation between bone mineral density and the cumulative dosage of corticosteroid but no significant correlation between bone mineral density and duration or activity of the disease (262).

Growth retardation is a major concern in children treated for several years with corticosteroids, particularly those who need to be maintain on daily steroid therapy. Other complications of corticosteroids include cataracts, gastrointestinal hemorrhage, and diabetes mellitus. A cushingoid aspect is frequent and often badly tolerated by adolescent girls. It may explain poor compliance leading to severe relapses.

Side effects of cytotoxic drugs are common. The incidence of hemorrhagic cystitis following IV cyclophosphamide is very low provided adequate hydration using the IV route is given (263). To minimize the risk of hemorrhagic cystitis, mesna, which binds to cyclophosphamide metabolites in the urine, may be helpful. Nausea and vomiting may be in part prevented by the concomitant use of antiemetic agents such as ondansetron (Zofren). Cyclophosphamide pulses often results in neutropenia with a serious risk of infection, which may be life-threatening (225). Children and their families should be aware of the risk of transient alopecia. Ovarian toxicity is another serious complication (264, 265). The risk of amenorrhea depends on the age of the patient at start of the treatment and the total number of pulses (266–268). When treatment is given for 6 months, the risk of amenorrhea is very low if the patient is less than 25 years of age, whereas 25% of patients older than 30 years of age will develop this complication. When the total number of pulses exceed 15, the probability to develop amenorrhea is 17% for patients less than 25 years and nearly 100% for those older than 30 years. Gonadotrophin-releasing hormone antagonist may preserve ovarian function (269–272). There are no published data on long term gonadal toxicity of cyclophosphamide pulses given to prepubertal girls. The gonadal toxicity of pulse cyclophosphamide in men has not been studied. However, studies in children with idiopathic nephrotic syndrome suggest that this toxicity may occur if the cumulative dosage is higher than 200 mg/kg. Severe infections have been reported in children with lupus nephritis after IV cyclophosphamide (273). It should be noted that no disseminated malignancies have been reported in patients treated with cyclophosphamide pulses although longer follow-up periods are needed before any definite conclusions may be drawn.

48 Hemolytic Uremic Syndrome

S. Johnson · C. Mark Taylor

Introduction

The origin of the diagnostic term Hemolytic Uremic Syndrome (HUS) is found in the seminal report of five children by Gasser et al. (1). The children all had microangiopathic hemolytic anemia died of renal failure and were discovered to have acute cortical necrosis at post-mortem. From this emerged the triad of clinical features, *microangiopathic hemolytic anemia*, *thrombocytopenia*, and *renal impairment* that are used to diagnose the syndrome.

These clinical features are not exclusive to HUS and further conventions have evolved to focus more clearly on the syndrome. For example, patients with pre-existing sepsis and multi-organ failure who develop these clinical features are usually excluded from a diagnosis of HUS. Typically in these cases there is disseminated intravascular coagulation with consumption of circulating coagulation factors. By comparison, patients with HUS have activated coagulation and preservation of circulating coagulation factors even though platelets are consumed. The assumption is that in HUS, intravascular thrombosis is focal and not generalized. There are two exceptions to this convention. Septicemia with *Streptococcus pneumoniae* or *Shigella dysentery type 1* can lead to HUS in which there is accelerated coagulation, at least initially (discussed below). Patients with malignant hypertension can also develop the same triad of clinical features but would not be described as HUS. Given that some forms of HUS are associated with severe hypertension it is sometimes difficult, at least initially, to make the diagnostic distinction.

A generation before Gasser, Moscovitz described a teenage girl with fluctuating neurological disease, fever, mild renal impairment and microangiopathic hemolytic anemia, the condition now known as thrombotic thrombocytopenic purpura (TTP) (2). TTP overlaps HUS if the diagnostic criteria are restricted to the *clinical presentation alone*. Rarely, patients with TTP may have prominent renal impairment and therefore resemble HUS. More often, patients with HUS have neurological involvement and risk being inappropriately described as TTP.

Diagnostic precision can be improved by moving towards an etiological based classification. One such attempt by the European Paediatric Research Group for HUS is used in this chapter (3). Following a contemporary review of the literature subgroups of HUS and TTP were assigned to two diagnostic levels. In the first there was reasonable evidence of causation, and in the second there were clinical associations but evidence of causation was weak or absent. It seems increasingly likely that TTP will become clearly separated from HUS on the grounds that the etiology and pathogenesis are specifically related to deficiency or inactivation of the protease that cleaves von Willebrand factor. Because of this assumption only a brief review of TTP is included in this chapter.

For historical reasons some of the terminology surrounding HUS has become confusing. *Table 48-1* addresses the terminology.

Making the Diagnosis of HUS

Microangiopathic hemolytic anemia (MAHA) is a Coombs test negative hemolytic anemia in which fragmented red cells (schistocytes) appear in the peripheral blood, usually accompanied by thrombocytopenia (*Fig. 48-1*). The plasma concentration of lactate dehydrogenase is elevated and haptoglobin is reduced. In clinical practice the latter is a more sensitive test of intravascular hemolysis and is often the last parameter to normalize when MAHA resolves. Although a consistent feature of HUS, the severity of MAHA does not correlate with clinical outcome. Severe oligoanuria and acute cortical necrosis may occur with relatively mild anemia. It seems likely that MAHA is partly the result of mechanical damage to red cells as they pass through the renal microcirculation in which there is thrombotic microangiopathy. Red cell production is increased and reticulocytosis, macrocytosis and polychromasia are seen.

Thrombocytopenia is common to all types of HUS but is variable, transient, and can therefore be missed. Thrombocytopenia is due to platelet consumption. While some of this consumption occurs in the thrombotic microangiopathic lesion itself, labeling studies have shown that the majority of platelets are removed in the reticuloendothelial system. Despite thrombocytopenia, clinically significant hemorrhage is uncommon and this may be due to

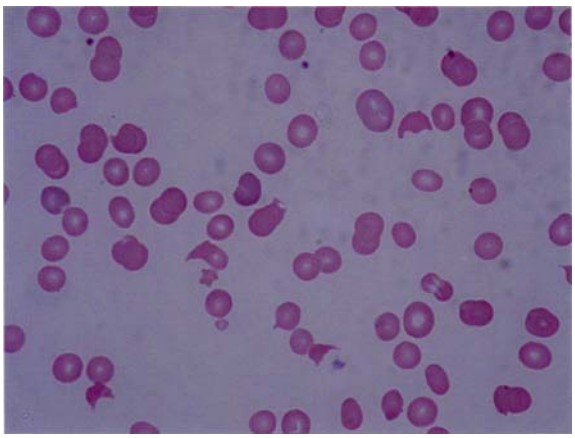
Table 48-1

Terminology used to describe HUS

Term	Comment
D + HUS	Refers to patients presenting with a prodrome of diarrhea, usually less than 2 weeks before disclosing HUS
Typical HUS	Refers to children with D + HUS. Used retrospectively it implies a single, self limited clinical event
Atypical HUS	Literally applies to patients with any pattern of clinical presentation other than D + HUS. There is drift of usage to imply those forms of HUS associated with complement dysregulation
Recurrent or relapsing HUS	Further episode of thrombocytopenia and/or MAHA after normalization of hematological parameters in a former episode. Implies that further renal injury is occurring or imminent. Also strongly suggests that the patient has an ongoing risk factor e.g., genetic, autoimmune
Thrombotic microangiopathy, glomerular thrombotic microangiopathy	These are pathological terms describing the characteristic findings in HUS, and should not be used to describe a clinical condition e.g., microangiopathic hemolytic anemia
Familial HUS	Needs to distinguish between *synchronous* HUS in family members, for example in an outbreak of enterohemorrhagic E. coli infection, and *asynchronous* disease that implies an inherited risk factor. Without this distinction the term lacks meaning

Figure 48-1

Photograph of a blood film characteristic of Microangiophathic hemolytic anemia. Fragmented erythrocytes (schistocytes) are seen.



activation of the coagulation system (4, 5). Typically, plasma concentrations of fibrinogen and factor V are normal and prothrombin and partial thromboplastin times are normal or short. Thrombin-antithrombin III complexes, prothrombin fragments, tissue plasminogen activator, plasminogen activator inhibitor-1 and D-dimers are increased reflecting increases in both thrombus formation and lysis. Overall the fibrinolytic activity of plasma is impaired.

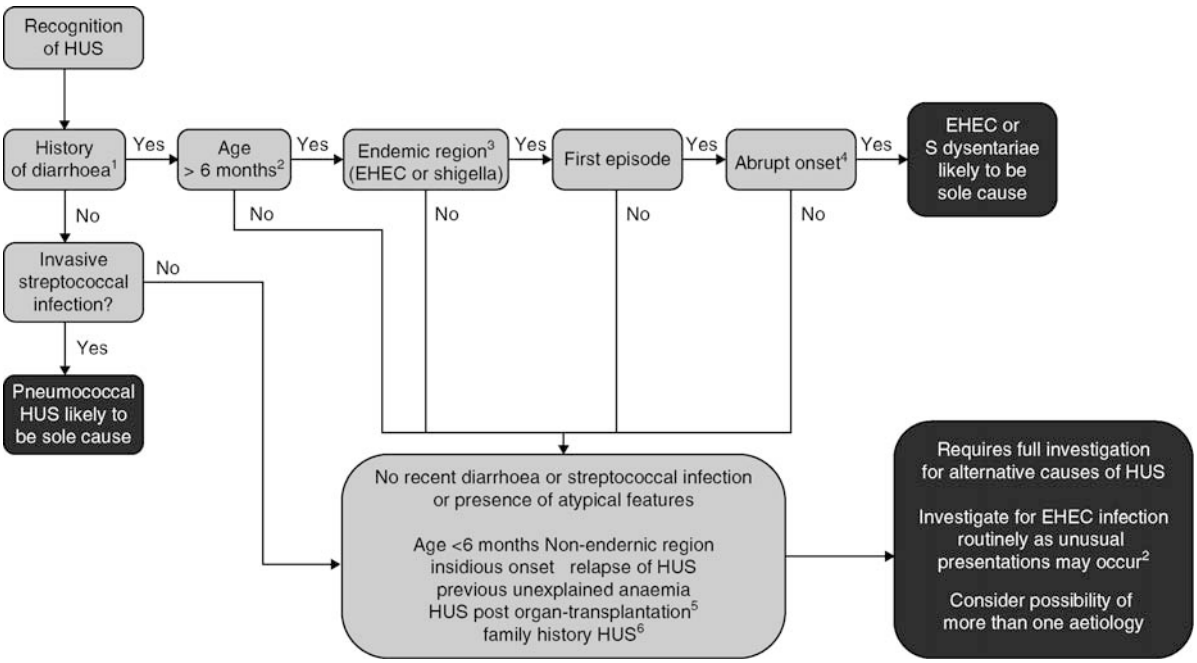
Renal failure occurs abruptly in post-infectious forms of HUS and is typically oligoanuric. Renal failure with high urine output is recognized but rare. In other forms of the syndrome that do not follow acute infections, the onset of renal impairment can be either abrupt or insidious. Proteinuria is a consistent finding in all types of HUS. Hypertension at onset is usually severe and difficult to control in patients with HUS associated with complement dysregulation. By contrast those with infection-induced HUS usually have normal blood pressure or only mild hypertension at onset, but commonly develop transient hypertension during the recovery of oliguric renal failure.

Classification of HUS

The clinical presentation provides a useful indication of the likely sub-group diagnosis of HUS. A diagnostic flow diagram for this is shown in *Fig. 48-2*, and a summary of sub-groups appears in *Table 48-2*. By far the commonest subgroup (>90% of childhood HUS) is induced by shiga toxin producing bacteria, usually enterohemorrhagic

Figure 48-2

Diagnostic flow diagram for HUS based upon clinical presentation. (1) Bloody or non-bloody diarrhea within 2 weeks prior to onset. (2) Infants less than 6 months of age are less likely to have EHEC infection, although this varies according to the local epidemiology of EHEC infection. (3) Refer to up to date reference on prevalence. (4) Insidious onset with fluctuating clinical signs and laboratory parameters increase the likelihood of a non-infective cause. (5) HUS can follow transplantation of several organs including kidney. The role of drugs, especially calcineurin inhibitors, has been suspected but not proven. (6) In an outbreak of EHEC infection several family members may develop HUS and do not require investigation beyond confirmation of the EHEC infection. Families with asynchronous HUS are likely to have inherited risk factors and require full investigation. (7) EHEC infection can cause HUS without diarrhea. Use locally developed public health/microbiological services to identify EHEC.



Escherichia coli (EHEC). *Shigella dysenteriae type 1* can induce the syndrome in endemic regions, and rarely other organisms such as *Citrobacter freundii* are responsible (6). These patients typically have a prodrome of diarrhea, often bloody diarrhea, a few days before the recognition of HUS (D + HUS) and are usually over 6 months of age.

Another important subgroup that is readily identified on clinical grounds follows invasive *Streptococcus pneumoniae* infection (7, 8). These infants tend to be younger than those with D + HUS, and the syndrome is very rare after the age of 4 years. They present with pneumonia, empyema, meningitis and less often, isolated septicemia.

Beyond the infection-induced forms, all other etiologies are rare and require specialist laboratory support to reach a diagnosis. An inherited predisposition to HUS is suggested by very early onset (< 6 months of age), lack of a diarrheal prodrome, insidious onset with lethargy, pallor, feeding difficulties, severe hypertension or a family history of HUS. Within this group patients may have mutations in complement regulators, and less often inherited deficiency of von Willebrand protease or an inborn error of cobalamin metabolism. There remains a small group of patients in whom the cause of HUS is not known in spite of extensive investigation, and no clinical association such as a suspected drug effect, cancer or bone marrow transplant that might hint at a causative process. In practice this is less than 5% of all childhood HUS. The majority of these have a single episode, and as long they make a good recovery of renal function, the prognosis appears favorable. However, amongst undiagnosed patients is a small group with relapsing or familial disease in whom novel risk factors await discovery.

Table 48-2

Subgroups of HUS based upon etiology

Diagnostic subgroup	Comment
HUS associated with shiga toxin (stx)-producing infections; enterohemorrhagic	D + HUS closely maps to this group where entero-hemorrhagic Escherichia coli infection is the source of toxin. Shigella dysenteriae type 1 is a well recognized and broadly similar form in parts of sub-Saharan Africa and Indian subcontinent. Occasionally other bacterial species such as *Citrobacter* produce stx and induce HUS. Stx is implicated in pathogenesis. This subgroup covers > 90% of HUS in children
Escherichia coli	
Shigella dysenteriae type 1	
Other stx producing organisms	
HUS associated with invasive *Streptococcus pneumoniae* infection	Rare but distinctive form of HUS usually with evidence of desialyation of host cell membranes and T-activation of erythrocytes induced by neuraminidase, a product of *pneumococcus*
HUS associated with complement dysregulation	May be genetic, sometimes familial, with mutations affecting the alternative pathway of complement (Factor H, Factor I, Membrane co-factor protein CD46, Factor B, C3). May also be acquired by autoantibody to Factor H
Inherited or acquired severe deficiency of von Willebrand cleaving protease	Inherited or acquired severe deficiency of vonWillebrand cleaving protease, ADAMTS13. Prominent early renal impairment is rare. These patients are better described as TTP rather than HUS
HUS associated with cobalamin deficiency	Usually due to homozygous mutation in methylenetetrahydrofolate reductase gene; cobalamin C deficiency
HUS associated with quinine	Adult patients only described so far, children rarely exposed to quinine

Pathological Findings in HUS

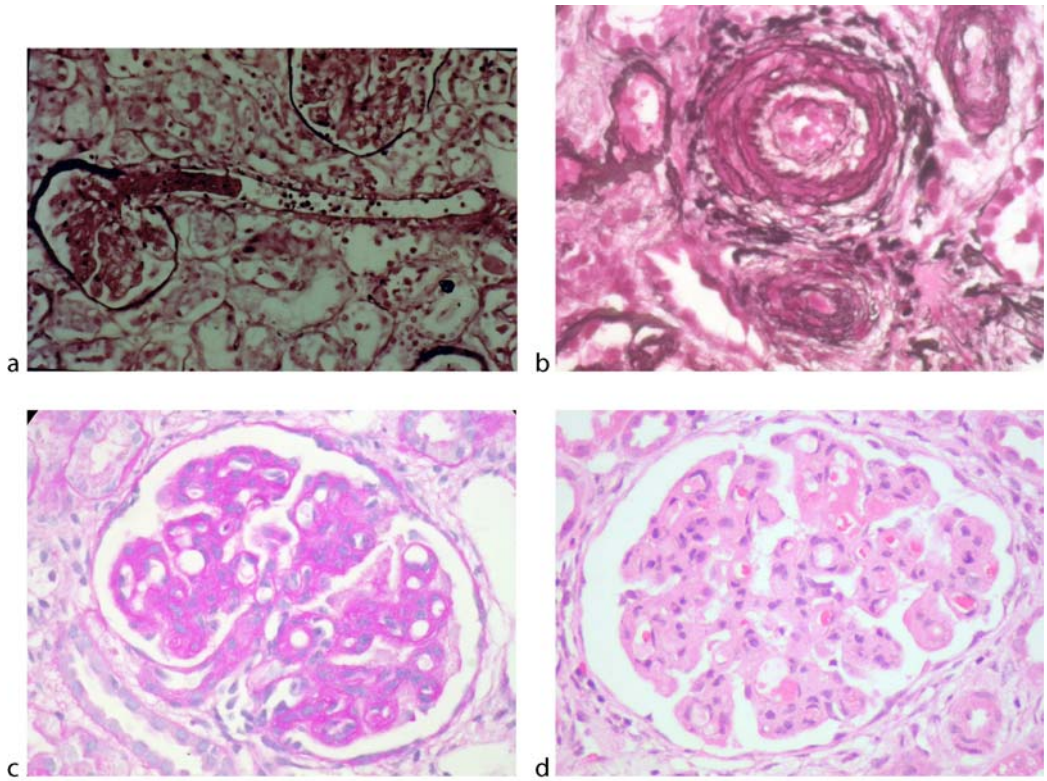
The term *thrombotic microangiopathy* (TMA) was coined by Symmers to describe hyaline thrombi that occurred in a distinctive arteriolo-capillary distribution in the absence of primary vascular inflammation (9). He found it in many organs of patients that would fit the current clinical description of TTP. Subsequently, Habib identified microvascular thrombi in the glomeruli of children with HUS, and with permission from Symmers proposed the term glomerular TMA (10). Broadly three types of TMA are seen. In the most common *glomerular type*, glomerular capillaries are distended with platelet-fibrin thrombi. Endothelial cells are swollen and may be detached from the underlying basement membrane, and the capillary wall appears thickened (*Fig. 48-3a*). *Acute cortical necrosis* may occur, in which case it is claimed that a careful search will reveal vascular thrombotic lesions. *Arterial TMA* is a form in which the afferent arteriole or the interlobular arteries are involved with endothelial swelling and replication, narrowing of the lumen, and varying amounts of intraluminal thrombus in differing stages of organization (*Fig. 48-3b*). Downstream, the glomeruli are shrunken and ischemic with wrinkled basement membranes and loss of resident cells.

The three histological groups offer some prognostic value (10). Cortical necrosis is irreversible and, if extensive, correlates with a failure to recover renal function. Pure glomerular TMA is characteristic of HUS induced by EHEC infection, and is to some extent reversible. Arterial forms are more often seen in adults, in relapsing disease, and associated with both severe hypertension and poor prognosis.

While there are good data to link EHEC-induced HUS to glomerular TMA, much of it obtained at post mortem, the correlation between other etiological subgroups of HUS and pathological findings is far less clear. Biopsies are not undertaken in HUS during the period of thrombocytopenia because of the risk of hemorrhage, and so they usually represent a later stage in the process. In patients with HUS secondary to complement dysregulation, the light microscopy findings include lobulated glomeruli and thickened capillary walls (*Fig. 48-3c*). In these biopsies, thrombus may be scanty or absent. In some this resembles mesangiocapillary glomerulonephritis. The assumption is that more thrombosis would have been seen if tissue had been obtained during the period of microangiopathic hemolytic anemia and thrombocytopenia (*Fig. 48-3d*). Complement C3 can be identified in the capillary walls in some cases but it is usually scanty. Overlap between complement dysregulation associated HUS and primary glomerulonephritis with isolated C3 deposition is recognized (11).

Figure 48-3

(a) Glomerular thrombotic microangiopathy: post mortem specimen from child with EHEC-induced HUS. (b) Arteriole showing endothelial swelling and replication in a patient with HUS secondary to a complement factor H mutation. (c) Lobulated glomerulus with thickened capillary walls. (d) Active thrombotic microangiopathy in a patient with factor H mutation showing capillary thrombi. (See color plate 31)



Other pathological changes such as mesangiolysis occur, but the cause is unclear and it remains unknown if this feature associates with specific subgroups of HUS. It is rare in early EHEC infection, perhaps because mesangial cells in culture are less sensitive to shiga toxin than other resident glomerular cells. Mesangiolysis is reported in the forms of glomerular TMA that complicate treatment with vascular endothelial growth factor, radiation and chemotherapy (10).

For most patients with HUS, TMA is an acute event, although in some it can be recurrent or chronic. Unless there is a rapid resolution of glomerular thrombosis, the lesion progresses to global glomerular sclerosis, downstream ischemia, interstitial fibrosis and tubular atrophy. Following an episode of TMA with moderate or severe nephron loss, surviving glomeruli and nephrons undergo compensatory hypertrophy, as with any other nephron destructive process. Later, hypertrophied glomeruli may show signs of focal segmental sclerosis and hyalinosis as a secondary process, typically associated with albuminuria (12).

TMA outside the renal microcirculation is recognized. In EHEC-induced HUS microthrombi at post mortem have been seen in gut, brain, heart and pancreas (13). In TTP platelet rich microthrombi can be widespread. By contrast extra-renal TMA is infrequently reported in HUS associated with complement disorders, although cerebral and retinal vascular damage has been reported (14–16).

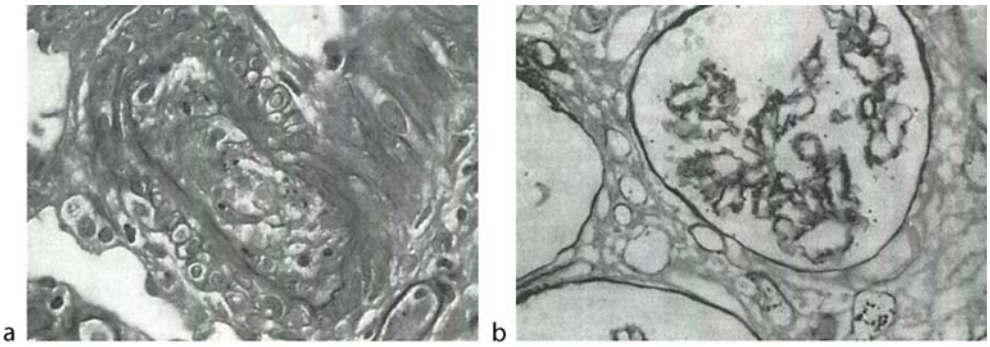
HUS Caused by Enterohemorrhagic *Escherichia coli*

Clinical Features

Prior to the identification of EHEC as a human pathogen, it was recognized that children who had diarrhea shortly before the diagnosis of HUS had a better outcome than

Figure 48-4

Extensive cerebral necrosis demonstrated by magnetic resonance imaging. Reproduced courtesy of Chantal Loirat.



those without diarrhea (17). The term D + HUS was subsequently adopted to describe the former group. Following the seminal paper by Karmali et al. (18) it was quickly established that D + HUS was attributable to infection with EHEC (19–24). EHEC infection is not always confirmed in patients with D + HUS, since its excretion can be transient. However, the clinical features are similar whether or not the organism is identified. This suggests that in practice nearly all D + HUS in temperate regions is attributable to these pathogens. In Europe, the Americas and Australia more than 90% of all childhood HUS is D + HUS (25, 26).

The peak age of presentation is between 1 and 5 years of age, with a small number of older children and adolescents affected. It is rare in adults and in the first 6 months of life. Diarrhea and abdominal cramps are abrupt in onset, and fresh blood is visible in the stools in about two thirds of cases. Fever is not a prominent feature. The infective colitis causes hemorrhage and infarction through all layers of the intestine. Toxic dilatation of the colon, perforation and massive hemorrhage are surgical emergencies. Delay in dealing with this risks cardiovascular collapse that is difficult to reverse. In the child who presents in a collapsed state these complications should be carefully considered.

Pallor and oliguria herald the onset of HUS and usually appear on about the fourth day of diarrhea with a range of 1–10 days. Purpura and bruising are usually mild or absent. Mild jaundice occurs in about a third of cases and there is often mild and transient elevation of liver enzymes, and less often hepatomegaly. Some patients are dehydrated and hypovolemic at the time of presentation, while others who have maintained fluid intake in the presence of oligoanuria may have hypervolemia. Hypertension at onset is rather unusual, but often appears transiently later in the course of the acute renal failure.

Extra-renal manifestations are an important cause of added morbidity and are the main cause of death (20). Central nervous system (CNS) disturbances are common and usually present early in the course of the illness. They include irritability, confusion, hallucination and seizures. Diffuse massive cerebral edema can induce hind brain compression leading to a decerebrate state and brainstem death. Less common is focal brain infarction leading to stroke (*Fig. 48-4*). A rare but well recognized complication is pancreatic involvement that can lead to overt diabetes mellitus (27). It usually appears a week or more after the onset of HUS. Cardiomyopathy and myocarditis are described and may occur several weeks after onset and may not be secondary to hypertension or vascular volume overload and may be secondary (28).

Microbiology of EHEC

Escherichia coli that are capable of inducing bloody diarrhea in humans, with or without HUS, are referred to as EHEC. These organisms have various virulence factors but the principal one is the ability to excrete a species of shiga toxin (stx) to which humans have receptors. The terms stx and verocytotoxin are equivalent, although the former is preferred as it indicates the relationship with the family of toxins that resemble the exotoxin of *Shigella dysentery* type 1. The latter is a historic term referring to the extreme sensitivity of vero cells to stx in culture.

Shiga toxins are species restricted. Not all stx are toxic to humans, thus not all shiga toxin-producing *E. coli* (STEC) are necessarily EHEC, but all EHEC are STEC (29). EHEC have not acquired enteroinvasive properties and patients almost never develop septicemia. However, HUS has been reported secondary to urinary infection with EHEC. These cases can occur without typical

gastrointestinal symptoms and septicemia in this circumstance is described (30). It is important to culture the urine from patients with HUS, and if *E. coli* are found, to investigate for toxigenic properties.

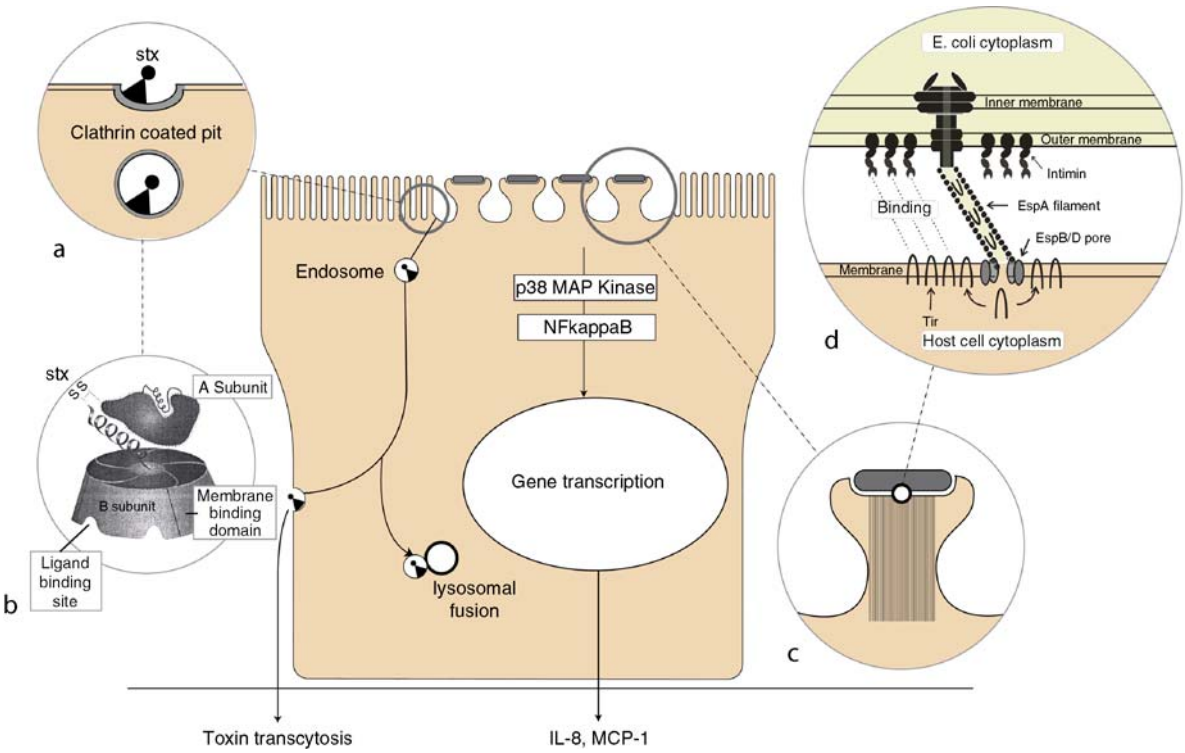
EHEC usually possess additional virulence factors such as the ability to attach to the luminal surface of host enterocytes and to cause effacement of the microvilli (Fig. 48-5) (31). This property is characteristic of enteropathogenic *E. coli* (EPEC) and explains their ability to cause watery diarrhea through loss of absorptive surface. The attaching and effacing lesion is a two-step process. During the first step the *E. coli* expresses the adhesin intimin on its surface. In the second step E. coli injects the intimin receptor into the host cell through a microtubular structure known as a type 3 secretion system. The intimin receptor in the host becomes oriented in the host cell membrane permitting the *E. coli* to adhere

Many of the bacterial proteins essential to type 3 secretion are known, and the genes that encode them occur in the *locus for enterocyte effacement* (LEE) (31). These include *eaeA* the gene for intimin and *tir* the gene for the translocated intimin receptor. EHEC seem to preferentially locate to the epithelium associated with Payer's patches, the clinical significance of which is unknown (31). Attachment induces various signaling events in the enterocyte, resulting in cytoskeletal rearrangements whereby the microvilli are lost and replaced by a pedestal on which the *E. coli* become firmly bound. It seems likely that "attachment and effacement" is an added virulence factor for EHEC and allows delivery of stx in immediate proximity to host enterocytes. Transcytosis of toxin across the intestinal epithelium has been demonstrated in vitro (32). However, attachment is not an absolute requirement for EHEC, and organisms that lack this ability occasionally cause HUS.

Many EHEC also secrete calcium-dependent alpha-hemolysin or possess the gene encoding it, *ehxA* (33, 34). Alpha-hemolysin is a pore-forming toxin that induces

Figure 48-5

Effect of enterohemorrhagic *Escherichia coli* on intestinal epithelial cells. (a) Shiga toxin released on the luminal side of the cell is taken up into an endosome. From here it is either transported and secreted from the basal surface, or degraded by a lysosome. (b) Cartoon of the structure of shiga toxin (from Donnelly JJ, Rappuoli R. *Nat Med* 200;6:257–258 with permission). (c) Attaching and effacing lesion with rearrangement of actin cytoskeleton. (d) Type 3 secretion system structure and protein components (courtesy of Dr S Knutton).



lysis of non-human red cells and is toxic to human brain microvascular cells in vitro (35). The association suggests that this is a virulence factor in human infection but it is not essential and its exact pathological role in hemorrhagic colitis and HUS is not known.

The *E. coli* serotypes that are associated with HUS vary in different parts of the world. In North America and North West Europe the dominant serotype is O157:H7, but other serotypes occur either sporadically or as causes of outbreaks of enterocolitis and HUS (19, 24, 36–38). In Southern Europe a high proportion of HUS is associated with O26 (24). In Australia, human infection with O157 is rare even though Australian cattle are known to harbor it, and O111 is the dominant causative strain (26). Several O-serotypes of EHEC are also well known as the same O-serotypes of EPEC, for example O26, O55, O111, further illustrating the importance of the combined virulence factor of attachment and effacement. Novel serotypes are continuously reported and sometimes clearly traced back to animal or environmental sources (39).

Toxicology

Shiga toxins (stx) have a common structure of a single A-subunit linked to five B-subunits (40). Whereas the gene for Shiga toxin itself is encoded in the chromosome of *Shigella dysenteriae-type 1*, genes for stx-1 and stx-2 are encoded in STEC by temperate bacteriophages which can integrate with the host genome. Exposure of STEC to certain antibiotics appears to increase toxin release in vitro (41). There has been concern that antibiotic use in the diarrheal phase of the illness might promote HUS by amplifying toxin release, but a meta-analysis, admittedly under-powered, did not confirm this (42). Stx bacteriophages, released during lysis, are available for uptake by other bacterial species including commensal organisms, not always *E. coli.* This may confer new pathogenetic properties and is thought to be the mechanism by which organisms not normally associated with toxigenic properties have caused HUS (e.g., *Citrobacter freudii* (6)). STEC may have more than one bacteriophage and therefore produce more than one toxin, e.g., stx-1 and stx-2.

Stx-1 is identical to Shiga toxin, the product of *Shigella dysenteriae* type 1. Stx-2 is approximately 60% homologous to stx-1 with different subtypes denoted by a suffix.

Within an EHEC serotype, e.g., O157, different stx phage types have geographical and temporal associations. EHEC responsible for HUS express stx-2 more often than stx-1 (4, 18, 19, 23, 43). Stx-2c is positively associated with HUS disease but Stx-2d, Stx-2e and Stx-2f are not. Recently a variant of Stx-2d, Stx-$2d_{(activatable)}$ has been associated with HUS (44). This toxin is modified by enzymes in intestinal mucus to increase its virulence. Moreover EHEC producing Stx-$2d_{(activatable)}$ do not seem to require the added virulence properties of attachment and effacement. Stx-2e is responsible for "edema disease" of pigs and recognizes Gb4 expressed in that species. Stx-2f has been associated with avians.

It seems likely that *E. coli* can lose stx bacteriophages as well as acquire them since O157 strains that do not possess stx genes are found in patients with D + HUS (45).

STEC Zoonosis

STEC that are clearly pathogenic in man may colonize animals particularly ruminants, without causing disease. In cows, the carriage of *E. coli* O157 varies according to age and feeding practices. The organisms locate to mucosal lymphoid tissue in the rectum (46). While contamination of meat and milk products has been a major concern for food hygiene, driven by well-publicized outbreaks involving undercooked ground beef, this is probably not the most common route for human exposure. STEC shed on to pastureland survive over a wide range of temperature and pH, and resist composting. Because they persist in soil they can readily contaminate surface water, well water, and water for bathing as well as fruits, salads and vegetables. However, in small children an important risk appears to be direct contact with animals for example from visits to farms (47). In industrialized countries, infection is more prevalent in summer than winter reflecting the seasonal exposure to countryside, animals and fresh uncooked foods.

Humans acquire antibodies to stx-2 during childhood and teenage years so that about half of adults have antibodies detectable by western blotting. Stx antibodies wane in old age. Family studies have found antibodies in close contacts of children with hemorrhagic colitis and HUS. Some of these will have had minor gastrointestinal symptoms and others may be asymptomatic which suggests that sub-clinical infection is common. A high proportion of abattoir workers have been shown to excrete STEC, although not necessarily EHEC (48). This raises the possibility that contact with STEC that lack the necessary additional virulence factors needed for a human pathogen might be immunogenic. Experimentally, anti-stx antibodies are protective in several models of EHEC infection and it is a reasonable hypothesis that adults are to some extent protected by acquiring anti-stx2, and that the high

incidence of HUS in pre-school children reflects immunological naivety.

Epidemiology

The greatest incidence of EHEC-induced HUS in Europe and North America is in children aged 1–5 years, whereas in Argentina the age of onset is lower, between 6 months and 4 years. The onset of HUS before 6 months of age raises concern that EHEC is unlikely to be the only cause. The incidence also differs between regions, generally being higher in cooler, temperate regions. For example the incidence in Scotland (3.4 per 10^5 children < 5 years of age) is greater than in England (1.54 per 10^5 children < 5 years (25). The incidence in England and France is similar, and greater than Italy (24). While the diagnosis of EHEC infection has increased over time, perhaps reflecting better laboratory techniques, the number of cases of children presenting with HUS has remained stable over the last 20 years in economically developed states, and the mortality has reduced (49). However, fluctuations in incidence may occur with local epidemics sometimes linked to a common source of infection. In such outbreaks it has been estimated that one in ten exposed to the infection develop symptoms of colicky abdominal pain and diarrhea, and 15% of children with diarrhea or bloody diarrhea will get HUS. Outbreaks may be biphasic, a second wave occurring 2 weeks later from person to person transmission. The time from exposure to onset of diarrhea is usually less than a week, mostly 3–4 days, and the mean interval between onset of diarrhea and disclosure of HUS is 4 days, range 1–10 days.

Laboratory Investigation

In regions where O157 is the predominant EHEC, it has been common practice to culture stools on sorbitol MacConkey agar enriched with tellurite to promote the growth of O157. Because this serotype is usually unable to ferment sorbitol, colonies can be inspected, picked and then tested specifically for O157 with agglutination or enzyme linked immunoassay. This approach will miss other serotypes of EHEC and any O157 that is capable of fermenting sorbitol. It will also identify stx-negative strains of O157.

Given that stx production is an essential feature of EHEC and central to the epidemiology, it is logical to investigate directly for this property rather than rely on identifying O-serotypes that may or may not be toxin producers (50). Historically, toxin identification was laborious and expensive. Stools were filtered to obtain free toxin that was tested on cell cultures, confirmation being sought by neutralizing the toxin with specific antibodies. Sensitive immunoassays to detect toxin in bacterial cultures or even in stool samples are becoming available (51). These can give quick results and are likely to become first line investigations. Polymerase chain reaction and DNA hybridization can also be used to amplify and detect stx genes. Neither of these methods identifies the organism, but colonies with these properties can be further identified and serotyped.

Genetic profiling of EHEC is valuable in research and in identifying emerging pathogenic strains, particularly in outbreaks. Lytic phage typing can also be useful to identify different strains of O157.

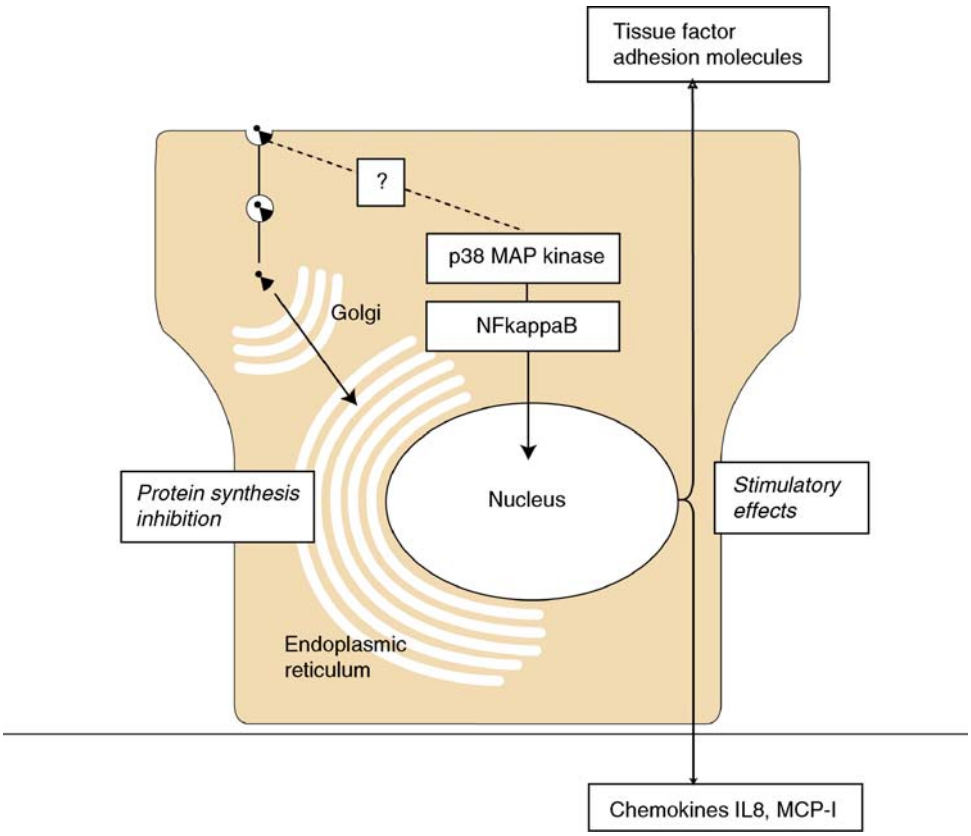
Pathogenesis

There is good evidence that stx can be transcytosed across the intestinal epithelium to reach the submucosa and the microvascular thrombosis and hemorrhage of the intestinal lesion is almost certainly a direct result of the toxin (*Fig. 48-5*). It is less clear how the glomerular and other distant vascular sites are affected. Toxin is very difficult to identify in blood, probably because the amount required to induce disease is small, and because the affinity with cellular glycolipid receptors would result in rapid clearance. A suggestion that stx was transported on neutrophils has been rescinded (52).

At target sites, the B subunit recognizes and binds to a eukaryotic cell glycolipid that is expressed differently in different species. In humans this is globotriaosylceremide, Gb3, and it is expressed on renal tubular cells and vascular cells in kidney, brain and intestine, in Paneth cells in the intestine but not on intestinal epithelium (53). Human glomerular endothelium has a high expression of Gb3 that is further upregulated by the inflammatory cytokine TNF-alpha (54, 55). Toxicity is dependent on recognition, binding and internalization of the toxin followed by cleavage and cytoplasmic release of the A-subunit (*Fig. 48-6*). The A-subunit is an N-glycosidase that cleaves ribosomal RNA, effectively blocking transcription. Stx cytotoxicity in vitro differs between cells types (56) and between stages in the cell cycle. It may result in cell death, but sub-lethal effects are also likely to be relevant to the pathogenesis. Experimentally, human vascular endothelium exposed to sub-lethal concentrations of stx exhibits upregulation of adhesion molecules, a change in phenotype from anticoagulant to procoagulant with the expression of tissue

Figure 48-6

Action of shiga toxin on target cells such as glomerular endothelium. High levels of toxin exposure induce protein synthesis inhibition, the toxin being transported in a retrograde fashion from the Golgi apparatus to the endoplasmic reticulum where it cleaves ribosomal RNA. Sublethal exposure induces cell signaling via p38 MAP kinase and nuclear factor kappa-B.



factor, and release of chemokines such as monocyte chemoattractant protein-1 (5). Whether endothelial cell death occurs in vivo is not known. Histology shows glomerular endothelial cell swelling and detachment from basement membrane, but not extensive endothelial loss. However, exposed basement membrane from cell retraction or detachment would in theory present a prothrombotic surface to platelets and support the coagulation cascade.

There is strong evidence that increased procoagulant and thrombolytic processes precede the impairment of kidney function in EHEC-induced HUS (57). This is indicated by a rise in pro-thrombin fragments, D-dimers, tissue plasminogen activator and its inhibitor before oliguria or a change in plasma creatinine. This fits well with the pathology of intraglomerular thrombosis seen post mortem in early deaths from HUS. Cortical necrosis is probably caused by severe ischemia secondary to glomerular thrombosis, however proximal tubular epithelial cells are sensitive to stx in vitro and direct toxic injury has also been proposed.

There is also evidence that acute inflammation plays a role in the development of HUS. Patients with HUS demonstrate a rise in C reactive protein, neutrophilia and an increase in circulating proinflammatory cytokines such as interleukin-8 and granulocyte colony-stimulating factor (5). The urinary excretion of MCP-1 and Interleukin-8 is also increased (58). Neutrophilia at onset (neutrophils > 20,000/mm^3) is a biomarker for an adverse outcome (5).

Treatment and Outcome

At present there is no treatment that directly reduces stx production, absorption or its cytopathic consequences.

Antibiotic therapy of EHEC infection is unnecessary as the intestinal infection is self limiting and non-invasive, and there remains a concern that antibiotics might encourage bacterial release of stx and increase the clinical risk. An attempt to sequester stx in the intestinal tract was unsuccessful even with a binding agent (Synsorb) that was capable of avid toxin uptake in vitro (59). Plasma exchange therapy has not shown benefit (60). Passive immunization with engineered monoclonal antibody to stx can reduce toxicity in animal studies but has not reached the stage of human clinical trials (61).

The mainstay of treatment is supportive, with particular attention to hydration and electrolyte balance. Children are often saline depleted during the initial period of diarrhea. Correction of the volume deficit with hyponatremic fluid is contraindicated. Even using oral rehydration, a dilute replacement fluid risks rapid onset hyponatremia, cerebral edema and seizures. Oral fluids often accentuate the gastro-colic reflex and worsen abdominal pain, a frequent symptom in the early course of the disease. Vomiting also makes oral rehydration unreliable. Volume is better replaced intravenously using isotonic saline. There is some evidence that vigorous initial rehydration with isotonic saline can reduce the risk of later oliguria, and even defer or prevent renal failure (62). Once oliguric renal failure has occurred, salt and water intake has to be restricted to prevent vascular volume overload. Acidosis is common and should be corrected with bicarbonate. Plasma potassium should be closely monitored as it can rise steeply in the presence of red cell fragmentation or with blood transfusion.

There is no advantage in early dialysis, and dialysis should only be instituted once it is clearly needed to correct biochemical abnormalities that carry short term clinical risks. Peritoneal dialysis can be undertaken as long as the colitis does not pose a surgical risk (see below). Hemodialysis is usually satisfactorily, but vascular access can be challenging in infants who are very anemic and thrombocytopenic. Approximately 80% of patients require transfusion of packed red cells to stabilize the anemia (25). The transfusion should be given slowly with careful monitoring of intravascular volume status. A target hemoglobin of 8–9 g/dL is sufficient. Where possible platelet transfusion should be avoided in HUS, as this has been associated with a deterioration when administered during other microangiopathic processes, perhaps acting as a substrate for further microthrombus formation (63). Use of platelets should be restricted to clinically significant hemorrhage or for invasive procedures.

Occasionally the colitis itself is life threatening. Children who present with abdominal distension may develop toxic megacolon, obstruction, bowel perforation and shock. Close surgical review is mandatory and an emergency resection may be life saving.

In most cases the blood pressure is in high normal range for most of the clinical course and it is common to see a transient hypertension for a few days about the time of recovery of oliguria. However there are exceptions, and safe limits for blood pressure need to be set. In cases where there are neurological complications, full intensive care facilities are needed including CNS imaging, control of seizures, and pre-emptive treatment of any respiratory dysfunction in addition to the fluid, electrolyte and blood pressure corrections outlined above. Endocrine pancreatic failure and cardiomyopathy can occur, sometimes relatively late when other aspects such the hematological component appear to be resolving. Monitoring for hyperglycemia and clinical observation to detect cardiac decompensation is required.

The 1 year survival for D + HUS has steadily improved since the 1980s, and is now above 98% (7). Early deaths are usually due to CNS complications, less often to abdominal catastrophes related to colitis. It is very unusual today for patients to progress immediately to end stage renal failure; almost all regain some independent function. However, between 2 and 5 years from onset about a quarter of survivors will have renal impairment or proteinuria (64). Hypertension may occur but usually in association with the former. The risk of developing a second episode of HUS is remote; certainly less than 1 in 500.

Late outcome after D + HUS is unknown. There are sufficient unpublished cases of patients showing worsening proteinuria and renal impairment after an apparently full early recovery to suggest that all survivors need long term follow up. It is also prudent to consider additional life-time renal risks that may be compounded by the nephron loss induced by HUS. Survivors should be advised against smoking and obesity. Women with proteinuria or hypertension need individual advice about the risks of pregnancy.

HUS and *Shigella dysenteriae* type 1

HUS is a well-recognized complication of *Shigella dysenteriae* type 1 infection (65). Many of the features of the syndrome resemble EHEC-induced HUS. The age range is wider, the median age of presentation being around 3 years, and the median time from the onset of diarrhea to the presentation of HUS is 7 days compared to 4 for most EHEC infections.

Shigella dysenteriae can be enteroinvasive while EHEC typically are not. Therefore, unlike EHEC infection, early and appropriate antibiotic treatment is indicated and appears to reduce the incidence of HUS (66). Shiga toxin is implicated in the pathogenesis. In some laboratory models of HUS a combination of a ribotoxin and lipopolysaccharide is more likely to induce glomerular thrombosis than toxin alone (67). Children with *Shigella dysenteriae*-induced HUS are exposed to bacterial lipopolysaccharide because of the enteroinvasive nature of the organism and this added stimulus is likely to be pathogenic (68). The neutrophilia at onset is typically greater than with EHEC but has a similar prediction for the development and severity of HUS (69, 70). In some patients disseminated intravascular coagulation leads to consumption of coagulation factors, a very rare event in EHEC-induced HUS. Cases of disseminated intravascular coagulation with consumption of coagulation factors, such as that seen in sepsis and multiorgan failure, are usually excluded from the definition of HUS, however *Shigella dysenteriae* and invasive *Steptococcus pneumoniae* infections that cause HUS are exceptions to that rule.

There is the general impression that HUS complicating *Shigella dysenteriae* is more severe, but the condition mostly occurs in economically disadvantaged regions where children may have co-morbidities and poor access to health care. Catastrophic dehydration, hyponatremia and central nervous system complications may in part reflect this. In epidemics in sub-Saharan Africa, mortality rates of 17 and 43% are described (65) whereas in an outbreak in France all five affected children recovered with normal renal function (71).

HUS in Pneumococcal Sepsis

A distinctive form of HUS occurs as a complication of infection with *Streptococcus pneumoniae* (8). This was first described by Klein et al. (8), who reported two infants who died from pneumococcal pneumonia with clinical features of HUS. Post mortem revealed renal cortical necrosis and glomerular arteriolar and capillary thromboses. Since then over 150 cases have been published (39, 72, 73). This form of HUS appears to be increasing in incidence, in parallel with an increase in empyema. This is a paradox since the overall incidence of invasive pneumococcal infection in infants is falling, partly because of immunization against prevalent strains of pneumococcus. Epidemiological studies in the UK identified no cases of pneumococcal HUS between 1985 and 1988, but 43 cases between 2000 and 2005 (39, 74, 75).

Patients are usually infants or children below 3 years of age. Pneumococcal infection typically precedes the onset of HUS by a few days. The majority of cases follow pneumococcal pneumonia, and two thirds of these have loculated infection in the form of empyema (64). HUS has also been reported following pneumococcal meningitis with or without subdural collections and less often pneumococcal septicemia without a discernable focus (76). Profound anemia, thrombocytopenia and oliguric renal failure occur abruptly with a rapid deterioration in the child's clinical condition.

Pathogenesis

Pneumococci all have the ability to secrete one or more species of neuraminidase, an enzyme capable of stripping sialic acid (N-acetyl-neuraminic acid, NANA) from host cell membranes. Neuraminidase activity has been identified in the serum of children with pneumococcal HUS (77). Cleavage of NANA by neuraminidase from the normally disialylated tetrasaccharides of the red cell membrane occurs in vivo. This exposes a crypt-antigen known as the Thomsen-Friedenreich (T)-antigen which has a distinctive terminal beta-linked galactosyl residue (Gal-β (1–3)-GalNAc) (78, 79). T-antigen exposure can be readily confirmed on a patient's erythrocytes using the lectin *arachis hypogea* that identifies the exposed T-antigen. T-antigen exposure has also been shown on platelets and endothelium in this form of HUS (7, 72, 80).

A frequent laboratory finding is that the patient's red cells are agglutinated in vitro by ABO compatible serum, a phenomenon known as red cell polyagglutination (81). Polyagglutination is explained by a naturally occurring anti-T IgM class antibody that is found in most individuals by 3 months of age, adult concentrations being reached by 2 years (39, 82–84). Although often referred to as "naturally occurring," these antibodies are probably generated following exposure to ubiquitous intestinal flora that possess antigens similar to T.

It was postulated that these pre-formed IgM antibodies bind to T and initiate a cascade of events leading to TMA (84, 85). However, the importance of anti-T in HUS is questionable. Hemolysis in the setting of T activation may have alternative causes, such as direct hemolytic action of bacterial enzymes and toxins, altered interaction of complement components with desialyated red cells (78, 85) or shortened survival of red cells with reduced membrane sialic acid content (86, 87). HUS with T-antigen detection has been described in the absence of detectable anti-T antibodies (88–90). In vivo studies show that treatment

of red cells with neuraminidase decreases red-cell survival independent of anti-T titer (7, 72). IgM anti-T antibodies are cold reactive and do not cause red-cell agglutination or complement activation at 37°C in vitro (8). Clinical observations do not consistently support a relationship between transfusion and hemolysis in patients with T-activated red cells. There are reports describing cases of T activation in which administration of plasma did not lead to hemolysis (7,91).

Treatment and Outcome

Thorough medical and surgical treatment of the invasive pneumococcal infection is essential. Intensive care is often needed because of the multi-organ involvement in these cases. Beyond that the management of this condition is only supportive. Because of the uncertainty over the role of anti-T in the pathogenesis of this form of HUS, many still advocate the strict avoidance of plasma containing products (11, 92–104) and advise that for transfusion, red cells and platelets are washed to avoid plasma administration. Some authors advocate screening donors for anti-T and use of low titer products only (although this is not well defined). However there are no documented reports of clinical deterioration following use of plasma products in this condition. In contrast, a number of cases have received plasma products without adverse effects (105).

The mortality associated with this form of HUS is at least five times higher than patients with EHEC-induced HUS, 11–25% in recent reports. Death is usually related to the complications of sepsis, pneumonia or central nervous system infection, but failure to recover renal function contributes to the late mortality. The morbidity exceeds that of D + HUS with the duration of oligoanuria, thrombocytopenia and hospital stay being twice as long, and there is a greater requirement for red cell and platelet transfusions (106). About a quarter of survivors have renal impairment, but those who fully recover renal function appear to do well, although long term follows up data are lacking. No cases of relapse of this form of HUS have been reported.

HUS and Disorders of Complement Regulation

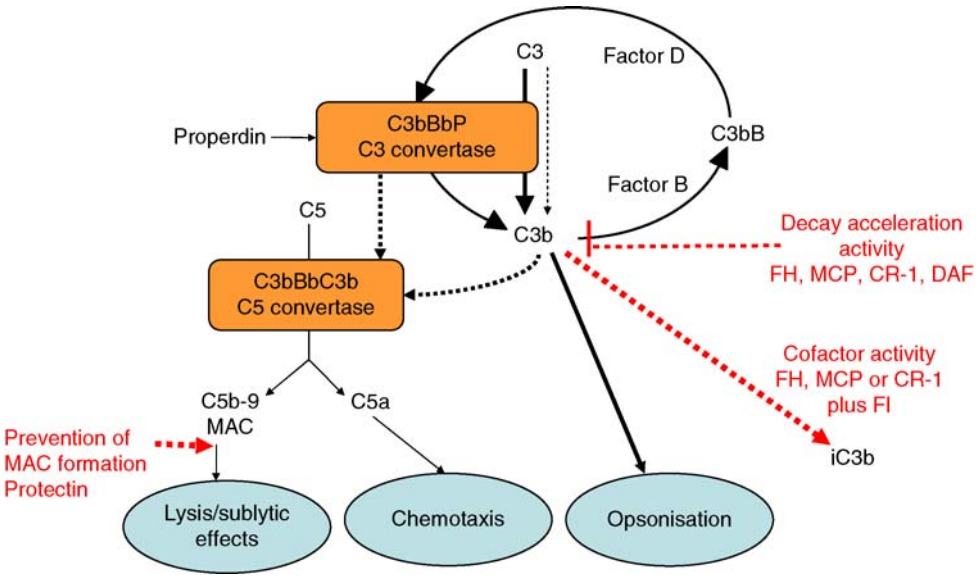
The seminal report of Warwicker et al. (107), in which HUS was associated with a complement factor H(FH) gene mutation, heralded the discovery of a number of different gene mutations in patients with HUS, all within genes encoding proteins of the alternative complement pathway (108). Various patterns of inheritance have been described, and genotype-phenotype correlations are starting to emerge. The likelihood of an underlying complement disorder is high if HUS present before 6 months of age, or if there is a family history of HUS occurring asynchronously, or unexplained past episodes of anemia, or HUS presents without an obvious infective cause, or if there is a relapse. Some patients with HUS secondary to complement dysregulation will have a low plasma concentration of C3, but these are a minority. While a low C3 increases the probability of a complement disorder, a normal C3 does not exclude it. The same is true for plasma FH concentration.

To understand the pathogenesis, a concept of the alternative complement pathway (ACP) is necessary (*Fig. 48-7*). The ACP provides rapid antibody-independent defense against micro-organisms. It is spontaneously activated by the slow hydrolysis of plasma C3 to a form of C3b that is able to combine with factor B (FB) to form C3bBb, the alternative pathway C3 convertase (109). This convertase cleaves further C3 into C3b, and also forms a C5 convertase, triggering the formation of C5b6789, the membrane attack complex (MAC). The pathway is strongly activated by microbial fragments (110) which become rapidly coated with C3b. C3b is an opsonin that assists effective phagocytosis and clearance of microbial components. The MAC is a pore-like structure that inserts into cell membranes resulting in cell lysis of invading pathogens. Host cells exposed to sub-lytic doses of the MAC undergo cell activation (111–113).

Since the ACP is spontaneously activated and positively amplified, its regulation is essential for host protection (*Fig. 48-7*). Host cells are protected by an array of membrane-bound complement regulatory proteins which interact with C3b to prevent the convertase from forming or promote its rapid dissociation ("decay acceleration" activity) (114). These include membrane co-factor protein (MCP, CD46), decay-accelerating factor (DAF, CD55) and complement receptor 1 (CR-1, CD35) (11, 115). The plasma protein FH performs this function in the fluid phase, and in addition binds to cell membranes to act as a membrane bound regulator (113). Additional regulation is provided by the inactivation of C3b by the plasma serine protease factor I (FI) in conjunction with co-factor activity from other regulators, including MCP, FH and CR-1 (113, 116, 117). Further defense against the effects of complement activation is provided by the cell membrane regulator protectin (CD59) (118). This regulator restricts the polymerization of C9 molecules essential for MAC formation.

Figure 48-7

Activation, amplification and regulation of the alternative complement pathway. The pathway is continuously activated through the spontaneous hydrolysis of C3 (black dashed line) to a form of C3b that combines with factor B to form a C3 convertase. This generates further C3b from C3 and a stable C3 convertase (C3bBb) is formed, which is further stabilized by the binding of properdin, amplifying the production of C3b. C3b is an opsonin, and triggers the formation of the terminal products of complement activation, C5a and C5b-9, the membrane attack complex (MAC). Host cell protection from complement activation is provided by complement regulatory proteins including membrane co-factor protein (MCP), decay-accelerating factor (DAF), complement receptor 1 (CR-1) and factor H (FH). Activation steps are shown in black and regulatory steps are shown in red.



Mutations in FH, MCP, FI, C3 and FB are all implicated in the pathogenesis of HUS (118).

Pathogenesis

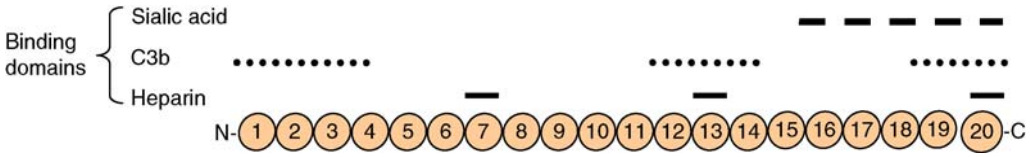
The mechanisms by which complement gene mutations lead to atypical HUS have been partly elucidated, and are summarized below.

Factor H (FH)

FH is a glycoprotein, produced by the liver. The gene (CFH) is located on chromosome 1q32, in the "Regulators of Complement Activation" (RCA) cluster. It acts as a co-factor for the proteolytic cleavage of C3b to inactivated C3b (iC3b) by FI (35) and promotes the decay of formed C3 convertases by competing with FB for binding to C3b (119–121). It is the main mechanism by which the ACP discriminates between foreign and host surfaces (121–123). Unlike many pathogens, host surfaces are rich in polyanions such as sialic acid and glycosaminoglycans. FH has high affinity for these anionic sites (124). FH consists of 20 globular domains known as short consensus repeats (SCRs) (*Fig. 48-8*) (125–129). The complement regulatory domains are found within the N-terminus (SCR 1–4) (130). The C-terminus (SCR 16–20) contains binding sites for surface-bound C3b, sialic acid and glycosaminoglycans and is important for attaching FH to host cell surfaces (125, 130). Over 60 different FH mutations have so far been described in HUS (131). Mutations are usually heterozygous and mostly occur in SCR 16–20. Most patients have normal plasma FH and C3 concentrations. Several important functions of mutant FH proteins have been studied. Mutations in SCR 20 generally lead to reduced binding of FH to heparin, to surface bound C3b and to endothelial cells (132). Mutant proteins display normal complement regulatory activity in the fluid phase (132), but reduced cell surface complement regulation (133). Taken together, this evidence suggests that mutant FH proteins are capable of controlling fluid

Figure 48-8

Schematic representation of complement factor H (FH). FH consists of 20 globular domains known as short consensus repeats (SCRs). The numbering of SCRs is indicated from 1 to 20. Domains known to interact with specific ligands are indicated. The N-terminus (SCR 1–4) exhibits complement regulatory activity whilst the C-terminus contains binding sites for polyanions and surface bound C3b, and thus mediates binding of FH onto cell surfaces. Adapted from (94).



phase complement activation, but their ability to bind to host cell surfaces and protect from complement mediated damage is impaired.

Auto-antibodies to FH have been reported in patients with HUS (108, 134). They appear to mimic the effect of C-terminal FH mutations, as they inhibit the regulatory function of FH at cell surfaces by blocking its C-terminal recognition region (92). In an intriguing development, the presence of FH autoantibodies appears to correlate with a genetic absence of the FH related proteins, FHR-1 and FHR-3 (11, 93, 95, 98).

Membrane Co-factor Protein (MCP, CD46)

MCP is a transmembrane protein expressed on almost every human cell except erythrocytes (95, 98). It is a co-factor for FI in the cleavage of C3b and C4b and also has decay acceleration activity (98). The gene encoding MCP is located in the RCA cluster. Mutations in MCP, usually heterozygous (113), have been detected in 8–14% of patients with familial or relapsing HUS (135). Most patients with MCP mutations show a 50% reduction in surface expression of MCP on peripheral blood mononuclear cells (PBMCs) (11, 136, 137). Other mutations produce a protein with normal surface expression but reduced binding to C3b (115). MCP mutations in HUS therefore lead to impaired MCP function, and presumably reduced cell surface protection from complement mediated damage.

Factor I

FI is a serine protease that cleaves the alpha chains of C3b and C4b, inactivating them and preventing convertase formation (11). FH and MCP are co-factors for its activity. The gene is located outside the RCA cluster on chromosome 4q25 (92, 99, 138, 139). FI mutations have been described in 4–10% of cases of familial or relapsing HUS and these mutations are heterozygous, and associated with either normal or reduced FI concentration, and a variable reduction of complement C3. Certain mutant proteins demonstrate reduced inactivation of C3b and C4b (95, 98).

Factor B

A recent publication reported mutations in the gene encoding FB and persistent activation of the ACP in two families with atypical HUS (24). Functional analyses demonstrated that the two mutations caused gain-of-function that resulted in enhanced formation of the C3bBb convertase or increased resistance to inactivation by complement regulators.

C3

C3 mutations have been found in a small number of patients in whom other complement mutations have not been identified (24). The majority were heterozygous missense mutations, and most gave rise to a gain of function of the ACP. Two mutations caused haplotype insufficiency of C3 and their role is presently unclear.

Together these findings indicate that increased ACP activation is central in the pathogenesis of this form of HUS (see *Table 48-3*).

Clinical Features

Patients with these forms of HUS more often have an insidious onset unlike the abrupt presentation of the post infective forms. Both initial onset and relapses may be precipitated by relatively minor illness such as upper respiratory tract infections. Consistent findings at onset

Table 48-3

Incidence of gene mutations in cohorts of familial or relapsing HUS patients

Gene	Cohort	Incidence of mutations	Reference
Factor H	Newcastle, UK	5 of 50 cases (10%)	Richards (99)
	Spain	4 of 13 cases (30%)	Perez-Caballero (98)
	Italy	4 of 4 pedigrees[a]	Caprioli (93)
	German speaking countries	17 of 111 cases (15%)	Neumann (95)
	France	10/46 children (22%)	Sellier-Leclerc (11)
MCP	Newcastle, UK	3 of 30 families (10%)	Richards (11)
	Spain	6 of 41 cases (14%)	Esparza-Gordillo (11)
	Italy	2 of 25 cases (8%)	Noris (93)
	France	10 of 77 cases (13%)	Fremeaux-Bacchi (115)
Factor I	France	8 of 77 cases (10%)	Fremeaux-Bacchi (11)
	Newcastle, UK	3 of 75 cases (4%)	Fremeaux-Bacchi
	Spain	2 of 41 cases (5%)	Esparza-Gordillo
Factor B	Spain	Not yet determined	Goicoechea de Jorge
C3	Newcastle, UK	Not yet determined	Fremeaux-Bacchi

[a]Cohort of atypical HUS with low C3

are hypertension which is often severe and can lead to heart failure and encephalopathy, and heavy proteinuria and hematuria in those who retain urine production. Extra renal manifestations may occur but are less frequent than in EHEC-induced HUS. Some, such as retinal thrombotic microangiopathy, seem to be reported particularly with FH mutations. This presents with pain in the eye and visual loss. Hematological relapse is common. This has been arbitrarily defined as a return of MAHA after a period of 2 weeks with normal platelet count. Patients presenting in early infancy have a high risk of progressing to end-stage in the first episode. Once end-stage renal failure has occurred the MAHA and thrombocytopenia tend to resolve.

Seventy percent of patients with FH mutations have their onset before 12 years of age, and historically 70% progress to irreversible renal failure or death (93). Those with FI mutations have a similarly adverse outcome. Patients with MCP mutations fare slightly better but also have a relapsing course with gradual progression to end-stage renal failure in up to half of patients (11). Those with autoantibody-induced FH deficiency tend to present in the later half of childhood and their outcome is unclear as yet.

The penetrance of disease in pedigrees with complement mutations varies with different mutations and pattern of inheritance. Overall approximately 50% of those carrying a heterozygous FH disease-associated mutation risk developing HUS themselves (140). Other genetic factors such as polymorphisms in FH and the MCP genes influence disease expression (141–148). This has led to the conclusion that the co-inheritance of different susceptibility alleles influences complement regulation, predisposes to HUS and explains the incomplete penetrance of HUS in mutation carriers (141, 142).

Therapy of HUS Associated with Disorders of Complement Regulation

Prior to the recognition of complement gene mutations in atypical HUS, anecdotal reports suggested benefit from plasma exchange or infusion (92, 99). More recently, the effects of plasma infusion have been described in children with homozygous or compound heterozygous deficiency of FH (92, 99). All improved, but one child became refractory to this regime (149, 150). Repeated plasma infusion is limited in oliguric patients by the risk of volume overload.

Plasma therapy has also been described in patients with heterozygous FH mutations with variable results (49). Patients with isolated MCP dysfunction do not appear to benefit from plasma therapy (99), probably because MCP is a membrane bound complement regulator not a circulating one, and there is a high spontaneous remission rate. Little is known about the role of plasma

therapy for other more recently identified forms of complement dysregulation.

The complex laboratory investigations needed to confirm the etiology of HUS take time, and therefore initial treatment is empirical. The European Paediatric Study Group for HUS argues for urgent plasma exchange, replacing with fresh frozen plasma or a standardized whole plasma product as a first line treatment. This is recommended on the basis that it would replace mutant complement proteins responsible for the disease and remove autoantibodies to FH. They justify the urgency and invasive nature of this approach on the fact that glomerular thrombotic microangiopathy is a destructive process and a first episode of HUS may lead rapidly to end-stage failure (92, 99).

Since complement dysregulation appears to be at the heart of the pathogenesis, synthetic complement inhibitors may become a therapeutic option, and a number of compounds are becoming available for clinical trials (151). Correcting the abnormal circulating complement regulator by liver transplantation is considered below.

Transplantation in HUS

Where EHEC infection is the cause of end-stage renal failure, renal transplantation is not complicated by an increased risk of graft loss through thrombosis or HUS recurrence (3). The only caveat is that very rarely EHEC can induce HUS in a patient with an added risk factor such as a disorder of complement regulation, and this may not be known at the time of their original presentation. In this unusual circumstance the possibility of recurrence cannot be excluded (92).

Prior to the recognition of complement mutations, up to 60% of patients with so-called atypical HUS progressed to ESRF, and about 50% of those who were transplanted lost their grafts to disease recurrence or thrombosis (11, 92, 99, 136). The application of complement genomics has now shown that for patients with FH mutations the rate of graft loss is 80% (92, 152, 153), with a broadly similar picture emerging for those with FI mutations (154). Worse, in families where living-related kidney donation was undertaken, HUS occurred in the donor who was carrying the disease associated FH mutation (155). By contrast, patients with MCP mutations rarely develop disease recurrence after renal transplantation, probably because of normal surface expression of MCP on the donor endothelium (92, 156, 157). In one case of recurrence in a MCP patient, the graft exhibited endothelial microchimerism, with recipient endothelial cells detected in the graft (158). Calcineurin inhibitor-free immunosuppression does not reduce the risk of recurrence despite previous concerns that they may contribute to post-transplant TMA (159).

Based upon the rational that FH is synthesized by the liver, isolated liver or combined liver-kidney transplantation has been attempted as a treatment for HUS associated with FH mutation (159). The former can be considered for patients who are dependent on frequent plasma exchange to maintain a remission, especially if they experience breakthrough relapses or worsening proteinuria or renal function. In such cases the procedure would need to be undertaken before extensive and irrevocable renal damage has occurred. For those already in chronic renal failure the decision to perform a combined liver and kidney graft trades the early high risks of the procedure against the late but accumulative risks of chronic dialysis. Although initial cases were unsuccessful, subsequent reports are more optimistic, with disease-free survival reported in 3/7 patients (160). Given this complexity, transplant management for HUS patients should be undertaken only in the full knowledge of the genotype. Liver or liver and kidney transplantation should only be performed in experienced centers, and with a clear strategy to minimize the risks of uncontrolled complement activation during surgery and increased peri-operative thrombosis.

HUS and Deficiency of von Willebrand Protease (ADAMTS13): Thrombotic Thrombocytopenic Purpura

HUS has a clinical overlap with TTP. The clinical "pentad" for the diagnosis of TTP comprises thrombocytopenia, microangiopathic hemolytic anemia, neurological signs, renal dysfunction and fever (62, 92), although the insidious onset and fluctuation of clinical findings may mean that not all of the pentad appears at once, and this can pose a diagnostic difficulty. The distinctive pathogenesis of TTP as outlined below permits the clinical definition of TTP to be aligned to severe deficiency of the von Willebrand protease, ADAMTS13, and patients with this etiology should be described as TTP rather than HUS (161).

Pathogenesis of TTP

The overwhelming majority of contemporary cases of TTP are associated with genetic or acquired abnormalities

von Willebrand Factor cleaving protease (also known as ADAMTS13, A Dysintegrin And Metalloprotease with Thrombospondin-like motifs type 13) (162). Von Willebrand factor (vWF) is synthesized by endothelial cells, stored in the Weibel-Palade bodies and secreted in multimeric form where it remains associated with the endothelial cell surface to provide binding sites for platelets, and promotes platelet aggregation (49). Injury to the endothelium, or stimulation by vasopressin increases vWF release. Physiologically the vWF multimers are cleaved after secretion to reduce the ability of platelets to aggregate.

Patients with relapsing TTP were initially shown to have ultra-large vWF multimers in their circulation, and deficiency of ADAMTS13 activity was confirmed later (163). Rarely, the ADAMTS13 deficiency is caused by genetic mutation that code for loss of function, and this presents as congenital TTP (Upshaw-Schulman syndrome) (164). More commonly, the deficiency is caused by an acquired inhibitor, usually an IgG auto-antibody (163) sometimes in association with the use of certain anti-platelet drugs such as *clopidogrel* and *ticlopidine*. For deficiency of the protease to be a primary cause of microvascular thrombosis the enzyme activity needs to be very low, typically less that 5% of normal. Moderate reductions in activity, down to 30% of normal, are found in several disease and physiological states and are not independent causes of TTP or HUS. The platelet rich microvascular thrombi of TTP are to be found at the arteriolar-capillary junction, a position of high sheer stress, in many tissues including brain, heart, spleen, kidneys, pancreas, adrenals, lungs and eyes.

In all cases of atypical HUS ADAMTS13 activity should be determined, and if it is low plasma mixing studies are indicated to determine the presence of an inhibitor. Veyradier et al. studied ADAMTS13 activity in a cohort of children with HUS (cases with and without diarrheal prodrome) (165). During the acute phase, only a single patient (1/41 cases) with post-diarrheal HUS exhibited a very low level (<5%) of ADAMTS13 activity, but this recovered to normal after 3 months and the significance of the finding is unclear. However, in the group without prodromal diarrhea, 6/23 cases had severely decreased ADAMTS13 activity (<5%) which remained undetectable during remission. Review of clinical data revealed that disease started at birth in all six children, with hemolysis and jaundice requiring exchange transfusion. This is typical of congenital ADAMTS13 deficiency. All had significant renal involvement, and half had neurological episodes.

Clinical Management

Historically the mortality of TTP was around 95% of cases. This fell to 20% with the institution of plasma therapy (97). In cases of congenital ADAMTS13 deficiency, regular plasma infusion, and more recently cryosupernatant, is very effective in preventing relapses (96). However in TTP generally, plasmapheresis is more effective than plasma infusion alone, presumably because it removes the inhibitor present in the majority of cases (92).

HUS and Cobalamin Metabolism

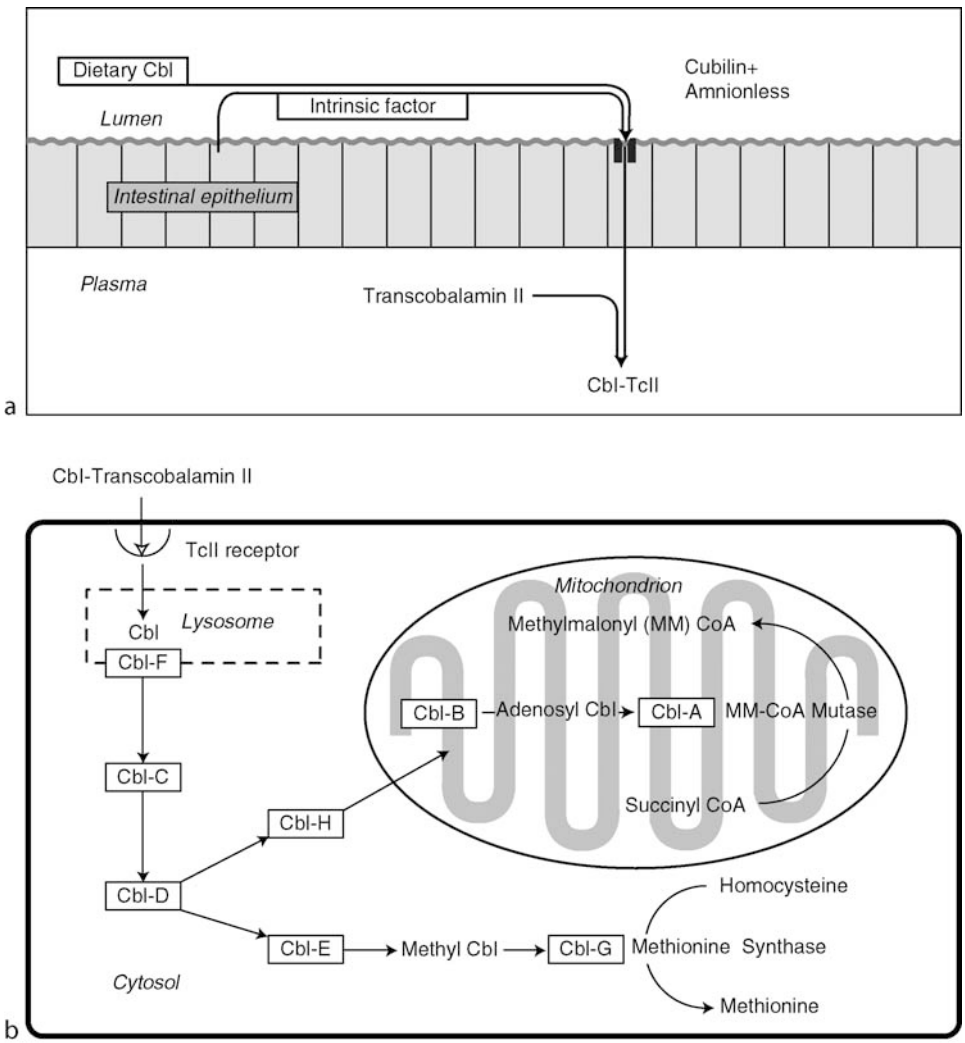
A rare form of HUS complicates an inherited defect of *intracellular* cobalamin (Cbl) metabolism. Defects in absorption and plasma transport have not been associated with HUS per se although anemia, thrombocytopenia and renal impairment can occur.

Cyanocobalamin, vitamin B12, is obtained entirely from the diet. Its absorption and plasma transport is outlined in *Fig. 48-9a*. All cells have a requirement for Cbl, and it is essential for two pathways. As methyl-cobalamin it is a cofactor for the methionine synthase that converts homocysteine to methionine in the cytosol: this methylation step requires 5-methyl tetrahydrofolate. As adenyl-cobalamin it is a cofactor for methylmalonyl-CoA mutase that converts L-methylmalonyl-CoA to succinyl-CoA within mitochondria. An outline of the intracellular pathway and the complementation steps is given in *Fig. 48-9b*. Some idea of the level at which Cbl metabolism is deranged can be gauged by whether there is an excess of methylmalonic acid or homocysteine in plasma or urine. Combined hyper-excretion of both products suggests an abnormality in the proximal part of the pathway, usually deficiency of Cbl-C deficiency, the commonest inherited defect of cobalamin metabolism, and rarely Cbl-D or Cbl-F (166). Patients who manifest HUS almost always have Cbl-C deficiency.

Defects in the intracellular metabolism of cobalamin were initially investigated by complementation studies. Cobalamin-C deficiency is attributable to homozygous or compound heterozygous mutations in the gene, methylmalonic aciduria and homocystinuria (*MMACHC*) on chromosome 1p34 (167). The condition is inherited as an autosomal recessive disorder. Over 40 mutations have been reported, but one mutation, 271dupA, accounts for 40% of cases mostly of European origin (168). It is predicted that this and other mutations code for loss of normal protein function, although the precise function

Figure 48-9

Metabolism of cobalamin. Gastric intrinsic factor is a prerequisite for vitamin B12 absorption in the terminal ileum. The B12-intrinsic factor complex enters a specific endocytotic pathway that depends on a receptor composed of cubilin and amnionless. Inherited deficiency of B12 absorption can be due to mutations in cubilin, amnionless or gastric intrinsic factor, and constitute Imerslund-Glasbeck syndrome. Patients with Imerslund-Glasbeck syndrome caused by a cubilin mutation have proteinuria because cubilin is a multi-ligand receptor that is essential in scavenging filtered proteins in the proximal tubule of the kidney. In the enterocyte, cobalamin is transferred onto the carrier protein transcobalamin-II (TCII) a 43 kDa globulin that is important for cellular uptake of the vitamin, and exported into the plasma. Recirculation of cobalamin occurs in that the Cbl-TCII complex is filtered in the kidney, avidly recovered in the proximal tubule and returned to the circulation attached to re-synthesized TCII. Cells take up the Cbl-TCII complex via a TCII receptor. The intracellular pathway of cobalamine is shown. Figure courtesy of Joanna Clothier.



of the *MMACHC* product in the metabolism of cobalamin has not yet been resolved.

Not all patients with Cbl-C deficiency develop HUS. How this metabolic defect promotes HUS is also unknown. Hyperhomocysteinemia is injurious to endothelium and shifts its normal anti-thrombotic property towards a procoagulant one. For example, patients with hyperhomocysteinemia secondary to cystathione synthase

deficiency exhibit intravascular thrombosis in arteries and veins but not TMA or HUS (169). Methylmalonicacidemia induces interstitial renal disease probably because of a disturbance in the production on intracellular energy, but not vascular disease.

Interestingly two siblings with thrombotic microangiopathy, renal failure and neurological disease were reported to have Cbl deficiency, a homozygous mutation in methylenetetrahydrofolate reductase (MTHFR), and a heterozygous mutation in complement factor H (170). While there is no support for MTHFR polymorphisms modifying the clinical presentation of patients with *MMACHC* mutations (168), the role of compounding risk factors such as a complement disorder should be considered in those who develop HUS.

The clinical presentation of patients with Cbl-C deficiency differs depending on the age of onset. The more severe is early presentation in the neonatal period and up to about 6 months. Multi-system involvement is typical with failure to thrive, vomiting, hypotonia poor feeding, hydrocephalus, seizures, pancytopenia, hemolysis, hypogammaglobulinemia, acidosis, gastric hemorrhage, hypoproteinemia and edema, hypertension and renal failure. The mortality is high. A later presentation is increasingly recognized and includes neurological deficit, retinopathy, developmental delay and lung disease. HUS can occur in either early or late onset cases. Glomerular thrombosis and endothelial swelling and detachment typical of TMA is seen. In post mortem cases thrombi can be found in other sites such as pulmonary arteries or brain. Hepatic steatosis and a distinctive atrophic gastritis have also been reported (169).

Prompt diagnosis is essential as delay contributes to adverse outcome. The finding of excess homocystine and methylmalonate in urine is a first step towards the diagnosis. Confirmation of the Cbl-C defect is made either on complementation studies on fibroblasts, or by genetic investigation for mutations in *MMACHC*. Parenteral administration of high doses of hydroxycobalamin (1–5 mg daily) has been shown to partly override the transport defects and control HUS. It does not consistently reverse or prevent the late acquisition of neurological deficits (171). Some authors have added betaine, folic acid and carnitine supplementation.

HUS and Quinine

HUS induced by quinine or quinidine dependant autoantibodies has been reported in adult patients, usually elderly women (172–174). Exposure to quinine may be slight, for example from quinine used for its bitter flavor in tonic water, although more often it occurs after taking quinine in tablet form, often used to prevent muscular cramp. The clinical presentation usually consists of nausea, vomiting, diarrhea, "chills," myalgia, abdominal pain, dyspnea and oliguric renal failure. Bruising and petechia are common. These symptoms occur as little as 12 h from the ingestion of quinine in a sensitized person (173). Neurological signs and symptoms are common and include confusional states (174). Schistocytes appear in the blood film with varying degrees of anemia. Thrombocytopenia is profound and there is evidence of increased fibrin degradation products. Prothrombin and partial thromboplastin times are normal, and there is no consumption of coagulation factors. Lactate dehydrogenase is increased and haptoglobin reduced. Glomerular thrombosis typical of TMA has been reported. So far there is no information about the role if any of ADAMTS13.

Initially it was thought that the renal impairment that accompanied the syndrome was relatively mild, with some individuals escaping renal involvement although having neurological signs. However more recent experience from the Oklahoma TTP-HUS registry (174) indicates that 4 of 17 patients died and 7 survivors had chronic renal failure. Plasma exchange has been undertaken and makes logical sense as it would seem likely to remove antibody.

HUS and Other Disease Associations

Glomerular endothelium is dependent on vascular endothelial growth factor (VEGF) produced by the opposing podocytes to maintain its fenestrated phenotype and the integrity of the capillary structure (175). Anti-VEGF monoclonal antibodies *Bevacizumab* and *Sunitinib* used to prevent metastatic vascular development in cancers has been associated with proteinuria, sometimes heavy enough to induce nephrotic syndrome, with or without hypertension in about a quarter of patients. In a few cases it has been associated with thrombocytopenia and renal failure. The full picture of MAHA appears to be inconsistent and intravascular hemolysis is mild, limiting qualification for the clinical diagnosis of HUS. Nevertheless, renal histology has revealed convincing glomerular thrombotic microangiopathy (176, 177). Further proof of the role for VEGF was provided by a murine model in which the podocyte-specific production of VEGF was conditionally knocked down. Affected animals developed proteinuria and hypertension and over half had red cell schistocytes in the blood film. Whether or not reduction

in locally produced VEGF has a role in other forms of HUS has yet to be investigated.

Cancer, particularly *disseminated adenocarcinoma* has been associated with HUS, usually in adults with primary gastric, colonic or prostatic disease, but rarely in children. Many but not all these patients were recipients of chemotherapeutic agents including *Mitomycin-C*, either alone or in combination with *5-fluorouracil and Doxorubicin* (178). Also implicated are *Bleomycin, Epirubicin, Cisplatin and Gemcitabine. Ionizing radiation* has been associated with HUS, again in the clinical setting of cancer therapy. The mode of action of the chemotherapeutic agents is not known. Experimentally, *Mitomycin* was shown to induce TMA in a rat model (179) and *ionizing radiation* has been shown to injure and detach vascular endothelial cells.

Transplantation of solid organs and bone marrow may be complicated by HUS. Calcineurin inhibitors *Cyclosporine A* and *Tacrolimus* have been implicated. They mediate vasoconstriction through endothelin-1 but this has not been shown to participate in the pathogenesis. The incidence of HUS and TTP in allogenic bone marrow transplantation varies between series. Coexisting infection with Aspergillus species, cytomegalovirus, adenovirus, human herpes virus 6, and parvovirus B19 may have contributed. The reviewers found evidence that von Willebrand protease activity was not severely reduced in these patients and no benefit could be found from plasma therapy. The mortality was high. While some cases has clear evidence of glomerular thrombotic microangiopathy, this was absent in some cases that had been described as HUS or TTP. Extra-renal TMA was not found (180).

HUS or TTP has been described in association with *pregnancy* (180) the *HELLP syndrome* (hemolytic anemia, elevated liver enzymes and low platelets) and with the use of *oral contraceptives*. Teenage girls presenting with HUS should be asked directly about their use of oral contraception and the possibility of pregnancy. In these associations the mechanism of microangiopathy is often unknown. However, some have severely reduced ADAMTS13 activity or mutations in complement regulators, and investigation for this possibility is needed.

HUS or TTP can complicate either *Systemic Lupus Erythematosus* (181, 182), usually in the presence of lupus anti-coagulant or anti-cardiolipin antibodies, or the *anti-phospholipid syndrome*. In a couple of cases of the latter, profound reduction was found in ADAMTS13 activity due to an autoantibody (183), again indicating the need for full investigation of the cause. There is some evidence that patients with anti phospholipids antibodies and HUS or TTP benefit more from plasma exchange than immunosuppression with steroids alone (184).

Human immunodeficiency virus infection-associated nephropathy (HIVAN) occurs late in the course of HIV infection and is often compounded by other chronic infections and immune abnormalities, and occasionally HUS (185). HIV in a primate model induces vascular endothelial damage that might suggest a direct mechanism.

49 Sickle Cell Nephropathy

Jon I. Scheinman

Introduction

The major clinical consequences of sickle cell disease (SCD) are vascular obstruction by sickled cells and anemia because of red blood cell (RBC) destruction. The sickling process may cause hematuria, renal papillary necrosis (RPN) and a urinary concentrating defect. There also is a chronic sickle cell glomerulopathy, which is less directly related to sickling, as well as unusual susceptibility to infections and to a specific form of malignancy.

Sickle hemoglobin (HbS) differs from normal (HbA) by the substitution of valine for glutamine in the 6-position of the β-globin chain (1). Under low oxygen tension in concentrated solution, HbS aggregates and forms intracellular fibers. These fibers prevent RBCs from deforming normally, so they do not pass easily through the microcirculation and thus cause occlusion. Their increased density, related to the Gardos channels, increase the tendency to sickle (2). Repeated cycles make some cells irreversibly sickled, and even in well-oxygenated blood they cause abnormal viscosity. In addition, these abnormal cells are easily lysed, causing anemia. The different measures of renal involvement and time line in SCD are illustrated in *Fig. 49-1* (adapted from (3)).

Hematuria and Renal Papillary Necrosis (RPN)

Clinical

Gross hematuria may be the most dramatic clinical event in SCD (4). It is often painless and usually unilateral, more commonly on the left side (5) explained by increased venous pressure due to the greater length of the left renal vein. Hematuria can occur at any age. It is more often reported with sickle trait (HbAS), probably because of a higher genetic frequency than HbSS (6). RPN is usually discovered in patients with painless gross hematuria (7). However, hematuria is not invariably present, and RPN can occur even in young children (5). When sought systematically, 40% of patients in one Nigerian series had RPN (8). In another series, there was no difference in the incidence of RPN between symptomatic (65%) and asymptomatic (62%) patients (9). The frequency of RPN on urography therefore suggests that the process develops subclinically without gross hematuria.

Pathogenesis

The pathology associated with isolated hematuria is rarely examined. In the past, kidneys removed from patients with uncontrolled bleeding in SCD showed relatively insignificant changes, primarily medullary congestion (6). The hematuria probably results from the sequence of renal medullary sickling, vascular obstruction, and RBC extravasation. This is precipitated by those factors present in the renal medulla that lead to sickling: The PaO_2 (35–40 mm Hg) is below the threshold (45 mm Hg) for sickling (10); the high osmolality of the medulla draws water from the RBC, leaving the HbS concentrated; and promotes the formation of hemoglobin polymers. The acidic environment of the renal medulla further increases the likelihood of sickling. This mechanism of microvascular occlusion explains many of the complications of SCD, but is overly simplistic. The distorted cell is also partly explained by dehydration of the cell, by enhanced KCl co-transport, and Gardos channel hyperactivity (2,11), in part induced by cell swelling and acidification. Further, K+ and water efflux are enhanced by transiently increased SS cell cytosolic Ca, induced by the membrane distortion.

Pathology

The pathology of RPN in SCD is a focal process, with some collecting ducts surviving within a diffuse area of fibrosis. Within the medullary fibrosis the vasa rectae are destroyed, following initial dilation and engorgement (12). The dependence of the papilla on that circulation results from repeated small focal infarctions of the papilla (13). This differs from the RPN found in analgesic abuse, in which the vasa rectae typically are spared, and most

lesions occur in peritubular capillaries (13). These same factors are present in sickle trait, although with a smaller proportion of sickling cells. Because calyces are affected separately and sequentially in SCD, acute obstruction, with sloughing of papillae, is uncommon (9,14).

Diagnosis

Continued gross hematuria likely represents a form of renal "sickle crisis" in a known HbSS or HbAS patient. Other treatable causes for hematuria, including the renal medullary carcinoma in patients with sickle hemoglobin, must be excluded (15). Severe pain makes the diagnosis of renal sickle crisis less likely, whereas moderate discomfort often lateralizes the bleeding. Renal and bladder ultrasound can rule out bleeding from a stone or tumor and an diagnose renal papillary necrosis (see below). The increased echodensity of medullary pyramids on ultrasound is typical of SCD, and in the absence of hypercalciuria, medullary echodensity in a patient with hematuria should suggest a sickle hemoglobinopathy (16). Walker (17) reviewed ultrasound reflectivity in young (age 10–20 year) SCD patients, and found diffuse echogenicity in 9%, and medullary echo-density in 3%. Surprisingly this was greater in the milder genotypes, 37% in SC and 79% of Sβ+ Thalassemia patients. This finding is unexplained, but is unlikely to represent RPN. This was found in 20% of patients with sickling processes and interpreted to suggest subclinical nephrocalcinosis or iron deposition.

The diagnosis of RPN in SCD was traditionally made by urography. In McCall's series 39% of 189 patients had calyceal clubbing, 23% with definite RPN (18). Cortical scarring as found in pyelonephritis does not accompany

the calyceal clubbing of SCD (19). Other urographic findings of RPN in SCD are distinctive. A "medullary" form in which there is an irregular medullary cavity, often with sinus tracts, is common (9). The base of the calyx and its normal outline are preserved (19). Sonography can sometimes identify the early medullary form of papillary necrosis. A later finding is calcification of the medullary pyramids in a "garland" pattern surrounding the pelvis. This pattern of "shadowing" echo density may be distinctive. The progression to the "papillary" form results in clubbing and caliectasis (*Figs. 49-2* and *49-3*). This is more common in analgesic nephropathy, in which an area of sequestration is often found, resulting from infarction of a large area of the papilla (20). A prospective survey of symptomatic SCD patients (9) found that 11 of 18 SA patients had a form of RPN, but 8 of these 11 had evidence of infection. Nine of 11 symptomatic SS patients had RPN, of which 5 had evidence of infection. Asymptomatic patients included 16 of 22 SS patients with RPN, 1 of 3 SA patients, 3 of 4 SC patients, and 5 of 8 S-Thal patients. It is not necessary to perform contrast urography to visualize the renal architecture in SCD.

Treatment

In view of the benign pathology in SCD hematuria, conservative management is appropriate (6). Bed rest is often recommended to avoid dislodging hemostatic clots. It is advisable to maintain high rates of urine flow by both hypotonic fluid intake (4 L/1.73 m^2 surface area per day) and diuretics (a thiazide or a loop diuretic such as furosemide), which should help clear clots from the bladder (5). In addition, a diuresis reduces medullary osmolarity and may therefore help alleviate sickling in the vasa rectae. Some caution is necessary in the administration of sodium-containing fluids because of potential sodium retention (see below).

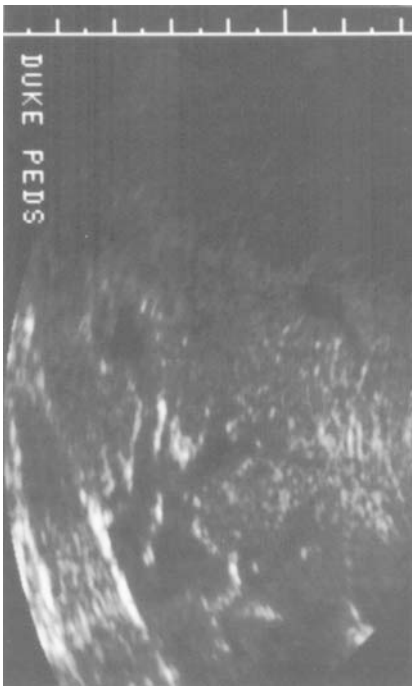
The combination of vasopressin and administration of hypotonic fluid to reduce plasma osmolality has been suggested. Hyponatremia induces water uptake by RBCs in vitro, thereby reducing the effective HbS concentration and making them less likely to sickle (6). This treatment is neither safe nor proven effective (6). Saline volume expansion would be especially ineffective, and coupled with hypertransfusion would predispose to congestive

Figure 49-2

Tomographic pyelography of an 18-year-old patient with abdominal pain and hematuria. Papillary necrosis is evident from blunted medullary cavities, especially the upper pole. The bases of the calyces are preserved. The middle pole calyx has a possible sinus tract.

Figure 49-3

Ultrasonographic visualization of the same kidney as in Figure 49-2. The middle pole exhibits deep extensions into the papilla, likely sinus tracts, typical of the "papillary" form of RPN.



heart failure. It would also be surprising if vasopressin were to increase the patient's urine concentration sufficiently to inhibit water diuresis (see below).

Because sickling is increased in an acid environment, alkalinization of the urine by 8–12 g $NaHCO_3$ (per 1.73 m^2) per day may reduce sickling in the urine environment, but this may not be relevant for medullary sickling (5). Alkalinizing the patient to increase the O_2 affinity of Hb is theoretically valid but not of proven value in practice (6). Transfusions may be necessary for blood loss and could be helpful by increasing the proportion of normal HbAA cells, reducing sickling cells.

Epsilon-aminocaproic acid (EACA) inhibits fibrinolysis, allowing clots to mediate hemostasis. The effective dosage in an adult is 8 g/day. In one series, 4 of 12 cases required EACA after failure of treatment with fluid administration and alkalinization (5). Unless other measures have failed, the risk of thrombosis should impose some caution in using EACA. Lower dosages may be adequate to arrest hematuria, starting with 1 g (per 1.73 m^2) orally three times daily and increasing the dose until hemostasis occurs (6). Nephrectomy is rarely required for uncontrolled bleeding. Arteriographic localization and local embolization of the involved renal segment may avoid nephrectomy.

RPN can be prevented experimentally by either diabetes insipidus or water diuresis, thereby eliminating the medullary concentration gradient (21). Thus the fluid administration prescribed for gross hematuria is also appropriate to prevent RPN. Angiotensin-converting enzyme (ACE) inhibition can experimentally induce a 50% increase in papillary blood flow (21). This may help prevent RPN, but it could aggravate hematuria acutely by increasing blood flow to a bleeding area.

Tubular Dysfunction

The relevant medullary pathology in SCD is found in the region of the collecting ducts, the inner medulla, and the papilla. This results in dysfunction of the collecting duct and juxtamedullary nephrons (21). Sickling and vascular congestion of the medulla, seen in gross hematuria (6), are probably responsible for reversible concentrating defects. The basis of irreversible medullary dysfunction in RPN is likely the medullary fibrosis and destruction of vasa rectae. Juxtamedullary nephrons and collecting ducts are destroyed, as is found in the model of RPN induced by bromoethylene-HBr in rats (22).

Clinicopathologic Features

Urinary Concentration

The most common tubular abnormality in SCD is a urinary concentrating defect. Typically, HbSS patients achieve a urine concentration of 414 mOsm/kg after 8–10 h of thirst, compared with 911 mOsm/kg in controls (23). Patients with sickle trait may have a diminished urinary concentrating capacity (24). This concentrating defect in children with SCD may result in enuresis (1) and an increased risk of dehydration during water deprivation.

The ability to concentrate urine depends on an intact collecting duct. The collecting ducts of juxtamedullary nephrons extend deepest into the medulla and are capable of generating the highest urine concentration. Poor sodium reabsorption in the collecting duct can result if the sluggish blood flow does not remove the reabsorbed sodium (21). The continued low-grade sickling and medullary congestion result in loss of the normal medullary concentration necessary for water reabsorption. This defective urine concentration can be transiently reversed by transfusion (25, 26). The permanent destruction of collecting ducts by medullary fibrosis in humans with SCD (12) and rats (22) results in an irreversible concentrating defect.

Vasopressin generation is normal in SCD, and the concentrating defect is not responsive to vasopressin. The concentrating defect is unique to sickling hemoglobinopathies; there is no concentrating defect in other anemias (27).

Diluting Capacity

Urinary dilution depends on the solute reabsorption in the ascending loop of Henle of cortical nephrons, which are not involved in SCD patients. They can usually dilute the urine normally (23, 25).

Hydrogen Ion and Potassium Excretion

A proton gradient from tubular cell to lumen underlies acid excretion. Proton secretion is associated with the "intercalated" collecting duct cells, most prominent in the cortical segment of the collecting duct (21). Damage to the papillary segment is therefore unlikely to cause a severe acidification defect. However, juxtamedullary nephrons, which reabsorb HCO_3^-, are also severely

involved in SCD. On this basis, some defect in acid excretion may occur (21).

An incomplete distal renal tubular acidosis (RTA) may complicate SCD, but it is usually not a clinical problem (25). The minimum urine pH achieved in response to NH_4Cl loading is not as low as in controls (5.8 vs. 5.1), but total NH_4 excretion is normal. Consequently, titratable acidity is reduced (28). Kurtzman has also described a "type IV RTA" in SCD, with a reduced ability to lower urine pH in response to Na_2SO_4, and inadequate K^+ secretion, especially in patients with decreased renal function (29). In one series, six of nine nephrotic SCD patients were reported to have type IV RTA (30).

Plasma renin and aldosterone may be increased in the face of medullary fibrosis (25). A protective mechanism likely exists: In the presence of inadequate K^+ secretion, a shift of K^+ to intracellular compartments probably occurs. Because this shift is under β_2 stimulation, β-blockers or ACE inhibition may result in hyperkalemia (25). The electrolyte abnormalities resemble those in type IV renal tubular acidosis but actually result from an aldosterone independent end organ failure secondary to medullary fibrosis.

Proximal Tubular Reabsorption

There is an increased capacity for sodium reabsorption and a decreased sodium excretion with loop diuretics in SCD (23,31). De Jong and van Eps have proposed that the alterations in renal cortical function are adaptive, compensating for defects in medullary sodium and water conservation (12). The increased proximal sodium reabsorption results in decreased distal sodium delivery. Diuretic response is poor, because it depends on this more distal sodium delivery. Proximal tubular phosphate reabsorption, which usually parallels sodium reabsorption, is also increased. This may cause hyperphosphatemia, especially in the presence of an increased phosphate load generated by hemolysis (25).

Tubular Secretion

There is a significant disparity between creatinine clearance (CCr) and inulin clearance (CIn) in SCD. For example, in a small group of patients with SCD and an increased glomerular filtration rate (GFR) measured by CIn (119 vs. normals 97 mL/min), CCr was significantly higher than CIn in SCD (154 vs. 119) but not in normals (114 vs. 97) (23). This is an expression of increased tubular secretion of creatinine in SCD (25). It is partly responsible for a difficulty in accurately assessing GFR in SCD (see below).

Uric acid secretion is similarly increased and is a functional adaptation to high uric acid generation (7). In patients with decreasing total GFR (and increasing GFR per nephron), fractional excretion of urate is further increased by decreased reabsorption (32).

Experimental Models of SCD Tubular Dysfunction

The rat model of RPN induced by bromoethylene-HBr exemplifies distal tubule physiologic disturbances (22). As a baseline, these rats have a more dilute urine than controls. The juxtamedullary nephrons are nonfunctional. Sodium excretion changes little in response to hypervolemia. Although the measured atrial natriuretic peptide (ANP) increases appropriately, an additional high-dose infusion of ANP can generate a normal response. The normal response to hypervolemia is likely mediated through inner medullary interstitial pressure, damaged in this model (and in SCD). In contrast, the response to salt loading generates a normal increased sodium excretion in experimental RPN, regulated by a more cortical mechanism (22).

Role of Prostaglandins in SCD Tubular Dysfunction

A series of studies begun by de Jong and van Eps explored the effects of prostaglandin (PG) inhibition on renal function (12,33). The effect of PG inhibition on tubular function is especially revealing: There was a greater fall (42%) in the fractional excretion of Na (FENa) in response to PG inhibition by indomethacin in SCD patients than in normals (16%). This reflects a greater than normal effect of PGs on the delivery of sodium to the distal diluting segment. Although normal urinary dilution is not affected by PG inhibition, PG inhibition decreases urinary dilution in SCD (23).

PGs increase proximal sodium reabsorption. Under PG inhibition, more solute is delivered to and then reabsorbed by the thick ascending limb of the loop of Henle, thereby increasing interstitial hypertonicity. More free water is then absorbed in the relatively solute-impermeable descending limb, resulting in a decreased

response to water loading (23). Thus, although urinary diluting capacity is normal in SCD, it is being maintained only by PG and will be decreased by indomethacin (12). PG inhibition increases distal delivery, preventing the appropriate effect of vasopressin suppression during water diuresis in SCD (12). Increased proximal sodium reabsorption in SCD results in a decreased natriuretic response to loop diuretics (22), and PG inhibition restores that response.

In contrast to normals, SCD patients fail to increase net acid excretion in response to inhibition of PG synthesis by indomethacin (28) because of decreased NH_4^+ excretion. It is likely that NH_4^+ excretion is maintained at maximum by endogenous PGs.

In summary, the tubular dysfunction of SCD manifests a defect in urine concentration, while dilution is maintained. Hydrogen ion and potassium secretion functions are only mildly affected, and proximal tubular mechanisms are exaggerated.

Treatment

Treatment of tubular disorders in SCD is usually unnecessary if renal function is normal. The risk of dehydration caused by decreased urinary concentrating ability requires earlier treatment of diarrhea or vomiting. There should be a cautious approach to volume expansion as treatment for sickle crises; administration of large volumes of standard sodium-containing fluids to significantly anemic patients with increased sodium reabsorption may result in congestive heart failure. Acidosis may require earlier treatment in the patient with SCD. Hyperuricemia, resulting from increased urate production, may be aggravated by diuretics (especially thiazides) that inhibit urate secretion. The edema accompanying severe anemia may be difficult to treat because the response to diuretics is diminished. Severe hemolysis may exceed the patient's ability to excrete potassium, especially if there is renal insufficiency. β-Blockers or ACE inhibition can aggravate hyperkalemia (25), especially in the presence of some degree of renal impairment (29).

Sickle Cell Glomerulopathy

Clinical

The association of significant proteinuria with SCD has been recognized sporadically and usually described as a nephritic process. As early as 1959 (34), nephrotic syndrome was recognized in SCD. Proteinuria was identified in 17 of 54 patients in 1978 (26). A population study found proteinuria in 20% of 284 patients in a single center, with a prevalence of 29% in adults but only 5% in children less than 10 years of age (35). Bakir et al. recognized nephrotic syndrome in 12 of 240 SCD adults, with 2–20 g protein per 24 h (30). In our series, 87 (26%) of 381 adult patients had significant proteinuria, with 12 in the nephrotic range (more than 2.5 g/24 h) (36). In a more recent study, of 34 adult patients with SCD, 7 had albuminuria with normal GFR and 17 had chronic renal failure, with glomerular injury and loss of ultrafiltration coefficient (37). In this series, GFR was related to hematocrit (38).

Lonsdorfer et al. (39) found that 40–45% of 31 SS patients aged 16–40 years had abnormal proteinuria, mostly selective (albumin). Twelve percent of the 17 patients who were under age 16 had abnormal proteinuria. Of 52 SA patients over age 16, approximately 18% had abnormal proteinuria. Those with S/Thal were similar to SS patients, those with SC disease were between SS and SA. Alvarex et al. (40) more recently noted that far more SS patients had microalbuminuria, but that the those with overt with proteinura tended (2 of 8) to progress in both proteinuria and decreased renal function, as noted by more sensitive cystatin-C. The 2006 study of 300 sickle hemoblobinpathy subjects by Guasch et al. (41) confirmed the progressive and expected development of albuminuria, and common (20%) development of renal insufficiency. The recent and most important long-term study by Powars (42) of over 1,000 SCD patients found an 12% incidence of chronic renal failure, at a median age of 37, as well as an even greater number with pulmonary hypertension.

The definition of sickle cell nephropathy that is most accepted is associated with nephrotic range proteinuria. While long-term studies have not been done, it appears to have a more rapid course than other causes of nephrotic syndrome. In the experience of Bakir (30) 2/3 developed renal failure within 2 years. The onset of renal failure was heralded by increasingly inadequate erythropoiesis (42), and carried a survival time of 4 years.

Pathology

The usual finding in sickle cell nephropathy is focal segmental glomerulosclerosis (FSGS), which is intimately associated with glomerular hypertrophy. Glomerular engorgement and hypertrophy were recognized as part of SCD, as well as FSGS in a 9-year-old nephrotic SCD patient in 1959 (34). Ten of our adult HbSS patients

without significant renal impairment underwent renal biopsy because of proteinuria (36). Eight had FSGS involving a mean of 27% of glomeruli, and the other two had focal global sclerosis. There was focal tubulointerstitial fibrosis adjacent to sclerotic glomeruli. The nonsclerotic glomeruli were all enlarged, with diameters of 186 ± 14.5 μm versus 137.9 ± 19.3 μm in 10 control biopsies. Immunofluorescence was positive only for IgM, C3, and C1q irregularly in sclerotic segments. Electron microscopy confirmed the absence of immune complex-type dense deposits. There was focal electron-lucent expansion of the subendothelial zone in six specimens, with occasional mesangial cell interposition. No new mesangial matrix material was observed to suggest membranoproliferative glomerulonephritis (MPGN).

These findings agree with the description by Churg (43). Glomerular hypertrophy was documented previously in adults with measured glomerular diameter (median 257 μ, range 220–316) greater than in controls (median 193 μ, range 142–253) (44). Bakir et al. described both the nonimmune MPGN-like lesion in nine patients, and FSGS (in 8% of glomeruli) or global sclerosis (in 14% of glomeruli) (30). In addition to FSGS, focal cortical infarcts have been described as a late finding in sickle cell nephropathy (10).

A report on the renal pathology in six HbSS patients with proteinuria described two patterns of FSGS: a "collapsing" and an "expansive" sclerosis (45). Glomeruli were significantly hypertrophied, with diameters of 233 ± 25.3 μ, compared with 158 ± 12.7 μ in normals. HbSS glomeruli were more hypertrophied than in idiopathic FSGS (188.2 ± 17.9 μm). The glomeruli from HbSS patients without clinical evidence of renal disease (243.5 ± 12.5 μm) were the same size as those with proteinuria.

Renal Function in Sickle Cell Glomerulopathy

Hyperfiltration

An increased GFR has been a recognized feature of SCD, especially in children, in studies dating from the 1950s (12). Renal plasma flow, as estimated by p-aminohippurate (PAH) clearance, is elevated in excess of GFR, resulting in a lower than normal filtration fraction (12.9 vs. 17.5) (23). The extraction ratio of PAH (normally 90–95%) is also lower (26). The cause and mechanism of this physiologic alteration is unclear, although it is likely that increased cortical blood flow itself can cause decreased secretion by limiting diffusion from rapidly flowing plasma (26). A more recent analysis suggests a distinctive pattern of increased glomerular permeability (to dextrans) in SCD nephropathy, an increase in pore radius, which is not explained by purely hemodynamic changes. When chronic renal failure develops, the total number of membrane pores is reduced and a size-selectivity defect occurs.

Role of Prostaglandins or Kinins in Glomerulopathy

It has been suggested that hyperfiltration and proximal tubular "hyperfunction" in SCD are a compensation for the distal tubular injury, mediated by the PG systems (12,22). In the studies by de Jong and van Eps (see previous discussion on tubular dysfunction) (12), indomethacin decreased GFR and the estimated renal plasma flow (ERPF) in SCD, without altering that of controls, suggesting that the PG system might be responsible for maintaining the GFR in SCD. Measured PGE_1 excretion did not differ from controls, but PGF_2 was lower (46), thus increasing the ratio of the vasodilator PGE_1 to the vasoconstrictor PGF_2. Allon et al. (23) found that indomethacin decreased PGF_1 (a metabolute and prostacyclin, a vasodilator hormone) more in SCD (46%) than in controls (15%). GFR was decreased 16% by indomethacin in SCD but was unchanged in normals. The more dramatically increased ERPF and decreased filtration fraction of SCD were returned toward normal, and the net effect of PG inhibition was to reverse hyperfiltration.

Overall renal Kallikrein excretion is altered, and while not significantly different from controls, could be related to microalbuminuria. Kinin influence could be hypothetically related to an effect upon vascular smooth muscle control in the presence of denuded endothelium, incapable of generating NO (47).

Pathogenesis

Immunopathogenic Mechanisms

In 1975, Strauss et al. (48) described an SCD membranoproliferative (MPGN) nephropathy in seven patients, four with nephrotic syndrome, three of these under 15 years, with immunopathologic studies suggesting an immunocomplex disease. One proposed cause for the sickle cell nephropathy has been immunologic reaction to renal tubular epithelial cell complexes (12). Most now agree that evidence of immunocomplex deposition is usually lacking in SCD patients with heavy proteinuria.

Relationship to Other Glomerulopathies

The relationship of the pathologic findings of SCD to other nephropathies is unclear. Glomerular hypertrophy with FSGS is also found in the setting of reduced renal mass. Examples are reflux nephropathy, severe obesity (49), and rat models of renoprival glomerulosclerosis (50). In FSGS associated with idiopathic nephrotic syndrome, the glomeruli that develop sclerosis are hypertrophied (53). The nephropathy associated with type I glycogen storage disease (GSD-1) includes both hyperfiltration and FSGS (53) (see Chapter 51). The nephropathy associated with cyanotic congenital heart disease may arise from mechanisms similar to those operating in SCD: low oxygenation and increased blood viscosity from polycythemia (25,52).

Possible Mechanisms of SCD Nephropathy

Hyperfiltration, in concert with direct endothelial damage by occlusion with sickled cells might lead to endothelial hyperplasia and ultimately fibrosis (12,25). The iron deposited in tubular cells as hemosiderin has been suspected to have a role in the chronic nephropathy of SCD (10). The nonimmune complex deposits found in SCD might derive from iron-protein complexes (10). Experimentally, saturated-iron complexes can induce a nephrotic syndrome in rabbits (26). Lande et al. found decreased renal cortical spin-echo signal by magnetic resonance imaging in SCD, suggesting an abnormal renal cortical iron metabolism (55). This does not occur in β-thalassemia, despite similar iron overload. Nevertheless, the iron overload from multiple transfusions in both SCD and β-thalassemia is appropriately treated with deferoxamine, or the more recent oral desferasirox (54).

It is possible that FSGS is the consequence rather than the cause of interstitial fibrosis, which might obstruct the efferent glomerular capillaries, raising intraglomerular pressure and resulting in progressive (reactive) sclerosis (53). In SCD, in which medullary fibrosis is most prominent, the vasa rectae supplying the juxtamedullary nephrons would be most affected by FSGS. Bhathena et al. (45) suggested that the "collapsing" pattern of FSGS, superimposed on already maximally hypertrophied glomeruli, might be a consequence of sickling and ischemic collapse, similar to glomerular "microinfarcts" suggested by Chauhan et al. (10). The "expansive" form of FSGS is viewed as a mesangial cell reaction to capillary collapse.

Both the pathophysiologic and pathologic findings in sickle cell nephropathy resemble those in the rodent model of glomerular hypertension induced by renal mass reduction (56). Thus hyperfiltration, glomerular enlargement, and focal and segmental glomerulosclerosis could be a result of an increase in intraglomerular pressure as a consequence of efferent arteriolar vasoconstriction. In that model, and in others, the glomerular hypertension and the pathologic consequences are attenuated by angiotensin II-converting enzyme (ACE) inhibition.

Any hypothesis should take into account the glomerular hypertrophy that is always present in SCD, probably related to the anemia itself. Proteinuria is not invariable in SCD and appears to be unrelated to the number and severity of SCD crises or the presence of hematuria, RPN, etc. Therefore some other factors are likely to be operative in those at greatest risk of proteinuria and FSGS. Systemic hypertension is notably absent in these patients (36). The presence of hyperfiltration, glomerular hypertrophy, and FSGS does not imply that these findings are sequential or causative. A common stimulus may be operative, such as the growth promoting hormones and cytokines (57,58), to which the glomerulus may be sensitive.

Diagnosis

Hyperfiltration

The upper limit of the normal range for GFR is not certain, even with CIn, the "gold standard." The reliability of the clearance methods that can substitute for CIn have not been validated in the elevated range. In adult SCD subjects aged 40–75 years, CCr correlated well with the clearance of ^{51}Cr-EDTA when clearance did not exceed 110 mL/min, although ^{51}Cr-EDTA exceeded CCr by almost 30% (58). In normals, the urinary clearance of ^{51}Cr-EDTA is 85–95% that of CIn, while the clearances of ^{99m}Tc-DTPA and ^{125}I-iothalamate are nearly identical to that of inulin (59). Because CCr usually exceeds CIn in normals, its validity in SCD is uncertain. The simplest estimation of GFR, by several formulas, uses PCr alone (60), but an additional problem in the use of these formulas is the greater overestimation of GFR by CCr in SCD patients than in normals. The plasma clearance of ^{51}Cr-EDTA following bolus injection approximates CIn in normals (61) but at high clearances is far less accurate.

The attempt to simply and correctly assess GFR is an important recent effort, to detect early, and possibly preventable, decreases in GFR in a population with an intrinsically high GFR. A decrease in GFR, particularly when accompanied by proteinuria, is ominous (63). However, the effects of treatment are difficult to assess in other than a clinical research environment, although simplified methods for non-isotopic iothalamate and PAH measurement are now available (64).

As a further development, in a study of sickle-B-Thallasemia patients, Voscaridou et al. (65) found that plasma cystatin-C (Cys-C) measurement correlated well with CCr in patients with decreased CCR, and in those with demonstrable proteinuria, but not in those with CCr >90 ml/min. In the normal and elevated range, in obese type II diabetic Pima Indians, Perkins et al. (66) were able to show good correlation between Cys-C and iothalamate clearance, and could show that a progressive decrease in iothalamate GFR was best demonstrated by Cys-C, rather than Cr-based formulae. Alvarez et al. (67) were able to study CCr, Cr, Cys-C and microalbumuria and frank proteinuria in children with SCD, and found that while Cr, and CrCl did not distinguish this population, Cys-C showed progressive decreases in clearance with microalbuminuria and proteinuria.

We (Scheinman JI and Belmont JM, unpublished) examined a database of multiply-transfused SCD and β-thal patients, with eGFR (Cr) over 85 mL/min, in a control period before an experimental iron removal intervention, measuring simultaneous Cr (Schwartz (60) or Cockroft-Gault (68)) and Cys-C (Filler (69)) estimates of GFR. For all 169 SCD patients, the eGFR (Cr) and eGFR (Cys-C) were well correlated ($r = 0.35$, $p = 0.001$). For the 71 SCD patients with eGFR (Cr) >200 the correlation was poor ($r = 0.06$), but was strong for the 98 SCD patients with eGFR (Cr) <200 ($r = 0.36$), and the 35 with eGFR (Cr) <150 ($r = 0.43$). When the analysis was restricted to the 120 patients whose repeated measures varied by no more than 20%, a similar correlation was found when eGFR (Cr) <200 ($r = 0.35$), and the relationship was even stronger with eGFR (Cr) <150 ($r = 0.59$). The correlation of the two estimates of GFR in the 662 β-thal patients was poor at all ranges ($r <= 0.20$). Therefore our preliminary impression is that if an appropriate eGFR (Cr) formula yields a value <200 mL/min, that same formula may very well be able to adequately estimate a change in GFR within the normal to elevated ranges.

Proteinuria detected by dipstick in a patient with SCD should be quantified and renal function assessed. Diseases other than sickle cell glomerulopathy should be considered. If hematuria is present, RBC casts may point to pathology other than sickle cell glomerulopathy. Hypertension, hypocomplementemia, and antinuclear antibodies also suggest other diagnoses. Judging from the relatively uniform findings in our series (36), few other additional studies are indicated.

Treatment

The course of the progression of FSGS to chronic renal insufficiency (CRI) in SCD remains difficult to assess, in part because of the difficulties in quantitation of renal function described above (64). Without a known cause, it is difficult to prescribe a treatment for the nephropathy of SCD. The patients with proteinuria in our series (36) were not those with most frequent sickle crises, nor the severest anemia. Nevertheless, some factors in the sickle cell condition must predispose to the nephropathy. Therefore it is reasonable to attempt to minimize sickling and those factors known to promote FSGS in other primary diseases or in animal models, but it is controversial whether hemodynamic alterations can alter the progression of FSGS to CRI (57).

Protein Restriction. A high protein intake accelerates the development of FSGS in uninephrectomized rats, without necessarily causing glomerular hyperperfusion (53). It is therefore attractive to consider protein restriction in the management of SCD nephropathy, as is being tried in several forms of renal disease. In children, restriction of protein intake may carry unreasonable risks (71). Delayed growth and development is already a particular risk in the SCD patient. Therefore, we advise only the avoidance of an unusually high protein intake (greater than the recommended dietary allowance).

Angiotensin-Converting Enzyme Inhibition. Glomerular hyperperfusion and proteinuria could be mediated through increased glomerular capillary pressure, reduction of which by ACE inhibition might protect the glomerulus from FSGS.

In our 2-week trial of enalapril therapy of 10 patients with mild SCD nephropathy, BP, GFR (CIn), and ERPF (PAH clearance) did not change significantly, whereas proteinuria diminished by 57%, rebounding after treatment withdrawal (36). A more recent 6-month controlled trial of enalapril in 22 SCD patients with microalbuminuria showed a significant decrease in the treatment group, while the control group increased (72). Whether long-term ACE inhibitor therapy has a salutary effect in preventing renal insufficiency is untested.

Chronic Renal Insufficiency

Clinical

Renal failure is one of the major organ failures that occur in SCD, almost certainly the consequence of the progression of FSGS. Of 22 patients with nephrotic syndrome, 68% developed CRI (30). Population studies of SCD have all shown a significant incidence of CRI. Of 368 patients in one sickle cell center, 4.6% had CRI (73) associated with proteinuria and increased age. In our series of 375 patients, 6.7% had CRI (36). In a series of 785 patients from California, 33 had CRI (4.2%) (74). Overall, 5–18% of SCD patients develop CRI (75).

The epidemiology of renal involvement in SCD may depend upon other genetic factors that effect the levels of fetal hemoglobin (HbF), the tendency to sickle, and other contibutions. Powars (76) initially reported the association of β-globin gene cluster haplotypes with renal involvement: The Central African Republics (CAR) haplotypes (Bantu, Cameroon) or Benin (intermediate involvement) versus non-CAR (Senegalese and Arab/Indian) phenotypes. Guasch (77) found no association with these haplotypes, but instead, with microdeletions in the α- globin gene: Microalbuminuria was found in 22 of 76 (29%) adult SCD patients, but only 13% with the micro-deletions, versus 40% without those micro-deletions ($p = <0.01$). Those factors that effect the interactions of RBCs with endothelium may be equally important (see below).

Treatment

Specific treatment of the patient with SCD and renal failure has been poorly explored, and the problems of CRI are only magnified by SCD. Patients with renal failure, even if it is mild, sometimes have symptomatic anemia requiring transfusion. In some of these patients, treatment with erythropoietin can variably restore hemoglobin concentrations to higher levels (78). A few patients have been treated with hydroxyurea plus erythropoietin, with apparent benefit (79).

Dialysis and Transplantation. The U.S. Renal Data System reported the causes of renal failure for 255,573 patients treated from 1989 through 1993 (62). Overall, 235 were SCD patients. This is far less than the 1% expected from the incidence of HbSS in the total population. It is possible that physicians do not offer treatment to many SCD patients who develop CRI, assuming that the other problems are insurmountable.

Ojo (80) reviewed the transplant results in SCD and found 82 patients. There was no difference in the 1-year cadaveric graft survival (SCN: 78% vs. Other-ESRD: 77%), and the multivariable adjusted 1-year risk of graft loss indicated no significant effect of SCN (relative risk [RR] = 1.39, P = 0.149). However, the 3-year cadaveric graft survival tended to be lower in the SCN group (48% vs. 60%, P = 0.055) and their adjusted 3-year risk of graft loss was significantly greater (RR = 1.60, P = 0.003). There was a trend toward improved survival in the SCN transplant recipients compared to their dialysis-treated, wait-listed counterparts (RR = 0.14, P = 0.056). In comparison to the Other-ESRD (relative risk (RR) = 1.00), the adjusted mortality risk in the SCN group was higher both at 1 year (RR = 2.95, P = 0.001) and at 3 years (RR = 2.82, P = 0.0001) after renal transplantation. They also found a trend toward better patient survival with renal transplantation relative to dialysis in end-stage sickle cell nephropathy.

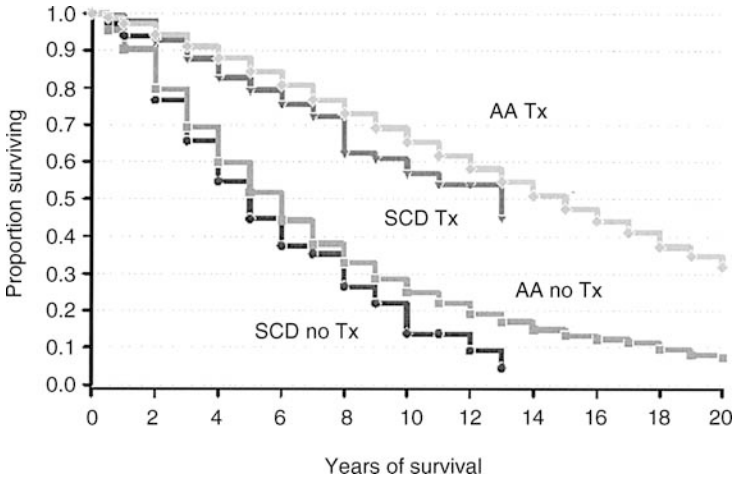
In an analysis of the UNOS registry from 1987 to 1996 (81), 54 patients were found with SCD, renal failure, and data on 1st renal transplant outcome. Patient survival for SCD was 90% at 1 year and (of 30 patients) 75% at 3 years. The proportional risk ratio (compared to IgA nephropathy) was 7.8, the greatest for any condition. First graft survival for SCD was 82.5% at 3 years, 54% at 3 years. The proportional risk ratio for graft survival was 1.77, but after correction for patient deaths with functioning graft, only 1.06 (barely an increased risk).

We have explored (unpublished) the USRDS Data files 2000, for evidence of the effect of SCD on the outcome of chronic renal failure. While the diagnostic code (assigned at the time of renal failure) for sickle cell nephropathy yielded 904 patients, further exploration of patients discovered by hospitalization codes to have SS disease yielded a total of 1,656 patients, 237 transplanted and 1,419 not transplanted, and even after eliminating other causes of renal failure (diabetes mellitus, etc.). SCD patients were compared to all other African American (AA) patients, for life-table survival. Without transplant, they significantly differed, with vastly different numbers, and projected 10-year survival was poor for both groups, 25% for AA, and 15% for SCD.

Further, the 36,264 transplanted AA patients had better survival than the 210 SCD patients, but the lifetable projected survivals were still quite close, approximately 50% survival at 15 years (*Fig. 49-4*). Using an age-adjusted cohort of AA patients as controls, the difference statistically disappeared ($p < 0.19$). Comparing the non-transplanted AA patients with the SCD patients was different, but both extremely poor: 25% for AA patient, and 14% for SCD patients at 10 years.

Figure 49-4

Lifetable analysis of patient survival, of end-stage renal failure patients having SCD or age-matched African-American (AA) controls, treated with kidney transplantation or dialysis alone. All curves differ significantly, due to the vastly greater numbers of AA patients (data unpublished).



A comparison of the 153 transplanted SCD patients with those who received no transplant showed a far better survival curve, 56% versus 14% at 10 years, even when compared to those 133 SCD patients who were placed on the transplant waiting list but never got a transplant. This was similar to the difference between all transplanted AA patients and Non-transplanted AA patients assigned to the transplant waiting list. Of 957 patients since 1991, essentially the cyclosporin era, only 53 SCD patients received transplants, versus 898 not Transplanted, and survival is projected at 67% at 7 years, versus 83% for the AA cohort.

These results continue to make the case that transplantation is a better option for the SCD patient with renal failure. However, results may be less satisfactory than for other AA patients, and grafts have been lost due to demonstrable massive sickling events.

The problems that have occurred in SCD patients after transplantation, especially the recurrent sickle crises, could have been aggravated by the increased blood viscosity associated with a rising hematocrit. These have been and treated with frequent partial exchange transfusions (82). In one early series, seven of eight had frequent sickle crises after transplantation (83). Renal venous thrombosis and infarction have been reported (84). In one patient with HbAS, the transplanted kidney was unfortunately removed for an apparently irreversible acute rejection that was actually intrarenal sickling (83).

The management of renal transplantation in SCD should then attend to potential immediate problems; it is reasonable to warm the kidney with 37°C saline, to infuse dopamine at 4 g/kg per min during and immediately postoperatively, and to provide 40% oxygen, with intravenous fluids to decrease viscosity. Partial exchange transfusion may be provided at 4-week intervals (83). It is possible that before an adequate erythropoietin (EPO) response occurs from the transplanted kidney, recombinant EPO should be given.

Sickle cell nephropathy has been reported to recur in as little as 3½ years, although other factors contributed (85). Accelerated recurrence of native disease has been noted in the transplanted kidney in other diseases, notably diabetic nephropathy (86). It is possible that the use of hydroxyurea, in itself likely to interact with other immunosupressants, can be utilized to prevent this. Bone marrow transplantation can cure SCD, and the possibility of its coupling with other transplants will undoubtedly be explored. Caution will be needed, in view of the possible increase in parvovirus (87), a common agent of aplastic crisis that might be especially dangerous in the transplant patient.

Other Problems in SCD Related to Nephrology

Anemia

In the presence of continued hemolysis, the patient with SCD depends on continued erythropoiesis, which

determines the level of anemia. Erythropoiesis can be measured by "erythron transferrin uptake" (88), independent of iron or transferrin saturation. A heme protein in the kidney senses a decreased level of O_2 delivery to the kidney and stimulates erythropoietin production (89). The SCD patient with renal failure loses this normal homeostatic mechanism, becoming far more anemic. Even in the presence of a competent bone marrow and erythropoietic stimulus, adequate iron is necessary. Patients with ulcers may subtly lose iron (10).

The Hb level should probably be maintained at 50–60% of normal in SCD, in view of the serious cardiac consequences of more severe anemia (90). Although an intrinsic cardiomyopathy has been suspected in SCD, a careful autopsy study of 52 patients with a mean age of 17 years, concluded that anemia alone caused heart failure (90).

Sickle Crises – Clinical Features

Sickle cell crises (1) are painful episodes of vaso-occlusion, often accompanied in the 2nd or 3rd day by fever without documented infection. Neither abnormal blood viscosity nor the number of sickle cells absolutely predicts the frequency of crises (4). The incidence of pain is 0.8/year in SS and 1/year in S-β-thalassemia (91). With greater degrees of anemia, there is less pain, probably because of diminished blood viscosity. With increasing HbF, there are proportionally fewer painful crises, suggesting a beneficial effect of even modest increases in HbF (91).

Crises may occur in infants as the hand-foot syndrome because of poorly developed collateral circulation. The chest syndrome is accompanied by radiologic "white-out" and is life threatening (92). The abdominal crisis is like a "surgical" abdomen but usually without rebound tenderness. In the presence of hematuria, the origin of the pain could be assumed to be the kidney. Neuromeningitis, multi-infarct dementia, or large-vessel occlusion (stroke) can occur (93), especially in infants and children (10). Genetic factors, related to the inflammatory mechanisms, may help to predict the risk of stroke (94) and other complications of SCD. A sudden anemia may be caused by sequestration crises in the spleen in the first 2 years of life, and thereafter, after development of splenic fibrosis, occurs more often in the liver. Aplastic crises arise from vaso-occlusion and hemolysis without compensatory erythropoiesis, often induced by a parvovirus-like agent.

Priapism

Priapism is a specialized vaso-occlusion of the penis, which was found as often as 42% in one series (1). Painful, hot, tender erection, most often on waking, lasts up to 3 h. This can be preceded by days or weeks of "stuttering." The engorgement is of the corpus-cavernosa, usually not the spongiosum in children, with the glans flaccid (10). The pain is referred to the perineum and to the abdomen, requiring analgesia, often exchange transfusion. Few require surgical drainage or a shunt. Fibrosis may result, with consequent impotence (10).

Pathophysiology of Sickling

The clinical heterogeneity of SCD is further determined by recently described aggravators of sickling related to oxidative stress. Hb from RBCs of SCD patients has increased auto-oxidation, increased generation of superoxide and H_2O_2, OH^-, and lipid peroxidation products (95). In a transgenic model of SCD, increased oxidant stress extends renal sickling from a more limited area in the renal medulla, to a more extensive distribution to the cortex (96). The aggravating factors of sickling are likely to include the agents of microvasular inflammation and constriction, and inhibitors of relaxation. Reactive species can divert vasoactive NO from mechanisms of vascular relaxation to agents of inflammation and constriction (95). Integrins (α4β1) of the sickled RBC bind to both fibronectin (an acute phase reactant) and vascular cell adhesion molecule 1 (VCAM-1) on endothelial cells, which itself is increased by inflammatory cytokines such as TNFα.

Hemoxygenase (HO-1) defends against and degrades heme, a lipophilic pro-oxidant, formed from the splitting of Hb (96), studied in a transgenic sickle mouse. In the HO-1 knockout model, administration of heme protein induces monocyte chemoattractive protein (MCP-1), mediated by NF-kB, and results in renal interstitial cell inflammation (97).

Thus increased induced oxidative stress from the sickling process precipitates acute vaso-occlusive disease, by mechanisms that affect the endothelium, and adhesion to it, as well as vasoconstriction.

The distorted sickle cell is partly explained by dehydration of the cell, by enhanced KCl co-transport, induced by cell swelling and acidification (98). Further, K+ and water efflux are enhanced by transiently increased SS cell cytosolic Ca, induced by the membrane distortion.

Acute Renal Failure

A doubling or more of PCr was found in 12 of 116 hospital admissions of patients with SCD. It was seen most often with infections and evidence of rhabdomyolysis, and in patients with lower Hb (mean 6.4 vs. 8.7 g/dL) (99). Volume depletion was the most common precipitating cause. In that study there was an 83% patient survival with recovery of function in all patients who survived, without progression to ESRD. It is likely that non-steroidal anti-inflammatory agents are partly responsible for some episodes of acute renal failure (100), in view of the likely maintenance of GFR in SCD by prostaglandin mechanisms.

Rhabdomyolysis with acute renal failure and disseminated intravascular coagulation has been seen (rarely) in sickle trait with rigorous military training (101). Similarly, there is an apparently increased risk of sudden unexplained death in patients with sickle trait (102).

Hypertension

Hypertension is unusual in SCD (2–6%) compared to the published incidence for the black population in the United States of 28%, as found by the Cooperative Study of Sickle Cell Disease (103), at all age ranges.

In our series (36), hypertension was rare, only found in 1 patient with nephrotic-range proteinuria, without renal insufficiency. The 1/3 incidence of hypertension in Powar's patients with renal insufficiency is unexplained (104). Nevertheless, she found a positive association between BP, stroke, and increased mortality in SCD (105).

Infections

Infections occur in HbSS as a result of vascular sequestration with tissue necrosis (e.g., osteomyelitis associated with avascular necrosis, or *Salmonella* infection with cholelithiasis) and the immune susceptibility of the splenectomized patient (1). The organisms most commonly found are *Diplococcus pneumoniae, Haemophilus influenzae, Mycoplasma,* and *Parvovirus* (10). Prophylactic penicillin is essential, as for any splenectomized patient. *H. influenza B* vaccination is also appropriate.

Urinary infections are uncommon in SCD, except perhaps in pregnancy. ^{99m}Tc-diphosphonate scan shows an increased renal localization in HbSS. This is apparently not caused by infection but more likely by regional stasis or tubular ischemia, causing peritubular extravasation (106).

Endocrine Abnormalities in SCD

Several clinical problem found in SCD can interact with both SCD itself, and with the nephrologic problems. Growth failure, hypogonadism, delayed puberty, and others may be independent endocrine defects or linked to iron overload (107).

General Treatment Strategies for Sickle Cell Disease

Institution of frequent transfusion can reduce the risk of recurrence of cerebral vasculopathy (93) by decreasing the proportion of rheologically abnormal cells. The risks of transfusion should be reserved for patients at greatest risk of sickling sequelae. Most recently, Doppler ultrasonography has helped identify cerebral vessels at risk of stroke (108). In turn, the long-term effects of iron overload are important with or without frequent transfusions, so that the use of new oral iron chelation agents is fortuitous (109).

Other hemoglobins modify the tendency of HbS RBCs to sickle. Fetal Hb (HbF) inhibits sickling. 5-Azacitidine can increase HbF, probably by recruitment of HbF cells, but may be a carcinogen (110). The only agent able to significantly decrease sickling by myelosuppression of HbSS cells, thus increasing HbF, is hydroxyurea. Hydroxyurea is a cytotoxic agent that inhibits growth of burst forming unit-erythroid (BFU-E) (111). In SCD, it is the SS cells that are suppressed, allowing an increase in HbF.

Charache et al. (112) achieved 8–18% HbF levels maintained over 2 years. It has been deduced that the level of HbF likely needed to produce a definitive clinical change is more than 20%, for either hemolysis or vasoocclusion (113). A trial in 59 patients (114) suggested that a mean HbF of 15% could be achieved. Trials of hydroxyurea in adults and children (115) have shown a safe reduction in acute episodes, and allowed normal growth and development (116). In addition to its effect on RBC generation, it induces oxidative damage to SS cells greater than to AA cells, even more than to HbF (117). Antioxidants such as α-tocopherol and ascorbate are protective in vitro, and may enhance the safety of hydroxyurea.

Other mechanisms that can minimize the tendency to sickling and vaso-occlusion have been explored. Duffy

glycoprotein on RBCs may help to clear inflammatory cytokines, and therby protect from organ damage (118). Reversing the cellular dehydration in SCD has been explored by blocking cation-transport (Gardos) channels in erythrocyte membranes and can shift cellular cation content and cell density toward normal (119). Clotrimazole, an antifungal drug, reduced cellular dehydration in vitro in transgenic mice with sickle cell disease and in patients with sickle cell anemia. Magnesium salts also interfere with cation transport and cause cell rehydration (120). Zinc sulfate was shown in a well-designed controlled study to decrease sickle crises by this mechanism (121).

Whether the cellular changes induced by clotrimazole, magnesium salts, Gardos channel blockade or other approaches are of significant clinical value are not yet known. Combinations of hydroxyurea plus clotrimazole and erythropoietin to prevent sickling have been studied in transgenic mice.

Bone marrow transplantation can cure SCD, and the possibility of its coupling with other transplants will undoubtedly be explored. Less ablative conditioning for bone marrow transplant is being explored (122) Caution will be needed, in view of the possible increase in parvovirus (87), a common agent of aplastic crisis that might be especially dangerous in the transplant patient.

50 Diabetic Nephropathy

M. Loredana Marcovecchio · Francesco Chiarelli

Introduction

Over the last decades, the incidence of childhood-onset type 1 diabetes has significantly increased, particularly in children under the age of 5 years (1). Microvascular and macrovascular diseases represent serious long-term complications, which contribute to the poor prognosis of children and adolescents with diabetes (2–4). Recent data from the USA have shown that the number of life-years lost among children diagnosed with diabetes at the age of 10 years is 18.7 for boys and 19.0 for girls, thereby underlining the burden of the disease (5).

This chapter offers an overview of diabetic nephropathy (DN) in children and adolescents with type 1 diabetes.

Epidemiology

DN affects about 20–40% of subjects with diabetes and is the leading cause of end-stage renal disease (ESRD) in developed countries (6). The number of patients with DN is also growing in many parts of the developing world (6). In the USA, DN accounts for about 44% of new cases of ESRD (7) and similar data have been reported in Europe and other western countries (8). DN is also a major determinant of morbidity and mortality related to the increased risk of cardiovascular disease (9).

DN is defined as persistent proteinuria, greater than 500 mg/24 h, or albuminuria greater than 300 mg/24 h (10). A progressive increase in blood pressure and decline in glomerular filtration rate (GFR) are generally associated with the development of DN and they contribute to the progression towards ESRD (10).

Although overt DN or kidney failure is rarely seen in children with either type 1 or type 2 diabetes (less than 1% of pediatric patients) (11, 12), early structural and functional renal alterations develop soon after diagnosis in children, and accelerate during puberty (13, 14). Microalbuminuria (MA), defined as an albumin excretion rate (AER) between 20 and 200 μg/min or 30–300 mg/24 h, is the earliest stage of clinical nephropathy and its persistence is highly predictive of progression to overt nephropathy and also of cardiovascular disease (15, 16). The cumulative prevalence of MA in people with childhood-onset type 1 diabetes is 12–25% after 5-10 year diabetes duration (11, 17–21). Recent data from a prospective observational study has shown a cumulative prevalence of MA of 25.7% after 10 years and of 50.7% after 19 years of duration (22). Longitudinal studies suggest that MA is persistent only in 50% of children and adolescents, whereas in the other 50% MA can revert to normoalbuminuria at the end of puberty (21, 22). However, in 20–30% of patients with transient MA, it recurs during follow-up. With regard to overt nephropathy, in a recent population-based study of childhood-onset type 1 diabetes (22), the cumulative prevalence of macroalbuminuria has been found to be 13.9% after 19 years of diabetes duration, but lower rates were detected in previous clinical-based studies (18–20).

In addition, in children and adolescents, as in adults, a progressive increase in albumin excretion within the normal range has been found to be an important predictor of future development of MA (23, 24). Therefore, detecting these early alterations might help in identifying children and adolescents with type 1 diabetes at risk of DN and to implement preventive and therapeutic strategies to reduce the burden associated with this complication.

Natural History

The changes occurring in the kidney in patients with type 1 diabetes are generally classified into five stages, reflecting specific alterations in renal morphology and function (25) (*Table 50-1*).

The first stage in the natural history of DN is characterized by functional anomalies, including hyperfiltration and hyperperfusion, which are associated with increased renal size (25). These alterations are present at the diagnosis of diabetes in 25–50% of patients (25). Blood pressure is generally normal during this period, whereas albumin excretion may be increased, but it is reversible (25). These early functional anomalies are related to hyperglycemia and they generally reverse after insulin treatment, even though they can persist in some patients (25). Apart from hyperglycemia, several other

Table 50-1

Stages of Diabetic Nephropathy: structural alterations, changes in albumin excretion, glomerular filtration rate and blood pressure

	Main structural alterations	Albumin excretion	Glomerular filtration rate	Blood pressure
STAGE 1 (at diagnosis): Hyperfunction/Hypertrophy	Increased renal size	May be increased, but it becomes normal after starting insulin treatment	Increased by 20–50%	Normal
STAGE 2 (after 2–5 years): Normoalbuminuria/Silent phase	Basement membrane thickening	Normal with transient increases related to poor glycemic control or exercise	Normal/ increased by 20–50%	Normal
STAGE 3 (after 6–15 years): Incipient diabetic nephropathy/ Microalbuminuria	Further basement membrane thickening and mesangial expansion	Increased: 20–200 μg/min or 30–300 mg/24 h	Normal/ increased	Increasing
STAGE 4 (after 15–25 years): Overt diabetic nephropathy/ Macroalbuminuria	Marked renal abnormalities	Further increased:>200 μg/min or >300 mg/24 h	Decreased	Increased
STAGE 5 (after 25–30 years): End stage renal failure	Advanced glomerulopathy	Macroalbuminuria/Often decreased due to glomerular occlusion	Marked decreased	Increased

mechanisms have been implicated in the pathogenesis of increased GFR, such as angiotensin II, prostaglandins, kinins, growth hormone (GH) and insulin-like factor-I (IGF-I), nitric oxide, and glucagon (26). It is not clear yet whether the primary abnormality in this phase is hyperfiltration or renal hypertrophy. On the basis of the "vascular hypothesis," the first alteration is hyperfiltration, as a consequence of defects in vascular control, and this is then followed by renal hypertrophy (26). In contrast, the "tubular hypothesis" suggests that renal hypertrophy comes first, due to an increased production of growth factors and cytokines induced by hyperglycemia (26). Longitudinal studies in children and adolescents with type 1 diabetes have suggested hyperfiltration as an independent predictor for MA and DN (27–30). However, other studies have failed to detect such a predictive value for hyperfiltration (31, 32) and therefore this topic still remains controversial.

The second stage in the natural history of DN is represented by a "silent phase," which develops over 2–5 years after diagnosis and is characterized by subtle morphological changes, including basement membrane thickening, mesangial expansion, glomerular hypertrophy and a modest expansion of the tubulo-interstitium (24). During this phase, patients may occasionally present MA, particularly during periods of poor metabolic control or intensive exercise. There is increasing evidence suggesting that during this phase, there is already a progressive increase in albumin excretion within the normal range, which represents an important predictor for MA, DN and cardiovascular disease (23, 24).

A progressive increase in albumin excretion leads to the phase of MA (or incipient nephropathy), defined as a urinary AER of 20–200 μg/min or 30–300 mg/24 h (10). The development of persistent MA may be associated with increased arterial blood pressure and a progressive decline in renal function, with a high risk of developing ESRD and an increased risk for cardiovascular disease (10). At the stage of MA there are already well-established histological and functional renal alterations (33).

A progressive increase in AER leads to the fourth stage of DN, which corresponds to overt nephropathy or macroalbuminuria, as defined by albustix-positive proteinuria (AER > 200 μg/min or >300 mg/24 h). Overt nephropathy is characterized by proteinuria, hypertension and a progressive decline in GFR, which, without treatment, evolve to ESRD (fifth stage of DN), generally 5–10 years after the diagnosis of proteinuria (25).

Risk Factors

Several risk factors, both modifiable (glycemic control, hypertension, dyslipidemia, diet, smoking) and non-modifiable (diabetes duration, puberty, genes, constitutional factors), have been related to the development of DN.

Glycemic Control

Several observational studies have shown a strong correlation between glycaemic control, as assessed by HbA1c, and DN in adults and children with type 1 and type 2 diabetes (20, 22, 34). In addition, it has been demonstrated that the probability of reverting from MA to normoalbuminuria is significantly related to a better glycemic control (35). Further evidence for the fundamental role of hyperglycemia in the pathogenesis of DN in type 1 and type 2 diabetes comes from two landmark interventional studies, such as the Diabetes Control and Complication Trial (DCCT) (36) and the United Kingdom Prospective Diabetes Study (UKPDS) (37). The DCCT, a multicentre prospective controlled clinical trial involving 1,441 patients with type 1 diabetes, has proved the effect of maintaining low levels of HbA1c in reducing the development of MA by one third, during a mean follow-up of 6.5 years. The DCCT cohort included a group of 195 adolescents, aged 13–17 years, but not prepubertal children. In this adolescent cohort, intensive compared to conventional treatment reduced the risk and progression of MA by 54% (38). In addition, the DCCT follow-up study, the Epidemiology of Diabetes Interventions and Complications (EDIC) (39), highlighted the important phenomenon of "metabolic memory." In fact, even though 2 years after the end of the DCCT, HbA1c levels were already similar between the previously intensive and conventional treated groups, those who benefited in the past from a better metabolic control still had an advantage in terms of development of complications (39). With regard to the adolescent cohort, the EDIC study showed that, in the previously intensively treated group, the risk of MA and proteinuria decreased by 48 and 85%, respectively (39). Another interesting finding that emerged from both the DCCT and the UKPDS (36, 37) was the lack of a clear threshold for HbA1c below which the risk of complications is annulled; instead there was a continuous reduction in complication risk as glycemic control improved. In contrast, another study showed a threshold effect for the development of MA at an HbA1c value of about 8.1% (40).

Hyperglycemia contributes to the development of DN through several mechanisms: activation of the polyol and hexosamine pathways, activation of protein kinase C (PKC), increased oxidative stress, increased production of advanced glycation end-products (AGEs), increased synthesis of growth factors, cytokines and angiotensin II (41). These factors can induce relevant structural and functional changes in the kidney. Furthermore, many of these factors can also promote early alterations in endothelial cells, which are responsible of the development of endothelial dysfunction. Several studies have shown that endothelial dysfunction is associated with the development not only of macrovascular disease but also of microvascular complications, such as MA and DN (42).

Blood Pressure

Increased blood pressure in people with diabetes significantly increases the risk of progression towards ESRD (28). Evidence also exists of a link between increased blood pressure and earlier stages of DN, such as MA (10). A direct correlation between albumin excretion and increases in blood pressure is present, even when both these parameters are still in the normal range and, in patients with MA, improvements in albumin excretion are often seen after antihypertensive treatment (43, 44). However, the temporal relationship between MA and rises in blood pressure has not been clarified yet, as different studies have often reached different conclusions (45–48). On one hand, increases in blood pressure have been found to precede MA and therefore to influence its development (46, 48). On the other hand, other studies have not supported this hypothesis and suggest that the two phenomena could appear together (45, 49). Increases in blood pressure, particularly at night, are often associated with MA and DN (50). However, subtle alterations in blood pressure and an impairment of its circadian rhythm can often be undiagnosed through assessment of office blood pressure. In contrast, the use of ambulatory blood pressure monitoring has allowed the identification of early alterations in blood pressure, both in adults and children with diabetes (50). An impairment in the nocturnal fall in blood pressure has been suggested as a predictor of future development of MA (51). In a group of 75 adolescents followed for a mean of 5 years, an impaired circadian variation in blood pressure with loss of the nocturnal dipping was detected before the onset of MA (51). However, the predictive value of the non-dipping phenomenon has not been consistently reported in all studies. In particular, some studies have shown significant overlaps in the nocturnal fall in blood pressure between normoalbuminuric and microalbuminuric subjects (52). In addition, differences between these two groups often disappear after adjusting for potential confounders, such as diabetes duration (52).

Dyslipidemia

It has been suggested that measurement of plasma lipids can add to the prognostic value of albumin excretion rate

measure in the prediction of subjects at risk of developing DN (53). Based on adult studies, subjects developing MA have higher cholesterol levels than subjects who do not progress (54) and reduction in cholesterol levels predicts regression of MA to normoalbuminuria (54). Triglyceride levels have also been suggested as a predictor of progression or regression of MA (55, 56). However, there is a lack of longitudinal studies investigating the relationship between lipid levels and the development of MA and DN in children and adolescents. On the basis of available cross-sectional studies, it appears that total cholesterol and low density lipoprotein cholesterol levels can influence the development of DN (57, 58). Similarly, from a longitudinal study it has emerged that cholesterol levels could influence the development of MA in children and adolescents with type 1 diabetes (59).

Puberty

Puberty represents an important risk factor for DN and MA often develops during this period of life in children with type 1 diabetes (60). Pubertal development is characterized by many physiological changes, involving both hormonal and metabolic processes (61). These factors together with psychological issues are frequently responsible of a poor metabolic control (61). However, there is also clear evidence that puberty itself, independently of glycemic control, is a risk factor for the development of MA, with a significantly higher risk for female than for male subjects (62). Changes in sex hormones and in the GH-IGF axis have been shown to play an important role in this context (63). These changes can interact with the diabetic milieu and the genetic background and cause a higher predisposition to the development of complications, such as DN. The higher testosterone levels and free androgen index found in adolescent girls with MA when compared with matched controls without MA (63) could contribute to renal disease and also to the female predominance of this complication during puberty (22, 62, 63).

Puberty is generally associated with a decrease in insulin sensitivity, which reaches a peak at stages 3 and 4 (64, 65). Adolescents with type 1 diabetes are more insulin resistant when compared with healthy controls (61), and this has mainly been attributed to the effect of increased GH. Circulating GH levels are increased in adolescents with type 1 diabetes, whereas circulating IGF-I levels are decreased, due to reduced portal insulin and consequent lack of effect of insulin on the expression of GH receptors in the liver (66, 67). In contrast, as the expression of GH receptors seems to be insulin-independent in other peripheral organs and tissues, such as the kidney, an increased local production of IGF-I with an associated paracrine action could be implicated in renal disease (66, 67). In cross-sectional studies these high renal levels of IGF-I have been associated with the development of DN (68). Increased urinary GH and IGF-I levels have been found in adolescents with type 1 diabetes and correlated with albumin excretion (68). In addition, increased urinary GH has been related to increased renal size, which in turn is a risk factor for MA (68).

Age at Diagnosis and Duration of Diabetes

Duration of diabetes is another major factor associated with the risk of complications (4). In children, the relationship between diabetes duration and risk of MA has been found in some studies (14, 19, 62), but not confirmed in others (12). The role of prepubertal duration of diabetes has been the object of wide discussion, generated by discordant results that emerged from several studies. Although in some studies (14, 69–71) the risk of developing MA was higher in children with onset of diabetes at or after puberty, suggesting that prepubertal duration was not a main determinant, other studies have underlined the contribution of prepubertal duration to the risk of developing MA (72–75). Children with onset of diabetes before the age of 5 years may have a delayed onset of complications, but after puberty there is an acceleration in their development (62, 76). Furthermore, some children with an early prepubertal onset of diabetes can also develop MA before puberty (62). Similar data have been found also for the risk of retinopathy in children with prepubertal onset of diabetes (77). Therefore, it appears that prepubertal years contribute to the development of microvascular complications, even though to a lesser extent than post-pubertal years.

Genetic Factors

The finding that, irrespective of a good glycemic control, some patients still develop complications (78), suggests that other factors, either environmental or genetic, are implicated in their etiology.

Only 30–50% of subjects with type 1 diabetes are at risk for DN and epidemiological and family-based studies support the role of genetic factors in its pathogenesis. The increasing prevalence of DN during the first 20 years after

diagnosis, followed by a plateau (78), suggests that only a subset of patients is really susceptible to this complication. The DCCT and other studies have shown a familial cluster of DN, with an increased risk of developing nephropathy for siblings of a proband with DN when compared to siblings of a proband without DN (79).

A family history of hypertension has also been shown to be a risk factor for developing DN (80). Parents of patients developing DN have higher blood pressure when compared to parents of subjects free of this complication (81, 82), and the risk seems to be increased by three-four fold. In addition, a family history of dyslipidemia, insulin resistance, type 2 diabetes or of a cluster of these cardiovascular risk factors, significantly increases the risk of diabetic kidney disease (83, 84), suggesting a role for cardiovascular genes in predisposing to nephropathy.

DN appears to be a complex genetic trait, with the contribution of different genes and an effect of their interaction with environmental factors (85). Several genes have been suggested as potential candidates in the pathogenesis of DN, but there is no evidence for a major effect of a single gene so far (85). DN is the combination of albuminuria and reduced GFR and it has been shown that both these components are highly heritable traits and that they have a different genetic basis (85). However, the results of genetic studies have been often conflicting, due to differences in the populations studied, to the small sample size, and also to differences in the definition of the trait analyzed (86). Among the most common genes that have been investigated for their potential relationship with DN are those encoding for components of the renin-angiotensin system, and mainly the angiotensin converting enzyme (ACE) gene and the angiotensin receptor I gene. In particular, the insertion/deletion polymorphism in the ACE gene has been the object of intense investigations. However, as emerged from a meta-analysis, it appears to have a small effect on the risk for developing DN in European populations (87). Polymorphisms in the ACE gene have been related also to differences in the response to treatment with ACE inhibitors (ACEIs) (88), thus suggesting the importance of future pharmacogenomic approaches in this area.

Other candidate genes have been those encoding lipoproteins (in particular apolipoprotein E), aldose reductase and heparane sulfate (89). In addition, as it is well known that inflammation, glycation and oxidation pathways as well as growth factors play an important role in the development of vascular complications, other possible candidate genes might be those encoding for components of these systems (89).

Smoking

Smoking is an independent risk factor for the development and progression of DN in adults with diabetes (90, 91). In a large prospective study in young individuals with type 1 diabetes, smoking was associated with 2.8-fold increased risk of MA whereas smoking cessation caused a significant improvement in AER (92). The link between smoking and DN can be related to an increased oxidant burden caused by cigarette smoking (93). In addition, as smokers have also higher blood pressure then non-smokers (94), this can represents an additional connection between smoking and the risk of developing DN.

Diet

A high protein intake has been suggested as a potential risk factor for the development of DN, with a normalization of GFR associated to a reduction of protein intake (95, 96). It seems that animal proteins exert a stronger effect than vegetable proteins (97), whereas a high intake of fish proteins has emerged as a factor able to reduce the risk of DN (98). The exact mechanisms to explain the association between protein intake and DN are not completely clear, although glucagon, prostaglandin and the renin-angiotensin system have been suggested as potential mediators (97, 99).

Other factors investigated in relation to DN are fat, minerals, vitamins and fibers (100–102). In particular, as DN is associated with an increased oxidant burden, the potential effect of treatment with anti-oxidants has been investigated, but the results have been inconclusive (103–105).

Other Factors

Recently, it has been shown that in adolescents with type 1 diabetes, clinical markers of insulin resistance, such as body mass index, are associated with the development of MA, in addition to glycemic control (106).

Another factor that has been related to DN is low birth weight (107). Intrauterine growth retardation, due to intrauterine or genetic factors, might lead to reduced nephron number and a decreased renal functional reserve with increased susceptibility to DN, in response to other environmental factors (107). This theory could also explain the association of short stature and risk of DN (107, 108).

Pathogenesis

DN is the result of an interplay between hemodynamic and metabolic factors in the renal microcirculation (109), and the consequent activation of common intermediate pathways, associated with increased synthesis and release of growth factors, cytokines, chemokines and oxidant species, which are all final mediators of renal damage (109) (*Fig. 50-1*). Typical morphological changes in the diabetic kidney are represented by diffuse glomerular basement membrane thickening, mesangial expansion, hyalinosis of the mesangium and arteriolar walls, broadening and effacement of podocyte foot processes, reduction in podocyte number, glomerulosclerosis and tubulointerstitial fibrosis (110). These morphological changes in the kidney develop years before the clinical appearance of MA and overt proteinuria and this is an alarming aspect of DN, given that when the disease is clinically evident, some of the structural damage is already irreversible (33).

Thickening of the basement membrane is a common bioptic finding related to DN; it is associated with loss of glycosaminoglycans and therefore of negative charges, with consequent increased loss of anionic albumin (111, 112). A subsequent increase in the size of membrane pores leads to the development of non-selective proteinuria. An imbalance between the production and the degradation of mesangial matrix proteins, together with an increase in mesangial cells number, is responsible for mesangial expansion in DN (112). Hyperglycemia and renal hypertension together with other factors can activate pathways leading to an increased synthesis and deposition of matrix proteins, particularly by stimulating local production of cytokines and growth factors (113).

Figure 50-1

Furthermore, the same factors can inhibit proteins and enzymes implicated in the degradation of the extracellular matrix, for example by a non-enzymatic glycation of these components (113).

As in other progressive glomerulopathies, changes in podocyte characteristics are a key feature of DN (114). Podocytes are highly specialized epithelial cells, interconnected by foot processes, which delimit the slit diaphragm, the main size-selective barrier in the glomerulus. The diabetic milieu can induce several morphological changes in these epithelial cells, as emerged from both human and experimental studies (111). The first detectable alteration in podocytes in the context of DN is a broadening and effacement of their foot processes (111). These progressive podocyte changes lead to a decrease in their density and number and a detachment from the glomerular basement membrane. The last phenomenon is directly correlated to levels of AER and to the decline in GFR (111). Podocytes can also undergo hypertrophy, apoptosis and increased synthesis of collagen IV, whereas there is a decreased synthesis of proteins such as nephrin (111).

Another characteristic of DN is the hyalinosis of the afferent and efferent arterioles in the glomerulus, due to the accumulation of complement components, fibrinogen, immunoglobulins, albumin and other plasma proteins (115). Hypertrophy and sclerosis of the iuxtaglomerular apparatus is another frequent finding in DN (116).

Hemodynamic Factors

Hemodynamic factors implicated in the pathogenesis of DN include systemic and intraglomerular pressure and activation of vaso-active mediators (109). Glomerular hypertension is the result of reduced resistance in both the afferent and efferent arterioles, an effect which is predominant in the former. On the basis of several experimental studies it has been suggested that a subset of patients with diabetes could be predisposed to intraglomerular hypertension, due to defects in the renal mechanisms of flow autoregulation (117). The lack of the normal vasoconstriction in the afferent arteriole in response to increased systemic hypertension, associated with the constriction of the efferent arteriole, contribute to the increase in intraglomerular blood pressure (113). A potential mediator of the afferent arteriole dilation is an increased oxidative burden. It has been hypothesized that some reactive oxygen species (ROS) might affect K+ channels in the afferent arteriole with consequent hyperpolarization and increased Ca+ influx and vasodilatation. K+ channels have a dominant role in the electromechanical function of the afferent arteriole but only a minor effect on the efferent arteriole (118). Glomerular hypertension can in turn induce the activation of several pathways and molecules, which can mediate renal injury. In particular, it has been shown that it can, for example, activate GLUT-1 in glomerular cells, thereby inducing an intracellular hyperglycemic milieu (113).

Angiotensin II is a key mediator of DN, exerting both hemodynamic and non-hemodynamic effects (109). The hemodynamic effects of angiotensin II include both systemic and renal vasoconstriction (119). In the kidney, angiotensin II also increases glomerular capillary pressure and permeability. Non-hemodynamic effects of angiotensin II include activation of transforming growth factor-beta 1 (TGF-ß1) and other cytokines, activation of ROS production in mesangial cells, stimulation of extracellular matrix and inhibition of its degradation, activation of the intracellular NF-kB and reduction in podocyte nephrin expression (119, 120). Other factors that have been implicated in the hemodynamic changes related to DN are vasoactive factors, which can influence intrarenal circulation by acting on the afferent and efferent arterioles. In particular, endothelin and angiotensin II are the most relevant vasoconstrictors in this context, whereas nitric oxide, bradykinin and prostaglandins are the main vasodilators (109).

Metabolic Factors

Growth Factors

Several growth factors have been implicated in the pathogenesis of DN, through complex intra-renal systems (121–123). GH/IGF, TGF-ß, vascular endothelial growth factor (VEGF), epidermal growth factor, and connective tissue growth factor (CTGF) are among those better known and investigated (121–123).

The implication of the GH-IGF system in the pathogenesis of DN is well established (121, 122). Diabetes is associated with decreased hepatic production of IGF-I related to portal insulinopenia, with consequent lack of the inhibitory feedback of IGF-I on the anterior pituitary and therefore GH hypersecretion (66, 67). The integrity of GH receptors in peripheral tissues, other than the liver, can cause a local increased production of IGF-I, which can in turn exert paracrine effects (66, 67). Antagonist of the GH/IGF-I system, including somatostatin analogues, GH and IGF-I receptors antagonists as well as antagonists of downstream factors activated by GH/IGF-I, such as the

ACE and AGEs systems, have been found to have beneficial effects on the diabetic kidney in animal models (121).

TGF-ß is considered a crucial factor in the development of renal kidney disease (121–123). It appears to be a key point of convergence of both hemodynamic and metabolic pathways activated in DN. In the diabetic milieu several factors can induce increased expression of this growth factor, such as PKC, hyperglycemia and hypertension, and mechanical strains. TGF-ß is a profibrotic cytokine, thus having an important role in the expansion of the extracellular matrix, by stimulating the production of several components of the matrix and, in the meantime, by altering extracellular matrix composition (121–123).

VEGF is another relevant growth factor implicated in the pathogenesis of DN, even though its role in this context is not as well defined as for diabetic retinopathy (121–123). In particular, VEGF is a key angiogenic factor, which influences the proliferation of endothelial cells and exerts a pivotal role in vascular integrity (123). Anoxia is an important stimulus for its production as well as AGEs, angiotensin II and oxidative stress (123). VEGF is expressed in different cells in the kidney, including podocytes and tubular cells. Increased VEGF levels have been reported in both type 1 and type 2 diabetes and have been related to DN (124). In children with type 1 diabetes developing MA, VEGF levels are increased when compared with diabetic children with normoalbuminuria, and they have an independent predictive value for future development of DN (125).

CTGF is one of the most recent identified growth factors with a role in DN. Increased concentrations of CTGF have been detected in the glomerulus of diabetic patients and animals (126–128). In adult patients with type 1 diabetes, increased levels of CTGF are strongly correlated with the severity of DN (129, 130) and are an independent predictor of ESRD and mortality (131). CTGF is considered the downstream mediator of TGF-ß in extracellular matrix synthesis. However, there is also evidence of a TGF-ß-independent regulation of CTGF, which is related to a direct activation of its synthesis by hyperglycemia, AGEs and static pressure (128, 132, 133).

Cytokines

DN is considered an inflammatory disease and several cytokines have been implicated in its pathogenesis: interleukin (IL)-1, IL-6, IL-18, and tumor necrosis factor-alpha (TNF-α) (134). In the kidney, inflammatory cytokines are synthesized and released by endothelial, mesangial, glomerular and tubular cells (134). IL-1 has been implicated in increased vascular permeability, proliferation of extracellular matrix and abnormalities in microcirculation (134). IL-6 can also induce changes in the extracellular matrix (134). TNF-α has been shown to have a cytotoxic effect on glomerular, mesangial and epithelial cells in the kidney (123, 134).

Chemokines and cytokines implicated in the recruitment of monocytes/macrophages have been related to the development and progress of DN (135). Monocytes chemoattractant protein-1 (MCP-1) is a chemokine with the highest chemotactic activity towards monocytes. A causative role in the development of DN has been suggested for MCP-1, as a result of the recruitment of monocyte/macrophage in the kidney (136). Furthermore, in vitro studies have shown that MCP-1, by interacting with its receptor (CCR2), can promote fibronectin deposition in the diabetic glomerulus (137). Blocking the MCP-1/CCR2 pathway ameliorates glomerulosclerosis, indicating that the MCP-1/CCR2 pathway could play a crucial role in the progression of DN (138). Increased MCP-1 levels have been reported in subjects with diabetes when compared with controls and it has been shown that plasma and urine MCP-1 levels can be used to assess renal inflammation in this disease (139).

AGEs and their Receptors

Another link between elevated glucose levels and DN is the direct effect of non-enzymatic glycosilation on cellular macromolecules, causing alterations in their structural and functional properties (140–143). AGEs have been implicated in several biologic activities, mostly by binding to the AGE-specific receptors (RAGEs) on many cells (141, 142). In particular, they can enhance oxidative stress and stimulate the release of cytokines and growth factors, which in turn accelerate chronic inflammation and endothelial dysfunction (141). Increased serum levels of AGEs have been detected in children and adolescents with type 1 diabetes, even before the development of clinically evident signs of microvascular complications (144).

Animal studies support the role of AGE in the pathogenesis of DN. In fact, blocking of AGE, with aminoguanidine, significantly reduces renal changes (145).

There is also a large body of evidence of a predictive role for the soluble form of the RAGE (sRAGE) in the development of vascular diabetic complications, including DN (146). sRAGE can be measured in peripheral blood and it seems to result from the expression of a RAGE splice gene variant that encodes an amino-terminally

truncated form of the receptor and/or from the cleavage of the native membranous receptor (146). Serum sRAGE levels are significantly higher in type 2 diabetic patients than in non-diabetic subjects and positively associated with the presence of coronary artery disease (147) and also independently related to albumin excretion (146). A circulating C-truncated form of RAGE (esRAGE) exists and seems to work as a scavenger for AGEs and in this way could exert a protective influence for diabetic complications. Reduced circulating levels of esRAGE have been found in patients with type 1 diabetes, and related to the severity of vascular complications (148).

Oxidative Stress

Oxidative stress is one of the most important factors involved in the pathogenesis of DN (113, 143). Several pathways have been related to an increased production of oxidative stress in the context of DN: increased mitochondrial electron transport, the AGEs-RAGE system, an increased activity of cytochrome P-450, xantine oxidase, cyclooxigenase and lipoxigenase, increased glucose autooxidation and an impaired activity of endothelial nitric oxide synthase (149). Many of the pathways activated by hyperglycemia can induce mitochondrial superoxide overproduction and blocking of this effect can reduce damage related to high glucose levels (150, 151). This increased mitochondrial production of ROS can in turn stimulate different processes, including PKC activity, synthesis of growth factors and cytokines, and stimulation of NF-kB. Oxidative stress seems to play an important role also in the context of the so-called "metabolic memory" (41). In fact, increased mitocondrial superoxide production consequent to hyperglycemia could induce not only immediate effects, such as activation of PKC or other pathways, but might also damage mitocondrial DNA (41). This, in turn, could lead to synthesis of altered subunits of the electron-transport system, which could produce increased amounts of superoxide, even in the presence of physiological glucose levels (41).

Intracellular Factors

Polyol and Hexosamine Pathways

The polyol pathway has been implicated in the pathogenesis of DN, through the action of aldose reductase, the first and rate-limiting enzyme in this pathway (41). Aldose reductase reduces the aldeide form of glucose to sorbitol in a reaction which consumes NADPH. In physiological situations sorbitol is then oxidized to fructose by sorbitol dehydrogenase and therefore addressed again into the glycolisis. In the presence of hyperglycemia, the production of sorbitol overcomes the potential of its oxidation by sorbitol dehydrogenase, with accumulation in several cells, including renal tubular and glomerular cells. Several mechanisms have been suggested to link the polyol pathway to the development of diabetic complications. These include a dysregulation of the cellular osmotic status, reduction of Na+/K+-ATPase activity, cytosolic increase in NADH/NAD+ and decrease in NADPH (41). The depletion of NADPH appears to be the most important mediator, as it is associated with an impairment of several enzymatic reactions requiring this enzyme, such as nitric oxide synthase, cytochrome P450, and glutathione reductase, thereby altering the intracellular oxidant-antioxidant status and inducing vasoconstriction and poor blood supply (41).

The hexosamine pathway converts fructose-6 phosphate in N-acetyl glucosamine, which is a substrate for reactions such as proteoglycan synthesis and generation of *O*-linked glycoprotein (41, 152). N-acetyl-glucosamine has been implicated in the activation of the transcriptional factor Sp1, which is associated with increased synthesis of factors, such as TGF-ß1 and plasminogen activator inhbitor-1, which in turn are associated with the development of vascular complications (41, 152). In addition, the hexosamine pathway is also associated with increased oxidative stress and the effects of the activation of this pathway can be prevented by overexpression of antioxidants, such as superoxide dismutase (150).

Diacylglycerol (DAG)-PKC Pathway

The DAG-PKC system can induce several alterations, which can contribute to DN (41, 153, 154). These mechanisms include changes in endothelial permeability, vasoconstriction, increased synthesis of extracellular matrix and stimulation of cytokine synthesis, cell growth, angiogenesis, and leukocyte adhesion (41, 153, 154).

Hyperglycemia can stimulate de novo synthesis of DAG, followed by the activation of PKC (41). PKC modulates the activity of various enzymes, including phospholipase A2 and Na+/K+ ATPase, as well as the expression of genes related to components of the extracellular matrix (41, 153). PKC-beta is the major isoform induced in the kidney by hyperglycemia and ruboxistaurin, a PKC-beta isoform selective inhibitor, has been shown to have a beneficial effect on microvascular complications, by

normalizing endothelial dysfunction and GFR and reducing loss of visual function (145).

Screening and Diagnosis

Assessment of Albumin Excretion and GFR

Albumin excretion. Measurement of albumin excretion is the basis for the diagnosis of DN (25). MA is the earliest detectable marker of DN and represents an important risk factor for the development of DN and cardiovascular disease (53). MA is not only a phenomenon related to renal damage, but is associated with a more generalized sieving of albumin from the blood bed, due to a diffuse endothelial dysfunction (42).

Screening for MA can be performed in three ways: (1) 24-h collection (2) timed collection (e.g. 4-h or overnight); (3) a spot urinary sample (155). 24-h or timed urine collections are often difficult to be performed with accuracy, particularly in children. Therefore, the easiest way is the assessment of the albumin-creatinine ratio (ACR) on a spot urine sample, preferably using the first voided urine in the morning, in order to avoid bias related to the known diurnal variation in albumin excretion. The correct interpretation of albumin excretion requires that other factors and conditions which could influence it are excluded. Exercise, urinary tract infections, acute febrile illness, immunoglobulin A or other forms of nephritis, marked hypertension, and menstrual cycle in women can all cause transient increase in albumin excretion. Given that the intra-individual daily variation in albumin excretion may fluctuate by 40–50%, multiple measurements of albumin excretion are required (155).

The definition of MA can be: (1) AER between 20 and 200 μg/min or 30–300 mg in 24-h urine collection; (2) ACR 2.5–25 mg/mmol in males or 3.5–25 mg/mmol in females; (3) albumin concentration 30–300 mg/l in early morning urine sample (155). Persistent MA is defined as 2 out of 3 abnormal samples collected over a period of 3–6 months (155). Values above the upper limit for MA definition are diagnostic of macroalbuminuria or overt nephropathy.

Based on the guidelines of the International Society for Pediatric and Adolescent Diabetes, screening should be performed from the age of 11 years with 2 years of diabetes duration and from the age of 9 years with 5 years diabetes duration (155) (*Table 50-2*). The American Diabetes Association recommends that annual screening should start once the child is 10 years of age and has had a diabetes duration of 5 years and to test more frequently if the values are increasing (156).

Table 50-2

Screening recommendations based on the International Society for Pediatric and Adolescent Diabetes (ISPAD) guidelines 2006–2007

Screening recommendation for MA
• Annually assessment of albumin excretion from age 11 years with 2 years of diabetes duration and from age 9 years with 5 years of duration
• Method: Urinary albumin/creatinine ratio
• Exclude other causes of increased albumin excretion: strenuous exercise, orthostatic proteinuria, hypertension, acute febrile illnesses, smoking, urinary infections, nephritis, menstruation

GFR. The National Kidney Foundation (NKF) strongly recommends measuring GFR in subjects at risk of kidney disease, such as diabetic patients (157). Alterations in GFR can be predictive of future deterioration of renal disease and, in addition, are an important predictor of cardiovascular events (158). A 10-year follow up study has clearly shown the role of reduced GFR in identifying adult patients with diabetes at high risk for cardiovascular mortality (159). Evaluation of GFR has an important role in identifying alteration in renal function, even in the presence of albumin excretion in the normal range (160, 161). A recent study performed in patients with type 1 diabetes has shown a progressive decline in renal function as an early event in patients with MA (162). Furthermore, an increased GFR is a common finding during the early stages of diabetes and is associated with hyperperfusion and increased renal size (27, 163, 164). In human studies, this early stage of hyperfiltration has been found to be an important predictor of future development of nephropathy (27–30, 165), independent from glycemic control, even though this has not been confirmed in all studies.

The direct evaluation of GFR is difficult to perform, being time-consuming and requiring expertise and specific laboratory techniques for the analysis (166). The evaluation of creatinine clearance is a possible alternative but it requires timed urine collection and consequently it can be difficult to be performed accurately, particularly in children. Plasma creatinine should be an easier alternative (167). However, it is influenced by several factors, particularly in children and adolescents. In fact, plasma creatinine levels are influenced not only by renal filtration rate but also by tubular secretion, age, gender, changes in muscle mass related to growth and puberty (167).

Formulae based on creatinine levels and allowing for confounding factors, such as body composition, have been developed and used for a long time in children. The NKF recommends the use of the Schwartz or the Counahan-Barratt formulae (168, 169) for the estimation of GFR in subjects below 18 years of age (157). These formulae represent a simple mathematical calculation applicable for the day-to-day clinical evaluation of GFR in children. However, the determination of height at the time of creatinine measurement is a fundamental point in applying these formulae. This represents a relevant limitation because height is not easily available or verifiable in the laboratory where creatinine is measured and GFR calculated. Another important point in the application of these formulae is that, as they include a constant k, each laboratory needs to derive its own constant to increase the accuracy of the GFR estimation (170). Furthermore, creatinine-based formulae as well as creatinine clearance are unreliable in the hyperfiltration state. Therefore, the search for a new endogenous surrogate marker of GFR to be applied instead of the cumbersome direct assessment of GFR is highly required and different plasma markers, such as cystatin C or symmetric dimethylarginine, are under consideration in both adult and pediatric populations (171).

Emerging Roles of Proteomic and Genomic Approaches in the Prediction, Detection and Monitoring of Diabetic Nephropathy

DN is a complex disease, with different mechanisms implicated in its pathogenesis and progression (109). The disease is often silent for years, even though during this period of time significant morphological alterations have already occurred in the kidney (111). The characterization of predisposing genetic factors and of blood or urinary markers is particularly important for the identification of subjects at risk and the implementation of preventive and therapeutic strategies, ideally by personalizing them on the basis of the patient risk profile (172). This is the basis for the role of a genomic and proteomic approach in DN (173, 174). In particular, genome-wide association studies represent an important attempt at the identification of the genetic basis of DN and the development of clinical proteomic investigations to possibly highlight new molecular markers diagnostic and/or prognostic of DN (174). Several large multicenter studies such as the Genetics of Kidneys in Diabetes, the Family Investigation of Nephropathy and Diabetes, the Epidemiology of Diabetes Interventions and Complications, and the European rational approach for the genetics of diabetic complications study, are currently underway, searching for DN susceptibility genes (175). Genomic and proteomic technologies could be used to assess gene expression and specific protein expression directly in kidney tissues, even at the time of onset of diabetes to characterize the patient's risk profile. Several experimental studies have already explored the protein expression profile in the kidney (173). However, in humans, a potential limitation for this application of genomics and proteomics is represented by the need for kidney biopsies. A valid alternative is the application of these new technologies on urinary and blood samples. Initial studies in humans have applied proteomics to assess the potential urinary protein profile, which could help in identifying subjects at risk of DN (174). A pilot study in adolescents with type 1 diabetes has detected specific urinary polipeptides associated with diabetes and, even more interestingly, a specific pattern of peptides associated with early nephropathy (176). Similarly, in adults with type 2 diabetes, specific urinary polypeptides have been related to the risk of developing DN (177). Therefore, the application of proteomics for the identification of the pattern of urinary or plasma proteins appears to be a reliable and feasible way to predict and monitor DN.

Prevention and Treatment (◉ *Table 50-3*)

Intensive Blood Glucose Control

The DCCT and the EDIC have provided strong evidence for the important role of strict glycemic control for the reduction of risk of micro- and macro-vascular complications in subjects with type 1 diabetes, including adolescents (36, 38, 39). In the adolescent cohort of the DCCT, beneficial effects on complications were obtained, even though the mean HbA1c was significantly higher, by about 1%, when compared to the adult cohort (38). This

Table 50-3

Preventive and treatment strategies for DN in children and adolescents

Preventive and treatment strategies
• Optimizing glycemic control
• Control blood pressure
• Control lipid levels
• Moderate decrease in protein intake
• Avoid smoking

underlines an important issue in achieving good metabolic control during puberty. Psychological issues, together with the effect of the physiological insulin resistance (64, 65) that occurs during puberty and the numerous changes in the hormonal milieu (61), give rise to several problems in managing adolescents with type 1 diabetes (61). Other studies have also shown the difficulties in achieving good glycemic control and avoiding the risk of episodes of hypoglycemia and weight gain in the meantime (178). The issue of weight gain is of particular relevance for adolescent girls, who often drop their insulin injection to avoid overweight (179). Therefore, other strategies need to be implemented to improve glycemic control, particularly during adolescence.

Blood Pressure Control

In adults with type 1 diabetes and MA, treatment with ACEIs or angiotensin receptor blockers (ARBs) is recommended, based on the evidence of a positive effect in reducing the rate of progression and promoting regression of MA (10). A beneficial effect of ACEIs has been shown in microalbuminuric normotensive patients, in whom the ACE inhibition arrests the increase, and even reduces, AER (180). Furthermore, in patients with diabetes but with albumin excretion within the normal range, ACEIs have been proved to be effective in reducing the risk of developing MA (43). This effect appears to be independent of baseline blood pressure, renal function and type of diabetes (181). Both ACEIs and ARBs have been shown to be effective, but the use of ARBs has been associated with increased risk of all-cause mortality when compared to placebo (182).

However, there is no guidance for the use of ACEIs or ARBs in the pediatric population in the context of MA. In fact, these drugs have been approved and used in the treatment of hypertension, but there is no indication regarding MA. Four small studies have been performed and confirmed the likely efficacy of ACEIs in adolescents with MA but there have been no formal randomized controlled trials (RCT) (183–186). Overall these studies have shown that ACEIs lead to a reduction in albumin excretion. However, it is difficult to draw definite conclusions from these studies and the issue of the potential long-term use of ACEIs in individuals with MA also raises the problem of potential side effects of these drugs.

The ADA recommends starting treatment with ACEIs for persistent MA (156). Similarly the recent ISPAD guidelines suggest using ACEIs or ARB for persistent MA to prevent progress to proteinuria, even though they acknowledge the lack of evidence in this context (155).

Management of Dyslipidemia

Many large-scale interventional trials have demonstrated that treatment with statins, the most effective lipid lowering drug class, significantly reduces the risk of coronary heart disease events and total mortality (187). People with diabetes and DN often present with dyslipidemia and statin therapy has been associated with a significant reduction in the risk of macrovascular complications (187). Statins have effects other than the reduction in cholesterol levels (188). In fact, they also have other beneficial properties, such as inhibition of arterial smooth muscle cell proliferation, prevention of oxidation of LDL cholesterol, plaque stabilization, effect on macrophages, improvement of endothelial dysfunction, and anti-inflammatory and anti-thrombotic effects (188). These actions might be beneficial at the renal side. Even though dyslipidemia is often found in children and adolescents with diabetes (59, 189–191), there is no consensus on the role of statin treatment in this age group, mainly because no RCTs have been conducted.

Diet Intervention and Smoking Cessation

A low protein diet seems to reduce the increase in albumin excretion rate and the decline in GFR in adults with type 1 diabetes. A meta-analysis of studies investigating the effect of protein intake has shown that a diet restriction to 0.5–0.8 g/kg/day reduces the risk of progression of DN (192). However, there are no specific data for children and adolescents, where generally a minimum of protein intake of 1 g/kg is sufficient for normal growth, but it is not clear whether this reduces the risk of DN (193).

As smoking is common among adolescents with type 1 diabetes (194) and it is related to the development of DN (90), it is important to discourage young people as early as possible from smoking.

New Potential Therapeutic Strategies

New potential therapeutic possibilities for the treatment of DN are emerging and they include drugs targetting

specific pathways implicated in the pathogenesis of DN (inhibitors of advanced glycation, PKC inhibitors, and glycosaminoglycans) (145, 195).

Glycosaminoglycans are among the biochemical components of the glomerular basement membrane matrix structure (196). Sulodexide, an oral formulation of the natural glycosaminoglycan, composed of 80% fast-moving heparan sulphate and 20% dermatan sulphate, has been shown to have potential nephroprotective effects, through several mechanisms, which could explain its remodeling effect (196). Several studies have analyzed its effects on albumin excretion and two RCTs in particular have shown a significant anti-albuminuric action (196). However, till now there are no available studies on this new drug in children and adolescents with diabetes.

Ruboxistaurin, a selective inhibitor of PKC–beta, has been shown to have beneficial effects in experimental models of diabetes, with reduction of glomerular hyperfiltration and albuminuria (145). Drug development with ruboxistaurin has reached the stage of phase II evaluation with uncertain results (145).

Another potential new therapeutic strategy is targeted toward AGE inhibition (145). Pyridoxamine, in particular, is an AGE inhibitor, with positive effects on animal models of nephropathy. A phase II study in patients with DN has shown mixed efficacy with a good safety profile (145).

Future studies are required for a better evaluation of these drugs as well as for the development of new therapies, which could target other specific metabolic or hemodynamic pathways implicated in the pathogenesis of DN.

Conclusions

DN represents a serious complication of childhood-onset diabetes associated with significant morbidity due to progressive loss in renal function and the associated risk for cardiovascular disease. Even though kidney failure and overt nephropathy are not common in children and adolescents, important structural and functional alterations at the renal level occur even during childhood and accelerate during puberty. Several risk factors have been associated with the development of DN, but a lot still needs to be clarified to develop better preventive and therapeutic strategies, which could reduce the burden associated with DN and thereby improve the prognosis for young people with type 1 diabetes.

51 Renal Manifestations of Metabolic Disorders

William G. van't Hoff

Introduction

While the majority of children with renal dysfunction have a structural, immunological or infective disorder, there are some who have a metabolic defect arising from an abnormality in the biochemical pathways of cell metabolism. In many metabolic disorders, substrate accumulation or an enzyme deficiency can be documented in the kidney but without evidence of renal dysfunction (e.g., some of the lysosomal storage disorders). This review concentrates on those disorders in which there is a clear renal functional or structural abnormality. Several of these conditions are described in detail elsewhere in this book, this chapter highlights a number of other metabolic disorders and provides, in tabular form of the various metabolic causes of renal symptomatology (see *Tables 51-1–51-7*). Many metabolic disorders can cause acute or chronic renal failure however it is rare for this to be the sole manifestation therefore these conditions are listed under the most important renal feature.

The proximal renal tubule has a very high-energy expenditure and is therefore sensitive to metabolic disorders that interfere with the generation of ATP. Mitochondrial dysfunction, alterations in glutathione metabolism and reduced ATP levels are felt to be important in the pathogenesis of the Fanconi syndrome which is one of the commonest renal manifestations of metabolic disease (*Table 51-1*), a fuller description is given in Chapter 42. Nephrocalcinosis and urolithiasis may also be manifestations of metabolic dysfunction, usually arising from defective reabsorption of a solute (e.g., cystine in cystinuria) or as a result of the urinary excretion of abnormally elevated plasma constituents (e.g., oxalate in hyperoxaluria). Renal glomerular involvement is less common but can occur as a result of abnormal deposition of storage material or due to a defect in the synthesis of the glomerular components (see *Table 51-4*). As a result of improvements in the care of children with metabolic disorders, longer term manifestations are becoming more apparent. Cystinosis was once described as a renal disorder, but as a result of successful renal transplantation, patients survive into adulthood and in the long term develop extra-renal problems (1). In addition, in some disorders increased survival has led to the development of renal dysfunction (e.g., methylmalonic acidemia). Thus pediatric nephrologists need to remain vigilant to the possibility of a metabolic disorder especially in children with extra-renal symptoms.

Methylmalonic Acidemia

Methylmalonic acidemia (MMA) is an autosomal recessive disorder of the metabolism of methylmalonyl Coenzyme A caused either by a defect of methylmalonyl Coenzyme A mutase or of the cofactor, adenosyl cobalamin (2). Patients usually present in the neonatal period or early infancy with lethargy, vomiting, poor feeding, failure to thrive and recurrent metabolic acidosis. Patients deficient in the cofactor respond favorably to cobalamin supplements but for those who have a partial or complete deficiency of the apoenzyme, the prognosis is poor with a mortality of approximately 50% within the first decade. In the cobalamin-unresponsive patients, there is a significant incidence of neurological and renal manifestations.

Renal Tubular and Glomerular Dysfunction

Children with methylmalonic academia have evidence of renal tubular dysfunction which becomes very profound during episodes of metabolic decompensation (usually triggered by intercurrent infection) with massive renal salt and bicarbonate losses. In a study of seven cobalmin-unresponsive patients, five had defects in urine concentration, two had impaired urine acidification and several had hyporeninemic hypoaldosteronism (3). Chronic renal impairment has also been documented in cobalamin-unresponsive MMA patients. Walter et al. documented a low GFR in eight of 12 such children, five of whom had a GFR < 40 ml/min/1.73 m^2 (4). In a retrospective survey of patients with all forms of MMA, Baumgartner and

Table 51-1

Fanconi syndrome (See Chapter 42 for full description)

Disorder	Main features	Renal features	References
Cystinosis	Poor growth, vomiting, rickets, often blond, fair hair, corneal cystine crystals, multisystem involvement	Fanconi syndrome, chronic renal failure, rarely urinary tract dilatation, calculi (urate/calcium oxalate)	See Chapter 42 (111)
Tyrosinaemia type 1	Hepatomegaly, liver disease, rickets, neurological crises	Fanconi syndrome, nephromegaly, nephrocalcinosis, calculi, chronic renal impairment	See Chapter 42 (112, 113)
Mitochondrial disorders	Myopathy, poor growth, cardiomyopathy, liver dysfunction, neuropathy, retinopathy, ophthalmoplegia, endocrinopathy	Fanconi syndrome, Bartter-like features	See Chapter 42 (49–70)
		Proteinuria	
		Tubulo-interstitial nephritis	
		Cysts	
Galactosemia	Vomiting, diarrhea, poor growth, jaundice, liver disease, hypotonia, cataracts	Fanconi syndrome	See Chapter 42
Dent's disease	Hypercalciuria, tubular proteinuria, X-linked	Partial Fanconi syndrome (low molecular weight proteinuria), nephrocalcinosis/ nephrolithiasis, chronic renal failure	(114, 115) See Chapter 42
Oculo-cerebro-renal (Lowe's) syndrome	Congenital cataracts, other ocular abnormalities, hypotonia, delayed development, X linked	Partial Fanconi syndrome (low molecular weight proteinuria), chronic renal failure, nephrocalcinosis, rarely calculi	(116) See Chapter 42
Wilson's disease	Liver disease, neurological symptoms, Kayser-Fleischer rings, cardiomyopathy	Fanconi syndrome, proteinuria, rarely acute renal failure, distal RTA, hypercalciuria, calculi	See Chapter 42 (117, 118)
Glycogen storage disease type 1	Hepatomegaly, hypoglycemia, seizures, poor growth, lactic acidosis	Fanconi syndrome, hypercalciuria, hyperfiltration, rarely distal tubular acidosis, renal calculi, proteinuria, focal segmental glomerulosclerosis, chronic renal impairment	See Chapter 42 (30–43)
Fanconi Bickel syndrome	Hepatomegaly, rickets, poor growth, hypoglycemia	Fanconi syndrome, hyperfiltration, "diabetic-like" nephropathy	See Chapter 42 (44–48)
Fructosemia	Acute onset after fructose ingestion: poor feeding, vomiting, poor growth, hypoglycemia, liver failure	Fanconi syndrome, rarely acute renal failure	See Chapter 42 (119)
Lysinuric Protein Intolerance	Failure to thrive, growth retardation, hypotonia, hepatosplenomegaly	One report of Fanconi syndrome, proteinuria, hematuria, chronic kidney disease, hypertension	(109, 110)
GRACILE syndrome	Severe growth retardation, neonatal lactic acidosis, cholestasis, liver hemosiderosis	Fanconi syndrome	(120)

Viardot found that 20% of patients had a GFR < 60 ml/min/1.73 m^2 (5) although this may be an underestimate of the incidence of renal impairment because, in some patients, GFR had to be estimated from plasma creatinine concentrations. A review of long term renal function in children with early-onset cobalamin-unresponsive MMA in London, studied by single injection slope clearance chromium-EDTA GFR, indicated that virtually every GFR value was below the normal range and every child surviving to 12 years had a GFR < 40 ml/min/1.73 m^2 (6). In a review of 30 French patients, chronic kidney disease occurred in 47% with a median onset of 6.8 years (7). The mainstay of treatment is a low protein, high calorie diet and many such children have poor growth and reduced muscle bulk. Consequently neither plasma creatinine concentrations nor GFR estimated by Schwartz-Haycock formula, accurately reflect glomerular function in MMA (4, 8). Proteinuria and hematuria are absent and renal histopathology shows changes of tubulo-interstitial nephritis (4, 11, 12). It is likely that the tubular dysfunction noted

Table 51-2

Other tubular dysfunction

Disorder	Main features	Renal features	References
Carbonic anhydrase II deficiency	Osteopetrosis, fractures, cerebral calcification, mental retardation, poor growth,	Mixed type of RTA	(121, 122)
Methylmalonic acidemia	Vomiting, acidosis, hypotonia, poor growth	Type IV RTA, tubulo-interstitial changes, chronic renal failure	(3)
Pyruvate carboxylase deficiency (some forms)	Metabolic acidosis, neurological symptoms, hepatomegaly	Tubular acidosis, renal impairment	(123)
Ehlers-Danlos syndrome	Skin fragility, joint hypermobility, visceral or vascular dilatation/rupture	Renal tubular acidosis, medullary sponge kidney, diverticulae, hypoplasia	(124, 125)
Carnitine palmitoyl transferase deficiency type 1	Fasting/illness leading to encephalopathy, seizures, hepatomegaly	Renal tubular acidosis	(126)
Adenosine deaminase deficiency	Severe combined immunodeficiency	Transient RTA, proteinuria, mesangial sclerosis	(127)
Lysinuric protein intolerance	See *Table 51-4*	Renal tubular acidosis, aminoaciduria, glomerulo-nephritis, renal failure	(109, 110)
Nephrogenic diabetes insipidus	Polyuria, polydipsia, hyposthenuria	Hydronephrosis, hydroureter, megacystis (in long term)	See Chapter 40
Kearns Sayre syndrome	Ophthalmoplegia, retinal degeneration, heart block, ataxia, hyperparathyroidism	Bartter-like syndrome, hypomagnesemia	(57–61)
Fabry's disease	See text	Hyposthenuria, renal tubular acidosis, proteinuria, chronic renal failure	(93–99)
Metachromatic leucodystrophy	Neurologic and intellectual regression, spasticity, incontinence	Renal tubular acidosis, mild aminoaciduria, mild renal impairment	(128)
Transaldolase deficiency	Liver failure, cirrhosis. Neonatal multi-system form (hydrops)	Undefined tubulopathy Genitourinary malformations	(129)
Fatty acid oxidation disorders	Liver disease (steatosis, hypoketotic hypoglycemia, hepatomegaly), acute neonatal illness, cardiomyopathy, myopathy, encephalopathy	Renal tubulopathy, acute renal failure	(130)

in MMA is related to hyporeninemic hypoaldosteronism observed in patients with tubulo-interstitial nephritis and renal impairment (3).

The exact mechanisms of nephrotoxicity in MMA are not yet known. Methylmalonic acid administration to rats causes tubular (but not glomerular) injury and leads to proteinuria (9). There is structural similarity between methylmalonate (which accumulates as a result of the enzyme deficiency) and maleic acid, used experimentally in animals to create a model of the renal Fanconi syndrome. However the tubular manifestations of MMA do not correspond to generalized proximal tubular dysfunction. More recent work on the pathophysiology of MMA has focused on the interaction of methylmalonate on transporter proteins in the kidney. The tubular uptake of dicarboxylic and tricarboxylic acid intermediates of the TCA cycle is mediated by Na^+-coupled carboxylate transporters (hNACs). Both methylmalonate and 2-methylciytrate (which also accumulates in MMA) share structural similarities to dicarboxylates that are known to inhibit hNACs and this could lead to energy depletion in the tubular cells (10). Likewise accumulation of methylmalonate and 2-methylcitrate may also disrupt glutathione transport into the mitochondrion. (10) It seems likely

Table 51-3

Nephrocalcinosis and urolithiasis

Disorder	Main features	Other renal features	References
Cystinuria	Calculi		See Chapter 41
Primary Hyperoxaluria	Calculi/nephrocalcinosis	Acute/chronic renal failure (presentation in infants)	See Chapter 43
Familial hyperuricemic nephropathy	Gout, chronic renal failure		(89–92)
Hypoxanthine-guanine phosphoribosyl transferase (HGPRT) deficiency	Lesch Nyhan syndrome (complete deficiency): developmental delay, choreo-athetoid movements, self mutilation	Acute/chronic renal failure	(81–83)
	Partial deficiency: gouty arthritis		
Adenine phosphoribosyl-transferase deficiency	Calculi 2,8-dihydroxyadenine (2,8-DHA)	Acute/chronic renal failure	(82)
Hereditary renal hypouricemia	Urolithiasis (urate/calcium oxalate), hyperuricemia, hypercalciuria,	Uric acid nephropathy/acute renal failure	(86–88, 131)
Blue diaper syndrome	Hypercalcemia, hypercalciuria, indicanuria → blue discolouration urine	Nephrocalcinosis	(132)
Xanthinuria	Calculi, myopathy, arthropathy	Acute/chronic renal failure	See Chapter 58 (145)
		Renal cysts (rare)	
Hereditary orotic aciduria	Megaloblastic anemia, orotic acid crystalluria, hematuria, immunodeficiency	Crystalluria, obstructive uropathy	(133–135)
Glycogen storage disease type 1	See *Table 51-1*	Tubular dysfunction, nephrocalcinosis, proteinuria, chronic renal impairment	(30, 31)
Wilson's disease	See *Table 51-1*	Acute renal failure, tubular dysfunction	(117)
Congenital lactase deficiency	Watery diarrhea, poor weight gain	Nephrocalcinosis, hypercalciuria, hypercalcemia	(136)
Glucose-galactose malabsorption	Watery diarrhea	Calculi, nephrocalcinosis, hypercalcemia	(137)
Cystinosis	See *Table 51-1*	Rarely calculi	See Chapter 41, (111)
Dent's disease/X-linked nephrolihthiasis	See *Table 51-1*	Nephrocalcinosis, aminoaciduria, partial Fanconi syndrome, chronic kidney disease	(114)
Hypophosphatasia (infantile form)	Rickets, developmental delay, hypercalcemia, craniosynostosis	Hypercalciuria, nephrocalcinosis	(138)
Cystic fibrosis	Chronic lung disease, poor growth, pancreatic dysfunction	Microscopic nephrocalcinosis, calculi, proteinuria, rarely nephrotic syndrome (amyloidosis), chronic renal failure	(139–142)
Tyrosinemia type 1	See *Table 51-1*	Nephrocalcinosis, Fanconi syndrome, nephromegaly, chronic renal impairment	See Chapter 42 (112, 113)
McCune-Albright syndrome	Fibrous bony dysplasia, café-au-lait pigmentation, precocious puberty	Nephrocalcinosis, some have hypophosphatemic rickets	(143)
Apparent mineralocorticoid syndrome	Hypertension, hypokalaemia, alkalosis, reduced plasma renin	Nephrocalcinosis, medullary cysts	(144)

Table 51-4

Proteinuria/glomerulonephritis

Disorder	Main features	Renal features	References
Fabry's disease	See text Sensory changes in extremities, angiokeratoma, hyperhidrosis, corneal, lens opacities	Hyposthenuria, renal tubular acidosis, proteinuria, chronic renal failure	(93–99)
Imerslund-Grasbeck syndrome	See text	Proteinuria, urinary tract abnormalities	(26)
Lecithin: cholesterol acyltransferase deficiency	See text	Proteinuria, hematuria, renal failure	(104, 105)
Galactosialidosis (early infantile form)	Hydrops, edema, coarse facies, inguinal hernias, visceromegaly, spinal involvement, corneal and fundal abnormalities, cardiomyopathy, developmental delay, telangiectasias	Proteinuria, nephrotic syndrome	(146–149)
Glutamyl ribose-5-phosphate glycoproteinosis	Coarse facies, optic atrophy, muscle wasting, failure to thrive, seizures, neurological deterioration	Proteinuria, chronic renal failure	(150)
Mucopolysaccharidosis type I (Hurler syndrome)	Coarse facies, corneal clouding, visceromergaly, dysostosis multiplex, developmental delay	Nephrotic syndrome, hypertension (due to aortic luminal narrowing)	(151)
Congenital disorder of glycosylation type 1	See text and *Table 51-5*	Proteinuria (congenital nephrotic syndrome), microcysts	(71–77)
Infantile sialic acid storage disease	Hydrops, edema, dysmorphism, hepatosplenomegaly, hypotonia, poor growth	Proteinuria, nephrotic syndrome	(152)
Cystic fibrosis	See *Table 51-3*	Proteinuria, nephrotic syndrome (amyloidosis), microscopic nephrocalcinosis, calculi, chronic renal failure	(139–142)
α_1-antitrypsin deficiency	Liver and lung disease	Hematuria, membranoproliferative GN (only seen with advanced liver disease), chronic renal failure	(153, 154)
Lipoprotein glomerulopathy	Elevated apolipoprotein E	Nephrotic syndrome (resistant to treatment), hematuria, hypertension, renal failure. Glomerular lipoprotein thrombi	(155, 156)
Lysinuric protein intolerance	Vomiting, diarrhea after weaning, poor appetite and growth, hypotonia, visceromegaly, interstitial pneumonitis, encephalopathy	Proteinuria, hematuria, nephrotic syndrome, immune complex glomerulonephritis, tubulo-interstitial nephritis, renal tubular acidosis, renal failure	(109, 110)
Prolidase deficiency	Rash, dysmorphism, anemia, splenomegaly, recurrent infections	Systemic lupus erythematosus	(157)
Cobalamin C deficiency	See text	Hemolytic uremic syndrome, glomerulopathy	(23–25)
Mitochondrial disorders	See text	Fanconi syndrome Rarely proteinuria, nephrotic syndrome, tubulo-interstitial nephritis	(49–70)
Gaucher's disease	Hepatosplenomegaly, hypersplenism	Proteinuria, hematuria, acute glomerulonephritis Calculi (personal communication)	(158, 159)

Table 51-5

Metabolic causes of Renal cysts

Disorder	Main features	Renal features	References
Zellweger's syndrome	Facial dysmorphism, hypotonia, severe developmental delay, hepatomegaly	Microcysts/large cortical cysts	(160)
Alagille's syndrome	Intrahepatic cholestasis, dysmorphism, posterior embryotoxin, butterfly vertebrae, hypogonadism, peripheral pulmonary stenosis	Cysts, multicystic dysplastic kidney, unilateral agenesis, hypoplasia, urinary concentration defect, calculi, glomerular mesangiolipidosis, renal failure	(161, 162)
Congenital disorders of glycosylation	See text and *Table 51-4*	Cysts, proteinuria	(71–77)
Glutaric aciduria type II (Neonatal onset)	Prematurity, hepatomegaly, dysmorphism, genitourinary abnormalities, hypotonia, odor, metabolic acidosis, hypoglycemia	Cystic change (microcysts/polycystic kidneys), nephromegaly, renal dysgenesis	(163–166)
Nephronophthisis	Can be associated abnormalities: (Leber's amaurosis, retinopathy, liver disease, neurological and skeletal abnormalities)	Hyposthenuria, chronic renal failure.	See Chapter 35
Smith-Lemli-Opitz syndrome	Facial dysmorphism, hypotonia, mental retardation, abnormalities limbs, brain, genitalia. Cholesterol biosynthesis defect	Cystic dysplasia, hypoplasia, agenesis, duplication, PUJ obstruction, VUR	(167, 168)
Cystinosis	See *Table 51-1*	Cysts are very rare	(169)
Pearson's syndrome	Pancytopaenia, pancreatic dysfunction, tubulopathy See text (mitochondrial disorders)	Cortical cysts	(51, 54)
Fabry's disease	See text Sensory changes in extremities, angiokeratoma, hyperhidrosis, corneal, lens opacities	Renal sinus parapelvic cysts, hyposthenuria, proteinuria, chronic kidney disease	(94, 95, 99)
Apparent mineralocorticoid syndrome	Hypertension, hypokalaemia, alkalosis, reduced plasma renin	Nephrocalcinosis, medullary cysts	(144)

that disruption of mitochondrial function underpins the nephrotoxicity (2, 10).

Patients with MMA have hyperuricemia which might also be a factor in causing renal damage. Urate crystals have not however been observed in renal biopsy material and plasma urate is easily controlled in these patients with allopurinol (3).

Management of ESRF in Methylmalonic Acidemia

There are relatively few reports of the management of end-stage renal failure in MMA patients. Plasma methylmalonate appears to rise in association with plasma creatinine either due to reduced filtration or because it is nephrotoxic (10, 11, 13, 14). Hemodialysis clearly reduces plasma methylmalonate and may improve metabolic and nutritional status (10, 13). Since the deficient methylmalonyl CoA mutase is expressed in liver, a liver transplant should provide replacement enzyme. Several patients with MMA have now received liver transplants, usually as an isolated organ in young children in an attempt to prevent multisystem damage. (15). However there remains a significant mortality and morbidity rate with a number of survivors demonstrating chronic kidney disease and neurological dysfunction.

The first patient who received a combined liver-kidney transplant (10, 13) remains well with good renal and hepatic function 13 years after surgery (W. van't Hoff, personal communication). While here have been other successes (16), other patients have died shortly after the procedure and, worryingly, liver transplantation does not seem to protect the child from further neurological toxicity (12, 13, 17–19).There have been a few reports of isolated renal transplant in MMA. A 24 year old patient

Table 51-6

Abnormal Urine (with acknowledgment to Timo Kouri)

Disorder	Main features	Renal features	References
Alkaptonuria	Ochronotic pigmentation of cartilage and collagen, arthritis	Urine turns black on standing if alkaline, calculi (adults)	(170)
Porphyria (Acute intermittent)	Abdominal pain, constipation, neurologic features (usually after puberty)	Urine may turn red/purple	(171–173)
		Acute or chronic renal failure, urinary retention	
		Acute hypertension	
Some Organic acidemias	Progressive infantile encephalopathy, weight loss	Characteristic urine smell	(174)
		Maple syrup urine disease	(175)
	Recurrent acidosis	"Sweaty feet" in isovaleric/glutaric acidemia	
Some aminoacidurias	Developmental delay (untreated), light pigmentation, abnormal gait, eczema, epilepsy	Characteristic urine smell Musty/ mousy in phenylketonuria	(176)
			(112, 113)
	Hepatomegaly, liver disease, rickets, neurological crises	Rancid smell in tyrosinemia	
Blue diaper syndrome	Hypercalcemia, hypercalciuria	Nephrocalcinosis Indicanuria → blue discoloration urine	(132)

Table 51-7

Other manifestations

Disorder	Main features	Renal features	References
Menke's syndrome/ Ehlers-Danlos type IX/ Occipital Horn Syndrome (OHS)	X-linked disorders, abnormal hair and facies, developmental delay and regression. OHS have lax skin, herniae, no neurological features	Bladder or ureteric diverticulae	(177, 178)
Homocystinuria	Ectopia lentis, skeletal abnormalities, neuropsychiatric symptoms, thromboembolism	Renal infarction, hypertension	(179)
Carnitine palmitoyl transferase deficiency type II	Neonatal onset encephalopathy, hepatomegaly, cardiomyopathy	Renal dysgenesis	(180)
Glucose-6-phosphatase deficiency	Hemolytic anemia, jaundice	Acute renal failure	(181)
Exercise intolerance and myoglobinuria syndrome (various causes)	Recurrent hemolysis, muscle cramps, weakness, exercise intolerance, vomiting	Myoglobinuria, oligo/anuric acute renal failure (McArdle disease and carnitine palmitoyl transferase type II deficiency can also present in this way in adults).	(182–184)

demonstrated improved clinical and metabolic control after an isolated renal transplant although she developed diabetes mellitus and suffered marked cyclosporin toxicity (14, 20). A similarly favorable outcome, 10 years after transplant, with an improvement in urine methylmalonate excretion has been demonstrated in a 17 year old patient after renal transplantation (15, 21). Several other cases of renal transplantation in MMA have not been reported (personal communication) but in the author's view, this modality of treatment appears, at this time, to have a safer outcome at least in the short-term. The long term prognosis for any transplanted patient with MMA remains uncertain (16, 22).

Cobalamin Defects

Early-onset hemolytic uremic syndrome has been reported in a number of patients with cobalamin C or G deficiency (17, 18, 23, 24), in which there are defects in the synthesis of adenosylcobalamin and methylcobalamin (cobalamin C defect) or of methionine synthase (cobalamin G defect). Patients with cobalamin C deficiency have defective function of the two enzymes dependent on these cofactors (methylmalonyl CoA mutase and *N*-methyl tetrahydrofolate: homocysteine methyltransferase). These children therefore have homocystinuria, hypomethioninemia and cystathioninuria in addition to methylmalonic aciduria. Most present in early infancy with poor feeding, failure to thrive, hypotonia, retinitis, respiratory distress and cardiomyopathy. Investigation shows a megaloblastic anemia, pancytopenia and liver dysfunction. Generally the prognosis has been poor. There have been rare case reports of older children with cobalamin C deficiency who developed hypertension, proteinuria and chronic renal impairment, in association with FSGS or an unclassified glomerulopathy (18, 25).

A number of patients with defective absorption of the cobalamin-Intrinsic factor (IF) complex (Imerslund-Grasbeck syndrome) have persistent proteinuria (20, 26). The Cobalamin-IF complex binds to cubilin in the intestinal brush border. Cubilin is also expressed in the renal proximal tubule where it interacts with megalin to form a tandem endocytic receptor complex (21, 27). Cubilin is the major receptor for proximal tubular albumin reabsorption, thus patients with Imerslund-Grasbeck syndrome in which the cubilin gene is defective, and have albuminuria (22, 28). Other manifestations include megaloblastic anemia and biochemically, homocystinuria, homocystinemi, and methylmalonic aciduria (20, 26). In addition to the metabolic abnormalities, two children with this disorder were reported as suffering from recurrent urinary tract infections secondary to neuropathic bladders (23, 29).

Glycogen Storage Diseases

Clinical

The glycogen storage diseases (GSD) are genetic disorders of the metabolism and regulation of glycogen. Some forms of GSD have significant renal manifestations: GSD type 1 can lead to a tubulopathy and chronioc kidney disease, Fanconi-Bickel syndrome has a characteristic tubulaopathy and Tarui disease (type VII) can lead to acute rhabdomyolysis and renal failure. GSD type 1 is characterized by a deficiency of glucose-6-phosphatase in the liver, kidne, and intestine, causing excessive glycogen storage, hepatomegaly, hypoglycemia, lactic acidosis, hyperuricemia, hyperlipidemia, and poor growth. Long term complications include delayed puberty, hepatic adenomata and renal disease. Chen and colleagues drew attention to the complication of ESRF in older GSD patients (24, 30). In their review in 1988, 18 children under 10 years had normal renal function, while 4 of 20 patients aged 13–47 years, had renal dysfunction (proteinuria, hypertension or chronic renal failure). Subsequent investigators have demonstrated renal tubular and glomerular abnormalities. Ultrasonography demonstrates the renal enlargement secondary to glycogen deposition (25–28, 31–33).

The mechanisms of renal damage are not fully understood although there may be important compasisons with diabetic nephropathy (34). Both diabetes mellitus and GSD I involve increased flux through the pentose phosphate pathway, increasing triose phosphates and diacylglycerol and thereby stimulating protein kinase C and the renin-angiotensin system. Yiu and colleagues demonstrated upregulation of angiotensin in a mouse model of GSD 1a (35).

Renal Tubular Dysfunction

Proximal tubular dysfunction occurs as an early feature in GSD 1 but is generally sub-clinical and a Frank Fanconi syndrome is rare. Although tubular proteinuria (RBP, β2 M) and enzymuria (NAG) is significantly elevated in GSD 1 patients, plasma electrolytes are less disturbed (26, 27, 32, 33). Distal tubular function is also perturbed with hypercalciuria and hypocitraturia, predisposing GSD 1 patients to nephrolithiasis (29, 30, 36, 37). A Gitelman-like syndrome of hypomagnesemia and hypocalciuria has also been described in a patient with glycogen storage disease type II (31, 38).

Glomerular Dysfunction

Patients with GSD 1 develop albuminuria and hyperfiltration (26, 27, 30, 32, 33). In a Dutch study, mean GFR and ERPF were 188 and 927 ml/min/1.73 m^2, respectively (normal values for adult controls 90–145 and 327–697, respectively) in a group of 23 GSD 1 patients, aged 2–22 years (26, 32). Persistent hyperfiltration leads to focal and global glomerulosclerosis and a decline in GFR

(32, 33, 39, 40). Other histologic abnormalities include glycogen deposition in proximal tubules, glomerular enlargement and thickening and lamellation of GBM (34, 35, 41). Management of the metabolic abnormalities, including frequent feeds and the use of uncooked cornstarch are the mainstays of treatment of GSD nephropathy. Anti-proteinuric and lipid lowering agents may have a role (42). Liver transplantation has been performed to prevent malignant change in hepatic adenomata and combined liver-kidney transplantation has also been successful (43).

Fanconi Bickel Syndrome

The Fanconi Bickel syndrome is a very rare autosomal recessive disorder of monosaccharide transport, presenting in the first year of life with hepatomegaly (due to glycogen storage), hypoglycemia and a severe generalized proximal tubulopathy leading to rickets. The extent of the Fanconi syndrome can be equal in magnitude to that in disorders such as cystinosis or tyrosinemia, but is particularly characterized by heavy glycosuria and galactosuria (37–39, 44–46). Treatment is directed towards frequent feeds (and the use of uncooked cornstarch) together with management of the tubulopathy. The condition arises due to mutations in the GLUT2 facilitative glucose transporter, which is expressed in hepatocytes, pancreatic beta cells and the basolateral membranes of intestinal and renal tubular epithelial cells (40, 47). Decreased monosaccharide uptake by the liver explains the post-prandial hyperglycemia and hypergalactosemia (which is exacerbated by inappropriately low insulin secretion due to abnormal glucose-sensing by pancreatic beta cells). The inability of the liver to transport glucose, together with heavy losses of glucose from the renal tubule, contributes to pre-prandial hypoglycemia (40, 47). Renal glomerular hyperfiltration, microalbuminuri, and diffuse mesangial expansion have been reported in one child (41, 48) and reduced GFR has been observed in some adults.

Mitochondrial Disorders

Introduction

Mitochondrial disorders are caused by defects in the respiratory chain enzymes, which are located in this organelle. The respiratory chain is responsible for the process of oxidative phosphorylation in which electrons are transferred to oxygen generating a proton gradient. The flow of protons back through the mitochondrial membrane releases energy, which allows for the formation of ATP. The respiratory chain enzyme complexes are encoded partly by mitochondrial and partly by nuclear DNA. Mitochondrial DNA (mtDNA) differs from nuclear DNA: it is much smaller, has a unique genetic code, exists as a double stranded loop and is inherited exclusively from the mother. In contrast to nuclear DNA, mtDNA is randomly segregated during cell division. The proportion of mutant and wild-type mtDNA can therefore vary from tissue to tissue and can also alter over time, explaining the enormous heterogeneity of mitochondrial disorders (42, 49). The classification of mitochondrial disorders has been based on clinical, biochemica, and molecular phenotypes. The clinical features are extremely heterogeneous and often change with time but virtually all patients have neurological symptoms at some point. Frequent manifestations include myopathy, encephalopathy, seizures, developmental delay, ophthalmoplegia, retinal degeneration, cardiomyopathy, endocrinopathy, and liver disease.

Renal Manifestations

In a review of 42 patients with mitochondrial disorders, 21 had renal involvement (50). Varying degrees of tubular dysfunction may be seen but the commonest distinct renal phenotype is a Fanconi syndrome, usually occurring in an infant with multisystem dysfunction in which case the prognosis is poor (43, 44, 51, 52). Generalized proximal tubular dysfunction has also been reported in children with other mitochondrial syndromes including Kearns-Sayre, Pearson's, Leigh's encephalopathy and Coenzyme Q (CoQ(10)) deficiency (43, 45–49, 51, 53–56). In some children, hypomagnesemia and hypocalcemia are the predominant electrolyte abnormalities (48–50, 57–59). Other tubular manifestations include a Bartter-like syndrome (51, 60, 61), renal tubular acidosis, and hypercalciuria (52, 53, 62, 63). Renal glomerular involvement with proteinuria, congenital nephrotic syndrome, focal segmental glomerulosclerosis, nephronophthisis, tubulo-interstitial nephritis or chronic renal impairment are rarer associations of mitochondrial disorders (43, 51, 54–56, 64–67). An Alport-like phenotype of sensorineural deafness, nephropathy and diabetes has been reported in an adult pedigree subsequently found to have a mitochondrial mutation (68). Renal cysts have been reported in both adults and children with mitochondrial disorders (57, 58, 69, 70). In most children the renal lesion is part of multisystem dysfunction, but there are occasional reports of patients presenting with FSGS and later developing

other manifestations of mitochondrial disease (54, 59, 65, 70). A high index of suspicion is therefore required to diagnose a mitochondrial disorder. Unfortunately measurement of the plasma lactate/pyruvate ratio which is the first investigation of a child with mitochondrial dysfunction may give a normal result in a patient with a renal tubulopathy due to loss of lactate in the urine (43, 51). In such a case, careful delineation of other system involvement, biopsy and detailed biochemical and molecular studies may be required to confirm a defect in mitochondrial function.

Congenital Disorders of Glycosylation

The congenital disorders of glycosylation (CDG) are a group of inherited multisytem disorders in which there is defective *N*- and/or *O*-glycosylation of proteins (60, 71–73). Many sub-types have been described and the presentation is very heterogeneous, ranging from multiple exostoses, progeria, developmental delay in older children to a fatal multisystem disorder in infancy (72). Children with the commonest form, CDG Ia may have dysmorphism, hypotonia, failure to thrive, diarrhea, abnormal fat pads, inverted nipples, abnormal eye movements, hepatomegal, and cardiomyopathy. Investigations often show hypothyroidism and olivoponto-cerebellar atrophy (72). Diagnostically, abnormal isoelectric focusing of serum transferrin is the first screening test (although will not identify some rarer forms), and if abnormal, should lead to more detailed enzymatic and other tests (72).

The commonest renal manifestation is the presence of microcysts which produce a hyperechoic picture on ultrasonography, most commonly found in children with multisystem variants (61, 62, 74–76). The cysts are located in the cortex and probably arise from the tubules (63, 77). The kidneys may be enlarged and single cysts have also been reported (62, 75). Microcysts are not seen in all patients; even within a pair of affected siblings, only one had renal cysts (61, 74). Proteinuria has been recorded in several cases and may contribute to the severe edema and ascites that these infants can develop (62, 75). There have also been reports of nephrotic syndrome, both occurring within the first two months of life (63–65, 77, 78). One of these infants also developed renal failure and at post mortem the kidneys showed features of diffuse mesangial sclerosis (64, 78). Transferrin isoelectric focusing should be added to the list of investigations required to exclude a metabolic cause of nephrotic syndrome in infants (the test is not affected by the nephrotic state or by renal failure (64, 72)).

Disorders of Purine Metabolism and Transport

Children who develop renal calculi, acute renal failure in the neonatal period or crystal nephropathy require investigation of their purine metabolism. Purines are involved in the synthesis of nucleotides and coenzymes, in signal transduction (e.g., cAMP) and in the generation of ATP. The metabolic end product, uric acid, and its immediate precursor (xanthine) are insoluble in urine, so that overproduction can predispose to the development of crystal formation. Urate is normally extensively reabsorbed in the proximal tubule. The process is age- and sex-dependent with children reabsorbing less of the filtered urate and consequently having lower plasma urate concentrations (66, 79). As glomerular filtration rate declines, the fractional excretion of urate increases (67, 80).

Urolithiasis is the commonest renal manifestation of a disorder of purine production (e.g., in adenine phosphoribosyl transferase (APRT) deficiency and hypoxanthine-guanine phosphoribosyl transferase (HGPRT) deficiency; see chapter XX Urolithiasis etc.). Children may or may not have typical features of calculi (pain, hematuria, infection). In some the diagnosis is made following family studies or during investigation of crystalluria. Very rarely, these disorders present with oliguric or anuric acute renal failure, either due to bilateral obstructive calculi (81) or due to crystal nephropathy which can sometimes occur within the neonatal period (82, 83). Lesch-Nyhan syndrome is inherited in an X-linked recessive manner and nearly always presents in males. However very rarely heterozygous females can manifest equally severe symptoms (84). In both APRT and HGPRT deficiencies the urinary urate/creatinine ratio is normal, the plasma urate is also normal in APRT deficiency but is grossly elevated in HGPRT deficiency (79). In these cases detailed investigation of purine metabolism is required. Both conditions are treated with a high fluid intake, restriction of dietary purines and with allopurinol, which inhibits xanthine oxidase. Rasburicase, a urate oxidase enzyme, has also been used to control hyperuricemia in a neonate with Lesch-Nyhan nephropathy (85).

Hyperuricemia with subsequent hyperuricosuria is also a feature of glycogen storage disease type I. Calculi and renal failure can also occur as a result of disorders of urate transport in the renal tubule. Hyperuricosuria and hypouricemia can occur as a result of generalized proximal tubular dysfunction (e.g., Fanconi syndrome) but has also been described as an isolated transport defect associated with hypercalciuria, decreased bone density and

the development of calculi composed of a mixture of calcium oxalate and urate (69–72, 86–88).

Familial juvenile hyperuricemic nephropathy (FJHN) is an autosomal dominant disorder leading to hyperuricemia, gou, and progressive renal failure (66, 67, 79, 89). The onset is frequently in childhood or early adult life. The disorder is characterized biochemically by hyperuricemia due to a reduced fractional excretion of urate (<12%). There is evidence that hyperuricemia predates renal impairment and it is known that allopurinol reduces the progression of the nephropathy suggesting that renal damage is related to hyperuricemia (73, 74, 89, 90). There is a considerable overlap in this phenotype with that of medullary cystic kidney disease type 2, an autosomal dominant disorder causing a urinary concentrating defect, salt wasting, polyuria, and also associated with hyperuricemia and gout. Despite its name, renal cysts are not necessarily seen. The genetic bases of these disorders are complex. Four mutations in the gene encoding Uromodulin (UMOD) have been identified in three families with MDCK2 and one with FJHN (91). Further studies have demonstrated the clinical and genetic overlap and variability in these disorders (92).

Fabry's Disease

Fabry's disease is an X-linked disorder in which glycosphingolipids (predominantly globotriaosylceramide) accumulate in plasma and tissues as a result of a deficiency of α-galactosidase A (75, 93, 94). Affected males usually present in childhood (median age about 9 years) with recurrent painful crises of the hands and feet, a characteristic skin rash (angiokeratoma corporis) and hypohidrosis but the diagnosis is often delayed for years. Slit lamp examination reveals corneal and lenticular opacities. Progressive glycosphingolipid deposition in the heart, blood vessels and kidneys leads to the development of valvular and conduction abnormalities, angina, cerebrovascular disease, and progressive renal damage, usually in adult life. Overt renal disease is rare in children but renal histological changes can be demonstrated in children even without proteinuria (95). However, proteinuria, chronic renal failure, and even ESRF can occur by 15 years of age (76, 77, 94, 96). The urine may contain casts and desquamated cells containing lipid globules (78, 98). Subsequently, polyuria and polydipsia indicate defective tubular function and end-stage renal failure occurs typically around the fourth decade (76, 77, 96). Histological examination of the kidney will demonstrate inclusions with a characteristic "onion skin" appearance, in tubular epithelia, glomerular cells (especially podocytes) and endothelium (98). Glycosphingolipid deposits are seen in endothelial and epithelial cells of the glomerulus, Bowman's capsule and in the distal tubules (98). In an adult review of 24 patients, mean age 38 years, 50% had renal sinus cysts compared to 7% in healthy matched controls, leading the authors to suggest that multiple renal sinus cysts in a patient with kidney disease should raise suspicion of Fabry's (99).

The renal prognosis may bear some relationship to the level of detectable α-galactosidase A activity: onset of CRF was significantly later in those with > 1% activity compared to those with undetectable activity (77, 94). Recent studies indicate that approximately 1% adult males with undiagnosed causes of ESRF, have Fabry disease (80, 81, 100). Affected females (heterozygotes) generally have milder or delayed manifestations although as a result of random X-inactivation, these can be variable (76, 94). In an adult review, proteinuria was found in most patients, 28% males and 13% of females had chronic kidney disease with eGFR < 60 ml/min/1.73 m^2 generally with heavier proteinuria (101). There is good evidence in both adults and children, that treatment with recombinant human alpha-galactosidase A can ameliorate symptoms, maintain renal function and lead to good clearance of GL-3 in plasma, kidney, skin, and heart (102, 103, 104).

Lecithin-Cholesterol Acyl Transferase (LCAT) Deficiency

LCAT is required for the esterification of cholesterol with unsaturated fatty acid derived from lecithin. Patients with LCAT deficiency accumulate unesterified cholesterol and phosphatidylcholine in plasma and tissues (104). Sequelae of tissue accumulation occur within childhood and include grayish corneal opacities, a hemolytic anemia and proteinuria (sometimes in the nephrotic range) leading to progressive renal failure in adulthood (104, 105). Tendon xanthomata and atherosclerosis have been described in a few cases. Biochemically, LCAT deficiency is characterized by a low total cholesterol concentration, variable triglyceride concentration and abnormalities of lipoprotein structure and composition. The histology of the kidney shows mesangial hypercellularity and expansion with foam lipid deposits, holes and vacuolization in the glomerular basement membrane, arteriolar narrowing due to intimal thickening and subendothelial lipid deposits (105).

Lysinuric Protein Intolerance

Lysinuric protein intolerance (LPI) is a rare autosomal recessive disorder, prevalent in Finland and characterized by defective gastrointestinal and renal transport of the amino acids ornithine, arginine, and lysine. Low plasma concentrations of these amino acids impair urea cycle function, causing reduced nitrogen tolerance and hyperammonemia. Patients self-select a protein poor diet, but as a consequence are nutritionally deficient in many other substrates (106). LPI is due to mutations in the SLC7A7 gene, which encodes the y(+)LAT-1 protein, the catalytic light chain subunit of the heterodimeric amino acid transporter (107, 108). In a review of 39 patients, 74% had proteinuria, 38% hematuria, 36% hypertension, 38% a raised plasma creatinine and 4 patients required dialysis (109). A renal Fanconi syndrome has also been described (110).

52 Infectious Diseases and the Kidney

Jethro Herberg · Amitava Pahari · Sam Walters · Michael Levin

The kidney is involved in a wide range of bacterial, viral, fungal, and parasitic diseases. In most systemic infections, renal involvement is a minor component of the illness, but in some, renal failure may be the presenting feature and the major problem in management. Although individual infectious processes may have a predilection to involve the renal vasculature, glomeruli, interstitium, or collecting systems, a purely anatomic approach to the classification of infectious diseases affecting the kidney is rarely helpful because most infections may involve several different aspects of renal function. In this chapter, a microbiologic classification of the organisms affecting the kidney is adopted. Although they are important causes of renal dysfunction in infectious diseases, urinary tract infections and hemolytic uremic syndrome (HUS) are not discussed in detail because they are considered separately in Chapters 54 and 48 respectively.

Elucidation of the cause of renal involvement in a child with evidence of infection must be based on a careful consideration of the geographic distribution of infectious diseases in different countries. A history of foreign travel; exposure to animals, insects, or unusual foods or drinks; outdoor activities such as swimming or hiking; and contact with infectious diseases must be sought in every case. The clinical examination should include a careful assessment of skin and mucous membranes and a search for insect bites, lymphadenopathy, and involvement of other organs. A close collaboration with a pediatric infectious disease specialist and hospital microbiologist will aid the diagnosis and management of the underlying infection.

A tantalizing clue to the pathogenesis of glomerular disease is the marked difference in the incidence of nephrosis and nephritis in developed and underdeveloped areas of the world. In several tropical countries, glomerulonephritis (GN) accounts for up to 4% of pediatric hospital admissions; the incidence in temperate climates is 10- to 100-fold less. This difference might be explained by a complex interaction of several different factors, including nutrition, racial and genetically determined differences in immune responses, and exposure to infectious diseases. A growing body of evidence, however, suggests that long-term exposure to infectious agents is a major factor in the increased prevalence of glomerular diseases in developing countries.

Renal involvement in infectious diseases may occur by a variety of mechanisms: direct microbial invasion of the renal tissues or collecting system may take place in conditions such as staphylococcal abscess of the kidney as a result of septicemic spread of the organism or as a consequence of ascending infection; damage to the kidney may be caused by the systemic release of endotoxin or other toxins and activation of the inflammatory cascade during septicemia or by a focus of infection distant from the kidney; ischemic damage may result from inadequate perfusion induced by septic shock; the kidney may be damaged by activation of the immunologic pathways or by immune complexes resulting from the infectious process. In many conditions, a combination of these mechanisms may be operative. In the assessment of renal complications occurring in infectious diseases, the possibility of drug-induced nephrotoxicity caused by antimicrobial therapy should always be considered. The nephrotoxic effects of antibiotics and other antimicrobial agents are not addressed in this chapter but are covered in Chapter 53.

Bacterial Infections

Bacterial infections associated with renal disease and the likely mechanisms causing renal dysfunction are shown in *Table 52-1.*

Systemic Sepsis and Septic Shock

Impaired renal function is a common occurrence in systemic sepsis (1). Depending on the severity of the infection and the organism responsible, the renal involvement may vary from insignificant proteinuria to acute renal failure requiring dialysis. The organisms causing acute renal failure as part of systemic sepsis vary with age and geographic location and also differ in normal and immunocompromised children. In the neonatal period, group B streptococci, coliforms, *Staphylococcus aureus*, and *Listeria monocytogenes* are the organisms usually

Yersinia species	Enteritis				+	+ (HUS)
Campylobacter jejuni	Enteritis				+	
Mycobacteria tuberculosis	Tuberculosis	+			+	
Treponema pallidum	Syphilis				+	

Table 52-1 (Continued)

Organism	Site/infection	Infection localized to kidney	Systemic infection; toxin/ inflammation	Ischemia/ hypoperfusion; vasomotor nephropathy	Distant infection; "immunologic/ delayed"	Others
Mycoplasma pneumoniae	Pneumonia				+	+ (HUS)
Legionella	Pneumonia	+				Rhabdomyolysis
Rickettsia rickettsii	Rocky mountain spotted fever	+		+		
Coxiella burnetii	Q fever				+	

++, frequent complication of infection; +, uncommon but recognized complication; APSGN, acute post-streptococcal glomerulonephritis; HUS, hemolytic uremic syndrome

responsible. In older children, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *S. aureus* account for most of the infections. In people who are immunocompromised, a wide range of bacteria are seen, and, similarly, in tropical countries other pathogens, including *Haemophilus influenzae*, Salmonella species, and *Pseudomonas pseudomallei*, must be considered. Where *H. influenzae* type B vaccine has been introduced, however, the incidence of severe systemic infections due to this organism has shown a sharp fall.

Systemic sepsis usually presents with nonspecific features: fever, tachypnea, tachycardia, and evidence of skin and organ underperfusion. The pathophysiology of renal involvement in systemic sepsis is multifactorial (1, 2). Hypovolemia with diminished renal perfusion is the earliest event and is a consequence of the increased vascular permeability and loss of plasma from the intravascular space. Hypovolemia commonly coexists with depressed myocardial function because of the myocardial depressant effects of endotoxin or other toxins. The renal vasoconstrictor response to diminished circulating volume and reduced cardiac output further reduces glomerular filtration, and oliguria is thus a consistent and early event in severe sepsis (1, 3). A number of vasodilator pathways are activated in sepsis, including Nitric Oxide and the Kinin pathways. This may lead to inappropriate dilatation of vascular beds. Vasodilation of capillary beds leading to warm shock is common in adults with sepsis due to Gram-negative organisms but is less commonly seen in children, in whom intense vasoconstriction is the usual response to sepsis. If renal underperfusion and vasoconstriction are persistent and severe, the reversible prerenal failure is followed by established renal failure with the characteristic features of vasomotor nephropathy or acute tubular necrosis. Other mechanisms of renal damage in systemic sepsis include direct effects of endotoxin and other toxins on the kidney, and release of inflammatory mediators such as tumor necrosis factor (TNF) and other cytokines, arachidonic acid metabolites, and proteolytic enzymes (3). Nitric oxide (NO) is postulated to play a key role in the pathophysiology of renal failure in sepsis. Whether the renal effects of increased NO are beneficial or harmful remains unclear. Trials of selective NO synthetase inhibition did not offer any advantages over saline resuscitation (4). NO in endotoxemia is possibly beneficial because it maintains renal blood flow and glomerular filtration. Activation of coagulation is an important component of the pathophysiology of septic shock and may contribute to renal impairment. Activation of multiple prothrombotic and antifibrinolytic pathways occurs, together with downregulation of antithrombotic mechanisms such as the protein C pathway. Treatment with Activated protein C has been shown to improve outcome of adult septic shock, but has not been confirmed to have benefit in pediatric sepsis, and may carry a risk of bleeding particularly in infants (5).

The renal findings early in septic shock are oliguria, with high urine/plasma urea and creatinine ratios, low urine sodium concentration, and a high urine/plasma osmolarity ratio. Once established, renal failure supervenes, and the urine is of poor quality with low urine/plasma urea and creatinine ratios, elevated urine sodium concentration, and low urine osmolarity. Proteinuria is usually present, and the urine sediment may contain red cells and small numbers of white cells (1).

Management of Acute Renal Failure in Systemic Sepsis

The management of acute renal failure in systemic sepsis depends on early diagnosis and administration of appropriate antibiotics to cover the expected pathogens.

In addition, management is directed at improving renal perfusion and oxygenation. Volume replacement with crystalloid or colloid should be undertaken to optimize preload. Central venous pressure or pulmonary wedge pressure monitoring is essential to guide volume replacement in children in severe shock (1, 2). The use of low-dose (2–5 pg/kg/min) dopamine to reduce renal vasoconstriction together with administration of inotropic agents such as dobutamine or epinephrine to improve cardiac output may reverse prerenal failure. Early elective ventilation should be undertaken in patients with severe shock. If oliguria persists despite volume replacement and inotropic therapy, dialysis should be instituted early, because septic and catabolic patients may rapidly develop hyperkalemia and severe electrolyte imbalance.

In most children who develop acute renal failure as part of systemic sepsis or septic shock, the renal failure is of short duration, and recovery can be expected within a few days of achieving cardiovascular stability and eradication of the underlying infection. Occasionally, renal cortical necrosis or infarction of the kidney may result in prolonged or permanent loss of renal function.

Specific Infections Causing the Systemic Sepsis Syndrome

Meningococcus

N. meningitidis continues to be a major cause of systemic sepsis and meningitis in both developed and underdeveloped parts of the world (6). In developed countries, most cases are caused by group B and Y strains, particularly after introduction of meningococcal C vaccination, whereas epidemics of Meningococcus groups A, C and W135 continue to occur in many underdeveloped regions of the world (6, 7). Infants and young adults are most commonly affected, but cases in adolescents and young children are also common. There are two major presentations of meningococcal disease (6): *Meningococcal meningitis* presents with features indistinguishable from those of other forms of meningitis, including headache, stiff neck, and photophobia. Lumbar puncture is required to identify the causative agent and distinguish this from other forms of meningitis. Despite the acute nature of the illness, the prognosis is good, and most patients with the purely meningitic form of the illness recover without sequelae.

Meningococcemia with purpuric rash and shock is the second and more devastating form of the illness. Affected patients present with nonspecific symptoms of fever, vomiting, abdominal pain, and muscle ache. The diagnosis is only obvious once the characteristic petechial or purpuric rash appears. Patients with a rapidly progressive purpuric rash, hypotension, and evidence of skin and organ underperfusion have a poor prognosis, with a mortality of 10–30%. Adverse prognostic features include hypotension, a low white cell count, absence of meningeal inflammation, thrombocytopenia, and disturbed coagulation indices (8).

Renal failure was seldom reported in early series of patients with meningococcemia, perhaps because most patients died rapidly of uncontrolled septic shock. With advances in intensive care, however, more children are surviving the initial period of profound hemodynamic derangement, and renal failure is more often seen as a major management problem. Approximately 10% of children with fulminant meningococcemia develop renal failure, which usually occurs 24–48 h after the onset of illness (9).

The pathophysiology of meningococcal septicemia involves the activation of cytokines and inflammatory cells by endotoxin (6, 7). Mortality is directly related to both the plasma endotoxin concentration and the intensity of the inflammatory response, as indicated by levels of TNF and other inflammatory markers (10). Patients with meningococcemia have a profound capillary leak leading to severe hypovolemia. Loss of plasma proteins from the intravascular space is probably the major cause of shock (11), but myocardial suppression secondary to IL-6 production is also important (12). Intense vasoconstriction further impairs tissue and organ perfusion, and vasculitis with intravascular thrombosis and consumption of platelets and coagulation factors is also present (6).

Oliguria is invariably present in children with meningococcemia during the initial phase of the disorder. This is prerenal in origin and may respond to volume replacement and inotropic support. If cardiac output cannot be improved and renal underperfusion persists, established renal failure supervenes. Occasionally, cortical necrosis or infarction of the kidneys occurs. Children with meningococcemia should be aggressively managed in a pediatric intensive care unit, with early administration of antibiotics (penicillin or a third-generation cephalosporin), volume replacement, hemodynamic monitoring, and the use of inotropic agents and vasodilators. If oliguria persists despite measures to improve cardiac output, elective ventilation and dialysis should be instituted early (6, 7). Because activation of coagulation pathways occurs, severe acquired protein-C deficiency may result and is usually associated with substantial mortality (13). Protein C is a natural anticoagulant which also has important anti-inflammatory activity. Despite evidence for impaired function of the activated protein C pathway in meningococcal diseases (14), and adult trials suggesting benefit of

activated protein C administration in Septic shock (PROWESS trial) (15), pediatric trials of activated protein C showed no clear benefit, and were associated with increased risk of intracranial bleeding in very young infants (5). The role of aPC therapy in pediatric sepsis remains unclear. Most patients who survive the initial 24–48 h of the illness and regain hemodynamic stability will ultimately recover renal function even if dialysis is required for several weeks.

The least common presentation of meningococcal sepsis is chronic meningococcemia. Patients with this form of the illness present insidiously with a vasculitic rash, arthritis, and evidence of multiorgan involvement. The features may overlap those of Henoch-Schonlein purpura or subacute bacterial endocarditis (SBE), and the diagnosis must be considered in patients presenting with fever, arthritis, and vasculitic rash, often accompanied by proteinuria or hematuria. Response to antibiotic treatment is good, but some patients may have persistent symptoms for many days resulting from an immune-complex vasculitis.

Staphylococcus Aureus

Staphylococcal infections may affect the kidneys by direct focal invasion during staphylococcal septicemia, forming a renal abscess; by causing staphylococcal bacteremia; or by toxin-mediated mechanisms, as in the staphylococcal toxic shock syndrome.

Staphylococcal Abscess. Staphylococcal renal abscess presents with fever, loin pain and tenderness, and abnormal urine sediment, as do abscesses caused by other organisms (16). The illness often follows either septicemia or pyelonephritis. The diagnosis is usually considered only when a patient with clinical pyelonephritis shows an inadequate response to antibiotic treatment. The diagnosis is confirmed by ultrasonography or computed tomographic scan, which shows swelling of the kidney and intrarenal collections of fluid. Antibiotic therapy alone may result in cure, but if the patient remains unwell with evidence of persistent inflammation despite use of appropriate antibiotics, surgical intervention may be required. Percutaneous drainage under ultrasonographic or computed tomographic scan guidance is often effective and may avoid the need for a more direct surgical approach (16, 17).

Staphylococcal Toxic Shock Syndrome. The staphylococcal toxic shock syndrome is a systemic illness characterized by fever, shock, erythematous rash, diarrhea, confusion, and renal failure. The disorder was first described by Todd et al. in 1978 in a series of seven children (18). During the 1980s, thousands of cases were reported in the United States. Most cases were in menstruating women, in associated with tampon use. Although most cases worldwide are seen in women and are associated with menstruation, children of both sexes and of all ages are affected (19).

The illness usually begins suddenly with high fever, diarrhea, and hypotension, together with a diffuse erythroderma (20). Mucous membrane involvement with hyperemia and ulceration of the lips and oral mucosa or vaginal mucosa, strawberry tongue, and conjunctival injection are usually seen. Desquamation of the rash occurs in the convalescent phase of the illness. Confusion is often present in the early stages of the illness and may progress to coma in severe cases. Multiple organ failure with evidence of impaired renal function, elevated levels of hepatic transaminases, thrombocytopenia, elevated CPK and disseminated intravascular coagulation (DIC) is often seen.

According to CDC criteria, the diagnosis is made on the basis of the clinical features of fever, rash, hypotension, and subsequent desquamation along with deranged function of three or more of the following organ systems: gastrointestinal (GI), mucous membranes, renal, hepatic, hematologic, central nervous system, and muscle. Other disorders causing a similar picture, such as Rocky Mountain spotted fever, leptospirosis, measles, and streptococcal infection, must be excluded.

The staphylococcal toxic shock syndrome is now known to be due to infection or colonization with strains of *S. aureus* that produce one or more protein exotoxins (21). Most cases in adults are associated with toxic shock toxin I; in children, many of the isolates associated with the syndrome produce other enterotoxins (A to F). The staphylococcal enterotoxins appear to induce disease by acting as superantigens (22), which activate T cells bearing specific V beta regions of the T-cell receptor; this causes proliferation and cytokine release (23). The systemic illness and toxicity are believed to result largely from an intense inflammatory response induced by the toxin. The site of toxin production is often a trivial focus of infection or simple colonization, and bacteremia is rarely observed.

Renal failure in toxic shock syndrome is usually caused by shock and renal hypoperfusion. In the early stages of the illness, oliguria and renal impairment are usually prerenal and respond to treatment of shock and measures to improve perfusion. In severe cases and in patients in whom treatment is delayed, acute renal failure develops as a consequence of prolonged renal underperfusion, and dialysis may be required. In addition to underperfusion, direct effects of the toxin or inflammatory

mediators may also contribute to the renal damage. Recovery of renal function usually occurs, but in severe cases with cortical necrosis or intense renal vasculitis, prolonged dialysis may be required.

The management of staphylococcal toxic shock syndrome depends on early diagnosis and aggressive cardiovascular support with volume replacement, inotropic support, and, in severe cases, elective ventilation. If oliguria persists despite optimization of intravascular volume and administration of inotropic agents, dialysis should be commenced early (20).

Anti-staphylococcal antibiotics should be started as soon as the diagnosis is suspected and the site of infection identified. Initial empiric antimicrobial therapy should include an anti-staphylococcal antibiotic effective against betalactamase-resistant organisms and a protein synthesis-inhibiting antibiotic such as clindamycin to stop further toxin production (24). If there is a focus of infection such as a vaginal tampon, surgical wound, or infected sinuses, the site should be drained early to prevent continued toxin release into the circulation. The intravenous administration of immune globulins may be considered when infection is refractory to several hours of aggressive therapy, an undrainable focus is present, or persistent oliguria with pulmonary edema occurs (24). With aggressive intensive care, most affected patients survive, and renal recovery is usual, even in patients who have had severe shock and multiorgan failure. Relapses and recurrences of staphylococcal toxic shock syndrome occur in a proportion of affected patients because immune responses to the toxin are ineffective in some individuals.

Panton Valentine Leucocidin (PVL) producing staphylococcal infection: In recent years there have been increasing reports of severe staphylococcal disease, associated with shock and multiorgan failure, caused by strains of staphylococci producing the PVL toxin. Panton-Valentine Leukocidin (PVL) is a phage-encoded toxin, which profoundly impairs the host response due to its toxic effect on leucocytes (see review (25)). PVL producing strains are associated with tissue necrosis and increased propensity to cause abscesses in lung, bone, joint, and soft tissue infections. Perinephric abscesses have been reported (26). There are increasing numbers of children and adults admitted with fulminant sepsis, and shock due to PVL producing strains, and renal failure is a significant component of the multiorgan failure. In addition to intensive care support, antibiotic treatment of PVL strains should include antibiotics which reduce toxin production, such as clindamycin, linezolid or rifampicin, as well as vancomycin if the strain is resistant to methicillin. Beta-lactam antibiotics should be avoided, as there is some data to suggest that PVL toxin production can increased by these antibiotics under some conditions (27). Immunoglobulin infusion may also be of benefit. Aggressive surgical drainage of all collections requires close consultation with orthopedic and surgical teams.

Streptococcus Pyogenes

The group A streptococci (GAS) are a major worldwide cause of renal disease, usually as poststreptococcal nephritis. However, in addition to this post-infection immunologically mediated disorder, in recent years there have been increasing reports of GAS causing acute renal failure as part of an invasive infection with many features of the staphylococcal toxic shock syndrome (28).

Acute Poststreptococcal Glomerulonephritis. Acute poststreptococcal GN (APSGN) is a delayed complication of pharyngeal infection or impetigo with certain nephritogenic strains of GAS. Different strains can be serotyped according to the antigenic properties of the M protein found in the outer portion of the bacterial wall. APSGN after pharyngeal infection is most commonly associated with serotype M12. In contrast, in APSGN after impetigo, serotype M49 is most commonly identified (29). On occasions, other serotypes and non-typeable strains have been described as causing GN.

The pathology and pathogenesis of the disorder is discussed in detail in Chapter 30. APSGN has a worldwide distribution. Epidemiologic differences are observed between pharyngitis-associated and impetigo-associated streptococcal infections. Pharyngitis-associated APSGN is most common during school age and has an unexplained male/female ratio of 2:1. It occurs more often in the cooler months, and familial occurrences are commonly described. The latent period is 1–2 weeks, in notable contrast to impetigo-associated cases, which have a latent period of 2–6 weeks. In many developing countries, children have chronic skin infections, and it may be difficult to establish the latent period with accuracy. Impetigo-associated cases are more common in the warmer months, sex distribution is equal, and children tend to be younger. Introduction of a nephritogenic strain into a family often results in the occurrence of several cases within that family, and in some cases, attack rates of up to 20% have been described (30). The incidence is linked to poor socioeconomic conditions.

Renal involvement in APSGN can be mild, and in many patients, the disease may not be manifested clinically. Studies of epidemics with nephritogenic strains of streptococci have shown that up to 50% of those infected had subclinical evidence of renal disease (30, 31). In a typical case a sudden onset of facial or generalized edema

occurs. Hypertension is usually modest but is severe in 5% of cases, and occasionally may lead to encephalopathy or left ventricular failure. The urine is smoky or tea colored in 30–50% of cases. Pallor, headache, backache, lethargy, malaise, anorexia, and weakness are all common nonspecific features.

The urine volume is decreased. Proteinuria is present (up to 100 mg/dL), and microscopy shows white cells, red cells, and granular and hyaline casts. Urea, electrolyte, and creatinine levels are normal in subclinical cases but show features of acute renal failure in severe cases. It may be possible to culture GAS from the skin or the throat in some patients. Other evidence of infection with a GAS can be obtained through the antistreptolysin-O titer (ASOT), which is increased in 60–80% of cases. Early antibiotic treatment can reduce the proportion of cases with elevated ASOT to 30%. Anti-deoxyribonuclease B and anti-hyaluronidase testing has been shown to be of more value than ASOT in confirming group A streptococcal infection in impetigo-associated cases. Measurement of anti-M protein antibodies is of more value for epidemiologic purposes than for the diagnosis of individual cases (31). Decreased C3 and total hemolytic complement levels are found in 90% of cases during the first 2 weeks of illness and return to normal after 4–6 weeks.

Penicillin should be given to eradicate the GAS organisms. Erythromycin, clindamycin, or a first-generation cephalosporin can be given to patients allergic to penicillin. Antibiotic treatment probably has no influence on the course of renal disease but will prevent the spread of a nephritogenic strain (32). Close contacts and family members who are culture-positive for GAS should also be given penicillin, although antibiotic treatment is not always effective in eliminating secondary cases. Recurrent episodes are rare, and immunity to the particular nephritogenic strain that caused the disease is probably lifelong. Antibiotic prophylaxis is therefore unnecessary.

Most studies suggest that the prognosis for children with APSGN is good, with more than 90% making a complete recovery. However, 10% of cases may have a prolonged and more serious course with long-term chronic renal failure (33).

Other Streptococci. APSGN has also been described after outbreaks of group C Streptococcus infection (34). This has occurred after consumption of unpasteurized milk from cattle with mastitis. Patients developed pharyngitis followed by APSGN. Endostreptosin was found in the cytoplasm of these group C strains, and during the course of the illness, patients developed anti-endostreptosin antibodies. This antigen has been postulated to be the nephritogenic component of GAS.

In addition, strains of group G streptococci have been implicated in occasional cases of APSGN (35). Isolates possessed the type M12 protein antigen identical to the nephritogenic type M12 antigen of some group A streptococcal strains.

Streptococcal Toxic Shock Syndrome and Invasive Group A Streptococcal Infection. Since 1988, there have been several reports of an illness with many similarities to the staphylococcal toxic shock syndrome, occurring in both children (36) and adults, associated with invasive group A streptococcal disease (32, 37, 38). Patients with this syndrome present acutely with high fever, erythematous rash, mucous membrane involvement, hypotension, and multiorgan failure. Unlike staphylococcal toxic shock syndrome, in which the focus of infection is usually trivial and bacteremia is seldom seen, the streptococcal toxic shock syndrome is usually associated with bacteremia or a serious focus of infection such as septic arthritis, myositis, or osteomyelitis (36, 38). Laboratory findings of anemia, neutrophil leukocytosis, thrombocytopenia, and DIC are often present, together with impaired renal function, hepatic derangement, and acidosis. Acute renal failure requiring dialysis occurs in a significant proportion of cases.

It is not clear why there are increasing numbers of cases with invasive disease caused by GAS, nor why there has been an emergence of streptococcal toxic shock syndrome, and indeed a similar syndrome caused by some pseudomonas and klebsiella strains. The most common antecedent of invasive GAS disease is varicella infection, with the streptococcal infection developing after the initial vesicular phase of the disease is subsiding. Strains causing toxic shock syndrome and invasive disease appear to differ from common isolates of GAS in producing large amounts of pyrogenic toxins that may have superantigen-like activity. Another important mechanism is the production by invasive GAS of an IL8 protease. IL8 serves as a molecular bridge between receptors on neutrophils and the vascular endothelium. Cleavage of this protein prevents neutrophil attachment to the endothelium, and results in uncontrolled spread of the bacteria through the tissues (39). In severe cases necrotizing fasciitis occurs with extensive destruction of the subcutaneous tissues, and is often associated with multiorgan failure. The pathophysiology of streptococcal toxic shock syndrome and that of invasive disease is similar in that superantigen toxins that induce release of cytokines and other inflammatory mediators play a role in both conditions. However GAS toxic shock is usually more severe, carries a higher mortality, and is more often associated with focal collections or necrotizing fasciitis.

Treatment of streptococcal toxic shock syndrome depends on the administration of appropriate antibiotics, aggressive circulatory support, and treatment of any multiorgan failure. Surgical intervention to drain the infective focus in muscle, bone, joint, or body cavities is often required. Antibiotic therapy with beta-lactams should be supplemented by treatment with a protein synthesis-inhibiting antibiotic, such as clindamycin, and it is suggested that this limits new toxin production (40, 41).

A number of new therapies are in development. Firstly, pooled intravenous immunoglobulins are now in widespread use in the treatment of toxic shock, particularly when caused by streptococcus (42, 43).

The role of steroids remains unclear, with their hemodynamic benefit set against the detrimental effects of hyperglycemia secondary to gluconeogenesis. (44). The benefit of insulin therapy to control hyperglycemia is unclear. A recent study in adults found that intensive insulin therapy increased the risk of serious adverse events (45). In contrast to adult patients, in children with severe sepsis, the use of activated protein C (Drotrecogin) cannot be recommended, as in a multicenter trial, fatality was increased in the treatment group (5). Recovery of renal function occurs in patients who respond to treatment of shock and the eradication of the infection.

Leptospira

Leptospirosis is an acute generalized infectious disease caused by spirochetes of the genus Leptospira (46). It is primarily a disease of wild and domestic animals, and humans are infected only occasionally through contact with animals. Most human cases occur in summer or autumn and are associated with exposure to leptospira-contaminated water or soil during recreational activities such as swimming or camping. In adolescents and adults, occupational exposure through farming or other contact with animals is the route of infection.

The spirochete penetrates intact mucous membranes or abraded skin and disseminates to all parts of the body, including the cerebrospinal fluid (CSF). Although leptospires do not contain classic endotoxins, the pathophysiology of the disorder has many similarities to that of endotoxemia. In severe cases, jaundice occurs because of hepatocellular dysfunction and cholestasis. Renal functional abnormalities may be profound and out of proportion to the histologic changes in the kidney (47). Renal involvement is predominantly a result of tubular damage, and spirochetes are commonly seen in the tubular lesions. The inflammatory changes in the kidney may result from either a direct toxic effect of the organism or immune-complex nephritis. However, hypovolemia, hypotension, and reduced cardiac output caused by myocarditis may contribute to the development of renal failure. In severe cases, a hemorrhagic disorder caused by widespread vasculitis and capillary injury also occurs (47, 48).

The clinical manifestations of leptospirosis are variable. Of affected patients, 90% have the milder anicteric form of the disorder, and only 5–10% have severe leptospirosis with jaundice. The illness may follow a biphasic course. After an incubation period of 7–12 days, a nonspecific flu-like illness lasting 4–7 days occurs, associated with septicemic spread of the spirochete. The fever then subsides, only to recur for the second, "immune," phase of the illness. During this phase, the fever is low grade and there may be headache and delirium caused by meningeal involvement, as well as intense muscular aching. Nausea and vomiting are common. Examination usually reveals conjunctival suffusion, erythematous rash, lymphadenopathy, and meningism.

The severe form of the disease (Weil's disease) presents with fever, impaired renal and hepatic function, hemorrhage, vascular collapse, and altered consciousness. In one series the most common organs involved were the liver (71%) and kidney (63%). Cardiovascular (31%), pulmonary (26%), neurologic (5%), and hematologic (21%) involvements were less common (49). Vasculitis, thrombocytopenia, and uremia are considered important factors in the pathogenesis of hemorrhagic disturbances and the main cause of death in severe leptospirosis (50). Urinalysis results are abnormal during the leptospiremic phase with proteinuria, hematuria, and casts. Uremia usually appears in the second week, and acute renal failure may develop once cardiovascular collapse and DIC are present (48).

The clinical features of leptospirosis overlap with those of several other acute infectious diseases, including Rocky Mountain spotted fever, toxic shock syndrome, and streptococcal sepsis. The diagnosis of leptospirosis should be considered in febrile patients with evidence of renal, hepatic, and mucous membrane changes and rash, particularly if a history of exposure to fresh water is found. Diagnosis can be confirmed by isolation of the spirochetes from blood or CSF in the first 10 days of the illness or from urine in the second week (48). The organism may be seen in biopsy specimens of the kidney or skin or in the CSF by dark-field microscopy or silver staining. Serologic tests to detect leptospirosis are now sensitive and considerably aid the diagnosis. Immunoglobulin M (IgM) antibody may be detected as early as 6–10 days into the illness, and antibody titers rise progressively over the next 2–4 weeks. Some patients remain seronegative, and negative serologic test results do not completely exclude the

diagnosis. In one series levels of IgM and IgG anticardiolipin concentrations were significantly increased in leptospirosis patients with acute renal failure (50). Leptospirosis is treated with intravenous penicillin or other beta-lactam antibiotics. The severity of leptospirosis is reduced by antibiotic treatment, even if started late in the course of the illness (51). Supportive treatment with volume replacement to correct hypovolemia, administration of inotropes, and correction of coagulopathy is essential in severe cases. Dialysis may be required in severe cases and may be needed for prolonged periods until recovery occurs.

Streptococcus Pneumoniae

Infection with *S. pneumoniae* is one of the most common infections in humans and causes a wide spectrum of disease, including pneumonia, otitis media, sinusitis, septicemia, and meningitis. Despite the prevalence of the organism, significant renal involvement is relatively rare but is seen in two situations: pneumococcal septicemia in asplenic individuals or in those with other immune deficiencies presents with fulminant septic shock in which renal failure may occur as part of a multisystem derangement. The mortality from pneumococcal sepsis in asplenic patients is high, even with early antibiotic treatment and intensive support.

The second nephrologi syndrome associated with *S. pneumoniae* is a rare form of HUS. In 1955, Gasser and colleagues described HUS as a clinical entity in children, and they included two infants with pneumonia among the five patients they described (52). HUS associated with pneumococcal infection is induced by the enzyme neuraminidase released from *S. pneumoniae* (53, 54). Thomsen-Friedenrich antigen (T antigen) is present on the surface of red blood cells, platelets, and glomerular capillary endothelia against which antibodies are present in normal serum. Neuraminidase causes desialation of red blood cells, and possibly other blood cells and endothelium, by the removal of terminal neuraminic acid, which leads to unmasking of the T antigen. The resultant widespread agglutination of blood cells causes intravascular obstruction, hemolysis, thrombocytopenia, and renal failure. Results of the direct Coombs test are frequently positive, either from bound anti-T IgM or from anti-T antibodies. The diagnosis of Thomsen-Friedenrich antibody-induced HUS should be suspected in patients with acute renal failure, thrombocytopenia and hemolysis after an episode of pneumonia or bacteremia caused by *S. pneumoniae*. Fragmented red blood cells will usually be present on blood film.

Association with *S. pneumoniae* is defined by culture of pneumococci from a normally sterile site within a week before or after onset of signs of HUS. Clues to a pneumococcal cause, in addition to culture results, include severe clinical disease, especially pneumonia, empyema, pleural effusion, or meningitis; hemolytic anemia without a reticulocyte response; positive results on a direct Coombs test; and difficulties in ABO crossmatching or a positive minor crossmatch incompatibility (55). However, when renal disease is seen in the context of severe pneumococcal infection, it is important to maintain a broad diagnostic perspective, because the occurrence of acute tubular necrosis due to septic shock and DIC is well described (56, 57).

Therapy for this syndrome should be with supportive treatment and antibiotics (usually a third generation cephalosporin); dialysis may be required if renal failure occurs. Because normal serum contains antibodies against the Thomsen-Friedenrich antigen, blood transfusion should be undertaken with washed red blood cells resuspended in albumin rather than plasma (53, 54). Exchange transfusion and plasmapheresis have been used in some patients, with the rationale that these procedures may improve outcome by eliminating circulating neuraminidase (53, 57, 58). Intravenous IgG has been used in a patient and was shown to neutralize neuraminidase present in the patient's serum (59).

In comparison to patients with the more common diarrhea-associated HUS, *S. pneumoniae*-induced HUS patients have a more severe renal disease. They are more likely to require dialysis. Their long-term outcome maybe affected by the severity of the invasive streptococcal disease itself, and a significant proportion of surviving patients (30–70%) develop end-stage renal failure (60, 61). A recent review of UK cases found an eightfold increase in early mortality as compared to diarrhoea-induced HUS (62).

Gastrointestinal Infections (*Escherichia coli*, Salmonella, Campylobacter, Yersinia, Shigella, *Vibrio cholerae*)

The diarrheal diseases caused by *Escherichia coli*, Salmonella, Shigella, Campylobacter, vibrios, and Yersinia remain important and common bacterial infections of humans. Although improvements in hygiene and living conditions have reduced the incidence of bacterial gastroenteritis in developed countries, these infections remain common in underdeveloped areas of the world, and outbreaks and epidemics continue to occur in both developed and underdeveloped countries. Renal involvement in the enteric infections may result from any of four possible mechanisms.

Severe Diarrhea and Dehydration

Regardless of the causative organism, diarrhea results in hypovolemia, abnormalities of plasma electrolyte composition, and renal underperfusion. If severe dehydration occurs and is persistent, oliguria from prerenal failure is followed by vasomotor nephropathy and established renal failure.

Systemic Sepsis and Endotoxemia

E. coli, Shigella, and Salmonella (particularly *Salmonella typhi*) may invade the bloodstream and induce septicemia or septic shock. Acute renal failure is commonly seen in infants with *E. coli* sepsis but is also reported with Klebsiella, Salmonella, and Shigella infections. Its pathophysiology and treatment were discussed previously.

Enteric Pathogen-Associated Nephritis

Enteric infections with *E. coli*, Yersinia, Campylobacter, and Salmonella have been associated with several different forms of GN, including membranoproliferative GN (MPGN), interstitial nephritis, diffuse proliferative GN, and IgA nephropathy (63–65).

In typhoid fever, GN ranging from mild asymptomatic proteinuria and hematuria to acute renal failure may occur (64, 66–68). Renal biopsy findings show focal proliferation of mesangial cells, hypertrophy of endothelial cells, and congested capillary lumina. Immunofluorescent studies show IgM, IgG, and C3 deposition in the glomeruli, with Salmonella antigens detected within the granular deposits in the mesangial areas. In the IgA nephropathy after typhoid fever, Salmonella vi antigens have been demonstrated within the glomeruli.

Yersinia infection has been reported as a precipitant of GN in several studies (65, 69). Transient proteinuria and hematuria are found in 24% of patients with acute yersinia infection, and elevated creatinine levels in 10%. Renal biopsy reveals mild mesangial GN or IgA nephropathy. Yersinia antigens, immunoglobulin, and complement have been detected in the glomeruli. *Yersinia pseudotuberculosis* is well recognized as one of the causes of acute tubulointerstitial nephritis causing acute renal failure, especially in children; patients have histories of drinking untreated water in endemic areas (70–72). The illness begins with the sudden onset of high fever, skin rash, and GI symptoms. Later in the course, periungual desquamation develops, mimicking Kawasaki disease. Elevated erythrocyte sedimentation rate, C-reactive protein level, and thrombocytosis are noticeable, and mild degrees of proteinuria, glycosuria, and sterile pyuria are common. Acute renal failure, which typically develops 1–3 weeks after the onset of fever, follows a benign course with complete recovery. Renal biopsy mainly reveals findings of acute tubulointerstitial nephritis. Antibiotic therapy, although recommended, does not alter the clinical course, but reduces the fecal excretion of the organism (73, 74).

Enteric Pathogen-Induced Hemolytic Uremic Syndrome

HUS is characterized by three distinct clinical signs: acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. It was first described in 1955 and was associated with infection by Shiga toxin-producing *Shigella dysenteriae*. A major breakthrough in the search for the cause of HUS occurred in the 1980s when Karmali *et al.* reported that 11 of 15 children with diarrhea-associated HUS had evidence of infection with a strain of *E. coli* that produced a toxin active on Vero cells (75). In diarrhea-associated HUS in the United States and most of Europe, *E. coli* 0157:H7 is the most important of these strains. *E. coli* 0157:H7 occurs naturally in the GI tract of cattle and other animals, and humans become infected through contaminated food products. Most outbreaks have been associated with consumption of undercooked meat, but unpasteurized milk and cider, drinking water, and poorly chlorinated water for recreational use have also been implicated as vehicles for bacterial spread. HUS is discussed in detail in Chapter 67.

Mycobacterium Tuberculosis

The global epidemic of Mycobacterium tuberculosis is growing. Several factors have contributed to this increase, including the emergence of the human immunodeficiency virus (HIV) infection epidemic, large influxes of immigrants from countries in which tuberculosis (TB) is common, the emergence of multiple-drug-resistant *M. tuberculosis*, and breakdown of the health services for effective control of TB in various countries. It is generally estimated that, overall, one-third of the world's population is currently infected with the TB bacillus. There are more than 8 million cases of TB, which result in the death of approximately 2 million people each year. Furthermore, 5–10% of people who are infected with the TB bacillus develop TB disease or become infectious at some time during their lives (76, 77). After respiratory illness in children, mycobacteria are widely distributed to many organs of the body during the lymphohematogenous phase of childhood TB (78). Tubercle bacilli can be recovered from the urine in many cases of miliary TB. Hematogenously-spread tuberculomata develop in the

glomeruli, which results in caseating, sloughing lesions that discharge bacilli into the tubules. In most cases, the renal lesions are asymptomatic and manifest as mycobacteria in the urine or as sterile pyuria.

Tuberculomata in the cortex may calcify and cavitate or may rupture into the pelvis, discharging infective organisms into the tubules, urethra, and bladder. Dysuria, loin pain, hematuria, and pyuria are the presenting features of this complication, but in many cases, the renal involvement is asymptomatic, even when radiologic and pathologic abnormalities are very extensive. Continuing tuberculous bacilluria may cause cystitis with urinary frequency and, in late cases, a contracted bladder (79). The intravenous urogram is abnormal in most cases. Early findings are pyelonephritis with calyceal blunting and calyceal-interstitial reflux. Later, papillary cavities may be seen, indicating papillary necrosis. Ureteric strictures, focal calcification, hydronephrosis, and cavitation may also be seen. Renal function is usually well preserved, and hypertension is uncommon. In some cases, either the infection itself or reactions to the chemotherapeutic agents may result in renal failure with evidence of an interstitial nephritis (79–81).

Classic symptomatic renal TB is a late and uncommon complication in children, rarely occurring less than 4 or 5 years after the primary infection, and therefore is most commonly diagnosed after adolescence (78, 80). Adult studies have shown that 26–75% of renal TB coexists with active pulmonary TB and 6–10% of screened sputum-positive pulmonary TB patients have renal involvement.

The diagnosis is established by isolation of mycobacteria from the urine or by the presence of the characteristic clinical and radiographic features in a child with current or previous TB. Renal TB is treated with drug regimens similar to those used for other forms of TB, with isoniazid, rifampicin, pyrazinamide and ethambutol administered initially for 2 months, and isoniazid and rifampicin then continued for a further 7–10 months. Late scarring and urinary obstruction may occur in cases with extensive renal involvement, and such patients should be followed by ultrasonography or intravenous urogram.

Mycobacteria, both *M. tuberculosis* and atypical mycobacteria, have also emerged as important causes of opportunistic infection in immunocompromised patients undergoing dialysis and in patients undergoing renal transplantation. The possibility of mycobacterial disease must be considered in patients with fever of unknown origin or unexplained disease in the lungs or other organs. Results of the Mantoux test are often negative, and diagnosis depends on maintaining a high index of suspicion and isolating the organism from the infected site.

Treponema Pallidum

Renal involvement has been well documented in both congenital and acquired syphilis, with an estimated occurrence of 0.3% in patients with secondary syphilis and up to 5% in those with congenital syphilis (82, 83). The most common manifestation of renal disease in congenital syphilis is the nephrotic syndrome, with proteinuria, hypoalbuminemia, and edema. In some patients, hematuria, uremia, and hypertension may be seen. The renal disease is usually associated with other manifestations of congenital syphilis, including hepatosplenomegaly, rash, and mucous membrane findings.

Nephritis in congenital syphilis is usually associated with evidence of complement activation, with depressed levels of Clq, C4, C3, and C5. Histologic findings are a diffuse proliferative GN or a membranous nephropathy. The interstitium shows a cellular infiltrate of polymorphonuclear and mononuclear cells (84). Immunofluorescent microscopy reveals diffuse granular deposits of IgG and C3 along the glomerular basement membrane (GBM). Mesangial deposits may also contain IgM. On electron microscopy, scattered subepithelial electron-dense deposits are seen, with fusion of epithelial cell foot processes (84).

Good evidence exists that renal disease is due to an immunologically mediated reaction to treponemal antigens. Antibodies reactive against treponemal antigens can be eluted from the glomerular deposits, and treponemal antigens are present in the immune deposits. Treatment of both congenital and acquired syphilis with antibiotics results in rapid improvement in the renal manifestations (82, 84).

Mycoplasma Pneumoniae

Renal involvement is surprisingly rare in *Mycoplasma pneumoniae* infection considering the prevalence of this organism and its propensity to trigger immunologically mediated diseases such as erythema multiforme, arthritis, and hemolysis. Acute nephritis associated with Mycoplasma infection may occur 10–40 days after the respiratory tract infection (85, 86). Renal histopathologic findings include type 1 MPGN, proliferative endocapillary GN, and minimal change disease (87). Antibiotic treatment of the infection does not appear to affect the renal disease, which is self-limited in most cases (85, 86).

Legionnaires' Disease

Since its recognition in 1976, Legionnaires' disease, caused by *Legionella pneumophila*, has emerged as an important

cause of pneumonia. The disease most commonly affects the elderly but has been reported in both normal and immunocompromised children (97, 98). Renal dysfunction occurs in a minority of patients (98). Patients who develop renal impairment present with oliguria and rising urea and creatinine levels. They are usually severely ill, with bilateral pulmonary infiltrates, fever, and leukocytosis. Shock may be present, and the renal impairment has been associated with acute rhabdomyolysis with high levels of creatine phosphokinase and myoglobinuria. Renal histologic examination usually shows a tubulointerstitial nephritis or acute tubular necrosis (98, 99). The pathogenesis of the renal impairment is uncertain, but the organism has been detected within the kidney on electron microscopy and immunofluorescent studies, which suggests a direct toxic effect. Myoglobinuria and decreased perfusion may also be contributing factors, however. Mortality has been high in reported cases of Legionnaires' disease complicated by renal failure. Treatment is based on dialysis, intensive care, and antimicrobial therapy with erythromycin (98). Steroid therapy may be effective for tubulointerstitial nephritis (99).

Rickettsial Diseases

The rickettsial diseases are caused by a family of microorganisms that have characteristics common to both bacteria and viruses and that cause acute febrile illnesses associated with widespread vasculitis. With the exception of Q fever, all are associated with erythematous rashes. There are four groups of rickettsial diseases:

1. The typhus group includes louse-borne and murine typhus, spread by lice and fleas, respectively.
2. The spotted fever group includes Rocky Mountain spotted fever, tick typhus and related Mediterranean spotted fever and rickettsial pox, which are spread by ticks and mites, with rodents as the natural reservoir.
3. Scrub typhus, which is spread by mites.
4. Q fever, which is spread by inhalation of infected particles from infected animals.

Rickettsial diseases have a worldwide distribution and vary widely in severity, from self-limited infections to fulminant and often fatal illnesses (88). In view of the widespread vasculitis associated with these infections, subclinical renal involvement probably occurs in many of the rickettsial diseases. However, in Rocky Mountain spotted fever, tick typhus, and Q fever, the renal involvement may be an important component of the illness.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is the most severe of the rickettsial diseases (89, 90). The onset occurs 2–8 days after the bite of an infected tick. High fever develops initially, followed by the pathognomonic rash, which occurs between the second and sixth days of the illness. The rash initially consists of small erythematous macules, but later these become maculopapular and petechial, and in untreated patients, confluent hemorrhagic areas may be seen. The rash first appears at the periphery and spreads up the trunk. Involvement of the palms and soles is a characteristic feature (88).

Headache, restlessness, meningism, and confusion may occur together with other neurologic signs. Cardiac involvement with congestive heart failure and arrhythmia are common. Pulmonary involvement occurs in 10–40% of cases. Infection is associated with an initial leucopenia, followed by neutrophil leukocytosis. Thrombocytopenia occurs in most cases.

Histopathologically, the predominant lesions are in the vascular system (91). Rickettsiae multiply in the endothelial cells, which results in focal areas of endothelial cell proliferation, perivascular mononuclear cell infiltration, thrombosis, and leakage of red cells into the tissues. The renal lesions involve both blood vessels and interstitium, and acute tubular necrosis may occur. Acute GN with immune-complex deposition has been reported (92), but in most cases the pathology appears to be a direct consequence of the invading organism on the renal vasculature (90, 93).

Renal dysfunction is an important complication of Rocky Mountain spotted fever. Elevation of urea and creatinine levels occurs in a significant proportion of cases, and acidosis is common. Prerenal renal failure caused by hypovolemia and impaired cardiac function may respond to volume replacement and inotropic support, but acute renal failure may subsequently occur, necessitating dialysis.

Rocky Mountain spotted fever is diagnosed by the characteristic clinical picture, the exclusion of disorders with similar manifestations (e.g., measles, meningococcal disease, and leptospirosis), and detection of specific antibodies in convalescence. Culture of *Rickettsia rickettsii*, immunofluorescent staining, and polymerase chain reaction (PCR) testing of blood and skin biopsy specimens are available only in reference laboratories. Antibiotics should be administered in suspected cases without awaiting confirmation of the diagnosis (93). Doxycycline is the drug of choice for children of any age. Chloramphenicol is also effective (94). Intensive support of shock and multiorgan

failure may be required in severe cases, and peritoneal dialysis or hemodialysis may be required until renal function returns. Before the advent of specific therapy, mortality was 25%. Today the overall mortality in the United States is still 5–7%. Death predominantly occurs in cases in which the diagnosis is delayed.

Q Fever

Q fever is caused by *Coxiella burnetii* and has a worldwide distribution, with the animal reservoir being cattle, sheep, and goats. Human infection follows inhalation of infected particles from the environment. The clinical manifestations range from an acute self-limited febrile illness with atypical pneumonia to involvement of specific organs that causes endocarditis, hepatitis, osteomyelitis, and central nervous system disease (95).

Proliferative GN may be associated with either Q fever endocarditis, rhabdomyolysis or a chronic infection elsewhere in the body (96). Renal manifestations range from asymptomatic proteinuria and hematuria to acute renal failure, hypertension, and nephrotic syndrome. Renal histologic findings are those of a diffuse proliferative GN, focal segmental GN, or mesangial GN. Immunofluorescent studies reveal diffuse glomerular deposits of IgM in the mesangium, together with C3 and fibrin. *C. burnetii* antigen has not been identified within the renal lesions.

Treatment of the underlying infection may result in remission of the renal disease, but prolonged treatment may be required for endocarditis. Tetracycline has been used in conjunction with rifampicin, co-trimoxazole, or a fluoroquinolone.

Intravascular and Focal Infections

Nephritis has been reported in association with the presence of a wide range of microorganisms that cause chronic or persistent infection (*Table 52-2*) (63, 100). It is likely that any infectious agent that releases foreign antigens into the circulation, including those of very low virulence, can cause renal injury either by deposition of foreign antigens in the kidney or by the formation of immune complexes in the circulation, which are then deposited within the kidney. Nephritis is most commonly seen in association with intravascular infections such as SBE or infected ventriculoatrial shunts, but it is also seen after focal extravascular infections; ear, nose, and throat infections; and abscesses.

Bacterial Endocarditis

Renal involvement is one of the diagnostic features of bacterial endocarditis. Virtually all organisms that cause endocarditis also produce renal involvement (*Table 52-2*). Although endocarditis caused by bacteria is the most common and is readily diagnosed by blood culture (100), unusual but important causes of culture-negative endocarditis include Q fever (101) and Legionella infection (102). In the immunocompromised individual, opportunistic pathogens such as fungi and mycobacteria are important causes.

The usual renal manifestations of SBE are asymptomatic proteinuria, hematuria, and pyuria. Loin pain, hypertension, nephrotic syndrome, and renal failure may occur in more severe cases.

The renal lesions occurring in endocarditis are variable, and focal embolic and immune-complex-mediated features may coexist (100, 103, 104). Embolic foci may be evident as areas of infarction, intracapillary thrombosis, or hemorrhage. More commonly, there is a focal necrotizing or diffuse proliferative GN. Immunofluorescent studies show glomerular deposits of IgG, IgM, IgA, and C3 along the GBM and within the mesangium. Electron microscopy reveals typical electron-dense deposits along the GBM and within the mesangium (100, 103, 104).

Early reports suggested that the renal lesions were caused by microemboli from infected vegetations depositing in the kidney, a hypothesis supported by the occasional presence of bacteria within the renal lesions. Most subsequent evidence, however, indicates that immunologic mechanisms rather than emboli are involved in the pathogenesis in most cases: bacteria are rarely found within the kidney, and renal involvement occurs with lesions of the right side of the heart, which would not be likely to embolize to the kidney. Immune complexes containing bacterial antigens are present in the circulation, and both bacterial antigens and bacteria-specific antibodies can be demonstrated within the immune deposits in the kidney. Serum C3 level is usually low, and complement can be found within both the circulating and the deposited immune complexes. These features all support an immune-complex-mediated pathogenesis of the renal injury (100, 103, 104).

Treatment of the endocarditis with antibiotics usually results in resolution of the GN and is associated with the disappearance of immune complexes from the circulation and return of C3 levels to normal. The prognosis of the renal lesions in SBE generally depends on the response of the underlying endocarditis to antibiotics or, in cases of antibiotic failure, to surgical removal of the infective vegetations (105).

Shunt Nephritis

In patients previously treated by shunting for hydrocephalus, there is a well-documented association of GN with infected ventriculoatrial shunts. This condition is another example of an immune-complex nephritis similar to that seen in endocarditis (106). Coagulase-negative staphylococci are the causative organisms in 75% of cases. The clinical and pathologic findings are similar to those in SBE. Presenting features are proteinuria, hematuria, and pyuria, and they may progress to renal failure. Immune complexes containing the bacterial antigens and complement are present in the serum, and C3 is depressed. Histologic findings are those of a diffuse mesangiocapillary GN. Immunofluorescent microscopy demonstrates deposits of immunoglobulin and C3 along the GBM, and bacterial antigen can be demonstrated in the renal lesions (107).

The prognosis for the renal lesion is good if the infection is treated early. This usually involves removal of the infected shunt and administration of appropriate antibiotics (106, 108). The possible progression to end-stage renal disease requires frequent nephrologic monitoring of patients with ventriculoatrial shunts (106). There are a few reports in the literature of a similar renal complication occurring in chronic infection of ventriculoperitoneal shunts.

Other Focal Infections

GN has been reported after chronic abscesses (63), osteomyelitis, otitis media, pneumonia, and other focal infections (*Table 52-2*). Acute renal failure has been the presenting feature of focal infections in various sites, including the lung, pleura, abdominal cavity, sinuses, and pelvis. Many different organisms have been responsible, including *S. aureus, Pseudomonas, E. coli,* and *Proteus* species. This is probably another example of immune-complex GN. C3 level is decreased in approximately one-third of reported cases, and immunofluorescent studies reveal diffuse granular deposits of C3 in the glomeruli of all reported instances, with a variable presence of immunoglobulin. The renal lesion is that of MPGN and crescentic nephritis. The renal outcome is reported to be good with successful early treatment of the underlying infection.

Viral Infections

The role of viral infections in the causation of renal disease has been less well defined than that of bacterial infections. Clearly defined associations of renal disease have been made with hepatitis B virus (HBV), hepatitis C virus (HCV), HIV, and hantaviruses, but the role of most other viruses in the pathogenesis of renal disease is not clearly defined. Most viruses causing systemic infection may trigger immunologically mediated renal injury. With increasing application of molecular techniques, it may be that a significant proportion of GNs currently considered to be idiopathic will ultimately be shown to be virus induced. In children with immunodeficiency states and those undergoing renal transplantation, viruses such as cytomegalovirus (CMV) and polyoma virus have been recognized to be associated with nephropathy.

Hepatitis B Virus

Since the discovery of hepatitis B surface antigen (HBsAg) in 1964, hepatitis virus has been shown to infect more than 5% of the world's population and is a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma worldwide. Some 350 million people have HBsAg in the circulation (WHO figures). The infection is most common in Africa and the Orient, where it is acquired in childhood by vertical transmission from infected mothers or by horizontal transmission from other children or adults. In developed countries, transmission in adults occurs more often by blood product exposure, sexual contact, or intravenous drug use. The epidemiology of HBV infection in children is changing following the widespread use of effective vaccination at birth, in both developed and developing countries.

HBV is a complex DNA virus with an outer surface envelope (HBsAg) and an inner nucleocapsid core containing the hepatitis B core antigen (HBcAg), DNA polymerase, protein kinase activity, and viral DNA. Incomplete spherical and filamentous viral particles consisting solely of HBsAg are the major viral products in the circulation and may be present in concentrations of up to 1014 particles per mL of serum. Hepatitis B e antigen (HBeAg) can be released from HBcAg by proteolytic treatment and may be found in the circulation either free or complexed to albumin or IgG antibodies. The presence of HBeAg correlates with the presence of complete viral particles and the infectivity of the individual (109).

Infection with HBV may result in either a self-limited infectious hepatitis followed by clearance of the virus and complete recovery, or a chronic or persistent infection in which the immune response is ineffective in eliminating the virus. Chronic HBV infection with continued presence of viral antigens in the circulation caused by an ineffective

Table 52-2
Focal infections causing glomerulonephritis

Site of infection	Organism
Infective endocarditis	Coagulase-negative staphylococci

host immune response provides the best-documented example of immunologically mediated renal injury caused by persistent infection (110). Development of chronic HBV infection is positively associated with infection at a younger age, particularly in infancy, where the rate of chronic infection is up to 90%. In contrast, the likelihood of an acute, symptomatic illness increases with age, to a level where approximately 40% of infections are symptomatic in children above 15 years.

Patterns of Hepatitis B Virus Immunologically Mediated Renal Disease

Prodromal illness

In the early prodromal phase of HBV hepatitis, before the onset of jaundice, some patients develop fever, maculopapular or urticarial rash, and transient arthralgias or arthritis. Occasionally, proteinuria, hematuria, or sterile pyuria are observed. The syndrome usually lasts 3–10 days and often resolves before the onset of jaundice (110, 111). There have been no histologic studies of the renal changes during this prodromal period.

Hepatitis B Virus-Associated Polyarteritis Nodosa

Since 1970, numerous reports have linked HBV infection with polyarteritis nodosa (PAN). Most of these cases have been in adults, but the disorder has also been reported in children (112, 113), where it is estimated that approximately one third of PAN cases are caused by HBV (114). HBV PAN appears to be uncommon in Africa and the Orient, where infection is usually acquired in childhood, and has declined in incidence following the introduction of HBV vaccination (115).

HBV PAN presents weeks to months after a clinically mild hepatitis but may occasionally predate the hepatitis. After a prodromal illness, frank vasculitis affecting virtually any organ appears. Abdominal pain, fever, mononeuritis multiplex, and pulmonary and renal involvement may occur. The renal involvement may appear as hypertension, hematuria, proteinuria, or renal failure (see Chapter 61). Laboratory investigations reveal a florid acute-phase response, leukocytosis, and anemia. Transaminase levels are usually elevated, and HBsAg is present in the circulation. The pathology consists of focal inflammation of small and medium-sized arteries, with fibrinoid necrosis, leukocyte infiltration, and fibrin deposition. Renal pathology may be limited to the medium-sized arteries or may coexist with GN (110, 116).

Circulating immune complexes containing HBsAg and anti-HBs antibodies are usually present in the circulation (110, 116). C3, C4, and total hemolytic complement levels are depressed. HBsAg, IgG, and IgM antibodies to HBV and C3 have been identified by immunofluorescence in the blood vessels (116). A positive ANCA excludes HBV-PAN (115). Although most evidence suggests that the pathogenesis involves an immune-complex-mediated vasculitis, autoantibody or cell-mediated vascular injury may coexist. If the condition is untreated, the mortality is high (112). Most studies suggest that steroids or immunosuppressants help to suppress the vasculitis but potentially predispose to chronic infection

or progressive liver disease (110, 112). Successful treatment of hepatitis B-associated PAN with nucleoside analogues such as lamivudine or newer anti-viral drugs, either alone or in combination with interferon-alpha and conventional immunosuppressive therapy, has been reported (117–119).

Hepatitis B Virus-Associated Membranous Glomerulonephritis

HBV is now the major cause of membranous GN (MGN) in children worldwide. The proportion of patients with MGN caused by HBV is directly related to the incidence of HBsAg in the population, with 80–100% of all cases of MGN in some African and Oriental countries being associated with HBV (110, 120) (see Chapter 26).

HBV MGN usually presents in children aged 2–12. There is a striking male predominance; in the United States, 80% of patients are males (121). The virus is usually acquired by vertical transmission from infected mothers or horizontally from infected family members. Unlike adults with HBV MGN, children do not usually have a history of hepatitis or of active liver disease, but liver function test results are generally mildly abnormal. Liver biopsy specimens may show minimal abnormalities, chronic persistent hepatitis, or (occasionally) more severe changes (121).

The renal manifestations are usually of proteinuria, nephrotic syndrome, microscopic hematuria, or (rarely) macroscopic hematuria. Hypertension occurs in less than 25% of cases, and renal insufficiency is rare.

HBsAg and HBcAg are usually present in the circulation, and HBe antigenemia is seen in a high proportion of cases. Occasionally, HBsAg may be found in the glomeruli but is absent from the circulation. C3 and C4 levels are often low, and circulating immune complexes are found in most cases.

Immunohistologic study reveals deposits of IgG and C3 and (less commonly) IgM and IgA in subepithelial, subendothelial, or mesangial tissue. HBV particles may be seen on electron microscopy, and all the major hepatitis B antigens, including HBsAg, HBcAg, and HBeAg, have been localized in the glomerular capillary wall on immunofluorescence.

Immunologic deposition of HBV and antibody in the glomerular capillary wall is clearly involved in the glomerular injury, but the underlying immunologic events are incompletely understood (110, 122). Passive trapping of circulating immune complexes may be involved, but the circulating immune complexes containing HBsAg are usually larger than would be expected to penetrate the basement membrane. HBsAg and HBcAg are anionic and are therefore unlikely to penetrate the glomerular capillary wall. In contrast, HBeAg forms smaller complexes with anti-HBe antibodies and may readily penetrate the GBM. This may explain the observation that HBeAg in the circulation frequently correlates with the severity of the disease (110). An alternative mechanism for immune-mediated glomerular injury is the trapping of HBV antigens by antibody previously deposited in the kidney. Anti-HBe antibodies are cationic and may readily localize in the glomerulus and subsequently bind circulating antigen and complement. The third possibility is that the depositions of HBV and antibodies are consequences of glomerular injury by cellular mechanisms or autoantibodies. Little evidence supports this view at present (110). A transgenic mouse model of HBV-associated nephropathy has been developed, in which HBsAg and HBcAg is expressed in liver and kidney, particularly tubular epithelial cells, without viral replication. In these mice, gene expression analysis revealed upregulation of acute-phase proteins, particularly C3, although measurable serum C3 levels were reduced. This supports the notion that local persistent expression of HBV viral proteins contributes to HBV-associated nephropathy (123).

Other Hepatitis B Virus Glomerulonephritides

HBV infection has been associated with a variety of other forms of GN in both adults and children. In one small series in children, MPGN was found to be equal in incidence to MGN in the spectrum of HBV-associated GNs (124). Both MPGN and mesangial proliferative GN may be triggered by HBV. In several countries where HBV is common, the proportion of patients with these forms of nephritides who test positive for HBV greatly exceeds the incidence of positivity in the general population (122). As with MGN and HBV-associated PAN, circulating immune complexes and localization of HBV antigens in the glomeruli have been reported in both MPGN and mesangial proliferative GN, and it is likely that similar mechanisms are occurring (110, 125). Several other forms of GN have been associated with HBV, including IgA nephropathy, focal glomerulosclerosis, crescentic nephritis, and systemic lupus erythematosus, but the evidence for these associations is less consistent than for the entities discussed earlier (125).

Treatment of Hepatitis B Virus Glomerulonephritis

HBV is normally cleared as a result of cell-mediated responses in which cytotoxic T cells and natural killer

cells eliminate infected hepatocytes. It is not surprising, therefore, that the administration of steroids and immunosuppressive agents either may have no effect on HBV disease or may increase the risk of progressive disease (126). Children with HBV MGN have a good prognosis, and two-thirds undergo spontaneous remission within 3 years of diagnosis. Steroid therapy does not appear to provide any additional benefit (110, 120, 110). Antiviral therapy with pegylated interferon-alpha and lamivudine shows promise in facilitating clearance of HBV, and in some cases, elimination of the infection with antiviral therapy in both children and adults is associated with improvement or resolution of the coexisting renal disease. There is considerable effort being put into the development of newer anti-viral agents which avoid the common problems of resistance associated with lamivudine (127–129).

Hepatitis C Virus

HCV is an enveloped, single-stranded RNA virus of approximately 9.4 kb in the Flaviviridae family. There are six major HCV genotypes. Hepatitis C is a common disease affecting approximately 400 million people worldwide. In the United States, 4.1 million persons are estimated to be anti-HCV positive, and 3.2 million may be chronically infected (130). An estimated 240,000 children in the United States have antibody to HCV and 68,000–100,000 are chronically infected (131). Children become infected through receipt of contaminated blood products or through vertical transmission. The risk of vertical transmission increases with higher maternal viremia and maternal co-infection with HIV.

Acute HCV infection is rarely recognized in children outside of special circumstances such as a known exposure from an HCV-infected mother or after blood transfusion. Most chronically infected children are asymptomatic and have normal or only mildly abnormal alanine aminotransferase levels. Although the natural history of HCV infection during childhood seems benign in the majority of instances, the infection can take an aggressive course in a proportion of children, leading to cirrhosis and end-stage liver disease during childhood. The factors responsible for this more aggressive course are unidentified (131). Even in adults, the natural history of HCV infection has a variable course, but a significant proportion of patients will develop some degree of liver dysfunction, and 20–30% will eventually have end-stage liver disease as a result of cirrhosis. The risk of hepatocellular carcinoma is significant for those who have established cirrhosis. Hepatitis C is currently the most common condition leading to liver transplantation in adults in the "Western world."

GN has been described as an important complication of chronic infection with HCV in adults. The clinical presentation is usually of nephrotic syndrome or proteinuria, hypertension, or hematuria, with or without azotemia (132). MPGN, with or without cryoglobulinemia, and MGN are most commonly described. Isolated case reports of other, more unusual patterns of glomerular injury, including IgA nephropathy, focal segmental glomerulosclerosis, crescentic GN, fibrillary GN, and thrombotic microangiopathy, have also been associated with HCV infection (132, 133). Glomerular deposition of hepatitis antigens and antibodies has been described and is believed to play a role in pathogenesis. Cryoglobulinemia is a common accompaniment of GN that is associated with the depression of serum complement levels (132). Renal failure may develop in 40–100% of patients who have MPGN (132, 134). The presence of virus-like particles as well as viral RNA within the kidney sections of patients with HCV-associated glomerulopathies has been reported (135).

The diagnosis should be suspected if glomerular disease is associated with chronic hepatitis, particularly with the presence of cryoglobulins, but renal biopsy is necessary to establish a definitive diagnosis.

HCV infection is relatively common in children with end-stage renal disease and is an important cause of liver disease in this population. Acquisition of HCV infection continues to occur in dialysis patients because of nosocomial spread (136). Elevation of transaminase level is not a sensitive marker of infection in children and HCV enzyme-linked immunosorbent assay or PCR testing should be used to increase sensitivity (137). HCV-infected renal transplant recipients had higher mortality and hospitalization rates than other transplant recipients (138), and HCV infection has been reported to be associated with de novo immune-mediated GN, especially type 1 MPGN, in renal allografts, resulting in accelerated loss of graft function (139, 140).

No large randomized, controlled trials of treatment of children with chronic hepatitis C have been performed, although one study (PEDS-C) is currently recruiting patients into a trial of pegylated interferon +/− ribavirin (141). Small heterogeneous studies of interferon monotherapy have reported sustained virologic response rates of 35–40% (131). In adults, improvement of proteinuria and renal function often follows interferon-alpha treatment (132, 134), but relapses are common after cessation of treatment. Combination of interferon with ribavirin in

patients with chronic liver disease has been shown to increase the rate of sustained response in these patients (142). As yet, however, there are few data regarding the use of combination therapy with interferon and ribavirin in children. Moreover, interferon-alpha therapy is associated with acute or subacute renal failure in more than one-third of the patients with renal transplants (143).

Hepatitis C may be complicated by systemic mixed cryoglobulinemic (MC) vasculitis, and in some cases by a polyarteritis nodosa (PAN)-type non-cryoglobulinemic vasculitis (144). Treatment with interferon-α (IFN-α) and ribavirin mostly is associated with an improvement of vasculitic symptoms. In some cases, exacerbation and rarely new onset of vasculitis of the peripheral nervous system have been described after this treatment. In fulminant cases immunosuppressive therapy with steroids, and cyclophosphamide, or rituximab may be needed to control life threatening vasculitis prior to antiviral treatment (144).

Herpes Viruses

Cytomegalovirus

CMV is one of the eight human herpes viruses. Transmission of the virus requires exposure to infected body fluids such as breast milk, saliva, urine, or blood. Individuals initially infected with CMV may be asymptomatic or display nonspecific flu-like symptoms. After the initial infection CMV, like all herpes viruses, establishes latency for life but will be periodically excreted by an asymptomatic host. CMV replicates within renal cells, and on biopsy samples from immunocompromised hosts, viral inclusions can be visualized by light microscopy in cells of the convoluted tubules and collecting ducts (145). Glomerular cells and shed renal tubular cells may have characteristic inclusions, but clinically evident renal disease is rare and is seen virtually only in immunocompromised or congenitally infected children (145, 146).

The clinical manifestations of CMV-induced renal disease in congenitally infected infants are variable and range from asymptomatic proteinuria to nephrotic syndrome and renal impairment. In congenital CMV infection, histologic changes of viral inclusions commonly occur in the tubules. In addition, proliferative GN has been reported, with evidence on electron microscopy of viral immune deposits in glomerular cells (146, 147). In CMV-infected immunocompromised patients, immune-complex GN has been documented with mesangial deposits of IgG, IgA, C3, and CMV antigens within glomeruli. Eluted glomerular immunoglobulins have been shown to contain CMV antigens (148).

CMV is the most common viral infection after kidney transplantation. Experience with pediatric kidney transplant recipients suggests a 67% incidence of CMV infection (149). The direct and indirect effects of CMV infection result in significant morbidity and mortality among kidney transplant recipients. CMV-negative patients who receive a CMV-positive allograft are at risk for primary infection and graft dysfunction. Patients who are CMV seropositive at the time of transplantation are also at risk of reactivation and superinfection. Tubulointerstitial nephritis is a well-characterized pathologic feature of renal allograft CMV disease, which can be difficult to distinguish from injury caused by rejection. Histologic evidence of endothelial cell injury and mononuclear cell infiltration in the glomeruli has been reported (148). CMV glomerular vasculopathy in the absence of tubulointerstitial disease, causing renal allograft dysfunction, has also been reported (150). Beyond the acute allograft nephropathy associated with CMV viremia, CMV is known to cause chronic vascular injury. This may adversely affect the long-term outcome of the allograft and may be the explanation for the observed association with chronic allograft nephropathy (151).

Newer techniques for rapidly diagnosing CMV infection are becoming widely available and include shell vial culture, pp65 antigenemia assay, PCR, and the hybrid-capture RNA-DNA hybridization assay for qualitative detection of CMV PCR. Quantitative plasma PCR testing (PCR viral load) is increasingly used for diagnosis and monitoring of CMV viremia in renal transplant recipients.

Antiviral agents that have been shown to be effective against CMV include ganciclovir, valganciclovir, foscarnet, and cidofovir. Ganciclovir remains the drug of choice for treating established disease. Intravenous ganciclovir therapy is preferred in children because of the erratic absorption of oral ganciclovir. Major limitations of ganciclovir therapy are the induction of renal tubular dysfunction and bone marrow toxicity, principally neutropenia and thrombocytopenia. Dosage adjustments are necessary for recipients with renal dysfunction. Oral valganciclovir is now used for CMV prophylaxis post-transplant (152). Use of other antiviral agents such as foscarnet and cidofovir is limited because of nephrotoxicity and difficulty of administration. A number of reports have demonstrated the effectiveness of high-titer CMV immune globulin therapy in reducing severe CMV-associated disease when used in combination with ganciclovir (149, 153).

Varicella-Zoster Virus

The association of varicella with nephritis has been known for more than 100 years since Henoch reported on four children with nephritis that occurred after the appearance of varicella vesicles. Varicella, however, is rarely associated with renal complications (154). In fatal cases with disseminated varicella and in the immunocompromised individual, renal involvement is more common. Cases in which varicella infection caused GN in renal transplant recipients have been reported (155). Histologic findings in fatal cases include congested hemorrhagic glomeruli, endothelial cell hyperplasia, and tubular necrosis. In mild and nonfatal cases and in non-immunocompromised individuals, varicella is occasionally associated with a variety of renal manifestations, ranging from mild nephritis to nephrotic syndrome and acute renal failure (156). Histologic findings include endocapillary cell proliferation, epithelial and endothelial cell hyperplasia, and inflammatory cell infiltration (154). Rapidly progressive nephritis has also been reported. Immunohistochemical studies reveal glomerular deposition of IgG, IgM, IgA, and C3. On electron microscopy, granular electron-dense deposits have been found in the paramesangial region, and varicella antigens may be deposited in the glomeruli. The features suggest an immune-complex nephritis. Elevated circulating levels of IgG and IgA immune complexes and depressed C3 and C4 levels support this possibility (154).

Fulminant disseminated varicella and varicella in immunocompromised patients should be treated with intravenous acyclovir.

Epstein-Barr Virus

Renal involvement is common during acute infectious mononucleosis, usually manifesting as an abnormal urine sediment, with hematuria in up to 60% of cases. Hematuria, either microscopic or macroscopic, usually appears within the first week of the illness and lasts for a few weeks to a few months. Proteinuria is usually absent or low grade. More severe renal involvement with proteinuria, nephrotic syndrome, or acute nephritis with renal failure is much less common. Acute renal failure may be seen during the course of fulminant infectious mononucleosis with associated hepatic failure, thrombocytopenia, and encephalitis. It is usually caused by interstitial nephritis that is likely the result of immunopathologic injury precipitated by Epstein-Barr virus (EBV) infection. However, the identification of EBV DNA in the kidney raises the possibility that direct infection might play a role (157). The renal involvement must be distinguished from myoglobinuria caused by rhabdomyolysis, which may occur in infectious mononucleosis, and from bleeding into the renal tract as a result of thrombocytopenia.

Renal histologic findings in EBV nephritis are an interstitial nephritis with mononuclear cell infiltration and foci of tubular necrosis. Glomeruli may show varying degrees of mesangial proliferation. On immunohistochemical study, EBV antigens are seen in glomerular and tubular deposits. The prognosis for complete recovery of renal function is good. Treatment with corticosteroids may have a role in the management of EBV-induced acute renal failure and may shorten the duration of renal failure (158).

EBV-associated post-transplantation lymphoproliferative disease is a recognized complication in renal transplant recipients. Latent infection of EBV in renal proximal tubular epithelial cells has recently been described as causing idiopathic chronic tubulointerstitial nephritis (159).

Herpes Simplex Virus

The herpes simplex virus (HSV) causes persistent infection characterized by asymptomatic latent periods interspersed with acute relapses. As with other chronic and persistent infections, immunologically mediated disorders triggered by HSV are well recognized, and it is perhaps surprising that HSV has rarely been linked to nephritis. Acute nephritis and nephrotic syndrome have been associated with herpes simplex encephalitis. Renal histology shows focal segmental GN with mesangial and segmental deposits of IgM, C3, and HSV antigens. As with other herpes viruses, HSV has been suggested as a trigger for IgA nephritis, MPGN, and membranous nephropathy. Elevated levels of HSV antibodies have been reported in patients with a variety of forms of GN, but no conclusive evidence exists of an etiologic role for HSV (160).

Adenovirus and Enterovirus

Adenovirus and enterovirus, are unrelated ubiquitous pathogens that infect large proportions of the population annually and yet are rarely associated with renal disease. The literature contains scattered reports of acute nephritis after infection with each of these viruses.

Adenovirus is a major cause of hemorrhagic cystitis and was implicated as the cause of hemorrhagic cystitis in 23–51% of children with this disorder (161). Boys are affected more often than girls, and hematuria persists for 3–5 days. Microscopic hematuria, dysuria, and frequency may occur for longer periods. Adenovirus types 11 and 21 are the usual strains isolated.

Picornaviruses, including enteroviruses, echovirus and coxsackieviruses, have been linked with acute nephritis and acute renal failure associated with rhabdomyolysis. Coxsackie B virus can be isolated in urine. Direct infection of kidney cells is supported by *in vitro* work demonstrating lytic infection of human podocyte and proximal tubular epithelial cell cultures, although different strains exhibit variable degrees of nephrotropism. Renal damage *in vivo* may have both a direct lytic mechanism and an immune-complex basis (162). In the newborn, enteroviruses cause fulminant disease with DIC, shock, and liver failure, and acute renal failure may occur.

Measles Virus

Renal involvement from measles virus is uncommon, although measles virus can be cultured from the kidney in fatal cases. An acute GN has been reported to follow measles with evidence of immune deposits containing measles virus antigen within the glomeruli. The nephritis is generally self-limiting (163).

Mumps Virus

Mild renal involvement is common during the acute phase of mumps infection. One-third of children with mumps have abnormal urinalysis results, with microscopic hematuria or proteinuria. Mumps virus may be isolated from urine during the first 5 days of the illness, at a time when urinalysis findings are abnormal. Plasma creatinine concentrations usually remain normal, despite the abnormal urine sediment, but more severe cases in adults have been associated with evidence of acute nephritis with impaired renal function. Renal biopsy specimens demonstrate an MPGN with deposition of IgA, IgM, C3, and mumps virus antigen in the glomeruli, which suggests an immune-complex-mediated process (164).

Human Immunodeficiency Virus

Despite the increasing availability of interventions to limit vertical HIV transmission, an estimated 1,500 children continue to acquire HIV each day. The World Health Organization estimated that there were 33.2 million people, including 2.1 million children, living with HIV infection at the end of 2007. Of 2.1 million AIDS deaths, 330,000 were in children. The number of children on anti-retroviral treatment (ART) rose from 75,000 in 2005 to almost 200,000 in 2007.

Renal involvement in HIV infection was first described in 1984 in adults (165–167) and in children (168), and renal involvement occurs in 2–15% of HIV-infected children in the United States (169–171). Since the development of highly active antiretroviral therapy (HAART), however, the incidence of end-stage renal disease in HIV infection in both adults and children in industrialized countries has declined, but it is predicted that the dramatic decline in AIDS-related deaths will lead to an ageing population of HIV-infected individuals who will be at risk of non-HIV related renal problems, such that the numbers of HIV-positive ESRD patients will increase in the United States (172).

HIV infection is associated with a number of renal pathologies. HIV-associated nephropathy (HIVAN) is a syndrome of glomerular and tubular dysfunction, which can progress to end-stage renal failure. It is discussed more fully below. Glomerular syndromes other than HIVAN include MGN that resembles lupus nephritis and immune-complex GN, with IgA nephropathy and HCV-associated MPGN being the most common forms. There have also been several case reports of amyloid kidney (171, 173, 174). The kidneys may be affected by various other mechanisms. Opportunistic infections with organisms such as BK virus (BKV) that give rise to nephropathy and hemorrhagic cystitis have been reported in association with HIV infection (175). Systemic infections accompanied by hypotension can cause prerenal failure leading to acute tubular necrosis. Acute tubular necrosis has also been reported in HIV patients after the use of nephrotoxic drugs such as pentamidine, foscarnet, cidofovir, amphotericin B, and aminoglycosides. Intratubular obstruction with crystal precipitation can occur with the use of sulfonamides and intravenous acyclovir. Indinavir is well recognized to cause nephropathy and renal calculi (176). MPGN associated with mixed cryoglobulinemia and thrombotic microangiopathy/atypical-cal HUS in association with HIV infections have been reported (177, 178).

HIV-Associated Nephropathy (HIVAN)

HIVAN is characterized by both glomerular and tubular dysfunction, the pathogenesis of which is not entirely known. HIVAN is a clinico-pathologic entity that includes proteinuria, azotemia, focal segmental glomerulosclerosis

or mesangial hyperplasia, and tubulointerstitial disease (171). In adults in the United States, there is a markedly increased risk of nephropathy among African American persons with HIV infection. This appears to be true in children as well, but the data are sparse. The spectrum of HIVAN seems to be coincident with the degree of AIDS symptomatology. It is thought that HIVAN can present at any point in HIV infection, but most patients with HIVAN have CD4 counts of less than 200×10^6/200 cells/mL, which suggests that it may be primarily a manifestation of late-stage disease (179).

Although a spectrum of clinicopathologic entities including mesangial hyperplasia, focal segmental glomerulosclerosis, minimal change disease, and systemic lupus erythematosus nephritis has been described, the classic pathologic feature of HIVAN is the collapsing form of focal and segmental glomerulosclerosis (180). In the affected glomeruli, visceral epithelial cells are hypertrophied and hyperplastic, and contain large cytoplasmic vacuoles and numerous protein resorption droplets. There is microcystic distortion of tubule segments, which contributes to increasing kidney size. Podocyte hyperplasia can become so marked that it causes obliteration of much of the urinary space, forming "pseudocrescents" (173). Capillary walls are wrinkled and collapsed with obliteration of the capillary lumina. The interstitium is edematous with a variable degree of T-cell infiltration (181). The Bowman capsule can also be dilated and filled with a precipitate of plasma protein that represents the glomerular ultrafiltrate. One of the most distinctive features of HIVAN, however, is the presence of numerous tubuloreticular inclusions within the cytoplasm of glomerular and peritubular capillary endothelial cells (173). Immunofluorescence testing is positive for IgM and C3 in capillary walls in a coarsely granular to amorphous pattern in a segmental distribution (180, 181).

The presence of the HIV genome in glomerular and tubular epithelium has been demonstrated using complementary DNA probes and in situ hybridization. Proviral DNA has been detected by PCR in the glomeruli, tubules, and interstitium of micro dissected kidneys from patients who had pathologic evidence of HIVAN, but it has also been detected in the kidneys of HIV-positive patients with other glomerulopathies (182). A combination of both proliferation and apoptosis of renal cells may cause the loss of nephron architecture. Apoptosis has been demonstrated in cells in the glomerulus, tubules, and interstitium of biopsy specimens from HIV-positive patients with focal segmental glomerulosclerosis. In addition, the role of various cytokines and growth factors, specifically transforming growth factor beta (TGF-beta), in the development of sclerosis has been studied (183, 184).

Transgenic murine models provide some of the strongest evidence for a direct role of HIV-1 in the induction of HIVAN. These mice do not produce infectious virus but express the HIV envelope and regulatory genes at levels sufficient to re-create the HIVAN that is seen in humans (183). Serial deletion experiments have concluded that the *nef* and *vpr* genes are necessary though not sufficient for HIVAN pathogenesis. Additional factors such as genetic predisposition are thought to explain the fact that African Americans have a far greater likelihood of developing HIVAN than other racial groups, and that HIVAN is more likely in patients with a family history of ESRD.

HIVAN can manifest as mild proteinuria, nephrotic syndrome, renal tubular acidosis, hematuria, and/or acute renal failure (168–171). Nephrotic syndrome and chronic renal insufficiency are late manifestations of HIVAN. Children with HIVAN are likely to develop transient electrolytic disorders, heavy proteinuria, and acute renal failure due to systemic infectious episodes or nephrotoxic drugs.

Early stages of HIVAN can be identified by the presence of proteinuria and "urine microcysts" along with renal sonograms showing enlarged echogenic kidneys. Urinary renal tubular epithelial cells are frequently grouped together to form these microcysts, which were found in the urine of children with HIVAN who had renal tubular injury (171). Advanced stages of HIVAN typically present with nephrotic syndrome with edema, heavy proteinuria, hypoalbuminemia, and few red or white blood cells in urinary sediments. Hypertension may be present, but usually blood pressure is within or below the normal range. HIVAN in adults follows a rapidly progressive course, with end-stage renal disease developing within 1–4 months, but in children this rapid progression does not necessarily occur. Definitive diagnosis of HIVAN should be based on biopsy results, and biopsy should be performed if significant proteinuria is present, because in approximately 50% of HIV-infected patients with azotemia and/or proteinuria (>1 g/24 h) who undergo renal biopsy, the specimen will have histologic features consistent with other renal diseases (179).

When available, HAART should be given to children with symptomatic HIV disease. Specific treatment of HIVAN remains controversial. Several studies have looked at the role of HAART, angiotensin I-converting enzyme (ACE) inhibitors, steroids, and even cyclosporin with somewhat encouraging results. However, as yet no randomized case-controlled trials have been undertaken. Most of the studies have been small and retrospective, and many have included patients both with and without renal biopsy-proven HIVAN. Cyclosporin has been used to treat HIVAN in children with remission of nephrotic

syndrome (169). Similar responses have been reported to treatment with corticosteroids in various studies (185–188). ACE inhibitors have been used with encouraging results (189).

The general regimen used to treat patients with HIV, including HAART, should be applied to children with HIVAN. The dosages of some medications must be adjusted to the patients glomerular filtration. There are reports of spontaneous regression of HIVAN with supportive management and treatment with HAART, particularly with regimes containing protease inhibitors (190–193). It should be emphasized that the improvement reported with other modalities of treatment such as corticosteroids, cyclosporin, and ACE inhibitors always occurs when these agents are given in conjunction with antiretroviral therapy.

The kidneys of transgenic mice have been found to have elevated levels of TGF-beta messenger RNA and protein (184). Furthermore, gene expression analysis on tubular epithelial cells from a patient with HIVAN found upregulation of several inflammatory mediator genes downstream of interleukin 6 and of the transcription factor NFkB (194). Several other therapeutic options have been suggested, aimed specifically at the presumed role of TGF-beta in the pathogenesis of HIVAN. Treatment directed at its synthesis using gene therapy to block TGF-beta gene expression is being explored. Therapy directed at decreasing the activity of TGF-beta using anti-TGF-beta antibodies or other inhibitory substances is also an area of investigation. In addition, blocking renal receptors for chemokines such as RANTES (regulated upon derivation, normal T cell expressed and secreted), interleukin-8, and monocyte-chemoattractant protein-1 has been proposed as another possible treatment alternative (195).

In the HAART era, the outlook for HIV patients with ESRD has improved, but these patients fare worse than ESRD patients without HIV (196). Most reports of HIV-infected patients on hemodialysis have shown poor prognosis, with mean patient survival times ranging from 14–47 months. Mortality is therefore still close to 50% within the first year of dialysis. In general, improved survival is associated with younger age at initiation of hemodialysis and with higher CD4 counts. Access complications such as infection and thrombosis tend to occur at a higher rate in HIV-infected hemodialysis patients. Cross infection with HIV in dialysis patients is very rare. No patient-to-patient HIV transmission has yet been reported in a hemodialysis unit in the United States, although several such cases have occurred in South America (195, 197).

Peritoneal dialysis is an alternative for HIV-infected patients. The incidence of peritonitis varies across studies, but some studies did report a higher incidence of Pseudomonas and fungal peritonitis in the HIV-positive population (195). Infections with unusual organisms such as *Pasteurella multocida*, *Trichosporon beigelii*, and *Mycobacterium avium intracellulare* complex have also been reported. Several studies, however, have suggested that there is no significant difference between the HIV-infected and non-HIV-infected populations. Of note is that virus capable of replication *in vitro* has been recovered from the peritoneal dialysis effluent, and it can be recoverable for up to 7 days in dialysis bags at room temperature and for up to 48 h in dry exchange tubing (195).

Previously, long-term dialysis had been thought to be preferable to renal transplantation, primarily because of the concern that the immunosuppressive therapy required after transplantation could promote progression of HIV/AIDS. A multicenter prospective study has been addressing these questions (198). Data so far indicate that the outcome for liver and kidney transplantation is not considerably different from patients without HIV, with good graft persistence, and a low rate of development of opportunistic infections in those with well-controlled HIV and relatively high CD4 counts (199).

Human Polyoma Viruses

The human polyoma viruses are members of the papovavirus family and have received increasing attention as pathogens in immunocompromised patients. They are nonenveloped viruses ranging in size from 45–55 nm, with a circular, double-stranded DNA genome that replicates in the host nucleus. The best-known species in this genus are the BKV, the JC virus (JCV), and the simian virus SV40. BKV was first isolated from the urine of a 39-year-old man who developed ureteral stenosis 4 months after renal transplantation (200). The name of the virus refers to the first patients initials, which is also true of JCV. BKV establishes infection in the kidney and the urinary tract, and its activation causes a number of disorders, including nephropathy and hemorrhagic cystitis. BKV-associated nephropathy has become an increasingly recognized cause of renal dysfunction in renal transplantation patients (201–205). JCV establishes latency mainly in the kidney, and its reactivation can result in the development of progressive multifocal leukoencephalopathy. There are a few reports of nephropathy in association with JCV infection (see references in (206)), but BKV poses a much bigger problem in this regard. Recent studies have reported SV40 in the allografts of children who received renal transplants and in the urine, blood, and kidneys of adults with focal segmental glomerulosclerosis,

which is a cause of end-stage renal disease and an indication for kidney transplantation (207).

BKV infection is endemic worldwide

Seroprevalence rates as high as 60–80% have been reported among adults in the United States and Europe. The peak incidence of primary infection (as measured by acquisition of antibody) occurs in children 2–5 years of age. BKV antibody may be detected in as many as 50% of children by 3 years of age, and in 60–100% of children by 9 or 10 years of age; antibodies wane thereafter. BKV infection may be particularly important in the pediatric transplantation population, in whom primary infection has a high probability of occurring while the children are immunosuppressed (208).

Primary infection with BKV in healthy children is rarely associated with clinical manifestations. Mild pyrexia, malaise, vomiting, respiratory illness, pericarditis, and transient hepatic dysfunction have been reported with primary infection. Investigators hypothesize that after an initial round of viral replication at the site of entry, viremia follows with dissemination of the virus to distant sites at which latent infection is established. The most frequently recognized secondary sites of latent infection are renal and uroepithelial cells. Secondary infection has been reported to cause tubulointerstitial nephritis and ureteral stenosis in renal transplantation patients. It may be that renal impairment in immunocompromised patients and in non renal solid organ transplant recipients is found to be frequently associated with BKV infection.

BK Virus Nephropathy in Patients Undergoing Renal Transplantation

The reported prevalence of BKV nephropathy in renal allografts is between 1 and 8% (201, 202, 205, 209, 210). Asymptomatic infection is characterized by viral shedding without any apparent clinical features. Viruria, resulting from either primary or secondary infection, can persist from several weeks to years. Tubulointerstitial nephritis associated with BKV in renal transplant recipients is accompanied by histopathologic changes, with or without functional impairment. "Infection" and "disease" must be differentiated carefully. BKV infection (either primary or reactivated) can progress to BKV disease, but will not always do so (208). Furthermore, not all cases of BKV disease lead to renal impairment. However, infection can progress to transplant dysfunction and graft loss, although the diagnosis may be complicated by the coexistence of active allograft rejection.

BKV nephritis is reported to have a bimodal distribution, with 50% of BKV-related interstitial nephritis cases occurring 4–8 weeks after transplantation and the remainder of patients developing disease months to years after transplantation (211). Allograft failure is due mainly to extensive viral replication in tubular epithelial cells leading to frank tubular necrosis (203). Although damage is potentially fully reversible early in the disease, persisting viral damage leads to irreversible interstitial fibrosis. Tubular atrophy and allograft loss has been observed in 45% of affected patients (203, 212).

In most cases, BKV nephropathy in adult renal transplant recipients represents a secondary infection associated with rejection and its treatment. In children, however, primary BKV infection giving rise to allograft dysfunction may occur (208).

The definitive diagnosis of BKV nephropathy requires renal biopsy. Histopathologic features include severe tubular injury with cellular enlargement, marked nuclear atypia, epithelial necrosis, denudation of tubular basement membranes, focal intratubular neutrophilic infiltration, and mononuclear interstitial infiltration, with or without concurrent tubulins. This constellation of histologic features, particularly severe tubulitis, is often misinterpreted as rejection, even by the experienced pathologist. The presence of well-demarcated basophilic or amphophilic intranuclear viral inclusions, primarily within the tubular and parietal epithelium of the Bowman capsule, can help distinguish BKV disease from rejection (202, 203, 205). Additional tests such as immunohistochemistry, PCR analysis, or electron microscopy of biopsied tissue aimed at the identification of BKV may be required.

A practical diagnostic approach for identifying BKV in renal transplant patients is summarized in *Table 52-3*.

Other Implications of BK Virus in Renal Transplantation

BKV infection may cause ureteral obstruction due to ureteral ulceration and stenosis at the ureteric anastomosis. BKV-associated ureteral stenosis has been reported in 3% of renal transplant patients and usually occurs between 50 and 300 days after transplantation. Ulceration due to inflammation, proliferation of the transitional epithelial cells, and smooth muscle proliferation may lead to partial or total obstruction.

High-level BKV replication is implicated in acute, late-onset, long-duration hemorrhagic cystitis after bone marrow transplantation (213).

There are two case reports in children of renal carcinomas arising in the transplanted kidney in association with BK virus nephropathy. It remains unclear whether

BK virus itself has oncogenic potential in the transplant setting, but this is possible given that the big T antigen (T-Ag) expressed by polyomavirus family viruses has been shown to have the ability to disrupt chromosomal integrity (214, 215).

Treatment

Whether patients with asymptomatic viremia or viruria need specific therapeutic intervention is not certain. Review of the literature suggests that careful reduction of immune suppression, combined with active surveillance for rejection, will result in clinical improvement. Reduction in immunosuppression may precipitate episodes of acute cellular rejection, which need to be judiciously treated with corticosteroids. The outcome of BKV nephropathy is unpredictable, and stabilization of renal function may occur regardless of whether maintenance immunotherapy is altered or not (216).

Some reports favor the use of cidofovir. Cidofovir has important nephrotoxic side effects in the usual therapeutic dosage recommended for the treatment of CMV infection, and for BKV nephropathy a reduced dosage regime is generally used. The efficacy of cidofovir in reducing viremia has been demonstrated (see review in (210)). However, spontaneous clearance of viral infection after reduction of immunosuppression (without cidofovir) has also been reported. There are also case studies of the use of leflunamide.

Presence of BKV by PCR or decoy cells in urine signifies BKV replication. Decoy cells are caused by infection of the urinary epithelial cells with human polyoma viruses. The nuclei are enlarged and nuclear chromatin is completely homogenized by viral cytopathic effect. Positive PCR results for BKV viruria and presence of decoy cells have poor predictive value. Specificity is increased if >10 cells/Cytospin along with presence of inflammatory cells.

Presence of antibody is usually indicative of previous infection; however, positive results for BKV DNA PCR on serum signifies BK viremia. BKV PCR testing of plasma has proven to be a sensitive (100%) and specific (88%) means to identify BKV-associated nephropathy in adults. Viral load has also been used to monitor infection and clearance. However, because primary infection occurs in childhood, it might not be applicable to the pediatric population.

The definitive diagnosis of BKV nephropathy requires renal biopsy. Histopathology might mimic rejection or drug toxicity. However, characteristic findings have been described. Electron microscopy and immune staining are helpful in confirming the diagnosis. PCR assays of viral load in tubular cells have been reported to be a sensitive marker for diagnosis and monitoring.

Viral Hemorrhagic Fever

Viral hemorrhagic fever involves at least 12 distinct RNA viruses that share the propensity to cause severe disease with prominent hemorrhagic manifestations (*Table 52-4*). The viral hemorrhagic fevers, widely distributed throughout both temperate and tropical regions of the world, are important causes of mortality and morbidity in many countries. Most viral hemorrhagic fevers are zoonoses (with the possible exception of dengue virus), in which the virus is endemic in animals and human infection is acquired through the bite of an insect vector. Aerosol and nosocomial transmissions from infected patients are important for Lassa, Junin, Machupo, and Congo-Crimean hemorrhagic fevers, and Marburg and Ebola viruses (217).

Viral hemorrhagic fevers have many clinical similarities but also important differences in their severity, major organs affected, prognosis, and response to treatment. In all viral hemorrhagic fevers, severe cases occur in only a minority of those affected; subclinical infection or nonspecific febrile illness occurs in the majority. Fever, myalgia, headache, conjunctival suffusion, and erythematous rash occur in all the viral hemorrhagic fevers (218). Hemorrhagic manifestations range from petechiae and bleeding from venepuncture sites to severe hemorrhage into the GI tract, kidney, and other organs. A capillary leak syndrome, with evidence of hemoconcentration, pulmonary edema, oliguria, and ultimately shock, occurs in the most severely affected patients (218). Renal involvement occurs in all the viral hemorrhagic fevers, proteinuria is common, and prerenal failure is seen in all severe cases complicated by shock. However, in Congo-Crimean hemorrhagic fever and hemorrhagic fever with renal syndrome (HFRS), an interstitial nephritis, which may be hemorrhagic, is characteristic, and renal impairment is a major component of the illness.

Dengue

Dengue is caused by a flavivirus that is endemic and epidemic in tropical America, Africa, and Asia, where the mosquito vector *Aedes aegypti* is present (219). Classic dengue is a self-limited nonfatal disease; dengue hemorrhagic fever and dengue shock syndrome, which occur in a minority of patients, have a high mortality if not aggressively treated with fluids. After an incubation period of 5–8 days, the illness begins with fever, headache, arthralgia, weakness, vomiting, and hyperesthesia. In uncomplicated dengue the fever usually lasts 5–7 days. Shortly after

Specificity is increased if >10 cells/Cytospin along with presence of inflammatory cells.
Serum	
Antibody assays BKV BKV PCR	Presence of antibody is usually indicative of previous infection; however, positive results for BKV DNA PCR on serum signifies BK viremia. BKV PCR testing of plasma has proven to be a sensitive (100%) and specific (88%) means to identify BKV-associated nephropathy in adults. Viral load has also been used to monitor infection and clearance. However, because primary infection occurs in childhood, it might not be applicable to the pediatric population.
Tissue	
Histopathology, electron microscopy, BKV PCR	The definitive diagnosis of BKV nephropathy requires renal biopsy. Histopathology might mimic rejection or drug toxicity. However, characteristic findings have been described. Electron microscopy and immune staining are helpful in confirming the diagnosis. PCR assays of viral load in tubular cells have been reported to be a sensitive marker for diagnosis and monitoring.

HPV, human polyoma virus; PCR, polymerase chain reaction

onset a maculopapular rash appears, sparing the palms and the soles, and is occasionally followed by desquamation. Fever may reappear at the onset of the rash.

In dengue hemorrhagic fever and dengue shock syndrome, the typical febrile illness is complicated by hemorrhagic manifestations, ranging from a positive tourniquet test result or petechiae to purpura, epistaxis, and GI bleeding with thrombocytopenia and evidence of a consumptive coagulopathy. Increased capillary permeability is suggested by hemoconcentration, edema, and pleural effusions (219). In severe cases, hypotension and shock supervene, largely as a result of hypovolemia. Renal manifestations include oliguria, proteinuria, hematuria, and rising urea and creatinine. Acute renal failure occurs in patients with severe shock, primarily as a result of renal underperfusion. However, glomerular inflammatory changes may also occur. Children with dengue hemorrhagic fever show hypertrophy of endothelial and mesangial cells, mononuclear cell infiltrate, thinning of basement membranes, and deposition of IgG, IgM, and C3. Electron microscopy shows viral particles within glomerular mononuclear cells (220).

The diagnosis of dengue is made by isolation of the virus from blood or by serologic testing. There is no specific antiviral treatment, and management of patients with dengue shock syndrome or dengue hemorrhagic fever depends on aggressive circulatory support and volume replacement with colloid and crystalloid (221, 222). With correction of hypovolemia, renal impairment is usually reversible, but dialysis may be required in patients with established acute renal failure.

Yellow Fever

Yellow fever is caused by a flavivirus, and is transmitted by mosquito bites, typically *Aedes* species. It remains an important public health problem in Africa and South America. Renal manifestations are common and include albuminuria and oliguria. Over the next few days after first manifestation of infection, shock, delirium, coma, and renal failure develop, and death occurs 7–10 days after onset of symptoms. Laboratory findings include thrombocytopenia and evidence of hemoconcentration, rising urea and creatinine levels, hyponatremia, and deranged liver function test results. Pathologic findings include necrosis of liver lobules, cloudy swelling and fatty degeneration of the proximal renal tubules, and, often, petechiae in other organs. The oliguria appears to be prerenal and is due to hypovolemia; later, acute tubular necrosis supervenes. At present, there is no effective antiviral agent for yellow fever.

Table 52-4

Viral hemorrhagic fevers (hf)

Virus	Geographic distribution	Source of human infection	Incubation period (days)	Renal involvement	Renal pathology	Treatment
Dengue	Tropical Africa, South America, Asia	Mosquito	5–8	Rare, only in Dengue HF or shock	Vasomotor nephropathy, immune complex	Supportive
Yellow fever	Africa, South America	Mosquito	3–6	Common	Vasomotor nephropathy	Supportive
Congo-Crimean	Eastern Europe, Africa, Asia	Tick, nosocomial	2–7	In severe cases	Vasomotor nephropathy	Supportive ? Ribavirin
Hantaan viruses (Puumala, Seoul strains)	Europe, Asia, Africa, America	Rodents	4–42	HF and renal syndrome (Korean, Chinese, and Japanese epidemic HF, nephropathia epidemica)	Vasomotor nephropathy Interstitial nephropathy	Supportive ? Ribavirin
Rift Valley fever	Sub-Saharan Africa	Mosquito, contact with infected animals	3–7	Rare, only in fulminant cases	Vasomotor nephropathy	Supportive
Lassa fever	West Africa	Rodents, nosocomial	3–16	In cases with shock	Vasomotor nephropathy	Supportive and ribavirin
Junin, Argentine HF	Argentina	Rodents, nosocomial	5–19	In cases with shock	Vasomotor nephropathy	Supportive
Machupo, Bolivian HF	Bolivia	Rodents, nosocomial	5–19	In cases with shock	Vasomotor nephropathy	Supportive
Marburg	Africa	?, nosocomial	5–10	In cases with shock	Vasomotor nephropathy	Supportive
Ebola	Africa	?, nosocomial	5–10	In cases with shock	Vasomotor nephropathy	Supportive
Omsk	Eastern Europe	Tick	2–4	In cases with shock	Vasomotor nephropathy	Supportive
Kyasanur forest	India	Tick	3–8	In cases with shock	Vasomotor nephropathy	Supportive

Congo-Crimean Hemorrhagic Fever

Congo-Crimean hemorrhagic fever, first recognized in the Soviet Union, is now an important human disease in Eastern Europe, Asia, and Africa (223). Severely affected patients become stuporous or comatose 5–7 days into the illness, with evidence of hepatic and renal failure and shock. Proteinuria and hematuria are often present. The disease is fatal in 15–50% of cases. The virus is sensitive to ribavirin, but in one small trial of i.v. ribavirin versus supportive treatment only, there was no significant improvement in outcome in the treatment group (224).

Rift Valley Fever

Rift Valley fever is found in many areas of sub-Saharan Africa. In humans, most infections follow mosquito bites or animal exposure. The infection may present as an uncomplicated febrile illness, with muscle aches and

headaches. In 10% of patients, encephalitis or retinal vasculitis occurs as a complication. In a small proportion of cases, a fulminant and often fatal hemorrhagic illness occurs with hematemesis, melena, epistaxis, and evidence of profound DIC. Severe hepatic derangement, renal failure, and encephalopathy are often present. Despite intensive care, mortality is high.

Hemorrhagic Fever and Renal Syndrome (Hantavirus)

The viruses causing HFRS all belong to the Hantavirus genus in the Bunyaviridae family. The hantaviruses are distributed worldwide and are maintained in nature through chronic infection of rodents and small mammals. Transmission to humans is by aerosolized infectious excreta. Human disease usually occurs in summer among rural populations with exposure to rodent-infested barns or grain stores. Urban transmission can occur, however. At least five hantaviruses are known to cause HFRS: Hantaan, Seoul, Puumala, Porogia, and Belgrade viruses (225). HFRS is endemic in a belt from Norway in the west through Sweden, Finland, the Soviet Union, China, and Korea to Japan in the east. The clinical severity of HFRS varies throughout this belt (226). Clinical entities include Korean hemorrhagic fever, nephropathia epidemica in Scandinavia, and epidemic hemorrhagic fever in Japan and China.

In general, HFRS due to Hantaan, Porogia, and Belgrade viruses is more severe and has higher mortality than that due to Puumala virus (*nephropathia epidemica*) or Seoul virus. Hantaan is predominant in the Far East, Porogia and Belgrade in the Balkans, and Puumala in Western Europe; Seoul has a worldwide distribution (225). The clinical features of the disease vary. The incubation period is 4–42 days. Although HFRS occurs with the same clinical picture in children as in adults, both incidence rates and antibody prevalence rates are very low in children under 10 years of age. Men of working age make up the bulk of clinical cases (226). Mild cases are indistinguishable from other febrile illnesses. In more severe cases, fever, headache, myalgia, abdominal pain, and dizziness are associated with the development of periorbital edema, proteinuria, and hematuria. There is often conjunctival injection, pharyngeal injection, petechiae, and epistaxis or GI bleeding. The most severely affected patients develop shock and renal failure. The disease usually passes through five phases: febrile, hypotensive, oliguric, diuretic, and convalescent. Laboratory findings include anemia, lymphocytosis, thrombocytopenia, prolonged prothrombin and bleeding times, and elevated levels of fibrin degradation products. Liver enzyme levels are elevated, and urea and creatinine levels are elevated during the oliguric phase. Proteinuria and hematuria are consistent findings.

The renal histopathologic findings are those of an interstitial nephritis with prominent hemorrhages in the renal medullary interstitium and renal cortex. Acute tubular necrosis may also be seen. Immunohistochemical analysis reveals deposition of IgG and C3, and the GBM, mesangial, and subendothelial deposits may be seen on electron microscopy (227).

Recovery from Hantavirus-associated disease is generally complete, although chronic renal insufficiency is a rare sequela of HFRS. In mildly affected patients, the disease is self-limiting and spontaneous recovery occurs. However, in severe cases, with shock, bleeding, and renal failure, dialysis and intensive circulatory support may be required (228). Mortality rates vary depending on the strain of virus; rates are 5–15% for hemorrhagic fever and renal syndrome in China and significantly lower for the milder Finnish form associated with the Puumala virus strain.

Ribavirin is active against Hantaan viruses *in vitro*, and clinical trials indicate that both mortality and morbidity can be reduced by treatment with this antiviral agent if it is administered early in the course of illness. Dosages of 33 mg/kg followed by 16 mg/kg every 6 h for 4 days and then 8 mg/kg every 8 h for 3 days have been used (229).

Lassa Fever

Lassa fever is a common infection in West Africa, caused by an arenavirus, and usually manifests as a nonspecific febrile illness. In 10% of cases, a fulminant hemorrhagic disease occurs. In severe cases, proteinuria and hematuria are usually present, and renal failure may occur. Ribavirin is effective in decreasing mortality. As in other hemorrhagic fevers, intensive hemodynamic support and correction of the hemostatic derangements are important components of therapy (230).

Argentine and Bolivian Hemorrhagic Fevers

Junin and Machupo viruses, the agents of Argentine and Bolivian hemorrhagic fever, respectively, cause hemorrhagic fevers with prominent neurologic features and systemic and hemorrhagic features similar to those of Lassa fever. Oliguria, shock, and renal failure occur in the most severe cases.

Marburg Disease and Ebola Hemorrhagic Fever

Marburg and Ebola viruses have been associated with outbreaks of nosocomially transmitted hemorrhagic fever. Both viruses cause fulminant hemorrhagic fever. Onset is with high fever, headache, sore throat, myalgia, and profound prostration. An erythematous rash on the trunk is followed by hemorrhagic conjunctivitis, bleeding, impaired renal function, shock, and respiratory failure. The mortality rate is high. Renal histopathologic findings in fatal cases are of tubular necrosis, with fibrin deposition in the glomeruli. There is no specific treatment for these disorders.

Emerging Viral Infections

The important role played by a number of other recently characterized viruses is only now being recognized, as improved molecular diagnostic techniques allow identification of hitherto unrecognized viruses. Two examples of recently described viruses are metapneumovirus (237) and bocavirus (238). While both have significant prevalence, and may make an important contribution to the burden of childhood viral infection, as yet there are no reports indicative of significant renal pathology in association with these infections.

Influenza H5N1

Influenza virus has been linked with nephritis and acute renal failure. An emerging infectious disease is avian flu, caused by highly pathogenic H5N1 strains which have hitherto been confined to an avian reservoir, and there have been several outbreaks of infection in humans, particularly in the first part of this decade. Commonly, these patients develop a flu-like illness with prominent respiratory and gastrointestinal symptoms. Renal failure may develop alongside multi-organ failure in the context of acute respiratory distress syndrome (231). As yet, there is no clear correlation of degree of initial renal insufficiency, and outcome (232). There is little data available on treatment, but based on the known resistance patterns of H5N1 strains, oseltamivir and zanamivir are the preferred agents to be used for treatment of infection with H5N1.

SARS

Severe Acute Respiratory Syndrome (SARS) is a newly-emerged infectious disease which was first seen in South China in 2002. It is caused by a SARS coronavirus (SARS CoV). Predominantly, it causes a viral pneumonia, with diffuse alveolar damage; it has considerable mortality (233). Renal effects are not generally significant in the pathophysiology of SARS. However, SARS CoV has been found in kidney tissue at post-mortem (234) (235). SARS CoV enters cells via Angiotensin Converting Enzyme 2 (ACE2) (236), and it is thought that the invasion of kidney tissue reflects the virus' tropism for ACE2, which is expressed on kidney cells.

Parasitic Infections

Chronic exposure to infectious agents is a major factor in the increased prevalence of glomerular diseases in developing countries. Malaria is the best-documented parasitic infection associated with glomerular disease, but other parasitic infections including schistosomiasis, filariasis, leishmaniasis, and possibly helminth infections may also induce nephritis or nephrosis.

Malaria and Renal Disease

Malaria is estimated to cause up to 500 million clinical cases of illness and more than 1 million deaths each year (239). The association of quartan malaria and nephritis has been well known in both temperate and tropical zones since the end of the nineteenth century.

Epidemiologic studies provide the most conclusive evidence for a role of *Plasmodium malariae* in glomerular disease (240, 241). Chronic renal disease was a major cause of morbidity and mortality in British Guiana in the 1920s. The frequent occurrence of *P. malariae* in the blood of these patients led to detailed epidemiologic studies that implicated malaria as a cause of the nephrosis. After the eradication of malaria from British Guiana, chronic renal disease ceased to be a major cause of death in that country (240).

The link between malaria and nephrotic syndrome was strengthened by studies in West Africa in the 1950s and 1960s that demonstrated a high prevalence of nephrotic syndrome in the Nigerian population (242). The pattern of nephrotic syndrome differed from that in temperate climates, with an older peak age, extremely poor prognosis, and unusual histologic features. The incidence of *P. malariae* parasitemia in patients with the nephrotic syndrome in Nigeria was vastly in excess of that occurring in the general population, whereas the incidence of *Plasmodium falciparum* parasitemia was similar

to that in the general population. The age distribution of nephrotic syndrome also closely paralleled that of *P. malariae* infection (242). In some affected patients, circulating immune complexes and immunoglobulin, complement, and antigens were present in the glomeruli that were recognized by *P. malariae*-species antisera.

There is now a view that the patterns of childhood renal disease described in the last century may no longer be representative of the current situation. The variable patterns of renal disease throughout Africa may no longer reflect a dominant role for "malarial glomerulopathy," and the relative causative role of tropical infections in nephropathy remains an unanswered question (243).

Clinical and Histopathologic Features of Quartan Malaria Nephropathy

Most patients have poorly selective proteinuria and are unresponsive to treatment with steroids or immunosuppressive agents. The characteristic lesions of *P. malariae* nephropathy are capillary wall thickening and segmental glomerular sclerosis, which lead to progressive glomerular changes and secondary tubular atrophy (242). Cellular proliferation is conspicuously absent. Electron microscopy shows foot-process fusion, thickening of the basement membrane, and increase in subendothelial basement membrane-like material. Immunofluorescent studies show granular deposits of immunoglobulin, complement, and *P. malariae* antigen in approximately one-third of patients.

In addition to the histologic pattern, termed quartan malaria nephropathy, *P. malariae* infection is associated with a variety of other forms of histologic appearance, including proliferative GN and MGN (244).

Although quartan malaria nephropathy has been clearly linked to *P. malariae* infection in Nigeria, a number of studies from other regions in Africa have not revealed the typical histopathologic findings described in the Nigerian studies (245). Furthermore, quartan malaria nephropathy may be seen in children with no evidence of *P. malariae* infection or deposition of malaria antigens in the kidney. This, together with the fact that antimalarial treatment does not affect the progression of the disorder, raises the possibility that factors other than malaria might be involved in the initiation and perpetuation of the disorder. Although there is undoubtedly a strong association between *P. malariae* infection and nephrotic syndrome on epidemiologic grounds, the direct causal link is not proven. Most likely, a number of different infectious processes, including malaria, hepatitis B, schistosomiasis, and perhaps other parasitic infections that cause chronic or persistent infections and often occur concurrently in malaria areas, may all result in glomerular injury and a range of overlapping histopathologic features. The prognosis for the nephrotic syndrome in most African studies has been poor, regardless of whether the histologic findings were typical of quartan malaria nephropathy or whether *P. malariae* parasitemia was implicated. Treatment with steroids and azathioprine is generally ineffective, and a significant proportion of patients progress to renal failure.

Disease Associated with *Plasmodium Falciparum* Infection

P. falciparum appears to be much less likely to cause significant glomerular pathology. Epidemiologic studies have failed to show a clear association between *P. falciparum* parasitemia and the nephrotic syndrome. Whereas renal failure appears to be a common complication of severe malaria in adults, it seldom occurs in children.

Renal biopsy specimens from adult patients with acute *P. falciparum* infections who have proteinuria or hematuria show evidence of glomerular changes, including hypercellularity, thickening of basement membranes, and hyperplasia and hypertrophy of endothelial cells (246). Electron microscopy reveals electron-dense deposits in the subendothelial and paramesangial areas. Deposits of IgM, with or without IgG, are localized mainly in the mesangial areas. *P. falciparum* antigens can be demonstrated in the mesangial areas and along the capillary wall, which suggests an immune-complex GN. The changes, generally mild and transient, are probably unrelated to the acute renal failure that may complicate severe *P. falciparum* infection (246). Heavily parasitized erythrocytes play a central role in the various pathologic factors (247).

Renal failure occurring in severe *P. falciparum* malaria is usually associated with acidosis, volume depletion, acute intravascular hemolysis or heavy parasitic infection that leads to acute tubular necrosis. Recent studies have confirmed an important role for volume depletion in children with severe falciparum malaria, who characteristically have evidence of tachycardia, tachypnoea, poor perfusion and in severe cases hypotension (248). Volume expansion with either colloid or crystalloid results in improvement in hemodynamic indices and reduction in acidosis (249). There is growing evidence that volume expansion with albumin is associated with a better outcome than saline or synthetic colloids (250, 251). Treatment with antimalarials, correction of hypoglycemia and

electrolyte imbalance, and volume expansion reduces mortality to less than 5%. Although renal failure is usually associated with infection by *P. falciparum*, acute renal failure has been described with *Plasmodium vivax* infection and mixed infections (252).

Blackwater Fever

The term blackwater fever refers to the combination of severe hemolysis, hemoglobinuria, and renal failure. It was more common at the start of the twentieth century in nonimmune individuals receiving intermittent quinine therapy for *P. falciparum* malaria. Blackwater fever has become rare since 1950, when quinine was replaced by chloroquine. However, the disease reappeared in the 1990s, after the reuse of quinine because of the development of chloroquine-resistant organisms. Since then, several cases have been described after therapy with halofantrine and mefloquine, two new molecules similar to quinine (amino-alcohol family) (253). Renal failure generally occurred in the context of severe hemolytic anemia, hemoglobinuria, and jaundice. The pathophysiology of the disorder is unclear; however, it appears that a double sensitization of the red blood cells to the *P. falciparum* and to the amino-alcohols is necessary to provoke the hemolysis. Histopathologic findings include swelling and vacuolization of proximal tubules, necrosis and degeneration of more distal tubules, and hemoglobin deposition in the renal tubules. Recent studies indicates a better outcome with earlier initiation of intensive care and dialysis combined with necessary changes in antimalarial medications.

Schistosomiasis

Schistosomiasis affects 200 million people living in endemic areas of Asia, Africa, and South America (254). The infection is usually acquired in childhood, but repeated infections occur throughout life. *Schistosoma japonicum* is found only in the Orient, whereas *Schistosoma haematobium* occurs throughout Africa, the Middle East, and areas of southwest Asia. *Schistosoma mansoni* is widespread in Africa, South America, and southwest Asia.

Human infection begins when the cercarial forms invade through the skin, develop into schistosomula, and move to the lungs via the lymphatics or blood. They then migrate to the liver and mature in the intrahepatic portal venules, where male:female pairing takes place. The adult worm pairs then migrate to their final resting site - the venules of the mesenteric venous system of the large intestine (*S. mansoni*) or in the venules of the urinary tract (*S. haematobium*). The females release large numbers of eggs, which may remain embedded in the tissues, embolize to the liver or lungs, or pass into the feces or urine.

Clinical manifestations may occur at any stage of the infection. Cercarial invasion may cause an intense itchy papular rash. Katayama fever is an acute serum sickness-like illness that occurs several weeks after infection, as eggs are being deposited in the tissues. Deposition of the eggs in tissues results in inflammation of the intestines, fibrosis of the liver, and portal hypertension. With *S. haematobium*, chronic inflammation and fibrosis of the ureters and bladder may lead to obstructive uropathy (255).

Renal manifestations of schistosomiasis occur most commonly in *S. mansoni* infection. Schistosomal nephropathy usually presents with symptoms including granulomatous inflammation in the ureters and bladder, but glomerular disease (probably on an immune-complex basis) may also occur. Renal disease usually occurs in older children or young adults with long-term infection, but serious disease may also occur in young children (255).

The early renal tract manifestations of schistosomiasis are suprapubic discomfort, frequency, dysuria, and terminal hematuria. In more severe cases, evidence of urinary obstruction appears. Poor urinary stream, straining on micturition, a feeling of incomplete bladder emptying, and a constant urge to urinate may be severely disabling symptoms. The fibrosis and inflammation of ureters, urethra, and bladder may be followed by calcification and may result in hydroureter, hydronephrosis, and bladder neck obstruction. Renal failure may ultimately develop, and there is a suspicion that squamous cell carcinoma of the bladder may be linked to the chronic infective and inflammatory process. Secondary bacterial infection is common within the obstructed and inflamed urinary tract (254).

The hepatosplenic form of *S. mansoni* infection may be accompanied by a glomerulopathy in 12–15% of cases, manifested in the majority as nephrotic syndrome (256). Histopathologic findings include mesangioproliferative GN, focal segmental glomerulosclerosis, mesangiocapillary GN, MGN, and focal segmental hyalinosis (257). Immune complexes may be detected in the circulation of these patients, and glomerular granular deposition of IgM, C3, and schistosomal antigens are seen on immunofluorescence. Usually Schistosoma-specific nephropathy is a progressive disease and is not influenced by antiparasitic or immunosuppressive therapy (258), but isolated case reports of remission after treatment with praziquantel have been reported (259).

The diagnosis is confirmed by the detection of Schistosoma eggs in feces, urine, or biopsy specimens. Eggs are shed into the urine with a diurnal rhythm, and urine collected between 11 AM and 1 PM is the most useful. Urinary sediment obtained by centrifugation or filtration through a Nuclepore membrane should be examined.

In cases in which studies of urine and feces yield negative results in patients in whom the diagnosis is suspected, rectal biopsy specimens taken approximately 9 cm from the anus have a high diagnostic yield for both *S. mansoni* and *S. haematobium* infection. Biopsy of liver or bladder may be required to establish the diagnosis.

Antibodies indicating previous infection can be detected using enzyme-linked immunosorbent assay or radioimmunoassay. The tests are sensitive but lack specificity and may not differentiate between past exposure and current infection.

Praziquantel is the drug of choice for treatment of schistosomiasis. A single oral dose of 40 mg/kg is effective in *S.haematobium* and *S. mansoni* infection and is usually well tolerated. The alternative drug for *S. mansoni* infection is oxamniquine. Complete remission of urinary symptoms may occur in renal disease of short duration, but in late disease with extensive fibrosis, scarring, and calcification, obstructive uropathy and renal failure may persist after the infection has been eradicated. There are reports of a drastic decrease in the number of severe hepatosplenic forms of *S. mansoni* infection after mass treatment of the population in endemic areas with oxamniquine. This also reduced schistosomal nephropathy (256).

Leishmaniasis

Visceral leishmaniasis is a chronic protozoon infection characterized by fever, hepatosplenomegaly, anemia, leukopenia, and hyperglobulinemia. Proteinuria and/or microscopic hematuria or pyuria have been reported in 50% of patients with visceral leishmaniasis (260). Acute renal failure in association with interstitial nephritis has also been reported (261). Renal histologic analysis in patients with visceral leishmaniasis reveals glomerular changes, with features of a mesangial proliferative GN or a focal proliferative GN, or a generalized interstitial nephritis with interstitial edema, mononuclear cell infiltration, and focal tubular degeneration. Immunofluorescence reveals deposition of IgG, IgM, and C3 within the glomeruli, as well as electron-dense deposits in the basement membrane and mesangium on electron microscopy (260). Circulating immune complexes together with immunoglobulin and complement deposition in the glomeruli suggests an immune-complex cause.

Renal disease in leishmaniasis is usually mild and may resolve after treatment of the infection. Renal dysfunction may be associated with treatment for visceral leishmaniasis with antimony compounds.

Filariasis

Proteinuria is more common in filarial hyperendemic regions of West Africa than in nonfilarial areas. Renal histologic analysis has shown a variety of different histopathologic appearances; the most common is diffuse mesangial proliferative GN with C3 deposition in the glomeruli (262). Renal biopsy specimens also demonstrate large numbers of eosinophils in the glomeruli, and microfilariae may be seen in the lumen of glomerular capillaries. Filarial antigens have been detected within immune deposits within the glomeruli.

Hydatid Disease

Echinococcus granulosus causes chronic cysts within a variety of organs. In addition, nephrotic syndrome in association with hydatid disease has been reported. Membranous nephropathy, minimal change lesions, and mesangiocapillary GN have been described in association with hydatid disease (263, 264). Immunofluorescence reveals deposits of immunoglobulin, complement, and hydatid antigens within the glomeruli. Remission of nephrotic syndrome has been reported with treatment by antiparasitic agents such as albendazole (263, 264).

Trypanosomiasis

Few reports have been published of renal disease occurring in patients with trypanosomiasis. The trypanosomal antigens can induce GN in a variety of experimental animals (265).

Toxoplasmosis

Nephrotic syndrome has occasionally been reported as a manifestation of congenital toxoplasmosis.

Dissemination of previously latent toxoplasma infection in patients undergoing treatment with immunosuppressive drugs has been increasingly recognized in recent years. Reactivation of toxoplasmosis or progression of recently acquired primary infection should be considered in patients undergoing renal transplantation or immunotherapy for renal disease who develop unexplained inflammation of any organ.

Fungal Infections

Fungal infections of the kidneys and urinary tract occur most commonly as part of systemic fungal infections in patients with underlying immunodeficiency, as focal urinary tract infections in patients with obstructive lesions, or as a result of indwelling catheters. Although Candida infection is the most common fungal infection in both immunocompromised and non immunocompromised hosts, virtually all other fungal pathogens may invade the renal tract during severe immunocompromise.

Urinary infection with *Candida albicans* is most commonly a component of systemic candidiasis in patients who are severely immunocompromised. Systemic candidiasis is also seen in premature and term infants with perinatally acquired invasive candidiasis. Presentation is usually with systemic sepsis, fever or hypothermia, hepatosplenomegaly, erythematous rash, and thrombocytopenia. Systemic candidiasis may be seen on ophthalmologic investigation as microemboli in the retina. The first clue to the underlying diagnosis may be the presence of yeasts in the urine (266).

Candida involvement of the urinary tract may affect all structures including the glomeruli, tubules, collecting system, ureters, and bladder. Microabscesses may form within the renal parenchyma, and large balls of fungi may completely obstruct the urinary tract at any level. Acute renal failure caused by systemic candidiasis or obstruction of the renal tracts with fungal hyphae is a well-recognized complication of systemic candidal infection (266, 267). Indwelling catheters (which form a nidus for persistent infection) should be removed. Successful treatment of non-obstructing bilateral renal fungal balls by fluconazole either alone or in combination with liposomal amphotericin B has been reported (268, 269). In the presence of obstruction, however, percutaneous nephrostomy to relieve the obstruction with antegrade amphotericin B irrigation, coupled with systemic antifungal therapy, is the mainstay of treatment (267). Amphotericin B is the most effective antifungal agent, but it is not excreted in the urine. Local irrigation via nephrostomy provides good results, however. For treatment of urinary tract candidiasis, it is usually combined with fluconazole or 5-flucytosine, both of which are excreted in high concentrations in the urine. Treatment is required for weeks to months to ensure complete elimination of the fungus, and the ultimate outcome is largely dependent on whether there is a permanent defect in immunity.

Miscellaneous Conditions

Hemorrhagic Shock and Encephalopathy

In 1983, Levin et al. first described hemorrhagic shock and encephalopathy, which appeared to be distinct from previously recognized pediatric disorders (270). Other cases have subsequently been reported from several centers in the United Kingdom, Europe, Israel, the United States, and Australia, and the syndrome is now recognized as a new and relatively common severe childhood disorder (271).

Hemorrhagic shock and encephalopathy usually affects infants in the first year of life, with a peak onset at 3–4 months of age. A prodromal illness with fever, irritability, diarrhea, or upper respiratory infection occurs 2–5 days before the onset in two-thirds of cases. Affected infants develop profound shock, coma, convulsions, bleeding and evidence of DIC, diarrhea, and oliguria. Laboratory findings include acidosis, falling hemoglobin and platelet levels, elevated urea and creatinine levels, and elevated levels of hepatic transaminases. Despite vigorous intensive care, the prognosis is poor, and most affected infants die or are left severely neurologically damaged (271, 272). A small number of patients have been reported to survive without residual sequelae.

The renal impairment appears to be largely prerenal in origin, and when aggressive volume replacement and treatment of the shock results in improved renal perfusion, rapid improvement in renal function is usually observed. In patients with profound shock unresponsive to initial resuscitation, vasomotor nephropathy supervenes and dialysis may be required. Myoglobinuria in association with hemorrhagic shock and encephalopathy has been reported.

Kawasaki Disease

Following the description of the mucocutaneous lymph node syndrome by Kawasaki in 1968, Kawasaki disease has been recognized as a common and serious childhood

illness with a worldwide distribution. Although the etiology remains unknown, epidemiologic features clearly suggest an infective cause. The disease occurs in epidemics, and wavelike spread has been demonstrated during outbreaks in Japan.

Amyloidosis

Deposition of amyloid within the kidney is an important complication of chronic and persistent infection. Amyloidosis is most common in patients with chronic osteomyelitis and chronic pulmonary infections such as bronchiectasis and is seen occasionally in those with persistent infections such as leprosy or malaria (273–275).

53 Nephrotoxins

Deborah P. Jones · Russell W. Chesney

The kidney is responsible for the elimination and metabolism of many foreign organic compounds, including pharmacologic agents. Ultimately these agents reach the urinary space for excretion via glomerular filtration or tubular secretion (*Fig. 53-1*). In some instances drugs must undergo transformation into metabolites, a reaction that may actually take place within tubular cells before secretion into the tubular lumen. While performing its role as an excretory and metabolic organ, the kidney may be at risk for drug-induced toxicity.

Factors that contribute to the susceptibility of the kidney to injury include the magnitude of blood flow through glomerular and peritubular vessels; the large surface area available for uptake of potentially harmful compounds; the concentration of specific substrates within tubular fluid which may induce injury or promote accumulation of the toxin within the renal tubular cell; dependence of the renal tubular cell on a high metabolic rate to maintain function; and the distribution of unique transport systems that concentrate drugs or toxins within the tubular cell (1).

Nephrotoxins may preferentially damage specific nephron segments, depending on the area of maximal exposure, the location of specific uptake systems, and the tubular location of specific intracellular sites that are susceptible to the toxin (1). The concentration of a drug within the renal tubular cell may be affected by the dissociation constant of the compound, its lipid solubility, tubular secretory or reabsorptive activity, water handling, competitive tubular transport mechanisms, urinary pH, and urinary flow rate. The concentration also may be affected by the distribution of enzymes that metabolize individual drugs and intracellular protective systems important in the maintenance of normal cell metabolism.

Potential mechanisms for drug-induced renal dysfunction include alterations in renal perfusion and glomerular filtration rate, tubular cell damage, and tubular obstruction (1). Toxic nephropathy, or drug-induced renal dysfunction, is primarily a disorder of the renal tubule; however, significant tubular damage eventually results in alterations in glomerular function. In addition, drugs or their metabolites may alter glomerular blood flow through vasoconstriction of the glomerular capillaries (1). This may be a primary event through actions on the endothelial cell or a secondary event via activation of tubuloglomerular feedback after tubular damage allows increased distal delivery of solute and fluid.

Drugs may undergo redox recycling, which results in oxidative stress within the cell and alters the normal antioxidant defense mechanisms. The elaboration of reactive oxygen species by the cytochrome P-450 system may enable reactive intermediates to initiate damage directly or to combine with glutathione (GSH) to deplete available GSH (2). GSH protects cells from oxidant stress as it participates in detoxification reactions during vital cell processes such as protein and nucleic acid synthesis. Depletion of cellular levels of GSH is a common pathway for nephrotoxic injury (2). Drugs or metabolites may either directly conjugate GSH or be metabolized to compounds that are reactive and may bind to GSH. Ultimately, reactive species promote injury, which interferes with normal cellular functions such as energy production, detoxification, transport, and macromolecular synthesis. Although they may come from widely different chemical classes and have different renal distributions, toxic compounds may ultimately affect renal integrity and function through inhibition of cellular energy production, disruption of membrane integrity, perturbation of vital cell functions such as protein or nucleic acid synthesis, or alteration in intracellular calcium homeostasis.

This chapter focuses on the clinical characteristics, and mechanisms of injury, as well as methods to reduce or prevent drug-associated renal damage. The most common offending agents have been chosen; this discussion is not meant to be all inclusive.

Organic Anion Transporters

Organic anions comprise a chemically heterogeneous group of compounds including drugs, environmental chemicals, including plant and animal toxins, as well as metabolites of endogenous and exogenous substances. A list of drugs which are organic anions is found in *Table 53-1* (3). Organic anions are primarily eliminated by the kidneys and liver via a family of organic anion transporters

Figure 53-1

Renal drug elimination is s combination of glomerular filtration and tubular secretion. Many factors have an impact on renal cell accumulation and net excretion.

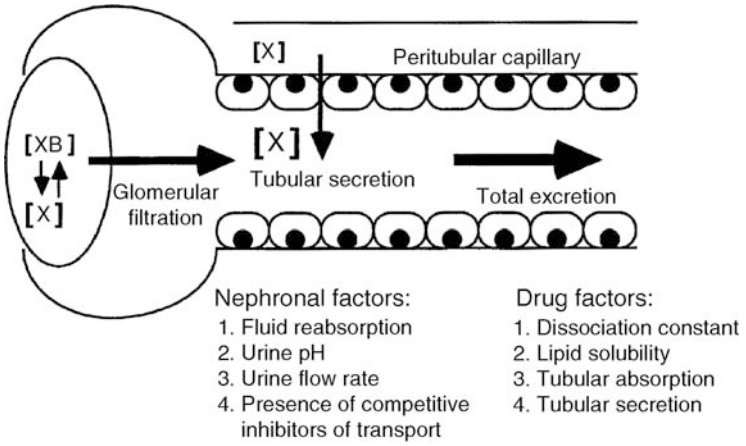

Table 53-1

Substances transported by OAT1 (from reference (5))

Endogenous
cAMP, cGMP, PGE1, PGE2, 6-ketoPGF1a, urate, folate, neurotransmitter metabolites
Drugs
Antibiotics: penicillin antibiotics, cephem antibiotics, carbapenem antibiotics
Antiviral: acyclovir, amantidine, adefovir, cidofovir
NSAIDs: salicylates, indomethacin, ibuprofen, diclofenac, naproxen, sulindac
Diuretics: loop diuretics, thiazide diuretics
Antihypertensives: ACE inhibitors, angiotensin receptor antagonists
Anti-neoplastic: methotrexate, azathioprine, Ara-C, 5-FU, cyclophosphamide, chlorambucil, anti-epileptic: valproate
Uricosuric: probenecid

known as the OAT. This family of transporters is essential to the renal elimination of numerous substrates; altered function of the OAT family may be responsible for interindividual variation in the toxicity of its substrates (3). The first OAT transporter characterized was OAT1, which is also known as the p-aminohippurate (PAH) transporter since PAH is the classic substrate for this transport system. Five structurally similar OATs belong to this family of transporters: OAT2, OAT3, OAT4, URAT1 and OAT5. OAT1 and OAT3 are localized to the basolateral membrane of the proximal tubule, where they function as the major pathway for organic anion entry into the proximal tubular cell (*Fig. 53-2*) (4). One of the main features of the OAT family of transporters is that substrate specificity is quite broad. In contrast to OAT1 and OAT2, OAT4 is localized to the apical membrane of the proximal tubular cell. These transporters are anion exchangers, as uptake of substrate is stimulated by an outwardly directed concentration gradient of dicarboxylate compounds.

The OAT1 transporter interacts with numerous drugs including β-lactam antibiotics, antiviral agents, diuretics, antineoplastic compounds, angiotensin converting enzyme inhibitors and nonsteroidal antiinflammatory drugs (NSAIDs) (4). OAT3 has somewhat different substrate specificity and has been found to interact with histamine II receptor antagonists, estrone sulfate, β-lactam antibiotics, antiviral agents, diuretics, antineoplastic compounds, angiotensin converting enzyme inhibitors and NSAIDs (5). Coadministration of substrates which also rely upon this transport system for elimination results in reduced accumulation of both substrates; this interaction can markedly influence the proximal tubular cell accumulation and ultimately the renal elimination of these compounds. Examples include the increased half-life noted for penicillin when it is given with probenecid. Similarly, increased toxicity secondary to increased plasma drug levels is observed when methotrexate is coadministered with NSAIDs or β-lactam antibiotics. Similar interactions have been reported for antiviral agents, diuretics and nucleoside derivatives (5).

Multidrug Resistance Proteins

The multidrug resistance protein (MRP) family is comprised of active transporters with ATP-binding cassette motifs (*Fig. 53-2*). The main renal MRP is MRP4, which is located on the apical membrane of the proximal tubular cell where is facilitates efflux of a wide variety of organic acids, both endogenous and exogenous, including numerous drugs (*Table 53-2*) (6). Interaction among substrates for MRP4 is complex, as evidenced by allosteric stimulation of MRP4 mediated transport by some substrates but not others. Current evidence supports the presence of two independent transport sites that can be modified by multiple allosteric binding sites, such that binding of certain substrates is dependent upon the presence of others (7).

Figure 53-2

Proximal tubular transport systems important to drug excretion. The organic anion transporters (OAT) and multidrug resistance-associated proteins (MRP) in the proximal tubular cell. Uptake of organic anions across the basolateral membrane is mediated by anion exchange via OAT 1 and OAT3. MRP2 and MRP 4 mediate basolateral efflux. The luminal organic anion exchanger, OAT 4, may also allow luminal efflux of organic anions. From reference (5).

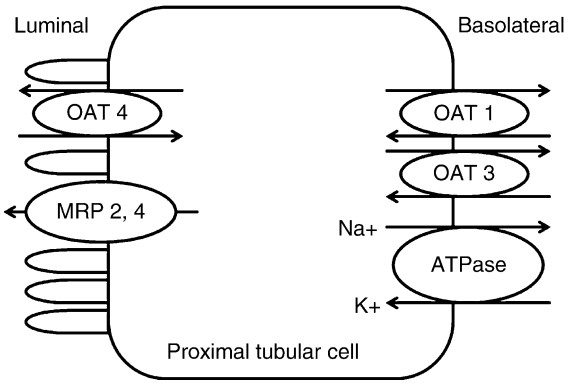

Table 53-2

Selected endogenous and exogenous substrates which interact with MRP4 (from reference (7))

Endogenous substrates
cAMP, cGMP, urate, PGE1, PGE2, folate, conjugated steroids
Exogenous substrates
Methotrexate, leucovorin, topotecan, adefovir, tenofovir, ceftizoxime, cefazolin, cefotaxime, hydrochlorothiazide, furosemide, olmesartan, PAH
Inhibitors of MRP4
Dipyridamole, sildenafil, indomethacin, sulindac, losartan, probenecid

Nephrotoxicity from Antibiotics

The concentration of antibiotics by renal tissue exposes the kidney to toxicity that other organs do not experience (8). Nephrotoxic clinical syndromes include acute tubular necrosis (ATN), acute interstitial nephritis (AIN), direct tubular effects on transport systems (electrolytes, protons leading to acidosis, concentration defects, or the full-blown Fanconi syndrome), and tubular obstruction from drug precipitation.

Aminoglycosides

Aminoglycoside antibiotics are widely used antimicrobials that are particularly nephrotoxic; these compounds are concentrated within the renal tubular cell (9). Aminoglycosides are excreted primarily by glomerular filtration. Reabsorption by the proximal tubule cell occurs after charge interaction and binding to the brushborder membrane of the proximal tubule, followed by transport into the cell by pinocytosis via vesicles directed to lysosomes (10, 11). Although less significant, reabsorption from the basolateral surface of the tubular cell may also contribute to total intracellular uptake (12). The molecular mechanism for aminoglycoside uptake by the brush border of the proximal tubular cell involves binding to megalin, a multiligand endocytic receptor (13). Depletion of megalin or coadministration of ligands that bind megalin in animal models of aminoglycoside nephrotoxicity result in reduced accumulation of the drug within the proximal tubular cell, and prevention of cell damage (14). Accumulation of the drug within the lysosome results in phospholipid hydrolysis and the formation of electron-dense myeloid bodies, which are membranous structures found within lysosomes (9). Aminoglycosides appear to have a generalized effect on phospholipid membranes, resulting in decreased surface charge and alterations in fluidity and permeability of tubular cell membranes (8, 9).

Pathologic alterations have been reported after a single dose of aminoglycoside, but most animal models of aminoglycoside toxicity use multiple doses over several days to produce a model of toxic nephropathy. Once appreciable injury occurs, lysosomal membranes release sequestered aminoglycosides as well as lysosomal

enzymes, which cause generalized cell injury and eventual necrosis (15, 16).

The main pathologic finding in aminoglycoside nephrotoxicity is tubular cell necrosis, involving principally the most proximal segments of the nephron: the convoluted tubule and pars recta (S1 and S2) (1, 17). The earliest pathologic finding is an increased number of lysosomes, followed by alterations in the brush-border architecture and mitochondrial swelling (18). This process may be focal or diffuse. Of interest, even during continued aminoglycoside administration, tubular cell regeneration can be evident. Gentamicin also interferes with mitochondrial respiration by enhancing hydrogen peroxide generation, which includes iron mobilization from the mitochondria. Hydroxyl-radical scavengers and iron chelators are protective in the rat model of aminoglycoside toxicity (2).

Clinical features of aminoglycoside nephrotoxicity include subtle perturbation of tubular and/or glomerular function; nephrotoxicity occasionally progresses to renal failure. The earliest clinically detectable abnormality is enzymuria, which results from loss of brushborder membrane segments bearing the enzymes (19). Tubular damage may rarely produce a Fanconi syndrome with proximal tubular wasting of glucose, phosphate, amino acids, and bicarbonate as well as numerous ions including magnesium (9, 17). Initially, urine volume may be increased because of a vasopressin-resistant concentrating defect. Renal dysfunction is most commonly detected after a rise in serum creatinine concentration or elevated aminoglycoside trough levels. Although it is rare, severe, sustained renal dysfunction has been described with peak serum creatinine levels at 3–10 days after cessation of aminoglycoside therapy and full recovery in weeks (20).

Glomerular filtration rate (GFR) may decrease after gentamicin administration in the absence of tubular necrosis as a result of angiotensin II–mediated afferent arteriolar vasoconstriction. Prostaglandin synthetase inhibitors potentiate the vasoconstriction and hypofiltration; this provides indirect evidence of a palliative role of locally produced vasodilatory prostaglandins in this form of nephrotoxic injury (21). In addition to the microvascular and tubular changes, K_f (glomerular capillary ultrafiltration coefficient) is decreased because of a decrease in the number and density of glomerular capillary wall fenestrae (22, 23).

The relative toxicity of the aminoglycosides, in order from most toxic to least, is neomycin, gentamicin, tobramycin, and amikacin (17). This order is dependent on the number of ionizable amino groups, which affects brushborder membrane binding (24). Several factors may contribute to or predispose to aminoglycoside nephrotoxicity. Drug dosage and duration of therapy, particularly repeated and prolonged courses, determine the severity of the tubular toxicity. Concomitant administration of other nephrotoxic drugs, concomitant administration of cationic amino acids, volume depletion, potassium depletion, endotoxemia, hypokalemia, and hyperphosphatemia further potentiate renal injury (10, 17, 25) Prevention of aminoglycoside toxicity involves the prudent use of aminoglycosides along with planned monitoring for early nephrotoxicity.

β-Lactam Antibiotics

The β-lactam antibiotics are related to the penicillins, and include the cephalosporins and the penems. Structurally, they are bicyclic compounds that acylate bacterial wall proteins and penetrate the bacterium to inactivate vital enzymes. Whereas most penicillin-like compounds are not nephrotoxic, certain cephalosporins and carbapenem compounds are associated with renal toxicity (26).

The β-lactams are extracted from renal venous blood by the organic acid transport system (OAT 1 and OAT3) located on the basolateral surface of the tubular cell. Intracellular accumulation results because of the limited ability of the proximal tubular cell to secrete the β-lactam at the luminal membrane into the luminal fluid (urine). Differences in organic acid transporter characteristics between basolateral and apical membranes result in marked accumulation with high intracellular levels, sometimes a thousand times higher than the levels found in plasma or other types of cells (26). Because of the very specific distribution of the organic acid transporters, renal injury in the form of tubular cell necrosis is limited to the proximal tubule (26). The initial event is thought to be lipid peroxidation with particular damage to the mitochondrial membrane, possibly through acylation of important membrane-associated transporters. Mitochondrial damage interferes with energy production, which leads to decreased levels of adenosine triphosphate and subsequent cell damage and death. Replacement of deficient cellular substrates can reverse toxicity (16). Damage secondary to β-lactams is related to decreased mitochondrial respiration and decreased succinate uptake by mitochondria within hours after drug administration (26).

The original compounds cephaloridine and cephaloglycin are no longer used; the new compound imipenem, which is a carbapenem, is nephrotoxic and is used only in combination with cilastin, an inhibitor of brushborder dehydropeptidase I. Cilastin inhibits the metabolism of imipenem to metabolites with structural similarity to cephaloridine (27). Meropenem, another agent in the

carbapenem class, is not metabolized to an appreciable degree and therefore does not require coadministration with cilastin. Cilastatin was designed as a nephroprotective OAT inhibitor, allowing higher serum levels and lower proximal renal tubular intracellular levels of the penems (28).

Clinical characteristics of β-lactam–associated nephrotoxicity include ATN with or without oliguria, which lasts days to weeks. Drug dosage should be adjusted according to the patient's renal function. Administration of organic anion transporter inhibitors (probenecid) may help to prevent injury. However, because these agents also impair tubular secretion, and thus drug elimination, blood levels of the β-lactam would be expected to be higher in the presence of organic anion inhibitors.

Renal toxicity from β-lactams can also result from hypersensitivity reactions. The molecular weights of all β-lactams are insufficient to be directly immunogenic. These antibiotics or their metabolites can bind to larger molecules, which then act as haptens. Although exposure to many penicillins and cephalosporins can result in acute interstitial nephritis (AIN), AIN is most common with methicillin (29, 30). This syndrome consists of fever, rash, oliguria, and, rarely, arthralgias. Laboratory findings are prominent in the urine with pyuria, eosinophiluria, and proteinuria with azotemia. The main therapy is discontinuation of the β-lactam, but glucocorticoids have been used and may enhance recovery (31).

Antifungal Agents

Amphotericin B

Amphotericin B is an antifungal agent that exerts its effect by interaction with membrane sterols. This chemical interaction is the basis for its antifungal action as well as renal toxicity (17). Amphotericin B has two major pathophysiologic effects on the kidney: renal tubular cell injury, which is manifest as hypokalemia, hypomagnesemia, and acidosis; and decreased GFR secondary to afferent arteriolar vasoconstriction (9, 32).

Unlike most other drug-associated renal tubular toxicity, the primary tubular site of amphotericin B–induced injury is the distal tubule (17). The interaction of this drug with membrane cholesterol leads to the formation of aqueous pores, which greatly increase the permeability of the normally tight epithelium of the distal tubule; this results first in a backleak of H^+, Na^+, and Cl^-, and then to a vasopressin-resistant polyuria (17, 33). Use of this agent will result in the formation of pores in all patients exposed. Increased permeability to Cl^- may stimulate increased tubuloglomerular feedback and reduce GFR, which ultimately results in renal ischemia and azotemia. In a canine model, amphotericin administration led to a decrease in urine flow and GFR within 1 h, accompanied by increased renal vascular resistance as a result of afferent arteriolar constriction (34). Aminophylline blocks amphotericin B–induced vasoconstriction, which suggests a role for adenosine as a potential mediator (35). Verapamil also protects the kidney from vasoconstriction, which indicates that increased calcium in vascular smooth muscle may mediate the acute effects (36).

Amphotericin B nephrotoxicity may become clinically evident as a reduction in GFR, usually detected as an increase in plasma creatinine level or as distal tubular dysfunction with metabolic acidosis (secondary to the distal type of renal tubular acidification defect), salt wasting, polyuria, hypomagnesemia, or hypokalemia (10, 17). Nephrotoxicity is predictable and usually reversible, although irreversible azotemia has been observed at large dosages. The severity of tubular toxicity and glomerular dysfunction is proportional to the cumulative dose. In adults, a cumulative dose exceeding 5 g was associated with significant renal dysfunction, whereas patients who received less than a 600 mg cumulative dose rarely suffered renal toxicity (37). Concomitant use of diuretics, cyclosporine, or aminoglycoside antibiotics and abnormal pretreatment renal function increase the risk of amphotericin toxicity (17, 37).

Sodium loading appears to have a beneficial effect on amphotericin B–induced nephrotoxicity by maintaining intravascular volume and reducing renal vasoconstriction (17, 37). Mannitol has been shown to ameliorate nephrotoxicity in animal studies, but the benefit of this agent in humans has not been consistently demonstrated (38, 39).

Lipid formulations of amphotericin B have been developed in an attempt to reduce renal toxicity. The aim of the lipid preparations of amphotericin B is to direct the drug to preferentially bind to fungal membranes rather than mammalian membranes (40). In one study of HIV patients with invasive histoplasmosis, nephrotoxicity occurred in 37% of patients treated with amphotericin B compared to 9% of patients treated with liposomal amphotericin B (41). However, as noted above, nephrotoxicity can occur with the liposomal preparation, an effect which appears to be dose-related. In a pediatric study which assessed the change in serum creatinine before and after amphotericin B lipid complex, the mean serum creatinine did not change, however, approximately 15% of patients had higher posttreatment creatinine compared to pretreatment levels (42).

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase and thereby reduce prostaglandin synthesis from arachidonic acid. Prostaglandin production can be stimulated by angiotensin II, arginine vasopressin, catecholamines, and renal sympathetic nerve stimulation. Stimulation of prostaglandin synthesis occurs by hormone-mediated activation of phospholipases, which release arachidonic acid from membrane-associated phospholipids (43).

Under conditions such as impaired GFR, alterations in renal hemodynamics, and sodium depletion, however, the compensatory release of vasodilatory prostaglandins I_2 and E_2 helps to maintain renal blood flow and GFR, and modifies the effect of local vasoconstrictive substances such as angiotensin II (43). Therefore, it is in the presence of such altered physiologic states that renal functional alterations associated with NSAIDs are likely to occur, because the normal compensatory mechanisms are blocked. NSAIDs potentiate prerenal ischemia, increasing sodium reabsorption by the proximal tubule and the ascending limb of the loop of Henle. NSAIDs also increase the sensitivity of the collecting tubule to vasopressin, which further adds to salt and water retention and may produce a hyporeninemic hypoaldosteronism through reduction of renin release (43).

The organic anion transporter family (OAT) is likely to play a significant role in the pathogenesis of NSAID-induced acute kidney injury, as this basolateral transport system regulates the proximal tubular cell accumulation of this class of drugs. In addition, concomitant administration of NSAIDs with other drugs that are substrates for the basolaterally located OAT1 or OAT3 may affect toxicity induced by either agent (28).

Acute renal failure secondary to NSAIDs results from excessive vasoconstriction at the level of the afferent arteriole. An acute phenomenon often associated with oliguria, NSAID-induced acute renal failure is usually reversible. Risk factors include volume depletion, diabetes mellitus, congestive heart failure, hepatic failure with ascites, and hypoalbuminemia (43).

In addition to having physiologic actions that produce renal functional changes, NSAIDs may cause tubulointerstitial nephritis. Arising after 2–23 months of therapy, this syndrome is associated with an interstitial mononuclear cell infiltrate and occasionally epithelial cell podocyte fusion on electron microscopy (44). Renal functional recovery typically occurs when the agent is discontinued.

Long-term use of NSAIDs may cause papillary necrosis as well as chronic renal insufficiency through chronic ischemia (44). The risk of chronic renal disease (serum creatinine level above 1.5 mg/dL) in daily users of NSAIDs was 2.1% (43). Although most epidemiologic studies were performed in adults, children also are at risk for renal failure (45). Prenatal exposure may lead to renal failure-associated deaths after administration of 140–400 mg of indomethacin per day for anywhere between 2 and 11 weeks of therapy (46). Risk factors for renal functional changes are underlying volume depletion and renal disease (43). Acute administration of NSAIDs to patients with chronic renal insufficiency results in decreased renal plasma flow, decreased GFR, decreased fractional excretion of sodium, and decreased fractional free water clearance (47). Most healthy, normal subjects who take NSAIDs for a limited duration tolerate these agents without adverse events, but a subset of individuals appears to be at risk. Because ibuprofen is now commercially available for treatment of fever in children, the incidence of NSAID-related renal disease may increase. Febrile children often have reduced fluid intake in the face of increased insensible fluid losses with clinically mild but significant hypovolemia, which places them at risk for NSAID toxicity.

Antiviral Agents

Acyclovir and Ganciclovir

Acyclovir and ganciclovir are active against herpes viruses and cytomegalovirus (CMV). Acyclovir is excreted primarily by the kidney. Anywhere from 30 to 90% of the drug is excreted unchanged in the urine in patients with normal glomerular filtration. Acyclovir is probably excreted by both glomerular filtration and tubular secretion (8). Pretreatment with probenecid decreases renal clearance of the drug by 32%, which supports a role for tubular secretion as a partial mechanism of excretion. The dosing interval must be adjusted in the setting of a decreased GFR.

Acyclovir administration is complicated by renal, hepatic, and neurologic dysfunction (8). Renal toxicity is associated with plasma concentrations of acyclovir exceeding 20 mg/mL. Renal levels of acyclovir can be 20 times the plasma levels. Crystals form within the renal tubule, which leads to intratubular obstruction followed by a rise in the serum creatinine concentration within 24–48 h (48, 49). Needle-shaped crystals may form in the urine even in those who do not have clinical evidence of renal dysfunction. In most cases, renal failure is not associated with oliguria and GFR returns to normal within 1 week. Urinary findings include hematuria, pyuria, proteinuria, and

crystalluria. Histologically, ATN may be observed along with patchy interstitial infiltration (49).

Renal toxicity was noted in rats during preclinical toxicology studies. An obstructive nephropathy developed, with associated drug crystallization within the collecting ducts. The development of crystalluria was dosage-related. Acyclovir administration to rats was accompanied by a reduction in GFR and significant increase in total renal vascular resistance without changes in urinary flow rate (50). Ganciclovir administration did not induce a decrease in GFR or change in renal vascular resistance in this rat model. In a large series of patients who received acyclovir for serious infections, 16% of adult patients experienced elevations of the serum creatinine level (49). Among children given acyclovir, 12% had elevated serum creatinine concentrations (51). Some of the elevations were transient, with improvement in the creatinine levels during continued administration of the drug. In most patients, renal function returns to normal after discontinuation of the drug. Most importantly, one must adjust dosing intervals in the face of decreased GFR.

Risk factors for renal toxicity include high peak concentrations after rapid intravenous administration, dehydration (or conditions in which urine flow is diminished), coadministration of other nephrotoxic drugs and preexisting renal disease (51). Therefore, consideration of the individual's renal function, adequate hydration, and slow infusion rates (over a minimum of 1 h) should lower the risk for renal toxicity.

Ganciclovir is excreted entirely by glomerular filtration, with 99% of the dose appearing in the urine (8). In addition, plasma clearance is highly correlated with creatinine clearance and is approximately twice that of creatinine clearance, which indicates significant elimination by proximal tubular secretion. Ganciclovir is seldom associated with renal insufficiency or damage except in the setting of impaired GFR and concomitant administration of nephrotoxic agents.

Foscarnet

Foscarnet is an antiviral agent with promising results against herpes viruses. Foscarnet is a pyrophosphate analogue that interferes with viral replication by binding to a site on the herpes virus DNA polymerase or human immunodeficiency virus (HIV) reverse transcriptase (52, 53). Foscarnet is used to treat CMV infection alone or in combination with ganciclovir, usually in the setting of CMV prophylaxis, CMV retinitis, or disease after bonemarrow transplantation or in immunodeficient states.

Foscarnet appears to be excreted primarily by glomerular filtration, with little contribution by tubular secretion (52, 53). Foscarnet causes reversible decreases in GFR in 20–60% of patients. Two mechanisms for renal damage have been reported: tubular necrosis and crystallization within glomerular capillaries resulting in crescentic glomerulonephritis. Hydration at the time of administration is thought to reduce the incidence of acute renal failure considerably.

Functional renal tubular effects of foscarnet include hypophosphatemia, hypokalemia, renal tubular acidosis, and vasopressin-resistant diabetes insipidus (54). Alterations in mineral metabolism associated with foscarnet therapy include hyperphosphatemia, hypocalcemia, and transient increases in parathyroid hormone level (55). Explanation of these alterations is difficult because animal studies demonstrated inhibition of proximal tubular reabsorption of phosphate and would have predicted hypophosphatemia. One group of investigators postulated that direct binding of foscarnet with ionized calcium is responsible for the acute hypocalcemia and that reducing the dosage may allow continued therapy.

In a series of bone marrow transplant recipients, increased creatinine levels occurred in 17 of 19 patients, with four requiring hemodialysis (56). Hypocalcemia was reported in 16 and hypophosphatemia in 17. When 26 courses of foscarnet were given to patients with HIV infection, two patients experienced a creatinine level higher than 3.0 mg/dL, six had hyperphosphatemia, three had hypophosphatemia, three had hypocalcemia, and two had hypokalemia (57). Acute renal failure associated with foscarnet also has been reported (58). Hydration with saline may reduce the risk of nephrotoxicity. An increase in the serum creatinine level (defined as more than 25% above baseline) occurred in 66% of nonhydrated adults but only 13% of hydrated adults. Even those with abnormal pretreatment GFR tolerated foscarnet therapy if the drug was given along with hydration (59). Twenty-five percent of pediatric allogeneic stem cell recipients given prophylaxis against CMV required discontinuation of foscarnet due to renal dysfunction or electrolyte imbalance (60).

Cidofovir

Cidofovir, a nucleoside analogue of cytosine, is an antiviral agent with activity against herpes viruses and the BK virus (polyoma virus). The drug is filtered in its parent state without significant biotransformation. In addition, cidofovir interacts with OAT1 at the basolateral

membrane of the proximal tubular cell and exits the luminal membrane via OAT 4 or the MRP4. (28) It causes increased creatinine concentration and proteinuria by direct proximal tubular toxicity characterized by proximal tubular necrosis. Although the precise mechanism of renal damage is not known, one theory proposed that cidofovir may interfere with synthesis or degradation of membrane phospholipids (61). Cidofovir (as well as adefovir) uses the basolateral organic anion transporter for tubular secretory elimination. Renal toxicity of cidofovir is dependent on its uptake into the proximal tubular cells via this organic acid exchanger (61).

Administration of saline and probenecid are thought to reduce renal toxicity. Renal damage is occasionally irreversible (62). In the days before the administration of protective treatment, acute renal insufficiency was reported in one-third of patients.

Tenofovir

Tenofovir is an acyclic nucleoside phosphonate used for treatment of HIV. The compound is administered as a prodrug, tenofovir disoproxil fumarate (TDF). Tenofovir is excreted by glomerular filtration and tubular secretion. In the proximal tubule, tenofovir enters the basolateral cell membrane via the organic anion transporter, OAT-1, and is secreted into the proximal tubular lumen by the multidrug resistance protein (MRP-2) (63).

Tenofovir has been associated with nephrotoxicity in the form of reduced GFR with or without tubular toxicity (63). Occasionally Fanconi syndrome has been reported. Administration of other potentially nephrotoxic medications with TDF increases the risk for renal toxicity; this is likely related to changes in GFR which are followed by delayed renal clearance. In addition, the choice of other antiretroviral therapy appears to affect the degree of renal toxicity attributed to tenofovir. Regimens that include ritonavir in combination with TDF are accompanied by a greater decrement and a greater rate of decline in GFR (based upon estimated creatinine clearance). Those HIV patient receiving TDF in combination with ritonavir were 3.7 times more likely to experience a significant decline in GFR (>15%) as compared to those not receiving the drug (64). Reduced renal clearance of tenofovir is postulated as the mechanism for the increased risk for renal toxicity with the combination of drugs. Furthermore, there is evidence that polymorphisms in the apical transport system used by tenofovir may affect the susceptibility to nephrotoxicity (65). Ritonavir inhibits the multidrug-resistant transporter and may allow increased accumulation of tenofovir within the proximal tubular cell, thus accounting for the reduced renal clearance and site of toxicity (64).

Indinavir

The antiretroviral protease inhibitor indinavir is associated with renal toxicity in the form of acute renal failure, crystalluria leading to urinary colic, dysuria or/and nephrolithiasis and chronic renal dysfunction (63, 66). Indinavir is metabolized primarily by the liver through the P-450 system and approximately 20% of the drug is excreted unchanged in the urine (66). Drugs which inhibit the hepatic metabolic pathway or the presence of chronic liver disease result in increased plasma drug levels. The increased filtered load of drug in addition to factors such as urinary flow rate, GFR and urine pH (solubility decreases with increasing urine pH) may predispose to crystallization of indinavir in the urine. (66) Urinary crystals were identified in 20% of adults receiving the drug in a prospective study; the crystals were described as flat rectangular plates that may be found in fan-shaped or starburst aggregates (67). Chemical analysis confirmed that the crystals were composed of indinavir. Acute changes in serum creatinine have been observed in 13–26% of individuals taking indinavir (68–70). Crystalluria-related urologic symptoms, including loin pain, dysuria and nephrolithiasis (known as the indinavir-associated renal complication, or IRC) were identified in 7.3% of adults receiving the drug which translates into 6.7 events per 100 person years of indinavir exposure (70). Children appear to have a greater risk for IRC with a reported incidence of 29% as compared to an overall incidence rate of 19% among adults (71). Risk factors indentified for acute renal damage and IRC are longer duration of treatment, concomitant use of acyclovir, trimethoprim/sulfamethoxazole, lower body mass index, and presence of chronic hepatitis (68, 70, 72). Often a potential precipitating event was identified such as increased fluid loss or decreased oral intake (70). A third clinical syndrome associated with indinavir is that of a slow, asymptomatic rise in the serum creatinine (72). Urinary findings include low grade proteinuria, and leukocyturia/eosinophilluria (72, 73). When performed, the renal biopsy shows interstitial inflammation with fibrosis, and in some cases deposition of crystals within the renal parenchyma surrounded by an inflammatory infiltrate. Improvement in renal function was observed in most cases after continuation of the drug. (72) Recommendations for prevention of renal damage include liberal intake

of oral fluids, recognition of drugs and/or concomitant liver disease which may impair metabolism, and surveillance for chronic leukocyturia which may indicate chronic renal interstitial inflammation. Individuals taking indinavir who present with urinary complaints should be hydrated while imaging is undertaken to evaluate for nephrolithiasis. As indinavir stones are radiolucent, they will not be identified by routine radiographic studies (63).

Calcineurin Inhibitors

Cyclosporine and tacrolimus, the most widely used calcineurin inhibitors (CNI) are immunosuppressive agents used in posttransplantation combination therapy, treatment of nephrotic syndrome and autoimmune disease through their action to selectively target IL-2 dependent T-cell proliferation (74). However, the major dose limiting side effect is nephrotoxicity. Since cyclosporine has been in use longer than tacrolimus, there are many studies in animal models aimed at elucidating potential mechanisms for its nephrotoxicity. However, one may assume that the mechanism for toxicity is common to both agents (75). Both inhibit the enzymatic activity of calcineurin, a vital enzyme linking cytokine signaling in T cells to nuclear transcription factors such as the nuclear factor of activated T cells. Cyclosporine may also alter the transcription of other genes such as nitric oxide synthetase, transforming growth factor β, endothelin-1, and collagen proteins.

Acute toxicity associated with CNI is characterized by dose-dependent and reversible reduction in glomerular filtration rate and afferent arteriolar constriction (75). In addition, hypertrophy of the juxtaglomerular apparatus and increased renin production are found in kidneys exposed to CNI. Several mechanisms have been implicated in the hemodynamic alterations observed with CNI. These include activation of the renin-angiotensin system, activation of the sympathetic nervous system, increased release of endothelin-1, a potent vasoconstrictor, perturbation of the prostaglandin synthetic pathways favoring elaboration of vasoconstrictor species, and impaired generation of nitric oxide (74, 76). The summary of all of these potential mechanisms is renal vascular constriction. Studies using animal models of cyclosporine toxicity have found that inhibition of the above pathways will at least partially reverse the physiologic effects on the renal vasculature.

The chronic nephrotoxicity of CNI is characterized by progressive loss of renal function which is not dose-dependent, nor reversible. On biopsy, tubulointerstitial fibrosis, and arteriolar changes may be seen (77). In a meta-analysis of patients with autoimmune disease whose treatment regimens did or did not include cyclosporine, a risk difference of 21% was attributed to cyclosporine use (78). Furthermore, the risk for chronic renal insufficiency increases over time; this is the result of progressive renal arteriolar hyalinosis and tubulointerstitial fibrosis (76). The mechanisms underlying the chronic nephrotoxicity include angiotensin, transforming growth factor β, vascular endothelial growth factor and other compounds generated by infiltrating macrophages/mononuclear cells (77).

Tubular cell toxicity also accompanies the renal toxicity. Hyperkalemia, hyperuricemia and hypomagnesemia are common electrolyte disturbances associated with CNI use. In addition, CNI are associated with thrombotic microangiopathy, or a hemolytic-uremic syndrome-like picture characterized by extensive thrombosis of the renal microcirculation (77, 79). Endothelial injury is the primary event; however, the mechanisms have not been elucidated. One case report found decreased activity of the von Willebrand factor-cleaving metalloprotease ADAMTS13 in a renal allograft recipient; interestingly, the activity increased after cessation of cyclosporine (80).

Numerous potential drug interactions may occur with CNI. Because they are metabolized by the cytochrome P-450 system; concomitant administration of compounds that stimulate the hepatic cytochrome P-450 system can result in increased plasma clearance, whereas those that inhibit cytochrome P-450 increase cyclosporine plasma levels and potentiate toxicity (81).

Radiocontrast Agents

Radiographic contrast agents are freely filtered at the glomerulus and are excreted primarily by the kidney. Some concentration of the drug may occur within the renal tubular cell, but most of a bolus of contrast material is excreted directly and rapidly into the urine (17).

The incidence of nephrotoxicity after administration of radiocontrast agents is difficult to assess accurately because of differences in the definition of contrast nephropathy and the populations included in the clinical studies. Studies of adults indicate that between 1 and 20% of the general population may be at risk for acute renal failure after radiocontrast administration, with a somewhat higher incidence among hospitalized or critically ill patients (82). Risk factors for nephrotoxicity include preexisting renal insufficiency, diabetes mellitus, multiple myeloma, dehydration, and hyperuricemia (82).

Preexisting renal dysfunction is associated with a much greater risk of acute renal failure. Of patients who have renal insufficiency after radiocontrast administration, 50–75% had preexisting renal dysfunction, defined as a serum creatinine level of 2–3 mg/dL (17).

Nephrotoxicity may be mild, with minimal clinical symptoms. Most cases are manifested as nonoliguric acute renal dysfunction, although renal injury may be more severe with typical oliguric renal failure. The peak rise in the serum creatinine level usually occurs 3–5 days after contrast administration, with return to baseline by 10–14 days. If nephrotoxicity is severe, pronounced oliguria may be evident within 24 h of the injection (17). Pathologic changes are localized to the proximal tubular cell in the form of pronounced vacuolization, termed *osmotic nephrosis* (17). This form of acute tubular toxicity is characterized by a low fractional excretion of sodium.

Mechanisms responsible for the development of radiocontrast-induced renal dysfunction are not entirely understood. Several factors may interact to induce injury: tubular obstruction, direct tubular toxicity, and ischemia (82, 83). Contrast agents induce the precipitation of intratubular proteins such as the myeloma proteins and urinary mucoproteins (Tamm-Horsfall protein), which potentially leads to tubular obstruction by casts (84). Although this theory often has been proposed as a mechanism for renal toxicity after contrast agent administration, studies have failed to support a significant role of cast formation and secondary tubular obstruction in the development of contrast nephropathy (85). Of note, contrast agents are uricosuric and lead to urate crystal formation within renal tubular lumens, especially if urine flow or pH is reduced (86).

In support of a direct tubular toxicity, pathologic changes after radiocontrast administration include vacuolization of the proximal tubules, interstitial edema and inflammation, and tubular cell necrosis (82). Many studies demonstrate increased urinary excretion of enzymes and tubular proteins after administration of contrast agents. This is indicative of nonspecific renal tubular damage. Exposure of isolated proximal tubule segments to diatrizoate-containing contrast media resulted in cellular injury, and this effect was potentiated by hypoxia and addition of meglumine, a cationic compound often combined with diatrizoate (82). In addition, selected studies suggest altered renal tubular cell function secondary to the inhibition of tubular cell metabolism (17, 87). Both organic acid transport and sodium transport are reduced in experimental forms of contrast nephropathy. A direct tubulotoxic effect was found when renal tubular cells in culture were incubated in various concentrations of contrast agent (87).

The renal hemodynamic response to intravenous radiocontrast administration is transient vasodilation (increased renal blood flow) followed by vasoconstriction and a decrease in the renal blood flow and GFR (82, 88). The vasoconstriction occurs within minutes after injection of contrast agents and lasts for 10–20 min. This biphasic response in blood flow appears to be unique to the renal vasculature. The diminished filtration rate observed after administration of contrast agents cannot be mediated entirely by hypoperfusion because GFR remains decreased even after normalization of renal blood flow. Vasoconstriction is mediated by increased lipid peroxidation from the increased production and local release of oxygen free radicals and adenosine, a potent vasoconstrictor (82, 88). If there is a role for the renin-angiotensin system, it has not been consistently demonstrated. Reduced renal production of prostacyclin is associated with contrast-induced injury (88). Additional vasoconstrictive forces may involve endothelin, because plasma and urinary levels of endothelin are increased after administration of high-osmolar contrast media. Contrast agents may induce structural and functional alterations in the erythrocyte, which results in hyperviscosity with sludging in small blood vessels and hypoxemia (89). This phenomenon could explain the preferential distribution of ischemia to the medulla.

Prevention of contrast nephropathy requires identification of potential risk factors. These include dehydration, NSAID use, diabetes, and conditions associated with decreased effective plasma volume, such as congestive heart failure, nephrosis, or cirrhosis, in which renal perfusion may already be compromised (82, 83). Hydration has been said to be completely effective in prevention of injury. Administration of furosemide did not appear to offer protection. Mannitol administration was protective in nondiabetic patients but may have potentiated injury in diabetic patients (82). Likewise, dopamine afforded some renal protection in nondiabetic patients, yet offered no benefit in diabetic patients (82). *N*-acetyl cysteine given by intravenous and/or oral route has become a popular method for prevention of contrast-associated nephrotoxicity in adults. Unfortunately, its use remains controversial due to conflicting findings of the available randomized trials, insufficient number of study participants and heterogenetity of study design (90).

Recommendations from one consensus panel include (1) evaluation of all patients for risk factors, (2) optimization of intravascular volume status prior to contrast administration, (3) use of low osmolality contrast in all patients, (4) discontinuation of all drugs that may adversely alter renal function for at least 24 h prior to

contrast, (5) pharmacologic prophylaxis for high risk patients with the caveat that only therapies supported by clinical evidence should be used, (6) measurement of serum creatinine within 24–72 h after contrast exposure (91).

Cancer Chemotherapeutic Agents

Ifosfamide

Ifosfamide is a cancer chemotherapeutic agent with impressive activity against a wide variety of solid tumors in children, including neuroblastoma, osteosarcoma, rhabdomyosarcoma, soft tissue sarcomas, testicular tumors, and Wilms' tumor (92). Ifosfamide is a structural isomer of cyclophosphamide. The tumoricidal action of these compounds is related to the alkylation and cross-linking of DNA to inhibit cell replication. Although both ifosfamide and cyclophosphamide are associated with hemorrhagic cystitis as well as myelosuppression, alopecia, and gastrointestinal symptoms, ifosfamide is associated with significant renal toxicity, which is not observed after administration of cyclophosphamide.

Ifosfamide may induce tubular wasting of glucose, amino acids, protein, and phosphate as well as decreased GFR (92, 93). Although there is a great deal of interpatient variability in the pattern of ifosfamide-induced renal toxicity, in general ifosfamide toxicity is initially manifest as subclinical tubular damage with increased urinary excretion of brushborder enzymes from cell membrane loss, and a transient increase in urinary excretion of amino acids, phosphate, glucose, and protein. A progressive increase in renal tubular toxicity was observed after the initial three or four courses of ifosfamide treatment, with return to normal in between courses (93). Subsequent courses were characterized by failure to return to pretreatment levels between courses, with fixed tubular functional changes. In addition, glomerular damage and decreased GFR (presumably secondary to chronic tubular damage and fibrosis) were observed in five of seven patients at the end of therapy (92). Although less commonly observed, distal tubular dysfunction may occur after ifosfamide administration. Skinner reported a concentrating defect in 50% of the patients in his series, and hypokalemia occurred in patients reported by Husband et al. (94). In some patients evidence that ifosfamide has significantly affected renal function is a delay in the clearance of drugs such as methotrexate. Tubulopathy may become persistent, often in association with impaired glomerular function. One should be reminded that, even in patients with obvious renal toxicity, the plasma creatinine level is often within normal limits because it is an insensitive marker of glomerular function in these patients. In general, patients do not manifest reductions in GFR in the absence of established tubular injury.

Not only are there acute effects of ifosfamide administration, but a subset of patients experience continued renal dysfunction, manifest as tubular wasting syndromes, or reduced GFR. The incidence of chronic renal failure secondary to ifosfamide therapy is reported to be 1–4% (93). Another late complication of ifosfamide administration is the occurrence of rickets caused by chronic hypophosphatemia (95–97). Of 12 children on whom Skinner reported, eight had what was considered to be significant renal damage, six had reduced GFR, four had hypophosphatemia, five had glycosuria, 10 had generalized aminoaciduria, and three had radiographic evidence of rickets (97).

The incidence of ifosfamide-associated renal injury is highly variable, depending on the cumulative dosage, rapidity of administration, previous or concomitant administration of platinums or other nephrotoxic drugs or radiation, presence of a unilateral kidney, and age. Ifosfamide nephrotoxicity seems to be dose dependent and is more likely to occur in younger children or those who have undergone nephrectomy (92, 95, 98). Previous or sequential administration of other nephrotoxic agents increases the likelihood that renal toxicity will be observed with ifosfamide treatment. Most notably, patients who have previously been treated with cisplatin are at a greater risk for ifosfamide nephrotoxicity (98, 99). Carboplatin administration also increases the risk of tubular toxicity after ifosfamide therapy (100). This phenomenon is interesting, because the major site of injury after the platinums is the late proximal and collecting duct, whereas that after ifosfamide appears to be the early proximal tubule.

The clinical pattern of renal injury is one of initially transient, reversible tubular wasting of glucose, potassium, bicarbonate, phosphate, and amino acids as well as low-molecular-weight proteins such as β2-microglobulin. With early toxicity, tubular function tends to return nearly to baseline at the time of the next course. A few long-term follow-up studies have been published. These suggest that the renal defect in many of these children is chronic and may be progressive in nature. This is in contrast with results of long-term follow-up of cisplatin injury, in which GFR may improve over time although tubular defects may persist.

Numerous studies have looked at the incidence and pattern of renal injury associated with ifosfamide. Findings are highly variable, and partly this reflects the

aggressiveness with which the studies of renal tubular and glomerular function were performed. If serum creatinine or creatinine clearance is used to assess the presence of decreased GFR, the incidence of glomerular dysfunction is underestimated, as evidenced by the study of Ashraf et al., who found that 7 of 20 patients had abnormal GFR values as assessed by chromium ethylenediaminetetra-acetic acid (Cr-EDTA) clearance, yet none of these had elevated plasma creatinine levels compared to age-related controls (101). In addition, a subset of children demonstrated increased fractional excretion of phosphate, yet fewer had overt hypophosphatemia.

The activation of ifosfamide to its tumoricidal metabolites, 4-hydroxyifosfamide (4-OH-IF) and aldoifosfamide, occurs in the liver, with further metabolism to either isophosphoramide or carboxyifosfamide. The parent drug and its metabolites are excreted in the urine (102). When attempts are made to contrast the metabolites of cyclophosphamide and ifosfamide to incriminate the nephrotoxic species, ifosfamide metabolism is found to produce significantly greater quantities of chloracetaldehyde than cyclophosphamide. Because this compound has been noted to be toxic to cells and is found in high concentration in both the urine and plasma, it may play a role in the renal toxicity after ifosfamide therapy.

The mechanism of the renal tubular injury secondary to ifosfamide administration is unknown. Studies in which cultured proximal tubular cells are incubated in the parent drug or metabolites have been performed (103). The parent drug, ifosfamide, did not have an effect on amino acid or glucose transport, but the metabolite 4-OH-IF clearly inhibited transport of both substrates after 24 h in 100 μmol/L. Another potentially active metabolite, chloracetaldehyde, stimulated uptake at low concentrations (<200 μmol/L) and shorter incubations but inhibited uptake at higher concentrations and longer exposure times. In low concentrations, 4-OH-IF stimulated phosphate transport, but transport was decreased at higher dosages (100 μmol/L). At even higher concentrations (300–400 μmol/L), Na^+–K^+-adenosine triphosphatase (Na^+–K^+-ATPase) activity was inhibited. Chloracetaldehyde (at concentrations greater than 175 μmol/L), reduced phosphate transport and the activity of the mitochondrial enzyme succinate cytochrome *c* oxidoreductase.

The bladder toxicity of the oxazaphosphorine compounds results primarily from the metabolite acrolein, although 4-OH-IF has also been implicated (92). Mesna, sodium-2 mercaptoethane sulfonate, has been used to reduce ifosfamide- and cyclophosphamide-related bladder toxicity without alteration of tumoricidal effects. Mesna binds to acrolein, chloracetaldehyde, and 4-OH-IF (104). Unfortunately, mesna does not seem to offer protection against tubular toxicity, although its failure to do so has been postulated to be related to the availability of mesna at the site of tubular injury (105). Mesna is oxidized to dimesna, which has no protective action. Dimesna can be converted back to mesna by renal tubular cells, but at the dosages currently used in clinical practice, free mesna levels may not be adequate or may be highly variable and thus inadequate for tubular protection.

Platinum Compounds

Cisplatin (*cis*-diaminedichloroplatinum II) is an inorganic platinum compound that may induce both acute and chronic renal toxicity with magnesium, sodium, and potassium wasting as well as decreased GFR (106). The drug contains a platinum atom surrounded by two chloride atoms and two ammonia molecules in the *cis* position. Carboplatin (*cis*-diammine-1, 1-cyclobutane-dicarboxylato) platinum (II) has been introduced as a less nephrotoxic form of platinum, although it is now known that this compound also may cause renal injury. Cisplatin and carboplatin may undergo aquation with substitution of the chloride ions with hydroxyl groups, a reaction favored by low chloride concentrations such as are found in the cell, to form positively charged complexes that are likely to be the active form of the drug. Platinum compounds are excreted by the kidney via glomerular filtration. Platinum is concentrated in the renal cortex, with levels higher than in plasma, and appears to be accumulated via some transport process. Data suggest that elimination of the drug is delayed in the setting of a decreased GFR.

Proximal tubular cells are believed to accumulate platinum compounds by an energy-requiring mechanism or possibly by the organic base transport system (106). Differences in uptake of the platinum compounds might be related to stereospecificity or relative solubility and reactivity. Shortly after intravenous injection of cisplatin into rats, accumulation can be observed in the juxtamedullary region and outer stripe. This pattern is consistent with localization within the S3 portion of the proximal convoluted tubule, which is thought to be particularly susceptible to platinum. Acute changes in renal function occur after cisplatin administration, and these appear to be hemodynamically mediated, with reduced renal blood flow as well as tubular injury. Histologically, platinum-induced renal toxicity is characterized by tubular dilation, cytoplasmic vacuolization, nuclear pyknosis, and hydropic degeneration of cells in the corticomedullary region or S3 segment of the proximal tubule.

In a series of 22 children receiving cisplatin, 18 demonstrated GFR of less than 80 mL/min/1.73 m^2 as assessed by Cr-EDTA clearance (107). There was a mean decrease in GFR of 8% per course, but a great deal of individual variability was seen. In addition, the authors noted that neither plasma creatinine nor creatinine clearance was reliable in screening patients with significant reductions in GFR.

Long-term outcome for children who received cisplatin as part of their anticancer chemotherapy was studied by Brock et al. (108). Of 40 children available for study at the completion of therapy, 16 had a GFR above 80 mL/min/1.73 m^2, 13 had a GFR of 60–80 mL/min/1.73 m^2, and 11 had a GFR below 60 mL/min/1.73 m^2. Clearance measurements were repeated a mean of 2 years and 6 months from the end of therapy. A statistically significant improvement in GFR was found. Children with a GFR between 60 and 80 mL/min/1.73 m^2 at the end of treatment had a better chance of regaining a normal GFR; however, all of the 11 children with a GFR below 60 mL/min/1.73 m^2 improved, and three had normal GFR at last follow-up. Hypomagnesemia was found in 6 of 21 children at last follow-up.

The mechanism of platinum-related renal injury is controversial. It has been suggested that cisplatin is a direct tubular toxin and must be present in the tubular lumen at a minimum concentration of 1 mmol/L or 200 mg/mL (106). Several cellular perturbations have been identified in renal proximal tubular cells. These include inactivation of Na^+–K^+-ATPase, impaired mitochondrial function, altered gluconeogenesis, impaired substrate transport, lipid peroxidation, oxidation of sulfhydryl groups, and inhibition of nucleic acid and protein synthesis (109). The nephrotoxicity of cisplatin, transplatin, and carboplatin was examined in two continuous proximal tubular cell lines: primary cultures of rabbit cortical cells and OK cells (a continuous proximal tubular cell line). OK cells were spared from injury, probably because of decreased cellular uptake of the compounds. The rabbit proximal cells exhibited reduced viability at concentrations of cisplatin approximating 100 fmol/L, similar to peak levels in cancer patients. Toxicity was related to intracellular levels of platinum (109).

Isolated S3 segments of proximal tubules from rats given either transplatin or cisplatin were examined for alterations in oxygen consumption and respiration. No consistent abnormalities were detected, which makes mitochondria unlikely candidates for early nephrotoxicity (106). Other studies noted changes in mitochondrial function. Cisplatin also increased the oxidation of mitochondrial sulfhydryl groups, depleting GSH and leading to perturbations in mitochondrial calcium uptake and membrane potential (110). Antioxidants did not prevent the associated nephrotoxicity, which indicates that platinum probably exerts its effect by interacting directly with thiol groups rather than by inducing lipid peroxidation. Unfortunately, the concentrations of cisplatin used were considerably higher than would be expected from *in vivo* dosing. DNA synthesis was significantly inhibited by small concentrations of cisplatin, whereas greater concentrations of the other compounds were required. Cisplatin in the concentration range of 30–100 mmol/L induced a decrease in the activity of Na^+–K^+-ATPase as well as glucose uptake; the effect on glucose transport is probably secondary to a reduction in Na^+–K^+-ATPase activity because the sodium gradient would be decreased. Other experiments have shown that cisplatin may decrease glucose as well as phosphate transport. Similar findings were observed with carboplatin, but concentrations 20 times higher were necessary to induce the same alterations in cell functions (109).

Many favor inhibition of DNA synthesis as the primary biochemical effect. Cisplatin damages DNA by inducing interstrand and intrastrand cross-links and preventing normal replication. The amount of platinum cross-linkage correlates with toxicity as well as mutagenicity (106). Intrastrand cross-links are not found with transplatin, which is a much less toxic form of this class of agent.

Polyuria is a common finding after cisplatin administration and appears in two phases: urine osmolality falls over the first 24–48 h after administration, and the second phase of increased urine volume and decreased osmolality occurs between 72 and 96 h and is accompanied by decreased GFR as well (106). During the early phase, blood vasopressin levels are low and the kidney may concentrate urine in response to large doses of vasopressin. The latter phase of polyuria is thought to be secondary to the dilution of the medullary urea gradient, possibly related to abnormal urea recycling in the loop of Henle. In a model of chronic cisplatin nephrotoxicity, rats received three doses over 3 weeks. Polyuria, increased urinary sodium excretion, and decreased GFR along with decreased urinary cyclic adenosine monophosphate (cAMP) excretion were observed in the cisplatin-treated animals (106). Production of cAMP by inner medullary collecting duct cells was decreased after vasopressin stimulation in cisplatin-treated rats. Forskolin, a direct activator of adenyl cyclase, induced similar cAMP production in treated and control rats. In contrast, cAMP production after administration of sodium fluorescein, an agent that stimulates cAMP production via the guanine nucleotide

regulatory protein, was significantly lower in cisplatin-treated animals than in controls. These results led the investigators to conclude that the polyuria associated with cisplatin is caused by an abnormality in signal transduction at the level of the G-protein component of the vasopressin receptor (111).

Hypomagnesemia is another common manifestation of cisplatin-induced renal toxicity and commonly persists long after therapy ceases (112). Rats receiving intraperitoneal cisplatin (2.5 mg/kg) for 3 weeks developed hypomagnesemia by the second week, which persisted to the eighth week after therapy (113). Urinary excretion of magnesium was inappropriately elevated. In addition, gut absorption of magnesium was decreased. Calcium and magnesium transport by the superficial proximal and distal tubules appeared to be unaffected when measured at 7 weeks, even though urinary excretion was elevated. Bone and muscle magnesium levels were significantly reduced at the end of the eighth week, which suggests depletion of mineral stores. Cisplatin increases distal tubular sodium conductance. Infusion of cisplatin into rat distal tubular segments caused an attenuation of the normally negative luminal charge generated by active sodium reabsorption in this segment (104). The effect of cisplatin on the luminal charge was reversed by addition of amiloride, a diuretic that blocks sodium channels. The authors conclude that cisplatin may interact with distal tubular Na^+ channels to increase potassium and magnesium excretion and that this is attenuated by coadministration of amiloride (114).

Therapeutic intervention to reduce renal toxicity associated with cisplatin has been aimed at reduced production and enhanced excretion of highly reactive metabolites (114, 115). Infusion of mannitol and saline is the clinical intervention most commonly used to reduce cisplatin nephrotoxicity. In addition to providing optimal hydration before, during, and after administration, the coadministration of saline may reduce the spontaneous aquation reaction. In addition, these maneuvers may enhance excretion of the drug and minimize the period of contact between the renal tubule and toxin. The compound sodium thiosulfate reverses cisplatin-induced DNA cross-links and has been reported to reduce cisplatin injury in animals and humans (116, 117). Amifostine is a thiol prodrug which is converted to its active form by nontumor cells; it scavenges freeradicals and protects cell membranes and DNA from damage. It has been approved by the FDA for use with cisplatin to prevent cumulative toxicity (118).

Another potential method for minimizing renal toxicity is to avoid increasing the exposure to renal toxins by detecting reduced GFR early and by taking the GFR into account in dosing. Dosing of carboplatin based on the patient's GFR has been practiced by many centers and may potentially prevent toxicity by allowing dosage modifications in patients who have experienced otherwise undetectable reductions in GFR.

The combination of ifosfamide and cisplatin potentiates renal injury (119). One study compared glomerular function (unfortunately, creatinine clearance was used as the measure) and tubular function after either low-dose ifosfamide or a combination of ifosfamide and cisplatin and then high-dose cisplatin. Tubular functions such as amino acid excretion and albuminuria were comparable for the high-dose ifosfamide and combination groups, but phosphate wasting was more pronounced in the combination group (119). Despite delivering a much lower cumulative ifosfamide dose, combination therapy resulted in lower phosphate reabsorption in significantly more patients and a trend toward more frequent occurrence of tubular dysfunction. The aminoglycoside gentamicin did not appear to contribute significantly to observed renal toxicity. Of the 14 children with overt renal tubular wasting syndrome, eight had received combination therapy. Experience with combination therapy reveals that acute toxicity from ifosfamide is higher when carboplatin is administered within the same week than when a period of months elapses between these toxic therapies (100).

In conclusion, renal dysfunction as a result of drug administration may be manifest as a reduction of GFR or tubular dysfunction, most commonly of the proximal tubule. In most cases, this form of renal injury is reversible. Occasionally, there may be long-term renal dysfunction, as in the case of amphotericin B, cisplatin, and ifosfamide. The clinician must be aware of the potential for renal toxicity and must be prepared to make adjustments in the dosage or discontinue the offending agent. Anticipation of potential renal toxicity allows for maneuvers that may prevent renal damage and subsequent functional changes. Drug-induced renal dysfunction provides a model for acute renal failure and provides insight into renal injury in the general sense, which gives hope that in the future it will be possible to prevent injury or enhance recovery.

Methotrexate

Methotrexate (MTX) is a folic acid antagonist that is used in the treatment of approximately 60% of all malignancies in children, including acute lymphoblastic

leukemia (ALL), non-Hodgkins lymphoma, osteosarcoma, and several malignant brain tumors (120). High-dose MTX (HDMTX), in which doses in the range of 1,000–33,000 mg/m^2 are used in combination with leucovorin, is associated with acute renal dysfunction in 0–12.4% of patients, for an overall incidence rate of 1.8% (121). MTX-induced renal dysfunction results in delayed elimination of the drug and its metabolites. Prolonged exposure to even relatively low levels of MTX markedly increases liver, gut, bone marrow and mucus membrane toxicities (122). There is evidence to support a role for the organic anion transporters 1 and 3 in the renal elimination of MTX. Furthermore, coadministration of agents that also interact with this transport system (such as NSAIDs or probenecid) results in delayed MTX clearance (3). Renal clearance of MTX accounts for 90% of its plasma elimination; urinary flow rate and urinary pH affect renal MTX clearance. Thus, aggressive hydration and urinary alkalinization are routine clinical measures employed to optimize MTX elimination. The mechanism for MTX nephrotoxicity is postulated to be precipitation of the drug and metabolites within the renal tubular lumen, although direct tubular toxicity may also be involved. Most studies assess acute changes in renal function associated with MTX by measurement of plasma creatinine with various definitions of renal dysfunction. However, a single center study of children who were given HDMTX for ALL noted a significant decline in GFR as measured by inulin clearance over the 3 days after administration of HDMTX (120). Mean GFR returned to baseline by 7 days posttreatment. Only 2 of the 58 patients had clinical evidence of renal dysfunction, with a doubling of their baseline serum creatinine levels. MTX-related nephrotoxicity appears to be entirely reversible, with a median time to recovery of renal function of 16 days (range 4–48 days) (121). Furthermore, subsequent doses of HDMTX have been successfully given to patients who previously experienced renal dysfunction without recurrence of acute renal failure. When acute renal failure occurs in the setting of HDMTX administration, removal of the remaining drug becomes an additional goal of therapy due to the potential for severe and possibly fatal toxicity. Dialytic methods including high flux hemodialysis may remove plasma MTX, however, a marked rebound in plasma MTX concentrations occurs with cessation of dialysis (122). Administration of carboxypeptidase-G2 metabolizes circulating MTX to the inactive metabolite 2, 4-diamino-N10-methylpteroic acid (DAMPA), which uses a nonrenal path of elimination, allowing for a >98% reduction in plasma MTX levels within 15 min of administration (122). There is a paucity of information regarding the long-term renal sequelae associated with MTX administration or in those individuals who experienced acute renal failure associated with HDMTX.

Bevacizumab

Bevacizumab is a humanized monoclonal antibody directed against vascular endothelial growth factor (VEGF) which has been added to chemotherapy against breast, colon, lung and renal cancers. Its use in the pediatric cancer patient is in the treatment of solid tumors such as osteosarcoma, neuroblastoma and some brain tumors. Its utility in such regimens is as an inhibitor of angiogenesis. Administration of bevacizumab is associated with proteinuria and hypertension (123). Unlike the vast majority of nephrotoxic agents discussed in this chapter, in which the major site of injury is the renal tubule, VEGF inhibitors primarily affect the integrity and function of the glomerulus. A review of all randomized clinical trials that used either bevacizumab in combination with standard chemotherapy or standard chemotherapy alone was conducted to ascertain the risk of the renal side effects of proteinuria and hypertension (123). Proteinuria occurred in 21–63%, but heavy proteinuria occurred in 1.0–1.8%. Overall the relative risk for developing proteinuria with treatment regimens which include bevacizumab was 40% (RR 1.4, CI 1.1, 1.7) higher as compared to control. This risk was higher among those who were given high-dose bevacizumab with a relative risk of 2.2 (CI 1.6, 2.9). The incidence of hypertension was 2.7–36%. Severe hypertension developed in 8.7% and 16% with relative risk of 3.0, and 7.5 of those on low dose and high dose bevacizumab, respectively, compared to those not given the anti-VEGF drug. Interestingly, a case series reported features of thrombotic microangiopathy in renal biopsies from patients who developed renal toxicity after bevacizumab administration (124). A mouse model developed to simulate the therapeutic effects of anti-VEGF by targeted podocyte VEGF ablation revealed that loss of VEGF production by the glomerular podocyte was accompanied by histopathologic changes characteristic of thrombotic microangiopathy (124). The animals developed hypertension which was preceded by the development of proteinuria and glomerular disease. The production of VEGF is necessary for normal maintenance and function of the endothelium; thus, inhibition of VEGF production by the glomerulus may result in endothelial damage and glomerular disease. Use of bevacizumab as an adjunctive therapy is in its early stages in childhood cancer, thus the risk for renal effects have not been reported in children.

Natural Nephrotoxins

Marine animals, reptiles, and insects produce a number of biologic nephrotoxins (111) (*Table 53-3*).

Many of these toxins result in acute renal failure either directly or indirectly. The main indirect mechanism of nephrotoxicity is biologictoxin-induced rhabdomyolysis (112). Although these natural nephrotoxins are uncommon causes of acute renal failure, they are of considerable interest.

Marine Animal Nephrotoxins

Fish poisons include at least three forms of biotoxins that result in ATN. First, there is an association between the ingestion of raw bile from the gall bladder of carp and acute renal failure. The belief that the raw bile of carp improves vision and rheumatism is found in Asia (125). Many of these Asian carp species have been introduced into the United States, and at least five species of carp have been implicated (126). All five carp species have ichthyogallotoxin in their bile, and this may represent the toxin. Alternatively, A C-27 bile alcohol, termed *cyprinol* and found in carp bile, is nephrotoxic in animals (127).

Table 53-3

Common biologic nephrotoxins produced by animals and plants

Snake
Phospholipase A_2
Myotoxins
Procoagulant activating factors V and X
Spider
Sphingomyelinase D *(Loxosceles)*
Neurotoxins *(Latrodectus)*
Bee
Melittin
Phospholipase A_2
Mast cell degranulating protein
Wasp
Antigen 5
Mastoparans
Carp
Ichhthyogallotoxin
Cyprinol

A second toxin as yet unidentified is responsible for Haff disease. Haff disease, characterized by acute rhabdomyolysis, can occur in humans and other animals that eat eels and burbot fish. Rhabdomyolysis can be found in subjects who ingest buffalo fish, a member of the carp family (128). These myotoxins or icthyosarcotoxins are unidentified.

A third agent is the palytoxin of the blue humphead parrotfish. Ingestion of this toxin can also result in cardiac muscle damage (129). Factors contributing to the pathogenesis of acute renal failure from rhabdomyolysis include the quality of myoglobin in nephrons, an acidic, highly concentrated urine, and delayed recognition of the disease.

Envenomation-Induced Acute Renal Failure

Snake Venoms

Four families of venomous snake are responsible for 40,000 deaths/year, and 5–30% of subjects bitten by these snakes develop acute renal failure. Two families are responsible for most deaths and cases of renal failure: (1) the cobras, African mambas, and coral snakes, and (2) the vipers, adders, moccasins, and rattlesnakes (130). Approximately 90% of venoms are proteins that are proteolytic enzymes, phospholipases, and hyaluronidases. Other enzymes include ribonucleases, deoxyribonucleases, nucleotidases, and acidic and basic phosphatases. Procoagulants that activate the clotting cascade via factors V and X are also present. Myotoxins can also lead to rhabdomyolysis and myocardial damage, which reduce cardiac contractility, and pigment nephropathy.

Patients may show ATN, hypersensitivity reactions, extracapillary glomerulonephritis, AIN, and necrotizing arteritis of interlobular arteries on histologic studies (127, 131). Laboratory investigations show evidence of intravascular hemolysis, disseminated intravascular coagulation, and azotemia (132). A number of snakebites lead mainly to rhabdomyolysis, including those of the king brown snake, sea snakes, diamondback rattler, canebrake rattler, and several vipers (133).

Spider Venoms

Two groups of spiders produce venom responsible for acute renal failure: the recluse spiders and the widow spiders (133). The mechanism of toxicity of the venom of the 56 recluse species is the presence of sphingomyelinase D,

which leads to necrotic skin lesions, edema, erythema, chills, nausea, and myalgias (134). The main recluse spider in the United States is the brown recluse. These bites are generally more serious in young children.

The widow spiders excrete neurotoxins that produce cramping and muscle spasms. These toxins can lead to a neurogenic bladder with urinary obstruction. The venom of the black widow spider of the United States can also lead to rhabdomyolysis.

Bee and Wasp Venoms

Acute renal failure due to bee and wasp venoms requires massive numbers of stings, usually more than 100, which generally follows disturbance of a hive or nest (127). The toxins include melittin and other hemolysins, hyaluronidase, and others (*Table 53-3*). The toxins in wasps differ and consist of active amines, kinins, and antigen 5. The mechanisms of renal failure include hemolysis, rhabdomyolysis, direct toxic effects, and dehydration. The venom of the dark scorpion of the southwest United States may also cause rhabdomyolysis (133). Hypersensitivity reactions to bee and wasp venoms may also occur. The treatment of acute renal failure is symptomatic and dialysis may be required.

Chinese Herb Nephropathy

Chinese herb nephropathy, initially described in the early 1990s by Vanherweghem et al. in Belgium, is characterized by a tubulointerstitial disease (135). Proximal tubular dysfunction with a Fanconi syndrome or, more commonly, insidious chronic renal failure has been described (136). Aristolochic acids are the likely etiologic agent. Substitution of *Aristolochia fangchi* for *Stephania tetrandra*, herbs which differ in name in Chinese by only one character, is thought to have been the historical event leading to the increased incidence of this indolent renal disorder. These herbs were generally taken for the purpose of weight loss.

Aristolochic acids are naturally occurring compounds with carcinogenic and nephrotoxic effects. Although there is still debate as to whether they are solely responsible for all of the reported cases of Chinese herbal nephropathy (137), they have been shown to cause an interstitial nephropathy in the rabbit (138) but not the rat (139). Isolated case reports also describe proximal tubular dysfunction with hypokalemia, abnormal urinary excretion of low-molecular-weight proteins, and glycosuria as the presenting features in several adults (140–142).

Pathologic evidence of renal injury was demonstrated in the rabbit model. As with human pathologic changes, there was a distinct corticomedullary gradient of acellular interstitial fibrosis. Three patterns of injury were described: (1) restriction of fibrosis to the medullary ray (S3 segments), (2) extension to the outer cortical labyrinth (convoluted proximal tubules, S1 and S2 segments), and (3) extension to the inner cortical labyrinth and outer medulla (proximal tubules of deep nephrons) (138). The exact mechanism of aristolochic acid-induced injury is not known.

Renal function continues to deteriorate despite cessation of consumption of herbal remedies. Oral corticosteroid therapy may slow the progression of renal insufficiency. A group of 81 adults with Chinese herb nephropathy were subdivided according to pattern of renal failure (143). Thirty-nine demonstrated moderate renal failure with progression. Of these, 14 received oral prednisone initiated at 1 mg/kg for 1 month and then tapered to 0.15 mg/kg. The rate of increase in the serum creatinine level was less in the steroid-treated group.

Pediatric cases have not been reported.

Environmental Toxins

Organic Solvents: Ethylene Glycol, Diethylene Glycol, Propylene Glycol

Ethylene glycol is a major constituent of antifreeze and may be accidentally ingested because it has a sweet taste. It is metabolized initially by alcohol dehydrogenase to glycoaldehyde and eventually to oxalate. Intermediate metabolites include glycolic acid and glyoxylic acid, which contribute to the associated metabolic acidosis. A change in the ratio of the unreduced form of nicotinamide adenine dinucleotide to the reduced form favors the accumulation of lactic acid. Central nervous system symptoms and cardiovascular instability precede the onset of renal disease. Renal toxicity takes two forms: crystallization of oxalate within the renal tubules and direct tubular damage resulting in acute renal failure. Metabolic acidosis with elevated anion gap and altered mental status should prompt the consideration of this poisoning. Examination of the urine sediment early in the course may reveal either needle-shaped calcium oxalate monohydrate crystals or octahedral calcium oxalate dihydrate crystals. An elevated plasma osmolar gap may also be an indirect clue. Treatment is aimed at clearance of the toxic metabolites and may include hemodialysis in the case of renal failure or severe metabolic acidosis.

Diethylene glycol has been responsible for accidental poisoning associated with acute renal failure in the form of medication contamination. Recently, an outbreak of renal failure in Haiti resulted after two acetaminophen preparations were inadvertently contaminated with diethylene glycol during manufacture using contaminated glycerin (144). The mechanism of renal toxicity is thought to be proximal tubular damage and necrosis. Other organ systems, including the liver, pancreas, and brain, are often severely injured and contribute to the overall mortality of this accidental poisoning.

Propylene glycol (PG) may be responsible for ATN. The renal failure is usually the result of intravenous administration of medication solubilized in PG (144). Parenteral medications that contain PG include diazepam, digoxin, esmolol, hydralazine, nitroglycerin, pentobarbital, phenobarbital, phenytoin, and sulfamethoxazole/trimethoprim. Vitamin preparations may also contain PG. Clinical manifestations are similar to those of ethylene glycol toxicity, including metabolic acidosis with increased anion gap. A potential mechanism for toxicity has been postulated to be the inhibition of proximal tubular transport processes and membrane disruption (145).

Heavy Metals (Excluding Platinum)

Lead, mercury, gold, bismuth, and copper are uncommon but serious causes of nephrotoxicity. They have common mechanisms of renal tubular toxicity, and chronic exposure may lead to presentation with an acute syndrome or dysfunction. The primary site of injury is the proximal renal tubule, where heavy metals cause impaired mitochondrial function and secondary alterations in membrane integrity. Exposure to mercury and lead is generally accidental due to environmental contamination and is much less common now than several decades ago. The reader is referred to previously published comprehensive reviews of heavy metal renal toxicity (146, 147).

Urinary Tract Disorders

54 Urinary Tract Infections

Albert Bensman · Olivier Dunand · Tim Ulinski

Introduction

Urinary tract infection (UTI) is defined by the presence of bacteria in bladder urine. The term "urinary tract infection" lacks precision. Once the diagnosis of UTI is made, it is important to classify the location and severity of tissue invasion. This determination has major implications for therapy and attendant morbidity (and in rare cases, mortality).

Acute pyelonephritis is an infection which involves the bacterial invasion of renal parenchyma. Acute cystitis is an infection limited to superficial invasion of the bladder. The term "asymptomatic bacteriuria" refers to the presence of infected urine which produces no clinical symptoms. In most instances, asymptomatic bacteriuria is diagnosed when urine cultures are obtained as part of a routine checkup; or obtained in "at risk" children to prevent the development of serious infection...

UTIs are relatively common in infants and young children. The risk before puberty is 3–5% in girls and 1–2% in boys (1, 2). In young febrile infants aged less than 24 months the prevalence is 3–5%. Prevalence is different depending on age and gender. Four subgroups of patients can be identified: males younger than 1 year (3%), males older than 1 year (2%), females younger than 1 year (7%) and females older than 1 year (8%) (3). Data from Ginsburg (4) and Wiswell (5, 6) show a strong risk reduction among circumcised males: the prevalence of UTI among febrile male circumcised infants is 0.2%.

In children, UTIs may serve as an important marker of structural or functional urinary tract abnormalities. Although the most common abnormality heralded by UTIs is vesico ureteral reflux; UTIs may be the first symptom of obstructive uropathy or bladder dysfunction.

Major morbidity, in terms of renal scarring, is the most significant sequelae of recurrent pyelonephritis. Extensive work from Jodal et al. (7) has demonstrated a significantly increased risk of renal scarring is with repeated episodes of pyelonephritis.

Diagnosis and Therapy of Childhood UTIs

There are four main steps in the clinical management of UTIs in childhood:

- Diagnosis of UTI
- Determination of the site of the infection
- Search for the cause of the UTI
- Treatment

Diagnosis of UTI

The definitive diagnosis of UTI is critical and involves a number of important considerations. False positive diagnosis may lead to unnecessary treatment, as well as invasive and expensive clinical and radiographic examinations. False-positive diagnoses are frequent in infants and small children because reliable collection of urine specimens without contamination is difficult. On the other hand, false negative diagnosis dramatically increases the risks of renal scarring and its attendant morbidity: hypertension, complications of pregnancy in women, and end-stage renal disease.

Methods to Obtain Urine Specimens

The gold standard for obtaining urine in an infant is by suprapubic aspiration. By using this method the risk of contamination is very low. Complications are rare with the use of ultrasound guidance. Further, experienced pediatricians have a low complication rate with aspiration following clinical palpation of the bladder (8). Urinary catheterization is also a very reliable method for obtaining urine without contamination, particularly in female infants. In some centers physicians and the nurses are reluctant to use this technique for fear of negative psychological effects or causing pain. No actual data support

© Springer-Verlag Berlin Heidelberg 2009

such concerns. Clean-catch mid-stream urine specimens can be collected in toilet-trained children. Ramage et al. (9) pointed out the accuracy of clean-catch urine (C.C.U.) collection in infancy. Using this simple technique, these authors demonstrated strong correlation with urine obtained by supra-pubic aspiration. Most would concur with standard use of the C.C.U. technique. The huge advantage of this method is that it is readily performed in private pediatric offices. The collection of urine in "collection bags" adhesively attached to the the perineal area *has no role in the diagnosis of childhood UTIs*. The high contamination rate, with "false positive" rates as high as 86% (10) may lead to unnecessary hospitalizations, and/or inappropriate clinical and radiological testing. This conclusion, has recently been endorsed by a subcommittee of the American Academy of Pediatrics (3). A new technique suitable for office use, "the midstream urinary collector," may be a valuable non-invasive method of obtaining children's urine for culture. With this apparatus, a bag collects urine except for the very last portion (which is free of contaminants from the urethra) and is caught in a test tube. The test tube is separated from the collector, sealed with a lid and sent to the laboratory (11). Additional large scale studies are awaited regarding the ultimate value of this interesting approach.

Urine Culture

It is very important to prevent the growth of contaminating bacteria. In order to achieve this goal, the urine should be maintained at 4°C, until it arrives at the bacteriologic laboratory (12). The standard culturing technique involves streaking on blood agar and MacConkey media. A simple dipslide culture system (suitable for office or outpatient clinic use) has approximately the same sensitivity. The studies of dipslide culture report sensitivities between 87 and 100% and specificities of approximately 92% (3). It is important to recognize that some uncommon bacteria do not grow on all media but require specially enriched culture media.

Bacteria that Cause UTI in Childhood

In the pediatric age group, 60–80% of the UTI are caused by uropathogenic E. coli (13, 14). The other common bacteria are Proteus, Klebsiella, Staphylococcus saprophyticus, Enterococcus, and Enterobacter (15, 16). Uncommon in uncomplicated infections, but reported with increased frequency with anatomical defects, following surgical manipulation of the genitourinary system, and following repeated courses of standard antimicrobials are Pseudomonas, Group B streptococcus, Staphyloccoccus aureus and epidermidis. Urinary tract infections caused by Haemophilus influenzae and parainfluenzae in children were studied recently by Hanson et al. (17). Over a 24 year period, only 36 children were identified. But the inability of this bacteria to grow on standard media suggests that the true frequency of these strains as a cause of UTI may be underestimated. These bacteria require blood agar or other rich culture media to grow, and are most commonly found in association with serious structural urinary tract abnormalities.

Interpretation of Urine Culture

Interpretation of culture results depends on the method of urine collection, and at times, the clinical setting. The Kass criteria are still used for midstream voided specimens (18): the cutoff level is 100,000 CFU/ml. By supra pubic aspiration, any growth is considered significant. In catheterized specimens, the cutoff level suggested by Hoberman et al. is 50,000 CFU/ml (19). Most of the time there is only one bacterial strain. The confluent growth of colonies of different types strongly indicates contamination.

Pyuria is usually present in children with UTI (80–90% of episodes of symptomatic UTI). A urine sample without pyuria does not exclude symptomatic UTI. Microscopy for leucocytes is variably sensitive (32–100%) and specific (45–97%) (3).

Urinalysis for Immediate Diagnostic Information

The various components include the reagent slide tests: nitrite, leucocytes (LE), protein and blood. Reagent strips (dipstick) simplify identification of these components. The LE test has a high sensitivity which ranges from 67 to 94% (3) but much lower specificity. The test for nitrite has a much higher specificity (90–100%) (3) but a lower sensitivity (16–82%). Nitrite testing may be useful for diagnosing a UTI when it is positive but it has less value when it is negative. Dipstick testing for blood or protein have poor sensitivity and specificity in the diagnosis of UTI. The microscopic examination of urine for bacteria is effective in diagnosis with experienced personnel (3, 20).

Localization of the UTI

The differentiation between upper (pyelonephritis) and lower (cystitis) UTI is very important. It particularly has major clinical implications in young children. The risk of renal scarring is significant with pyelonephritis, and not a concern with cystitis. Therefore the management (investigations, antibiotic used, length of therapy) is totally different for pyelonephritis and cystitis. The location of the site of infection is based on a combination of clinical, laboratory and imaging findings.

Clinical Signs

The main symptom of pyelonephritis is high fever. According to the American Academy of Pediatrics, UTI should be considered in any infant aged less than 2 years with unexplained fever (3, 21). This UTI should be managed as a pyelonephritis. Older children may complain of back or flank pain, chills. Renal tenderness may be found in these children. In cases of pyelonephritis, the clinical findings may include varied gastrointestinal symptoms: diarrhea, vomiting, and nausea which may confound the diagnosis of UTI. In addition, neurological symptoms such as irritability, and seizures (particularly with high fever) may exist. Acute focal bacterial nephritis is a severe form of pyelonephritis. It is an interstitial bacterial nephritis formely known as lobar nephronia. It is most often described in adults with diabetes but recent articles have described this condition in children (22). Signs described include flank pain, fever, and rapid deterioration into a "septic" picture (23).

In case of bacterial cystitis, there is rarely fever $>38°C$. Common findings include low grade abdominal pain and bladder/voiding symptoms such as frequency, pain with micturition, suprapublic discomfort, difficulty in voiding (retention) or hesitancy, urgency, and enuresis.

Specific Clinical Signs of UTIs in Neonates and Infants

The symptoms are nonspecific and require a high degree of clinical suspicion. They include fever, poor feeding, failure to thrive, abdominal pain, haematuria, and malodorous urine. Jaundice may be an early diagnostic sign of UTI in infancy. Garcia et al. (24) has shown that UTIs were found in 7.5% of asymptomatic, afebrile jaundiced infants younger than 8 weeks old. Infants with the onset of jaundice after 8 days of age were more likely to have a UTI in this study. The presence of UTI should be considered in all infants and young children 2 months to 2 years of age with unexplained fever (21). All UTIs in this age group (particularly with high fever) should be considered as pyelonephritis until proven otherwise.

Biological Tests

Most of these tests are not very specific. Winberg (25) described decreased renal concentrating capacity in pyelonephritis. A number tests were described in adults which differentiated the level of UTIs. Many studied the immune response, which reportedly was different according to the site of UTIs. Specific antibodies to the infecting bacteria were higher in cases of pyelonephritis (26, 27). This was confirmed in experimental models (28). The detection of antibody-coated bacteria in urine using fluorescein-labeled antiimmunoglobulin (29) was reported as diagnostic of pyelonephritis in adolescents and young adults. However, it was unreliable in children (30), presumably because there is a delay of several days before antibody is produced in younger age groups. An elevated erythrocyte sedimentation rate, a positive C-reactive protein, and an elevated peripheral WBC count with an increased absolute neutrophil counts have all been reported as are non-specific indicators of upper tract infection.

In children younger than 2 years of age Garin et al. (31) showed that patients with pyelonephritis had statistically higher white blood cell count (WBC), erythrocyte sedimentation rate (ESR) C-reactive protein (CRP) than those with cystitis. Although the sensitivity of the test was 80–100%, their specificity was $< 28\%$. In the NICE Clinical Guideline 54 (32), it was concluded that C-reactive protein alone should not be used to differentiate acute pyelonephritis from cystitis in infants and children. Recently a high procalcitonin concentration was described as a validated predictor of acute pyelonephritis in febrile UTI (33) (confirmed by early renal scintigraphy) and for late renal scars (34, 35). Such interesting findings await large scale confirmatory studies, particularly in infants and young children.

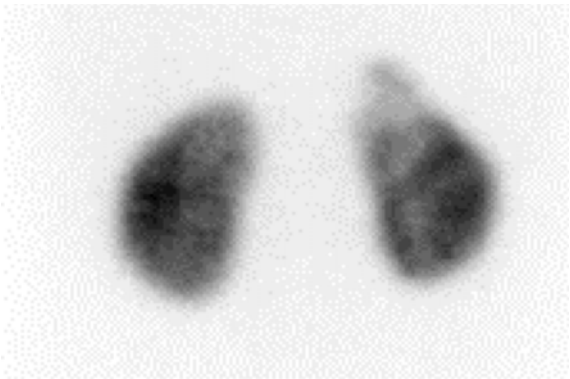
Imaging Tests in Localizing the Site of Infection

Renal cortical scintigraphy (with 99 m Tc-DMSA or 99 m Tc-glucoheptonate) is widely accepted for the diagnosis of pyelonephritis in all pediatric age groups. However, with this technique it is difficult to

distinguish between new, acute inflammatory changes and previously established renal scars. A meta analysis of animal studies of acute pyelonephritis showed an overall sensitivity of 86% and specificity of 91% (36) As seen in *Fig. 54-1* renal cortical scintigraphy shows decreased uptake of radiotracer in lesions of pyelonephritis (37). Despite a large body of published literature, the role of radionuclide renal scans in the clinical management of the child with UTI still is unclear (3). Most of the time such imaging has no role in the specific management of childhood UTIs. For that reason, the use of DMSA scintigraphy scanning is only recommended by the NICE clinical guidelines (32) in situations when it is clinically important to confirm or exclude acute pyelonephritis, and when the power Doppler ultrasound (see below) is not available or the diagnosis still cannot be confirmed.

Figure 54-1

Scintigraphy with 99 mTcDMSA. Decreased uptake of radionuclide in the upper pole of left kidney.



Renal Ultrasound

Most of the time, conventional renal ultrasound is insensitive for the diagnosis of pyelonephritis. Signs of pyelonephritis include focal or diffuse renal enlargement and abnormal cortical echogenicity mostly areas of increased echogenicity which may mimic a renal mass (*Fig. 54-2*). In case of hypoechoic area, it may presage a renal abscess in formation. D. Morin et al. described the abnormal sonogram renal changes (38) in children with acute pyelonephritis. Using a high frequency transducer they found abnormal sonogram changes in 87% of the cases including increased renal pelvis, focal hyper or hypoechogenicity, or diffuse hyperecogenicity. According to their experience, when performed by a trained radiologist this technic is nearly as sensitive as the DMSA scan in diagnosing renal involvement in children with unobstructed acute pyelonephritis.

Power Doppler ultrasound is more sensitive than a gray-scale ultrasound (*Fig. 54-3*).

Pyelonephritis is associated with renal ischemia. It is seen as a hypovascular zone in the renal cortex (39).

Computed Tomography

The features of pyelonephritis by CT have been well-described (40), and are shown in *Fig. 54-4*. After intravenous contrast, areas of infected renal parenchyma have decreased contrast enhancement due to the renal ischemia, whereas normal renal parenchyma becomes brighter. Despite its potential value, this technique many disadvantages including significant exposure to ionizing radiation, danger of reaction to intravenous iodinated contrast, and

Figure 54-2

Power Doppler ultrasound. Triangular area of cortical ischemia which is well correlated with the results of DMSA Scintigraphy (Pr J. J. Dacher).

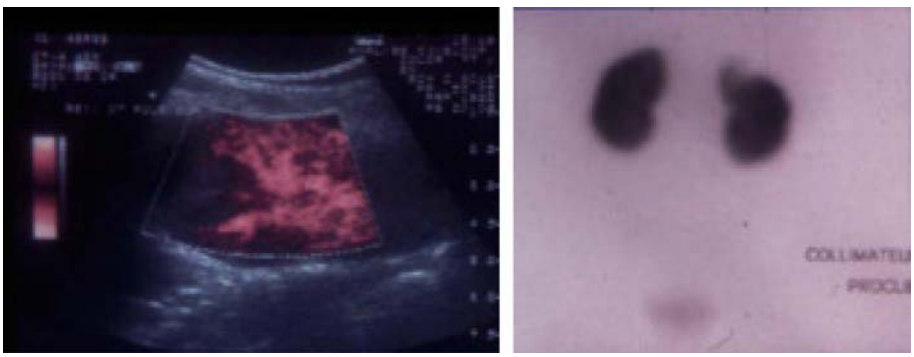


Figure 54-3
Renal ultrasound. Increased echogenicity in a triangular part of the renal parenchyma.

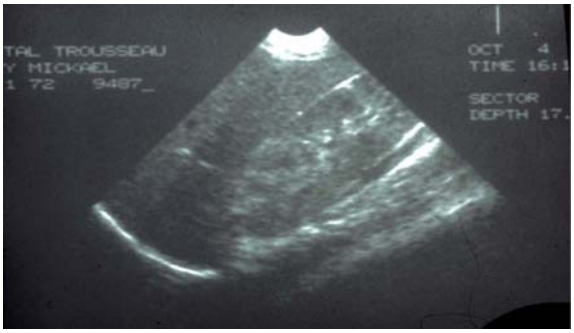

Figure 54-4
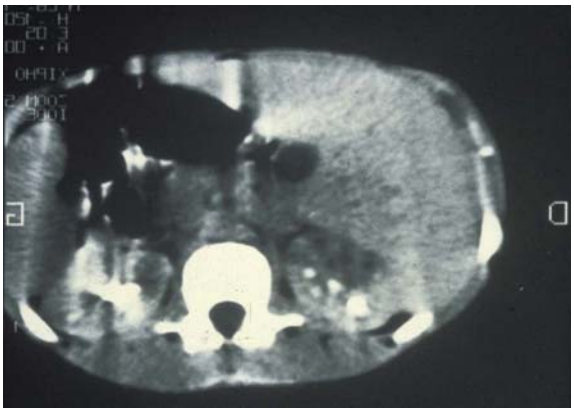
Computed tomography. Images of cortical ischemia: decreased contrast enhaucement in infected region, whereas normal renal parenchyma becomes brighter after intravenous contrast.



the need for deep sedation in younger children. For these reasons it is reserved for rare situations despite its ready availability and the wide- spread expertise of radiologists in its use.

Magnetic Resonance Imaging

MRI imaging is shown in *Fig. 54-5*. There is a darkening of normal renal parenchyma whereas lesions of pyelonephritis remain bright after intravenous gadolinium contrast (41). The main disadvantages of MRI are the cost and the need for sedation but the lack of ionizing radiation is appealing in the pediatric age group.

Figure 54-5
Magnetic resonance imaging. After IV gadolinium contrast: the lesions of pyelonephritis remain bright and the normal renal parenchyma is dark.

Given the other imaging modalities described, the use of MRI in the diagnosis of pyelonephritis is not necessary. A major disadvantage is the danger of IV gadolinium injection in case of renal insufficiency (42), which has caused strict restriction and in some areas, removal from routine clinical use.

Asymptomatic Bacteriuria (ABU) – Localization of the Infection

In some cases, growth of 100,000 colony forming units is found in freshly voided-urines, but the child is symptom-free (43). Neither symptoms of lower tract infections (dysuria, urgency or frequency) nor symptoms of upper tract infections (fever, shaking, chills and flank pain) are present. In this condition, bacteriuria may be due external contamination leading to a false-positive result. Therefore the diagnosis of ABU requires repeated samples which all demonstrate significant growth of the same organism in a child who has not been ill for at last 2 weeks (44).

There are several lines of evidence that indicate why children with ABU are symptom free and at little risk for clinical problems. The bacteria tend to be of low virulence and do not have significany ability to damage the kidney even if they were to reach the upper tracts (45). ABU is not a significant risk factor for renal scarring. The Escherichia coli isolated from children with ABU are different from those causing symptomatic infections.

In most instances, the organisms cannot be assigned to serogroups, they have an increased sensitivity to the bactericidal effect of serum, and they have poor intrinsic ability to adhere to epithelial surfaces.

The study of Ottolini et al. (46) concluded that ABU was not a significant risk factor for renal scarring in a group of 207 patients with neurogenic bladder treated with clean intermittent catheterization. In this group of patients, ABU was common, persisted for weeks, and was not treated. There was no deterioration of the upper urinary tracts in any patients. The same conclusions were drawn by Shekarriz et al. (47). They studied the morbidity associated with urodynamic evaluation in 69 pediatric patient with ABU. Most of these children had a neurogenic bladder. No patient developed symptomatic UTI. They concluded that routine use of urine cultures or prophylactic antibiotics before urodynamic studies in pediatric patients with a neurogenic bladder is not indicated in the presence of ABU.

Search for the Cause of UTI

The main cause of UTI is the ascending route of the bacteria from the periuretral area. The bacteria originate in the bowel. In boys, the prepuce plays an important role as a reservoir. Several data (5, 6) show a dramatic risk reduction of UTI among circumcised males. There are many published studies that demonstrate that pyelonephritis may be the first indication of an underlying pathological condition such as urinary tract obstruction, nephrolithiasis, vesico-ureteral reflux (VUR), bladder dyssynergy, or incomplete bladder emptying from any cause (48).

The investigation starts with a complete history and physical examination. Recognition of spinal deformaties, history or physical signs of constipation, and/or abnormal bowel or bladder function may suggest a dysfunctional voiding syndrome (49). It may be due to a neurogenic bladder. In most of the cases no underlying neuropathy can be found.

Bladder instability is the most common voiding dysfunction. It frequently is a cause or exacerbating factor in childhood UTIs. It may also be manifested by urge incontinence with and without enuresis, which leads to a characteristic "holding posture" such as squatting. Bladder instability may be due to chronic constipation (50). In this case its treatment may lead to the resolution of urinary incontinence and urinary tract infections.

The Hinman syndrome (51) and the Ochoa syndrome (52) are associated with severe bladder dysfunction and frequent UTIs with no underlying neuropathy.

Imaging Studies

Previous guidelines regarding the utilization of imaging studies in the investigation of childhood UTI recommended that all children undergo renal tract imaging after a first episode of confirmed UTI. The USA guidelines (1999) of the American Academy of Pediatrics (3, 21) recommended a renal ultrasonography and either a voiding cystourethrography (VCUG) or a radionuclide cystography (RNC) in infants and young children less that 2 years of age after a first UTI. The goal of such studies is to identify factors that predispose to recurrent UTI and that increase the risk of renal scarring at the earliest opportunity. More recent studies of Rosenberg (53) and Jodal (54) led to the conclusions that DMSA scintigraphy could replace VCUG. The latter could then be applied selectively, in cases when the DMSA scan or the ultrasound was abnormal. Most of the children with uptake defects on the acute DMSA scan had reflux with dilatation of the upper urinary tract. These guidelines remain open to ongoing discussion among pediatric nephrologists, urologists, and radiologists in many parts of the world. DMSA scintigraphy is very expensive, not often available and requires pediatric experience of diagnostic departments.

A more provocative concern regarding these imaging studies is their actual value in altering management or improving outcomes following a documented case of pyelonephritis in the pediatric population. In a systematic overview of the literature, Dick et al. (55) and Gordon et al. (56) determined that no extant studies provided clear evidence that routine imaging had any effects on the development of renal scars or on improving clinical outcomes in children with their first UTI. They concluded that current recommendations are not evidence-based. Additional studies confirm these findings (57–59).

There is a well-documented association between VUR, renal damage, and pyelonephritis. However, the belief that infection and VUR are the cause of upper tract parenchymal damage is undergoing critical review. There has been increasing knowledge that reflux nephropathy is not always acquired renal, but rather reflects reflux-associated damage related to congenital dysplastic kidneys (60). It may be considered part of the "congenital abnormality of the kidney and the urinary tract" (CAKUT) syndrome (61).

Prior to 2006 most pediatric societies recommended routine voiding cystourethrography for all children with a first febrile UTI. The likelihood of finding a VUR with such a strategy is quite low (20–40%) (62). Most of the VUR diagnosed is low grade. Two recent studies of children with low grade VUR have shown no significant differences in risk for UTI between antibiotic prophylaxis

and no treatment (63, 64). The fact that antibiotic prophylaxis is not necessary in cases of low grade VUR is likely going to affect current guidelines. Regarding the utilization of VCUG in the evaluation of all children with their first febrile UTI. Current practice guidelines focus on performing selected investigations in high-risk children. This group of children have an increased risk of having an abnormal urinary tract that warrants investigations. By targeting investigations to specific children, many unnecessary and invasive investigations will be avoided (65). This is in accordance with the guideline published in August 2007 by the National Institute of Health and Clinical Excellence (NICE) (32, 66) High risk children include:(1) those with an increase in procalcitonin (PCT), which has high sensitivity in identifying children with severe reflux (67); or (2) those with high fever who are younger than 6 months of age, recurrent UTI, clinical signs such as poor urinary stream or palpable kidneys, infection with atypical organisms, bacteriemia or septicemia, prolonged clinical course with failure to respond fully to antibiotic treatment within 48–72 h; unusual clinical presentations such as an older boy, or with a known abnormality on antenatal ultrasound screening of the urinary tract (32, 65, 68). Such high risk children should undergo ultrasonography and VCUG with their first episode of UTI (3, 57, 69). According to the Swedish state of the art conference in children over 2 years of age a DMSA scintigraphy (70) alone with ultrasonography were suggested as methods for identifying risk patients. A voiding cystourethrogram is performed only if the DMSA scintigraphy is abnormal. Therefore, the traditional recommendation to perform the VCUG at 3–6 weeks after the diagnosis of UTI should be reconsidered. Further the recommendation to perform a VCUG, when indicated, early in the course of infection should be reconsidered as the rate of detection of VUR does not increase in relation to the timing of the study (71, 72).

Other Causes of UTI

Malformations of the urinary tract, urolithiasis and bladder dysfuntions are not the only causes of UTI. After an episode of pyelonephritis, none of these causes are found in many children. The urinary tract epithelium plays an important role in UTI through coordination of the innate immune response to infection (73). Urinary tract epithelia express toll-like receptors (TLRs) with the capacity to recognize bacterial components. Engagement of TLRs can lead to activation of inflammatory mediator cascades. The resulting inflammatory infiltration serves to aid bacterial clearance. Dysfunction in this complex innate immune response may lead to recurrent UTI. Host resistance is not the only determinant. The virulence of the infecting strain is also a factor in pathogenesis (74). Specific virulence genes are the focus of ongoing studies. Virulence factors like fimbriae may modify the mucosal chemokine response. This modification may allow the host to adjust the inflammatory response to match the infecting strain (74, 75). There are other poorly understood factors which modify the susceptivility to renal scarring, including the renin-angiotensin system, the plaminogen activating inhibitor, TGFβ, and polymorphisms in collagen (76). Recent findings describe a novel hormonal regulation of innate immune cellular activation. Such studies demonstrate that deamino – 8 – D – arginine vasopressin (dDAVP) is a potent modulator of microbial-induced inflammation in the kidney (77).

Treatment

Treatment is based on the location of the UTI: cystitis and pyelonephritis require different treatment. Most of the time asymptomatic bacteriuria should not be treated with antibiotics. A child with a symptomatic UTI should be given antibiotics without delay. Before the beginning of the treatment a urine sample must be acquired to isolate the bacteria causing the UTI and to define any antimicrobial resistance. A delay in treatment has been identified as a major risk factor in renal scarring with pyelonephritis. Therefore, antibiotic should be initiated on an empiric basis and then modified according to the result of the culture.

Treatment of Acute Cystitis

Oral antibiotics for 3–5 days are recommended (32, 78, 79). The choice of antibiotics should be directed by established guidlines (*Table 54-1*). Cephalosporins should be

Table 54-1
Antibiotics for oral treatment of cystitis in children

Drug	Dose (mg/kg/day)
Trimethoprim-Sulfamethoxazole	30/6 BID
Nitrofurantoin	5 BID
Amoxicillin	25–40 TID
Amoxicillin-clavulanate	40 BID
Cephalosporin – Cefixime	8 BID

avoided if possible and reserved for the treatment of pyelonephritis, given the risk of development of antimicrobial resistance to these agents.

Treatment of Pyelonephritis

A recent Cochrane (80) review of antibiotic treatment for acute pyelonephritis in children identified 18 randomized trials. They compared initial (3–4 days) intravenous treatment followed by oral treatment with completely intravenous treatment (7–14 days). There were no significant differences in the risk of persistant renal damage. These studies suggest that long term parental treatment is not necessary. The recent French guidelines (79) recommend initial treatment with a parenteral antibiotic (2–4 days) followed by oral antibiotics A recent prospective randomized trial (80) confirmed that the incidence of renal scars was similar in patients who received 3 days of intravenous ceftriaxone (1) followed by oral antibiotics compared with treatment utilising 8 days of IV Ceftriaxone.

Hoberman (81), in a randomized controlled trial of 306 children, compared oral treatment (Cefixime) with parenteral treatment. They did not find any significant difference between the two groups in term of renal scarring at six months. The same conclusions were drawn by Montini et al. (82). This multicenter randomized controlled trial demonstrated that oral antibiotics (co-amoxiclav 50 mg/kg/day in three doses for 10 days) was effective as parenteral ceftriaxone (50 mg/kg/day in a single parenteral dose) for three days, followed by oral co-amoxiclav (50 mg/kg/day in three divided doses for 7 days). Despite this new data, caution should be exercised when using only oral antibiotics for the treatment of high-risk children with pyelonephritis (83). Most such children were excluded from the Hoberman and Montini trials noted above. The results of these studies should not be generalized and apply to all children without clear identification of high risk groups (as noted above) who require parenteral therapy to minimize renal scarring. Further, in many countries, antibiotic resistance may limit the empiric use of certain oral antibiotics (84).

The duration of treatment should range between 10 and 14 days according to several guidelines (3, 22, 32) and the review of randomized controlled trials (80, 85). In cases of severe pyelonephritis (acute lobar nephronia, effective treatment can prevent progression to renal abscess. A total of 3 weeks of intravenous and oral antibiotic therapy tailored to the pathogen noted in cultures should be the treatment of choice for pediatric patients with pyelonephritis (22, 23).

The choice of antibiotics should be based on knowledge of local antimicrobial resistance patterns. There is a correlation between pharmacokinetic/pharmacodynamic parameters (*Table 54-2*) and the efficacy of antibiotics in the treatment of UTI (86). A better understanding of these parameters, as well as the rapidly growing field of pharmacogenomics, may increase the efficacy of "individualized" treatments (87). The sensitivity of most urinary pathogens is close to 96% to both Gentamicin and Ceftriaxone. These factors should guide empirical treatment until culture results are known.

Table 54-2

Pharmacokinetic/Pharmacodynamic parameters of the antibiotics studies in acute pyelonephritis (79)

	Amoxillin	Amoxillin clavulanic	Cotrimoxazole	Cefixine	Gentamicin	Cefotaxime	Ceftriaxone	Ciprofloxacin
Dosage	33 mg/kg	33 mg/kg	15 mg/kg	4 mg/kg	3 mg/kg. day	33 mg/kg	50 mg/kg	15 mg/kg
	TID	TID	BID	BID	once a day	TID	once a day	BID
% of sensitive strains	50	70	80	95	97	99	99	98
MIC 50 (mg/l)	4	4	0.5	0.125	0.5	0.06	0.06	0.01
Serum concentration peak	12	10	50/2	2,5	12	30	190	4
Half life (h)	1	1	10	3.3	2	1	8	6
T < MIC (%)	20	20	100	100	100	100	100	100

Antibacterial Prophylaxis

Low-dose, long term prophylaxis has been traditionally used in patients prone to develop recurrent acute pyelonephritis or frequently recurrent lower tract infections. Such therapy has been particularly used in high risk children including those with vesico-ureteral reflux with dilatation of the upper urinary tract, obstructive uropathies, and other high risk conditions. The efficacy of antibacterial prophylaxis has been recently questioned. It is not necessary in case of low grade VUR (63, 64), and may increase the risk of antimicrobial resistance (88). The clinician must decide in any given case whether the risks of scarring justify the use of prophylactic therapy. In some instances, long-term low dose antimicrobial prophylaxis has markedly decreased the recurrence pattern (as well as clinic visits with associated parental/child anxiety) of children with frequent lower tract infections (*Tables 54-3*).

The International VUR Study of Children was specifically designed to study the comparative effectiveness of long term antimicrobial prophylaxis and surgical correction in children with high grades of VUR. Initial reports have described the outcome at 10 years of study (89–92). There was no difference between the two groups of children in terms of renal scarring and/or its complications. These results might lead to the conclusion that antibacterial prophylaxis is efficient in case of high grade reflux. The efficacy of circumcision in decreasing the incidence of UTI in male infants is clear. Data from several groups (4–6) show a dramatic risk reduction of UTI among circumcised males.

In general, there is global agreement that children with totally asymptomatic bacteriuria do not require antimicrobial therapy. Indeed, such therapy may increase antimicrobial resistance and is to be avoided. A child with asymptomatic bacteria is symptom -free because the bacteria tend to be of low virulence, and there is little or no risk of renal scarring.

Table 54-3

Antibiotics used for prophylaxis

Antibiotic	Recommended dosage (mg/kg/day)
Nitrofurantoin	1
Trimethoprim	0.5
Trimethoprim Sulfanamide	0.5 (of trimethoprim component)
Cefadroxil	3–5
Ciprofloxacin	1

Conclusion

Despite the recognition that underlying renal anomalies may be the cause of renal scarring previously attributed to infection, the prevention of renal scarring remains the goal of all therapies for childhood UTI. Although new data has questioned previous "dogmas" re: urinary tract imaging, parenteral therapy of pyelonephritis, and use of antimicrobial prophylaxis, the clinician must be vigilant in recognizing children at risk for complications from UTI. *Such high risk children (those under the age of 6 months with high fever, those with abnormal GU anatomy, and those with a septic presentation at any age) should be treated and investigated aggressively.* The recognition of antenatal urinary abnormalities, improved imaging strategies, better understanding of the molecular and cellular pathophysiology of renal scarring, and the development of new, pharmacogenomically-derived individualized antimicrobial treatment regimens offers the hope of reducing renal scarring and its complications.

55 Vesicoureteral Reflux and Renal Scarring

Tej K. Mattoo · Ranjiv Mathews

Introduction

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the kidneys. This retrograde flow of urine, while the norm in some animals, is not normal in humans. VUR may be an isolated abnormality (primary VUR) or it may occur in association with other congenital anomalies of the kidney and urinary tract (CAKUT), including renal dysplasia, and obstructive uropathy or neurogenic bladder (secondary VUR).

Most cases with VUR are diagnosed after urinary tract infection (UTI). The common belief has been that the presence of VUR increases the risk of UTI and the two together cause renal scarring (reflux nephropathy), which may lead to hypertension, toxemia of pregnancy, chronic renal insufficiency and even end-stage renal disease (ESRD). The traditional management has included a prompt treatment of UTI and long-term antimicrobial prophylaxis until the resolution of VUR. Surgical correction has been advocated in those with high grade VUR, recurrent UTI in spite of antimicrobial prophylaxis, or non-compliance with medical management. Over the years, many studies have debated if one treatment modality is superior to another in preventing renal injury, with most of the studies concluding that the long-term outcome with one intervention is no better than the other. However, the exact role of VUR in the development of renal injury has been difficult to elucidate. Recently, new data have been published regarding the heterogeneity of the secondary effects of reflux, and the role played by voiding dysfunction and/or constipation in the resolution of VUR or the frequency of UTI. In this chapter, we will provide an overview of the important issues concerning primary VUR. This will include: the embryology and anatomy of the ureterovesical junction; the current modalities for diagnosis and management; and a review of current controversies and emerging consensus concerning the role of primary VUR in the pathophysiology of renal scarring.

Prevalence of VUR

The exact incidence of VUR is not known because it is not feasible to do voiding cystourethrograms (VCUG) in a large cohort of healthy children. Its prevalence varies from 1.3% of healthy children (1) to 8–50% of children evaluated after UTI (2–4). In newborns and infants, the incidence of VUR diagnosed after UTI is 36–49% (5–7). Children with VUR detected after UTI are predominantly females (2, 3, 8, 9), though in some studies no gender difference (3, 10, 11) or even male predominance was reported (12). VUR is less common in African American children (13, 14). Only about one-third as many African American as white girls with UTI have VUR and no significant differences in age or mode of presentation exist between the two races (13, 15). The severity of VUR in African American children is less than that in Caucasian children (16).

Embryology and Anatomy

Primary VUR is a congenital anomaly of the structure of the vesicoureteral junction. This is felt to be secondary to a preexisting anatomic abnormality with shortening of the intravesical submucosal length of the ureter. The formation of the ureteral bud from the mesonephric duct signals the beginning of the development of the metanephric kidney – the final stage of renal development. The ureteral bud interacts with the mesenchyme to give rise to the metanephric kidney. As the mesonephric duct is gradually absorbed into the enlarging urogenital sinus (the precursor of the developing bladder) the location of the ureteral bud plays a role in the eventual location of the ureteral meatus within the bladder. If the ureteral bud reaches the urogenital sinus too early, due to the absorption pattern of the mesonephric duct, it is eventually located more laterally and proximally in the bladder.

© Springer-Verlag Berlin Heidelberg 2009

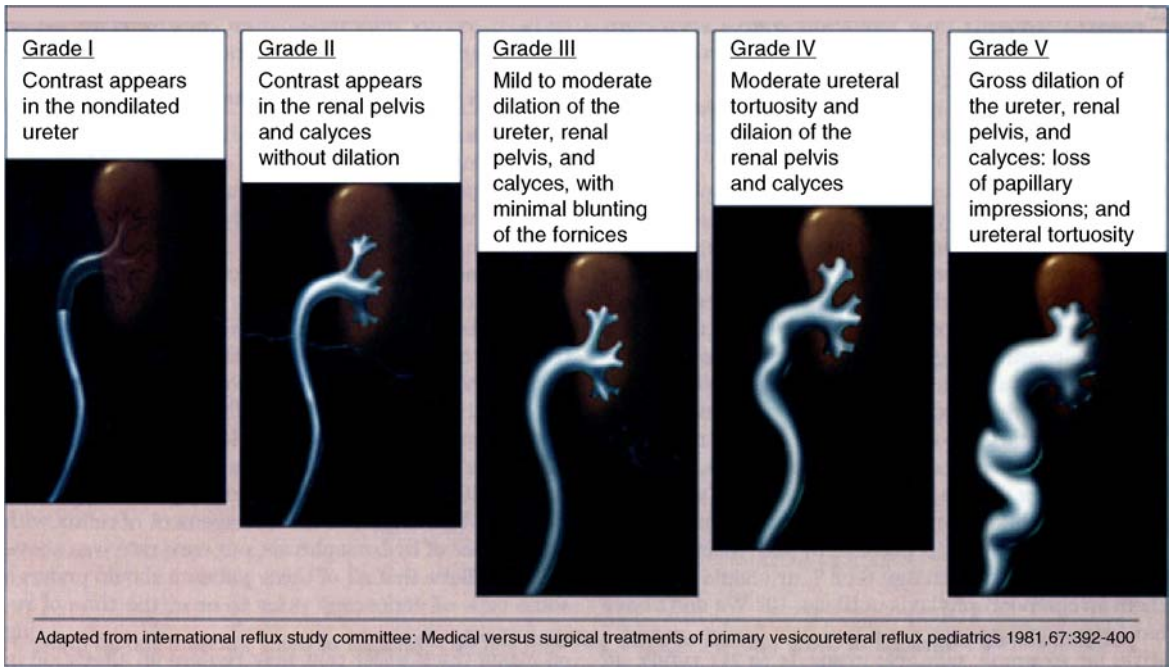
This location is associated with the development of reflux as there is reduction in the intravesical submucosal length of the ureter. Multiple genes have been noted to be involved in the development of VUR. PAX2 (necessary for ureteral budding in mice) and glial-derived neurotrophic factor (GDNF) have been shown to have an impact in the development of VUR in mice, however their role in human VUR remains controversial (17, 18). Comparison of the autonomic innervation and histology of the ureterovesical junction in mutant mice indicated that there was no difference between those associated with VUR as compared to controls (19).

The ureterovesical junction is designed to prevent free reflux of urine from the bladder to the kidney. The ureters pass into the bladder through the detrusor in an oblique path. The distal end of the ureter is located submucosally within the bladder. The length of the submucosal ureter has been noted to be a major component in the prevention of VUR. The muscles of the ureter extend into the trigone of the bladder and enmesh with the fibers from the opposite ureter. This intermingling of fibers allows a degree of fixation of the ureters into the trigone of the bladder. The distal submucosal segment is compressed against the muscular bladder wall with bladder filing acting as an additional mechanism to prevent reflux of urine. Finally, as urine is actively transported down the ureter in an antegrade manner, the tone of the ureter and the meatus in the bladder also work to prevent reflux.

Grading of VUR

Grading has been used in an effort to predict the outcomes of children with VUR. It has long been known that the VUR has the potential to resolve spontaneously, and grading has been used to standardize potential management strategies as well as to compare clinical outcomes. The system that has been most widely accepted classifies VUR into 5 grades based on the appearance of specific features of the voiding cystourethrogram (VCUG) (*Fig. 55-1*). This system was proposed by the International Reflux Study in children (IRSC) (20). Grade I is reflux into the ureter, grade II is reflux into the renal pelvis, without any dilation of the calyces, grade III is reflux to the renal pelvis with mild dilation of the renal pelvis, grade IV is reflux to the renal pelvis with greater dilation of the renal pelvis and papillary blunting. Grade V

Figure 55-1
International classification of vesicoureteral reflux.



reflux includes reflux to the renal pelvis with massive ureteral and pelvic dilation, including ureteric tortuosity. This system, although widely utilized, does have some shortcomings. The differences between grades III and IV are not always obvious. The degree of reflux may be modified by how aggressively the bladder is filled during the VCUG. Also, ureteral dilatation may be present without calyceal dilation leading to further difficulties with grading.

Radionuclide voiding cystourethrogram has also been used to diagnose and follow children with VUR. Unfortunately, exact grading into the five grades as noted above is difficult using radionuclide imaging. Using this modality, VUR can only be graded into mild, moderate and severe. Attempts have been made to correlate this grading system with the IRSC grading as mentioned above (21). Although, good correlation has been noted when combining the radiographic grades into two grades only, this method of evaluation has not been used to predict outcomes of VUR.

Clinical Presentation of Primary VUR

Patients with primary VUR most often present in one of three ways – following diagnostic evaluation of a UTI, during follow-up for antenatal hydronephrosis, and while screening a sibling of a patient with VUR. Some children may present with urinary symptoms only with no fever. Occasionally, an older child with undiagnosed reflux nephropathy may present with symptoms other than UTI, which are noted in *Table 55-1*.

Table 55-1
Presenting Clinical Symptoms of VUR and/or Renal Parenchymal Injury

1. Fever with or without urinary symptoms
2. Urinary symptoms without fever
3. Flank pain
4. Proteinuria
5. Nephrotic syndrome due to focal segmental glomerulosclerosis
6. Hypertension
7. Secondary enuresis due to coexisting voiding dysfunction or diminished urine concentrating ability
8. Renal stone, mostly due to *Proteus mirabilis* UTI
9. Renal failure, including end-stage renal disease

Reflux Identified following a Urinary Tract Infection

The most common clinical setting in which VUR is identified is during a radiographic evaluation following a UTI, particularly in a young child. In a large cohort of children with urinary tract infections, VUR was diagnosed in 46% of infants and 9% of preschool children (22). Patients may present following a febrile or symptomatic UTI. It has long been recognized that the presence of VUR may potentiate clinical symptoms of UTI in children (23). Current recommendations for evaluation of UTI include performance of ultrasonography and VCUG after the first UTI in both boys and girls. A search for other modifiable host factors e.g., voiding dysfunction, constipation – is crucial following documentation of a UTI. The identification of VUR can lead to an increased awareness and early identification and treatment of UTI. Following a diagnosed UTI, DMSA renal scanning has been suggested to determine if scarring is present. The majority of children identified following a documented UTI are girls, however when considering infants <6 months of age no gender difference is noted (24). Additionally, 65% of children diagnosed with VUR following a UTI were less than 7 years of age. Toilet trained children that are diagnosed with VUR following UTI have a 43% incidence of dysfunctional voiding (25) that can potentially lead to recurrent infections and compromise the resolution of VUR.

Reflux Identified Secondary to Antenatal Hydronephrosis

Diagnosis may be suspected in utero with unilateral or bilateral hydronephrosis and confirmed at birth with VCUG. When prenatal hydronephrosis has been noted, post natal evaluation with VCUG will demonstrate the presence of VUR in 10–30% of infants (26). There is a higher incidence of boys in the group of infants diagnosed with VUR following identification of antenatal hydronephrosis (27). Infant boys with VUR that are left uncircumcised have a significant incidence of UTI despite antibiotic prophylaxis (28). Studies have indicated that the natural history of VUR identified following antenatal evaluation of hydronephrosis indicates a high potential for spontaneous resolution (59% by age 4 years) even in those with grades IV – V reflux (29). Analysis of children with resolution of the VUR revealed that that there was higher incidence of resolution in boys with lower grades and unilateral reflux; infection rates were noted to be low in this cohort (30). Further study of this group of infants

revealed that the VUR was of lower grade in female infants and less likely to be associated with renal damage as compared to newborn boys (31). The higher grade of VUR in newborn boys was noted to be secondary to abnormal urodynamic patterns indicating higher bladder pressures associated with dyssynergia of the urethral sphincter which improves with time (32, 33).

Sibling Reflux

Initial studies by Jerkins and Noe (34) indicated that 32% of siblings of an index patient have VUR. Sirota et al. in 1986 studied a cohort of 16 families with VUR in 33 children. These children were noted to have a higher incidence of bilateral VUR than non-familial cases (35). In a study of asymptomatic siblings VUR was identified in 45% using radionuclide cystography (36). A follow-up study by Noe et al. indicated that 75% of children identified with VUR by sibling screening were asymptomatic, and there was a slightly higher incidence of VUR in female siblings of female index patients. The incidence of renal damage was much lower in the siblings diagnosed with VUR as compared to the index patient with VUR (37). Evaluation of children of parents with VUR revealed that 66% of the children had VUR indicating a significant parent to child transmission (38). With the identification of sibling/familial reflux, debate began about the benefit of screening of asymptomatic siblings of index patients (39, 40). Review of the natural history of VUR in siblings, indicated that 52% had resolution of the reflux at follow-up of 18 months, with yearly resolution rates of 28% indicating that most could be managed non-operatively (41). Children over age 7 were found to have less potential to have VUR when screened, although renal injury was noted irrespective of age (42).

UTI with progression of scar was noted in only 5% of siblings with VUR followed for 3–7 years and the vast majority of those with grades I & II VUR had resolution (43). The more "benign" course of sibling reflux compared to reflux identified following a UTI (44) has led many to suggest limitation of those being screened. Analysis of siblings presenting with renal injury indicated that reflux grade, history of UTI and age at diagnosis were the most significant factors (45). Interestingly, Houle et al. identified a higher incidence of scarring in those siblings evaluated after age 2 years than those identified prior to age 2 and therefore recommended early screening (46). Their findings were supported by a later report indicating that in siblings with lower grades of reflux, greater scars were noted when evaluation was performed after age 3 years (47). At this time, most would suggest screening younger siblings (<age 5 years) of index children with VUR and would reserve screening of older siblings to those who present with a UTI or other symptoms.

Voiding Dysfunction and Constipation in VUR

VUR may be associated with voiding dysfunction, which in some cases may present as dysfunctional elimination syndrome (DES). The symptoms of DES include daytime wetness, urgency, frequency, infrequency, constipation or fecal incontinence in "toilet trained" children with no underlying anatomic or neurological abnormality (25, 48, 49). The exact pathogenesis of voiding dysfunction or DES is not known. It seems to be an abnormally learned spectrum of voiding, which evolves from poorly learned voiding technique and attempts to suppress impending or active bladder contractions by inappropriately contracting the pelvic floor muscles and tightening external sphincter (49, 50). This results in increased voiding pressure and/or inefficient voiding (51, 52).

Voiding dysfunction predisposes to recurrent UTI, induces and perpetuates VUR, and may result in permanent renal damage (53, 54). In a study by Koff et al., DES, besides increasing the rate of breakthrough UTI, delayed resolution of reflux and adversely affected the results of ureteric reimplantation (25). In another study that involved use of a questionnaire in 310 children enrolled in the European branch of the International Reflux Study in Children, a strong negative correlation was seen between recurrences of UTI, as well as disappearance of VUR and nonneuropathic bladder/sphincter dysfunction (55).

Voiding dysfunction or DES is a diagnosis of exclusion that mandates a detailed history and physical examination to rule out any underlying neurological or neuromuscular etiology. The diagnosis is usually evident clinically, and urinalysis, bladder ultrasound, and VCUG in selected cases are helpful in making a diagnosis. The role of urodynamic studies is not well-established, partly because study results are inconsistent (49, 56, 57). The procedure is invasive and the study result does not change therapy or influence the final outcome. A thorough history and physical examination lead to the correct diagnosis and treatment in the majority of children (58).

Constipation, besides being a part of dysfunctional elimination syndrome, may be an isolated finding, which, by itself, increases the risk of recurrent UTI or voiding dysfunction in children with VUR. This is believed to result from compression of bladder and

bladder neck that increases bladder storage pressure and post-void residual urine volume. Also, distended colon and/or soiling provide an abundant reservoir of pathogens (59–61). Constipation in children increases the likelihood of urinary incontinence, bladder overactivity, dyscoordinated voiding, a large capacity and poorly emptying bladder, recurrent UTI, and deterioration of VUR (62). In a study that involved 366 children, constipation/encopresis was reported in 30% cases, day-time wetting in 89%, night-wetting in 79%, and recurrent UTI in 60% of the patients. VUR was present in 20% of the patients who underwent VCUG. A multidisciplinary management helped resolution of VUR in 53% of the patients after a mean follow-up period of 22 months (63).

Adults with VUR Diagnosed in Childhood

Studies in adults who were diagnosed with VUR in childhood revealed interesting results. In a study in 21 adults (mean age 23.9 years) with gross VUR diagnosed in infancy, proteinuria and renal insufficiency was diagnosed in 3(23%) of the 13 patients with unilateral reflux nephropathy and 2 (50%) of the 4 patients with bilateral reflux nephropathy (64). In another study of 127 adults (mean age 41 years) with VUR diagnosed during childhood, 44 (35%) had unilateral renal scarring, 30 (24%) had bilateral renal scarring, 30 (24%) had albuminuria, and 14 (11%) had hypertension. Of the 30 patients with bilateral renal scars, 25 (83%) had abnormal GFR (65).

Genetics of VUR

A genetic basis for VUR is supported by an increased incidence of VUR in children of affected parents as well as siblings of an affected child, a low incidence in African Americans, occurrence in some inherited syndromes, and a 100% concordance in identical twins and 50% concordance among dizygotic twins (35, 36, 66). In comparison to the general population, the first-degree relatives of individuals with VUR have a 30–50% increased risk of having VUR (37, 38). The inheritance is variable, with most cases demonstrating a dominant inheritance, which may be related to a single gene (67) or polygenic (68). Recessive (69) as well as X-linked inheritance has also been reported (66, 70).

Numerous studies have reported candidate regions/genes with VUR in association with other renal abnormalities and syndromes (71, 72). Renal-coloboma syndrome which is associated with VUR is caused by PAX2 mutations of chromosome 10q (73). VUR in some patients with CAKUT has been linked to mutations in ROBO2 gene (74). Weak linkage to the HLA locus has been reported (75). While targeted disruption of uroplakin III genes (an integral bladder protein) or angiotensin type II receptor genes in animals results in the phenotype of VUR, other studies in uroplakin III (76) and angiotensin II (77) have excluded linkage to these human loci. Similarly, while some studies suggested an increase in the D allele of the angiotensin converting enzyme (ACE) gene in patients with VUR (78), other studies have failed to support those findings (79).

In the first genome-wide search of VUR and reflux nephropathy, 7 European families with apparently dominant inheritance were studied. The study demonstrated linkage to chromosome 1p13 *(GATA176C01 to D1S1653);* genetic heterogeneity at chromosome 1 locus, and 12 additional loci were identified genome-wide. No significant linkage to chromosome 6p or to PAX2 was detected (80). Another genome-wide search in 31 patients from eight families from a single geographic region in southern Italy with primary VUR identified four genomic areas on chromosome 1, 3, 4, and 22, with the best results corresponding to chromosome 3 (D3S3681 to D3S1569); no common ancestral haplotype was identified., (81). The presence of several loci in both studies once again demonstrates genetic heterogeneity of VUR.

Some of the difficulties with genetic studies in VUR relate to difficulties with sample size, study design differences, the clinical variability of study subjects, difficulties in diagnosing asymptomatic carriers, change in phenotype by spontaneous resolution of VUR by the time genetic study is done, difficulties in explaining why only one side is involved, and possible role for environmental factors leading to phenotypic variability (72, 80, 81).

Natural History of VUR

Primary VUR generally improves with time, and this is attributed to the lengthening of the submucosal segment of the ureter (82). Most important factors identified with resolution of VUR are non-white race, lower grades of reflux, absence of renal damage and lack of voiding dysfunction (83). The reported rate of improvement is not consistent because of differences in patient selection, definition of resolution, duration of follow-up, and the use of one compared to two negative VCUGs to confirm resolution of VUR.

The Birmingham Reflux Study, which used a single negative VCUG, reported about 50% cessation of VUR

after 5-year follow up in medically managed moderate to severe VUR (84). In the International Reflux Study in Children, which used two consecutive negative VCUGs, the corresponding number was 25.0% (85). In a study by Wennerstrom and colleagues, the end point of reflux grade I or less was reached in approximately 75% of children after 10 years of followup (3). The rate of resolution is higher in younger children. In a 5 year followup study in children less than 5-years old, including 60% less than 2-years old, grade I VUR resolved in 82%, grade II in 80% and grade III in 46% of the ureters (5).

The rate of resolution is better in undilated as compared to dilated ureters and low grade VUR as compared to high grade VUR. The International Reflux Study in Children reported that VUR disappeared in more than 80% of undilated and about 40% of dilated ureters (2). Schwab and colleagues reported that grades I-III VUR resolve at a rate of 13% per year for the first 5 years of followup and 3.5% per year during subsequent years; whereas grades IV and V VUR resolve at a rate of 5% per year (86). In the International Reflux Study in Children (IRSC), resolution of VUR was significantly better in grade III versus grade IV VUR (87). In newborn babies with prenatal VUR, 67% of severe VUR and 78% of mild or moderate VUR resolved by the age of 2 years (74).

Many studies have reported that the resolution of VUR occurs slower in children with bilateral VUR (85–88), but no such difference has been reported by others (3). Arant and colleagues reported that in children less than 5-years old with grade I-III VUR, the resolution rate of left unilateral VUR was better than right VUR (5). There are contradictory reports on the effect of age (3, 87), recurrent UTI and bladder dysfunction (86, 89, 90), and gender (3, 87), on the rate of resolution of VUR. VUR resolution occurs earlier in black children. In one study, the mean time until spontaneous resolution in black children was 14.6 months, which was significantly shorter than the mean of 21.4 months in white children (15). A systematic review of published literature on the resolution of VUR, concluded that increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV VUR has a particularly low chance of spontaneous resolution (88).

VUR & Renal Scarring

VUR predisposes to pyelonephritis in patients with UTI, and the two are associated with renal scarring. Hodson and Edwards in 1960 associated VUR with chronic pyelonephritis (91)), which subsequently came to be known as reflux nephropathy (92). Studies have revealed that more than 75% of children under the age of 5 years with febrile UTI have acute pyelonephritis (93–96), and renal scarring occurs in 10% to 64% of all children with febrile UTI (97–100). The two most important factors that are believed to influence the probability of renal injury in patients with VUR are the severity of the VUR and the age at the onset of UTI. The role of VUR, initially proven in piglets (1), has been reported in multiple clinical studies (101–103). Moreover, children with higher grades of VUR have an increased likelihood of developing renal scarring (6, 104–106). Young age at the onset of UTI is a major determinant of renal parenchymal injury in the presence of VUR. Renal injury is more common in infants because of their unique renal papillary morphology which permits intrarenal reflux (107, 108).

The International Reflux Study reported that renal injury is more frequent in children less than 2 years old, particularly in the presence of high grade VUR (109). Ditchfield and colleagues reported that the risk of renal injury is higher in children less than 2 years old, partly because of the greater severity and prevalence of VUR (110). Many studies have reported significant improvement in renal function and growth after antireflux surgery in infants operated for VUR in the first 2 years of life (111–113) or in babies before a UTI develops (114). A comprehensive literature review on febrile UTI in children by the Committee on Quality Improvement (Subcommittee on Urinary Tract Infection) of the American Academy of Pediatrics identified children less than 2 years old as being at highest risk of renal injury with febrile UTI (115). The risk is aggravated by diagnostic challenges, non-specific clinical presentation, difficulties in getting urine specimens, and a higher prevalence and severity of VUR in smaller children. Other factors that affect the probability of renal scarring in children with VUR and UTI include delayed treatment of UTI (116), recurrent UTI (117, 118), and bacterial virulence (119, 120). Finally, there is evidence that genetic factors predispose patients with VUR to scarring, as demonstrated by studies of angiotensin converting enzyme (ACE) gene polymorphisms (78, 121).

Prevalence of cortical defects with febrile UTI in the presence of VUR is about 45% as compared to 24% in those without VUR (122). A prospective study on a population-based cohort of 1221 children aged 0–15 years with symptomatic UTI revealed primary scarring during initial evaluation in 86% of the boys and 30% of the girls. Girls had significantly more febrile UTI recurrences and acquired renal scarring than boys. The authors concluded that most boys had primary, probably congenital, VUR-associated

renal damage, whereas most girls had acquired scarring related to recurrences of febrile UTI (123).

The possibility of congenital rather than acquired renal scarring due to UTI is also supported by the presence of renal parenchymal defects in children (1) with VUR diagnosed during follow-up for antenatal hydronephrosis and no history of UTI (31, 124, 125), (2) presence of dysplastic changes in kidneys believed to be scarred due to VUR and UTI (126), and (3) the presence of VUR and renal scarring without UTI in siblings of an index patients with VUR (37).

Furthermore, of patients that showed renal scars on DMSA renal scans that were done 6 months after the initial episode of pyelonephritis, none of the patients with grade II VUR had an abnormal DMSA scan, whereas 30% and 67% of those with grade III and IV, respectively, had abnormal scans. These percentages are similar to the number of abnormal DMSA scans in children with prenatal VUR and renal dysplasia (127).

These observations raise some doubts about the accuracy of previously published data on reflux nephropathy because it is quite possible that many such patients had preexisting renal injury that had nothing to do with UTI. It is very likely that the inclusion of such patients in the studies in the past may have falsely increased the number of patients reported to have reflux nephropathy.

Mechanism and Complications of Renal Injury

After acute pyelonephritis, renal scarring takes about 1–2 years to develop (128, 129). Shindo et al. reported that the mean time from discovery of VUR to the appearance of a renal scar was 6.1 years (130). Several studies have shown that scarring develops at the same site as previous infection (131, 132). The exact pathogenesis of renal scarring following acute pyelonephritis is not well understood. According to Roberts and colleagues, the acute inflammatory response that is meant to eradicate the invading bacteria is also responsible for early renal parenchymal damage and subsequent scarring (133). The process is an inflammatory response, with chemotaxis and phagocytosis, release of lysosomal enzymes and superoxides, production of peroxide and hydroxyl radicles, tubular ischemia, and reperfusion injury (134–136).The fibrosis that follows is initiated mainly by macrophages (137). Cytokines produced by these cells, which include transforming growth factor-beta 1, platelet-derived growth factor, and fibroblast growth factor, attract and stimulate proliferation of fibroblasts that are ultimately responsible for collagen production and scarring (138). Explanations for progressive parenchymal renal injury even after VUR has ceased include autologous tubular antigens, hyperfiltration of intact nephrons, reaction to Tamm-Horsfall protein, superoxide production, and persistent hypertension (139). Hyperfiltration of intact nephrons causes glomerulosclerosis, activation of rennin-angiotensin system, and a gradual deterioration of renal function (140, 141) Studies have indicated that the mesangial alterations occur early in the course of reflux nephropathy, even before proteinuria is detectable by routine analysis (142).

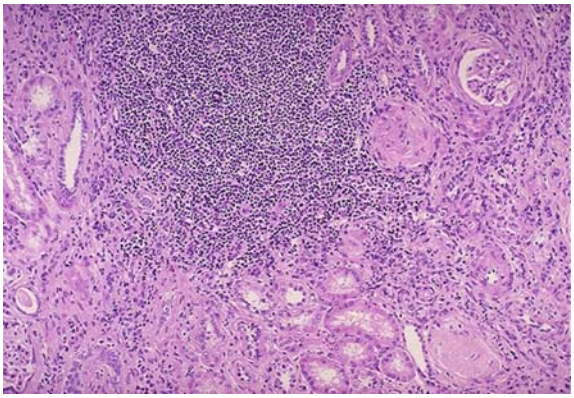
Significant bilateral renal scarring my lead to end-stage renal disease. Reflux nephropathy is responsible for 12–21% of all children with chronic renal failure (143, 144).According to the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) annual report of 2006, 536 (8.4%) of the 6405 children with chronic renal insufficiency had reflux nephropathy, which, according to the registry, is the fourth most common cause of chronic renal insufficiency after obstructive uropathy, renal aplasia/hypoplasia/dysplasia, and focal segmental glomerulosclerosis (FSGS) (145).

Renal parenchymal injury may cause persistent proteinuria, which may lead to nephrotic syndrome in some cases. The pathogenesis of proteinuria in reflux nephropathy is not well understood and is variably attributed to immunologic injury, macromolecular trapping and mesangial dysfunction, vascular alterations and hypertension, and glomerular hyperfiltration (146). Of these explanations, the one that is most widely accepted is that hyperfiltration in remnant nephrons result in modifications of permselectivity to macromolecules such as albumin and progression of renal disease (147, 148). The histologic hallmark in such patients is hypertrophy of surviving nephrons with focal and segmental glomerulosclerosis (149). Other glomerular changes that may occur are periglomerular fibrosis, sclerosis and retraction of the tuft towards the hilar pole with deposition of collagen within the capsular space (obsolescent glomerulus), solidified glomeruli that are reduced in size and eosinophilic with obliteration of capillaries, and necrotizing changes due to severe hypertension (*Fig. 55-2*).

Hypertension occurs in 10–30% of children and young adults with renal scarring (150, 151) and may take up to 8 years to develop (130). The exact cause for hypertension due to renal scarring is not known, but is believed to be due to segmental ischemia with increased rennin secretion and it does not depend on the severity of the scarring (99), (152, 153). Of the 306 patients entered into IRSC study, 3 had hypertension at study entry. Of the

Figure 55-2

Renal biopsy in reflux nephropathy showing glomerular solidification (obsolescence), tubular loss and substantial number of chronic inflammatory cells in the interstitium.



three, two became normotensive within 5 years of follow-up and the third one required antihypertensive medication at the end of the study. Three more patients became hypertensive during follow-up (154). In another study involving 664 patients diagnosed with VUR between 1970 and 2004, 20 (3%) developed hypertension. The estimated probability of hypertension was 2% (95%CI, 0.5–3%), 6% (95%CI, 2–10%), 15% (95%CI, 11–20%) at 10, 15, and 21 years of age, respectively. The survival analysis revealed that about 50% of children with unilateral and bilateral renal damage develop persistent hypertension at about 30 and 22 years of age, respectively. The presence of hypertension strongly correlated with the renal damage at entry (155).

An increased risk of nephrolithiasis has also been reported in children with VUR (156). Renal scarring may also cause pregnancy-related complications such as recurrent pyelonephritis, hypertension, toxemia or pregnancy, low birth weight babies, and miscarriage (157–161).

Diagnosis of VUR and Renal Injury

Ultrasonography

Ultrasonography is the initial modality for the evaluation of post natal hydronephrosis and UTI in children. Ultrasound has replaced the use of intravenous pyelography for the evaluation of the upper tract (162) and has the benefit of being free from contrast agents and radiation. Ultrasonography has been used to identify other urologic abnormalities, including renal and/or ureteral dilation associated with high grades of VUR (163, 164). Ultrasound is normal in lower grades of VUR and overall, it is poor for identifying VUR (165). Ultrasound has also been utilized for the follow-up of children after surgical correction of VUR (166). Ultrasonography has been used as a screening tool in siblings of children with VUR to determine if high grade reflux is present.

Efforts to use ultrasound for the primary diagnosis of VUR have been studied. The resistive index has been used as a method to identify various degrees of VUR in patients with prior confirmed diagnosis of VUR (167), however this has not had widespread acceptance. Color flow Doppler sonography has been used to identify ureteral jets associated with reflux. Good correlation was noted with VCU (168).

Renal US has very low sensitivity for diagnosing acute pyelonephritis. In one study, US abnormalities compatible with acute pyelonephritis were reported in only 20–69% of patients with acute pyelonephritis as compared to 40–92% by DMSA scintigraphy (169). Nonetheless, it is also useful in detection of renal abscess, pyonephrosis, and abnormalities of the perinephric space. Recently, there have been some encouraging results with power Doppler ultrasonography in the diagnosis of acute pyelonephritis, with a sensitivity of 80–87% and specificity of 81% and 92% (170, 171). Renal ultrasound is not a sensitive method for diagnosing renal scars. In a study involving 159 patients who underwent DMSA renal scan as well as renal US for the evaluation of hypertension of unknown etiology. Thirty-three (21%) patients were found to have renal scars. The sensitivity and specificity of renal US, in comparison with the DMSA renal scan, in diagnosing renal scars were 36% and 94%, respectively (172).

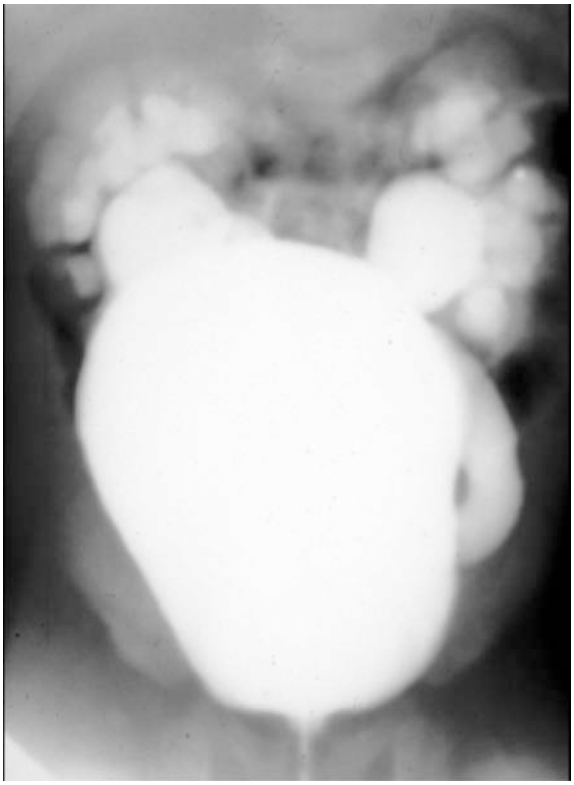
Ultrasound has been used to identify success of dextranomer/hyaluronic acid (DX/HA) injection therapy. The amount of DX/HA was measured to determine persistence of the implant in the immediate postoperative period as a correlate for resolution of VUR (173). Preservation of DX/HA on follow-up ultrasound has been not been noted to correlate with successful reflux correction (174).

Voiding Cystourethrogram

Voiding cystourethrogram is the primary diagnostic modality for the identifying VUR (*Fig. 55-3*). This is an invasive diagnostic procedure that requires catheterization. This requirement for catheterization has led to significant distress among both children and parents. The grading of VUR is based on appearance on radiographic VCUG.

Figure 55-3

Bilateral severe (grade V) vesicoureteral reflux with intrarenal reflux.



Concerns that early performance of VCUG would unmask low grades of insignificant reflux have not been borne out by studies to date (175). The VCUG should be obtained as soon as the child has completed the course of antibiotic therapy of the urinary tract infection. Delay in performance of the VCUG has led to 50% of children not getting the study leaving them at risk of undiagnosed VUR (176). Evaluation with VCU has been suggested after the first febrile infection in children younger than age five. VCUG has also been performed following successful surgical correction of VUR. The high success rates associated with open surgical correction has led to suggestion that VCUG can be avoided following open reimplantation. Avoiding VCU after open reimplantation can lead to significant cost savings (177) as well as reducing the necessity for an invasive procedure.

The results of the VCUG can be affected by size and type and position of the catheter, rate of bladder filling, height of the column of contrast media, state of hydration of the patient, and volume, temperature, and concentration of the contrast medium (178–180). Utilization of sedation to perform VCU is known to compromise the results of the study in identifying VUR, as children may be unable to void to completion when sedated for the study (181). The result of a VCUG is also affected by the number of bladder fillings during the procedure. In a study that involved multiple fillings of the bladder, Jequier reported discrepancy of presence and/or grade of VUR from one filling to the other in 12% of patients with two cycles and in 20% of patients with three cycles. No changes were observed with cyclic voiding in cases of grade IV reflux (182). The intermittent nature of VUR has been confirmed by other studies (183, 184) and was the basis for the International Reflux Study in Children using two successive negative VCUGs for confirmation of VUR resolution (85, 41). However, no prospective study has been done to study the clinical outcome differences between single versus two negative VCUGs for confirmation of VUR resolution. The clinical relevance of repeating this uncomfortable procedure in patients with no recurrence of UTI after the first negative VCUG is questionable, particularly since it is very likely that the missed VUR is most likely to be a low grade.

The timing and pressure of reflux during voiding cystourethrography has been used to attempt to predict spontaneous resolution of VUR. Arsanjani and Alagiri (185) in a recent article showed that reflux associated with filling was less likely to have spontaneous resolution as compared to reflux associated with voiding.

Follow-up of children on antibiotic prophylaxis for the management of VUR with the use of VCU has been studied to determine if an optimal time index could be identified that would balance duration of antibiotic prophylaxis with performance of multiple invasive studies. Thompson et al. have suggested that VCU every 2 years for mild reflux and every 3 years for moderate to severe reflux would lead to reduction in the number of VCUs by 42% with a subsequent reduction in cost of 33% over standard regimens and would only lead to a 19% increase in antibiotic use (186).

Nuclear cystography has been utilized to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, while being more sensitive, does not permit specific grading of VUR or reveal anatomical defects such as ureterocele or diverticulum. This is a very useful study in determining resolution of reflux during follow-up or after surgical correction.

The major concern with the VCUG has been the radiation exposure. However, recent introduction of low-dose radiographic equipment, including digital fluoroscopy, has helped reduce radiation exposure significantly (187, 188).

Technetium 99 m Dimercaptosuccinic Acid Renal Scan (DMSA Renal Scan)

DMSA is currently the accepted gold standard for diagnosing acute pyelonephritis (189, 190) and renal scarring (191, 192) (*Fig. 55-4*). Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planer imaging for detection of renal cortical damage (193, 194). DMSA scintigraphy is more sensitive than ultrasound, intravenous urography or CT scan in diagnosing renal scarring (169, 172, 195). The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92%, when compared to histological findings (196). Sensitivity of more than 92% and specificity of more than 98% has been reported in the clinical setting (197, 198). By using standardized criteria for its interpretation, high levels of intra- (95.9% and 90.6% respectively, $p < 0.05$) and inter-observer agreement (84.4%, $p < 0.05$) were reported (199).

An abnormal DMSA scan during a febrile UTI allows the identification of children at risk of developing renal scars (200). For acute pyelonephritis, DMSA scintigraphy can be performed within 2–4 weeks (122, 201) after the onset of UTI symptoms. For renal scarring, DMSA scintigraphy should ideally be performed 6 months after acute infection in order to allow acute reversible lesions to resolve (202).

Dysplasia secondary to congenital reflux will appear similar to renal scarring following post natal infections. A baseline DMSA scan in a child presenting with VUR will allow identification of renal dysplasia and permit subsequent identification of scarring following an infection (203).

Recently, Jodal et al. have suggested the use of DMSA renal scanning as an initial study in the evaluation of urinary tract infections in children. This "top down" approach has been suggested as a way to identify significant VUR in children that have a presenting urinary tract infection. DMSA renal scanning was able to identify 26/27 children that had VUR (204). Since the studied cohort included all children with UTI that would have gone on to have VCU, that authors concluded limiting VCU to those children that had positive DMSA scans would save many children from requiring VCU. The benefit of using DMSA renal scanning as a screening tool in this manner should be balanced with the fact that at many institutions, DMSA scanning is an expensive study.

Figure 55-4
DMSA renal scan showing bilateral reflux nephropathy (R > L).

PIC Cystography

Positional Instillation of Contrast (PIC) cystography has been used to identify children with "occult" VUR that present with recurrent febrile UTI in whom standard and nuclear cystograms fail to reveal VUR (205). Under general anesthesia, the ureteral orifice is identified and contrast is injected directly at the ureteral orifice with fluoroscopic evaluation to identify VUR. Treatment of children with VUR identified on PIC cystography that had resolution of VUR, did not have febrile infections develop during immediate follow-up (205). This method for evaluation and management of VUR remains controversial. Proponents point to reduction in the numbers of febrile infections following identification and resolution of "occult" VUR (206).

Magnetic Resonance Imaging (MRI)

Recently great interest has developed in MRI for the diagnosis of renal scars because it allows discrimination between areas of swelling from scarring, both of which would be interpreted by DMSA scintigraphy as renal scarring. MRI also allows diagnosis of other coexisting conditions such as nephrolithiasis (207, 208), which is not diagnosed by DMSA scintigraphy. Newer imaging methods that show promise in diagnosing renal scarring include dynamic contrast-enhanced MRI (209), and MRI using a gadolinium-enhanced short-tau inversion-recovery (STIR) sequence (210, 224). However, routine use of MRI is less practical because of limited availability, need for prolonged sedation, and high cost.

Biomarkers of Renal Injury

Numerous non-invasive biomarkers have been investigated for their usefulness in early diagnosis and monitoring of the progression of renal scarring. These include proteinuria, renal tubular enzymes such as N-acetyl-beta-d-glucosaminidase (NAG) (211), renal tubular brush-border antigens (BBA) (212), epidermal growth factor (213), cytokines

such as interleukin (IL)-8 (214) and IL-6, soluble tumor necrosis factor (TNF) receptor-1 (215), endothelin-1 (216), and prostaglandin E2 (217). Low molecular weight (LMWP) proteins, such as beta 2-microglobin (B2M), retinol-binding protein (RBP), alfa 1-microglobin (A1M) and lysozyme pass relatively freely through the glomerular basement membrane and are almost completely reabsorbed by the proximal renal tubule (218). Their urinary excretion increases in proximal tubular damage, including that due to reflux nephropathy (219, 220). An increased serum level of B2M has also been reported as being a marker of reflux nephropathy (221).

Proteinuria is a well-known predictor of renal disease progression due to reflux nephropathy (142). Proteinuria is severe when associated with focal segmental glomerular sclerosis (FSGS). A significant correlation exists between albuminuria and GFR (219). In contrast to overt proteinuria, persistent excretion of small amounts of albumin, also called microalbuminuria, is helpful in diagnosing glomerular damage at a very early stage, as has been amply demonstrated in patients with diabetes mellitus (222). In patients with reflux nephropathy, microalbuminuria has been reported at the same time as the appearance of low molecular weight (LMW) proteins in urine (219, 220), and its excretion increases with increasing severity of VUR and renal scarring (223). In a study in children with bilateral VUR with renal scarring and normal creatinine clearance, microalbuminuria was detected in 53.5% of the cases (148). The diagnosis and monitoring of microalbuminuria offers the potential therapeutic possibility of using an angiotensin converting enzyme inhibitor (ACEI) and/or an angiotensin receptor blocker (ARB) to slow the progression of renal damage (224, 225).

Medical Versus Surgical Management of VUR

For many decades, the management of VUR has been driven by the belief that VUR predisposes to recurrent UTI and renal parenchymal damage. Various treatment strategies have been used with the ultimate objective of preventing renal injury. The two main treatment modalities that have been practiced for a long time are long-term antimicrobial prophylaxis and surgical correction. Surgical correction of VUR was common until the concept of antimicrobial prophylaxis for childhood UTI was introduced in 1975 (226). Numerous subsequent studies revealed that medical management of VUR is as good as the surgical treatment and there is no significant outcome difference between the two treatment modalities.

In the International Reflux Study in Children (IRCS), which included 306 patients, no significant difference in outcome was found between medical or surgical management in terms of the development of new renal lesions or the progression of established renal scars (227). Similar results were reported by Birmingham Study (84). In the International Reflux Study Group in Europe, 287 children with severe VUR were randomly allocated to medical (n = 147) or surgical (n = 140) groups. Follow-up with DMSA renal scans for a period of 5 years revealed no difference in outcome between children managed surgically or medically (109).

In its final report, the IRSC compared long-term outcome of medical versus surgical management in 252 children less than 11 years old with non-obstructed grade III/IV VUR, history of UTI, and a GFR of $\geq$ 70 ml/min/1.73 m^2. The follow-up period was 10 years. UTI recurrences and renal growth were similar in the two groups except that medically treated group had more febrile infections. The report concluded that with close supervision and prompt treatment of UTI recurrence, children in medical or surgical group did equally well (154).

In 1997, American Urologic Association (AUA) published its guidelines on the management of VUR in children. The recommendations were based on a systematic review that involved 168 articles on VUR that were published from 1965 to 1994. The seven treatment modalities that were studied included (1) intermittent antibiotic therapy, (2) bladder training, (3) continuous antibiotic prophylaxis, (4) antibiotic prophylaxis and bladder training, (5) antibiotic prophylaxis, anticholinergics and bladder training, (6) open surgical repair, (7) endoscopic repair. The key outcome measures were resolution of VUR, risk of pyelonephritis and scarring, and complications of medical versus surgical management. The study panel recommended antibiotic prophylaxis for all grades of VUR in children less than a year old because of a very high rate of spontaneous resolution. For children 1–5 years old, it recommended antibiotic prophylaxis for all grades of VUR with surgical options in grades III to V if VUR is bilateral or renal scarring is present. For children older than 6 years it recommended antibiotic prophylaxis for grades 1 and II (unilateral or bilateral) and unilateral grades III and IV, with surgical options if renal scarring is present; and surgical repair for bilateral grade III and IV, and unilateral or bilateral grade V VUR with or without scarring as the VUR has the least possibility of spontaneous resolution (228).

The Swedish Medical Research Council published its recommendations in 1999, which suggested no antimicrobial prophylaxis for VUR grade I and II at first examination,

for those with VUR grades III and IV on first examination, it recommended antimicrobial prophylaxis for 1 year at the end of which it should be discontinued if VUR grade decreased to grades 0–II. If there is no change in the VUR grade and the patient is a boy, the prophylaxis can be discontinued whereas it recommended continuation of prophylaxis or surgical intervention in such girls. For grade V VUR at all ages and bilateral grade IV in children less than a year old on the first examination, antimicrobial prophylaxis should be started, the management should be individualized, and surgical intervention should be considered if there is no change in VUR 1 year. The importance of bladder function evaluation and hygiene, and a careful follow-up of patients, including DMSA renal scan emphasized (229).

Medical management seems appropriate for VUR grades I–III unless patient has recurrent UTI, has allergy to the antimicrobial agent, or has compliance issues, For VUR grade IV, medical versus surgical management is controversial. Spontaneous resolution rate is <40% after 5-year follow up. Decision for surgical intervention depends on patient's age, renal function, duration of follow-up, and other factors as for those with VUR grades 1-III. VUR grade V has the lowest rate of spontaneous resolution, particularly in older children, and some advise surgical intervention if there is no improvement within a year, certainly if patient has recurrent infections on antimicrobial prophylaxis (230–232).

Cost Considerations in the Management of VUR

Multiple studies have evaluated the cost efficacy of the various management strategies for VUR. Using a computer based analysis, the cost of medical management was compared to upfront surgery (233). This analysis indicated that medical management was the most cost effective for grades I–IV of VUR. The presence of dysfunctional voiding in children with VUR increased the cost of management by 50% in some children due to the increased incidence of recurrent infections (234). Further extension of this model was used to compare the use of endoscopic management with dextranomer/hyaluronidase as an immediate option for management (235) and then compared to open surgical management for those failing medical management (236). Using these models, the use of dextranomer/hyaluronidase was not shown to be cost effective when compared to standard medical management, however when compared to open surgical management for those failing medical management, there was a cost benefit for those with lower grades of VUR (I–III). Similar cost benefit has been noted by other investigators, however these benefits seem to be best when lower grades of VUR are considered (237). There was no cost benefit for those with higher grades of reflux. There are increased numbers of surgical procedures – specifically endoscopic procedures – for the management of VUR indicating that this management strategy is increasingly being embraced by physicians and patients (238).

Medical Management of VUR

Since the natural tendency of the VUR is to improve with time, the medical management is generally tailored to cover the period during which the VUR is likely to cause the renal damage. The medical management of VUR involves long-term antimicrobial prophylaxis, appropriate management of voiding dysfunction and/or constipation, if present, and follow-up renal imaging to assess the resolution of VUR and the renal injury.

The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole (TMP-SMZ), trimethoprim alone, nitrofurantoin, or cephalexin (115, 239). According to one report, nitrofurantoin is more effective than TMP-SMZ as a prophylactic agent (240). In view of an increasing resistance of *E.coli*, ampicillin or amoxicillin are less effective as prophylactic agents (115, 241, 242), and are not used for this purpose beyond the first 2 months of life during which period it is advisable to avoid TMP-SMZ. In toilet trained children, the medication is generally administered at bed time, though this recommendation is not evidence-based.

The prophylactic dose of antimicrobials is one-fourth to one-half of the therapeutic dose for acute infection (115, 239). The dosage for commonly used antimicrobials is shown in *Table 55-2*.

Follow-up of patients with VUR and UTI requires close monitoring for an early detection and prompt treatment of UTI, change of antimicrobial prophylaxis if the patient has recurrent breakthrough UTI, and the monitoring of the VUR by periodic VCUG examinations. The timing for follow-up VCUG is not well-defined though most practitioners do it yearly. In an effort to figure out the optimum timing for follow-up VCUG examinations, Thompson et al. derived a decision-tree model from the published data on VUR and validated the model by using a retrospective cohort of 76 patients. The authors concluded that delaying the VCUG from yearly to every 2 years in children with mild VUR (grades I and II) and every 3 years in children with moderate/severe VUR

Table 55-2
Dosage of Antimicrobial agents for UTI Prophylaxis

TMP-SMZ	TMP 2 mg per kg as a single dose OR
	5 mg of TMP per kg twice per week
Nitrofurantoin	1–2 mg/kg as a single daily dose
Cephalexin	10 mg/kg as a single daily dose
Ampicillin	20 mg/kg as a single daily dose
Amoxicillin	10 mg/kg, all as a single daily dose

(grades III or higher) yields substantial reductions in the average numbers of VCUG examinations and costs, with a modest increase in antimicrobial exposure (186).

The duration of antimicrobial prophylaxis and the potential surgical intervention depends on the age of the patient, the severity of the VUR, frequency of UTI, and the degree of renal scarring, if present. Some recommend cessation of antimicrobial prophylaxis after age 5–7 years even if the low-grade VUR persists (243).

Limitations of Antimicrobial Prophylaxis

Long-term antimicrobial prophylaxis has its limitations. It is not always effective, the breakthrough UTI rates in children with VUR range from 25–38% (84, 230). Antimicrobial resistance is a major concern with long-term antimicrobial prophylaxis. In one study, children who received the medication for more than 4 weeks in the preceding 6 months had more resistant *E.Coli* when compared to those not on such treatment (OR = 13.9; 95% CI, 8.2–23.5) (244). In another study on childhood UTI, a generalized decrease in bacterial susceptibility to common antibiotics was seen in the year 1999 when compared to those previously seen in 1991 (244). Approximately 10% of children on long-term prophylaxis have adverse reactions, the most of which occur within the first 6 months. These include gastrointestinal symptoms, skin rashes, hepatotoxicity, and hematological complications with SMZ-TMP, and mostly gastrointestinal symptoms with nitrofurantoin. More adverse reactions such as marrow suppression, and rarely Stevens-Johnson syndrome may also occur with SMZ-TMP (245, 246). Compliance for daily administration of the medication over a prolonged period of time is questionable. In one study, 97% of the parents reported compliance with low-dose daily antimicrobial prophylaxis and yet the medicine was found in only 31% of the patients' urine (247). Other concerns with long-term antimicrobial prophylaxis are the patient inconvenience with repeated follow-up VCUG examinations to monitor the VUR resolution and the cost of the procedure.

Controversies Over Antimicrobial Prophylaxis

Many studies have raised serious doubts about the relevance of long-term antimicrobial prophylaxis in the prevention of renal injury in patients with VUR. Shindo et al. observed that renal scarring, the injury presumably having been initiated by VUR, can progress despite correction of the reflux and prevention of UTI (130). Arant et al. reported that in spite of good medical management, even mild and moderate VUR can be associated with renal injury (5). In a study on 51 children (mean age 8.6 years) with VUR (grades I–IV), the prophylactic antibiotic was discontinued after a mean period of 4.8 years. After a mean follow-up period of 3.7 years, only 11.8% patients had UTI and no new scars developed in any of the patients (243). Other reports that raise doubts about the usefulness of long-term antimicrobial prophylaxis include the observation that up to half of patents with severe VUR exhibit no evidence of renal damage (9), incidence of renal scars does not always match the severity of VUR (248), and the frequency of pyelonephritis is similar with and without the resolution of VUR (230). In a retrospective study in 611 children aged less than 6 years with first UTI, patient gender and low grade VUR (I–III) were not associated with risk of UTI recurrence. Factors associated with increased risk included white race, age 3–5 years, and grades IV-V VUR. The authors concluded that antimicrobial prophylaxis in the studied patient population was not associated with decreased risk of recurrent UTI, but was associated with increased risk of resistant infections (249).

In a systematic analysis that compared antibiotics with placebo or no treatment for preventing UTI in susceptible children, Williams and colleagues concluded that most published studies to date have been poorly designed with biases known to overestimate the true treatment effect (250). Another systematic analysis, which evaluated the value of identification of VUR after a symptomatic UTI and the effects of various interventions on the occurrence of UTI and subsequent renal parenchymal damage, concluded that it is uncertain whether the identification and treatment of children with VUR confers clinically important benefit and any intervention, including antibiotic prophylaxis or surgery for VUR, is better than no treatment (251). Another systematic analysis, which evaluated the predictability of renal parenchymal damage by

diagnosing VUR in hospitalized children with febrile UTI, revealed that VUR is a weak predictor of renal damage in such children (252).

Voiding Dysfunction and Constipation

Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps reduce UTI recurrence and the resolution of enuresis and uninhibited bladder contractions (60, 253). The treatment of voiding dysfunction or DES may include the use of laxatives and timed frequent voiding every 2–3 hours. Pelvic floor exercises, behavioral modification, and/or anticholinergic medication may be required. A combined conservative medical and computer game assisted pelvic floor muscle retraining decreased the incidence of breakthrough UTI and facilitated VUR resolution in children with voiding dysfunction and VUR (254). Similar results of improved outcome with medical management have been reported by others (63, 255).

Hypertension and/or Proteinuria

Appropriate management of hypertension and/or proteinuria is important to decrease the progression of renal disease. Despite the large number of available antihypertensive drugs, the angiotensin converting enzyme inhibitors (ACEI) or angiotensin II receptor blockers (ARB) are preferred ones because of their renoprotective effect. Studies have revealed that ACEI, besides lowering the blood pressure, reduce proteinuria due to reflux nephropathy (256). In a study by Lama et al. (224), 15.5% of children with VUR and reflux nephropathy had microalbuminuria. Treatment with an ACEI (captopril) for 2 years was associated with decreased microalbuminuria, whereas GFR, serum creatinine, and BP remained stable. Microalbuminuria decreased from 69.5 + 58–12.5 + 9.7 mg/l during the first 6 months of therapy and remained stable during the subsequent 18 months of treatment in most patients. Therapy with ACEI may be particularly beneficial for patients with reflux nephropathy, especially those born with D alleles of the ACE gene (225). A combination of ACEI and ARB significantly improves the renoprotective effects of ACEI (257). However, it is not known whether this antiproteinuric effect slows down the progression of the renal disease. In some patients with very poorly functioning scarred kidney and a healthy other kidney, the removal of a poorly functioning kidney may help cure hypertension (258).

Surgical Management of VUR

Surgical management of VUR has been relegated a second line management strategy for those patients that fail medical management with prophylaxis and follow-up. Current indications for surgical management of vesicoureteral reflux are recurrent infections despite compliance with a prophylactic antibiotic regimen, worsening of renal scars following a urinary tract infection or inability to comply with a prophylactic regimen. The recent introduction of minimally invasive modalities for the management of VUR, have made some clinicians consider surgical correction as a potential first line therapy. Immediate correction could potentially offset the need to keep children on prophylactic antibiotics. Although most surgical techniques have high success rates, most studies indicate that surgical correction of VUR does not prevent urinary tract infections or eventual renal scarring (259).

Endoscopic Management

Endoscopic treatment is performed in an outpatient setting and involves the injection of a bulking agent in a sub trigonal location at the ureterovesical junction in the bladder (STING procedure). With the use of cystoscopy, the ureteral orifice is identified and a special endoscopic needle is utilized to inject material under the ureter. Endoscopic correction of VUR was initially described using a porcine model by Puri and O'Donnell in 1984. This technique with the use of polytetrafluoroethylene paste (PTFE/Teflon) was noted to be very successful in the correction of reflux in children (260).

Unfortunately questions were raised regarding the migration of particles of Teflon to other organs in the body (261). These concerns led to restriction of the use of Teflon in the United States. Use has continued successfully in Europe with very high short and long term successes reported (262–264). Teflon has also been shown to have good efficacy in those children with high grades of reflux and those associated with other congenital anomalies e.g., Ureteroceles (262, 265).

The concerns regarding the use of Teflon in the United States has lead to consideration of other bulking agents. Experimental success with the use of blood was not met with ongoing clinical application (266). Collagen was widely utilized for the correction of reflux in children (267). Success rates were noted to be 69% at 1 year follow-up (267). Long-term follow-up however has demonstrated eventual recurrence of reflux in many children that were initially successful with the use of collagen.

Bovine collagen was utilized for VUR correction and skin testing was required to identify those that were allergic to collagen – therefore not all children were candidates. Endoscopic management with collagen was found to have a cost benefit when compared to open ureteral reimplantation (268). Atala et al. devised a implantable balloon that was used with good success in a porcine model (269). They were also able to demonstrate success with the use of alginate seeded with chondrocytes in both animal models (270, 271) and in human trials (272). This technique requires the use of chondrocytes obtained via prior biopsy of the ear, necessitating two surgical procedures with their attending anesthetic risks. Overall success was noted to be 83% (272).

Polydimethylsiloxane was used as an alternative to Teflon and was found to have no migration in animal studies (273). This agent was not approved for use in the United States but results from European centers have indicated good long-term success rates (86%) for correction of reflux (274). In 1995 Stenberg and Lackgren published the first evidence for the use of dextranomer/hyaluronidase in animals and children (275). The dextranomer microsphere implant promotes the ingrowth of collagen and maintains the increased resistance of the ureteral orifice that prevents VUR (*Figs. 55-5–55-7*). This implantable material marketed as Deflux (Q Med Inc) has become widely accepted as the injectable bulking agent of choice for the management of vesicoureteral reflux. Five year follow-up indicated success rates of 68% (276). There has not been any demonstrable evidence of particle migration with the use of Deflux (277). Significant experience has been gained with the use of dextranomer and success rates of 89% have been noted with improved implantation techniques (278, 279). These improvements in clinical results have led clinicians to utilize dextranomer for reflux associated with increasingly complex urological conditions (280) including ureteroceles, duplicated systems and those associated with prior failed reimplants. Cost analysis has indicated a benefit for the use of dextranomer when compared to open surgery for the management of VUR (236).

The success of dextranomer has led many to consider changing the management paradigm for VUR. Concerns regarding patient compliance with antibiotic prophylaxis and the frequency of urinary tract infections in some children with VUR have led to consideration of dextranomer injection as first line therapy (281, 282). One study has shown a benefit with the use of dextranomer injection in the prevention of urinary tract infections when compared to antibiotic prophylaxis (283). A recent report has also indicated reduction in urinary tract infections in those children managed with dextranomer when compared to those having reflux correction with open surgery although no concrete explanation was offered for this improved outcome (284). This management strategy has not been shown to have a cost benefit over standard medical management with antibiotic prophylaxis (235). The presence of a refluxing megaureter was felt to be a contraindication to the use of dextranomer in children (285).

Meta- analysis of all of the endoscopic modalities used for management of VUR indicate that rates of cure per ureter for grades I and II was 78.5%, grade III was 72%, grade IV was 63% and grade V was 51%. Success rates of 68% were noted for those patients failing first injection and 34% for those failing a second injection. Reduced success rates were noted for those patients with duplicated systems and had neurogenic bladders (286). The success rates and the minimally invasive nature of endoscopic procedures have led to the substantial increase in the number of procedures being performed (238).

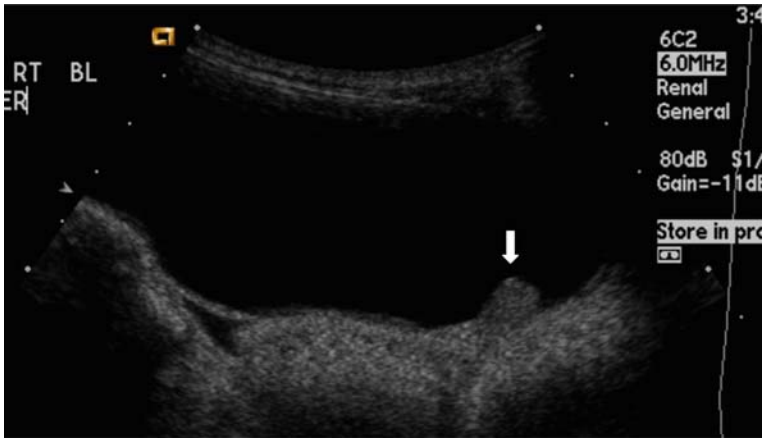

Figure 55-7

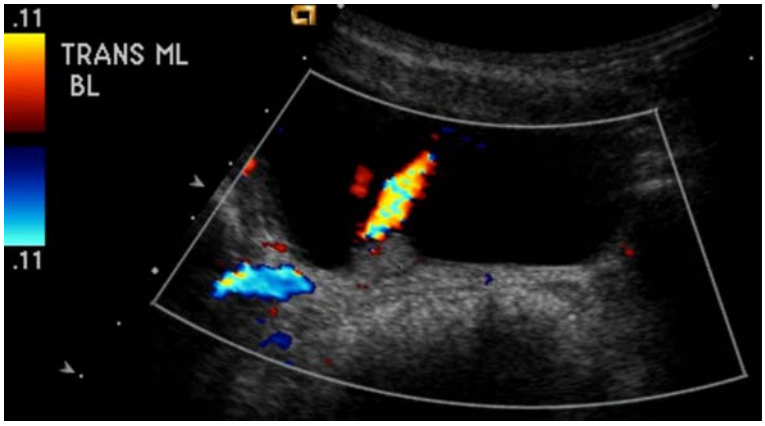
Trans Doppler ultrasound with jet ("lava from volcano") after Deflux procedure.



Persistent of VUR is considered a failure of injection therapy. Contralateral VUR is noted in 13% of children having unilateral injection therapy with dextranomer/hyaluronidase (287). There was a higher incidence in girls younger than 5 years of age. Many of these children will require repeat injection treatment or open surgical correction. The low incidence of this entity however does not justify preemptive injection of the contralateral ureter at the time of initial DX/HA injection (288). Open surgical correction for endoscopic failure has similar success rates as when performed as a primary procedure (289). Post operative ureteral obstruction has been noted in patients following injection therapy. This is a rare complication and occurs in 0.7% of patients injected. There is a higher incidence of this complication in children with voiding dysfunction and neurogenic bladder (290). Calcification of the implant of dextranomer/hyaluronic acid has been shown to mimic a distal ureteral calculus (291). Patients have been mistaken as having abdominal pain secondary to this and have had delay in diagnosis of the true cause of the abdominal pain.

Minimally Invasive Procedures

Trigonoplasty was described by Gil Vernet in 1984. This procedure was performed by placing an imbricating

stitch in the trigone and pulling the two ureteral orifices together to the midline (292). This open technique has been performed using an endoscopic technique to make it a minimally invasive procedure. While associated with reasonable initial success, long-term failure rates were high (293), and most have abandoned this approach in favor of endoscopic injection techniques.

Another minimally invasive outpatient procedure has been described with the use of small inguinal incisions to correct reflux. This method utilizes an extravesical surgical approach to the correction of VUR (see below). Although good results have been reported by a single center (294), the successful use of endoscopic bulking agents has overshadowed this and other minimally invasive techniques.

Laparoscopic Ureteral Reimplantation

Laparoscopic ureteral reimplantation has the benefits of providing results that are comparable to open surgery, with the promise of a minimally invasive approach. Initial enthusiasm has been tempered by the long operative times and potential for complications. The procedure is typically performed using a transperitoneal approach and reimplantation is performed using an extravesical technique (295) (see below). This is a technically challenging procedure in the young child and most patients require a 24–48 hour hospitalization. Intravesical laparoscopic ureteral reimplantation has also been described with good success rates. This also is a challenging procedure and requires a reasonable bladder capacity to allow the instruments to be placed successfully (296, 297). The intravesical approaches either utilize the trigonoplasty as described by Gil Vernet, or a standard intravesical cross trigonal approach as described below. Success rates are noted to be high, however, the technical challenge associated with these procedures as well as the widespread acceptance of endoscopic techniques has made these approaches less utilized.

Laparoscopic reimplantation has been associated with long operative times (298) and high cost when disposable equipment is utilized. Additionally, appropriate patient selection is critical for surgical success using laparoscopy. Ureteral injury has been noted with this procedure (295) and is typically felt to be related to the steep learning curve associated with complex laparoscopy. Additional complications that have been noted include ureteral leak in 12.5% and ureteral stricture in 6.3% (299). Overall success with correction of VUR is similar to the open procedures (299).

Open Surgical Techniques

The gold standard for the surgical management of VUR remains the open approaches. The most commonly performed open technique is the Cohen Cross Trigonal reimplantation (300). This procedure has wide applicability and can be performed even in the presence of duplicated systems and other intravesical abnormalities. The procedure involves mobilization of the ureters from their intravesical submucosal tunnels, and placement in a longer submucosal tunnel. The success rates of this procedure for the correction of reflux are 98% (301) and can so consistently be achieved that most clinicians have stopped performing follow-up studies to confirm reflux resolution (177). Improvements in surgical anesthesia and post operative pain management have allowed children to be managed with a 24–48 h hospitalization. Some children have been managed as outpatients.

The Lich Gregoir extravesical reimplantation has also been used successfully for the management of children with reflux. The ureter is dissected outside of the bladder and then placed into a submucosal tunnel by incising the bladder muscle over the ureteral path. While high success rates have been noted for the correction of reflux, extensive mobilization of the bladder when performing bilateral reimplantation has been associated with transient urinary retention, requiring intermittent catheterization in some children (302). To limit this complication, nerve sparing procedures have been developed (303). Many clinicians have restricted this procedure to those children that have isolated unilateral VUR.

Older procedures including the Politano – Leadbetter reimplantation have been successfully utilized for ureteral reimplantation in special circumstances. All of the open techniques have very high success rates for correction of VUR and have been widely accepted as the gold standard for comparison of newer modalities for management.

Following open correction, expected success rates for reflux correction are 97–99% (304). If residual VUR is noted following surgical reimplantation, continued monitoring of the patient and repeat VCU in 3–4 months may show further resolution in many. Most children that have residual VUR following open surgery, have a lower grade of VUR. Contralateral VUR is noted in 19% of patients that had unilateral ureteral reimplantation (305), the majority resolve over the ensuing 2 years and are felt to be secondary to trigonal changes following ureteral reimplantation. Ureteral stricture has also been reported and is secondary to ischemia of the distal ureter. Endoscopic access to the ureter following ureteral reimplantation can be difficult and therefore later management of stones may be difficult.

Intervention Versus Surveillance in VUR

Recently, studies have compared surveillance only with antibiotic prophylaxis in children with primary VUR. In the first such study, Garin et al. randomized study involving 236 with acute pyelonephritis in the age group of 3 months to 18 years. Included in the study were 113 children with grade I-III VUR (age group 3 months to 12 years) and 115 patents without VUR (age group 3 months to 17 years). Patients were randomly assigned to prophylactic antibiotic (SMZ/TMP) or no prophylaxis. DMSA renal scans were done to document renal scarring. At the end of 1 year no difference was noted the incidence of UTI, pyelonephritis, or renal scarring between the two groups. The authors concluded that the study did not support any role for prophylactic antibiotics in preventing the recurrence of infection or the development of renal scars after acute pyelonephritis in children with or without VUR (306).

In another study, Roussey-Kesler et al. randomized 225 children with grade I-III VUR to daily antibiotic prophylaxis (SMZ/TMP) or no prophylaxis. The age of the patients ranged from 1 month to 3 years. After a follow up period of 18 months, there was no significant difference in the occurrence UTI (17% in treatment group and 26%, in untreated control group ($p = 0.2$) between the two groups. No difference based on the grade of VUR was noted. A significant association was found between treatment and patient gender ($p = 0.017$) with significantly reduced UTI in boys, particularly in those with grade III VUR (307).

In the third study, Pennesi et al. recruited 100 children with grade II to IV VUR diagnosed after first episode of acute pyelonephritis. Patients were randomly assigned to receive SMZ/TMP antibiotic prophylaxis or no prophylaxis. The mean ages of patients in the prophylaxis and no prophylaxis groups were 9 months and 8.3 months, respectively. At the end of 2 years, prophylaxis was discontinued and patients were followed for another 2 year period, for a total follow up period of 4 years. DMSA renal scans were done to diagnose renal scars. There was no difference in recurrence of acute pyelonephritis at 2-year (36% versus 30% for prophylaxis and no prophylaxis, respectively) or 4-year period. DMSA renal scans in were abnormal in 0%, 30%, and 67% of patients with grade II, III, and IV VUR, respectively. No significant differences in renal scarring was noted at 2 years and no patients were noted to have new renal scars during the 4 year period (127).

These trials, though important, do not conclusively invalidate the role of antimicrobial prophylaxis in VUR. They were limited by lack of blindness, no use of placebo, a relatively small number of patients, urine collection by sterile bags in non-toilet trained children, exclusion of patients with high grade VUR that are normally associated with a highest risk of renal injury, relatively short duration of follow up, wide age group in one study, and not addressing the issue of interobserver variability in the interpretation of DMSA renal scans.

Conclusion

The emerging knowledge about VUR has generated a lot of interest among clinicians as well as researchers. Clinical and possibly genetic differences between VUR diagnosed during sibling screening, during follow-up for antenatal hydronephrosis or after UTI, as well as the role played by voiding dysfunction and/or chronic constipation in the resolution of VUR or the frequency of UTI, have not been completely elucidated. Prevention of renal scars in children with VUR and the preservation of renal function in those with renal scars remain the most important objectives. While in the midst of a potential paradigm shift in the management of VUR, there lies a risk of not appropriately investigating young children with UTI or not using long-term antimicrobial prophylaxis in those with VUR. It is advisable that until the results of more, appropriately designed studies, particularly placebo-controlled and double blind study such as the RIVUR (Randomized Intervention for Children with Vesicoureteral) study or any other similar study become available, that VUR and UTI continue to be considered major risk factors for renal scarring.

56 Obstructive Uropathy

Robert L. Chevalier · Craig A. Peters

Introduction

Urinary tract obstruction initiates a complex sequence of events resulting in impaired renal function (1), and obstructive uropathy is a major cause of renal impairment in infants and children. In early development, chronic urinary tract obstruction impairs renal growth and development. In view of its clinical importance, the pathophysiology of urinary tract obstruction has been studied intensively, leading to the development of numerous experimental models, including complete and partial ureteral obstruction, unilateral and bilateral obstruction, and acute and chronic obstruction. Most experiments have been performed in adult animals: therefore comparisons with obstructive uropathy in human infants and children must be made with caution. To address this concern, studies of urinary tract obstruction have been performed in fetal or neonatal animal models. Advantages of surgical models include experimental manipulation of the severity, duration, and timing of obstruction, as well as the study of recovery following release of obstruction. The functional effects of obstruction are directly dependent on the cellular responses, with the resultant effects on renal growth. The latter are of particular importance in the period of rapid somatic growth.

Congenital Urinary Tract Obstruction: Candidate Genes

As with most congenital anomalies, those of the kidneys and urinary tract are likely to be polygenic. A number of transgenic mice have been found with phenotypes including hydronephrosis or evidence of urinary tract obstruction. These include knock-outs for genes involved in formation and patterning of the ureteric bud, ureteral differentiation, and junction formation with the bladder and pelvis (2). Mice lacking a functional gene for a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS)-1 develop fibrotic changes at the ureteropelvic junction, with a renal phenotype of obstructive uropathy (3). Mice lacking lysosomal membrane protein LIMP-2/LGP85 develop unilateral or bilateral ureteropelvic junction obstruction (UPJO) secondary to disturbed uroplakin expression (4). Deletion of most of the components of the renin-angiotensin system or calcineurin results in defective pyeloureteral peristalsis, functional UPJO, and obstructive uropathy (*Fig. 56-1*) (2, 5, 6). A mutant mouse has also been developed which develops megabladder (mgb) due to a primary defect in the development of smooth bladder muscles (*Fig. 56-2*) (7). These animals develop progressive hydroureteronephrosis and renal failure similar to patients with Posterior Ureteral Valves (PUV). Although these mutant animals have not yet revealed the primary morphogenetic mechanisms responsible for clinical congenital obstructive uropathy, they underscore the importance of a functional urinary tract in assuring normal renal development.

Effects of Urinary Tract Obstruction on the Fetal Kidney

The determination of the effect of relief of fetal urinary tract obstruction on functional development of the kidney is of primary clinical importance. Moreover, in view of the association of pulmonary hypoplasia and oligohydramnios, the effect of severe urinary tract obstruction on the development of the fetal lung is of more immediate importance to the neonatal infant. Several laboratories have attempted to develop such models in the fetus or embryo (8, 9). Ureteral obstruction in the chick embryo results in hydronephrosis, but not in dysplastic changes as are present in infants with severe degrees of obstruction (10). Ureteral ligation in the fetal rabbit results in a rapid decrease in the number of glomeruli, whereas relief of obstruction partially restores them (11, 12). The opossum has also been studied because it is a marsupial and most "fetal" development is completed in the maternal pouch rather than while attached to a placenta in utero. Unilateral ureteral obstruction (UUO) in the fetal opossum results in tubular atrophy and interstitial fibrosis, with interstitial fibroblasts appearing similar to undifferentiated mesenchyme (13). In this model, relief of UUO does not affect weight or function of the ipsilateral kidney (14). In fact, relief of obstruction tends to further decrease the

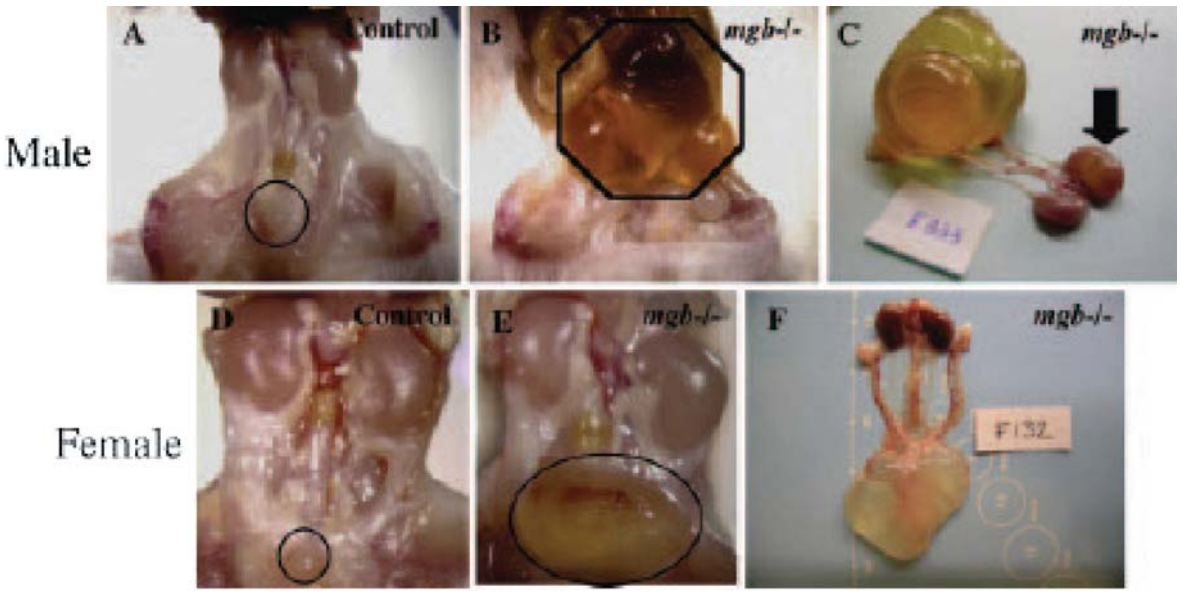
weight and function of the kidney, an effect that is ascribed to a renal inflammatory response (14). In addition, growth of the intact opposite kidney is also greater following relief of obstruction (14), results that are the reverse of those following relief of partial UUO in the neonatal guinea pig (15). As in the neonatal rat (16), the administration of insulin-like growth factor ameliorates the development of interstitial fibrosis in the fetal opossum subjected to complete UUO (17). This supports the role of growth factors in mediating or modulating the renal cellular response to UUO in the fetus; as well as postnatally.

Because of their larger size and presumed greater similarity to the human fetus, a number of investigators have studied urinary tract obstruction in the fetal sheep. Initial studies in this species revealed that urethral obstruction prior to closure of the urachus results in a persistent umbilical fistula that prevents the development of hydronephrosis (18). Ureteral ligation performed during the first half of gestation results in dysplastic changes, whereas delay in obstruction until the last half of gestation results in preservation of renal architecture with little interstitial fibrosis or inflammation (19). It is likely that the dependence of the renal response to the timing of obstruction in the fetus relates to the changing rate of cellular proliferation, which is maximal near the midpoint of gestation (20). Partial bladder outlet obstruction in the fetal sheep increases renal renin expression, and increases renal expression of the AT2 receptor (21). A greater abundance of the AT2 receptor would be expected to enhance the apoptotic response to endogenous angiotensin.

Harrison and his colleagues have described an elegant model of bladder outlet obstruction in the fetal sheep, in which the urachus as well as the urethra are obstructed (22). Relief of obstruction at 112–124 days' gestation after 15–27 days' obstruction in the fetus lessens the degree of hydronephrosis and of pulmonary hypoplasia, resulting in a marked improvement in viability (22). Ureteral obstruction in the first trimester (43–45 days' gestation) or early midtrimester (58–66 days gestation) results in marked interstitial fibrosis, primitive epithelial structures, and parenchymal disorganization typical of dysplasia (23, 24). One animal developed a

Figure 56-2

Mouse model of congenital bladder outlet obstruction. Homozygotic *mgb* mice develop megabladder and hydronephrosis. Postnatal day 17 control male mouse bladder (A, circle) *versus* male *mgb–/–* mouse shows severely enlarged bladder (B, hexagon, and C) and grossly evident hydronephrotic kidney (C, arrow). Postnatal day 12 control female mouse bladder (D, circle) *versus* female *mgb–/–* mouse shows enlarged bladder (E, oval, and F). From reference (7) with permission. (See color plate 33)



wrinkled, distended abdomen, deficient abdominal wall musculature, and undescended testes, comparable to the prune belly syndrome in man. Recovery of renal function following relief of obstruction was found to be directly proportional to the duration of intrauterine decompression, and inversely proportional to the duration of obstruction (25). As in the fetal rabbit model, relief of obstruction prior to the completion of nephrogenesis in the fetal sheep can lead to preservation of nephrons (26).

Chronic partial bladder obstruction in midtrimester in the sheep actually increases RBF and GFR, while renal architecture appears normal despite thinning of the cortex (27). These findings, which are the reverse of those described in postnatal animals, underscore the importance of the degree of obstruction in the determination of the renal response in the fetus. In contrast to bladder outlet obstruction, complete UUO in the fetal sheep decreases RBF, but not as severely as in adults (28). Complete UUO in the fetal sheep reduces ipsilateral renal blood flow (29), with a reduction in the number of glomeruli proportional to the duration of obstruction (30). Peters et al. (31) report that UUO early in gestation results in compensatory growth of the opposite kidney in the fetal lamb. This finding illustrates the operation of counterbalance in the fetus, which indicates that compensatory renal growth is not dependent on functional demand.

Experimental UPJO in the fetal monkey impairs growth of the kidney, which exhibits cystic dysplastic changes, interstitial expansion, and collecting duct apoptosis (32). A novel observation in this model is the prominent glomerular abnormality, with significant podocyte apoptosis (32, 33). Although data are limited, congenital human obstructive uropathy is also associated with glomerular as well as tubular changes (34, 35).

Effects of Urinary Tract Obstruction on Renal Growth and Maturation

Unlike the primate, the sheep, and guinea pig, in which nephrogenesis is completed before parturition, only 10% of nephrons are present at birth in the rat or mouse, with the remainder being formed postnatally (36). Thus, the early postnatal period in these species is analogous to the midgestational period in the human, and serves as a model for urinary tract obstruction during the critical period of rapid nephrogenesis. Surgical models of UUO in the neonatal rat and mouse permit the study of the direct effects of obstruction on the developing kidney,

without intrinsic defects of renal development. The use of genetically altered mice permits the elucidation of molecular mechanisms involved in the response of the developing kidney to obstructive injury (37).

A number of studies indicate that the developing kidney is uniquely susceptible to impaired growth from chronic ipsilateral (UUO). Complete UUO in the neonatal rat impairs the normal maturational increase in renal mass and the DNA content of the ipsilateral kidney (38). In the adult, in contrast, kidney DNA content is significantly increased by UUO (39). Chronic UUO in the neonatal rat results in prolonged renal expression of Wnt-4, and impairs the normal differentiation of mesenchyme to epithelium (40). Three weeks of partial UUO in the neonatal rat increases interstitial collagen deposition (primarily types I, III, and V), with an increase in type IV in the thickened and tortuous tubular basement membrane (41). The quantity of collagen deposited is directly correlated with the degree of pelvic distention (41). Renal growth impairment is dependent on the severity of partial UUO, with greater than 60% stenosis leading to a marked slowing of renal growth (*Fig. 56-3*) (42).

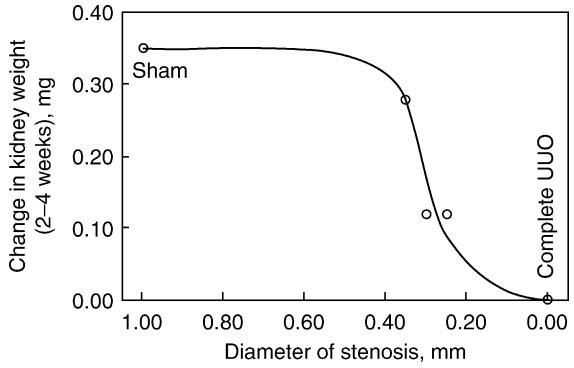
Number of Nephrons

In both human studies and animal models, fetal and neonatal urinary tract obstruction is associated with a significant reduction in the number of nephrons. Two days of UUO in the fetal rabbit reduces the number of nephrons by one third, while UUO in the fetal sheep can decrease the number of nephrons by 50% (11, 31, 43). In the human fetus, urinary tract obstruction also reduces the number of nephrons (44). Following partial UUO in neonatal pigs, the number of glomeruli is reduced by 28% (45). Either partial or complete UUO in the neonatal rat decreases the number of nephrons, with the magnitude of reduction being dependent on the duration and severity of obstruction (42, 46, 47). Interestingly, UUO in the neonatal rat in the period immediately following the completion of nephrogenesis also significantly reduces the number of nephrons, most likely due to massive cystic tubular dilatation that compresses the neighboring nephrons (47). Severe tubular dilatation also contributes to nephron loss in human obstructive uropathy (48).

Nephron loss due to urinary tract obstruction can occur through a number of mechanisms. Following relief of complete UUO in the neonatal rat, glomeruli may undergo sclerosis (49). Severe partial UUO in the neonatal rat leads to phenotypic transition of glomerular cells and delayed disappearance of glomeruli (42). In contrast, severe partial UUO in the neonatal mouse leads to apoptosis of the glomerulotubular junction and formation of atubular glomeruli (*Fig. 56-4*) (50). An improved understanding of the process of nephron loss may lead to new therapies to slow or prevent progression of renal insufficiency in obstructive uropathy.

Figure 56-3

Interval renal growth as a function of unilateral ureteral obstruction (UUO) between 14 and 28 days after surgical partial obstruction of left ureter of neonatal rat. Each point represents mean for group. Complete UUO is represented by luminal diameter = 0, while sham operation is represented by luminal diameter = 1.0 mm. From reference (42) with permission.



Renal Vascular Development

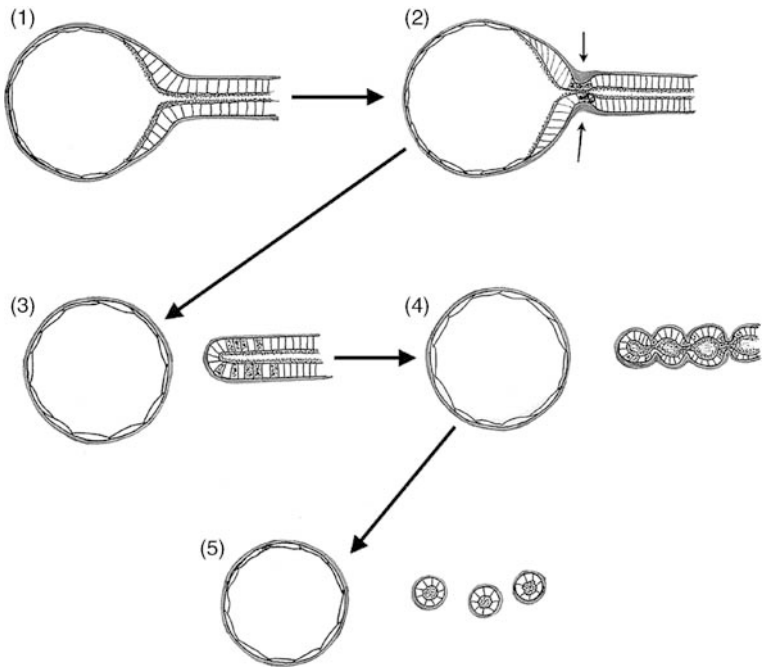
Chronic UUO in the neonatal rat leads to a marked increase in renal renin expression, and persistence of the fetal pattern of renin distribution (38, 51). It is now clear that renin expression by the renal microvasculature is a marker of vascular immaturity, rather than of terminal differentiation (52). As described below, relief of obstruction reduces the extent of renin distribution along afferent arterioles of the neonatal rat (53), and normalizes the renin content of the postobstructed kidney of the neonatal guinea pig (54). Tubular vascular endothelial growth factor (VEGF) decreases with neonatal UUO, while vascular VEGF receptors increase (55). Notably, the administration of exogenous VEGF to neonatal rats with UUO aggravates interstitial lesions (56).

Glomerular Development

Following the induction of glomeruli, glomerular capillaries increase in number, associated with flattening of

Figure 56-4

Steps in the separation of the glomerulus from its proximal tubule in the neonatal mouse subjected to partial UUO. Glomerular tuft is omitted for clarity in this diagram. (1) In the mouse glomerulus tall epithelial cells make up part of Bowman's capsule, blending into the proximal convoluted tubules (PCT). (2) Apoptotic nuclei appear in the neck region where the PCT emerges from the glomerulus, leading there to thickening of the basement membrane (between small arrows) and marked thinning of the tubule diameter. (3) The PCT becomes disconnected from the glomerulus. The severed PCT begins to undergo degeneration through a combination of epithelial cell apoptosis and necrosis. (4) Though the glomerulus remains intact, the disconnected tubule continues to degenerate, assuming an irregular shrunken profile. (5) Eventually the PCT breaks into spherical fragments, while the atubular glomerulus persists for an indeterminate time, though it may undergo ultimate resorption. From reference (50) with permission.



podocytes and increasing surface area for filtration (57). Chronic UUO in the neonatal rat either during nephrogenesis or during the subsequent maturational phase delays glomerular maturation (47, 53), a response that can be prevented by the administration of exogenous epidermal growth factor (58).

Tubular Development

Tubular maturation can be measured by the progressive disappearance of markers normally expressed only in early development, such as Wnt-4 and clusterin (glycoproteins) (40, 59), or KS (a kidney-specific gene with unknown function) (60). Chronic UUO in the neonatal rat leads to persistent tubular expression of clusterin, Wnt-4 (40) and KS (39, 60). Additionally, chronic UUO in the neonatal rat suppresses the normal maturational increase in tubular expression of EGF (38), while administration of exogenous EGF reduces clusterin expression (61).

Renal Interstitial Development

The normal maturation of renal interstitial fibroblasts is reflected by the transformation of myofibroblasts to fibroblasts, such that fibroblasts lose their expression of vimentin and alpha-smooth muscle actin (62). Chronic UUO in the neonatal rat causes prolonged expression of alpha-smooth muscle actin by interstitial fibroblasts (38), and dilated tubules from infants with severe congenital obstructive uropathy are also surrounded by myofibroblasts (63).

Summary

During normal renal development, nephrogenesis proceeds with increasing numbers of glomeruli and progressive glomerular maturation with proliferation of capillary loops. The maturing renal vasculature is characterized by the disappearance of renin from the length of the afferent arteriole, such that its localization is restricted to the juxtaglomerular region. Tubular maturation is reflected by the disappearance of vimentin and the increasing expression of EGF, while interstitial fibroblasts lose their expression of alpha-smooth muscle actin and vimentin. Chronic UUO causes a delayed or arrested maturation of the entire nephron and interstitium. The effects of chronic UUO on maturation of the developing kidney are shown in *Fig. 56-5*.

Mechanisms of Obstructive Renal Cellular Injury

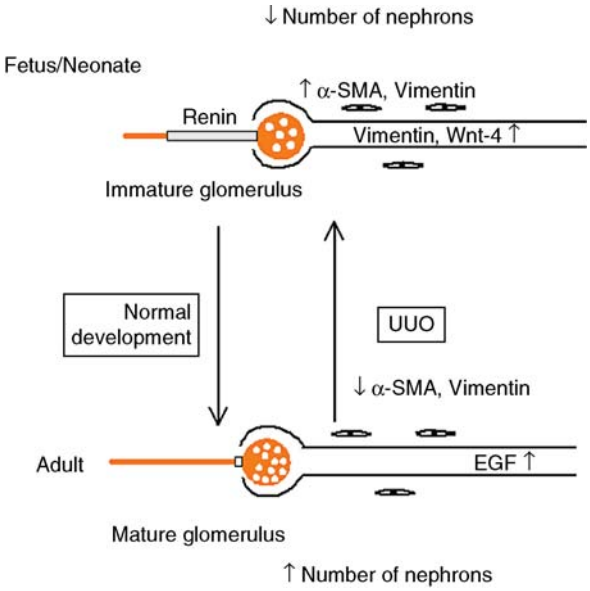
Many of the cellular mechanisms responsible for obstructive uropathy are being elucidated using models of surgically-induced UUO in mutant mice with targeted deletion of key molecules (37). These studies show that obstructive uropathy results from dysregulation of apoptosis, cellular phenotypic transition (epithelial-mesenchymal transition), interstitial inflammation, and interstitial fibrosis (64, 65). As discussed in the following sections, the creation of surgical models of UUO in the neonatal rodent has revealed the unique responses of the developing and maturing kidney to obstructive injury.

The Role of Cell Death

Urinary tract obstruction results in epithelial cell death of proximal tubules and collecting ducts. Cell death in the proximal tubule occurs by necrosis or apoptosis, whereas in the collecting duct, cells primarily die by apoptosis (50, 66). Apoptosis is characterized by condensed chromatin and cytoplasmic blebs (67, 68). Compared to the adult, UUO in the neonatal rat results in greater ipsilateral renal apoptosis (39). This may account at least in part for the fall in renal DNA content in the neonate (39). Apoptosis has also been reported in renal tubules of fetuses and infants with obstructive uropathy (69, 70). Because renal tubular apoptosis leads to tubular atrophy (67), attention has focused on factors regulating apoptosis in the hydronephrotic kidney.

Figure 56-5

Effects of unilateral ureteral obstruction (UUO) on the developing kidney. The fetal/neonatal nephron is shown in the upper panel, and the adult nephron in the lower panel. With normal maturation, the number of nephrons increases, and the glomeruli develop increased numbers of capillary loops. In addition, whereas renin extends along the afferent arteriole in the fetal kidney, renin is localized to the juxtaglomerular region of the mature kidney. During maturation, renal tubular vimentin and Wnt-4 expression disappears, and EGF expression increases. Whereas fetal interstitial fibroblasts express vimentin and α-smooth muscle actin, fibroblasts normally lose these markers with maturation. As a consequence of chronic UUO, the immature pattern of renal development persists. Adapted from reference (58) with permission.



Chronic UUO in the neonatal mouse results in apoptosis and necrosis of renal proximal tubular cells, and apoptosis of distal tubular and collecting duct cells (50). Since proximal tubules undergo significant hypoxia following UUO, it is likely that necrosis of this tubular segment is consequent to decreased oxygen tension and reactive oxygen species, as is the case following ischemic acute renal failure. Whereas the proximal tubule undergoes minimal dilatation following complete UUO in the neonatal mouse, the collecting duct is significantly dilated (66). Moreover, tubular apoptosis is directly related to the magnitude of dilatation. Since apoptosis can be triggered by the mechanical stretch of tubular cells, and is proportional to the magnitude of axial strain, it is likely that the

greater compliance of distal tubules contributes to the greater apoptosis of this tubular segment. However, partial UUO leads to proximal and distal tubular dilatation in the neonatal mouse, as is found also in the primate (32) and in human studies (48, 69).

Growth Factors

Ureteral obstruction in the adult rat decreases the expression of endogenous renal prepro epidermal growth factor (EGF) (71, 72). While EGF does not appear in the kidney until after birth (73), it is likely that activation of the EGF receptor plays a role in perinatal renal development (74). The normal developmental increase in renal EGF expression is prevented by ipsilateral UUO in the neonatal rat (38), while the administration of exogenous EGF to neonatal rats with UUO decreases tubular apoptosis in the obstructed kidney by 80% (61). In addition, EGF treatment reduces clusterin expression by renal tubular cells, and significantly reduces tubular atrophy (61). Moreover, short-term administration of EGF markedly attenuates both tubular and interstitial renal injury one month following the release of UUO in the neonatal rat (75). Although the renal expression of IGF-1 or its receptor is not altered by UUO in the neonatal rat, the administration of exogenous IGF-1, like EGF, significantly reduces renal tubular apoptosis, tubular atrophy, and interstitial fibrosis (16). Chronic UUO induces transient tubular expression of heparin-binding EGF, which can be induced also in tubular cells subjected to stretch (76). Since heparin-binding EGF is also anti-apoptotic, it is likely that expression of this growth factor serves to minimize apoptotic damage in the hydronephrotic kidney.

The mechanism whereby growth factors reduce apoptosis in the hydronephrotic kidney has been localized to the phosphorylation state of BAD, a proapoptotic molecule. When stretched, rat tubular cells undergo apoptosis, which can be reduced by 50% by treatment with either EGF or IGF-1(77). Either UUO in vivo or cell stretch in vitro decreases tubular cell BAD phosphorylation, which is inhibited by growth factors (77). When dephosphorylated, BAD dissociates from cytoplasmic chaperone proteins and complexes with BclX on the mitochondrial membrane, resulting in the release of cytochrome C and the initiation of apoptosis. EGF and IGF-1 activate their respective kinases to maintain BAD phosphorylation and thereby increase cell survival. However, in contrast to the rat and man, EGF *potentiates* tubular cell death in the neonatal mouse, a species-specific response mediated by elevated Src activity in mouse tubular cells (78, 79). These observations underscore the importance of understanding the mechanisms of cell signaling in the species being used to test therapeutic agents for potential implementation in human disorders. Stretching of human renal tubular epithelial cells increases their susceptibility to tumor-necrosis factor-α (TNF-α)-induced apoptosis, which is caspase-dependent (80); inhibition of TNF-α activity in the rat with UUO reduces caspase activity and tubular apoptosis (81).

Although transforming growth factor-β1 is generally considered a fibrogenic cytokine (see below), it also plays a significant role in promoting apoptosis in the hydronephrotic kidney (82). Stretching of tubular epithelial cells stimulates their expression of TGF-β1, and induces their apoptosis, a response that can be inhibited by antibody to TGF-β1 (83). The stretch-induced apoptotic response may therefore result at least in part from increased production of this pro-apoptotic cytokine. The action of TGF-β1 can be attenuated by an endogenous renal proteoglycan, decorin. Mice lacking a functional decorin gene manifest increased tubular apoptosis and tubular atrophy following UUO (84). Another member of the TGF-β superfamily, bone morphogenetic protein-7 (BMP-7) is also produced by the kidney, and acts as a survival factor by suppressing tubular apoptosis. Administration of exogenous BMP-7 attenuates tubular apoptosis and interstitial fibrosis following relief of UUO (85). In addition to its anti-inflammatory role, BMP-7 reverses TGF-β-dependent epithelial-mesenchymal transition (EMT) of renal tubular cells by reinduction of E-cadherin (86).

Other Molecules Modulating Apoptosis

Chronic UUO induces the renal expression of a number of apoptosis-promoting molecules, including Fas, Fas ligand, TNF-R1, TRAIL, TRADD, RIP, caspases, FADD, and FAP (87, 88). The rise and fall of expression of these molecules parallel changes in renal apoptosis in the hydronephrotic kidney. The presence of a nonfunctioning Fas receptor in C57B16/lpr mice reduces distal tubular apoptosis resulting from chronic UUO (89). Similarly, p53-deficient mice exhibit a significant reduction in apoptosis following UUO (90). These findings underscore the importance of apoptosis-regulatory molecules in the hydronephrotic kidney. Complete UUO in the fetal opossum kidney induces tubular apoptosis that is associated with an increase in Bax, a pro-apoptotic molecule, and a decrease in Bcl-2, an anti-apoptotic molecule (91). In the neonatal rat subjected to UUO, renal tubular Bcl-2 expression is reduced in dilated apoptotic tubules,

but not in nondilated tubules (92). This is consistent with endogenous Bcl-2 normally inhibiting tubular apoptosis, which is dysregulated in the obstructed kidney. Gene therapy with hepatocyte growth factor (HGF) increases Bcl-2 expression, and inhibits tubular apoptosis in experimental UUO (93). Whereas osteopontin stimulates the accumulation of interstitial macrophages in the obstructed kidney (thereby contributing to interstitial fibrosis), this phosphoprotein also inhibits tubular apoptosis, and maintains tubular integrity (94). In contrast, death-associated protein kinase (DAPK) mediates tubular apoptosis in mice with UUO, but inhibits interstitial fibrosis (95). These observations underscore the complexity of cell signaling in the obstructed kidney, such that molecules serving a protective role in one renal compartment may aggravate injury in another compartment. While tubular cells themselves generate molecules regulating their own apoptosis, infiltrating cells can do so as well. Chronic UUO in mice deficient in selectins (an adhesion molecule) have reduced interstitial macrophage infiltration, along with decreased tubular apoptosis and tubular atrophy (96).

The sphingolipid ceramide has been shown to induce apoptosis in the kidney (97). The very high prevalence of renal apoptosis in the normal developing rat is associated with elevated levels of intrarenal ceramide, and both ceramide production and endogenous renal apoptosis decrease to adult levels during the first month of life (98). Prolonged UUO in the neonatal rat (but not the adult rat) increases endogenous renal ceramide, and probably contributes to the prolonged renal apoptotic response of the neonatal obstructed kidney (99). Chronic UUO results in a maladaptive downregulation of endogenous renal antioxidant enzymes (100), and tubular catalase is protective against both tubular apoptosis and interstitial fibrosis due to UUO (101). Treatment with antioxidants may therefore have therapeutic benefit in slowing the progression of obstructive uropathy.

Summary

As shown in *Fig. 56-6*, the regulation of tubular apoptosis in the hydronephrotic kidney is extremely complex, and represents a balance between factors promoting apoptosis and countering survival factors. Stimuli for apoptosis include mechanical stretching of tubular cells which results from the initial increase in hydrostatic pressure in a compliant tubular segment. Infiltrating macrophages contribute to apoptosis of tubular cells. Enhanced renal production of ceramide may also contribute to the increased susceptibility of the developing kidney to apoptosis. Apoptosis can be activated by oxidant injury, TGF-β1, caspases, DAPK, Fas, or p53. In contrast, growth factors such as EGF, HB-EGF IGF-1, HGF, and BMP-7 can inhibit apoptosis, and tilt the balance in favor of survival. A better understanding of the renal cell biology of apoptosis should lead to improved means of preserving renal mass in patients with obstructive uropathy.

Interstitial Infiltration and Fibrosis

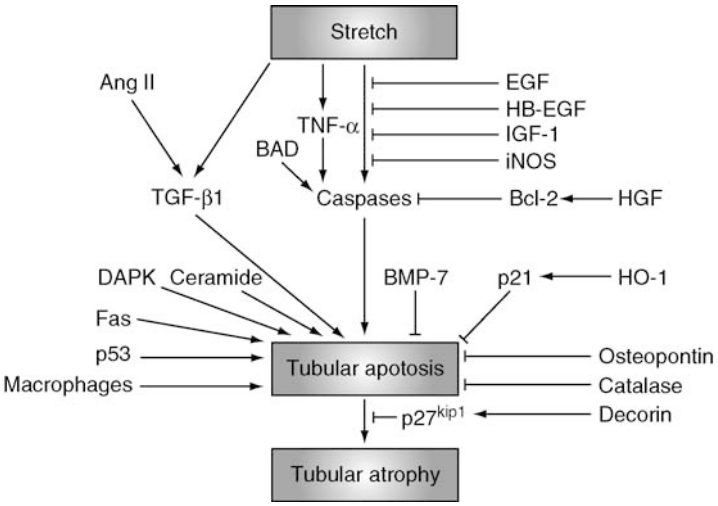
Following UUO in the adult rat, the renal interstitium of the ipsilateral kidney is infiltrated with leukocytes, beginning after 4 h and becoming maximal at 24 h (102). The cells produce a variety of vasoactive compounds, including prostaglandins, thromboxanes, and leukotrienes (103, 104). Inflammation is mediated in part by activation of the intrarenal renin-angiotensin system, with subsequent upregulation of NFκB (105), osteopontin (106), and rho/ROCK (107).

Macrophages

Although lymphocyte infiltration is not required for progressive tubular atrophy and interstitial fibrosis following UUO (108), macrophages appear to play a major role. Adhesion molecules, such as selectins, play a significant role in localizing macrophages to the renal interstitium in the developing kidney subjected to UUO (96). Mac-1 is the predominant leukocyte integrin responsible for leukocyte recruitment to the kidney after UUO (109). The macrophages, in turn, induce apoptosis of adjacent tubular epithelial cells (96), mediated by the release of soluble factors (110). Infiltrating macrophages may produce tissue inhibitors of metalloproteinase (TIMP), which in turn prevent degradation of extracellular matrix (111, 112). Following partial UUO in juvenile rats, renal expression of monocyte chemoattractant protein-1 (MCP-1) is increased (113). Since urinary excretion follows renal expression of MCP-1, and levels parallel the severity of obstruction, this molecule shows promise as a prognostic marker for infants and children with congenital hydronephrosis (114). Moreover, therapeutic inhibition of such chemokines may attenuate interstitial cellular influx and interstitial fibrosis in the hydronephrotic kidney (115, 116). While plasminogen activator inhibitor-1 (PAI-1) contributes to interstitial fibrosis resulting from UUO (117, 118), tissue inhibitor of metalloproteinase-1 (TIMP-1) does not (119).

Figure 56-6

Pathogenesis of renal tubular apoptosis in obstructive nephropathy. Several factors activated during obstructive nephropathy contribute to apoptosis of tubular epithelial cells, a major pathway to tubular atrophy. The fate of cells is determined by a balance between death signals (indicated with arrows on the left side of the figure) and survival signals (indicated by blunt arrows on the right side). Main factors and pathways identified to date are delineated, and described in the text. Axial strain on tubular cells due to stretching of dilated tubules activates caspases, and contributes to tubular apoptosis. Cytokines – such as TGF-β1 and TNF-α – released by tubular cells and macrophages provide additional apoptotic stimuli. Growth factors such as EGF, HB-EGF, IGF-1, HGF, and BMP-7 act as survival factors in most models. Ang II, angiotensin II; BMP-7, bone morphogenetic protein-7; DAPK, death-associated protein kinase; EGF, epidermal growth factor; HB-EGF, heparin binding EGF-like growth factor; HGF, hepatocyte growth factor; HO-1, heme oxygenase-1; IGF-1, insulin-like growth factor-1; iNOS, inducible nitric oxide synthase; TGF-β1, transforming growth factor-β1; TNF-α, tumor necrosis factor-α. From reference (64) with permission.



In contrast to the evidence for the role of renal interstitial inflammation in postnatal obstructive uropathy, complete UUO in the fetal sheep causes renal interstitial fibrosis without apparent inflammatory infiltrate (30). However, renal interstitial inflammation is present in human fetal obstructive dysplasia. Increases in urinary MCP-1 in rodent models as well as infants and children with obstructive uropathy suggests that inflammation is likely to contribute to the postnatal progression of clinically significant obstructive uropathy (113, 114).

Fibroblasts and Transforming Growth Factor-β

The source of interstitial fibroblasts appearing in the obstructed kidney is not clear at this time. Possibilities include proliferation of resident interstitial fibroblasts, pericytes, or transdifferentiation of renal tubular epithelial cells (epithelial-mesenchymal transition, or EMT) (120). Myofibroblast transformation, in which fibroblasts express α-smooth muscle actin, takes place in the interstitium of the obstructed kidney (121). Whereas α-smooth muscle actin normally disappears from the interstitium in the neonatal rat, this process is delayed by ipsilateral UUO (38). Myofibroblasts appear to be involved in extracellular matrix accumulation (122), and may play a role in the enhanced contractility of the renal cortex following UUO (123).

Transforming growth factor-β1 (TGF-β1), a cytokine, stimulates extracellular matrix synthesis, inhibits its degradation, and induces the expression of α-smooth muscle actin in myofibroblasts (124, 125). TGF-β1 has been localized to renal tubular epithelial cells (126) and renal interstitial cells (127, 128). Chronic UUO results in a significant increase in renal TGF-β1 expression (38, 72, 126, 127). It is possible that expression of α-smooth muscle actin by fibroblasts is controlled by the increased generation of TGF-β1 in the obstructed kidney (121, 122, 129). TGF-β1 also inhibits collagen degradation, and UUO results in a ten-fold reduction in interstitial collagenolytic activity (130).

The role of TGF-β1 in mediating renal interstitial fibrosis following UUO has been elegantly demonstrated by the introduction of TGF-β1 antisense oligodeoxynucleotides into interstitial fibroblasts (131). With the recent elucidation of TGF-β signaling, a number of studies have shown that manipulation of the downstream Smad intracellular proteins can markedly alter the severity of interstitial fibrosis resulting from UUO (64). In mice subjected to UUO, renal production of phosphorylated Smad2 and Smad3 (profibrotic Smads) is increased, while Smad7 (inhibitory) is decreased (132). Conversely, either deletion of Smad3 or gene transfer of Smad7 attenuates renal fibrosis in rodents with UUO (133, 134). Administration of exogenous hepatocyte growth factor to mice with UUO markedly reduces endogenous TGF-β1 expression, myofibroblast activation and interstitial fibrosis in the hydronephrotic kidney (135, 136). Bone morphogenetic protein-7 (BMP-7) can also counter the effects of TGF-β1 by preventing EMT (86). While it appears likely that apoptosis of renal tubular epithelial cells contributes to the development of tubular atrophy, apoptosis may also be beneficial in countering fibrosis by clearing myofibroblasts from the interstitium (137, 138). Although interstitial cells play a role in progressive interstitial fibrosis resulting from UUO, tubular cells also contribute to the fibrotic process. Administration of osteogenic protein-1 inhibits tubular apoptosis in rats with UUO, as well as inhibiting interstitial cellular infiltration (139).

Oxidative Stress

As a consequence of UUO, oxidative stress increases in the renal interstitium of the hydronephrotic kidney (140). Inhibition of oxidative stress reduces interstitial fibrosis resulting from UUO (141). Following UUO, endogenous renal antioxidant enzyme activity is reduced (100). While sodium depletion stimulates renal antioxidant enzyme production in the intact kidney, UUO inhibits this normal adaptive response (100). The impaired antioxidant production by the hydronephrotic kidney is a maladaptive response that presumably contributes to the progressive renal injury resulting from urinary tract obstruction.

The Renin-Angiotensin System

Cellular and Molecular Role of Angiotensin in Hydronephrosis

The increased generation of a pressor material in the kidney with ipsilateral UUO has been known for over 50 years. Beckwith reported that extracts of kidneys from rats with UUO induce hypertension when injected into normal animals (142). More recent detailed studies of the intrarenal renin-angiotensin system have been performed in rats subjected to complete UUO during the first 48 h of life. In contrast to kidneys from sham-operated rats, in which 55% of juxtaglomerular apparatuses contain immunoreactive renin, the fraction is increased to approximately 75% of glomeruli in kidneys of 4 week-old rats with chronic ipsilateral UUO (51). Moreover, in contrast to the pattern of distribution in sham-operated rats, in which immunoreactive renin is localized to the juxtaglomerular apparatus; renin protein extends along the length of the afferent arteriole of 4 week-old rats with UUO (51). This pattern is similar to that of the late gestational normal rat fetus (143). While renal renin content is increased in the kidney with ipsilateral UUO, it is suppressed in the intact opposite kidney (51). In contrast to the neonate, UUO in the adult rat does not result in redistribution of immunoreactive renin along the renal microvasculature.

Studies of renin secretion in vivo, or in isolated perfused kidneys, generally rely on measurements of plasma renin activity. The hemolytic plaque assay, however, permits direct measurement of hormone secretion by isolated cells (144). This technique has been used to determine whether renin secretion is increased by cortical cells from the rat kidney with ipsilateral UUO since birth. Rather than there being an increased amount of renin secretion per cell, the obstructed neonatal rat kidney demonstrates a recruitment of cortical cells secreting renin (145). It is likely that the enhanced secretion results from the increased transcription and storage of renin in the microvasculature of the immature kidney.

Following acute UUO in the adult rat, renin expression is increased after only 1 hour (146). Following 24 h UUO in the adult rat, blood vessels of the post-obstructed kidney overexpress angiotensin converting enzyme and angiotensinogen (147). In addition to increased renin production, these changes may contribute to increased intrarenal angiotensin II production following ipsilateral UUO.

Additional studies in the neonatal rat with UUO have addressed the mechanism of activation of the renin-angiotensin system in both ipsilateral and intact opposite kidneys. Renal denervation in developing rats with UUO prevents the expected increased proportion of juxtaglomerular apparatuses containing detectable immunostaining renin, as well as the extension of renin along afferent arterioles (148). In addition, denervation also suppresses the increased renin gene expression of the immature kidney with ipsilateral UUO, indicating that renal nerves modulate

renin gene expression (148). While renal nerves do not mediate the vasoconstriction of the obstructed kidney, they modulate vascular tone of the intact opposite kidney (149). Renal nerves have also been shown to play a role in the enhanced renin gene expression normally observed at the time of birth in the fetal sheep (150). Chronic UUO in the guinea pig increases angiotensin-dependent vasoconstriction in the obstructed kidney independent of renal innervation (151). However, UUO decreases angiotensin-dependent vasoconstriction of the opposite kidney, an effect unmasked by sympathectomy (151).

Modulation of growth by ANG II depends on the type of receptor present on the cell (152). Whereas the angiotensin AT1 receptor appears to mediate many forms of renal vascular and tubular growth (153, 154), activation of the AT2 receptor has been shown to inhibit cell growth (152, 155), and even to induce apoptosis (156, 157). AT1 receptors are present along the afferent and efferent arterioles, proximal tubules, and the luminal surface of the distal nephron (158). Although renal AT1 and AT2 receptors are downregulated following acute UUO in the neonatal rat, the AT1 receptor is upregulated after 28 days of UUO, at a time when intrarenal angiotensin II is increased (159). El Dahr et al. have shown that renal angiotensinogen, angiotensin converting enzyme, and ANG II are also increased in the obstructed kidney (160). It is possible that increased ANG II levels contribute to upregulation of AT1 receptor levels, as has been described in the proximal tubule (161). UUO in the neonatal rat reduces proliferation and stimulates apoptosis at least in part through the activation of AT2 receptors (162). In addition, ANG II stimulation of AT2 receptors promotes clusterin expression in the neonatal obstructed kidney (163).

The quantitative contribution of angiotensin to interstitial fibrosis resulting from neonatal UUO has been demonstrated using mice having zero to four functional copies of the angiotensinogen gene (164). Renal interstitial collagen in neonatal mice with chronic UUO increases linearly with angiotensinogen expression, from a fractional area of 25% in zero-copy mice to 54% in two-copy mice (164). Thus, angiotensin regulates at least 50% of the renal interstitial fibrotic response in obstructive uropathy. The remaining fibrotic response may be due in part to endogenous renal production of tumor necrosis factor-α (TNF-α) (165), whose expression is greater in the neonatal kidney than the adult kidney following UUO (166).

Angiotensin-Induced Molecules

In addition to its direct actions as a growth factor, angiotensin also stimulates other growth-related compounds, including TGF-β1 (167), platelet-derived growth factor (PDGF) (168), osteopontin (169), adhesion molecules (170) and α-smooth muscle actin (168). These have been associated with deposition of collagen, the development of interstitial fibrosis, and tubular atrophy and dilatation (168).

The increase in TGF-β1 in the obstructed adult kidney is regulated by ANG II (126, 128, 171, 172), and intrarenal injection of a transgene expressing angiotensinogen antisense mRNA in rats with UUO reduces renal TGF-β1 production and collagen accumulation (173). In addition, ANG II has been shown to convert TGF-β1 to its active form (174). While the administration of enalapril *reduces* hydronephrosis and proteinuria following 21 days of partial UUO in the weanling rat (175), inhibition of endogenous angiotensin with enalapril or losartan within the first 20 days of life in rats with partial UUO actually *exacerbates* the renal lesions (176, 177). This is because angiotensin is necessary for normal renal development and maturation: caution must therefore be exercised in administering angiotensin converting enzyme inhibitors or angiotensin receptor blockers in the early postnatal period.

Whereas α-smooth muscle actin normally disappears from the interstitium in the neonatal rat, this process is delayed by ipsilateral UUO (38). Since ANG II exerts transcriptional regulation of the human α-smooth muscle actin gene (178), the persistent α-smooth muscle actin expressed by the interstitial vasculature of the neonatal obstructed kidney may be due to greater generation of tissue angiotensin resulting from recruitment of renin-secreting cells (145). It is also possible that expression of α-smooth muscle actin by fibroblasts is controlled by increased generation of TGF-β1 in the obstructed kidney (121, 122, 129).

Angiotensin and the Genesis of Obstructive Uropathy

Although the AT2 receptor mediates apoptosis induced by ANG II, this receptor also appears to be important in limiting renal interstitial myofibroblast transformation in the hydronephrotic kidney (179). Moreover, there is evidence that by interfering with the apoptosis of undifferentiated mesenchymal cells, mutations in the AT2 receptor may underlie a variety of urinary tract malformations, including obstructive uropathy (180, 181). However, such mutations could not be confirmed in all populations (182).

In addition to the importance of ANG II in mediating the renal response to UUO, this peptide may also play a role in the development of the lower urinary tract. Mice

lacking a functional AT1 receptor develop functional urinary tract obstruction similar to wild-type mice subjected to complete UUO (183). The renin-angiotensin system clearly plays a critical role in many of the processes involved in congenital obstructive uropathy, and many of its protean effects remain to be elucidated.

Renal Functional Effects of Ureteral Obstruction

Ureteral ligation initially causes increased ureteral pressure and a transient increase in renal blood flow (RBF), followed 12–24 h later by decreased RBF (184, 185). A decrease in GFR follows the decline in RBF due to ipsilateral ureteral obstruction (186). Ureteral obstruction does not affect all nephrons equally: deeper nephron function is lost at the expense of compensation by cortical nephrons (187). Following 18 h after the release of UUO in the weanling rat, however, superficial nephron GFR is reduced to a greater extent than that of juxtamedullary nephrons (188). Following either UUO or bilateral ureteral obstruction (BUO), the number of filtering nephrons increases steadily during the 1st hours following relief of obstruction (189).

The chromium EDTA technique has been used to measure GFR in adult rats with complete UUO (190). Glomerular filtration rate is reduced more severely than RBF, and following relief of obstruction of 7–14 days, recovery of GFR diminishes with the duration of obstruction (190). Scanning electron microscopic examination of the rat kidney 24 h after the release of 2 weeks of UUO reveals ballooning of tubular epithelial cells, resulting in obliteration of the lumen despite relief of obstruction (191). After 2 weeks of recovery, the epithelial lining normalizes in some tubules, but deteriorates further in others, indicating a marked heterogeneity in nephron injury (191). Tubular fluid flow is present in most nephrons 5–7 weeks after relief of 2–35 days of UUO and subsequent contralateral nephrectomy in the adult rat (192). However, the number of nephrons capable of recovery decreases with the duration of obstruction (192).

Hemodynamic Effects of Urinary Tract Obstruction

In all mammalian species studied to date, complete postnatal ipsilateral UUO results in significant renal vasoconstriction. Complete UUO in the neonatal rat reduces renal blood flow by 77% (149). It is likely that at least some of the renal consequences of UUO are the result of ischemia secondary to afferent arteriolar vasoconstriction, which develops even following single nephron obstruction (193). However, there is no catch-up growth of the ipsilateral kidney despite improved renal blood flow following relief of partial UUO in the neonatal guinea pig (15). The dissociation of renal growth from renal vasoconstriction resulting from neonatal UUO suggests that hemodynamic factors alone cannot account for the impaired renal growth. Alterations in renal growth factors (discussed above) probably contribute to these effects.

Eicosanoids
